Hyperlipidemia Although hyperlipidemia may result from a bout of pancreatitis, hyperlipidemia may also precipitate acute or chronic pancreatitis. [70] The breakdown products of triglycerides are probably responsible for inducing pancreatitis. When lipase in the pancreatic capillary bed acts on the high levels of triglycerides in the serum, toxic free fatty acids are generated. The endothelial lining of small pancreatic blood vessels is the first site of injury. Damage of small blood vessels leads to recruitment of inflammatory cells and thrombosis. This predicted mechanism is consistent with the clinical observation that the earliest injury in hyperlipidemia-associated pancreatitis is located in small pancreatic blood vessels. Although triglyceride levels greater than 2000 to 3000 mg/ dL usually are required for development of pancreatitis, a few patients seem to manifest this condition when serum levels are lower. In general, a level of greater than 1000 mg/dL should prompt suspicion of an underlying hyperlipidemic cause for pancreatitis. Striking increases in serum triglycerides after a fatty meal, with lower values while fasting, have been observed in some forms of hypertriglyceridemia. It is important to measure serum triglycerides on the first serum sample obtained from a patient with otherwise unexplained pancreatitis. Measuring postprandial triglyceride levels after recovery may also be required to detect markedly elevated values. In addition to patients with primary hyperlipidemia, elevated triglycerides may result from therapy with estrogen, retinoid derivatives, and HIV-protease inhibitors. Typically, estrogen-related pancreatitis occurs within the first months on medication. Patients who are obese, and have underlying glucose intolerance or hypertriglyceridemia, are at greater risk. Treatment of acute hyperlipidemic pancreatitis includes standard supportive care. If parenteral nutrition is given, serum triglyceride levels should be monitored. Occasionally, patients with acute pancreatitis and severe hyperlipidemia (serum levels of over 10,000 mg/dL) may benefit from plasmapheresis. Once the patient recovers from their acute symptoms, the cornerstone of therapy for hyperlipidemic pancreatitis is a low-fat diet. Attention must also be given to underlying diabetes or thyroid disease, as well as alcohol use, all of which can elevate serum triglycerides. In some cases, treatment with lipid-lowering drugs may be indicated.
Hypercalcemia The relationship of hypercalcemia to pancreatitis has been a topic of discussion. Experimentally, acute calcium infusion causes increased pancreatic duct permeability that may lead to a nonspecific increase in serum enzymes. [71] In animals, acute hypercalcemia may induce a very mild form of pancreatic injury. [72] Virtually all causes of hypercalcemia, including hyperalimentation, infusions associated with cardiac bypass, immobilization, multiple myeloma, and hyperparathyroidism have been linked to hyperamylasemia. [73] These studies indicate that hypercalcemia is associated with an increase in serum enzymes, but probably causes pancreatitis infrequently.

Infectious

Viral Including AIDS The most common viral infections that involve the pancreas are mumps and coxsackie B virus. These are self-limited and may account for lone bouts of pancreatitis. Viral hepatitis and fulminant hepatitis, especially hepatitis B, have been associated with pancreatitis. Influenza A and B, Enterovirus, Cytomegalovirus, and rubella may cause acute pancreatitis. The high incidence of pancreatic abnormalities in patients with AIDS deserves comment. Hyperamylasemia has been reported in up to 40% of patients with AIDS. [74] Clinical pancreatitis, however, probably occurs in less than 10% of all patients with AIDS and even fewer of those not receiving toxic medications. The diagnosis of pancreatitis should be based on bedside findings and imaging tests in combination with elevated enzyme levels, and not on the basis of elevated pancreatic enzymes alone. Unless pancreatitis is associated with medications, it usually is mild. In addition to drugs (see section “ Drugs”) and the other common causes of pancreatitis, at least three pathological processes contribute to pancreatitis in patients with AIDS:

1. HIV may infect the pancreas. This involvement may be responsible for the elevated serum amylase that sometimes precedes or accompanies the clinical onset of AIDS, and may account for the changes of otherwise unexplained chronic pancreatitis that have be seen at autopsy of patients with AIDS. However, HIV infection alone seems rarely to lead to clinical pancreatitis.
2. Opportunistic infections may involve the pancreas. Most infections are caused by Cytomegalovirus or *Mycobacterium avium.* In the remainder, *Cryptococcus, Toxoplasma gondii, Mycobacterium tuberculosis,* and *Candida* species have been reported. Usually, opportunistic infections in the pancreas involve other, more accessible organs. While histological evidence of pancreatic opportunistic infection is common at autopsy, it is unusual for these opportunistic infections to produce clinical pancreatitis during life.
3. Pancreatic neoplasms develop in up to 5% of patients with AIDS. Kaposi sarcoma and lymphoma are the most common and usually involve the pancreas in the setting of widely disseminated disease. Pancreatitis, however, is not a common manifestation of this tumor involvement.

Bacterial and Parasitic The list of bacteria associated with acute pancreatitis includes *Salmonella* species, *Shigella* species, *Campylobacter* species, hemorrhagic *Escherichia coli, Legionella* species, *Leptospira* species, and even *Brucella* species. [75], [76] Pancreatitis associated with these infections is most likely secondary to released toxins. Usually, acute pancreatitis is not the primary manifestation of these infections. Direct involvement of the pancreas or ampulla with parasites is a common cause of pancreatitis in some populations. Almost 15% of cases of biliary pancreatitis in a series from Hong Kong could be ascribed to *Ascaris lumbricoides* infection. [31]

Autoimmune

Sclerosing Pancreatitis Sclerosing pancreatitis, also called “autoimmune pancreatitis,” has distinctive clinical and laboratory features and responds to corticosteroid therapy. Patients present with subacute symptoms of pancreatitis and frequently have obstructive jaundice. Some patients also have other autoimmune illnesses. Cross-sectional imaging shows a diffusely enlarged pancreas, often with a focal pancreatic mass, and without marked peripancreatic inflammatory changes. The gland may appear to have a capsule-like edge on computed tomography (CT) or MR, and there may be delayed enhancement with intravenous contrast. [77] ERCP shows irregular narrowing of the main pancreatic duct, with either focal or diffuse changes (Fig. 94-4). Histology shows a prominent lymphocytic infiltrate especially in the region of the ducts, with little or no pancreatic calcification.

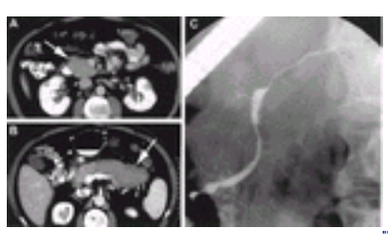

FIGURE 94-4. Sclerosing pancreatitis. **A** and **B**: Computed tomography demonstrates a diffusely enlarged pancreas with the appearance of a mass in both the head and tail of the gland (*arrows*). **C**: Endoscopic retrograde cholangiopancreatography shows diffuse irregularity of the main pancreatic duct and side branches. This patient improved with oral steroid therapy. (Courtesy of John Dobbins, M.D., New Haven, CT.)

A variety of laboratory abnormalities have been described, including elevated autoantibody levels and serum immunoglobulin E (IgE) concentrations, but the most characteristic laboratory findings appear to be an elevated serum IgG4 level. [78] The differential diagnosis often includes pancreatic neoplasm. Patients may have involvement of adjacent vessels or new onset hyperglycemia, further increasing the clinical suspicion of malignancy. Intraductal brushings obtained during ERCP or EUS-guided needle aspiration of a mass may be appropriate in some cases. A key feature of the disease is the good response to oral glucocorticoids with resolution of pancreatic swelling and a decrease in IgG4 and circulating immune complex levels. [78] Impaired pancreatic endocrine function may also improve. [79] Recurrence after a slow taper of steroids appears to be uncommon.
Inflammatory Bowel Disease Pancreatitis encountered in patients with inflammatory bowel disease may be related to drugs, structural and inflammatory changes, or may be idiopathic in nature. Most medications used for the treatment of inflammatory bowel disease have been reported to precipitate pancreatitis. This list includes azathioprine, 6-mercaptopurine, sulfasalazine, and 5-aminosalicylic acid, as discussed. Reports linking corticosteroids and metronidazole to pancreatitis are rare. Patients with pancreatitis and Crohn’s disease often have inflammatory bowel disease involving the duodenum. The inflammatory process may be associated with stenosis of the ampulla or a fistula into the pancreatic duct. The increased incidence of gallstones in patients with Crohn’s disease should always direct one to look for biliary causes of pancreatitis. In a small number of patients, however, no etiology is identified. [80] Sclerosing cholangitis is occasionally associated with clinical pancreatitis. This may be due to passage of small pigment stones through the ampulla, or to a sclerosing process affecting the pancreatic ducts as well as the bile ducts. [81]
Systemic Autoimmune Diseases Pancreatitis may occur in the setting of a systemic autoimmune disorder. Vasculitis affecting the pancreas has been described in systemic lupus erythematosus, [82] periarteritis nodosa, Wegner disease, [83] and Behçet disease. [84] Pancreatitis may respond to successful treatment of the underlying vasculitis.

Genetic

The best-described form of familial pancreatitis is the autosomal dominant disorder known as hereditary pancreatitis. Penetrance is probably less than 80%. Affected family members have bouts of pancreatitis that often begin in childhood and typically progress to chronic pancreatitis (see Chapter 95). The course of the disease appears to be accelerated by alcohol. These patients have been found to have mutations in the trypsinogen gene. The most common mutation (at arginine 117) may make trypsin resistant to proteolytic degradation. [6] Patients with hereditary pancreatitis have a dramatically increased risk of pancreatic cancer. [85] Mutations in the pancreatic trypsin inhibitor may also predispose to disease. [7], [8]

Mutations in the cystic fibrosis transmembrane regulator (CFTR) cause two patterns of pancreatic disease. First, classic cystic fibrosis results in pulmonary disease and pancreatic insufficiency, but rarely pancreatitis. These patients have elevated sweat chloride levels and diminished CFTR function in the nasal mucosa. Second, a pancreatitic phenotype is recognized that is not associated with pulmonary disease but can likely cause both acute and chronic pancreatitis. [86], [87] These patients have normal sweat chloride values, but the CFTR function in the nasal mucosa is diminished. Although the pancreatitic patients exhibit mutations in CFTR, they are not homozygous for the mutations that result in classic cystic fibrosis. The link between pancreatic disease and mutations in the CFTR gene is not understood. The prevalence of CFTR-related disease in patients with idiopathic pancreatitis appears to be increased compared to the general population. Its contribution to alcoholic pancreatitis remains unclear.

Iatrogenic

ERCP Acute pancreatitis is the commonest complication of ERCP. Retrospective studies report an incidence of 1%, but subsequent prospective studies with careful patient follow-up document an incidence of about 5%. [88] In most cases the pancreatitis is mild and resolves within several days; complications requiring surgery are infrequent. Diabetes can rarely result from an episode of severe post-ERCP pancreatitis, and deaths due to pancreatitis have been reported in 0.02% of patients undergoing the procedure.

Risk factors. The chance of developing post-ERCP pancreatitis varies depending on both patient-related and procedure-related factors. The skill and experience of the endoscopist also affect the chance of pancreatitis, with low case volume increasing the risk for the patient. [89], [90] The risk of post-ERCP pancreatitis is substantially higher when the pancreatic duct is visualized than when it is not. [91] The number and hydrostatic pressure of pancreatic duct injections are probably also important, as well as the volume of fluid injected. In one study, more than four pancreatic duct injections was associated with an increased risk. Acinarization (visualization of the pancreatic parenchyma with injected contrast) is associated with subsequent pancreatitis about a third of the time. In addition to filling and overfilling of the pancreatic duct, pancreatic outflow obstruction due to ampullary edema or spasm is a likely contributor to post-ERCP pancreatitis. Repeated attempts at bile duct cannulation may in this way cause postprocedure pancreatitis, even in the absence of pancreatic duct cannulation. [89] Pancreatitis has been reported after percutaneous biliary drains are advanced through the ampulla into the duodenum, with no injection or manipulation of the pancreatic duct. Endoscopic sphincterotomy further increases the risk of pancreatitis, and may do so both by thermal injury to the pancreas and by provoking ampullary edema. Precut sphincterotomy appears to increase the risk in some centers, but not in others where this technique is used routinely. Sphincter of Oddi manometry has been thought to increase the risk, perhaps because of the volume of fluid perfused into the pancreatic duct. The development of a manometry catheter that permits aspiration of fluid from the duct during manometry has decreased the incidence of postmanometry pancreatitis, and a large study of postsphincterotomy complications found that the performance of manometry did not affect the incidence of pancreatitis in patients with suspected sphincter of Oddi dysfunction. [89] Patient factors also affect the chances of ERCP-induced pancreatitis. Patients with suspected sphincter of Oddi dysfunction are at higher risk. About 20% of such patients undergoing sphincterotomy without prophylactic pancreatic duct stenting develop pancreatitis. The risk is especially high in patients with small bile ducts. [89] Younger age and obesity probably also predispose patients to pancreatitis after ERCP. Conversely, patients with a chronically diseased or obstructed pancreatic duct appear to be at decreased risk for pancreatitis from ERCP. The presence of acute biliary pancreatitis does not seem to increase the risk of the procedure. A history of contrast allergy has been reported not to increase the risk of post-ERCP pancreatitis, but many endoscopists favor pretreatment with steroids or use of nonionic contrast media in such patients. [92] Pretreatment may be especially important in patients with a history of serious allergic reactions to topical or ingested iodine.

Diagnosis. Symptoms of post-ERCP pancreatitis typically develop within 2 to 6 hours of the procedure, although occasionally patients will first develop symptoms the following day. The presence of abdominal symptoms shortly after the procedure is a poor predictor of subsequent pancreatitis. Consensus criteria for diagnosis of pancreatitis after ERCP require elevation of serum amylase and/or lipase to three times the upper limit of normal on the day after the procedure, together with compatible clinical symptoms. [92] Early predictors of post-ERCP pancreatitis have been identified. Although elevation of the serum amylase is a nonspecific finding in the hours following ERCP, the height of amylase elevation may be useful. In one prospective study, a serum amylase less than 276 U/L (upper limit of normal 115 U/L) was a strong negative predictor of pancreatitis when measured 2 hours after ERCP. [93] Post-ERCP pancreatitis may occur even if the procedure is easily accomplished and all identified risk factors are avoided. Patients sent home after ERCP should be instructed to seek help promptly if pain or vomiting develop. It is our practice to use a clear liquid diet until the morning following ERCP in many patients, in order to limit pancreatic stimulation in the postprocedure period.

Prevention. Both pharmacological and endoscopic strategies for the prevention of post-ERCP pancreatitis have been proposed. Some, such as use of low-osmolarity contrast media or pretreatment with calcium channel blockers, octreotide, or aprotinin (a protease inhibitor) have yielded disappointing results. Other prophylactic treatments, however, may be useful. A protease inhibitor, an antisecretory drug, and a cytokine that inhibits inflammation each appear to have some efficacy. Gabexate mesilate is a protease inhibitor that inhibits proteolytic activity of pancreatic enzymes. The few individual trials of gabexate for prevention of post-ERCP pancreatitis have all shown a benefit, although not statistically significant in most cases. A metaanalysis demonstrated a statistically significant benefit with gabexate pretreatment, decreasing the incidence of pancreatitis from 6.5% to 1.6%. [94] Pretreatment of 27 patients would prevent one episode of pancreatitis. This agent is not licensed for use in the United States, and enthusiasm has been tempered by the drug's cost and its adminstration as a prolonged intravenous infusion (beginning one hour before ERCP and continuing for 12 hours afterward). Somatostatin also appears to decrease the incidence of post-ERCP pancreatitis. Numerous controlled trials of somatostatin have shown a benefit, often not statistically significant; however, in metaanalysis a significant benefit was found. [94] Taken together, the incidence of pancreatitis was decreased from 13.5% to 5.6% in these studies. Pretreatment of 13 patients would prevent one episode of pancreatitis. Somatostatin appears to be effective when given either as a 12-hour intravenous infusion or as a bolus intravenous injection immediately before cannulation of the papilla. [95] Somatostatin is not licensed for use in the United States. The lack of benefit of octreotide, a somatostatin analog, may be due to its effects on sphincter of Oddi function and pancreatic blood flow. A recent study of IL-10, administered as a single intravenous injection 30 minutes before therapeutic ERCP, demonstrated a significant reduction in postprocedure pancreatitis from 24% in the placebo group to 9% in the treatment groups. [15] However, another study did not find benefit from IL-10. [16] Since gabexate, somatostatin, and IL-10 have different mechanisms of action, combination therapy could theoretically increase the benefit of pharmacological prophylaxis. Temporary pancreatic duct stenting dramatically decreases the risk of postsphincterotomy pancreatitis in patients with sphincter of Oddi dysfunction affecting the pancreatic sphincter. [96] This finding highlights the usefulness of sphincter of Oddi manometry in patients with suspected sphincter dysfunction. The benefit of prophylactic stenting may not apply to patients without sphincter dysfunction. A controlled trial of pancreatic duct stenting immediately after biliary sphincterotomy in a mixed group of patients did not show a reduction in postprocedure pancreatitis. [97]

Postoperative In the postoperative period there is an increase in the incidence of hyperamylasemia, even after extra-abdominal procedures. [98] It appears that in many cases these increases are nonspecific and unrelated to clinically overt pancreatitis, although severe pancreatitis may ensue and can be related to hypotension, medication, or pancreatic trauma. Postoperative pancreatitis is described after renal lithotripsy and percutaneous pancreatic biopsy. [99], [100]

Coronary Artery Bypass In a prospective study, Rattner and colleagues reported that 32% of patients had hyperamylasemia after cardiac bypass, but only 2.7% had overt pancreatitis. [73] In a retrospective study of 4473 patients who underwent cardiopulmonary bypass, Huddy and associates [101] reported acute pancreatitis in only 0.1% of patients, all of whom died. In a similar study by Lefor and colleagues, [98] acute pancreatitis was observed in 0.44% of those undergoing bypass, with a mortality of 44%. Finally, Fernandez-del Castillo and colleagues [73] demonstrated a direct correlation between the elevation of pancreatic enzymes and the amount of calcium administered to patients during cardiac bypass. Together, these studies indicate that although elevations in pancreatic enzymes are common after cardiac bypass surgery and may relate to a nonspecific effect of calcium on pancreatic duct permeability, overt pancreatitis is uncommon. A severe form of pancreatitis sometimes does occur after cardiac bypass, however, and may be related to pancreatic ischemia.

Neoplastic

Pancreatitis is associated with both primary pancreatic tumors and metastases. In one series, 3% of patients with pancreatitis admitted to a university hospital were found to have pancreatic malignancy. [102] Pancreatitis has been reported in up to 10% of patients with pancreatic cancer, but it is usually mild. [103] Cancer can mimic chronic pancreatitis, presenting with a dilated pancreatic duct, or a pseudocyst that forms because of downstream ductal obstruction by the tumor. It can also mimic acute pancreatitis, especially when bleeding into the pancreatic duct (hemosuccus pancreaticus) temporarily obstructs the duct. As clots pass through the papilla the serum liver enzymes may rise together with the amylase. Frequently, symptoms of pancreatitis are associated with an early-stage pancreatic neoplasm and may precede the diagnosis of pancreatic cancer by months. Older patients with unexplained pancreatitis should undergo a careful evaluation for occult malignancy looking

for a minute pancreatic cancer amenable to resection. [104]

Vascular

Ischemia is an uncommon cause of acute pancreatitis. Pancreatic infarcts may occur in patients with underlying atherosclerotic vascular disease, but are unusual because the pancreas is richly perfused from several different arterial sources. Cholesterol emboli may cause pancreatitis, cholecystitis, or bowel ulceration or infarction, and should be suspected when acute pancreatitis occurs after vascular interventions such as cardiac catheterization. [105] Patients may have associated evidence of renal, gut, or peripheral cholesterol emboli. Ischemic pancreatic and hepatic injury may be associated with malignant hypertension, low flow states due to severe heart failure, or administration of potent vasoconstrictors. Vasculitis may cause pancreatitis associated with systemic autoimmune diseases, as noted previously.

Other Etiologies

Trauma Traumatic pancreatitis from penetrating or blunt injury is an important cause of disease in both adults and children. The symptoms of pancreatic trauma may be difficult to elicit in the severely ill patient and suspected only by the location of the injury. On occasion, recurrent bouts of pancreatitis may develop months to years after injury. The midpancreatic duct as it crosses the vertebral column is particularly susceptible to fracture from blunt trauma. In the acute setting, CT is useful in detecting a disrupted pancreatic duct, focal pancreatitis, and pancreatic necrosis (Fig. 94-5). Similarly, ERCP has been used to demonstrate persistent duct disruption, ductal stricture, and focal pancreatitis. Traumatic pancreatitis has been treated with stenting of the disrupted duct, pancreatic resection, or drainage. [106]

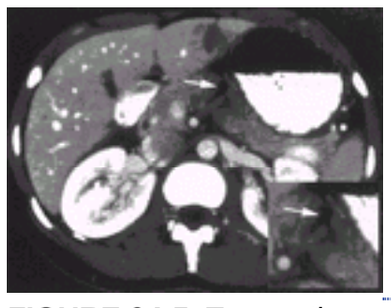

FIGURE 94-5. Traumatic pancreatitis. There is disruption of the pancreatic body anterior to the spine (*arrow*). The left lobe of the liver is also injured. (Courtesy of Jeffrey Neitlich, M.D., Yale University.)

Peptic Ulcer Ulcers located at the posterior duodenal bulb may burrow into the head of the pancreas. Pancreatitis associated with duodenal ulcers is rarely severe and is usually not associated with dramatic increases in the serum amylase. This diagnosis should be considered in patients with ulcer disease when the typical epigastric burning pain of an ulcer begins to radiate to the back and is less responsive to ulcer medications.
Childhood Pancreatitis may first present in childhood. Many cases of childhood pancreatitis are associated with multisystem disease such as sepsis, viral infections, hemolytic-uremic syndrome, and Reye syndrome. Blunt trauma caused by accidents or child-abuse is the single most common cause of acute childhood pancreatitis, followed in decreasing incidence by congenital defects (including biliary cysts, anomalous pancreatobiliary junctions, and pancreas divisum), metabolic diseases, and drugs. Children with hemolytic disorders such as sickle cell anemia commonly form pigment stones in the gallbladder or bile ducts. Rarely, annular pancreas, duodenal diverticulum, ectopic pancreatic tissue, and duodenal duplication cysts may cause pancreatitis.
Miscellaneous An increased incidence of pancreatitis has been reported during pregnancy and the early postpartum period. The increased incidence of hypertriglyceridemia and biliary stone formation during pregnancy may contribute to this predisposition. [107] An increased risk of acute pancreatitis is reported in patients undergoing renal dialysis. The risk may be limited to those treated with chronic peritoneal dialysis and not hemodialysis. [108] Refeeding after long periods of fasting is said to precipitate pancreatitis, but this has not been well characterized. A few patients with possible food allergy-associated pancreatitis have been reported. [109]
Idiopathic The number of patients having unexplained bouts of pancreatitis has diminished in large part owing to improvements in imaging tests and increased insight into the genetic abnormalities in unexplained pancreatitis. The compelling evidence that biliary microlithiasis causes pancreatitis, as well as the wider use of sphincter of Oddi manometry, has further decreased the size of the idiopathic group.

DIAGNOSIS

The diagnosis of acute pancreatitis is almost always based on the presence of severe abdominal pain together with biochemical evidence of pancreatic injury. Rarely, patients with severe acute pancreatitis present without complaints of abdominal pain, but with respiratory failure or changes in mental status. The diagnosis of pancreatitis may be missed entirely when organ failure dominates the clinical picture. For example, in series published during the 1980s, fatal pancreatitis went undetected until postmortem 22% to 42% of the time. [110]

Symptoms

Pain is the most common symptom of acute pancreatitis and occurs in 95% of patients. It is often located in the epigastric and umbilical region and may radiate to the low thoracic region of the back. The pain usually does not reach its peak for 30 minutes to several hours and may last for hours to days. This deep, visceral pain is among the most severe and often leaves even the medicated patient in discomfort. In some, pain will decrease when sitting and leaning forward or curling up on the left side, compared to laying flat. This symptom is due to the retroperitoneal position of the pancreas and may be produced by other retroperitoneal processes. Nausea and vomiting are present in 85% of patients and may occur without an ileus or gastric outlet obstruction. Unlike patients with ulcer disease, vomiting does not relieve pain.

Signs

Low-grade fevers are reported in 60% of patients, and high-grade fevers may indicate the presence of cholangitis or either sterile or infected necrosis. Tachycardia and hypotension are found in up to 40% of patients and may result from intravascular volume depletion, enhanced vascular permeability, vasodilation, and hemorrhage. Abdominal tenderness and guarding is common, and bowel sounds are often decreased or absent. Pleural effusions are most often found on the left, but may be bilateral. Mild jaundice is not unusual, but bilirubin levels greater than 4 mg/dL suggest extrahepatic obstruction or underlying liver disease. Dark discoloration in the back, flank, or the paraumbilical region may arise from any retroperitoneal hemorrhage, including hemorrhage from pancreatitis.

Laboratory Tests

Markers of Pancreatic Injury Although the gold standard for diagnosing acute pancreatitis is a direct histological examination of the pancreas, this is rarely available. The goals of diagnostic tests for pancreatitis are to establish the diagnosis and cause noninvasively in patients with abdominal pain and to determine the prognosis. Clinicians should be mindful that a number of factors influence the level of serum markers of pancreatitis. First, serum levels of pancreatic enzymes are the sum of tissue production, release into the blood, and clearance. Thus, in patients with renal failure, the serum amylase may increase because the kidney does not clear the enzyme. Second, the measured enzyme activities may be influenced by a number of “serum factors” and may not reflect absolute enzyme levels. For example, hyperlipidemia is known erroneously to reduce routine serum amylase determinations. Third, enzymes may be produced from nonpancreatic tissues, and this may limit the specificity of serum enzyme assays. In general, the higher the enzyme levels the better the chances that one is dealing with pancreatitis. Finally, standard enzyme assays, such as amylase and lipase, provide no information on the severity of the pancreatitis.
Amylase. The serum amylase level has been the biochemical standard for diagnosing acute pancreatitis. Many organs generate amylase, an activity that hydrolyzes the internal 1–4 a-linkages of starch. Because there are no circulating inhibitors of amylase activity, measurements of amylase activity in serum are reliable. Lactescent sera may inhibit amylase, but this effect can be eliminated by sample dilution. Although many tissues synthesize amylase, most of the serum activity originates from the pancreas (approximately 40%) and the salivary glands (approximately 60%). P-isoamylase arises from the pancreas and S-isoamylase from the salivary glands as well as other tissues such as the fallopian tubes and lungs. Pancreatic amylase enters the blood through an unknown pathway and has a serum half-life of about 2 hours. Although the major portion of serum amylase and other pancreatic enzymes is probably cleared by the reticuloendothelial system, about one fourth of serum amylase is excreted in its intact form by the kidney. Increased serum amylase during acute pancreatitis results from both enhanced release into the blood and decreased renal clearance. Serum amylase levels increase within the first hours after the onset of pancreatitis and parallel serum lipase levels. After an

attack, however, the serum amylase falls much more rapidly than lipase, and may return to normal within 24 hours. Lipase levels are more reliable indicators of pancreatitis in patients who are first seen several days after the onset of their illness (Fig. 94-6). In most situations, the degree of amylase elevation does not reflect the cause or severity of pancreatitis. Amylase levels tend to be lower in patients with alcoholic pancreatitis, pancreatic cancer, or penetrating ulcers, compared to patients with gallstone disease.

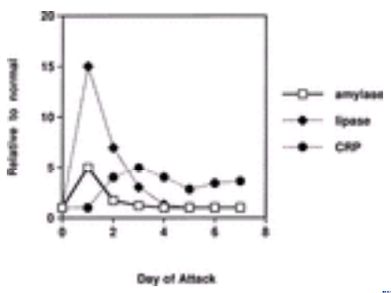

FIGURE 94-6. Serum markers of pancreatic injury.

Defining abnormal values influences the sensitivity and specificity of the total serum amylase. Cutoff values of just above the normal range have been estimated to yield sensitivities greater than 90%, but specificities less than 70% for acute pancreatitis. If the cutoff value is increased to three times the upper limit of normal, the specificity is near 100%, but the sensitivity may fall below 60%. Nonspecific increases of one- to twofold in the serum amylase have been reported after cigarette smoking. [111] In an attempt to enhance the specificity of amylase measurements, amylase isoforms may be measured. P-isoamylase is probably best used to confirm that an elevated total amylase level arises from the pancreas. [112] The clinical value of measuring P-isoamylase may be compromised by the inability of the assay to accurately measure small amounts of this isoform. Furthermore, P-isoamylase levels may increase in the absence of pancreatitis in patients with biliary tract disease, intestinal perforation, intestinal obstruction or ischemia, and ruptured abdominal aortic aneurysms. Diseases of the salivary glands may lead to an elevated S-isoamylase. S-amylase levels, however, may increase in the absence of salivary disease in chronic alcoholics, postoperative states, lactic acidosis, in patients with anorexia nervosa and bulimia, after esophageal perforation, and in neoplasms such as pulmonary, gastric, and breast carcinoma, and myeloma.

Macroamylasemia. On occasion, a persistently elevated serum amylase is encountered in the absence of symptoms referable to the pancreas. A benign and uncommon condition that can lead to such an elevated serum amylase is macroamylasemia. Amylase is normally found in the bloodstream as a molecule with a molecular weight of 45 kd, but macroamylase often has a molecular weight of greater than 200 kd. The normal ratio of pancreatic to salivary amylase is maintained in macroamylasemia. The high-molecular-weight macroamylase may result from antibodies complexed to amylase or from amylase polymers. [113] Unlike normal amylase, the macroamylase complex cannot enter the renal tubule for excretion and accumulates in the serum. Several methods can be used to diagnose macroamylasemia. First, amylase-to-creatinine clearance ratios of less than 1% strongly support the diagnosis. To confirm the diagnosis in patients with a low clearance, the clinical laboratory may determine the molecular weight of the serum amylase. Alternatively, immunologic assays also may be used. Acquired macroamylasemia may occasionally signal the presence of a lymphoproliferative disorder.

Lipase. Rapid and reproducible methods for measuring serum lipase are available. A number of gastrointestinal tissues, including the pancreas, intestine, liver, and biliary tract generate lipase activity, as do lingual and gastric sources. In some laboratory assays, the serum lipoprotein lipase activity is also detected. [114] The contribution of these various sources of lipase to serum lipase activity is not clear. Furthermore, the different substrates used in the various commercial assays may affect the specificity of the lipase measurement for pancreatic lipase. The least specific seems to be the Ektachem test, which has been found to have a specificity as low as 25%. [115] For many clinicians, the serum lipase has supplanted the amylase as the single test of choice for the diagnosis of pancreatitis. In most series, it is as sensitive and more specific than the total serum amylase, and promises to improve further when the L2 pancreatic lipase is measured. This enhanced specificity of the lipase compared to the amylase level also has been reported in alcoholics. [116] Because lipase levels increase in parallel to serum amylase levels, lipase is a useful early marker of pancreatitis. The lipase level remains elevated longer than the amylase level, and thus may help to diagnose pancreatitis after an acute attack has passed (see Fig. 94-6). Another advantage of lipase is that levels are normal in diabetic ketoacidosis and macroamylasemia.

Other enzymes. Presumably all pancreatic enzymes are released into the blood during acute pancreatitis. Serum trypsin, chymotrypsin, elastase, ribonuclease, and phospholipase A_2 have all been reported to be elevated in acute pancreatitis, but the specificity of these tests has not been sufficiently defined.

Urinary enzymes. One of the most promising tests for acute pancreatitis measures urinary trypsinogen 2 using a rapid dipstick assay. In a series of 500 patients seen in the emergency department with abdominal pain, the test was found to have a sensitivity of 94% and a specificity of 95% for pancreatitis. [117] These values are superior to other enzymatic tests and this assay deserves broader use.

Trypsinogen activation peptide. Premature activation of trypsinogen within the pancreas is thought to be an early signal of pancreatitis. The small peptide removed during activation of trypsinogen to trypsin is known as trypsinogen activation peptide (TAP). Measurement of TAP levels in the blood or urine reflects trypsinogen conversion to trypsin. Serum levels of TAP have been reported to separate those with severe from those with mild pancreatitis when measured within the first 36 hours of disease. [118]

Inflammatory Markers The inflammatory response is a prominent component of pancreatitis and increases in parallel with its severity. Several serum markers have been used to quantitate the inflammatory response. Inflammatory cells release neutrophil-specific elastase, and elevated serum levels are detected within the first 12 to 24 hours of pancreatitis. Interleukin-6 (IL-6), released by macrophages, also increases during the acute phases of pancreatitis. Acute-phase reactants such as C-reactive protein are induced by IL-6 and increase by the second day after the onset of acute pancreatitis. [14] Inflammatory markers may increase during any inflammatory process, and would not be specific for pancreatitis. In contrast to amylase and lipase measurements, however, some of these markers have prognostic value (discussed subsequently).

Markers of Biliary Tract Involvement Differentiation between biliary and nonbiliary forms of pancreatitis has important implications for treatment. Both biochemical and radiologic tests are useful (Table 94-2), but in some patients identification of a biliary cause may require EUS, bile microscopy, or empiric cholecystectomy. The timing of laboratory tests and ultrasound also affects their interpretation, especially when biliary tract obstruction is early in its course or when it is intermittent.

DIAGNOSTIC TEST	BILIARY	ALCOHOLIC
Laboratory		
Amylase	Values >1000 IU	Values <500 IU
AST, ALT	Increased levels that fluctuate	Not increased or mild increases with liver disease that do not fluctuate
Alkaline phosphatase and direct hyperbilirubinemia	Increased with persistent obstruction	Not increased unless there is obstruction of the intrapancreatic portion of the common bile duct
Imaging		
X-ray	Gallstones	Pancreatic calcifications
Ultrasonography	Gallstones, dilation of biliary tract	Changes of chronic pancreatitis
CT/Spiral CT	Gallstones, dilation of biliary tract, common duct stones	Pancreatic calcification, pancreatic duct stones, dilated pancreatic duct

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CT, computed tomography.

TABLE 94-2 Laboratory Findings and Imaging in Biliary Versus Alcoholic Pancreatitis

Most patients with gallstone pancreatitis have elevations of the serum liver tests, and the alanine aminotransferase (ALT) is the single most sensitive liver test for acute biliary obstruction by a stone. A rapid rise and fall in the serum liver tests is characteristically seen in gallstone pancreatitis in association with transient biliary obstruction at the papilla. Fluctuation is especially helpful in patients with chronic liver disease who have stable baseline elevations in aspartate aminotransferase (AST) and ALT levels. In addition, marked elevations of the amylase of greater than 2000 IU/L also favor a biliary source. [119] The ratio of lipase to amylase may be greater in alcoholic than in biliary pancreatitis, but has not been a reproducible finding. Noninvasive indicators of persistent bile duct stones are needed for gallstone pancreatitis. Elevation of the serum bilirubin level over 3, or persistent elevation of the liver tests over time, have been advocated as useful screening tests. Laboratory scoring systems, such as the modified Glasgow criteria or the urea-glucose scale, can identify patients whose biliary pancreatitis is predicted to be severe; these patients, in turn, are more likely to harbor persistent ductal or ampullary stones. Early trends in the serum liver tests and pancreatic enzyme levels are also useful. Patients in whom all these values remain constant or decrease over the first 48 hours of hospitalization have a low (8%) risk of a persistent stone, while those in whom any of these laboratory values increase have a moderate (30%) risk of a persistent bile duct stone. [120] None of these predictors is accurate enough to replace direct bile duct imaging, but may be useful in selecting patients for EUS, MR cholangiopancreatography (MRCP), or ERCP rather than elective intraoperative

cholangiography.
Systemic Markers of Acute Pancreatitis A low-grade to moderate fever is not unusual in acute pancreatitis. Persistent high fevers suggest infection. Leukocytosis is common, and severe pancreatitis has been associated with leukemoid reactions even in the absence of infection. Inflammatory markers, such as the serum levels of neutrophil elastase, C-reactive protein, and IL-6, are good markers of severity, but elevations are not specific for pancreatitis.

Imaging

Abdominal Radiographs To exclude nonpancreatic diseases, such as intestinal perforation, standard and upright chest and abdominal radiographs are recommended for every patient with severe abdominal pain. Plain radiographs may be omitted in some cases if CT is available immediately. A variety of radiographic findings have been associated with pancreatitis. Pleural effusions are most common on the left, but may be bilateral and rarely are limited to the right pleural space.[121] Intestinal gas patterns may demonstrate an ileus pattern or an isolated dilated loop of small bowel overlying the pancreas, known as the sentinel loop. Colonic obstruction may result in air in the right and transverse colon that abruptly terminates at the splenic flexure, the so-called colon cutoff sign. Loss of the psoas margins and increased separation between the stomach and colon suggest pancreatic inflammation. Pancreatic calcification or calcified gallstones may suggest an alcohol or biliary etiology, respectively.
Sonography When the pancreas is inflamed it appears hypoechoic on sonography because of increased water in the parenchyma (Fig. 94-7). Ultrasound is thus a relatively sensitive test for the diagnosis of acute pancreatitis, when the pancreas is seen. Although ultrasonography can be performed rapidly and at the patient's beside, intestinal gas or adipose tissue limits pancreatic visualization in 30% to 40% of patients. This is especially common in patients with ileus due to their pancreatitis. Ultrasonography may miss focal masses or fluid collections, especially in and around the pancreatic tail. Its greatest value is in evaluating the biliary tract for gallstones, sludge, or ductal dilation. [33], [34] Ultrasound is the single best noninvasive test for the presence of gallbladder stones, with a sensitivity of about 95%. It is much less reliable for direct visualization of a bile duct stone because overlying bowel gas often obscures the common bile duct.

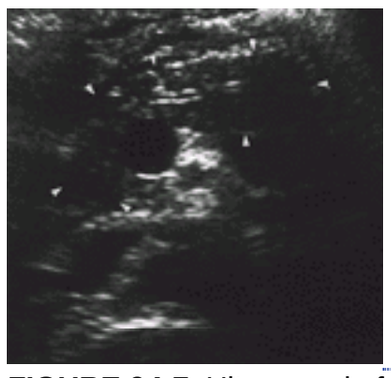

FIGURE 94-7. Ultrasound of acute pancreatitis. The pancreas (*arrowheads*) is hypoechoic; the walls of the pancreatic duct are prominent because of the surrounding parenchymal edema. (Courtesy of Jeffrey Neitlich, M.D., Yale University.)

Radionuclide Imaging Radionuclide imaging of the biliary tract has been used to detect obstruction of the biliary tract and gallbladder disease. Since pancreatitis of any etiology can be associated with obstruction of the biliary tract, radionuclide imaging does not reliably distinguish a biliary cause of disease.
Computed Tomography CT is a valuable tool for pancreatic imaging. In contrast to ultrasound, which demonstrates changing echogenicity in the parenchyma of the gland, the CT diagnosis of pancreatic inflammation is made based on pancreatic enlargement, effacement of the usual lobulated contour of the pancreas, inhomogeneity of the pancreatic parenchyma, or fluid infiltrating the peripancreatic fat (Fig. 94-8). While CT and ultrasound are equally sensitive for diagnosis of pancreatitis, missing the diagnosis in some mild cases, CT is better than ultrasound for detection of focal pancreatic masses or fluid collections because it reliably visualizes the entire gland.

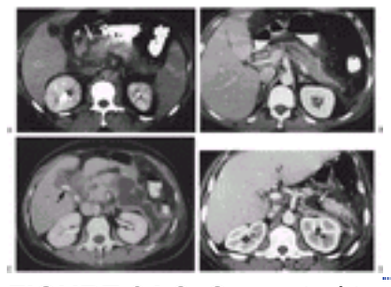

FIGURE 94-8. Computed tomography of acute pancreatitis. **A**: Mild pancreatitis. Fluid is seen between the antrum and the pancreatic head (*arrow)*. **B**: Moderate pancreatitis, with peripancreatic fluid infiltrating the retroperitoneum. The pancreas shows uniform contrast enhancement. **C**: Pancreatic necrosis, with no perfusion of the tail and part of the body. Stones are present in the gallbladder (*arrow*). **D**: Gas within an area of pancreatic necrosis (*arrow*), suggesting infection. (Courtesy of Jeffrey Neitlich, M.D., Yale University.)

Dynamic CT performed during bolus administration of intravenous contrast can demonstrate areas of poor perfusion or nonperfusion in the pancreas. [122] This finding is typically interpreted as necrosis of the poorly perfused segment; estimates of pancreatic necrosis by dynamic CT correlate with observations made at surgery. The CT finding of necrosis probably identifies patients who are at higher risk for pancreatic infection and death. Investigators have debated whether early administration of bolus intravenous contrast worsens pancreatitis. Studies in rats have shown decreased pancreatic capillary flow rates and decreased pancreatic oxygen saturation after intravenous contrast administration. [123] These effects persisted at 60 minutes after contrast was given. However, there is no compelling evidence of this phenomenon in humans. A retrospective study at a university hospital found that patients who underwent contrast-enhanced CT had longer hospitalizations than those who did not, despite similar Acute Physiology and Chronic Health Evaluation II (APACHE II) scores on admission. [124] A subsequent prospective study randomized patients with severe pancreatitis to CT on the first hospital day with or without bolus intravenous contrast. There was no difference in systemic markers of inflammation, length of hospital stay, or mortality. [125] In practice a contrast-enhanced CT is usually unnecessary in the first 24 hours of hospitalization, but early CT may be performed if it will have an important effect on early management of the individual patient. Helical CT technique has improved CT sensitivity for gallstones in the bile duct to 85% [126] (Fig. 94-9). CT detection of ductal stones is still limited by stone composition; calcium must be present in sufficient amounts to yield a CT density different than that of the surrounding bile or soft tissue. When looking for biliary stones, helical CT should be done without contrast so that a bright rim at the periphery of a stone is not mistaken for contrast enhancement of the bile duct wall.

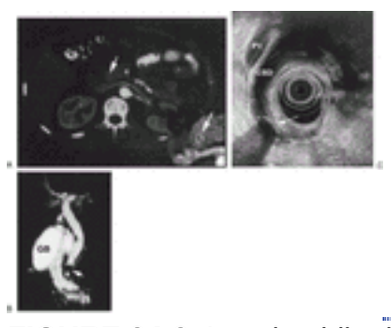

FIGURE 94-9. Imaging bile duct stones (*arrows)*. **A**: Computed tomography shows the calcified rim of a stone. **B**: Magnetic resonance cholangiopancreatography (MRCP) shows a filling defect in the distal bile duct. The gallbladder (*GB*) and duodenum (*Duod*) are seen because nonflowing fluid is visualized with this technique. **C**: Endoscopic ultrasound shows an oblong stone with an acoustic shadow. The bile duct (*CBD*) is thick walled due to cholangitis. A segment of portal vein (*PV*) is seen. (Images A and B courtesy of Jeffrey Neitlich, M.D., Yale University.)

Magnetic Resonance MR imaging has not been widely applied to acute pancreatitis, but is probably similar to CT when imaging the acutely inflamed pancreas. When intravenous gadolinium is given, MR demonstrates areas of poor pancreatic perfusion. Animal studies have shown no deleterious effect of intravenous gadolinium on the inflamed pancreas. Although MR is more cumbersome and expensive than CT and more difficult to obtain quickly, it does offer clinical advantages

in pregnant patients and those with contrast allergy. MR (like EUS) is more accurate than CT for demonstration of solid debris in a pancreatic fluid collection; complex collections often have a homogenous appearance on CT. [127] Secretin-stimulated MR may have a role in the diagnosis of functional pancreatic duct outlet obstruction. MR angiography (MRA) and MRCP are additional techniques that offer noninvasive diagnosis of vascular complications and persistent bile duct stones in acute pancreatitis. MRCP (see Fig. 94-9) has a sensitivity of over 90% for bile duct stones, although its yield in patients with normal caliber ducts and small ampullary stones is not as well defined.

Endoscopic Cholangiopancreatography ERCP does not play a role in establishing the diagnosis of acute pancreatitis. Most patients with acute pancreatitis have normal pancreatograms, although some may have pancreatic duct strictures or ductal disruptions. ERCP is useful in the differential diagnosis of otherwise unexplained, recurrent pancreatitis, especially for diagnosis of mild chronic pancreatitis, pancreas divisum, or sphincter of Oddi disease. ERCP has been used to diagnose and treat persistent bile duct stones in acute pancreatitis, as discussed elsewhere in this chapter.

Endoscopic Ultrasound EUS is useful in some patients with acute pancreatitis. EUS is a sensitive test for detection of persistent bile duct or ampullary stones (see Fig. 94-9) and can be used to identify patients likely to benefit from ERCP. [128] EUS is also useful for differential diagnosis of unexplained acute pancreatitis since it demonstrates biliary sludge and stones missed with other imaging modalities, as well as small pancreatic or ampullary tumors, pancreas divisum, and chronic pancreatitis. [129] Finally, EUS can demonstrate complex material within a pancreatic fluid collection and can guide endoscopic pseudocyst drainage.

Use of Cross-Sectional Imaging Studies in Acute Pancreatitis The choice of imaging modality for patients with acute pancreatitis depends on the clinical question that needs to be answered. Imaging studies can establish the diagnosis of pancreatitis, aid in differential diagnosis, provide prognostic information, or assess possible complications. When the diagnosis of pancreatitis is uncertain, both ultrasound and CT may be useful. A patient with rapidly resolving biliary pancreatitis may have near-normal serum enzymes but persistent pancreatic edema seen on ultrasound or peripancreatic inflammatory changes on CT. CT can show changes of chronic pancreatitis or focal pancreatic masses. For differential diagnosis, the choice of imaging test depends on the diagnosis suspected. When biliary pancreatitis seems likely, ultrasound is the standard investigation because it detects almost all gallbladder stones. When chronic pancreatitis or an underlying pancreatic malignancy is suspected, CT is more useful. When a metabolic or drug-induced pancreatitis is likely, imaging tests may still be indicated to exclude other common causes such as stones. In patients with biliary pancreatitis, imaging studies such as EUS or MRCP may usefully identify patients with persistent bile duct or ampullary stones. Early bile duct imaging is particularly appropriate when the pancreatitis is severe or laboratory trends suggest an increased risk of a persistent stone. Contrast-enhanced CT or MR can identify patients with necrosis, and these patients benefit from prophylactic antibiotics. CT, however, is not necessary in every patient with pancreatitis. Necrosis is uncommon in patients with clinically mild disease who improve rapidly in the hospital. Serial hematocrits and the C-reactive protein level on the second hospital day are useful predictors of the presence or absence of necrosis, as described in the section on “Local Complications” and following. When necrosis is suspected or the patient is not improving over the first 48 hours of hospitalization, contrast-enhanced CT is usually worthwhile. CT is also valuable in the diagnosis and management of local complications of acute pancreatitis. Jaundice or a marked drop in hematocrit may also be indications for CT. When thrombosis of the splenic or superior mesenteric veins is suspected, MRA or CT may be useful.

Evaluation of Severity

There are several important reasons to establish the severity in acute pancreatitis. Since severity correlates with prognosis, such evaluation may allow the clinician to predict the patient’s course and anticipate complications or the need for closer monitoring in an intensive care unit. Prognostic information should guide the use of prophylactic antibiotics, urgent bile duct imaging, and early ERCP. Finally, prognostic markers allow the clinical investigator to measure the success or failure of therapeutic interventions. The tools used to measure prognosis fall into three categories: specific laboratory tests, clinical and physiological assessment, and CT.

Laboratory Tests The standard laboratory tests used to diagnose pancreatitis provide little prognostic information, but other tests appear to separate patients with mild disease from those with severe disease. The first group of tests measures the severity of the inflammatory response. These include the neutrophil elastase and the monokine IL-6 tests. Both are elevated within 24 hours and correlate with the severity of pancreatitis. C-reactive protein is induced by IL-6 and is a later marker of severity, distinguishing patients with severe disease on the second hospital day (Fig. 94-10). Since the C-reactive protein is easily and inexpensively measured and appears to be a good prognostic marker, it should be used more widely to assess prognosis.

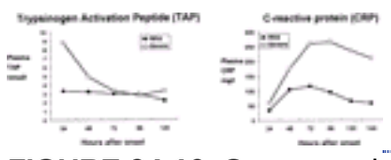

FIGURE 94-10. Serum markers of severity. Serum values of the trypsinogen activation peptide (TAP) and C-reactive protein (CRP) as a function of the duration and severity of acute pancreatitis. (Derived from ref. [118] and Wilson C, Heads A, Shenkin A, Imrie CW. C-reactive protein, antiproteases and complement factors as objective markers of severity in acute pancreatitis. Br J Surg 1989;76[2]:177.)

The TAP assay is an indirect measure of the amount of active trypsin. From a pathophysiological standpoint, this is an elegant measure of severity; the more trypsin activation, the more pancreatic damage. In a large prospective study, TAP levels discriminated between mild and severe disease. [118] Unfortunately, TAP assays are not yet widely available. With the exception of the TAP assay, these tests measure inflammatory activity only, and are not specific for pancreatitis.

Computed Tomography Both noncontrast CT and contrast-enhanced CT yield useful prognostic information. Noncontrast CT is the basis for a prognostic scoring system called the CT Severity Index (Table 94-3) that has been shown to correlate with the Ranson criteria for assessing severity. [122] In one study, patients with CT Severity Index scores up to 2 had only 4% morbidity and no mortality, but those with scores from 7 to 10 experienced 92% morbidity and 17% mortality [100] (Fig. 94-11). Contrast-enhanced CT demonstrates the presence and extent of pancreatic necrosis, and is therefore an important predictor of complications and death, as discussed in the section on “Necrosis and Infected Necrosis.”

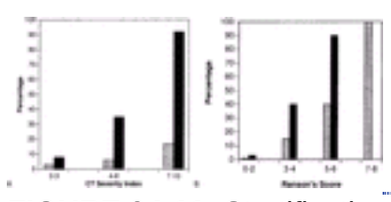

FIGURE 94-11. Stratification of severity according to Computed Tomography (CT) Severity Index (Table 94-3) and Ranson criteria (Table 94-4). The *light bar* represents mortality. Morbidity (*dark bar*) was defined as greater than 7 days in the intensive care unit. (Derived from refs. [122], [130].)

	POINTS
Grade of Acute Pancreatitis	
A: Normal pancreas	0
B: Pancreatic enlargement	1
C: Inflammation confined to pancreas and peripancreatic fat	2
D: One peripancreatic fluid collection	3
E: Two or more fluid collections	4
Degree of Necrosis	
No necrosis	0
Necrosis of one third of pancreas	2
Necrosis of one half of pancreas	4
Necrosis of more than one half	6

Computed tomography severity index = grade points + degree of necrosis. See the text and Figure 94-11 for correlation between the severity score and outcome.

TABLE 94-4 Ranson and Simplified Glasgow Prognostic Scoring Criteria

Clinical and Physiological Assessment

The Ranson criteria are still the most widely applied measure for the assessment of acute pancreatitis. Ranson criteria (Table 94-4) distinguish between mild and severe pancreatitis about 80% of the time. As shown in Figure 94-11, the Ranson score correlates with morbidity and mortality. [130] The disadvantage of Ranson criteria is that they include 11 values that must be monitored over 48 hours. Blamey and colleagues [131] developed the Glasgow classification, which can be calculated any time within the first 48 hours of hospitalization and measures only eight parameters (Table 94-4). The simplified Glasgow criteria appear to have prognostic accuracy similar to that of Ranson criteria. The Glasgow criteria were developed in a population of predominately biliary pancreatitis, while the Ranson criteria were developed in patients with more alcoholic pancreatitis.

Although some prognostic classifications have dropped the base deficit and fluid requirements from Ranson criteria, others have identified *obesity* as an independent risk factor. [132] The higher risk in the obese patient may result from respiratory compromise from physical restraints, or from the provision of toxic substrates such as free fatty acids from triglycerides and harmful cytokines from peritoneal fat stores.

The APACHE II has been used to establish the prognosis in patients with pancreatitis. [133] This system uses 14 routinely measured parameters of physiological activity and biochemical function, and generates a numerical score that depends on their deviation from the normal range. The patient's age, organ insufficiency, neurological state, and postoperative state are also weighted. The potential advantage of the APACHE II is that it can be calculated instantaneously from routine measurements. The initial value distinguishes patients at high risk for complications and death, and trends in the patient's APACHE II score over time add to its predictive value. A major shortcoming of this classification is its complexity. It is difficult to apply the APACHE system routinely outside of an intensive care unit.

Are these scoring systems of use to the clinician? A group of experienced pancreatic surgeons compared bedside assessment at admission and after 48 hours with the APACHE II, Ranson, and Glasgow [133] scores for predicting the severity of acute pancreatitis. Bedside assessment alone missed over half of the cases that ultimately proved to have a complicated course. Thus, a high score on a standardized scoring system alerts the clinician to the possibility of complications. This in turn should prompt frequent reevaluation of the patient and the adequacy of supportive treatment, perhaps in an intensive care unit.

Approach to the Patient with Unexplained Pancreatitis

In over 10% of patients, pancreatitis is idiopathic despite results of history and physical examination, routine laboratory tests, transabdominal ultrasound, and CT. An etiologic diagnosis can be made in most of these patients with further evaluation. A thorough diagnostic approach should be taken, including use of the medical history, laboratory tests, and additional imaging studies.

The patient's history should be reviewed, particularly with regard to alcohol and medication use, family history of pancreatic disease, and prior abdominal trauma. Metabolic disease should also be considered. Serum triglycerides decrease with fasting, and a hyperlipidemic cause of pancreatitis may be missed if triglycerides were not measured soon after the patient's symptoms began. Hypercalcemia may not be apparent until after the patient has recovered from pancreatitis, because acute pancreatitis often lowers serum calcium levels.

When there is evidence of chronic pancreatitis in the absence of alcohol use or familial pancreatitis, further evaluation can include laboratory tests for a-1-antitrypsin deficiency and hemochromatosis. Trypsinogen gene mutations may be present without a family history of pancreatitis due to occurrence of a new mutation or low penetrance, and patients with CFTR mutations and pancreatitis usually do not have a family history of disease. Genetic testing for these disorders can be performed; however, enthusiasm for this testing must be tempered. The absence of effective specific therapy, the lack of effective pancreatic cancer screening for patients with familial disease, and the possible psychological and insurability problems that may arise from the diagnosis of a genetic disorder are all arguments against genetic testing. Genetic diagnosis may nevertheless be desirable, particularly for patients who wish to have children. In general it is wise to refer the patient for genetic counseling before obtaining these tests.

Biliary microlithiasis is a leading cause of recurrent acute pancreatitis that should be actively pursued in patients with unexplained disease. EUS and bile microscopy appear to play a complementary role in diagnosis, and microlithiasis is unlikely if both of these investigations are negative. Nevertheless, empiric cholecystectomy may be a reasonable option in some patients, especially if the clinical features of their acute attacks suggest a biliary source and ampullary disease has been excluded.

Abnormalities of pancreatic duct drainage, including pancreas divisum, ampullary lesions, and sphincter of Oddi dysfunction, should be excluded in patients with recurrent acute attacks and no evidence of microlithiasis. While EUS and MRCP can diagnose ampullary masses and divisum, definitive diagnosis of these conditions is often made during ERCP. ERCP is particularly useful for diagnosis of sphincter dysfunction and "incomplete divisum," in which the dorsal and ventral ducts communicate but dominant drainage is via the minor papilla. Such patients may present with recurrent mild pancreatitis. [134] ERCP is also the most definitive diagnostic test for intraductal papillary mucinous tumors of the pancreas, which often present with pancreatic symptoms and serum enzyme elevations.

It is generally our practice to use EUS instead of ERCP as the first endoscopic test in unexplained pancreatitis. EUS is particularly useful in patients with intact gallbladders, who may have microlithiasis, and in those over 40 years old, in whom the possibility of an early pancreatic malignancy should be considered. Missed chronic pancreatitis, pancreas divisum, and ampullary lesions can be diagnosed during EUS as well. EUS makes a diagnosis in about two thirds of patients. [129] When disease remains idiopathic and is recurrent, ERCP (with the capability to perform sphincter of Oddi manometry) can be pursued.

LOCAL COMPLICATIONS

The commonest complication of acute pancreatitis is the development of a pancreatic or peripancreatic collection. A useful classification of pancreatic collections was adopted at a consensus conference on acute pancreatitis held in Atlanta in 1992 and has since been widely accepted, replacing older terminology such as "phlegmon." [2] The Atlanta classification distinguishes acute fluid collections, necrosis, pseudocysts, and abscesses. Each of these entities has a different pathology, natural history, and treatment.

Acute Fluid Collections

Acute fluid collections form in or near the pancreas, and are common among patients with pancreatitis. They occur early in the course of the acute illness, and do not have a defined wall. Fluid collections may be simple and exhibit a uniform CT density that approximates that of water, or complex and show multiple CT densities and poorly defined margins (Fig. 94-12).

FIGURE 94-12. Acute fluid collection complicating acute pancreatitis. Computed tomography of pancreatitis after coronary artery bypass graft demonstrates a mixed-attenuation fluid collection (*arrow*) contiguous with the tail of the pancreas (not shown). (Courtesy of Caroline Taylor, M.D., West Haven, CT.)

Most acute fluid collections resolve spontaneously. The factors determining resolution of an acute collection versus persistence of the collection and progression to a pseudocyst are incompletely understood. An underlying pancreatic duct disruption that empties into a fluid collection certainly contributes to their persistence and enlargement in some patients. Nevertheless, prospective studies show that ductal disruptions often resolve with conservative management alone, without surgical intervention. [135]

Although some have advocated drainage of acute fluid collections, evidence demonstrating a benefit for such intervention is lacking. Acute collections may be difficult to drain percutaneously, and CT scans often underestimate the complexity of these collections. Unless an acute collection is rapidly expanding or associated with clinical evidence of infection, it should be observed. Infection is an uncommon complication. Infected collections have to be drained and have been successfully treated using percutaneous catheters. Because fluid collections are frequently associated with acute pancreatitis and most resolve spontaneously, a fluid collection should be defined as a pseudocyst only if it persists for more than 4 weeks.

Necrosis and Infected Necrosis

Any form of acute pancreatitis may progress to severe disease and extensive pancreatic necrosis. Pancreatic necrosis may result from ischemia or marked inflammation and represents a severe form of disease. Necrosis may affect the pancreas diffusely or focally, and necrotic areas may be separated by segments of viable tissue. Histological examination may show devitalized pancreatic tissue with vessel damage and necrosis of parenchyma and ducts, as well as hemorrhage and fat necrosis.

Pancreatic necrosis is diagnosed clinically with dynamic contrast-enhanced CT, which demonstrates well-marginated zones of non-enhanced pancreatic tissue (see Fig. 94-8). Although some non-enhancing parenchyma may be viable, there is generally good correlation between CT, operative findings, and histology in patients with necrosis undergoing surgery. CT is less useful for diagnosis of peripancreatic fat necrosis.

Necrosis is uncommon in patients with clinically mild disease. Laboratory predictors of necrosis have been described. A serum C-reactive protein level greater than 150 mg/L is seen in 95% of patients with necrosis by the second hospital day [136] (see Fig. 94-10). Two useful and readily available laboratory predictors are:

- an admission hematocrit equal to or greater than 44%, and
- failure of the hematocrit to decrease 24 hours after admission.

When either of these criteria are present, necrosis can be found in about 50% of patients, while if both criteria are absent necrosis has been demonstrated in only 4%. [137]

Necrosis is associated with other major complications and death from acute pancreatitis. Major complications of necrosis include distant organ failure and infected pancreatic necrosis. Early in the course of necrotizing pancreatitis there may be a marked systemic inflammatory response with increased capillary permeability, a sepsis-like syndrome, and distant organ failure most often affecting the lungs. Organ failure is more likely in patients with necrosis of over 50% of the pancreas. [138] Somewhat later in the course, infection of the necrotic pancreatic tissue may develop. Since there is no fibrotic wall or capsule to contain the infection, adjacent inflamed tissues become involved and overwhelming sepsis is likely unless adequate debridement of the infected tissue is achieved.

Infected pancreatic necrosis is a leading risk factor for death from acute pancreatitis. Infection of pancreatic necrosis occurs in 30% to 70% of patients not receiving prophylactic antibiotics. [139] This high frequency is in large part due to increased bacterial translocation from the gut seeding the necrotic tissue. Alterations in mucosal villus architecture and bowel microvasculature occur in animal models of acute pancreatitis, with bacterial translocation from the intestine to the pancreas, liver, and spleen. [140] In patients, the same bacterial species that infect the pancreas can be previously cultured from the colon. [141] The prevention and treatment of infected necrosis is described in greater detail later in this chapter.

Infected necrosis may be heralded by a sudden increase in abdominal tenderness, high fever, marked leukocytosis, and bacteremia. The presentation may also be subtle, particularly in patients receiving prophylactic antibiotics, with persistent or worsening organ failure despite ongoing supportive care. Negative blood cultures do not exclude the diagnosis. Although infection of pancreatic necrosis was thought to occur mainly after the first 10 to 14 days of illness, recent reports have stressed its occurrence earlier and later in the course of necrotizing pancreatitis.

The main diagnostic modality for infected necrosis is CT-guided, fine-needle aspiration of the necrotic pancreatic tissue. Samples should be immediately examined by Gram stain, which has a high applicability in this setting. Fungal stains are advisable as well, and cultures are also mandatory. Polymicrobial, bacterial, gram-negative enteric and anaerobic organisms are most common, but with the widespread use of prophylactic antibiotics bacterial gram-positive and fungal infections are increasingly frequent. [142]

Laboratory predictors of infected pancreatic necrosis have been sought. The serum procalcitonin level has been useful in some studies, but not in others. [143], [144] Further clinical experience with this and other markers of infected necrosis is desirable.

Sterile pancreatic necrosis has a variable clinical course. The necrotic tissue may gradually disappear, leaving residual inflammation and scar. In other cases the necrotic region gradually evolves into a pseudocyst or a region of organized pancreatic necrosis (Fig. 94-13). In a minority of patients, a persistent sequestrum of sterile pancreatic necrosis is responsible for ongoing symptoms or persistent organ failure despite prolonged supportive care. Drainage of sterile necrosis may be considered in patients with persistent symptoms or organ failure, as described later in this chapter.

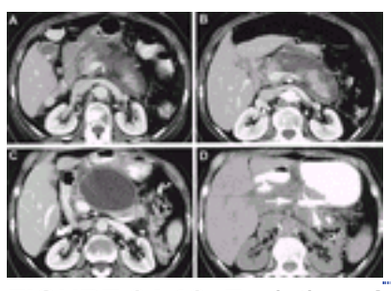

FIGURE 94-13. Evolution of central necrosis. **A**: Necrosis of the pancreatic body in a patient with gallstone pancreatitis. **B**: One week after onset of pancreatitis. **C**: Seven weeks after onset. **D**: The collection has resolved after endoscopic drainage with placement of multiple internal stents (*arrows*).

The term “organized pancreatic necrosis” has been used to describe a region of necrosis that is at least 4 weeks old and has developed a wall, but still contains necrotic material. [145] The distinction between organized pancreatic necrosis and pseudocyst has importance when nonsurgical drainage is considered. Aggressive endoscopic or percutaneous techniques are needed to adequately remove the thick necrotic material. Attempts at drainage may otherwise result in a poorly drained, infected collection. CT often underestimates the complexity of an organized area of pancreatic necrosis, and both EUS and MR have been used to identify solid material in these collections.

Pseudocysts

Pseudocysts are collections of pancreatic fluid contained by a wall of fibrosis or granulation tissue. The presence of a well-defined wall distinguishes pseudocysts from acute fluid collections and pancreatic necrosis. An epithelial lining is absent (in contrast to true pancreatic cysts). Formation of a well-defined wall generally requires at least 4 weeks. Pseudocysts usually contain fluid rich in pancreatic enzymes, and often contain particulate matter.

The advent of pancreatic imaging by ultrasonography and CT led to the realization that pancreatic pseudocysts are common and appear in up to 10% of patients with acute pancreatitis. [146] Although they may form most frequently in patients with alcoholic pancreatitis, up to 30% of cases arise in gallstone pancreatitis. The most common presenting symptom of a pseudocyst is upper abdominal pain that is either constant or postprandial. Other symptoms referable to a pseudocyst include early satiety and nausea and vomiting secondary to gastric outlet obstruction. Pseudocysts may also enlarge rapidly and rupture, hemorrhage, leak pancreatic fluid, obstruct the biliary tract, compress adjacent vessels, erode into surrounding structures, extend into the mediastinum, and become infected.

The risk of complications varies with the size of a pseudocyst and its age. Symptomatic pseudocysts may also be more prone to complications. Early reports based on ultrasound detection of pseudocysts in persistently symptomatic patients found a complication rate of 30% to 50% in pseudocysts that persisted for more than 6 weeks, and were the basis for recommendations to drain all persistent pseudocysts. More recent studies of asymptomatic pseudocysts detected with liberal use of CT document a low incidence of complications, even in large pseudocysts, and showed that most pseudocysts less than 6 cm in diameter resolved over time. A third of lesions more than 10 cm in diameter also resolved with observation alone. [146], [147]

Indications for early drainage include infection or progressive enlargement of the pseudocyst. Symptomatic pseudocysts typically require drainage. In the absence of symptoms, pseudocysts can be followed conservatively, although large lesions that fail to shrink with time should probably be drained. Pseudocysts can be drained endoscopically, percutaneously, or surgically. If there is a question of true pancreatic cyst or pancreatic cystic neoplasm rather than pseudocyst, surgical drainage provides the opportunity to obtain a large piece of the cavity’s wall for histological examination. This is especially important when a pancreatic “pseudocyst” is found in the absence of a clinical bout of pancreatitis, or in recent pancreatitis of unclear etiology (Fig. 94-14).

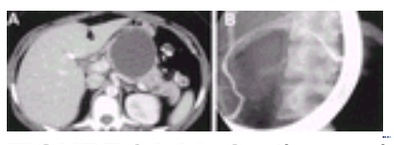

FIGURE 94-14. Cystic neoplasm simulating a pseudocyst. The patient developed epigastric pain without a discrete episode of pancreatitis. **A**: Computed tomography demonstrates a round fluid collection of the pancreatic body with a well-defined wall. **B**: Endoscopic retrograde cholangiopancreatography (ERCP) shows bowing of the pancreatic duct around the lesion, without communication. Pathology examination of the resected lesion showed cystadenocarcinoma.

The location of a pseudocyst and its relationship to the pancreatic duct can affect the approach taken for cyst drainage. Pancreatography may be helpful in delineating obstruction of the pancreatic duct and ductal communication with a pseudocyst. Those that do not communicate are amenable to either internal or external drainage. Pseudocysts that communicate with the duct, especially when the duct is strictured or disrupted, often resolve slowly when drained externally, and are best considered for internal drainage. Pseudocysts of the pancreatic head may be best treated with transpapillary stenting, especially if the cyst communicates with the pancreatic duct and there is an associated ductal stricture. [148] Pancreatography may be irrelevant if endoscopic internal drainage is planned, especially for pseudocysts of the pancreatic body and tail.

Endoscopic or percutaneous therapies are attractive nonsurgical options for pseudocyst drainage in many cases. Endoscopic techniques include transmural drainage into the stomach or duodenum with placement of an internal stent between the pseudocyst and the gut lumen. A high incidence of major hemorrhage was initially reported with endoscopic drainage, but use of an over-the-wire Seldinger technique, rather than electrocautery, may lower the risk of major complications such as bleeding or perforation to less than 5%. [149] EUS can facilitate pseudocyst drainage, particularly when an obvious bulge is not visible endoscopically, and may further decrease the risk of major hemorrhage by allowing the endoscopist to identify and avoid larger vessels between the stomach and pseudocyst lumens. [150] Endoscopic drainage of infected pseudocysts has been described.

Percutaneous drainage is also a well-established method for draining sterile or infected pseudocysts. When technically possible, a transgastric approach is favored, as internal drainage into the stomach through a mature catheter tract can result. External drainage may otherwise result in persistent drainage of pancreatic juice through the external fistula created by the catheter.

Incomplete pseudocyst drainage by either endoscopic or percutaneous means may result in infection of the pseudocyst contents. This is particularly common in patients with “organized pancreatic necrosis,” in whom the organized collection may have the CT appearance of a fluid-filled pseudocyst. A complex collection should be suspected in patients with necrosis that has evolved into a pseudocyst-like structure on serial CT scans. EUS or MR may be used to assess for solid material in the cavity prior to drainage. If solid matter is present in the collection more aggressive endoscopic or percutaneous techniques are necessary for adequate treatment, such as placement of multiple stents and a nasocystic tube to allow lavage of the pseudocyst cavity.

Fluid contents of a pseudocyst should be sampled during drainage for several reasons. First, a high amylase concentration within a cyst probably reflects its persistent communication with the pancreatic duct and bodes a poor outcome for external drainage. Second, symptoms of pseudocyst infection may be indolent and suspected only after bacterial and fungal culture. Third, true cystic lesions of the pancreas, including cystic neoplasms, may be mistaken for pseudocysts. Thus, amylase, viscosity, cytology, and tumor markers (including carcino embryonic antigen [CEA]) should be obtained from cyst aspirates when possible.

Pancreatic Abscesses

Pancreatic abscesses are circumscribed intra-abdominal collections of pus, usually within or in close proximity to the pancreas. In contrast to infected pancreatic necrosis, a pancreatic abscess contains little or no necrosis and typically presents later in the course of the illness, often more than 4 weeks after the onset of acute pancreatitis. Clinical and laboratory findings of acute pancreatitis have usually resolved before pancreatic abscess is detected. Because the infected collection is walled off and the surrounding tissue is viable, spread of infection to adjacent tissues is uncommon. Percutaneous drainage of pancreatic abscess is usually successful, although a minority of patients will require surgery. [151] Endoscopic transpapillary drainage is also feasible when the abscess cavity communicates with the pancreatic duct. [152]

Ascites and Fistulae

Several processes may contribute to the formation of ascites in acute pancreatitis. Peritoneal inflammation resulting from chemical peritonitis usually generates a small amount of fluid. Attendant chronic liver disease may contribute varying amounts of ascites. Pancreatic ascites refers to the presence of large amounts of fluid rich in pancreatic secretions and results from a communication between the pancreatic duct or a pseudocyst and the peritoneal cavity. Pancreatic ascites produces a gradual increase in abdominal girth, and is sometimes associated with subcutaneous fat necrosis. Since the pancreatic enzymes usually remain inactive, peritonitis is uncommon. The diagnosis should be suspected when ascites fails to respond to diuretic therapy and the serum amylase level is persistently elevated. Marked elevations of the ascitic fluid amylase and ascites protein concentrations above 3 g/dL are typical of pancreatic ascites. The site of ductal disruption can sometimes be

identified by CT, but ERCP is often required. [106]

Three forms of treatment have been used to treat massive pancreatic ascites. Endoscopically placed stents can be used to bridge the ductal disruption. Continuous infusion of somatostatin or octreotide with or without prior drainage of the ascites has also been used. However, some patients will require surgical drainage or pancreatic resection.

Pancreatic fistulae usually arise after a bout of alcoholic pancreatitis or from pancreatic pseudocysts, but also may form after pancreatic trauma, acute pancreatic duct disruptions, or pancreatic surgery. Anterior pancreatic ductal discontinuities can generate ascites, whereas posterior disruptions may result in fistulae that burrow through to the skin or track through the retroperitoneum. Fistulae sometimes extend through the esophageal or aortic hiatus into the chest, producing pleural effusions or mediastinal collections rich in amylase. Internal fistulae may communicate with the colon, gallbladder, and small bowel. Fistulae to vascular structures, such as the portal vein, have rarely been reported, and are often associated with subcutaneous fat necrosis.

The fluid from a pancreatic fistula has high protein and amylase content. The anatomy of an external fistula may be revealed by a fistulogram. Although ERCP is the most useful test for identifying an internal fistula, CT scanning may be very useful for fistulae that communicate with the thoracic cavity. Spontaneous healing is more common for cutaneous fistulae than internal fistulae. Drainage of fluid collections by thoracentesis or paracentesis may help to heal serosal discontinuities. Decreasing pancreatic secretion with somatostatin analogs has been reported to promote the resolution of fistulae, particularly those with cutaneous communications. Stenting of the pancreatic duct or surgical resection, however, are often required for internal fistulae.

Vascular and Splenic Complications

Pancreatitis infrequently results in bleeding or thrombosis of peripancreatic vessels. The commonest venous complication of pancreatitis is occlusion of the splenic vein, which is adjacent to the posterior superior margin of the pancreas throughout most of its course. Splenic vein thrombosis results in splenomegaly, gastric varices, and rarely colonic varices. Occlusion of the superior mesenteric vein can also occur, causing mesenteric venous congestion and small bowel edema and ischemia. Severe pancreatic inflammation or a large pseudocyst may thrombose or compress these vessels. When acute thrombosis of these veins is detected thrombolytic therapy is sometimes considered, but there are little data regarding the safety of such therapy and the risk of retroperitoneal hemorrhage in patients with ongoing pancreatitis.

Arterial hemorrhage may also occur as a result of pancreatitis, and is a ife-threatening event. This typically occurs when a pseudocyst erodes into a pancreatic artery, transforming the pseudocyst cavity into a pseudoaneurysm whose walls are partially formed by the artery and partially by the pseudocyst. (Fig. 94-15). The splenic artery may be involved if the pseudocyst is in the pancreatic body or tail, while the gastroduodenal artery or branches of the pancreaticoduodenal arcade are typically affected in the head of the pancreas. If the pseudocyst communicates with the pancreatic duct, hemosuccus pancreaticus (or bleeding into the duodenum via the pancreatic duct and ampulla) ensues. CT scanning and angiography are used to make the diagnosis. The bleeding artery often can be treated by embolization, but sometimes requires surgical ligation and, occasionally, broad surgical resection. [153] If hemorrhage is controlled angiographically, subsequent endoscopic treatment of the pseudocyst has been described. [154]

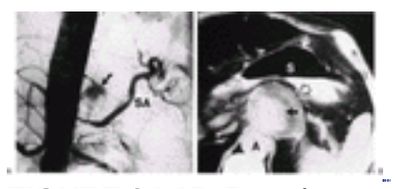

FIGURE 94-15. Pseudoaneurysm complicating acute pancreatitis. **A**: Angiogram demonstrates pseudoaneurysm arising from the splenic artery (*SA*) and a jet of contrast leaking from the pseudoaneurysm (*arrow*). **B**: Dynamic contrast-enhanced computed tomography of the same patient demonstrates the pseudoaneurysm (*open arrow*) with contrast enhancement (*black arrow*) anterior to the aorta (*A*) and posterior to the stomach (*S*). (Courtesy of Caroline Taylor, M.D., West Haven, CT.)

Extension of a pseudocyst, or occasionally inflammation alone, from the pancreas into the spleen may lead to a splenic hematoma and rupture. This complication is most often associated with chronic disease and may present with abdominal pain that is referred to the left shoulder, fever, and an abdominal mass. Ultrasonography or CT suggests the diagnosis. Arteriography may demonstrate splenic artery pseudoaneurysms. Emergency splenectomy is required for splenic rupture, and prophylactic splenectomy has been advocated by some authors even when splenic pseudocysts are asymptomatic. [155]

Gastrointestinal Obstruction

Severe acute pancreatitis may result in compression of the duodenum, with gastric outlet obstruction. Bile duct obstruction may also occur. These forms of gastric or biliary obstruction will usually resolve unless there is underlying chronic pancreatitis or pseudocyst.

It is common for pancreatic inflammation to extend to the transverse colon and splenic flexure. Obstruction secondary to spasm and edema may cause the classic colon cutoff sign, with gas present in the right colon but absent distal to the region of obstruction. This finding is seen in 1% to 10% of patients with acute disease, and cecostomy is occasionally required to prevent colonic perforation in patients with colonic obstruction progressive dilation of the proximal colon. [156] Extension of pancreatic inflammation may lead to persistent colonic strictures, fistulae, or even perforation. During surgery for acute pancreatitis, especially when performed for debridement, the colon is particularly susceptible to devitalization and subsequent perforation. Rarely, erosion into colonic blood vessels may result in acute lower gastrointestinal hemorrhage or inferior mesenteric vein thrombosis and colonic infarction.

SYSTEMIC COMPLICATIONS

Systemic complications of acute pancreatitis may be due to the direct toxicity of circulating activated pancreatic enzymes, the systemic inflammatory response to pancreatic injury and necrosis, circulating endotoxins due to bacterial translocation from the gut, or combinations of these factors. Organ failure can result, and may be manifested as respiratory insufficiency, shock, a sepsis-like syndrome, renal failure, gastrointestinal bleeding, and confusion or coma. [2] Coagulopathy and disseminated intravascular coagulation may also occur. The syndrome of multiple organ failure (MOF) may develop. Organ failure is seen uncommonly in interstitial pancreatitis, develops in about 50% of patients with pancreatic necrosis, and is an independent predictor of mortality. [157] Early mortality in acute pancreatitis is often due to multiple organ failure, while late mortality is more often related to infection.

Pulmonary

The most common form of organ failure in acute pancreatitis is pulmonary insufficiency due to the adult respiratory distress syndrome (ARDS). This hypoxemic state is associated with a normal pulmonary venous wedge pressure, decreased pulmonary compliance, and pulmonary capillary injury. It is often delayed in onset. Patients with hypertriglyceridemia are at increased risk for developing the complication. In patients with severe ARDS, pulmonary artery pressure monitoring and respiratory support with positive end expiratory pressure are generally required.

Pulmonary function may be further affected by pleural effusions and decreased diaphragmatic movement due to ascites or retroperitoneal inflammation. The contribution of decreased diaphragmatic movement is unclear, but may be a factor in the increased risk of a pulmonary death in those with acute pancreatitis and obesity. Effusions are reported in 4% to 17% of patients with acute pancreatitis; up to 50% may be associated with pseudocysts or pancreatic fistula. Most effusions are found on the left side or are bilateral, and most resolve spontaneously. [121] Early appearance of effusion has been associated with more severe disease. Thoracentesis is suggested when needed for diagnosis, to exclude infection, or when the size of the effusion results in respiratory compromise. Marked elevation of the pleural fluid amylase level may suggest an underlying pancreatic fistula, which may respond to antisecretory or endoscopic therapy.

Fat Necrosis

Clinically evident fat necrosis in regions distant from the pancreas is seen in less than 1% of patients with acute pancreatitis. Pancreatic enzymes have been detected in areas of fat necrosis and are presumably responsible for initiating this injury. The initial injury may arise from the cleavage of adipocyte plasma membrane glycerosphingolipids by phospholipase A. Adipocyte-associated or circulating lipase activities may then enter the cell and convert triglycerides to monoglycerides and toxic free fatty acids. Several clinical syndromes are associated with fat necrosis. Cutaneous necrosis generates widely disseminated, raised, erythematous, and tender nodules of less than 2 cm in diameter. The process is frequently associated with fever and eosinophilia. [158] The nodules typically resolve in days to weeks without residual; however, some may rupture and heal with hyperpigmentation. Fat necrosis may affect the marrow cavity and lead to vascular damage and bone infarction. The typical bone lesions are frequently painless, osteolytic, develop 3 to 6 weeks after the onset of pancreatitis, and involve the ends of long bones such as the femur. Synovial pad fat necrosis may be associated with arthritis. The increased amounts of free fatty acids recovered from such joints may initiate this inflammatory process. Fat necrosis may rarely affect the middle ear.

Other Complications

Renal insufficiency is not uncommon in acute pancreatitis. Confusion and coma can occur and may be due to cerebral edema. Gastrointestinal hemorrhage may be due to mucosal erosions and ulcerations, gastric varices, colonic varices, or a pancreatic pseudoaneurysm, as described earlier in the section on “Vascular and Splenic Complications.” Temporary blindness has been reported in pancreatitis and may be attributed to the retinal ischemia induced by leukocyte emboli.

ACUTE TREATMENT

The treatment of acute pancreatitis is largely supportive. Pancreatitis patients are often in critical need of such care, and appropriate treatment is frequently lifesaving. Aggressive fluid replacement, management of pain and nausea, prompt identification and treatment of complications, nutritional support, and prophylaxis and treatment of infection are important elements of supportive care.

Some treatments have lost favor due to lack of convincing efficacy. These include peritoneal lavage and nasogastric suction. The use of nasogastric suction in the past was based on the unproved concept that removing the acid-dependent stimulation of the pancreas would allow the inflamed organ to rest and promote recovery. However, clinical trials showed no benefit to nasogastric suction for treatment of underlying pancreatitis. Nasogastric suction should be reserved for patients with persistent emesis and the occasional patient with evidence of colonic obstruction complicating acute pancreatitis.

Supportive care includes careful observation of the patient. Regular assessment of vital signs and oxygen saturation should be a routine part of care. Decreased urine output, hemodynamic instability, or worsening oxygen saturation should lead to prompt evaluation and treatment, perhaps in an intensive care unit.

Parenteral narcotics are often required for treatment of pain in acute pancreatitis, and meperidine has traditionally been the narcotic of choice because it does not cause pancreatitis or significantly alter sphincter of Oddi function. [45] However meperidine is a less effective analgesic than many other narcotics, and accumulation of meperidine metabolites may cause paranoia, psychosis, or seizures. Morphine administration is discouraged in acute pancreatitis because it can cause sphincter of Oddi spasm and, rarely, pancreatitis. The effect of other narcotics on the sphincter of Oddi is less well studied, but hydromorphone or other agents may be appropriate in some cases, particularly if meperidine is ineffective, large doses are required, or prolonged use of narcotics is anticipated.

Fluid and Electrolyte Replacement

The cornerstone of supportive therapy is maintenance of an adequate intravascular volume. The analogy between the injury of severe pancreatitis and a burn is a useful one: pancreatitis often leads to “third spacing” of fluid and intravascular volume depletion. This may in turn worsen pancreatic perfusion and exacerbate the pancreatitis. Hemoconcentration is associated with the development of pancreatic necrosis. [137] The clinician should regularly reassess intravascular volume and aggressively replace fluids and electrolytes to avoid volume depletion. Often such assessment is made on the basis of urine output and vital signs. An elevated hematocrit or renal insufficiency may be signs of inadequate volume replacement. In severely ill patients, central venous pressure monitoring may be useful. Although dextrans have been used to expand intravascular volume and enhance pancreatic blood flow, their use has not been widely accepted.

Metabolic Abnormalities

Hyperglycemia is present in some patients with acute pancreatitis. It is wise to err on the side of maintaining the blood glucose level in the high range for several reasons. Limited glucagon and glycogen reserves, especially in alcoholics, diminish the ability of patients to respond to hypoglycemia. Furthermore, hyperglycemia is often transient, improving when the pancreatitis has resolved.

Serum calcium levels may be decreased during acute pancreatitis and levels below 7.5 mg/dL are associated with a poor prognosis. Factors that account for this decrease are sequestration of calcium by free fatty acids that have been generated by peritoneal fat necrosis and dilution by intravenous administration of calcium-poor fluids. In addition, hypoalbuminemia may result in low total serum calcium with normal serum ionized calcium. [159] Humoral factors, such as parathyroid hormone resistance associated with hypomagnesemia and hypersecretion of calcitonin and glucagon, have been implicated in hypocalcemia, but are unlikely to play a major role. Calcium should be slowly administered to patients with decreased ionized serum calcium.

Hyperlipidemia may lead to pancreatitis, accompany alcoholic pancreatitis, or be a consequence of acute pancreatitis. Therapy should generally not be instituted for hyperlipidemia encountered during acute pancreatitis, but values should be reassayed after recovery. One exception is patients with severe pancreatitis and respiratory failure. In this subgroup, and in the occasional patient with extreme hyperlipidemia, lowering serum triglycerides with plasmapheresis may be useful. [160]

Inhibition of Enzymes, Secretion, and Inflammation

Pharmacological therapy could theoretically be used to limit the severity of pancreatitis at several levels: by inhibiting active pancreatic enzymes, inhibiting pancreatic secretion, or interrupting the inflammatory cascade. The first agents to be tested extensively in humans were drugs that inhibit activated pancreatic enzymes. Of these “protease inhibitors” the best studied is gabexate mesilate, a drug that is not currently available in the United States.

Most studies of gabexate have shown a benefit in acute pancreatitis that did not reach statistical significance. Two meta-analyses have evaluated controlled clinical trials of gabexate in acute pancreatitis, and these metaanalyses reached similar conclusions. Gabexate does not reduce mortality from acute pancreatitis, but does appear to reduce the incidence of complications by about 30%. [161], [162] While a recent additional trial showed decreased early mortality in patients with severe disease, it is unlikely to alter the basic conclusions of the metaanalyses, which drew on studies enrolling over 800 patients with acute pancreatitis. [163] The lack of a more decisive clinical effect is consistent with the fact that activated pancreatic enzymes play their most important role early in the course of pancreatitis, before the patient presents for treatment.

Somatostatin and octreotide, two agents that inhibit pancreatic secretion, have also been extensively studied in clinical trials. When only randomized controlled trials were considered, metaanalysis showed a statistically significant reduction in mortality with somatostatin therapy, and a lesser benefit with octreotide that did not reach statistical significance. [161] Curiously, despite their effect on mortality, neither agent was shown to decrease complication rates. The lack of demonstrated benefit with octreotide therapy may reflect its effects on sphincter of Oddi function and pancreatic blood flow. While somatostatin appears to have a significant impact on mortality, it is not currently available in the United States.

Severity of the systemic immune response, as measured by blood levels of circulating proinflammatory cytokines, correlates with the development of local and systemic complications in pancreatitis. The inflammatory response often continues to increase after the patient is hospitalized, suggesting that pharmacological blockade of proinflammatory cytokines soon after hospital admission could ameliorate the consequences of pancreatitis. Although animal studies support this hypothesis, the one cytokine inhibitor tested in a large clinical trial did not have a significant effect on complication rates or mortality. [164] Experimental studies suggest that specific cytokines may promote injury in distinct tissues. Therefore, a different cytokine inhibitor or a combination of inhibitors might be needed to be fully

beneficial.

Enteral and Parenteral Nutrition

One long-standing tenet of supportive treatment has been to avoid pancreatic stimulation by giving the patient nothing to eat during the acute phase of illness. Patients with mild disease who rapidly improve and resume oral intake require no special form of nutritional support, but those with more protracted disease are generally given nutritional therapy.

Controlled trials of total parenteral nutrition (TPN) have shown little or no benefit in patients awaiting surgery or undergoing chemotherapy. While there are little controlled data in pancreatitis, some retrospective studies suggest that pancreatitis patients given early parenteral hyperalimentation are at increased risk for complications such as sepsis and pancreatic infection. While intravenous lipid infusion does not stimulate pancreatic secretion, it can produce hyperlipidemia that can then trigger further pancreatitis. Since TPN-induced elevations of the triglyceride level have been reported to cause pancreatitis, it seems prudent to monitor triglyceride levels and attempt to keep them below 500 mg/dL in patients with pancreatitis receiving TPN. [165]

A growing body of evidence suggests that enteral feeding is safe in pancreatitis, and preferable to parenteral nutrition. Oral feeding stimulates pancreatic secretion, but feeding directly into the distal small bowel may result in negligible pancreatic stimulation. [166] Theoretically, enteral feeding could limit the changes in gut mucosal integrity seen in pancreatitis, with a resultant decrease in bacterial translocation, systemic immune response, and pancreatic infection. These considerations have led to several controlled trials of enteral versus parenteral nutrition in pancreatitis.

In one randomized study enteral feeding via a nasojejunal tube was compared to TPN in patients with mild acute pancreatitis mostly attributed to alcohol. [167] Enteral feeding was begun within 48 hours of admission and was well tolerated in all cases. There was no significant difference between the two groups in major end points, including time to normalization of serum pancreatic enzyme levels, resolution of pain, time to oral feeding, or incidence of infection. Several patients tolerated enteral feeding well despite failing subsequent trials of oral intake, or had recurrent pancreatic symptoms when the tip of the enteric feeding tube fell back into the stomach.

Two other studies have randomized patients with severe disease to TPN or early enteric feeding. In both studies enteric feeding was safe and less costly than TPN, and was associated with improved outcomes in either laboratory markers of inflammation or in the incidence of infections and other complications. [166], [168] Patients with clinical evidence of ileus generally tolerated enteric feeding well. An additional study showed no benefit of enteral feeding on markers of immune response or intestinal permeability, but tube dislodgement was common and patients received only 20% of their predicted caloric requirements. [169]

Enteral feeding can be recommended in acute pancreatitis, especially when it is unlikely that the patient will quickly resume oral intake. Early initiation of nasojejunal feeding (within 48 hours of admission) is safe and may improve the course of the illness in patients with severe disease. The major impediment to this therapy is the logistical difficulties of placing a nasojejunal tube. Methods for simple enteric feeding tube placement have been described, including both fluoroscopic techniques and bedside transnasal endoscopy. [170] Isocaloric full-strength formula can be used, beginning at 25 mL/h, and increasing the rate every 4 hours until the patient's target rate is met. Feeding is generally successful even in the presence of ileus, but high gastric residuals or symptoms of nausea and abdominal fullness may prompt a decrease in the infusion rate.

When the patient is ready for oral feeding, tradition holds that they should be started on a low-fat diet, but there is little evidence that this restriction affects recovery. Indeed, lumenal amino acids are also potent stimulants of pancreatic enzyme secretion. Probably more important than fat restriction is the subjective response of the patient to feeding. The most reliable marker for beginning oral feeding is hunger. Steady improvement in pain and tenderness allowing discontinuation of parenteral pain medication is also a useful indicator. Persistently abnormal serum enzymes or CT scans in the absence of symptoms or complications should not dissuade the clinician from feeding a hungry patient.

Management of Necrosis

Prophylaxis of Infected Pancreatic Necrosis Infection of pancreatic necrosis is a life-threatening complication and a major risk factor for death from pancreatitis. [171] Strategies for the prevention of infected necrosis have been evaluated, including systemic antibiotic prophylaxis and selective decontamination of the gut. Older studies of antibiotics to prevent pancreatic infection did not find a benefit. These studies probably enrolled many patients at low risk for infection, and did not select antibiotics based on their ability to penetrate pancreatic tissue. Subsequent investigations demonstrated that penetration of pancreatic tissue by ampicillin and aminoglycosides is poor, whereas imipenem-cilastatin, mezlocillin, third generation cephalosporins, metronidazole, and quinolones exhibit moderate to excellent penetration. [172] More recent prospective studies have demonstrated benefits to prophylactic intravenous antibiotic therapy in patients with pancreatic necrosis. Prophylactic imipenem-cilastatin, cefuroxime, and a combination of ceftazidime, amikacin, and metronidazole have been tested against placebo, and each regimen resulted in a significant reduction in the incidence of infectious complications. [173], [174] and [175] Only the cefuroxime study showed a significant reduction in mortality, but this study has been criticized for a high rate of nonpancreatic and staphylococcal infections, failure to reduce the incidence of pancreatic infections significantly, and changes in the antibiotic regimens given to most patients in the course of the study. Two metaanalyses of antibiotic prophylaxis concluded that prophylaxis decreases sepsis and mortality in patients with necrosis. [176], [177] In a recent comparative study, pefloxacin was less effective than imipenem-cilastatin for prevention of infectious complications. [178] Taken together, these data support the prophylactic administration of antibiotics. Patients with necrosis documented by CT or, in the absence of early contrast-enhanced CT, patients with severe pancreatitis (who are at highest risk for necrosis) should be treated. Treatment should generally be started within 48 hours of admission and continued for 2 to 3 weeks, and imipenem-cilastatin (500 mg every 8 hours) is probably the most effective agent. Unfortunately, prophylactic antibiotics do not eliminate the risk of infected necrosis. Recent large series of patients treated with prophylactic antibiotics report an incidence of infected necrosis as high as 32%, with a shift toward gram-positive and fungal infections. [142] Fluconazole penetrates pancreatic tissue [179] but its role in prophylaxis of pancreatic fungal infections is unproven. An alternative to systemic antibiotic prophylaxis is "selective decontamination" of the gastrointestinal tract with lumenal antibiotics. The rationale for this approach is the finding that bacterial translocation from the gut is the likely source of infection in pancreatic necrosis. [140] Studies in animal models of severe pancreatitis show a benefit to intralumenal antibiotics and intestinal lavage. One large controlled clinical trial has tested this prophylactic strategy in patients with severe pancreatitis, who were randomized to receive no antibiotic prophylaxis or colistin sulfate (200 mg), amphotericin (500 mg), and norfloxacin (50 mg) orally every 6 hours, and in a rectal enema daily. Intravenous cefotaxime was also given until gram-negative bacteria were eliminated from the mouth and rectum. The incidence of pancreatic infection was halved by selective decontamination, and mortality was significantly decreased as well. [141]

Treatment of Infected Pancreatic Necrosis As discussed earlier in this chapter, the diagnosis of infected pancreatic necrosis should be entertained in patients with systemic signs of infection, or in patients with persistent or worsening organ failure despite supportive care. Diagnosis requires a high level of suspicion. Currently available noninvasive laboratory and imaging tests do not reliably exclude infection, and CT-guided aspiration of necrotic areas for Gram stain, fungal stain, and cultures are the most important diagnostic modalities. Anecdotal reports suggest that an occasional patient with infected necrosis will survive with antibiotic treatment alone. [180] However antibiotic treatment alone is generally inadequate for treatment of documented infected necrosis, and the infected necrotic material should be removed. Prompt surgical debridement has been the standard therapy, and repeated reexploration for further debridement is often necessary. This treatment reduces mortality to between 20% and 60%. [181] Better surgical outcomes are in part due to changes in technique, including open packing of the wound and prolonged postoperative lavage. Percutaneous drainage of infected necrosis was long thought to be an inadequate therapy, since the solid necrotic material would not drain out through small caliber percutaneous catheters, and the drainage tube would only serve to introduce other organisms into the necrotic debris. However, recent reports demonstrate that percutaneous catheter drainage may be effective. [182], [183] In contrast to percutaneous treatment of pseudocysts or pancreatic abscesses, repeated interventions and aggressive techniques are required to adequately remove the infected material. Techniques may include placement of multiple large bore (28 French) drainage tubes, frequent bedside catheter irrigation, periodic vigorous manual irrigation under fluoroscopic or CT guidance, and endoscopy of the percutaneous catheter tract for removal of debris using jet irrigation, forceps, and snares. Reported mortality rates of 15% to 20% from expert centers compare favorably with surgical series. Complications include hemorrhage from retroperitoneal vessels. Patients with persistent pancreatic sepsis requiring surgery had a high mortality rate.

Drainage of Sterile Necrosis The role of surgery in sterile necrosis has been debated. Although routine surgical debridement of sterile pancreatic necrosis was advocated in the past, the weight of available evidence does not show a benefit to surgery over supportive medical care. [184] Nevertheless, intervention may be warranted in a small subset of patients in whom sterile necrosis is associated with either a deteriorating course despite maximal supportive care, or prolonged organ failure. [185] In such patients the percutaneous techniques described previously may be appropriate as well. Some patients with sterile necrosis require intervention not because of organ failure or an ongoing systemic inflammatory response, but because of recurrent pancreatic symptoms and an enlarging collection with attempts at refeeding. This is particularly common in patients with "central necrosis" (extensive necrosis of the pancreatic body) and is usually associated with a persistent disruption of the pancreatic duct, resulting in an isolated pancreatic tail and ongoing leakage of pancreatic juice from the disruption. Internal drainage of the collection may suffice, but resection of the pancreatic tail is required in some cases. [182], [186] Endoscopic transmural or transpapillary drainage of regions of organized pancreatic

necrosis has also been described. [145] In contrast to patients drained surgically or percutaneously, patients treated endoscopically have generally been less ill, without organ failure, and were treated later in the course of their illness, on average 6 weeks after onset of pancreatitis. The drained collections had liquefied to some extent and developed a wall. Endoscopic drainage of “organized pancreatic necrosis” usually requires placement of multiple stents and a transnasal or transgastrostomy catheter for lavage of the collection. The endoscopist should be prepared to perform repeated endoscopic interventions over time as necessary to ensure adequate drainage.

ERCP and Sphincterotomy in Biliary Pancreatitis

Urgent ERCP in Gallstone Pancreatitis Persistent bile duct stones are associated with more severe pancreatitis, and both surgeons and endoscopists have investigated the theory that prompt relief of ampullary obstruction by removal of an impacted stone would decrease the severity of gallstone pancreatitis. While studies of urgent surgery have yielded disappointing results, [187] endoscopic studies have identified a subgroup of patients who benefit from urgent ERCP. Several randomized studies have assessed the value of urgent ERCP in patients with gallstone pancreatitis. The first, performed in Great Britain, found that ERCP within 2 days of presentation decreased the complication rate of gallstone pancreatitis. [188] Sphincterotomy was done only if stones were present in the ampulla or bile duct. The benefit was limited to the subset of patients who were predicted to have severe pancreatitis on initial assessment using the modified Glasgow criteria (Table 94-4). These results suggested that urgent ERCP might alter the course of an episode of gallstone pancreatitis. A similar study subsequently reported from Hong Kong also found a decreased complication rate when urgent ERCP was performed and sphincterotomy was done for ampullary or ductal stones. [31] This second study also showed that benefit was limited to patients predicted on admission to have severe pancreatitis, using the simpler urea-glucose criteria. The Hong Kong study included some patients with other causes of pancreatitis, and probably included more patients with primary pigment stones of the bile duct. Complications were reported in greater detail, and the benefit of ERCP appeared to be largely due to prevention of bacterial cholangitis rather than amelioration of pancreatitis. Both of these studies found a benefit in patients predicted to have severe pancreatitis and showed that ERCP can be safely performed in this setting. It remains unclear if the benefit was due to a decrease in the severity of pancreatitis or to treatment and prevention of cholangitis. CT of the pancreas was not used in these studies to direct image the severity of pancreatitis. ERCP was not shown to prevent a predicted mild episode of pancreatitis from progressing in severity, and there were no statistically significant changes in survival. A third large study showed a significant improvement in mortality with early ERCP and sphincterotomy, but was only published in abstract form. [189] A fourth study with a similar design from Germany showed a trend toward higher mortality and more severe complications in patients undergoing early ERCP. [190] This study excluded patients with a serum bilirubin above 5 mg/dL, probably excluding many patients with persistently impacted stones while including patients with nonobstructing ductal stones. Since nonobstructing stones theoretically have little effect on either the development of cholangitis or the severity of pancreatitis, this study probably excluded those patients most likely to benefit from urgent ERCP. Unfortunately, none of these studies reported the location of calculi or the degree of obstruction these stones caused. Further studies using noninvasive methods for visualization of ampullary stones and pancreatic inflammatory changes may shed more light on the benefit achieved by ERCP and sphincterotomy. When should the clinician consider urgent ERCP? The clearest indication is the presence or suspicion of biliary sepsis. Anicteric patients with mild pancreatitis and no signs of cholangitis are unlikely to require urgent ERCP. Jaundiced patients and those with predicted severe pancreatitis, especially those who fail to improve over the first 12 to 24 hours of observation, may benefit from prompt bile duct evaluation. In these patients, newer and less invasive methods of demonstrating ductal or ampullary stones (such as MRCP, helical CT, and EUS) will probably be helpful in choosing patients to undergo urgent ERCP [128] (see Fig. 94-9). Traditionally, cannulation of the pancreatic duct has been avoided when possible in patients with acute biliary pancreatitis undergoing ERCP. Some experts have advocated intentional visualization of the pancreatic duct early in the course of severe acute pancreatitis for identification and endoscopic treatment of pancreatic duct disruptions. However some disruptions resolve spontaneously, [135] and instrumentation may introduce infection into a previously sterile collection. Controlled data evaluating this strategy are needed before it can be generally recommended. Similarly, a strategy of early ERCP and sphincterotomy in all patients with biliary pancreatitis cannot be generally recommended.

Preoperative ERCP in Gallstone Pancreatitis Most patients with gallstone pancreatitis rapidly improve with supportive management, and by the time of their cholecystectomy only a minority have bile duct stones. The bile duct should be imaged in such patients, and the choice of imaging technique depends on the likelihood of finding a bile duct stone, the surgeon’s ability to extract bile duct stones laparoscopically, and the confidence of the biliary endoscopist. Patients with gallstone pancreatitis whose serum liver tests and pancreatic enzyme levels steadily fall after admission have a low (8%) incidence of bile duct stones, [120] and are best evaluated with intraoperative cholangiography. Patients in whom any of these chemistries increase in the first 48 hours of admission, and patients with a dilated bile duct on ultrasound, have an intermediate (30%) incidence of ductal stones. These patients may also best be evaluated with intraoperative cholangiography, depending on the comfort and skill of the available surgeon and endoscopist. Preoperative MRCP or EUS may also be appropriate in this patient group. Direct visualization of a ductal stone on ultrasound, CT, MR, or EUS establishes a high risk (60% or greater) of a bile duct stone in gallstone pancreatitis, and such patients, as well as those with persistent jaundice, may reasonably undergo preoperative ERCP.

Sphincterotomy as Sole Therapy for Gallstone Pancreatitis Endoscopic sphincterotomy usually eliminates the common channel between the bile duct and pancreatic duct, which afterward enter the duodenum at slightly different locations. Sphincterotomy appears to prevent recurrence of gallstone pancreatitis in patients whose gallbladder remains in place. At least 15% of patients treated in this fashion will subsequently develop other complications of gallstones, however, including biliary obstruction, cholangitis, and acute cholecystitis. [191] These complications are most common within 6 months of sphincterotomy but may occur years later. In addition, a small percentage will develop stenosis of the sphincterotomy site. Cholecystectomy thus remains preferable to sphincterotomy in patients with uncomplicated pancreatitis who are fit for surgery. When the risks of cholecystectomy are high (as in patients with unstable cardiovascular disease or advanced cirrhosis), endoscopic sphincterotomy is a reasonable therapeutic alternative.

CHAPTER 95

Chung Owyang

CHRONIC PANCREATITIS

The terminology surrounding the classification of inflammatory disease of the pancreas is confusing and based on both clinical and morphologic criteria. Since the 1970s, multiple classifications have been proposed. Differentiation by etiology allows for the prediction of responsible factors for pancreatitis but gives little information on potential overlapping pathophysiologic mechanisms. Clinical and pathological classifications by themselves have prognostic implications, with fulminant or hemorrhagic pancreatitis having a poor prognosis and edematous pancreatitis being associated with a good prognosis; only in a minority of patients is histological information ever obtained, however, and clinical classifications are not helpful pathophysiologically. In 1963, a symposium on pancreatitis was held in Marseilles, France, in which a clinical classification of pancreatitis was proposed, and this classification has since been widely used. [1] According to the Marseilles classification, pancreatitis can be divided into acute and chronic, with both types having relapsing and nonrelapsing varieties. The essential difference between acute and chronic pancreatitis is the presence of permanent and progressive morphologic or functional damage in the latter. Both subtypes are further classified into relapsing and nonrelapsing varieties depending on their clinical presentation. In acute pancreatitis, if the primary causes or factors are eliminated, clinical and morphologic restitution of the pancreas occurs. On the other hand, in the chronic form, anatomic or functional pancreatic damage remains even after the primary causes are eliminated.

The major drawback of the Marseilles classification is the frequent inability to distinguish acute and chronic forms of the disease based on clinical presentation. This prompted two subsequent international symposia in 1983 [2] and 1984 [3] to discuss the classification of pancreatitis. Some minor modifications of the original Marseilles classification were proposed. The classification of pancreatitis should be reduced to include only acute and chronic forms because it is frequently difficult to distinguish between recurrent acute pancreatitis and recurrent attacks of chronic pancreatitis, and several years' follow-up may be needed. Accordingly, chronic pancreatitis is defined as an inflammatory disease of the pancreas characterized by persistent and often progressive lesions, whereas lesions of acute pancreatitis regress when the cause is suppressed or removed. In an addendum, it was recognized that alcohol-induced pancreatitis may present acutely, and it is not inevitably progressive.

The second symposium of Marseilles [2] also proposed to distinguish obstructive chronic pancreatitis from other forms of chronic pancreatitis. Obstructive chronic pancreatitis is characterized by dilation of the ductal system, diffuse atrophy of the acinar parenchyma, and uniform fibrosis. In contrast to other forms of chronic pancreatitis, intraductal plugs or stones usually are rare or absent, and both structural and functional changes may improve when the obstruction is relieved. Based on morphology, biochemistry, molecular biology, and epidemiology, Sarles [4] reclassified chronic pancreatitis into four groups. The first and largest group, lithogenic pancreatitis (chronic calcifying pancreatitis), consists of five subgroups of stones: hereditary pancreatitis, transparent stones, nutritional pancreatitis, hypercalcemia pancreatitis, and pure calcium stones. The other three groups include obstructive pancreatitis caused by obstruction of pancreatic ducts preceding the onset of pancreatitis, with uniform distribution of the lesions caudal to the obstruction; inflammatory pancreatitis, which is characterized by diffuse fibrosis and the destruction of exocrine parenchyma with infiltration of mononuclear cells; and pancreatic fibrosis, characterized by silent, diffuse perilobular fibrosis.

INCIDENCE AND PREVALENCE

The prevalence of chronic pancreatitis in autopsy materials ranges from 0.04% [5] to 5%. [6] Epidemiologic studies based on clinical data are few. Most epidemiologic data are obtained either from retrospective studies [7], [8] and [9] or by calculation from data given in clinical material. [10], [11] The only prospective study on the incidence and prevalence of chronic pancreatitis was performed in Copenhagen, Denmark, in 1978 and 1979. [12] It showed an incidence of 8.2 new cases per 100,000 inhabitants per year, and a prevalence of 26.4 cases per 100,000 inhabitants. The epidemiologic studies clearly demonstrate that there is enormous difference in incidence rates between different areas. Alcohol consumption is considered to be the major factor in the development of chronic pancreatitis. This may well explain the low incidence (rate) of chronic pancreatitis in Japan, which has traditionally a very low alcohol intake. On the other hand, Switzerland has a substantially higher alcohol consumption than observed in Denmark, [13] but the incidence of chronic pancreatitis is lower in Switzerland than in Denmark. The reason for this discrepancy is unknown.

Environmental or hereditary factors may influence susceptibility to alcohol-induced pancreatitis. Alternatively, this may be related to regional differences in diagnostic criteria for chronic pancreatitis. Thus, figures for frequency of chronic pancreatitis differ markedly from one center to another. Most likely, this does not reflect a real

difference in frequency but points strongly to regional differences in patient selection and diagnostic criteria.

ETIOLOGY

Alcohol in Western societies (70% to 80%) and malnutrition worldwide represent the major etiologies of chronic pancreatitis. [14], [15] In addition, metabolic and mechanical disturbances, as well as hereditary disposition, have been implicated (Table 95-1).

Alcohol, 70%
Idiopathic (including tropical), 20%
Other, 10%

TABLE 95-1 Etiology of Chronic Pancreatitis

Alcohol

Alcohol consumption is the major cause of chronic pancreatitis. In Western societies, about 70% of cases are caused by alcohol. [16] The incidence of pancreatitis found at autopsy in alcoholics is as high as 45%—50 times the rate in nondrinking controls. [17] There is a linear relationship between the logarithm of the risk for development of chronic pancreatitis and the mean daily consumption of alcohol. [18] Furthermore, it has been demonstrated that the risk for abstainers is lower than the risk for people drinking a low quantity of alcohol (i.e., 1 to 20 g/day). Therefore, it appears that there is no statistical threshold for alcohol toxicity but a continuous spectrum of individual thresholds. This makes it difficult to distinguish between low-threshold alcohol-induced pancreatitis and idiopathic pancreatitis. The duration of alcohol consumption is also important. For the same daily intake, the risk increased with duration, [19] but the type of alcohol beverages and the pattern of drinking (weekend versus daily users) have no influence on the risk for development of chronic pancreatitis. [20] This concept, however, has been challenged. [21]

In general, prolonged alcohol intake is required to produce symptomatic chronic pancreatitis (6 to 12 years), although the length of time required for histological damage in humans is unknown. [22] Clinically, alcoholic chronic pancreatitis is characterized by an initial period of recurrent acute attacks lasting 5 to 6 years, followed by the development of chronic pain, exocrine and endocrine insufficiency, or both. A natural history study [23] demonstrated a median time to exocrine insufficiency of 13 years in patients with alcoholic chronic pancreatitis and a median time to endocrine insufficiency of 20 years. Interestingly, not all patients with an acute episode of alcohol-induced pancreatitis progress to clinical chronic pancreatitis. It is generally accepted that at the time of the initial attack of pancreatitis, histological, chronic pancreatitis is already present. Two retrospective studies [24], [25] reported that 15% to 20% of patients, followed for up to 30 years after an initial attack of alcoholic chronic pancreatitis, did not develop pancreatic calcification or exocrine or endocrine insufficiency. The factors responsible for this variability in progression of disease are not clear but do not appear to be caused by differences in avoiding further alcohol. Patients with progressive disease were more likely to have more severe and more frequent acute clinical attacks of pancreatitis, and these patients frequently developed significant abnormalities affecting the main pancreatic duct. Kondo and associates [26] emphasized that alcohol requires other factors to induce chronic pancreatitis. They reported that the aberrant pancreas might not be susceptible to alcoholic pancreatitis. Anatomic differences in the aberrant pancreas, such as innervation and different ductal drainage, may explain the lack of damage after chronic alcohol ingestion. In addition, dietary factors may play a significant role. Both experimental and epidemiologic studies indicate the risk for alcohol-induced pancreatitis is higher in people with high-fat, high-protein diets. Experimentally, focal lesions of chronic pancreatitis developed in more than 50% of rats that ingested alcohol for 20 to 30 months. [27] The pancreatic juice of these rats contained higher protein concentrations than controls, a condition that appears similar to chronic pancreatitis in humans. In separate studies, Tsukamoto and colleagues [28] showed that in rats with low dietary intake of corn oil fat, chronic alcohol intoxication produced only mild pancreatic injury. Severe focal lesions of chronic pancreatitis, however, were observed in rats fed higher amounts of fat, which resulted in striking potentiation of alcohol-induced pancreatic injury. Observations from these experimental studies were supported by clinical and epidemiologic studies. It has been observed in many European countries that alcoholics consuming a high-fat, high-protein diet are predisposed to chronic pancreatitis. [5], [29], [30] and [31] Durbec and Sarles [18] noted that the risk was less with average consumption of fat but was increased by both high (more than 100 g) and low (less than 85 g) daily fat intake. Furthermore, the effects of alcohol, protein, and fat consumption appear to be additive. This may explain why chronic pancreatitis is more commonly observed in patients who drink more alcohol and eat more protein and fat than controls. [19] Observations made in Europe, however, are not confirmed by studies reported from the United States and Australia. [32], [33] and [34] It appears that whereas a high-fat or high-protein diet may predispose to pancreatitis, such a diet is not a prerequisite for development of pancreatitis in chronic alcoholics. Differences in genetic predisposition, quantity of alcohol, and type of fat consumed by various populations may explain some of these conflicting observations.

The pathogenic mechanisms of alcohol-induced chronic pancreatitis are uncertain. Results from a prospective clinicopathological study of alcohol-induced recurrent attacks of acute pancreatitis evolving to chronic pancreatitis [35] support the hypothesis of the *necrosis-fibrosis* sequence, originally proposed in 1946 by Comfort and associates. [36] In this study of resected pancreatic tissue or autopsy specimens in 73 patients and in 10 patients with both types of specimens, it was found that after a mean of 4.1 years from the onset, focal necrosis and mild perilobular fibrosis were the predominant lesions. In contrast, the major lesions in the autopsy specimens, as compared with previous resected tissues (mean interval between biopsy and autopsy, 8 years), were severe perilobular and intralobular fibrosis and calcification but not necrosis. This suggests that the initial lesion in alcohol-induced pancreatic injury is cellular necrosis and, over time, that fibrosis will occur in those patients developing chronic pancreatitis. The cellular mechanisms by which alcohol produces chronic pancreatitis are not known. Inferences about the pathophysiologic basis of alcohol-induced progressive pancreatic inflammation can be made from the alcohol's effects on pancreatic secretion and the known pathological changes described by Sarles and others. Chronic alcoholism causes an increase in basal secretion of proteases, amylase, and lipase, and a decrease in trypsin inhibitor in rats. [37] Furthermore, an increased responsiveness of the pancreas to cholecystokinin (CCK) stimulation has been reported in dogs [38] and humans. [39] In addition to the perturbation in the content and secretion of pancreatic enzymes, chronic alcohol consumption also causes perturbation in the lysosomal enzymes; acid phosphatase was increased in cell fractions, and cathepsin B was increased in the mitochondrial-lysosomal fraction and the zymogen granule fractions of the pancreas from alcohol-fed rats. [40] Therefore, it is conceivable that alcohol produces pancreatitis by interfering with the intracellular transport and discharge of digestive enzyme, causing colocalization of digestive and lysosomal hydrolases, a condition conducive to the initiation of autodigestion. The augmented responsiveness of the exocrine pancreas may account for the high-protein, low-bicarbonate, and low-volume pancreatic secretory output after chronic alcohol consumption. [41] Theoretically, protein precipitates would be formed, particularly in low-flow-rate areas such as the secondary pancreatic ducts. This may explain the frequent involvement of the secondary duct, with relative sparing of the main pancreatic duct, in early stages of chronic pancreatitis.

The discovery of a pancreatic stone protein (lithostatin) found in pancreatic juice and calculi has generated considerable interest because this protein is capable of inhibiting the formation of insoluble calcium salts in a supersaturated milieu. [42], [43] Lithostatin has been found to be decreased in the pancreatic juice of patients with alcoholic pancreatitis and in some patients with nonalcoholic chronic pancreatitis. [44] Hence, it is conceivable that a deficiency of lithostatin may play an important role in the development of pancreatic calcification. [42] The importance of this protein remains unclear, however, because not all studies have shown a reduction in lithostatin in pancreatic juice from patients with chronic pancreatitis. [45]

One report [46] showed that GP2, a protein found on the zymogen membrane that is secreted into the pancreatic duct by exocytosis, is a reproducible integral component of protein plugs found in patients with noncalcific, chronic pancreatitis. On the other hand, lithostatin was found less frequently and in variable amounts. Interestingly, GP2 has significant homology with the urinary protein uromodulin (Tamm-Horsfall protein), which is involved in the formation of protein precipitates in urine. It has been suggested that GP2 may be involved in the formation of protein plugs in the pancreatic duct in patients with chronic pancreatitis.

In addition to hypersecretion of protein, viscosity of pancreatic juice is enhanced in chronic pancreatitis because of a higher concentration of hexosamine. [47] There is a correlation between the concentrations of protein, hydrolytic enzymes, hexosamine, and viscosity. [47] Hyperviscosity of pancreatic juice may result in decreased flow and contribute to protein precipitation in chronic pancreatitis. Therefore, it appears that chronic alcoholism results in a number of changes in the pancreatic juice that create a conducive environment for the formation of intraductal protein plugs that block small ductules in a random fashion. Ductal blockade produces progressive structural abnormalities in the ducts and acinar tissue. In time, calcium is complexed to protein plugs, initially in small ductules and, eventually, in the main pancreatic

duct. Progressive blockade results in injury and destruction of pancreatic tissue. [48]

The biochemical mechanisms responsible for fibrosis to occur in chronic pancreatitis are also unclear. Recent evidence suggests that pancreatic stellate cells are responsible for pancreatic fibrosis. [49], [50] Pancreatic stellate cells are perivascular [51] and derived from vitamin A–containing cells that can acquire a myofibroblast phenotype. [49], [52] These cells may be activated by transforming growth factor-ß $_1$ (TGB-ß $_1$) and basic fibroblast growth factor [49] during fibrosis in chronic pancreatitis. Transgenic mice that overexpress TGF-a develop interstitial pancreatic fibrosis. One study [53] demonstrated high levels of TGF-a and its messenger RNA in pancreatic tissue from patients with chronic pancreatitis, coupled with high levels of epidermal growth factor receptor, the receptor through which TGF-a acts. Another study [54] demonstrated overexpression of acidic and basic fibroblast growth factors in tissue from patients with chronic pancreatitis. These mitogenic peptides are involved in cellular proliferation and differentiation. Although these observations are intriguing, it remains to be determined whether these abnormalities are contributing to the progression of disease or are merely a result of the disease process.

Cigarette Smoking

Recent studies indicate that there may be a strong association between cigarette smoking and chronic pancreatitis. [55] Lin and associates [56] reported that the odd ratios (95% CI) for chronic pancreatitis for smokers compared with nonsmokers, after adjustment for body mass index, education level, and alcohol consumption, was 7.8 (2.2 to 27.3) for all smokers, and greater risk was observed for those who had smoked for 25 years or more. The risk for chronic pancreatitis significantly increased with increasing cumulative amount of smoking. Other studies showed that cigarette smoking increases the risk for pancreatic calcification of late-onset but not of early-onset idiopathic chronic pancreatitis. [57]

Based on these and other studies, the role of smoking in the causation of chronic pancreatitis in the absence of alcoholism is strongly suspected but not conclusively proved. However, it appears that smoking enhances the progression of chronic pancreatitis, especially of calcification. In hereditary pancreatitis, smoking increases the risk for pancreatic cancer and lowers the age at onset by about 20 years. [58] Hence, patients with chronic pancreatitis, regardless of the cause, should stop smoking.

Tropical (Nutritional) Pancreatitis

Tropical chronic pancreatitis, one of the major nutritional forms of chronic pancreatitis, is an important disease among juveniles and young adults in some Afro-Asian countries (Indonesia, southern India, and tropical Africa). [59], [60] The natural history of tropical chronic pancreatitis is succinctly summarized by Gee Varghese [60] as “recurrent abdominal pain in childhood, diabetes around puberty and death at the prime of life.” Abdominal pain characterizes the onset of tropical pancreatitis. The onset of diabetes typically occurs a few years after the onset of abdominal pain. Diabetes is characteristically brittle, with marked fluctuations of blood glucose. At this time, abdominal radiographs invariably show diffuse pancreatic calculi. Microscopically, dilation of the ducts, pancreatic lithiasis, chronic inflammatory cell infiltration, and atrophy of the pancreatic parenchyma are seen.

The etiology of tropical pancreatitis is not clearly understood, although the common denominator appears to be malnutrition in most cases. [61] Evidence suggests that other factors, such as toxic products in certain nutritional components (cassava), may be more important. [62] Cassava is consumed in large quantities by most poor people in many Afro-Asian countries. It contains 65 mg of toxic glycoside per 100 g. When glycosides react with gastric hydrochloric acid, hydrocyanic acid is liberated. The enzyme rhodanase acts on hydrocyanic acid, leading to thiocyanate production in the presence of adequate amounts of methionine and cysteine. Cyanogens impair a number of enzymes, including superoxide dismutase, an important scavenger of free radicals, which are proposed to cause cell injury. [63], [64] Associated nutritional deficiencies, such as deficiencies of zinc, copper, and selenium, which are common in malnutrition, interfere with detoxification of cyanogens. Thus, the pathogenesis of tropical pancreatitis may be partly explained by micronutrient-antioxidant deficiencies and unopposed free radical injury secondary to dietary cyanogens.

Hereditary Pancreatitis

The clinical picture of hereditary pancreatitis was well described in 1952 by Comfort and Steinberg. [65] Since then, many similar cases have been reported from different areas of the world (United States, Ireland, France, and New Zealand). It is an autosomal-dominant disorder, with 80% penetrance and variable expression, that begins in childhood. The incidence is about equal in both sexes. [66] Lebodic and colleagues [67] from France, and Whitcomb and associates [68] from the United States, concurrently mapped the gene to the long arm of chromosome 7 (7q55). Subsequently, by positional cloning, Whitcomb and colleagues [69], [70] identified two genetic mutations in the cationic trypsinogen gene in hereditary pancreatitis—a missense mutation R117H on exon 3 [69] and a mutation in the exon 2 of the gene (N21I) [70]—in kindred without the R117H mutation. It was hypothesized that cleavage at these sites of the trypsinogen molecule is part of a failsafe mechanism to inactivate trypsin within the pancreas. Gene mutations result in failure of cleavage and persistent tryptic activity, causing autodigestion of the pancreas and pancreatitis. These mutations have since been described in families with pancreatitis around the world. [71], [72], [73], [74] and [75] They represent the causative mutation in about two thirds of the families with classic hereditary pancreatitis and currently are the only mutations for which genetic testing is recommended.

In addition to the typical hereditary form described by Comfort and Steinberg, which begins at a young age, familial aggregations of two or three cases, with attacks beginning in the third or fourth decade, [76] have been reported. This suggests that there may be different forms of hereditary transmission. Mutations at codons 16, [77] 22, [78] and 23 [79] in the trypsinogen gene, although significantly associated with chronic pancreatitis, have a low penetrance. These mutations may be present in patients with a diagnosis of sporadic idiopathic pancreatitis. However, trypsinogen gene mutations are not the cause of tropical pancreatitis, even if many family members are affected. [80]

The clinical picture of hereditary pancreatitis differs little from that of nonhereditary pancreatitis [66] and carries a high risk for pancreatic cancer. [81] Patients frequently experience recurrent attacks of severe upper abdominal pain. Overt diabetes develops 8 to 10 years after the onset of pain in 20% of cases, and gross steatorrhea in 15% to 20%. The diagnosis of hereditary pancreatitis should be suspected if several family members have pancreatitis in the absence of alcohol consumption or other causes of chronic pancreatitis.

Hyperparathyroidism

Calcified chronic pancreatitis occurs in untreated hyperparathyroidism. Surveys suggest that the incidence is decreasing and is no greater than 1% to 2%. [82] A likely explanation is that serum calcium is measured routinely in virtually all patients who undergo a medical checkup, and, as a result, hyperparathyroidism does not remain undiscovered and untreated for many years. The pathogenesis of pancreatitis in hyperparathyroidism is presumed to be related to the effect of hypercalcemia. Acute hypercalcemia is a potent stimulus of human pancreatic enzyme secretion. [83], [84] Furthermore, chronic hypercalcemia causes a significant increase in pancreatic calcium secretion in patients with hyperparathyroidism and in experimental animals. This results in precipitation of intraductal calcium in pancreatic juices. Moreover, chronic hypercalcemia causes a decrease in the diffusion barrier between the pancreatic interstitial compartment and the ductular system, resulting in excessive diffusion of calcium into the pancreatic juices. These events may damage the pancreas and promote the development of calcified chronic pancreatitis.

Hyperlipidemia

As discussed in Chapter 94, it is well known that hyperlipidemia can cause acute pancreatitis. After repeated episodes of acute pancreatitis, hyperlipidemia may, on rare occasions, cause chronic pancreatitis. This unusual cause is important to consider because effective therapy is available. Glueck and associates [85] highlighted the risk for estrogen replacement in postmenopausal women with underlying hypertriglyceridemia. Twelve women receiving estrogen replacement were studied; 10 of these had fasting triglycerides greater than 1200 mg/dL while receiving estrogens, and 6 developed pancreatitis. Stopping estrogen replacement therapy and treatment of the underlying hypertriglyceridemia returned triglycerides to normal levels. Fasting triglyceride levels of less than 300 mg/dL pose no risk for estrogen-induced pancreatitis, whereas levels greater than 750 mg/dL are associated with a high risk. Therefore, it is important to measure fasting serum triglycerides before initiating estrogen replacement in postmenopausal women to prevent acute pancreatitis and avoid the potential for chronic pancreatitis.

Autoimmune Pancreatitis

Chronic pancreatitis may be caused by autoimmunity. [85], [86] In the Japanese literature, more than 100 cases of autoimmune pancreatitis have been reported. [86], [87] and [88] Several autoantibodies, such as antinuclear antibody, antilactoferrin antibody, anticarbonic anydrase II–antibody rheumatoid factor, and anti–smooth muscle antibody, are frequently present in patients with autoimmune pancreatitis. [89] This form of chronic pancreatitis is characterized by increased serum ß-globulin or immunoglobulin G levels, presence of diffuse enlargement of the pancreas, irregular narrowing of the main pancreatic duct, an extrinsic stenosis of the pancreatic portion of the common bile duct on endoscopic retrograde pancreatography, and cholestatic liver dysfunction. [87] Most patients have mild symptoms without attacks of acute pancreatitis. Obstructive jaundice caused by stenosis of the common bile duct is characteristic of autoimmune pancreatitis and is rare in other types of pancreatitis. [87] All these patients showed dramatic improvement with steroid treatment. Computed tomography (CT) and ultrasonography usually show a diffusely enlarged pancreas, with a sausage-like appearance and a capsule-like rim that is of low density on CT. Pancreatic calcification or pseudocyst is seldom observed. Endoscopic retrograde cholangiopancreatography (ERCP) usually shows segmental or diffuse narrowing of the main pancreatic duct and stenosis of the common bile duct, mainly in the intrapancreatic area, resulting in dilation of the proximal biliary tract. [87] Steroid therapy is usually effective in alleviating the stenosis of the common bile duct as well as that of the pancreatic duct. [90], [91] The differential diagnosis of diffuse pancreatic enlargement includes malignant lymphoma, plasmacytoma, metastasis and diffuse infiltrative pancreatic carcinoma. Definitive diagnosis can be made by histological findings that show fibrotic changes with infiltration of lymphocytes and plasma cells and sometimes, eosinophils around the pancreatic duct. The lymphocytes are usually $CD4^+$ and $HLA\text{-}DR^+$ T cells. [92], [93] and [94] HLA-DR is also expressed on pancreatic duct cells. [92], [95] Because pancreatic specimens are usually not available, the diagnosis of autoimmune pancreatitis is made from a combination of clinical and laboratory findings and pancreatic imaging studies.

Obstruction

Obstruction of the main pancreatic duct by tumors, benign vaterian stenosis, [96] scars (e.g., from traumatic pancreatitis), and pseudocysts [97] can lead to a distinct form of chronic pancreatitis known as *obstructive chronic pancreatitis*. This is characterized by acinar atrophy and fibrosis and dilation of the ductal system. In contrast to alcohol-induced chronic pancreatitis, intraductal plugs or stones are very rare in obstructive chronic pancreatitis, and both structural and functional changes may improve when obstruction is relieved. [96] The regression of fibrotic lesions may be explained by the finding that fibrosis in experimental obstructive pancreatitis consists of fractions of collagen with short half-lives (fibronectin, laminin, collagen III, and procollagen III) rather than the long-lived fraction collagen I. [98]

Trauma

Trauma to the abdomen or back may be clinically insignificant and still produce significant pancreatic injury, leading to chronic pancreatitis. The pathogenesis may follow that of the obstructive type, but inflammation and pseudocysts frequently develop. Recognition of trauma as the cause for chronic pancreatitis is important because most cases are associated with severe ductal disruption, which responds poorly to medical treatment, yet results of surgical correction (particularly partial pancreatectomy) have been excellent. [99], [100]

Pancreas Divisum

Pancreas divisum is the most common congenital abnormality of the pancreas (4% to 11%). [101], [102] Fusion of the dorsal and ventral pancreatic ducts is absent or incomplete, and drainage of the major portion of the pancreas occurs through the minor papilla. The clinical significance of pancreas divisum is unknown, although considerable controversy surrounds this issue. Several reports suggest that the incidence of pancreatitis is increased in subjects with pancreas divisum. Cotton reported that the incidence of pancreas divisum in patients with idiopathic pancreatitis undergoing ERCP was 25.6%, whereas only 3.6% of patients with biliary disease undergoing ERCP had pancreas divisum. [103] Similarly, Sahel and colleagues [104] noted that the incidence of pancreas divisum among patients with acute pancreatitis was 21%. This was much higher than a 5% incidence of pancreas divisum among all patients undergoing ERCP. Richter [105] also reported a 19% incidence of pancreas divisum in patients with idiopathic pancreatitis, compared with an overall 5% incidence of pancreas divisum in patients undergoing ERCP. These observations suggest that pancreas divisum might be an important cause of disease in patients with idiopathic pancreatitis. It has been hypothesized that the opening of the lesser papilla might be too small to permit free flow of pancreatic juice into the duodenum, and, as a result, pancreas divisum might cause a form of obstructive pancreatitis.

The clinical significance of pancreas divisum has been disputed. Delhaye and associates [106] reported the results of a study in Belgium involving 6324 patients undergoing ERCP for biliopancreatic complaints and noted that the incidence of pancreas divisum was similar in patients with chronic pancreatitis (6.4%), acute pancreatitis (7.5%), and nonpancreatic disease (5.5%). Similar results have been reported by Sugawa and colleagues, [107] who noted a 2.7% incidence of pancreas divisum among 1529 patients undergoing ERCP. There was no increase in incidence of pancreas divisum among patients with idiopathic pancreatitis or people with unexplained upper abdominal pain. Burtin and colleagues [108] reported a 5.9% prevalence of pancreatic divisum in more than 1000 patients undergoing ERCP. The proportion of patients with pancreas divisum was similar among patients with and without pancreatitis. Thus, the results reported by Burtin and colleagues, [108] Delhaye and associates, [106] and Sugawa and colleagues [107] contradict the earlier studies by Cotton, [103] Sahel and colleagues, [104] and Richter, [105] which indicated an increased incidence of pancreas divisum among patients with pancreatitis. It is possible that the results from earlier studies [103], [104] and [105] might be biased by patient selection. Patients with pancreas divisum and patients with idiopathic pancreatitis are likely to be referred to centers with exceptional endoscopic skills, and, as a result, the incidence of pancreas divisum may appear to be increased, whereas such an increase is not present in a more random sampling of patients.

Idiopathic Pancreatitis

The major form of nonalcoholic chronic pancreatitis in North America and Europe is the idiopathic type (10% to 40%). Epidemiology and clinical studies suggest that idiopathic chronic pancreatitis may be divided into two distinct groups: a juvenile type, with onset of symptomatic disease at a median age of 18 years; and a senile type, with an incidence peak at 60 years of age. In juvenile chronic pancreatitis, abdominal pain dominates the clinical picture at initial presentation, whereas in senile groups, painless disease is frequent, and most patients present with exocrine insufficiency, diabetes, and pancreatic calcification. [109]

Recent genetic studies indicate that cystic fibrosis transmembrane conductance regulator (*CFTR*) gene mutations are linked to some patients with chronic pancreatitis. Sharer and colleagues [110] searched for 22 *CFTR* mutations in 134 patients who had idiopathic chronic pancreatitis or chronic pancreatitis due to alcoholism, hyperparathyroidism, or hypertriglyceridemia. In these patients, *CFTR* mutations were seen at 2.5 times the expected frequency, and the frequency of the 5T allele (which is associated with a reduced proportion of functional *CFTR*) was twice the expected frequency. In a separate study, Cohn and associates [111] found that 10 of 27 patients with idiopathic chronic pancreatitis had at least one of 17 *CFTR* mutations; both alleles were affected in three patients. The 5T allele was present in 5 of 27 patients; this was twice the expected frequency. Hence, it is intriguing that at least a subset of patients who would be classified as having idiopathic chronic pancreatitis has *CFTR* mutations. The functional significance and clinical relevance of these mutations on the pancreas are unclear, but most patients in the above studies did not have classic cystic fibrosis. They all had normal sweat chloride test results and nasal potential difference. Cohn and associates, in a review, stated, “At present, the role of CFTR mutation testing in idiopathic chronic pancreatitis is uncertain because no guidelines exist for genetic counseling or altered clinical management of idiopathic chronic pancreatitis based on the results of such testing.” [112]

CLINICAL PRESENTATION

Pain

The presenting symptom of most patients with chronic pancreatitis is abdominal pain. The pain usually is epigastric, dull rather than sharp, and constant rather than colicky. Although the pain may radiate to both upper quadrants and, occasionally, to the lower quadrants, a characteristic feature is radiation directly through to the back. The pain is partially relieved by sitting with the trunk bent forward or lying prone; the supine posture aggravates the discomfort. The almost instantaneous aggravation of pain by food ingestion is characteristic of chronic pancreatitis or carcinoma of the pancreas, and this symptom always should raise the suspicion of pancreatic disease. Although food ingestion may aggravate the pain of other abdominal conditions (i.e., irritable bowel syndrome), there is usually a much greater interval between the meal and the discomfort than is the case with pancreatic disease. Ingestion of alcohol also may aggravate the pain, although a sizable fraction of patients claim that the pain develops after 12 to 24 hours of abstinence. [113]

Pain patterns may differ depending on the type of chronic pancreatitis. [23] At the beginning of disease, pain is present in 75% of patients with alcoholic chronic

pancreatitis, 50% of patients with late-onset idiopathic chronic pancreatitis, and nearly all patients with early-onset idiopathic chronic pancreatitis. Pain tends to be less severe in the late-onset idiopathic group. In a prospective longitudinal study of alcoholic chronic pancreatitis, Ammann and colleagues [114] identified two pain patterns: 44% of the patients had short episodes of pain, usually less than 10 days' duration, and were separated by pain-free intervals of months to years. None of these patients underwent surgery for pain relief. By contrast, 56% of patients had episodes of constant daily pain, occurring 2 or more days per week for at least 2 months. All these patients underwent surgery, and most had a complication such as pancreatic pseudocysts or cholestasis that was amenable to surgical correction. It is important to emphasize that the above study only evaluated alcoholic chronic pancreatitis patients not addicted to narcotics. Therefore, these findings are not applicable to patients who are addicted to narcotics and who have any form of chronic pancreatitis.

Pain in chronic pancreatitis may continue, diminish, or disappear completely. Several reports have suggested that pain may disappear as the severity of pancreatitis increases. [115], [116] and [117] According to Ammann, [117] pain disappears coincident with the appearance of calcifications, steatorrhea, and diabetes, which occurs 5 to 18 years after the onset of chronic pancreatitis. Chronic pancreatitis is painless or relatively painless (i.e., insufficient pain to require medical evaluation) in about 15% of patients. [118] Idiopathic pancreatitis is more likely to be painless than the alcoholic variety.

Weight Loss

Nausea, vomiting, anorexia, and weight loss are common in chronic pancreatitis. The major cause of weight loss is decreased caloric intake owing to fear of aggravation of the abdominal pain, although malabsorption or uncontrolled diabetes also may play a role. Marked weight loss is relatively unusual in other painful abdominal conditions, such as peptic ulcer or irritable bowel syndrome, and the combination of chronic upper abdominal pain and rapid loss of weight always should suggest the possibility of pancreatic disease.

Malabsorption

Diarrhea, steatorrhea, and azotorrhea occur when exocrine secretion of pancreatic enzymes is insufficient to maintain normal digestion. Although most attention has been directed to the malabsorption of fat and protein in this condition, studies using breath H_2 excretion also have demonstrated malabsorption of starch. [119]

Because malabsorption does not occur until enzyme secretion is reduced to less than 10% of normal, [120], [121] diarrhea and steatorrhea occur relatively late in the course of chronic pancreatitis. As a rule, fecal weight is less in pancreatic malabsorption than in other conditions with comparable steatorrhea. This relatively low fecal weight reflects a lesser quantity of fecal water, and patients may pass bulky, formed stool, as opposed to the frank watery diarrhea observed in other conditions. The relatively low fecal water in pancreatic insufficiency probably results from the better absorption of some carbohydrates, such as disaccharides, that occurs in conditions with mucosal pathology, such as celiac sprue. Occasionally, the patient observes that gross oil leaks from the rectum or floats as an "oil slick" on the surface of water in the toilet bowel. If ingestion of mineral oil is excluded, this finding usually is indicative of pancreatic steatorrhea. For a given degree of steatorrhea, the absorption of fat-soluble vitamins (A, D, E, and K) is much better in pancreatic insufficiency than in celiac sprue. [122] Marked deficiency of these vitamins seldom is observed in pancreatic insufficiency, and presumably this reflects the relative unimportance of lipolysis for the absorption of these compounds. The body stores of these vitamins, however, have been shown to be reduced in a large fraction of patients with chronic pancreatitis, although clinical manifestations of the deficiencies are quite rare. [123]

Pancreatic Diabetes

Although glucose intolerance is common early in the course of chronic pancreatitis, clinically evident diabetes occurs relatively late in the disease. Endocrine insufficiency eventually occurs in most patients with chronic pancreatitis. In a follow-up study of 500 patients with chronic pancreatitis, of whom 85% were alcoholic, it was reported that diabetes developed in 83% within 25 years after the clinical onset of chronic pancreatitis, and more than half required insulin treatment. [124] The prevalence of diabetes was similar in patients who underwent surgery and those who received medical treatment. However, for those who had pancreatic surgery, the prevalence of diabetes was significantly higher 5 years after distal pancreatectomy (57%) than after pancreaticoduodenectomy, pancreatic drainage, or cystic drainage (24% to 36%). Pancreatic drainage did not prevent the onset of diabetes. Distal pancreatectomy and early onset of pancreatic calcifications were the only independent risk factors for diabetes.

In most patients, the diagnosis of chronic pancreatitis is established long before the development of symptomatic hyperglycemia; however, the occasional patient with relatively painless pancreatitis may present initially with diabetes. Ketoacidosis and diabetic nephropathy are relatively uncommon in this form of diabetes. For a given duration of diabetes, however, retinopathy and neuropathy are thought to occur with a frequency similar to that in idiopathic diabetes mellitus. [125]

Other Clinical Features

Other clinical presentations of chronic pancreatitis include jaundice, secondary to common bile duct compression by the pancreas; ascites or pleural effusion, caused by leak of pancreatic secretions from a ruptured duct or pseudocyst; painful nodules, usually over the lower extremities, resulting from fat necrosis; and, rarely, a polyarthritis of the small joints of the hands. In the United States, at least 70% of chronic pancreatitis is attributed to prolonged, heavy ingestion of ethanol, whereas the bulk of the remaining 30% is idiopathic. Thus, historical information concerning length and duration of ethanol ingestion is critical in all suspected cases of chronic pancreatitis. In contrast, gallstone disease virtually never is the cause of chronic pancreatitis. A family history of pancreatitis or chronic abdominal pain of unknown origin may suggest the diagnosis of familial pancreatitis.

The physical examination usually is of limited assistance in the diagnosis of chronic pancreatitis. There is epigastric tenderness during the painful episodes (and sometimes during periods of remission). Tenderness ranges from mild to marked, but involuntary guarding and rebound are unusual. The physical signs characteristically are trivial relative to the intensity of the patient's complaints. Complications of chronic pancreatitis, such as pseudocysts, ascites, or pleural effusions, may be detected on physical examination.

PATHOMECHANISM OF SYMPTOMS

Abdominal pain and malabsorption are the major symptoms of chronic pancreatitis. The pathophysiologic processes responsible for the development of these symptoms are discussed in the following sections.

Pain

The mechanisms of pain in chronic pancreatitis are unclear. Possible causes include inflammation of the pancreas, increased intrapancreatic pressure, neural inflammation, and extrapancreatic causes, such as common bile duct stenosis and duodenal stenosis.

Acute inflammation of the pancreas, during a relapsing attack of chronic pancreatitis or peripancreatic inflammation involving the duodenum and retroperitoneum, may cause pain. This may be mediated by inflammation or fibrosis. Cytokines such as interleukin-6 (IL-6) and IL-8 [126] and chemokines such as MOB-1 and tumor necrosis factor-a may be involved. Whether fibrosis by itself produces pain is unclear, but in chronic pancreatitis the link between fibrosis and pain likely is related to pancreatic stellate cells, which are responsible for pancreatic fibrosis. [127] Because of their contractile potential and perivascular location, these cells could cause microvascular ischemia and pain [127] when stimulated by growth factors. [128]

Clinical and experimental evidence suggests that pain also may be related to increased intraductal pressure secondary to continued pancreatic secretion in the face of ductal obstruction caused by strictures or intraductal stones. [129] The increased pancreatic ductal and parenchymal pressure also may produce a compartment syndrome that induces ischemia and pain. This thesis is supported by experimental studies, which showed increased interstitial and perfusion pressures and decreased blood flow in feline chronic pancreatitis. [130], [131] These abnormalities were significantly reversed by surgical incision of the gland and draining the pancreatic duct. [131]

Several clinical studies showed that pain relief correlates with the development of pancreatic insufficiency in patients with alcohol-induced chronic pancreatitis. For example, Ammann and colleagues [115] noted that most patients with chronic calcific pancreatitis eventually became pain free, and the onset of relief was clearly

associated with decreased pancreatic secretion. A similar observation was made by Girdwood, [116] who reported that 31% of patients with painless pancreatitis had severe pancreatic insufficiency, compared with 3% who had painful pancreatitis. These observations suggest that decreased secretion may reduce intraductal pressure and relieve pain. Measurements of intraductal pressure have been made in patients without pancreatic disease and in those with ductal abnormalities. Among patients without pancreatic disease, intraductal pressure has been found to be 7 mm Hg by direct puncture at surgery in one patient and 10 to 16 mm Hg by ERCP among 33 patients without pancreatic disease. [132], [133], [134] and [135] By comparison, in 59 patients with a dilated duct, intraductal pressure measured by direct puncture at surgery ranged from 18 to 48 mm Hg. [135] In one study, [132] all 19 patients with a dilated main pancreatic duct with elevated intraductal pressure had prompt relief of pain after decompression surgery. Pancreatic tissue pressure also appears to be elevated among patients with chronic pancreatitis with a dilated pancreatic duct and those with pseudocyst. [129], [136] The pancreatic tissue pressure normalized after decompression of the duct or cyst, and this resulted in pain relief in 12 of the 14 patients. Hence, these observations support the thesis that pain in chronic pancreatitis is related to increased intraductal and pancreatic tissue pressure. This provides the rationale for treatments that may reduce pancreatic secretion, such as octreotide, specific diets, and pancreatic enzyme therapy.

Intrapancreatic neural inflammation is another factor that may play an important role in the genesis of pain in chronic pancreatitis. Morphologic studies indicate that pancreatic nerves appear to be larger and more numerous in chronic pancreatitis. [137] The organization of intraneural organelles, such as microtubules, is disrupted. Most significantly, however, there is an alteration in the perineurial sheath that ordinarily shields nerves from surrounding connective tissue. [137] The damaged perineurium allows penetration of biologically active materials from the surrounding extracellular matrix, and pain may result from the continual stimulation of the sensory fibers by noxious substances. In this regard, immunohistological studies have shown that the amount of neurotransmitters, such as substance P and calcitonin gene-related peptide, are increased in afferent pancreatic nerves in chronic pancreatitis. [138], [139] Immune cell infiltration and growth-associated protein 43 also correlate with pain intensity. [140] There is also evidence that eosinophils are increased in the perineurial space among patients with recent alcohol consumption. [141] It is conceivable that degranulation of these eosinophils might be a factor in the generation of pain.

Peripancreatic inflammation, involving the duodenum and retroperitoneum, may cause pain. Extension of active inflammation of the pancreatic tissue within the wall of the duodenum may result in extensive fibrosis and stenosis of the descending duodenum. [142] Peripancreatic inflammation may cause stenosis of the distal common bile duct, and this has been noted to be associated with severe abdominal pain. Pain may also result from continued inflammation of the head of the pancreas. [142] Thus, it is likely that pain in chronic pancreatitis is multifactorial. Depending on the etiologic factors, structure, alteration, severity of the disease, and degree of pancreatic insufficiency, different factors may predominate in the genesis of pain. A study correlating pancreatic pathological condition and symptoms found that intermittent attacks of pain resulted from recurrent tissue necrosis, whereas chronic pain appeared to be secondary to segmental distention behind obstructed ducts. [143]

Malabsorption

There is a 10-fold reserve for exocrine pancreatic enzyme secretion. Malabsorption occurs only after the capacity for enzyme secretion is reduced by more than 90% [120] (Fig. 95-1). In chronic pancreatitis secondary to alcoholism, it usually takes 10 to 20 years for severe pancreatic insufficiency to develop, but lipase secretion decreases more rapidly than secretion of proteolytic enzymes [121] (Fig. 95-2). Hence, steatorrhea is often an earlier and more severe problem than azotorrhea. The importance of colipase in fat malabsorption in adult patients is unknown, although colipase appears to be an important factor in children because steatorrhea and colipase correlate better than lipase and steatorrhea. [144]

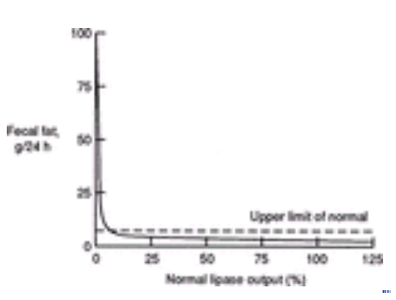

FIGURE 95-1. Relation between steatorrhea and lipase output. Steatorrhea does not occur until lipase output is reduced below 10% of normal. (Adapted from ref. [120].)

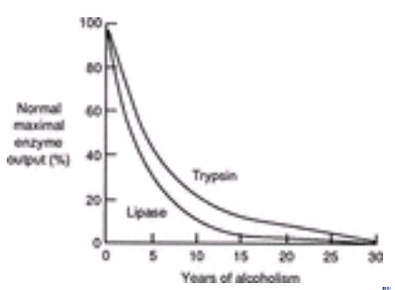

FIGURE 95-2. Relation between reductions in enzyme output and years of alcoholism in patients with alcoholic pancreatitis. (Adapted from ref. [121].)

Concurrent with the reduction of pancreatic enzyme secretion, there is also decreased bicarbonate secretion in patients with severe chronic pancreatitis. Not infrequently, the duodenal pH may fall to 4.0 or less [145], [146] 90 minutes after eating. The abnormally low duodenal pH (less than 4.0) reduces lipid digestion by inactivating pancreatic enzymes and precipitating bile acids. These factors are important to consider in the treatment of pancreatic steatorrhea.

DIAGNOSIS

Overview of Diagnostic Approaches

The diagnosis of chronic pancreatitis usually is suggested by historical information and then confirmed by radiography or laboratory tests. Over the years, an enormous number and variety of tests have been developed for the diagnosis of pancreatitis (Table 95-2). Many of these tests have not been adequately evaluated, and their true sensitivity and specificity are unknown. This section reviews many of the proposed tests for chronic pancreatitis; most are of limited clinical value. An understanding of the rationale underlying the test, however, often provides an insight into the physiologic alterations that occur in chronic pancreatitis. The diagnosis of chronic pancreatitis often can be made on the basis of history and relatively simple radiographic tests. Only the rare patient requires extensive and complicated testing. Thus, the workup should be tailored to the individual patient.

I. Measurement of pancreatic products in blood
A. Enzymes
B. Pancreatic polypeptide
II. Measurement of pancreatic exocrine secretions
A. Direct measurement
1. Enzymes
2. Bicarbonates
B. Indirect measurement
1. Bentiromide test
2. Dual Schilling test
3. Fecal chymotrypsin concentration
4. [^{14}C] olein absorption
III. Imaging techniques
A. Plain film radiography of abdomen
B. Ultrasonography
C. Computed tomography
D. Endoscopic retrograde cholangiopancreatography
E. Magnetic resonance cholangiopancreatography
F. Endoscopic ultrasonography

TABLE 95-2 Tests for Chronic Pancreatitis

Laboratory Evaluation

Routine Laboratory Findings Routine blood studies usually are not helpful in making the diagnosis of chronic pancreatitis. Leukocytosis may be observed during acute exacerbations. The anemia frequently associated with malabsorption secondary to celiac disease seldom is present in patients with pancreatic malabsorption. Although patients with chronic pancreatitis commonly have an abnormal Schilling test result owing to the inability to digest R protein normally, megaloblastic anemia is rare. [147] Fat-soluble vitamin deficiency states (hypocalcemia, hypoprothrombinemia) seldom are observed in association with the steatorrhea of chronic pancreatitis, in contrast to their frequent occurrence in celiac sprue. Compression of the common duct by a fibrotic process in the pancreas not infrequently leads to varying degrees of cholestasis. [148] Alkaline phosphatase elevation in the absence of jaundice or other symptoms is the most common manifestation. Clinical jaundice results from more severe compression. Although liver disease is extremely common in alcoholics, this condition usually does not take the form of relatively pure cholestasis. The finding of cholestatic liver function in patients with pancreatitis requires extensive radiologic testing, usually culminating in ERCP, to establish that the biliary obstruction results from chronic pancreatitis.

Specific Tests for the Diagnosis of Chronic Pancreatitis

The multiple tests available for the diagnosis of chronic pancreatitis can be separated into chemical measurements of pancreatic function and radiologic procedures that provide information on pancreatic structure.

Several factors make it difficult to determine accurately the true sensitivity and specificity of these tests. First, biopsies of the pancreas usually are not obtained in patients with possible chronic pancreatitis, and most series report that patients have not been followed for a period sufficient to establish the presence or absence of this condition with certainty. Thus, in most early or questionable cases, there is no histological gold standard that can be used to determine the accuracy of the more indirect chemical or radiologic tests. Second, the sensitivity of the various diagnostic tests depends on the extent of the pancreatic damage. In long-standing disease with marked functional and anatomic alterations, virtually all proposed tests are positive. The sensitivity of the tests falls dramatically in early or mild chronic pancreatitis, however. The apparent sensitivity and specificity of the various tests also depend on the composition of subjects used to establish the normal range. For example, patients with a variety of disease states such as diabetes mellitus, [149] celiac sprue, [150] and cirrhosis [151] may have subnormal pancreatic secretion of enzymes. If such patients are used to establish the normal range, the lower limits of normal are reduced, and the sensitivity of the test for chronic pancreatitis drops accordingly. If the normal range is established with healthy controls, the specificity of a low secretion is reduced. Thus, although claims are made with regard to the sensitivity and specificity of tests for chronic pancreatitis, these claims have to be interpreted in light of the types of patients composing the pancreatitis groups as well as the subjects used to establish the normal range.

Serum Pancreatic Enzymes In contrast to attacks of acute pancreatitis, in which the serum level of pancreatic enzymes is almost always elevated, serum enzyme levels may be elevated, normal, or low in chronic pancreatitis. In an acute exacerbation of the chronic process, the levels of these enzymes (amylase, lipase, trypsin) may be elevated; however, their serum concentrations seldom reach the levels observed in acute pancreatitis. A very high serum concentration of pancreatic enzymes during a painful episode in a patient with very advanced chronic pancreatitis should raise the possibility that some other abdominal process, such as gut perforation or infarction, is responsible for the pain.

Tests of Pancreatic Exocrine Function Tests of pancreatic exocrine function can be divided into those that directly assess pancreatic exocrine function (e.g., measurements of enzyme or bicarbonate secretion) and those that test some secondary effect of impaired enzyme secretion (e.g., malabsorption of a compound that requires pancreatic digestion for normal absorption).

Direct tests of pancreatic exocrine secretion. Because the basal secretory rate of the pancreas is highly variable, meaningful direct measurements of pancreatic secretion must be carried out in the stimulated state. Varying doses of secretin or CCK have been used for this purpose as well as a standard meal (the Lundh test). Early studies used simple drainage of the intestine at the ligament of Treitz to obtain pancreatic secretions. Because this technique does not recover all lumenal fluid passing the collection site, studies have used a constant perfusion of a nonabsorbable marker, such as polyethylene glycol, into the duodenal bulb. Measurements of the concentration of this marker passing the distal collection site permit assessment of the rate at which fluid passes this site and make it possible to quantitate the rate at which pancreatic secretory components pass this site. [120] A wide variety of pancreatic juice components, including the concentration or output of bicarbonate, amylase, lipase, and trypsin, have been assessed to find the most sensitive and specific indicator of chronic pancreatitis. Although claims have been made for the superiority of one of these measurements over another, comparative studies suggest that all of them tend to be equally depressed in chronic pancreatitis and that there is no clear-cut advantage of one measurement over another. Similarly, none of these measurements appears to be able to differentiate chronic pancreatitis from carcinoma of the pancreas. Collection of pure pancreatic juice by way of cannulation of the ampulla of Vater during ERCP apparently adds little to the accuracy of the test. [152] Stimulation of pancreatic secretion has been produced over a wide range of doses and dosing schedules using secretin, [153] CCK, [154] cerulein, [155] and bombesin, [156] singly or in combination. Although it is difficult to compare the results of different studies, there appears to be no clear-cut advantage of one stimulatory technique over another. The relative value of direct stimulation of the pancreas with secretin-CCK versus indirect stimulation by Lundh meal also is somewhat controversial, although most comparative studies suggest that direct stimulation is superior. [157], [158] For many years, the finding of a subnormal pancreatic secretion of enzymes or bicarbonate in aspirated duodenal contents was considered the most sensitive test for chronic pancreatitis, and, if pancreatic carcinoma could be excluded, a low secretion was assumed to be diagnostic of chronic pancreatitis. Recently, natural porcine secretin has been unavailable because of the unproven use of the agent for the treatment of autism. Synthetic porcine secretin has been produced and compared favorably to the natural porcine secretin in the diagnosis of chronic pancreatitis. [159] The sensitivity of the CCK or secretin pancreatic function tests was examined in 48 patients with suspected chronic pancreatitis. [160] All patients were evaluated with ultrasound, CT, and endoscopic retrograde pancreatography (ERP). All 10 patients with normal ERP results demonstrated normal function by direct hormonal stimulatory testing, and all 16 patients with advanced changes on ERP had grossly abnormal function testing. In 12 patients with mild to moderate changes on ERP, all demonstrated some abnormality of function, and of 10 patients with minimal or equivocal changes on ERP, all had some degree of functional impairment. CT and ultrasound were accurate in advanced chronic pancreatitis (94% to 100%) but performed poorly in patients with less advanced changes on ERP (40% to 50% accurate in patients with equivocal changes). This study is in agreement with other previous reports, which indicated direct hormonal stimulation testing may be the most sensitive test (70% to 95%) [161], [162], [163], [164] and [165] to diagnose chronic pancreatitis in all stages. However, it should be noted that patients with a variety of conditions, including diabetes mellitus, [149] hepatic cirrhosis, [151] Billroth II gastrectomy, [166] and celiac sprue, [150] may have diminished pancreatic secretory output with no clinical or radiologic evidence of chronic pancreatitis. Another major consideration is that direct hormonal stimulation testing is only available at a few centers; therefore, the search continues for a convenient and readily available diagnostic test.

Indirect tests of pancreatic exocrine secretion. The complexity and patient discomfort involved in the direct measurement of pancreatic secretory capacity have led to a variety of simpler tests that indirectly assess the secretion of pancreatic enzymes. Most of these tests measure the absorption of some compound that first requires digestion by pancreatic enzymes. Because clinically detectable malabsorption of nutrients does not occur until pancreatic enzyme secretion has diminished to less than 10% of normal, it is axiomatic that indirect tests of pancreatic function will not be able to detect early chronic pancreatitis and, thus, will have very poor sensitivity. One of the more commonly used of the indirect tests is the bentiromide test, which involves ingestion of *N*-benzoyl-L-tyrosyl- *p*-aminobenzoic acid (NBT-PABA), a tripeptide that is digested by chymotrypsin with the release of paraaminobenzoic acid (PABA). [167], [168] Free PABA is absorbed in the small bowel and excreted by the kidney; the quantity excreted in urine is used as a measure of pancreatic exocrine function. As appears to be the case with virtually every pancreatic function study, innumerable variations of the basic test (i.e., dosage alterations, length of urine collection, various forms of stimulation of pancreatic secretion) have been evaluated in an attempt to improve specificity, without appreciable success. The sensitivity of the bentiromide test varies with the extent of damage to the exocrine pancreas, with sensitivity as high as 100% [169] reported with very severe disease and as low as 40% to 50% with minor damage. [170], [171] The specificity of this test is far from perfect. Reduced PABA excretion has been reported to occur commonly in diabetes mellitus, [172] renal insufficiency, [173] liver diseases, [173] and malabsorption states other than pancreatic insufficiency, including celiac sprue, [174] Crohn's disease, [175] and postgastrectomy states. [173] The low excretion in malabsorptive states other than pancreatic insufficiency apparently results from failure to absorb the free PABA that has been split from the parent compound. These conditions can be separated from pancreatic insufficiency by testing the patient's ability to absorb free PABA in a subsequent test [169] or by simultaneously

administering free [^{14}C]PABA along with NBT-PABA and measuring the urinary excretion of the labeled and unlabeled PABA. [176] Because sensitivity of the NBT-PABA test is limited, the results of this measurement are helpful primarily when the test is positive (and other forms of malabsorption have been excluded). Thus, it appears that the major role of this test is not in diagnosis of chronic pancreatitis but rather in determining the extent of the pancreatic insufficiency present in patients with known chronic pancreatitis. The demonstration that vitamin B_{12} is malabsorbed in patients with pancreatic insufficiency, owing to their inability to degrade R protein, [177] provided the rationale for a test for chronic pancreatitis. In this test, the subject ingests both [^{57}Co]cobalamin bound to intrinsic factor and [^{58}Co]cobalamin bound to R protein, plus excess intrinsic factor and a cobalamin analog that saturates all empty R protein–binding sites. [178] Theoretically, the patient with pancreatic insufficiency should absorb the cobalamin bound to intrinsic factor much more efficiently than that bound to R protein. All other subjects should absorb both forms of cobalamin equally. Although the initial paper describing this technique reported excellent sensitivity and specificity for chronic pancreatitis, a subsequent study found very poor sensitivity. [179] The diagnosis of pancreatic insufficiency by way of measurements of fecal chymotrypsin was first described 40 years ago, [180] and a number of subsequent reports have evaluated the sensitivity and specificity of various modifications of the initial technique. The major advantage of this method is that it is rapid and simple. The far more cumbersome measurement of total fecal chymotrypsin output in timed fecal collections appears to offer little advantage over the much simpler measurement of chymotrypsin concentration in a random fecal sample. [180] Reports of sensitivity of the test range from 45% [181] to 100%, [182] depending on the extent of pancreatic damage in the study population. Specificity ranges from 49% [183] to 90%, [184] with false-positive results reported for malabsorptive conditions such as celiac sprue, damage secondary to Crohn's disease, and postgastrectomy states. [184], [185] Patients with appreciable chronic pancreatitis malabsorb fat when ingested in the form of triglyceride, and a number of indirect tests have been developed to assess such malabsorption. Most of these tests involve the feeding of [^{14}C]olein. Hydrolysis of the triglyceride and absorption of [^{14}C]oleate lead to the production and pulmonary excretion of $^{14}CO_2$. Measurement of breath $^{14}CO_2$ excretion can be used as a simple measure of the normality of the hydrolysis of the labeled triglyceride. [186] Unfortunately, the test is negative in a high percentage of patients with early chronic pancreatitis, and false-positive results are observed in many malabsorption states other than chronic pancreatitis. [187]

Imaging Studies

The demonstration of diffuse, speckled calcification of the pancreas on a plain film of the abdomen is diagnostic of chronic pancreatitis. Although the sensitivity of this finding is limited (perhaps, 30% to 40%), a plain film of the abdomen should be the first diagnostic test used when attempting to establish the diagnosis of chronic pancreatitis because a positive finding obviates the need for additional testing.

The development of ultrasound, CT, and ERCP has made it possible to assess, routinely, the gross structure of the pancreas. These tests all have excellent specificity and reasonably good sensitivity. Of major importance is the ability of these imaging procedures to differentiate between carcinoma of the pancreas and chronic pancreatitis. As a result, imaging techniques have largely supplanted tests of pancreatic function in the workup of the patient with possible chronic pancreatitis.

Ultrasound is the simplest and least expensive of the three imaging techniques. Findings on ultrasound that correlate with marked pancreatic changes on ERCP include dilation of the main pancreatic duct to greater than 4 mm, large (more than 1 cm) cavities, and calcifications. [188] Findings associated with less severe changes on ERCP include dilation of the duct up to but not exceeding 4 mm, small cavities, reduction in echogenicity or echogenic foci in the parenchyma, and an irregular contour to the gland. [188] When a satisfactory ultrasound examination is obtained, the reported sensitivity of this test for chronic pancreatitis is of the order of 70%, and the specificity is quite high, roughly 90%. [189], [190], [191] and [192] The finding of chronic pancreatitis on ultrasound usually requires no additional confirmatory testing.

CT is 10% to 20% more sensitive than ultrasound for the diagnosis of chronic pancreatitis [191], [192] and [193]; these two techniques have roughly comparable specificity. CT is more expensive than ultrasonography and involves exposure to ionizing radiation. Therefore, in the workup for chronic pancreatitis, CT usually should be limited to patients who have negative or unsatisfactory ultrasound examinations. The most common diagnostic findings of chronic pancreatitis on CT include duct dilation, calcifications, and cystic lesions [194], [195] and [196] (Fig. 95-3). Less common diagnostic findings include enlargement or atrophy of the pancreas and heterogeneous density of the parenchyma. This imaging technique is particularly helpful in the differentiation of chronic pancreatitis from carcinoma of the pancreas. The dilated duct system resulting from carcinoma tends to be smooth or beaded, in contrast to the irregular, calcified ducts that are typical of chronic pancreatitis. The sensitivity of CT for the diagnosis of chronic pancreatitis is in the neighborhood of 80%, whereas the specificity is roughly 90%. [191], [197], [198] ERCP commonly is considered to be the most sensitive and specific test available for the diagnosis of chronic pancreatitis, and this technique has become the gold standard against which all other tests are evaluated. In the absence of histological confirmation of disease in most patients, it is difficult to speak with complete certainty about the diagnostic accuracy of ERCP (because ERCP is the gold standard). Most studies indicate that the sensitivity and specificity of ERCP are 70% to 90% and 80% to 100%, respectively. [198], [199], [200], [201] and [202]

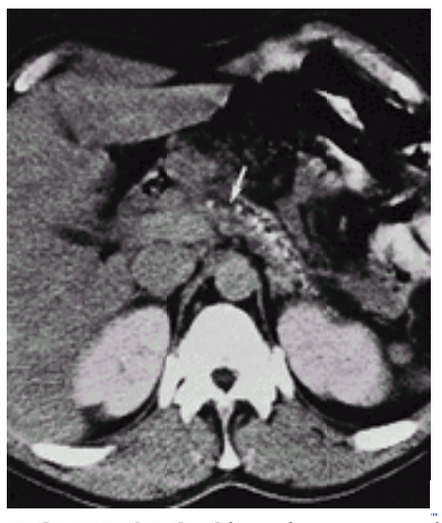

FIGURE 95-3. Chronic pancreatitis. Computed tomography scan shows pancreatic atrophy along with multiple intraductal calculi and dilation of the pancreatic duct (*arrow*).

The most commonly used classification of ERCP changes in chronic pancreatitis was developed at an international symposium. The Cambridge classification of chronic pancreatitis is based on abnormalities seen in the main pancreatic duct and in the side branches [203], [204] (Table 95-3). In minimal pancreatitis, the changes are limited to the branches and fine ducts (less than three), which show dilation and irregularity (Fig. 95-4). There is considerable observer variation in the detection of these minor changes, and differentiation of normal from abnormal is not always clear. Because minor ductal dilation and intraductal calculi may be observed in healthy elderly people, it may be difficult to differentiate early chronic pancreatitis from normal senile changes. [205] Moderate pancreatitis is characterized by abnormalities in at least three or more side branches and the additional finding of dilation, tortuosity, and stenosis of the main pancreatic duct (Fig. 95-5). Advanced pancreatitis has the additional findings of cyst formation, duct obstruction, severe ductal dilation, or irregularity (Fig. 95-6). Pancreatic carcinoma usually can be distinguished from chronic pancreatitis in that there is a single strictured region in malignant obstruction, in contrast to the multiple stenoses, irregular branching ducts, and intraductular calculi observed in chronic pancreatitis.

FIGURE 95-4. Endoscopic retrograde cholangiopancreatography (ERCP) study shows minimal changes consistent with chronic pancreatitis. The main duct is slightly irregular, and the branches are slightly dilated. These findings are not diagnostic.

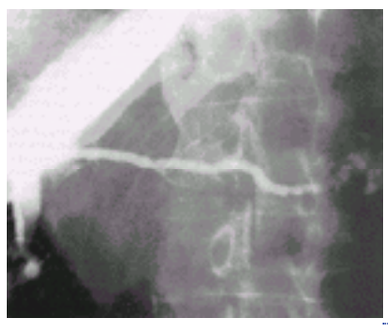

FIGURE 95-5. Endoscopic retrograde cholangiopancreatography (ERCP) study shows changes of moderate pancreatitis. The main duct is irregular and dilated, and there is a pseudocyst in the tail of the pancreas.

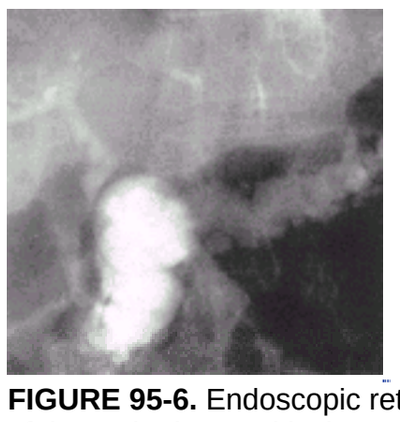

FIGURE 95-6. Endoscopic retrograde cholangiopancreatography (ERCP) study shows changes of advanced chronic pancreatitis. There are massive cystic dilations of the main duct and its branches.

GRADE	MAIN PANCREATIC DUCT	SIDE BRANCHES
Normal	Normal	Normal
Suggestive	Normal	<3 Abnormal
Mild	Normal	≥3 Abnormal
Moderate	Abnormal	>3 Abnormal
Severe	Abnormal plus at least one of the following: Large cavity Duct obstruction Dilation or irregularity Intraductal filling defects	

Modified from ref. 203.

TABLE 95-3 Cambridge Classification of Chronic Pancreatitis by Endoscopic Retrograde Pancreatography

In general, there is a good correlation between the changes observed on ERCP and measurements of pancreatic secretory capacity. An occasional patient, however, may have markedly diminished secretory function with seemingly minor changes on ERCP. Patients with minor abnormalities on ERCP often have normal secretory function.

It should be noted that pancreatitis occurs in about 5% of patients undergoing ERCP. [206] This risk for pancreatitis increases significantly in female patients with normal serum bilirubin, patients suspected of sphincter of Oddi dysfunction, and those with a previous history of post-ERCP pancreatitis. [206] In fact, patients with the least probability of harboring truly obstructive pathology are at highest risk for pancreatitis after ERCP, even if the procedure is for diagnosis alone. Because ERCP is an expensive procedure and has a low but not insignificant rate of associated complications, this test ordinarily should be reserved for the rare patient with chronic pancreatitis in whom the diagnosis cannot be clearly established by way of other imaging techniques.

Although chronic pancreatitis and carcinoma of the pancreas usually can be reliably distinguished based on imaging studies, in an occasional patient, this differentiation may be difficult. [207] Attempts to use serum or pancreatic juice tumor markers, such as CA 19-9, to differentiate benign from malignant pancreatic processes have not been impressive, [207] and it is usually necessary to make a tissue diagnosis. Although laparotomy with open biopsy was required in the past, percutaneous fine-needle aspiration biopsy now makes it possible to obtain a histological diagnosis in a very high percentage of patients with pancreatic carcinoma. Under CT or ultrasonographic guidance, a small-gauge needle is inserted into the pancreatic mass, and aspirated material is examined for the presence of malignant cells. The reported specificity of this test approaches 100%, and the sensitivity is 80% to 90%. [208]

In recent years, advances in magnetic resonance (MR) imaging have led to the development of MR cholangiopancreatography (MRCP) for the evaluation of the biliary and pancreatic ducts (Fig. 95-7). Similar to ERCP, MRCP allows direct visualization of the pancreatic duct but without radiation exposure or the use of oral or intravenous contrast. Hence, it can be used in patients who are pregnant or have contrast allergies. In severe chronic pancreatitis with marked changes of the main pancreatic duct, agreement between MRCP and ERCP is excellent. [209], [210], [211] and [212] However, MRCP is relatively insensitive in mild chronic pancreatitis, in which changes are limited to the secondary ducts. False-negative results may also be seen in patients with distal focal pancreatitis involving the tail of the pancreas. [209] Recently, secretin-enhanced MRCP has been proposed as a reliable test for assessment of pancreatic exocrine function. [213] The pancreatic T2 signal intensity and the diameter of the duodenum showed a significant increase after secretin administration in both healthy subjects and patients with chronic pancreatitis, but the increases were much smaller in patients with varying degrees of pancreatic insufficiency. [213] However, the validity of these findings requires further evaluation. It appears that the current generation of MR imaging is quite sensitive in the diagnosis of severe chronic pancreatitis, but it is rather ineffective in detecting mild to moderate pancreatitis, in which major ductal abnormalities are seen in the secondary branches. Currently, MRCP is used mainly as a backup when ERCP fails.

FIGURE 95-7. Magnetic resonance cholangiopancreatography shows calcification in the head of the pancreas and obstructions to both the pancreatic duct and common bile duct. (Courtesy of Dr. Theesa Rangsitwatana.)

Endoscopic ultrasonography (EUS) [214] is a major advance in imaging the pancreas because it may provide more detailed structural information of the pancreas than routine ultrasonography and CT scan. EUS features of chronic pancreatitis may be used to establish the diagnosis and evaluate the severity of the disease. [215] These include ductal changes and parenchymal changes, such as echo texture of the gland, calcifications, lobulations, and bands of fibrosis (Fig. 95-8 and Fig. 95-9; see Table 95-4). For EUS to be considered an accurate test for chronic pancreatitis, there must be good interobserver agreement. To address this issue, EUS was performed on 33 patients with suspected chronic pancreatitis based on typical symptoms as well as on 12 control patients. [216] Eleven experienced endosonographers blinded to clinical information independently evaluated all videotaped examinations for the presence of chronic pancreatitis based on nine validated features of chronic pancreatitis: echogenic foci, strands, lobularity, cysts, stones, duct dilation, duct irregularity, hyperechoic duct margins, and visible side branches. There was moderately good overall agreement for the final diagnosis of chronic pancreatitis (? = 0.45). Agreement was good for individual features of duct dilation (? = 0.6) and lobularity (? = 0.51) but poor for the other seven features (? < 0.4). The presence of stones was considered the most predictive feature of chronic pancreatitis, followed by visible side branches, cysts, lobularity, irregular main pancreatic duct, hyperechoic foci, hyperechoic strands, main pancreatic duct dilation, and main duct hyperechoic margins. Hence, EUS appears to be a reliable method for the diagnosis of chronic pancreatitis, with good interobserver agreement among experienced endosonographers. A prospective evaluation of EUS compared with ERP and secretin stimulation test in the diagnosis of chronic pancreatitis was conducted by Catalano and colleagues. [215] Eighty consecutive patients with recurrent pancreatitis participated in the study. EUS criteria for chronic pancreatitis included mild (one to two features), moderate (three to five features), and severe (more than five features; see Table 95-3). Abnormal EUS, ERP, and secretin test were observed in 63, 36, and 25 patients, respectively. Secretin test had 100% agreement with normal and severe chronic pancreatitis by EUS criteria, but agreement was poor for mild (13%) and moderate (50%) disease. On the other hand, the agreement between ERCP- and EUS-specific criteria was excellent for normal (100%), moderate (92%), and severe (100%) chronic pancreatitis and poor for mild (17%) disease. The main source of disagreement in this and other studies involves patients with abnormal results of EUS and normal ERCP or pancreatic function tests. Therefore, it appears that with the exception of mild changes noted on EUS, there is excellent agreement between EUS and ERCP in the diagnosis of chronic pancreatitis. Similar findings were reported in another prospective study to determine the ability of EUS to diagnose, exclude, or establish the severity of chronic pancreatitis found by ERP. [217] In general, histology is the most obvious candidate for a diagnostic gold standard, but very few studies have compared EUS with pancreatic histology. In a preliminary study comparing EUS with the histological features of chronic pancreatitis in 34 patients who underwent EUS and later pancreatic surgery (21 with chronic pancreatitis and 13 with pancreatic carcinoma), the sensitivity of EUS for diagnosis of chronic pancreatitis was 78%, specificity was 73%, and the threshold for diagnosis was four or more echo features. [218] However, these findings are only applicable to mostly severe pancreatitis. The specificity of EUS changes in mild or early chronic pancreatitis is unknown but probably very low. Reliance on a few EUS criteria, such as inhomogeneity, hyperechoic strands, and locularity, probably would give rise to many false diagnoses of chronic pancreatitis. Long-term follow-up of patients with mild EUS changes is needed to determine the usefulness of EUS in diagnosing mild chronic pancreatitis. In a recent study, 130 patients with a history of chronic use of alcohol and recurrent abdominal pain underwent ERCP and EUS. [219] All patients with chronic pancreatitis confirmed by ERCP (70.8%) had ductal or parenchymal changes detected with EUS. Among 38 patients (29.2%) with normal ERCP, 32 (84.2%) presented with morphologic features consistent with chronic pancreatitis by EUS. During follow-up (median, 18 months), chronic pancreatitis was confirmed by repeat ERCP in 22 of these 32 patients (68.8%). Hence, it appears that EUS is more sensitive than ERCP in the detection of early chronic pancreatitis in patients with abdominal pain and a history of chronic and continued ingestion of alcohol. More long-term follow-up studies are needed to determine the usefulness of EUS in diagnosing mild nonalcoholic chronic pancreatitis.

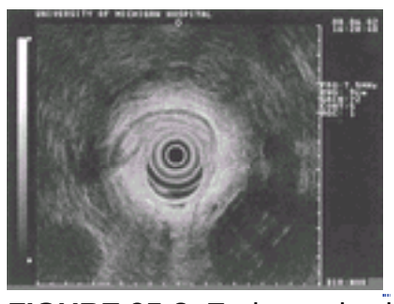

FIGURE 95-8. Endoscopic ultrasound showing mild chronic pancreatitis. Characteristic features include hyperechoic pancreatic duct margins and irregular contour of the pancreatic duct (*arrow*).

FIGURE 95-9. Endoscopic ultrasound showing a large pseudocyst (4.4 × 4.6 cm) with a calcified rim from a patient with chronic pancreatic pancreatitis.

ENDOSCOPIC ULTRASOUND FEATURE	IMPLICATION
Ductal changes	
Duct size >3 mm	Ductal dilation
Tortuous pancreatic duct	Ductal irregularity
Intraductal echogenic foci	Stones or calcification
Echogenic duct wall	Ductal fibrosis
Side-branch ectasia	Periductal fibrosis
Parenchymal changes	
Inhomogeneous echo pattern	Edema
Reduced echogenic foci (1–3 mm)	Edema
Enhanced echogenic foci	Calcifications
Prominent interlobular septae	Fibrosis
Lobular outer gland margin	Fibrosis, glandular atrophy
Large, echo-poor cavities (>5 mm)	Pseudocyst

TABLE 95-4 Endoscopic Ultrasound Features of Chronic Pancreatitis

Rational Use of Tests in the Diagnosis of Chronic Pancreatitis

The evaluation should begin with a plain film of the abdomen. The finding of pancreatic calcification is virtually diagnostic of chronic pancreatitis, and no further testing is required. If calcifications are not present, the next test should be ultrasound. Once again, if this test demonstrates findings indicative of chronic pancreatitis, further procedures are not necessary. If the ultrasound examination is nondiagnostic, CT is indicated only if there is a high degree of clinical suspicion of chronic pancreatitis. Only a small percentage of patients with chronic pancreatitis have negative ultrasound and CT findings. Thus, ERCP should be reserved for those patients in whom the diagnosis of chronic pancreatitis is thought to be very likely on clinical grounds or for patients in whom ultrasound, CT, and fine-needle biopsy have not been able to differentiate between carcinoma of the pancreas and chronic pancreatitis. If ultrasound, CT scan, and ERCP are normal, a secretin test may disclose evidence of mild chronic pancreatitis. Unfortunately, the secretin test is not widely available. Studies suggest that EUS may be useful to establish the diagnosis and evaluate the severity of the disease. Additional studies are needed to define the sensitivity of EUS for the diagnosis of early disease. MRCP may be used as a backup alternative if ERCP fails and EUS is unavailable or technically not feasible, such as in patients with Roux-en-Y-gastrojejunostomy.

COMPLICATIONS

Pseudocyst

A pseudocyst is a collection of pancreatic juice, outside the normal boundaries of the ductal system, that is enclosed by a fibrous tissue membrane. It is the most common complication of chronic pancreatitis, occurring in up to 25% of cases in some series. [220] Most chronic pseudocysts occur in patients with chronic alcoholic pancreatitis, [221] and they are found more commonly in the body of the pancreas than in the head or tail. [221]

Little is known about the mechanism responsible for the initial formation of pancreatic pseudocysts. They probably result from rupture of a pancreatic duct, activation of interstitial pancreatic juices, necrosis of the surrounding parenchyma, escape of the pancreatic juice into the lesser sac, and reaction of local mesothelial cells to wall off the collection by a fibrous membrane. Once initiated, expansion of the embryonic pseudocyst continues until the surrounding tissue pressure equals pancreatic secretory pressure, which is usually elevated in chronic obstructive pancreatitis. Although not conclusively demonstrated, some evidence exists to suggest that pancreatic juice contained within a pseudocyst can exchange with plasma. If so, this may represent a mechanism responsible for resorption of immature pseudocysts and spontaneous resolution of chronic pseudocysts.

Pain is the major symptom of pancreatic pseudocyst. Pseudocyst should be suspected in a patient with stable chronic pancreatitis who experiences worsening of abdominal pain. Abdominal ultrasonography is most frequently used in the diagnosis and management of pseudocysts. It is best used as a serial monitor of pseudocyst size in those patients in whom definitive drainage is delayed. CT has emerged as the single most accurate method of diagnosing pancreatic pseudocyst. [222] In addition to its high accuracy rate, it is capable of providing structural details, such as the size of the common duct or pancreatic duct. This has important bearing on the choice of an operative approach. In the presence of dilation of either or both the common bile duct and pancreatic duct, drainage of the pseudocyst alone is rarely sufficient. [223] Although some surgeons have advocated ERCP for all patients with pseudocysts, [224], [225] others have not found routine preoperative pancreatography desirable for fear of secondary infection, which may occur in up to 25% of cases. [225] It is generally agreed, however, that patients with suspected concomitant common duct obstruction should undergo ERCP before surgical drainage.

In contrast to acute pseudocysts, chronic pseudocysts, especially those larger than 6 cm, almost never resolve spontaneously. [226], [227] On the other hand, they also do not carry the same risk for serious complications as acute pseudocysts. In a study involving 75 patients with chronic pancreatitis and pseudocyst, about half of the patients could be managed conservatively. [228] Only one pseudocyst-related complication occurred in this group, and there was no mortality. According to this study, indications for operative management include persistent abdominal pain, enlargement, or complications of pseudocyst.

Effective treatment of pseudocyst includes excision and internal or external drainage. Surgical excision provides definitive treatment and is feasible when the cyst is localized to the tail of the pancreas. In most cases, however, internal drainage is the treatment of choice. Pseudocysts that are more than 6 weeks old usually have a mature cyst wall that permits internal drainage, where the cyst is anastomosed to the stomach (cystogastrostomy), duodenum (cystoduodenostomy), or jejunum (cystojejunostomy). The fluid in the pseudocyst drains into the gastrointestinal tract, and the cyst cavity collapses and becomes obliterated, usually within 1 week. There also have been reports of endoscopic drainage for the treatment of pseudocyst in chronic pancreatitis. [229], [230] A pseudocyst that indents the stomach or duodenum can be punctured transendoscopically using electrocautery or lasers to create a fistulous tract between the pseudocyst and the stomach or duodenum. Cremer and colleagues [229] reported a success rate of 96% for endoscopic cystoduodenostomy and 100% for endoscopic cystogastrostomy in 33 patients with chronic pancreatitis. No significant complications were observed after successful endoscopic cystoduodenostomy, and the two complications of endoscopic cystogastrostomy were gastric hemorrhage and iatrogenic pseudocyst infection. To decrease the risks for bleeding and perforation, the use of endosonography-guided drainage of pancreatic pseudocyst has been reported. [231] Potentially, the precise ultrasonographic definition of the cyst and local anatomy at the time of endoscopic drainage may improve the safety of endoscopic drainage, but the results are too preliminary for adequate evaluation.

External drainage usually is used for patients with infected pseudocysts and for those in whom the wall of the pseudocysts is not mature enough to hold sutures. Drainage is achieved by surgical placement of a large catheter in the pseudocyst, and the fluid drains externally through the abdominal wall. This form of treatment usually is safe but is associated with a higher recurrence rate than internal drainage. [232]

CT-guided, percutaneous, transabdominal catheter drainage of chronic pseudocysts has gained popularity and is considered by some a preferred alternative to surgical treatment in the management of pancreatic pseudocysts. Van Sonnenberg and colleagues [233] reported a 90% success rate in the percutaneous drainage of 101 pancreatic pseudocysts. The mean duration of drainage was 20 days. There was no mortality, and the only major complication was superinfection in four cases. Adams and Anderson, [234] in a retrospective study, also found that percutaneous catheter drainage was as effective as internal drainage in the management of pseudocyst, although drain tract infection was as high as 48%. In a long-term retrospective study of 42 patients undergoing percutaneous catheter drainage, however, Criado and associates [235] reported that in nine patients, the pseudocysts failed to resolve, and seven recurred after initial resolution. Hence, the effectiveness of percutaneous drainage in the management of pseudocysts remains to be established.

Somatostatin is a potent inhibitor of pancreatic secretion and therefore may be useful in the treatment of pancreatic pseudocyst. Gullo and Barbara [236] reported that 2-week treatment with octreotide, a long-acting somatostatin analog, resulted in a 42% reduction in size of the pseudocysts in four of seven patients. In addition, octreotide also appears to be effective in decreasing persistent catheter drainage from chronic pseudocyst. [237], [238] Therefore, patients with pancreatic pseudocyst resistant to drainage should be offered a course of octreotide before surgery is contemplated.

Pancreatic Ascites

The incidence of pancreatic ascites in chronic pancreatitis is usually considered to be less than 1%. It occurs as a consequence of persistent leakage of pancreatic juice from a pseudocyst or the pancreatic duct. Fifteen percent of patients with a pseudocyst may have pancreatic ascites. [239] On the other hand, 60% of patients with pancreatic ascites have pseudocysts. [240], [241] Pancreatic ascites occurs typically in alcoholic patients with cirrhosis, who may complain of mild to moderate abdominal pain because of distention. The diagnosis is often erroneously attributed to decompensated cirrhosis; however, paracentesis reveals elevation of pancreatic enzyme levels and a high total protein or albumin level. These findings are diagnostic.

Most patients need surgery. A period of 2 to 3 weeks of observation and medical treatment is warranted. During this period, the patients are given nothing orally and are placed on parenteral nutrition to improve their nutritional status. Suppression of pancreatic secretion by agents such as octreotide may be tried (100 to 250 µg subcutaneously every 4 hours). With this regimen, the ascites may resolve spontaneously in up to one third of patients, and surgery can be avoided. For patients who require an operation, ERCP should be performed to identify the precise site of the leak.

Pancreatic Fistula

External pancreatic fistula as a complication of chronic pancreatitis is rare. It occurs most commonly after operative or percutaneous drainage of a pseudocyst. It also may follow pancreatic biopsy or arise from a leaky pancreatic anastomosis. Clinically, pancreatic fistula should be suspected when clear fluid drains from a cutaneous

orifice, and the diagnosis is confirmed when the amylase content of the fluid is found to be elevated. Treatment is conservative and consists of fluid and electrolyte replacement, nutritional support, and eradication of infection if present. Somatostatin, which suppresses pancreatic secretion and decreases the volume of fistula drainage, may be used. During the course of therapy, a fistulogram should be obtained when the tract is well formed. If there is ductal obstruction between the site of the leak and the duodenum, surgical repair may be necessary. Most of the fistulas, however, close spontaneously.

Splenic Vein Thrombosis

Splenic vein thrombosis with extrahepatic (sinistral) portal hypertension is a well-known complication of chronic pancreatitis. [242], [243] Because the splenic vein courses along the posterior surface of the pancreas, thrombosis may occur as a result of peripancreatic inflammation associated with acute attacks or with pseudocyst formation and extension. Rosch and Herfort [244] found occlusion of the splenic vein in about 4% of cases of chronic pancreatitis studied with splenoportography. Almost all patients had some impingement on the splenic vein. Varices involving the esophagus, stomach, duodenum, and colon have been described with resultant hemorrhage. A more recent study [243] involving 484 consecutive patients with chronic pancreatitis reported that splenic vein thrombosis occurred in 7% (34 patients), of whom 35% (12 patients) had gastroesophageal varices. Overall, 18% of them bled either before first surgery or on follow-up. The 22 patients who underwent splenectomy never bled after surgery. These findings support the recommendation that patients who have symptomatic sinistral portal hypertension who are undergoing surgery should have concomitant splenectomy. Splenectomy also should be strongly considered in patients undergoing surgery for chronic pancreatitis who have varices secondary to splenic vein thrombosis regardless of presence or absence of prior history of variceal bleeding.

TREATMENT

Treatment of chronic pancreatitis is aimed mainly at the control of pain and the correction of malabsorption with adequate pancreatic enzyme replacement. Clinical diabetes occurs relatively late in the disease, and insulin is usually needed for its management.

Control of Pain

The management of pain in chronic pancreatitis can be a challenging problem. It is the symptom that most commonly prompts the patient to seek medical attention and is the one that is most difficult to manage. Pain patterns are highly variable, and this may reflect different causative mechanisms. The problem is further exacerbated by a lack of good controlled trials. As highlighted in an American Gastroenterological Association technical review on treatment of pain in chronic pancreatitis, [245], [246] "a reliable database for making sound judgements and recommendations is lacking in most areas."

Avoidance of Alcohol A long-held clinical aphorism is that avoiding alcohol ingestion decreases the frequency and severity of abdominal pain in chronic alcoholic pancreatitis. Trapnell [247] reported that 75% of his patients with chronic alcoholic pancreatitis experienced pain relief when they stopped drinking. This observation may be explained by the stimulatory effect of alcohol on pancreatic secretion. [248] The relationship between alcohol and pain in chronic pancreatitis, however, is controversial. Bornman and colleagues [248] noted that half of their patients with painful pancreatitis and half of their patients with painless pancreatitis continued to drink. Similar observations were made by Marks and associates. [249] These findings call into question whether continued alcohol ingestion is related to pain. It is conceivable that pancreatic pain is related to exocrine pancreatic secretion. In patients who maintain significant exocrine secretory function, pain may be provoked by alcohol, which acts as a secretagogue. In patients whose exocrine secretion is drastically reduced, alcohol no longer plays a role in the mechanism of pain. Further studies are needed to clarify the role of alcohol in pain production.
Analgesics Analgesics remain the main method for pain control in chronic pancreatitis. Initially, nonnarcotic analgesics, such as salicylates or acetaminophen, should be used. Preferably, these analgesics should be given before meals to prevent postprandial exacerbation of pain. Drug doses should be individualized, and the lowest effective dose should be used. As the severity of pain increases, the dose strength or frequency of these simpler analgesics should be increased before switching to narcotics. In severe cases, however, opiate analgesics are required, and they should not be withheld for fear of narcotic addiction.
Celiac Plexus Block Percutaneous, radiologically or ultrasonographically guided, celiac ganglion alcohol injection has been used for control of pancreatic pain. This technique has been helpful in patients who have severe pancreatic pain secondary to pancreatic cancer. [250] In small, uncontrolled series of patients with chronic pancreatitis and debilitating pain, this procedure has produced mixed results. The occasional benefits almost never last for more than a few months, [251] and repeated treatment may not be as effective. The risk for procedure-induced transient hypotension, nerve root pain, and focal neuropathic damage, combined with the need for repeated blocking, even if successful, make this an unattractive technique for most patients. [251] An open trial of celiac plexus block using botulinum toxin A instead of alcohol was unsuccessful. [252] The advances in EUS have allowed the performance of celiac plexus block under the guidance of EUS. This has become a relatively simple and short outpatient procedure. Because of the anterior transgastric approach taken during the procedure, it has mostly eliminated the risk for nerve or spinal cord injury. Recently, a prospective study with EUS-guided celiac plexus block was performed in 90 patients with painful chronic pancreatitis. [253] A significant improvement in pain score occurred in 55% of patients. Unfortunately, the benefit persisted beyond 24 weeks in only 10%. Hence, although EUS-guided celiac plexus block is safe and well tolerated, it is not very effective to treat pain in chronic pancreatitis because it offers only temporary relief.
Enzyme Therapy Much interest has been generated by a series of observations suggesting that the intralumenal action of pancreatic proteases plays an important role in regulating pancreatic enzyme secretion. The underlying concept of feedback regulation of the pancreas is based primarily on studies in rats that showed that diversion of pancreatic juice from the duodenum stimulates CCK release and pancreatic enzyme secretion. [254], [255] On the other hand, intraduodenal administration of trypsin or chymotrypsin inhibits the release of CCK and pancreatic enzyme secretion. The increased plasma CCK levels and pancreatic secretion after diversion of pancreatic juice appears to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine that has been designated CCK-releasing factor (CCK-RF). [256] When trypsin is present, this peptide is cleaved and inactivated. CCK-RF may act as a mediator of pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-RF. [257] The resulting increase of CCK-RF in the intestinal lumen enhances CCK release, stimulating pancreatic enzyme secretion. A number of CCK-releasing peptides have been identified. These include a peptide extracted from porcine intestinal extracts with a structure identical to the diazepam-binding protein [258] and a lumenal CCK-releasing peptide isolated from the duodenal secretion of rats. [259] The physiologic significance of these releasing peptides is yet to be defined. The protease-sensitive feedback mechanism was first reported to occur in humans in 1977. [260] Subsequently, several groups of investigators confirmed that intestinal administration of trypsin or chymotrypsin inhibits pancreatic enzyme secretion. [260], [261], [262], [263] and [264] Thus, it is conceivable that in patients with chronic pancreatitis, decreased enzyme secretion may result in the hyperstimulation of the pancreas by elevated plasma CCK levels, with resultant pain. Some, [265], [266] and [267] but not all, [268], [269] studies reported elevated plasma CCK levels in patients with chronic pancreatitis. It has been proposed that effective enzyme replacement therapy should reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. This hypothesis was tested in several clinical studies. In a double-blind, crossover study, Isaksson and Ihse [270] reported pain relief in 15 of 19 patients with chronic pancreatitis. There was a 30% reduction in pain intensity and a significant decrease in the frequency of pain attacks in patients on active enzymes. Slaff and colleagues [261] studied 20 patients with painful chronic pancreatitis in a double-blind, crossover study. Pain reduction was observed in 9 patients with mild to moderate pancreatic insufficiency, whereas only 2 of 11 with severe insufficiency responded to the treatment with enzyme replacement. Most of the good responders were women with idiopathic chronic pancreatitis, whereas most of the poor responders were men with alcohol-induced chronic pancreatitis. Favorable response was also reported by Ramo and associates, [271] who showed significant pain relief after self-administration (ad libitum) of an enzyme preparation, compared with administration of the regular dose in 10 patients with painful chronic pancreatitis. These three double-blind studies [261], [270], [271] demonstrated good results by enzyme treatment in 73% (36 of 49) of the patients evaluated. A double-blind, 4-week crossover study from Denmark, however, showed that oral administration of two capsules of Pancrease with each meal did not significantly control pain compared with placebo. [272] Another multicenter 2-week controlled study in more than 40 patients using an enteric-coated supplement also showed no benefit. [273] Feedback inhibition of pancreatic enzyme secretion depends on delivery of high concentrations of protease to the duodenal lumen. Enteric-coated preparations preferentially release most of their enzymes distal to the duodenum and may therefore be less effective at suppressing CCK levels and producing pain relief. [274] Finally, a 4-month double-blind, crossover study used an enteric-coated preparation with microspheres that release their contents at a lower pH (pH > 5.0) than most commonly used microspheres (pH > 6.0). Despite a high delivery rate of trypsin into the duodenum, this study showed no benefit in pain scores in patients receiving pancreatic enzymes compared with placebo. [275] However, this study contained a small number of women and evaluated patients with recurrent rather than chronic pain. Long-term trials comparing nonenteric and enteric-coated preparations in patients stratified according to etiology, severity, and pattern of disease should help to clarify these issues. Until then, it seems reasonable to initiate a trial of high-dose, non–enteric-coated oral pancreatic enzymes taken with meals for several weeks in any patient with painful chronic pancreatitis. The best results may be seen in pancreatitis of nonalcoholic etiology, with symptoms of constant, rather than recurrent, pain and only mild to moderate pancreatic insufficiency. [276]
Treatment with Octreotide Somatostatin is a naturally occurring hormone that has been shown to inhibit pancreatic secretion. [277] Theoretically, it may also have cytoprotective action and beneficial effects on the reticuloendothelial system in the setting of pancreatic inflammation. [278], [279] and [280] In addition, clinical studies have shown that somatostatin has antinociceptive activity in human [281], [282] and animal [283], [284] models of pain, suggesting that this peptide may be helpful for pain control in chronic pancreatitis. Somatostatin also appears to gain its beneficial effects in inflammatory conditions through its inhibition of cytokine release. In a recent study,

somatostatin was shown to reduce markedly the secretion of IL-8 and IL-1 from intestinal epithelial cells. [285] In another study, somatostatin significantly inhibited IL-8 and interferon-? production from activated peritoneal macrophages. [286] Octreotide is a synthetic, long-acting analog of somatostatin that has been shown to inhibit CCK release and both basally and neurally stimulated pancreatic secretion. [287], [288] and [289] Octreotide's long duration of action allows subcutaneous dosing and makes it a more practical alternative for the treatment of chronic pancreatitis than the short-acting native somatostatin. The drug is well tolerated, although long-term therapy predisposes to cholesterol gallstones. Unfortunately, controlled trials using octreotide for chronic pancreatitis pain are limited. Short 3-day studies, using 100 and 150 µg three times a day, showed no benefit. [290] A multicenter randomized 4-week study of 91 patients with advanced chronic pancreatitis and severe pain was performed. [291] Octreotide, at doses ranging from 40 to 100 µg three times daily, was compared with placebo. Although results in this pilot study did not reach statistical significance, 200 µg three times a day of octreotide produced the greatest pain relief (65% versus 35% of patients with placebo), especially in patients with constant as opposed to intermittent pain. Additional studies are needed to clarify the role of octreotide in the management of chronic pancreatitis pain. Recently, a long-acting formulation of octreotide acetate (Sandostatin LAR Depot) was developed for patients requiring long-term octreotide therapy. It consists of octreotide acetate microencapsulated by a biodegradable polymer. Drug release occurs slowly as cleavage of the polymer takes place primarily through tissue fluid hydrolysis. After single intramuscular injection, the serum octreotide level reaches plateau concentrations at about day 14 and remains relatively constant during the following 3 to 4 weeks. This long acting form of octreotide may provide significant benefit over octreotide because it requires only monthly injection. A double-blind, randomized, multicenter trial of the long-acting octreotide in the treatment of painful chronic pancreatitis is ongoing.

Endoscopic Therapy Endoscopic therapy has been used for control of pain in chronic pancreatitis, with the aim of alleviating obstruction of flow caused by ductal strictures, stones, or papillary stenosis. Ductal strictures are sometimes treated by balloons or dilating catheters, but in most cases, dilation is followed by stent placement across the stricture. Technical success in reported studies ranges from 82% to 100%, [292], [293], [294], [295], [296], [297] and [298] and pain improvement occurs in 55% to 100% of patients during a follow-up of 8 to 39 months. True success rates are difficult to decipher, however, because stent placement frequently was performed with other procedures. Ponchon and colleagues [298] used a standardized protocol to evaluate endoscopic stenting for pain relief in a highly selected subgroup of patients with chronic pancreatitis. Patients with multiple strictures, pancreatic calculi, pancreatic divisum, common duct narrowing, any duodenal impingement, or a pseudocyst larger than 1 cm were excluded. They successfully placed 10-French, multi–side-hole stents after biliary and pancreatic sphincterotomy and balloon dilation of strictures in 28% of 33 patients (85%) with a distal pancreatic duct stricture and upstream dilation. The stents were exchanged at 2-month intervals, for a total stenting duration of 6 months. The report was based on 23 patients observed for at least 1 year after removal of the stent. During the stenting period, 21 patients (91%) had resolution or reduction in pain, and 17 discontinued analgesic medications. Twelve patients (52%) had a persistent beneficial outcome for at least 1 year after stent removal. Disappearance of the stenosis on pancreatography, at stent removal, and 1 year later and reduction in the diameter of the pancreatic duct were significantly associated with relief of pain. Therefore, it appears that in patients with isolated stricture, endoscopic stenting may be useful to relieve pain. Based on reports in the literature, the incidence of occlusion of pancreatic stents appears to be similar to that for biliary stents. [299] Sherman and Lehman [300] reported that 50% of pancreatic stents (5 to 7 French) were occluded within 8 weeks of placement. Another complication is stent migration, which may be upstream (into the duct) or downstream (into the duodenum). Migration in either direction may be heralded by return of pain or pancreatitis. Johanson and associates [301] reported inward migration in 5.2% of patients and duodenal migration in 7.5%. Modifications in the design of pancreatic stents may reduce the frequency of such occurrences. [302] Long-term studies of stent placement also indicated that morphologic changes occurred in most patients. These usually are mild and reversible in most patients. [303], [304] Endoscopic techniques also have been used for the removal of pancreatic stones in chronic pancreatitis. In different series, pancreatic duct stones were removed after endoscopic sphincterotomy in 27% to 100% of patients. [305], [306] In some cases, stone removal was facilitated by fragmentation with extracorporeal shock wave lithotripsy, with clinical improvement observed in 50% to 80% of cases in which the stones were successfully removed. [306] Inherent in these various therapies is the belief that stones are themselves causing symptoms by intensifying obstruction and that their removal will improve pancreatic flow and thereby reduce symptoms. On the other hand, it is also possible that pancreatic stones form as a result of pancreatic stricture and abnormal pancreatic juice protein and have little to do with pain. None of the studies on endoscopic treatment of chronic pancreatitis is controlled, and no valid comparisons have been made among medical, surgical, and endoscopic treatments. These procedures should therefore be considered experimental and performed only in patients entered into prospective, randomized trials. In one study, minor papilla endoscopic sphincterotomy was performed in 52 patients with pancreas divisum who had either chronic abdominal pain, acute recurrent pancreatitis, or chronic pancreatitis. [307] Among the three groups of patients, only those with acute recurrent pancreatitis benefited from the endoscopic procedure. This suggests that minor papilla sphincterotomy should be avoided in patients with pancreatic divisum and chronic pancreatitis.

Surgical Treatment After all medical measures have failed to relieve pain, surgery should be considered. The type of surgery is selected according to the perceived mechanism for the pain. When the main pancreatic duct is dilated, it is assumed that there is pancreatic duct obstruction and that pancreatic duct hypertension is the cause of pain. On the other hand, if there is no ductal dilation, pain may result from diffuse parenchymal disease or blockage of small side ducts by stones, protein plugs, or scars. Relief of major duct obstruction should not affect this type of pain. Therefore, the type of surgery should be chosen according to the severity of pain, ductal morphology, and the extent of parenchymal disease. Patients who have ductal dilation have a 70% to 80% chance of obtaining pain relief with either a partial resection with pancreaticojejunostomy or lateral pancreaticojejunostomy (modified Puestow procedure). The modified Puestow pancreaticojejunostomy is particularly suitable for patients who have ductal obstruction and dilation. It is a safe and effective operation, with a morbidity rate of less than 5%, mortality rate of less than 2%, and effective pain relief rate on the order of 80%. [308], [309] On the other hand, for patients with moderate to severe parenchymal disease and no ductal dilation, partial pancreatic resection should be considered. Ninety-five percent distal resection is recommended for patients with diffuse parenchymal disease, [249] whereas local resection of major site of involvement may be sufficient for those with regional parenchymal disease. [249] Overall, 50% of these patients have had satisfactory results. Near-total pancreatectomy, or Whipple procedure, includes sacrificing portions of normal stomach and duodenum with resulting metabolic and digestive complications. To correct these problems, the original Whipple procedure underwent two subsequent procedural modifications. In 1978, Traverso and Longmire [310] described pylorus-preserving pancreatic duodenectomy, thereby avoiding the digestive complications of partial gastric resection. Several years later, Beger and associates [311] described a more conservative procedure that resected the diseased pancreatic head and preserved all extrapancreatic organs, including the duodenum (Fig. 95-10). A randomized trial comparing these two procedures in patients with painful chronic pancreatitis was performed. [312] There was no postoperative mortality, and morbidity was comparable in both groups (15% to 20%). After 6 months of follow-up, patients who underwent duodenum-preserving pancreatic head resection (the Beger procedure) experienced less pain, better preservation of insulin secretion and glucose tolerance, and more stable weight than those who underwent pylorus-preserving Whipple resection. This suggests clinical superiority of the Beger procedure as compared with the pylorus-preserving Whipple resection. However, the limited sample size and lack of long-term follow-up preclude any definitive conclusions at this time.

FIGURE 95-10. Duodenum-preserving resection of the pancreatic head as described by Beger. A metal probe is inserted through the common bile duct into the duodenum to prevent inadvertent injury during resection of the pancreatic head. **B:** Reconstruction includes an end-to-end pancreaticojejunostomy and a side-to-side anastomosis between the jejunum and the rim of the cavity remaining after resection of the pancreatic head. *D,* duodenum; *HA,* hepatic artery; *PD,* pancreatic duct; *RC,* resection cavity of the pancreatic head; *SMV,* superior mesenteric vein; *ST,* stomach; *T,* tube; *TC,* transverse colon. (From ref. [315].)

In 1987, Frey and Smith [313] described another operation for painful chronic pancreatitis that consisted of local resection of the pancreatic head combined with longitudinal pancreaticojejunostomy (Fig. 95-11). This procedure was designed to improve decompression of the head of the pancreas, which often was not drained well by conventional pancreaticojejunostomy. Frey and Amikura [314] reported their results in 50 patients with chronic pancreatitis in a 7-year follow-up study. There were no operative deaths, and 22% of patients developed postoperative complications. Pain relief was complete or improved in 87% of patients. Twenty percent of patients developed new-onset postoperative diabetes, and 11% experienced worsening of their diabetes.

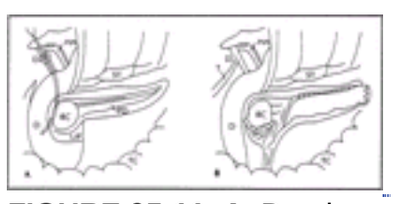

FIGURE 95-11. A: Duodenum-preserving resection of the pancreatic head as described by Frey. A metal probe is inserted through a choledochotomy into the duodenum before resecting the pancreatic head mass to minimize the risk for bile duct injury. **B:** Reconstruction consists of a side-to-side pancreaticojejunostomy including the resection cavity of the pancreatic head. *D,* duodenum; *HA,* hepatic artery; *PD,* pancreatic duct; *RC,* resection cavity of the pancreatic head; *ST,*

stomach; *T,* tube; *TC,* transverse colon; *UP,* uncinate process. (From ref. [315].)

The two techniques of duodenum-preserving resection of the pancreatic head (the Beger and Frey procedures) were compared in a prospective study. [315] There was no operative mortality in both groups, and postoperative morbidity was significantly lower in patients who had undergone the Frey procedure, which is technically less demanding. Both groups of patients reported similar postoperative decreases in pain and improved quality of life index scores. Postoperative pancreatic endocrine and exocrine function was also similar in both groups. These results are encouraging, but the mean follow-up of 1.5 years is relatively short. Long-term studies are needed to determine whether either or both procedures will suffer from attrition of the initial good results. It should also be noted that the duodenum-preserving resections are not appropriate for all patients with symptomatic chronic pancreatitis but seem especially useful for patients with predominant involvement of the pancreatic head. Recently, Nealon and Matin [316] evaluated the success rates of different surgical procedures in relieving both the chronic abdominal pain and the recurrent exacerbations associated with chronic pancreatitis. Patients were divided into three groups based on the characteristics of their pain: severe unrelenting pain alone, severe pain with intermittent acute exacerbations, and intermittent acute exacerbations only. Postoperative pain relief was achieved in 83% of patients overall, with 86% relief from lateral pancreaticojejunostomy, 67% from distal pancreatectomy, and 91% from pancreatic head resection. It appears that pancreatic head resection was most effective for relief of chronic pain (91%), whereas distal pancreatectomy was least effective (67%). On the other hand, lateral pancreaticojejunostomy gave the best relief of acute pain exacerbations (91%), whereas distal pancreatectomy was rather ineffective (33%). Pancreatic head resection was much more effective in relieving chronic pain (91%) than pain related to acute exacerbations (58%). These observations suggest that stratification of patients according to their pain patterns may be helpful to select the most effective surgical procedure for pain relief. In patients undergoing a near-total pancreatectomy, islet cell autotransplantation by infusion of islet cell preparations into the portal system may prevent diabetes. [317], [318] and [319] Islets from the resected pancreas can be isolated by mechanical disruption and collagenase digestion of the dispersed tissue and injected into the portal vein. Using this method, Farney and colleagues [319] reported that 9 of 22 patients with intraportal islet autografts were insulin independent for at least several months after surgery. Wahoff and associates [320] reported long-term insulin independence in 33% of 48 patients who underwent pancreatic resection combined with islet autotransplantation and followed up for 2 to 10 years. Insulin independence after islet autotransplantation correlated most closely with the number of islets transplanted and therefore relates to the available mass of pancreatic tissue and the degree of pancreatic fibrosis. Of those patients who received less than 200,000 islets, only 22% achieved long-term insulin independence. By comparison, nearly 60% of patients who received more than 300,000 islets achieved long-term independence. With recent advances in islet isolation techniques, there appears to be an overall improvement of the results of islet autotransplantation. Recent studies indicate that about 50% of patients undergoing total or subtotal pancreatectomy can become insulin independent after intraportal autologous islet transplantation. [321], [322] In the largest published series of 43 patients undergoing total or near-total pancreatectomy for chronic pancreatitis, insulin independence persisted in 34% of patients 2 to 10 years after surgery, and no graft failure occurred after 2 years. [323] Patient selection is important to determine the success of islet cell autotransplantation on diabetes after total pancreatectomy for chronic pancreatitis. Patients with end-stage fibrotic glands and those who are narcotic dependent are unlikely to do well postoperatively. [322]

Summary of Treatment Approach for Control of Pain We recommend the following approach to treat pain of chronic pancreatitis: When a patient first presents with pain or shows a different pain pattern, we determine whether there is an anatomic reason for the occurrence of or a change in pain. Pseudocyst, phlegmon, obstruction, and peptic ulcer are ruled out by appropriate tests. Patients are advised to stop all alcohol ingestion and to use salicylate or acetaminophen as needed. We also recommend the use of enzyme (e.g., 8 tablets of Viokase with each meal), especially in patients with non–alcohol-induced chronic pancreatitis. If pain continues, a trial of octreotide may be considered. After all medical measures have failed, we recommend surgery; some centers, however, may consider celiac plexus block before surgery (Fig. 95-12).

FIGURE 95-12. Algorithm for management of the patient with painful chronic pancreatitis.

Management of Pancreatic Insufficiency

At first glance, treating malabsorption secondary to pancreatic insufficiency might appear to be relatively easy. It would seem that simple oral replacement of pancreatic enzymes would be efficacious. Unfortunately, complete correction of steatorrhea is rarely accomplished. This is related to insufficient amounts of enzyme in oral supplements and acid pepsin inactivation of pancreatic enzymes.

The maximal postprandial delivery of pancreatic lipase is about 140,000 IU/hour for 4 hours after meals. [120] It has been shown that malabsorption does not occur if more than 5% of the normal maximal enzyme output is delivered to the duodenum. To meet this requirement, 28,000 IU of lipase should be delivered during a 4-hour postprandial period. Pancreatic supplements are highly variable in enzyme activity, with lipase content ranging from 0 to 8000 IU per tablet. [145], [324], [325] Therefore, if the clinician uses a commercially available preparation containing 3500 IU per tablet of lipase, then under the best of circumstances, at least 8 tablets or capsules must be taken per meal to abolish malabsorption. Smaller amounts of enzymes may reduce steatorrhea but not abolish it. Therefore, the clinician should choose those commercial enzyme preparations that have been shown to contain higher lipase activity, and ensure that sufficient amounts have been used (Table 95-5).

		CONTENT (UNITS)		
PREPARATION	TYPE	*Lipase*	*Amylase*	*Protease*
Cotazyme	C	8000	30,000	30,000
Cotazyme-S	ECMS	5000	20,000	20,000
Creon 10	ECMS	10,000	33,200	37,500
Creon 25	ECMS	25,000	74,700	62,500
Ilozyme	UCT	11,000	30,000	30,000
Ku-zyme HP	ECMS	8000	30,000	30,000
Pancrease	ECMS	4000	20,000	25,000
Pancrease MT-4	ECMT	4000	12,000	12,000
Pancrease MT-10	ECMT	10,000	30,000	30,000
Pancrease MT-16	ECMT	16,000	48,000	48,000
Protilase	ECMS	4000	20,000	25,000
Viokase	UCT	8000	30,000	30,000
Viokase	P	16,800	70,000	70,000
Zymase	ECMS	12,000	24,000	24,000

TABLE 95-5 Commercial Pancreatic Enzyme Preparations

Another important factor to consider is acid-peptic inactivation of pancreatic enzymes. When duodenal samples were examined for lipase and trypsin activity, less than 8% of ingested lipase and less than 22% of ingested trypsin was recovered, regardless of the dosing schedule used (either prandial or hourly dosing). To

eliminate steatorrhea in pancreatic insufficiency, a large number of tablets are necessary. Hyperuricosuria [326] and kidney stones have been associated with such high dosing of pancreatic supplements secondary to their high purine content, and therefore, this high dosing schedule may not be clinically justified. The relatively low delivery of lipase into the proximal small bowel compared with the delivery of trypsin with routine treatment schedules may explain the relative impossibility of completely correcting steatorrhea in pancreatic insufficiency as well as the usual correction of azotorrhea.

Preventing acid-peptic neutralization of enzyme supplements by coating capsules with acid-resistant and alkali-sensitive materials or by using antacids has produced mixed results. [327], [328] In most studies, there has been little success with oral antacids or enteric coating with regard to clinical improvement or alleviating steatorrhea. Antacids increase gastric secretion, and dilution of enzyme concentrations below critical levels may explain the relative ineffectiveness of antacids. [328] Enteric coating is effective only if pancreatic enzymes are delivered into the duodenum with ingested food from the stomach and adequate intraduodenal dissolution occurs. Because emptying of large tablets from the stomach may be different from that of typical antral contents, and duodenal and gastric pH have been shown to be low (pH < 4.0) for prolonged times in many patients with pancreatic insufficiency, [329], [330] enteric coating may not be an effective improvement over oral pancreatic supplements alone.

Pancrease (pancreatin coated with a pH-dependent polymer) is another improvement in pancreatic enzyme supplements. [331] Because this supplement is stable at an acidic pH (pH < 4.0) and dissolves at a pH of greater than 5.0, it is most effective (i.e., better than standard tablets alone) in patients who maintain acidic pH levels in the stomach postprandially. This maneuver delivers pancreatic enzymes to the upper small bowel intact, whereas standard supplements are irreversibly inactivated. In several studies, the mean reduction of steatorrhea with the use of Pancrease is not better than that with Viokase given with meals. [328], [332] Normally, in chronic pancreatitis, the gastric pH increases to above 5.0 in the early postprandial period and then decreases to less than 4.0. It is likely that, under these circumstances, pancreatin initially will be liberated from its enteric coat, but its enzyme activity will be irreversibly inactivated when the intragastric pH falls to less than 4.0. Conversely, if gastric and duodenal pH remain low (pH < 4.0) throughout the postprandial period, [333] the enteric coat of Pancrease remains intact as it traverses the upper gastrointestinal tract, and pancreatin is liberated en masse only as it reaches the jejunum, where intralumenal pH is greater than 5.0. This may explain the effectiveness of Pancrease in abolishing steatorrhea in some patients who secrete more acid and presumably can maintain an acidified upper small intestine for a prolonged period of time.

Until recently, the major criterion for determining the efficacy of enteric-coated enzyme preparations was the size of the microspheres, which influences the timing of enzyme delivery to the intestine. It has been shown that microspheres with a diameter of about 1.4 mm appear to mix with chyme most thoroughly and are emptied from the stomach at the same rate as food; large spheres remain in the stomach after food has been emptied into the small bowel and are less effective in correcting malabsorption in chronic pancreatitis. [334] Some commercially marketed microspheres (more than 2 mm) of pancreatin empty too slowly to be effective in digestion of food. This may explain why some enteric-coated preparations are not effective in correcting pancreatic steatorrhea. However, a recent prospective, randomized, double-blind, multicenter, crossover trial in chronic pancreatitis patients with a stool fat excretion of 7.5 g/day showed that there was no difference between Creon given as microspheres with a diameter of 1 to 2 mm and as mini-microspheres with a diameter of 0.7 to 1.6 mm. [335] The mean stool fat excretion per day was about 16 gm in both groups. Thus, reducing microsphere size does not improve the efficacy of the enzyme supplements. An explanation for this observation may be that in vivo microspheres aggregate into larger particles in the presence of free oil. [336] It should be noted that high doses of pancreatic enzyme supplements in children with cystic fibrosis have been associated with recurrent bowel obstruction due to fibrosing colonopathy characterized by dense submucosal fibrosis in the large bowel. In recent years, two cases of fibrosing colonopathy have been reported in adult patients, one with and one without cystic fibrosis. [337], [338] The cause of fibrosing colonopathy associated with high doses of pancreatins remains speculative. [339]

Histamine H_2 receptor antagonists decrease acid production, pepsin activity, and gastric secretory volume simultaneously and should optimize pancreatic enzyme concentrations. [328], [340] Duodenal lipase and trypsin activities are consistently increased with concomitant Viokase and histamine H_2 receptor antagonist treatment. Cimetidine should be considered only in patients who do not respond to standard oral pancreatic supplements because of lifelong increased cost and potential unknown long-term side effects. It has been shown that omeprazole further reduces fecal fat excretion in patients with cystic fibrosis receiving enzyme replacement for pancreatic insufficiency. [341] Therefore, in patients in whom histamine H_2 receptor antagonist fails to abolish steatorrhea, use of omeprazole should be considered.

We recommend the following approach to treat patients with pancreatic insufficiency. It is critical that sufficient amounts of enzyme tablets be given (e.g., 8 tablets of Viokase with each meal) to abolish azotorrhea and significantly reduce steatorrhea. Most patients on this regimen achieve satisfactory nutritional status and become relatively asymptomatic. In some of the symptomatic patients, the number of tablets given prandially can be increased or the amount of dietary fat reduced. These measures usually are effective in alleviating symptoms. In occasional patients, the use of Pancrease may be necessary. The addition of histamine H_2 receptor antagonist or omeprazole should be reserved for those patients who are resistant to these maneuvers and who have documented acidic duodenal pH levels, because of cost considerations as well as potential long-term side effects. If all of these measures are ineffective, documentation of diagnosis (by pancreatic function testing) and exclusion of other contributing causes (celiac sprue, terminal ileal disease, or bacterial overgrowth) must be done.

Management of Pancreatic Diabetes

Clinical diabetes occurs relatively late in the disease and is an independent predictor of mortality of chronic pancreatitis. Ketoacidosis and diabetic neuropathy were relatively uncommon in this form of diabetes. This is probably due to the fact that in pancreatic diabetes, insulin secretion is not completely lost, and glucagon secretion is reduced. Although some patients may respond to oral hypoglycemics, insulin is often needed in most patients. Insulin requirements are usually lower than for most patients with genetic diabetes because insulin receptors usually are not down-regulated and insulin antibodies initially are not present. Overzealous control of blood glucose should be avoided because this may result in life-threatening hypoglycemia.

CHAPTER 96

John P. Duffy and Howard A. Reber

NONENDOCRINE TUMORS OF THE PANCREAS

DUCTAL ADENOCARCINOMA OF THE PANCREAS

Approximately 29,000 new cases of pancreatic cancer occur every year in the United States, and almost all of these patients will eventually die from the disease. Although surgical resection of the tumor offers the only chance for cure, even after a “curative resection,” the median duration of survival is only 18 to 20 months, and the 5-year survival rate is 15%. [1] Although these overall statistics are sobering, certain groups of patients fare better. If the tumor is removed with clear surgical margins and no lymph node metastases are present, the 5-year survival is as high as 25%. [2] Patients with well-differentiated tumors may have as much as a 50% chance for surviving 5 years. Unfortunately, only a minority of patients fall into these categories.

A number of new and exciting developments have occurred in the field. They include a rapid growth in the characterization of the genetic abnormalities associated with the disease, the appearance of new diagnostic techniques that have improved our ability to rapidly diagnose and stage it, and effective new therapeutic modalities, which allow nonsurgical palliation in many patients. Curative surgery is performed with operative mortality rates of only 1% to 2%, compared to 10 times that figure a decade ago. A number of new operations exist, which hold the promise of more effective treatment and less morbidity. In this chapter, we discuss these advances and present a broad overview of the diagnosis and management of patients with pancreatic neoplasms.

EPIDEMIOLOGY AND RISK FACTORS

The peak incidence of pancreatic carcinoma occurs in the seventh decade of life, and there is a slight male to female predominance. [3] The overall incidence of the disease is 30% to 40% higher in the African-American population than in Caucasians. The highest incidence occurs in Maori men of New Zealand, in whom the likelihood of developing pancreatic cancer is twice that of Caucasians in the United States or Europe. [4]

A variety of observations support the notion that there are hereditary (genetic) factors that influence the development of pancreatic cancer. Reports of the disease in multiple family members of the same generation and within extended families show an autosomal dominant inheritance pattern. [5] Certain genetic disorders predispose to pancreatic cancer. They include multiple endocrine adenomatosis type I, hereditary nonpolyposis colorectal cancer, familial adenomatosis polyposis, Gardner syndrome, familial atypical multiple mole melanoma syndrome, Peutz-Jeghers (PJ) syndrome, and von Hippel-Lindau syndrome. [5], [6] However, genetic factors appear to play a role in only about 5% of all newly diagnosed cases of pancreatic cancer. [5]

Smoking

Around the world, the risk factor most strongly linked to pancreatic cancer is cigarette smoking. [6], [7] and [8] It approximately doubles the chance of developing the disease. The relation between number of pack years of smoking and the risk of pancreatic cancer is not as strong as it is with lung or oropharyngeal cancers, but it is generally true that the risk is greater with more cigarettes smoked. It is also curious that the risk of pancreatic cancer rapidly decreases when individuals discontinue cigarette use. The relative risk falls to about 1 only 10 to 15 years after quitting. The smoking of cigars and other forms of tobacco probably does not increase risk. Autopsy studies of smokers have revealed hyperplastic changes in the pancreatic ducts, alterations that have been noted to increase in proportion to cigarette consumption. [4]

Pancreatitis

A case control study in the United States Veterans Administration compared the occurrence of chronic pancreatitis in 2639 patients with pancreatic cancer to a

matched control group of 7774 subjects. A history of pancreatitis doubled the risk of developing pancreatic cancer. [9], [10] Other epidemiologic studies suggest that the relative risk of developing pancreatic cancer in patients with chronic pancreatitis is increased by up to 15 times when compared to control populations. This increase in risk also is seen in kindreds with hereditary pancreatitis. [11] This suggests that the etiology of the pancreatitis is not a factor, but that the changes associated with chronic inflammation and fibrosis in the pancreas are more important. Nevertheless, chronic pancreatitis accounts for only a small fraction of patients who have pancreatic cancer. [12] A multicenter international study found that 1.8% of patients with chronic pancreatitis developed pancreatic cancer during a mean follow-up of 7.4 years. [10]

Surgery

In one study, patients who had undergone a partial gastrectomy had a five to seven times greater risk of developing pancreatic cancer. [13] Another study found that there was an approximately threefold elevation in the risk of pancreatic cancer in patients who had undergone previous gastrectomy for peptic ulcer. [14] The apparent increase in incidence may be caused by altered metabolism of ingested carcinogens by the remaining stomach and small intestine following surgery.

Ethanol

A large number of epidemiologic studies in both the United States and Europe failed to find any consistent etiologic association between alcohol consumption and the development of pancreatic cancer. The evidence at the present time does not support the view that it is a risk factor. [7], [8]

Coffee

In an Italian multicenter study, consumption of more than three cups of coffee per day increased the risk for pancreatic cancer even when the data were controlled for potential confounding factors such as cigarette smoking or alcohol use, and when the analysis was restricted to nonsmoking coffee drinkers. [15] However, a case-control study in Japan and a metaanalysis of data published between 1981 and 1993 did not support the notion that either caffeinated or decaffeinated coffee or tea were risk factors for pancreatic cancer. [16]

Diet

In general, a high total energy intake correlates with an increased risk of pancreatic cancer. Products of plant origin and dietary fiber, in particular, appear to be protective. Meats and foods of animal origin increase the risk. Protein and fat consumption have been shown to be promoters of pancreatic carcinogenesis in experimental animals. [3] In Japan, two clinical studies showed a correlation between meat consumption and pancreatic cancer. [4] Another study in the United States found a 2.5-fold increased risk of developing pancreatic cancer in men consuming protein, largely in the form of meat. [17]

Obesity

Prospective cohort studies including 46,648 men (ages 40–75) and 117,041 women (ages 30–55) showed that a body mass index (BMI) of at least 30 kg/m ^{2} was associated with an increased risk for pancreatic cancer. [18] In addition, total physical activity was shown to be inversely related to pancreatic cancer risk for those with a BMI of 25 or greater. [18] In the same study height was also found to be associated with increased risk. The increased risk associated with obesity is thought to be related to abnormal glucose metabolism, insulin resistance, and hyperinsulinemia commonly seen in obese individuals.

Genetic Factors

It is estimated that familial factors and genetic susceptibility play significant roles in the development of around 10% of pancreatic cancer cases. A recent review of the National Familial Pancreas Tumor Registry (NFPTR) demonstrated an 18-fold increase in the risk for malignancy among first-degree relatives of patients with familial pancreatic cancer compared to those with relatives with sporadic disease. [19] For those with three or more family members with familial disease, the risk increased a remarkable 57-fold. [19] Thus, first-degree relatives of patients with familial pancreatic cancer are at significant risk and may benefit from early screening methods.

MOLECULAR GENETICS

In recent years, many exciting advances have been made in the understanding of pancreatic cancer at its genetic level. Ductal adenocarcinomas of the pancreas appear to evolve from normal ductal epithelium that develops into benign, flat, mucinous duct lesions, a transition characterized by transformation of the normal, low-cuboidal ductal epithelium to a columnar morphology. [20] Upon microdissection, about half of these flat ductal lesions are found to contain *K-ras* mutations. [20] These lesions progress to papillary lesions without atypia, to papillary lesions with atypia, and finally to invasive adenocarcinoma. [20] The available evidence suggests that the cells that progress through this sequence have been genetically altered in ways that favor unrestrained growth. Such alterations can occur as mutations in oncogenes, which normally code for proteins that are critically involved in cellular transcription and growth, or in tumor suppressor genes, whose protein product functions to suppress cellular proliferation. Oncogene mutations—through point mutation, amplification, or chromosomal translocation—confer upon the pancreatic cancer cell a “gain in function,” usually manifested as a constitutively active and unrestrained growth-promoting protein. Mutations in tumor suppressor genes, on the other hand, usually result in “loss of function” for the transformed pancreatic ductal cell, as the altered or deleted protein cannot effectively control cellular growth and suppress tumor formation. Mutations in oncogenes and tumor suppressor genes are encountered in pancreatic ductal adenocarcinoma.

Genetic alterations associated with pancreatic cancer can be divided into two groups, those that occur with a high frequency or a low frequency.

High Frequency Alterations

Four genetic mutations represent the most frequent alterations in established pancreatic cancers:

- activation of the *K-ras* oncogene in 80% to 95% of cases
- inactivation of the tumor suppressor genes *p16* (80% to 90%)
- *p53* (75%)
- *DPC4* (50%). [20], [21], [22], [23], [24] and [25]

The *K-ras* mutations, which occur most commonly in codon 12, also have been found in the majority of noninvasive proliferating ductal lesions before cancer is seen. This suggests that the genetic alterations responsible for ductal cell malignant transformation occur at an early stage of carcinogenesis. [21]

K-ras is a member of the membrane-associated, guanine nucleotide-binding, protein family involved in signal transduction stimulated by growth-promoting effectors at the cell surface. [21] When *K-ras* is mutated, usually through point mutation, it is transformed into an oncogene whose abnormal protein product gains the capacity for unrestrained mitogenic signal transduction. Evidence indicates that *K-ras* mutations occur more frequently in pancreatic carcinomas than in other variants of periampullary carcinoma, suggesting a molecular difference may underlie their distinct tumor biology and clinical behavior. [21], [24] It is clinically significant that the *K-ras* mutation has been discovered in many benign human neoplasms and early lesions, indicating that it is not specific for invasive malignancy. This fact has hindered its development as a reliable screening tool for pancreatic ductal adenocarcinoma. [20]

p16, a tumor suppressor gene located on chromosome 9p, encodes a protein that serves as a cyclin-dependent kinase (CDK) inhibitor. Its interactions with cyclin-complexes effectively arrest cells in the G1 phase. [20], [21] Mutations in *p16*– deletions, missense, nonsense, frameshift, and hypermethy- lations—lead to loss of its restrictive action on cell growth. A germline mutation in *p16* associated with familial melanoma also increases risk of developing pancreatic carcinoma. [21]

p53 is a tumor suppressor gene located at chromosome 17p which encodes a 53 kd protein that negatively regulates cell growth and proliferation. This nuclear-binding protein regulates the transcription of factors important in cellular processes such as cell-cycle modulation, DNA surveillance and repair, differentiation, and apoptosis. [21] Nearly all mutated *p53* protein products lose the ability to bind DNA. [20] *p53* expression has been found to be induced by hypoxia, a

condition especially profound in pancreatic carcinomas. [22]

Cloned by Hahn and colleagues in 1994, *DPC4* (for *D*eleted in *P*ancreatic *C*ancer, Locus *4*) is a tumor suppressor gene related to the *Smad* gene family. [20] Its protein product is a cytoplasmic protein which, in response to transforming growth factor-ß (TGF-ß) binding to its receptor TGF-ßR $_2$, translocates to the nucleus, binds the *Smad*-binding element of DNA, and regulates transcription. [20] Germline mutations in *DPC4* have been shown to be associated with juvenile polyposis. [20] Interestingly, recent immunohistochemical analysis of 79 resected pancreatic intraductal papillary mucinous tumors (IPMTs) demonstrated uniform (100%) expression of the *DPC4* product, compared to only 70% and 45% expression in high-grade pancreatic intraepithelial neoplasms and infiltrating adenocarcinomas, respectively. [26] Thus, the *DPC4* deletion is thought to occur as a relatively late event in the process of ductal cell transformation; the presence of its protein product in IPMTs may contribute, in part, to the more favorable prognosis and more indolent course of these tumors.

Low Frequency Alterations

These less-frequent mutations comprise alterations in oncogenes, tumor suppressor genes, and growth factors and their receptors. The signal transducer AKT2 is a target oncogene thought to be involved in the amplification of chromosome 19q13, a change found in 10% to 20% of pancreatic cancers. [20] The MYB oncogene has been observed in 10% of cases of pancreatic cancer. [20]

The *BRCA2* tumor suppressor gene has been found to be inactivated in about 7% of pancreatic cancers. [21], [23] This mutation is especially significant in that it is a germline mutation which represents, as yet, the most common inherited predisposition to pancreatic carcinoma. [21] Patients with PJ syndrome, characterized by hamartomatous intestinal polyposis, have an increased risk of pancreatic and other gastrointestinal cancers. [21], [23] This syndrome is associated with mutation of the *LKB1/STK11* gene, a tumor suppressor gene which encodes a serine/threonine kinase. [20] About 5% of pancreatic cancers unrelated to the PJ syndrome contain this mutation. [20]

In addition to these gene mutations, there is also evidence that various growth factor receptors (e.g., epidermal growth factor [EGF] receptor, c-erbB2, c-erbB3, TGF-ß receptor 1–3), growth factors (e.g., EGF, TGF-a, TGF-ß $_{1-3}$, fibroblast growth factor [aFGF], bFGF], and intercellular and endothelial-leukocyte adhesion molecules (e.g., intercellular adhesion molecule-1, endothelial leukocyte adhesion molecule-1) are up-regulated in human pancreatic adenocarcinomas. [21] These changes may stimulate further tumor growth and enhance the metastatic behavior of pancreatic cancer cells, thus possibly contributing to shorter postoperative survival following tumor resection. [21], [24] Insulin-like growth factor-1 has been shown to enhance the growth of human pancreatic cancer cells. [27] Expression of the fibroblast growth factor receptor has been found to correlate with metastases and tumor stage. [21], [28] Finally, patients with familial recurrent pancreatitis have been found to express a mutated serine protease gene, *PRSS1,* also known as the *cationic trypsinogen gene*. A carrier of this mutation has an overall lifetime risk of developing pancreatic cancer of 40%, usually at an earlier age (average age of onset 39 years). [20] This increased cancer risk is thought to be related to the mitogenic response of ductal cells to multiple episodes of inflammatory damage. [20], [23]

PATHOLOGY

Ductal adenocarcinoma and its variants make up more than 90% of all malignant exocrine pancreatic tumors. Of the remainder, some are acinar cell carcinomas, some are sarcomas, a few are malignant lymphomas, and some are of uncertain histogenesis.

About two thirds of ductal adenocarcinomas occur in the head of the gland; the rest occur in the body or tail, or diffusely throughout the pancreas. They are characterized by an intense desmoplastic reaction in which ductlike structures of varying degrees of differentiation are seen. Because of their proximity to the intrapancreatic portion of the common bile duct, tumors in the head usually produce jaundice since they compress and obstruct the bile duct as they grow. They often obstruct the pancreatic duct as well, and although steatorrhea may result, there may not be any obvious symptoms. Tumors of the head of the pancreas are usually at least 2 cm in diameter when they are first diagnosed. Most tumors that are resected have a median diameter of 2.5 to 3.5 cm. Tumors of the body and tail commonly are larger (5–7 cm), and more advanced when they are discovered because they do not produce symptoms as early as head tumors do. The symptoms from tumors in the body and tail are usually caused by malignant infiltration of the retroperitoneal structures and nerves, which produces pain. By the time the diagnosis is made, almost all are unresectable. Nevertheless, there is evidence that resectable body tumors have a similar prognosis to resectable tumors in the head of the gland.

Approximately 70% to 80% of adenocarcinomas of the head of the pancreas have metastasized to regional lymph nodes by the time they are discovered, which worsens the prognosis but does not preclude cure. These tumors also commonly invade lymphatic channels and perineural spaces. The prognosis is also influenced by the degree of tumor differentiation and by the presence of invasion of the retroperitoneal tissues adjacent to the cancer. The best outcome is seen in patients who have well-differentiated neoplasms, without retroperitoneal invasion or lymph node metastases. Distant metastases (e.g., lung) may occur, but pancreatic cancer typically infiltrates locally into the adjacent structures (e.g., stomach, duodenum, colon, transverse mesocolon, portal and superior mesenteric veins, superior mesenteric artery). The liver is the most common site of intra-abdominal metastasis, and peritoneal seeding of the tumor is also seen. In patients without distant spread, vascular invasion by tumor is the most common reason for unresectability.

The most widely accepted staging system for pancreatic cancer is the Union Internationale Contre le Cancer (UICC) System, which is shown in Table 96-1. Since pancreatic cancer has usually spread to lymph nodes by the time the diagnosis is made, the majority of patients have at least stage III disease. Patients with stage IV disease (distant metastases) cannot be cured and are considered unresectable.

TNM CLASSIFICATION	CHARACTERISTICS
T1	Limited to the pancreas
T2	Direct extension to duodenum, bile duct, or peripancreatic tissues
T3	Direct extension to stomach, spleen, colon, adjacent large vessels
N0	Regional lymph nodes not involved
N1	Regional lymph nodes involved
M0	No distant metastasis
M1	Distant metastasis present
TNM STAGING SYSTEM	**CHARACTERISTICS**
Stage I	T1-2, N0, M0
Stage II	T3, N0, M0
Stage III	T1-3, N1, M0
Stage IV	T1-3, N0-1, M1

TNM, tumor nodes, metastasis.

TABLE 96-1 Staging of Carcinoma of the Pancreas

CLINICAL MANIFESTATIONS

The most common symptoms in patients with cancers in the head of the pancreas are jaundice and abdominal pain, usually with some degree of weight loss. In those with tumors of the pancreatic body, jaundice is unusual. Abdominal pain and back pain are common, and weight loss may be profound.

Pain

The cause of the pain associated with cancer in the head of the pancreas may be gallbladder and bile duct distension associated with biliary obstruction, pancreatic duct distension associated with pancreatic duct obstruction, and invasion of retroperitoneal or somatic nerves. Abdominal or back pain may occur. Abdominal pain is most commonly felt in the epigastrium (46%), but it also may be felt on either side or in the lower quadrants. Persistent severe back pain is likely to reflect unresectability, and is caused by tumor invasion of the retroperitoneal nerves.

Jaundice

Jaundice, accompanied by pain, is the presenting symptom in 80% to 90% of patients with cancer of the head of the pancreas. Painless jaundice is uncommon. Jaundice in the absence of any other symptoms is associated with a better prognosis, perhaps because the tumor is strategically located near the bile duct where, even at a small size, it has obstructed the duct early in its development.

Weight Loss

By the time the diagnosis is made, weight loss of more than 10% ideal body weight is common. There are several possible explanations for such weight loss. The pain associated with the tumor produces anorexia in almost all patients, so decreased food intake is the most common cause. Malabsorption also may occur, especially in patients with pancreatic duct obstruction in the head of the pancreas, as digestive enzyme output from the pancreas may be prevented from entering the duodenum. It is less likely in those with pancreatic duct obstruction from body tumors, since enzymes from the pancreatic head drain normally, and are enough to maintain normal fat and protein absorption. Finally, some workers hypothesize the existence of a humoral substance secreted by the tumor that increases catabolic activity, but it has yet to be characterized. [29]

Diabetes Mellitus

Diabetes sometimes appears as an early manifestation of pancreatic cancer, occurring many months before the tumor becomes evident. It has been postulated that the tumor may release a substance, as yet uncharacterized, that stimulates the secretion of islet amyloid polypeptide (IAPP) from the beta cells of the uninvolved islets. IAPP causes insulin resistance. In some patients with pancreatic cancer, diabetes, and elevated serum IAPP, the diabetes and high IAPP levels disappeared once the tumor was resected. [30] A case-controlled study showed no increase in the prevalence of long-standing diabetes mellitus among 116 patients with pancreatic cancer, 24% of whom had diabetes at the time of cancer diagnosis. [31] Thus, diabetes may be a consequence of cancer development rather than a risk factor for pancreatic cancer.

Other Clinical Features

Light-colored stools and dark urine are characteristic of obstructive jaundice. Other symptoms include pruritus, nausea, vomiting, and weakness. Vomiting may be caused by duodenal or gastric outlet obstruction caused by tumor invasion. In some cases, when there is no apparent obstruction, it may be caused by abnormal gastric motility for as yet obscure reasons. Less common findings include superficial thrombophlebitis and gastrointestinal bleeding. In advanced stages, gastrointestinal bleeding may occur from direct invasion of the tumor into the duodenum, stomach, or colon.

PHYSICAL FINDINGS

Physical examination may reveal hepatomegaly, a palpable abdominal mass, or ascites. In the past, a distended palpable gallbladder (Courvoisier sign) was thought to be pathognomonic for bile duct obstruction caused by a tumor. When gallstones caused the bile duct obstruction, gallbladder distention was thought to be less likely because chronic inflammation of the gallbladder wall caused scarring and contracture of the viscus. However, the gallbladder is palpable only in about one half of jaundiced patients with pancreatic cancer, so Courvoisier sign is of little practical diagnostic value. [32] In those patients with pruritus, persistent scratching produces excoriation and lichenification of the skin. Rarely, an abdominal bruit can be heard if the tumor compresses the aorta or splenic artery.

DIAGNOSTIC INVESTIGATIONS

Routine Clinical Tests

In patients with biliary obstruction, the total serum bilirubin and alkaline phosphatase concentrations are elevated. The total bilirubin level tends to be greater with malignant obstruction than obstruction from benign causes (>15 vs. 5 mg/dL). Serum amylase elevation is seen in only 5% of patients with pancreatic cancer.

Immunologic Tests: Tumor-Associated Antigens

A variety of tumor-associated antigens have been studied with the hope that one or more would be specific for pancreatic cancer, and sensitive enough to allow for early diagnosis when the tumor was still small and curable. The most sensitive (80%) and specific (90%) is CA 19-9, but it still falls short of the ideal since it is almost never positive with small tumors (<1 cm). CA 19-9 values also may be abnormal with other cancers (gastric, colorectal cancer) and with some benign conditions (cholangitis). Determination of serum CA 19-9 levels may be useful to provide some assurance that the tumor has been resected in its entirety, to signal the presence of recurrent disease after resection, and to determine the response to adjuvant therapy. [33], [34]

RATIONALE OF THE WORKUP IN PATIENTS WITH SUSPECTED PANCREATIC CANCER

There are two main goals of the diagnostic workup in patients who are thought to have a pancreatic malignancy. The first is to establish the diagnosis with a high degree of certainty. In patients who are candidates for surgery, this usually does not require histological proof of malignancy. The second is to decide whether the patient should undergo an operation in an effort to either resect or palliate the disease. A number of tests are available to help with these decisions, but it is rare that all of them are required in every patient. The clinician should strive to make the workup as cost- and time-efficient as possible, arriving at a treatment plan promptly. [35]

Noninvasive Techniques

Ultrasound (US) may be useful as a first-line investigation in patients with jaundice to distinguish between intrahepatic and extrahepatic causes. Extrahepatic obstruction from a pancreatic (or any periampullary) cancer would be expected to show dilated intrahepatic and extrahepatic biliary radicles (Fig. 96-1). The ducts are not dilated with obstruction at the intrahepatic level. US can also identify gallstones that may be the cause of obstruction. However, abdominal wall musculature, bony structure, and overlying bowel gas can obscure transabdominal visualization of the pancreas through a sonographic window. Although US provides some information about the relationship of the tumor to surrounding structures, computed tomography is much better in this regard. US is a relatively inexpensive test, with a sensitivity of 70% and a specificity of more than 90% for the diagnosis of pancreatic cancer. [36] In up to 25% of patients, however, the examination is unsatisfactory owing to body habitus or overlying bowel gas.

FIGURE 96-1. Transcutaneous ultrasound in a patient with common bile duct obstructed by a tumor in the head of the pancreas. The intra- and extrahepatic bile ducts

are dilated.

Currently, helical computed tomography (CT) is the best overall study for diagnosis, as well as the preoperative staging of pancreatic cancer. It provides information about the nature and site of the lesion (e.g., pancreatic vs. other periampullary tumors, hilar bile duct tumors), its resectability (e.g., presence of hepatic metastases, vascular invasion), and vascular anatomy. It is important to stress that the helical CT is the state-of-the-art procedure. When the helical CT is compared with the conventional technique, and especially when imaging of both the pancreas and liver is done separately according to published protocols, the differences in the sensitivity and specificity of the two approaches is dramatic. [37] The primary lesion itself, as well as liver metastases, may be evident with the helical CT, and these may not be seen with the standard scan (Fig. 96-2). Extraordinary detail is provided about vascular anatomy and vascular invasion by tumor (Fig. 96-3). If an experienced radiologist indicates that the tumor is unequivocally “unresectable” because of major vascular invasion, this is about 98% reliable. If the tumor is judged to be “resectable” on the basis of helical CT, this prediction is accurate in about 80% of cases. [35], [38]

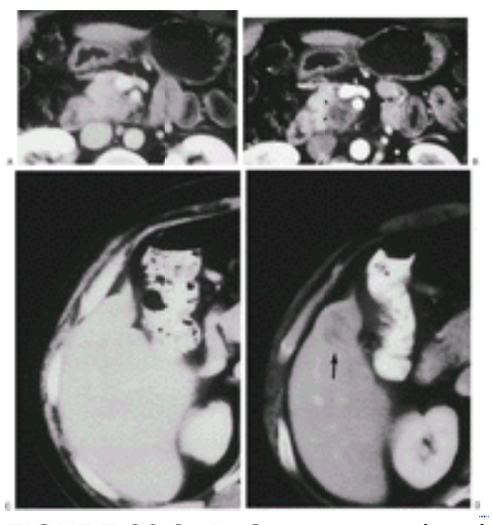

FIGURE 96-2. A: On a conventional computed tomography (CT) scan, the primary tumor in the uncinate process of the pancreas is not seen. **B:** The helical (spiral) CT scan performed 4 days later reveals the tumor (*arrowheads*). **C:** On a conventional CT scan, no liver metastases are seen. **D:** The helical CT performed 11 days later reveals an obvious metastatic lesion (*arrow*). (Courtesy of David Lu, M.D., UCLA Department of Radiology, Los Angeles.)

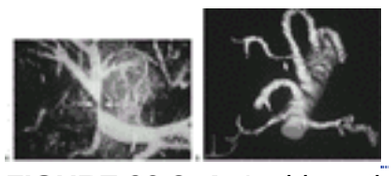

FIGURE 96-3. A: In this patient with unresectable pancreatic cancer, the helical computed tomography (CT) scan shows that the tumor has compressed the portal vein (*arrows*). **B:** In another similar patient, the tumor is compressing the hepatic artery at its origin from the celiac axis (*arrow*), which indicates that the tumor is unresectable. In this case, computer reconstruction of the CT images was performed to demonstrate the detailed anatomy of the aorta and its branches. (Courtesy of David Lu, M.D., UCLA Department of Radiology, Los Angeles.)

CT scan is able to detect tumors about 2 cm or greater in diameter, which appear as lucent areas, because they are less well perfused with blood than the adjacent pancreatic tissue. The technique has a false-positive rate of less than 10%, which is usually caused by focal pancreatitis, or variations in normal pancreatic anatomy that are mistaken for tumor.

Magnetic resonance imaging (MRI) may provide slightly better pancreatic tissue contrast than CT, but spatial resolution is inferior. It was hoped that MRI would be superior to CT in outlining the blood vessels, but such an advantage has not been demonstrated. This may change as better contrast agents are developed. In a recent study, MRI was shown to predict resectability with an accuracy of 77%. [39]

Endoscopic retrograde cholangiopancreatography (ERCP) has a sensitivity of 95% and a specificity of 85% for the diagnosis of pancreatic cancer. [40] The procedure can be performed successfully in over 90% of patients and it detects some tumors not seen on CT. The classic finding that suggests pancreatic cancer is obstruction of both the bile and pancreatic ducts in the head of the pancreas, the so-called double-duct sign (Fig. 96-4). In tumors of the body or tail of the pancreas, only the pancreatic duct is abnormal (Fig. 96-5). At the time of ERCP, brushings for cytology may be obtained from the pancreatic duct, which has a sensitivity of about 60% in proving the diagnosis of malignancy. Some have argued that ERCP should be done routinely in these patients, since it may be possible to determine the origin of the tumor (e.g., ampulla of Vater instead of the pancreas). Although this may be true in some cases, it usually does not affect subsequent management since the operation that is required is the same for all of the periampullary malignancies. At the time that the ERCP is done, a stent also can be placed into the obstructed common bile duct, which has an important role in the palliation of patients who do not require surgery. Stents, however, should not be used routinely for preoperative decompression (see section “ Nonsurgical Palliation of Biliary and Duodenal Obstruction ”).

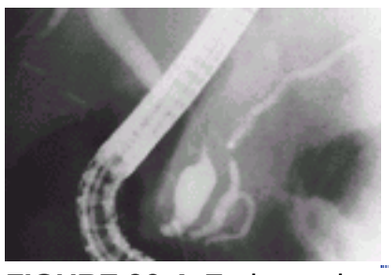

FIGURE 96-4. Endoscopic retrograde cholangiopancreatography (ERCP) of a patient with cancer of the head of the pancreas shows that both the pancreatic and bile ducts are compressed by the tumor. This produces the “double-duct sign.”

FIGURE 96-5. In this patient with cancer of the body of the pancreas, the duct is compressed in the body of the gland, and the obstructed ductal segment proximal to that point is dilated.

In spite of its value, ERCP is not required in all patients with pancreatic cancer. If a patient has a history typical for pancreatic cancer (e.g., pain, jaundice, weight loss) with a mass in the head of the pancreas evident on CT scan, then an ERCP is unnecessary for the diagnosis. An ERCP at this point generally adds nothing to the workup that is of value to either the patient or the surgeon. If the CT scan does not show a mass or raises questions about the diagnosis, ERCP should be done. If ERCP is done first, however, all patients still require a CT scan.

Endoscopic ultrasound (EUS) is not likely to be used as a first-line diagnostic study in most patients with pancreatic cancer. Once the diagnosis is suspected, however, it can provide valuable information that can aid in tumor staging and determination of resectability. With surgical pathology as the gold standard, recent studies have shown that EUS accuracy in tumor staging and estimation of lymph node involvement ranges from 69% to 85% and 54% to 75%, respectively. [39], [41], [42] Lymph nodes infiltrated by carcinoma usually appear as round, hypoechoic masses more than 1 cm in diameter. EUS can provide information about whether the tumor invades the portal, splenic, or superior mesenteric veins, the celiac axis, or superior mesenteric arteries. Common EUS criteria for vascular involvement include abnormal vessel contour, loss of vessel-parenchymal interface, tumor visible within the vessel lumen, and the presence of dilated peripancreatic venous collaterals. [43] When results are compared to surgical findings, EUS accuracy ranges from 69% to 93%, [42], [43], [44] and [45] and its ability to predict tumor resectability ranges from 72% to 93%. [42], [45]

EUS can detect tumors smaller than those currently detectable by CT scanning techniques (<2.0 cm diameter), with sensitivity and specificity for tumor detection as high as 99% and 100%, respectively. [43] The technique also permits accurate placement of biopsy needles (e.g., EUS-guided fine-needle aspiration [FNA] cytology) into a pancreatic mass when there is need to establish the diagnosis (Fig. 96-6). EUS-FNA has also been used to sample nearby lymph nodes to aid in local staging, with a low complication rate of 1% to 2%. [43]

FIGURE 96-6. Endoscopic ultrasound and fine-needle aspiration (FNA) of a 1.5-cm localized hypoechoic mass in the head of the pancreas. The FNA needle is seen in the top right hand corner (*solid arrow*). A biliary stent is seen in the center of this mass, which was not visualized on helical computed tomography scan of the pancreas. Cytologic analysis of the FNA revealed adenocarcinoma. (Courtesy of James J. Farrell, M.D., UCLA Department of Medicine, Division of Digestive Diseases, Los Angeles.)

The eventual role of EUS in the workup of these patients continues to evolve. Limitations of EUS and its applications include the considerable expertise required to perform it (still not widely available), interobserver variability in scan interpretation, inability to examine distant organs for metastasis, and a difficulty in distinguishing focal pancreatitis from a pancreatic mass. For the patient who presents with symptoms and signs suggestive of pancreatic carcinoma (jaundice, abdominal discomfort, weight loss), helical CT scan remains the best initial study for establishing the diagnosis, evaluating extent of disease, and determining resectability, making EUS unnecessary. In a patient with a negative CT scan but a history that suggests pancreatic cancer, EUS is a useful adjunctive examination given its increased sensitivity for detecting small tumors. Likewise, EUS may be useful to estimate resectability of the tumor if the CT scan does not resolve that issue, and to obtain tumor tissue to confirm the diagnosis if that seems appropriate.

Invasive Techniques

Percutaneous transhepatic cholangiography (PTC) is useful in patients with proximal bile duct obstruction (e.g., from a tumor at the hepatic duct bifurcation) to delineate the bile duct anatomy on the hepatic side of the obstruction. The intrahepatic ducts are opacified, which defines the degree of their involvement, an important determinant of resectability. In patients with periampullary tumors, ERCP is preferred to PTC if the bile duct anatomy needs to be defined.

Preoperative fine-needle aspiration (FNA) for cytology can be obtained percutaneously using a fine-gauge needle under CT or US (or EUS) guidance. Characteristic signs of malignancy are single or irregularly arranged clusters of cells exhibiting pleomorphism, large vesicular nuclei, and prominent nucleoli (Fig. 96-7). Complications include hemorrhage, pancreatitis, pancreatic fistula, and seeding of the needle tract with cancer cells, all of which are uncommon. FNA should not be done routinely in the workup of patients with suspected pancreatic cancer. It is uncomfortable for the patient, it is associated with considerable cost, and in patients who are operative candidates, it does not change management. FNA is indicated in situations where the cytologic proof of malignancy will alter management. For example, in a patient with an unresectable tumor in the body of the pancreas who has no symptoms for which surgical palliation is required, FNA could confirm the diagnosis, and chemotherapy, radiation, or both could be given. In a patient with obstructive jaundice and a mass in the head of the pancreas, who may not be a candidate for resection because of coexisting medical problems, FNA would be useful to confirm the diagnosis. Then, a stent could be placed to palliate the jaundice, and surgery, simply to obtain tissue for diagnosis, would have been avoided. *It is important to stress that a negative FNA never rules out the possibility of malignancy.*

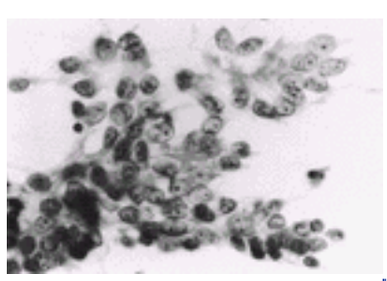

FIGURE 96-7. Fine-needle aspiration of a mass in the body of the pancreas shows cells characteristic of ductal adenocarcinoma of the pancreas. The tumor invaded the retroperitoneal structures and was unresectable.

The argument that preoperative knowledge of the diagnosis of cancer simplifies or speeds up the operation may be valid if the surgeon is inexperienced. However, most pancreatic surgeons do not require histological proof of malignancy before proceeding with resection. Resection is performed on the basis of the patient's history, the information from preoperative tests, and the gross findings at operation. Of course, this issue must always be discussed preoperatively with the patient. With this approach, experienced surgeons err less than 10% of the time (i.e., a resection is performed for what turns out to be benign disease). This is acceptable since the mortality rate of resection is quite low (1%–2%), and the majority of patients who undergo resection for benign disease have chronic pancreatitis for which resection is also appropriate.

Angiography, which was performed more commonly in the past, is unnecessary. Helical CT scans provide similar information about the presence of vascular anomalies, as well as displacement or constriction of major peripancreatic vessels (e.g., celiac or hepatic arteries, portal or superior mesenteric veins), which suggests unresectability.

Chronic Pancreatitis

Chronic pancreatitis is an independent risk factor for pancreatic cancer (see previous discussion), and the two diseases may share clinical (pain, weight loss, endocrine/exocrine dysfunction) and imaging characteristics (ductal abnormalities, mass, or cystic lesions). [46], [47], [48], [49] and [50] Because pancreatic cancers usually cause some degree of pancreatic duct obstruction, most patients with pancreatic cancer also have areas of chronic pancreatitis adjacent to the tumor. And pancreatic cancers themselves grow in a desmoplastic fashion that grossly may be indistinguishable from chronic pancreatitis without associated malignancy. Because there is no serologic or imaging study that can reliably distinguish chronic pancreatitis from pancreatic carcinoma, and a previous diagnosis of chronic pancreatitis can delay treatment of resectable pancreatic carcinoma, [46], [47] the clinician must maintain a high index of suspicion in patients known to have the benign disease. For example, any patient with a previously established diagnosis of chronic pancreatitis who experiences a significant alteration in symptomatology—accelerated weight loss or increasing pain—should be evaluated thoroughly for the presence of malignant disease.

TREATMENT

Surgery

Preoperative Management As in all patients about to undergo major surgery, it is important to optimize cardiac, pulmonary, and renal function preoperatively. This usually can be done in the outpatient setting. Although these patients have often lost weight, most are still adequately nourished to safely undergo the operation. However, if the serum albumin is less than 3 g/dL, or if surgery must be delayed for more than several weeks after the diagnosis is established, supplemental nutrition is often appropriate. Pancreatic enzyme replacement may also help. Nutrition can usually be provided enterally, but occasionally, such as with gastric outlet obstruction, parenteral alimentation is indicated. Because obstructive jaundice can cause defects in hepatic, renal, and immune function, it was hoped that preoperative relief of the jaundice would correct these defects, and decrease postoperative morbidity and mortality rates. Unfortunately, several randomized controlled studies have proven that routine preoperative bile duct stenting does not help. [51], [52], [53] and [54] However, if operation must be delayed several weeks or more, for any reason, or if cholangitis occurs, a plastic biliary stent (at least 10 French, if possible) should be placed endoscopically in jaundiced patients. *Metal Wallstents* (Boston Scientific, Boston) *should never be placed in patients who are candidates for resection.* These stents incite a severe inflammatory reaction and eventually may be incorporated into the bile duct wall. This can complicate or even prevent the resection.
Operative Management: Resection The first successful resection for a periampullary cancer was performed as a two-stage operation by the German surgeon Kausch in 1909. In 1935, Whipple performed a similar procedure for an ampullary carcinoma, which he had perfected to a one-stage resection by 1942. That operation has been called a pancreaticoduodenectomy, or Whipple resection, and it is similar to the one performed today (Fig. 96-8). It involves a partial gastrectomy (antrectomy), cholecystectomy, and removal of the distal common bile duct, head of the pancreas, duodenum, proximal jejunum, and regional lymph nodes. Reconstruction requires a pancreaticojejunostomy, hepaticojejunostomy, and a gastrojejunostomy. In the hands of experienced pancreatic surgeons around the world, the operative mortality rate of this procedure is now 2% or less.

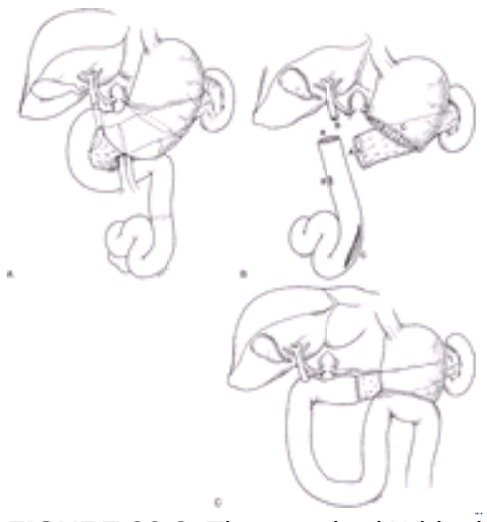

FIGURE 96-8. The standard Whipple pancreaticoduodenectomy. **A:** *Dashed lines* indicate the resection margins in the typical operation for a tumor in the head of the pancreas. **B:** The specimen has been resected. *A, B,* and *C* represent the sites for subsequent anastomoses between the bowel and the pancreas, bile duct, and stomach. **C:** The completed anastomoses are shown.

Resectable tumors in the body or tail of the pancreas require a distal pancreatectomy and splenectomy. The head of the pancreas, gallbladder, bile duct, stomach, and duodenum can usually be preserved since the tumor and its lymphatic drainage do not involve these structures. Mortality and morbidity rates are lower than after a Whipple resection.

Modifications of the Pancreaticoduodenectomy

Pylorus Preserving Whipple Resection Because of concern that the standard Whipple resection was associated with excessive weight loss and nutritional disturbances, many surgeons adopted this modification in which the stomach, pylorus, and first 3 to 4 cm of duodenum are preserved (Fig. 96-9). This maintains gastric reservoir function, and postoperative gastric emptying is closer to normal. The operation was first described in 1944, but it did not become popular until the 1970s when it was described for patients with chronic pancreatitis; later it became popular for pancreatic cancer as well. [55], [56] This less extensive procedure does not appear to compromise the chance for cure of the cancer. However, the few studies that compared it with the standard Whipple in regard to the amount of weight loss, various nutritional parameters, and overall quality of life associated with each operation, yielded conflicting results. Many surgeons perform the two procedures interchangeably, often reserving the standard Whipple for patients with larger, more extensive tumors.

FIGURE 96-9. The pylorus preserving modification of the standard Whipple pancreaticoduodenectomy is shown. The entire stomach, the pylorus, and several

centimeters of duodenum are retained.

Radical (Extended) Whipple Resection Some Japanese surgeons have advocated the use of a more radical pancreatic resection to improve cure rates. [57] The standard Whipple is modified by removal of more peripancreatic soft tissue and lymph nodes, often with resection of segments of the superior mesenteric and portal veins, when they appear to be involved by tumor. Although some of these studies have reported improved survival, there have been no properly designed, prospective trials that compare this operation with the standard resection. Most surgeons in the United States are skeptical that the radical operation cures more patients, and it is rarely done in this country.

Determination of Resectability at the Time of Operation

Although the majority of patients who undergo resection for pancreatic cancer are not cured by the operation, it is performed only in circumstances where cure appears to be possible. Thus, resection is not done in the presence of liver or peritoneal metastases, or metastases to lymph nodes, which are not normally removed as part of the Whipple operation. The operation is begun by carefully examining the peritoneal cavity and its contents, and by obtaining biopsies of any areas suspicious for metastasis. Frozen-section diagnoses are usually available within 20 minutes, and a preliminary decision can be made about resectability. In the absence of distant metastases, resectability usually depends on whether the tumor has invaded any major blood vessels. Assessment of vascular involvement requires mobilization of the tumor from surrounding structures, which is done next. Involvement of the superior mesenteric, celiac, or hepatic arteries precludes resection. In most cases, so too does invasion of the superior mesenteric or portal vein. If the vessels appear to be free of tumor, the resection proceeds.

It is unusual for vascular involvement to be found at the time of operation if it was not already suspected on the basis of helical CT scan or EUS done preoperatively. It is more common (10%–15% of cases) to find small hepatic or peritoneal metastases, which were not evident from the preoperative studies. For this reason, some surgeons prefer to begin the operation with laparoscopy, which permits examination of the liver and peritoneal surfaces, and biopsy of any suspicious areas. If metastatic tumor is found, laparotomy may be avoided, unless gastric and biliary bypasses are required for palliation. Even these may be done laparoscopically, in some cases. The major drawbacks of laparoscopy are the additional time and expense required for the procedure and the inability to determine the presence of vascular invasion. The latter requires more extensive dissection and is aided by the tactile senses available only during laparotomy.

Laparoscopy is indicated whenever there is a high likelihood of unresectability that has not been confirmed preoperatively. Examples include some patients with pancreatic cancer and CT evidence of liver or other metastases, which have not been proven with FNA; patients with pancreatic body or tail cancers, all of whom have a very low chance of having a resectable lesion; and patients with pancreatic cancer and ascites, which is probably caused by unrecognized peritoneal metastases.

A number of other factors have been discussed in relation to their influence on resectability. Advanced age is not a contraindication. Each patient must be assessed individually and an evaluation made of the associated risks caused by coexistent cardiovascular, pulmonary, and renal disease. Many patients who undergo Whipple resection are octogenarians; some patients under age 65 may be unacceptable operative risks. Large tumor size is also not a contraindication to resection. Although small pancreatic tumors (<2 cm diameter) are more likely to be resectable than larger ones, no patient should be denied the opportunity for cure because the tumor is “too large.” Indeed, in several major centers in the United States, most of the Whipple resections for cancers in the head of the gland are done for tumors between 3 to 5 cm in diameter. [58]

Experienced pancreatic surgeons usually proceed with pancreaticoduodenectomy without a biopsy of the primary tumor to confirm the diagnosis of malignancy. Indeed, if the history and clinical picture, the preoperative tests, and the operative findings are all consistent with the diagnosis, then the chance that cancer is present is over 90%. In those cases where cancer is not the cause of the symptoms, the most likely diagnosis is chronic pancreatitis, for which pancreaticoduodenectomy is also appropriate. In part, this approach has evolved because it may be difficult to establish the diagnosis of pancreatic cancer on frozen-section biopsy material, and to distinguish it from the surrounding zone of chronic pancreatitis. This is especially true when the cancer is small and most likely to be cured by resection.

SURGICAL PALLIATION

During exploration, when resection of the primary tumor is not possible, the surgeon must decide whether any palliative procedures should be done. Because most patients with cancer in the head of the pancreas are jaundiced at the time of operation, a bypass to relieve the biliary obstruction is the most common procedure. An anastomosis between the gallbladder and jejunum (cholecystojejunostomy) or common bile duct and jejunum (choledochojejunostomy) are both effective bypass techniques [32] (Fig. 96-10). Jaundice is relieved in about 90% of patients. In about 10% of patients however the bilirubin does not return to normal because of impaired hepatic function. This may be caused by long-standing obstruction or extensive hepatic metastases. [32] If the gallbladder is used for decompression, the surgeon should be certain that the cystic duct enters the common bile duct distant from the tumor. If the junction of the cystic and common ducts is close to the tumor, the former may become obstructed as the cancer grows. Then the cholecystojejunostomy cannot function and the jaundice will recur. In patients who have had a biliary stent placed preoperatively, the stent should be removed and a cholecystojejunostomy should be done, if it is technically possible. This eliminates the need for stent changes during the remaining months of the patient’s life. If it is not possible, a choledochojejunostomy should only be done if the common duct is still dilated (e.g., >1 cm diameter), which makes the operation easier. Otherwise, the stent, which also provides effective palliation, can be left in place, and a surgical biliary bypass is not done.

FIGURE 96-10. A: Choledochojejunostomy. **B:** Cholecystojejunostomy. Each of these operations effectively relieves biliary obstruction by diverting the bile into the small intestine proximal to the tumor.

At the time of the initial exploration, it is unusual that patients have duodenal obstruction from the tumor, but 15% to 20% develop it sometime before they die. Thus, most surgeons perform a prophylactic gastrojejunostomy at the same time that a biliary bypass is done (Fig. 96-11). This is not associated with increased morbidity or mortality rates. [59] Occasionally, patients complain of vomiting preoperatively, and no objective evidence can be found for duodenal obstruction. In these patients, a gastrojejunostomy usually does not relieve the symptom, and the patient may still be unable to eat. The problem is probably caused by abnormal gastric motility, perhaps because of tumor infiltration of the nerve plexus. Although prokinetic agents may help, the symptom is often refractory to all forms of treatment.

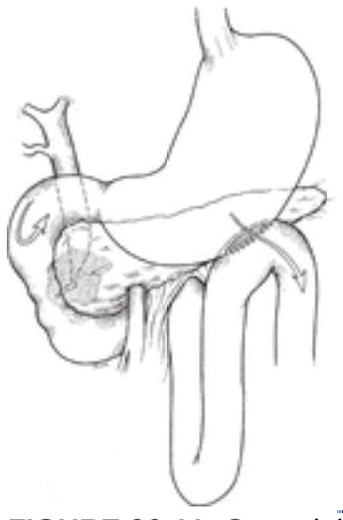

FIGURE 96-11. Gastrojejunostomy. The stomach can now empty into the small intestine directly when the tumor obstructs the duodenum.

NONSURGICAL PALLIATION OF BILIARY AND DUODENAL OBSTRUCTION

The development of techniques for endoscopic stenting of biliary obstruction represents a major advance in management, which allows many individuals with unresectable pancreatic cancer to avoid operation altogether. The advantages and problems associated with both surgical and endoscopic approaches have been defined in several prospective studies that compared the two. [60], [61], [62] and [63] In general, operative biliary bypass is more expensive, because of charges associated with the surgical procedure itself, and the hospitalization required for recovery. However, surgical bypass is more likely to provide permanent relief of the jaundice than are the endoscopically placed stents. The initial charges associated with endoscopic stenting are lower, but stents often become obstructed by bile pigment after 3 to 4 months and require replacement at intervals. Thus, the cumulative charges may exceed those of surgery, and there is added morbidity and inconvenience associated with recurrent jaundice and cholangitis, and multiple endoscopic procedures. Both approaches are equally effective, and have similar morbidity and mortality rates. As advances in both fields continue however, the advantages of each must be reassessed. For example, the metallic Wallstents developed are larger than the 10- to 12-French plastic stents in common use, and they are less likely to become obstructed. Laparoscopic techniques for both biliary bypass and gastrojejunostomy may decrease the cost and discomfort of the surgical approach, and permit more rapid hospital discharge. [64], [65] Duodenal obstruction is still usually treated surgically, but preliminary experience with duodenal stents suggests that this may be an option in selected patients. [66], [67] and [68]

MALABSORPTION

Some patients with unresectable pancreatic cancer experience fat malabsorption because the tumor obstructs the pancreatic duct, and insufficient amounts of pancreatic enzymes enter the duodenum. The result is diarrhea and steatorrhea, which interfere with the ability to gain weight and the quality of life. About 25% of patients who undergo pancreaticoduodenectomy also may suffer from malabsorption, which requires treatment. This is probably the result of poor mixing of the gastric chyme with the pancreatic enzymes that enter the gut at some distance from the gastrojejunostomy. Impaired stimulation of pancreatic secretion may also play a role.

Although fat absorption itself cannot be restored to normal, the goal should be to stop the diarrhea, restore adequate nutrition, and maintain body weight. The principles of treatment require that about 30,000 to 40,000 U of lipase be supplied with each of four to five meals spread throughout the day. A total of 100 g fat/day divided, equally among the meals, is usually tolerated. Patients who have undergone pancreatic resection almost always respond well to treatment; those with unresected cancer often do not. This is probably because of other poorly understood effects of the tumor for which medical management is still unsatisfactory.

PAIN

Conventional treatment of the pain associated with pancreatic cancer includes both opioid and nonopioid analgesics as well as nonsteroidal antiinflammatory drugs, tricyclic antidepressants, and antineoplastic agents. [69] However, pain from advanced pancreatic cancer is often difficult to control, and narcotics may be ineffective in providing relief. If this occurs, visceral pain may be managed by celiac plexus block, either at the time of exploratory surgery or later by a percutaneous approach. Pain is relieved in up to 90% of patients, and significant complications are uncommon. [70] Thoracoscopic pancreatic denervation for pain control in unresectable pancreatic cancer has also been reported. The morbidity was low with this minimally invasive approach. [71] For relief of somatic pain, an intercostal nerve block may be beneficial. [72]

ADJUVANT THERAPY

5-Fluorouracil (5-FU), combined with supervoltage radiation, confers a modest prolongation of survival in patients with locally advanced pancreatic cancer. This was demonstrated in 1969 in a study in which unresected patients receiving radiation alone had a median survival of 6.3 months, compared to 10.4 months for patients who received 5-FU plus radiation. The Gastrointestinal Tumor Study Group (GITSG) confirmed these observations in 1981. The median survival of patients receiving radiation alone was 4.5 months; in those who received both 5-FU and radiation, it was about 10 months. The GITSG also demonstrated a survival advantage (10.9 vs. 21 months) for patients who were treated with this same combination following curative resection of pancreatic cancer. [73] The treatment regimen was a split course of 40 Gy, with a 2-week separation between each 20 Gy segment. [74] 5-FU, 500 mg/m ^{2} of body surface area, was given as a bolus dose daily for the first 3 days of each radiation cycle and weekly thereafter for 2 years. [74] While more recent European studies (European Organization for Research and Treatment of Cancer [EORTC], European Study Group for Pancreatic Cancer [ESPAC]) confirmed the value of chemotherapy, they cast doubt on the value of radiation. [75], [76]

Gemcitabine is being used increasingly in the management of pancreatic cancer. [77], [78] In several studies, where it was used as a single agent, it appeared to slightly increase survival in a small fraction of those treated, when compared to 5-FU alone. However, in about 25% of patients it reduced pain, increased weight, and improved the overall quality of life. The mechanism of action was unclear. [79]

PROGNOSIS

Surgical resection provides the only chance for cure, but the median survival after resection is only 18 to 20 months, and the overall 5-year survival is 15%. However, if the tumor is removed with clear surgical margins and no lymph node metastases are found, the 5-year survival may be as high as 25% to 30%.

Various prognostic indicators for survival after resection for pancreatic cancer have been evaluated. One of the strongest factors is negative lymph node status. In one center, a median survival of more than 4.5 years was seen in patients with negative nodes versus 11 months for patients with positive nodes. Unfortunately, even small tumors have metastasized to nodes in 75% to 80% of resected cases. Poorly differentiated tumors are associated with a worse prognosis than well-differentiated ones (10% vs. 50% 5-year survival). Patients with smaller tumors (<2.5 cm in diameter) tend to have a better prognosis than patients with larger tumors. Another important prognostic factor is whether the resection margins of the resection specimen are involved with tumor. For this reason, the pancreatic and bile duct margins are routinely evaluated during the operation. If tumor is present, more tissue is resected if possible, until negative margins are obtained.

Operative mortality rates for the Whipple resection are now 2%, or less, in major centers around the world. There is increasing evidence that the best outcomes (operative mortality rates and long-term survival figures) and lowest treatment costs in patients with pancreatic cancer are achieved at institutions with the most experience (>20 Whipple resections a year). This appears to be related not only to the surgical expertise, but to that of the numerous other ancillary services (e.g., nursing, radiology, gastrointestinal endoscopy) that all gain experience in the management of large numbers of these difficult-to-treat patients.

LESS COMMON EXOCRINE PANCREATIC TUMORS

Mucinous Cystadenoma and Cystadenocarcinoma

Mucinous cystic neoplasms are large (often >5 cm), bulky, uni- lobular, or multilobulated cysts containing mucin (Fig. 96-12). The cysts are lined with mucinous columnar epithelium that forms papillary projections, which may contain foci of dysplastic cells or invasive carcinoma. Radiographic studies reveal calcification within the cysts in about 10% of cases; calcification almost never occurs in pseudocysts. Because mucinous cystadenomas are premalignant, they should be resected. When the tumors occur in the body or tail of the pancreas, the appropriate treatment is distal pancreatectomy. When they occur in the head of the pancreas, a Whipple resection is required. These neoplasms comprise 1% to 2% of exocrine tumors and are more common in women (female-to-male ratio 6:1). The peak age of occurrence is 40 to 60 years. [80] They appear to have a better prognosis than ductal pancreatic cancers; the 5-year survival after a curative resection of a mucinous cystadenocarcinoma is at least 50%.

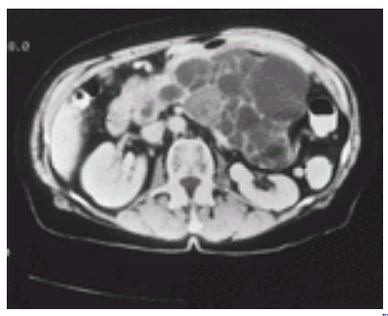

FIGURE 96-12. Computed tomography (CT) scan of a patient with a malignant mucinous cystic neoplasm, which was resected. Note the large cystic structure with internal septations creating multiple large cysts.

Serous Cystadenoma and Cystadenocarcinoma

These lesions are typically large, well-demarcated, multiloculated cystic tumors filled with watery fluid. They usually have a characteristic honeycomb appearance, and the individual cysts are 1 cm or less in diameter, which is smaller than the individual cysts in mucinous cystic neoplasms (Fig. 96-13). They account for about 1% of neoplastic pancreatic lesions and usually occur in older adult women in the sixth and seventh decades of life. These so-called microcystic adenomas are usually asymptomatic and are found incidentally when a US or CT scan is done for some other reason. One third of the tumors occur in the head of the pancreas. [81], [82] and [83] Although malignant transformation of serous lesions is uncommon, it does occur. These tumors also should be removed if removal can be done safely. These neoplasms, as well as the mucinous cystic tumors previously discussed, should not be confused with pseudocysts, where internal or external drainage procedures are acceptable forms of treatment.

FIGURE 96-13. Computed tomography (CT) scans of patients with benign serous cystadenomas, both of which were resected with a distal pancreatectomy. **A:** This large lesion suggests the honeycombed appearance of this tumor, which typically contains many very small cystic structures. It is to be contrasted with the large cysts seen in Figure 96-12. **B:** This smaller lesion demonstrates the central calcification, which is sometimes seen.

Solid and Papillary Epithelial Neoplasm

Solid and papillary epithelial neoplasms appear to be increasing in frequency. They are most common in adolescent girls and young women, and have a characteristic appearance on CT scan (Fig. 96-14). The tumors are often large and may produce vague abdominal discomfort, which leads to their discovery. They have a favorable prognosis, and most patients are cured by resection. Nevertheless, some of these tumors may recur locally and there is one report of liver metastasis. The majority of these tumors occur in the body or tail of the pancreas, where they are treated with distal pancreatectomy. When they occur in the head, pancreaticoduodenectomy is required.

FIGURE 96-14. Computed tomography (CT) scan of a solid and papillary neoplasm in a 21-year-old woman who underwent a Whipple resection. The tumor was removed completely.

Intraductal Papillary Mucinous Tumors (IPMT, Mucinous Ductal Ectasia)

Patients with IPMT often present with repeated episodes of inflammation from underlying chronic pancreatitis. In fact, these patients are likely to present with abdominal pain as the principal complaint. The pancreatitis is caused by obstruction of the pancreatic duct by intraductal tumor growth and inspissated mucus, which these tumors secrete (Fig. 96-15). CT scans reveal a dilated pancreatic duct. ERCP confirms the ductal dilation and often shows intraductal mucus, which appears as filling defects. A glob of mucus emanating from the gaping orifice of the ampulla of Vater is characteristically seen at the time of ERCP (Fig. 96-16). Approximately half the lesions show papillary malignant changes, but even these tumors have a better prognosis than usual ductal adenocarcinoma. Treatment is required both to remove any premalignant or malignant disease that may be present and also to relieve the episodes of pancreatitis. This may require total pancreatectomy because the entire pancreatic duct may be affected.

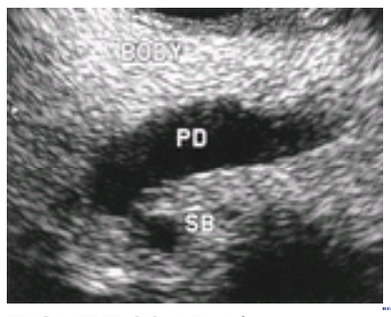

FIGURE 96-15. Linear array endoscopic ultrasound image of the pancreatic body showing dilated main pancreatic duct (PD) and dilated pancreatic ductal side branch (SB). Surgical resection confirmed main duct and side branch intraductal papillary mucinous tumor. (Courtesy of James J. Farrell, M.D., UCLA Department of Medicine, Division of Digestive Diseases, Los Angeles.)

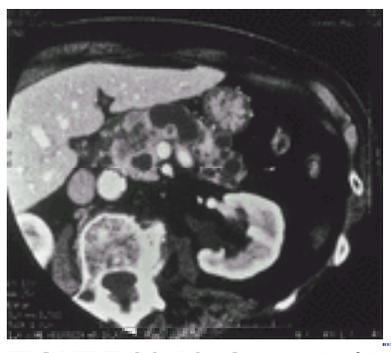

FIGURE 96-16. Computed tomography (CT) scan of a patient with mucinous ductal ectasia of the pancreas. In addition to multiple cystic lesions throughout the gland, there is a hypodense mass in the head of the pancreas consistent with a malignant neoplasm. The patient was 89 years old. Because a total pancreatectomy would have been required, surgery was not performed in this woman, who had multiple medical problems.

A recent review of a single center's experience with 60 resected IPMTs revealed that these tumors are being recognized more frequently. [84] In this series, 37% of the resected IPMTs were associated with an adjacent invasive adenocarcinoma, and the 5-year survival for those patients undergoing IPMT resection was 57%. [84]

Giant Cell Tumors

These rare tumors are characterized by the presence of bizarre giant cells and sarcomatoid cells supported by minimal fibrous tissue. Giant cell tumors have a poor prognosis, even worse than common ductal adenocarcinoma.

Acinar Cell Tumor

Acinar cell carcinomas are uncommon and characterized by acinar arrangement of cells supported by minimal fibrous stoma. Zymogen granules are present, which may be identified by electron microscopy. Patients may have elevated serum lipase levels and associated nonsuppurative panniculitis of the extremities and bone marrow and manifest subcutaneous nodules and poly- arthritis. These tumors usually occur in adults in their sixth to eighth decades of life.

CHAPTER 97

Robert T. Jensen

ENDOCRINE NEOPLASMS OF THE PANCREAS

Endocrine tumors of the pancreas are classified according to the type of clinical syndrome present (Table 97-1). In general they share a number of common features including various aspects of pathology, natural history, considerations in treatment, localization studies, and treatment of metastatic tumors. In each case, except for nonfunctioning pancreatic endocrine tumors (PETs), the principal clinical manifestations of the endocrine tumor are due to the extensive release of hormones by the tumor into the circulation. Each of the various hormones released in the different syndromes occur naturally and are important in mediating various physiological processes (see Chapter 4). However, in the PET syndromes these hormones are not under normal physiological regulation and are released autonomously by the tumor. PETs are classified as either functional or nonfunctional (see Table 97-1) depending on whether a clinical syndrome due to an ectopically released hormone is present (i.e., gastrinoma, insulinoma, VIPoma, glucagonoma, somatostatinoma, GRFoma, ACTHoma, PETs causing carcinoid syndrome, or hypercalcemia). Nonfunctional PETs frequently ectopically release hormones and peptides (pancreatic polypeptide [PP], chromogranin, neurotensin, neuron-specific enolase); however, these cause no distinct clinical syndromes. [1], [2], [3] and [4] The term *nonfunctional PET* is commonly used and will be retained here to mean any PET not secreting products that cause a distinct syndrome even though some actually release peptides and are, strictly speaking, functioning. The term *pancreatic endocrine tumor (PET)* is also retained in this chapter to indicate the tumors listed in Table 97-1, even though it is also a misnomer in that a number of these tumors also occur outside the pancreas (i.e., gastrinomas, VIPomas, somatostatinomas, GRFomas, ACTHomas [see Table 97-1]). These tumors are also frequently called islet cell tumors; however it is unproven that they originate from pancreatic islets. [5], [6] It is important to realize that even though these tumors are usually slow growing in many cases, some are aggressive, [2], [7], [8] and [9] therefore, effective therapy will require treatment of both the autonomous hormone overproduction as well as treatment directed at the tumor itself. In this chapter the common features of these tumors will be dealt with together and the distinctive features separately. Gastrinoma was discussed in Chapter 67 and will, in general, not be discussed here.

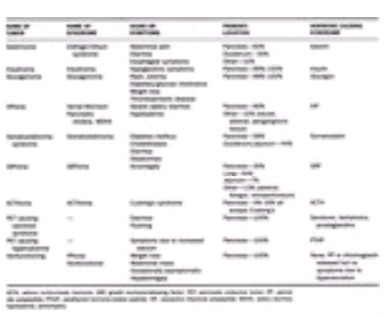

TABLE 97-1 Endocrine Tumors of the Pancreas

EPIDEMIOLOGY

In general, PETs are uncommon, having a prevalence of less than 10 per million population. [2], [10], [11] In some older series insulinomas were reported to be the most common PET with an incidence in various series of 0.8 to 0.9 per million population per year, whereas gastrinomas were reported to occur in 0.1 to 0.4 per million per year. [12] However, in more recent studies [10], [12] gastrinomas were as common as insulinomas (1–3 new cases/year/million population). The remaining symptomatic PETs each occur in less than 0.5 per million per year. [10], [11] Approximately 400 cases of glucagonoma have been reported worldwide, [13], [14], [15] and [16] 250 cases of VIPomas, [17], [18] and [19] less than 180 cases of somatostatinomas, [10], [20], [21], [22] and [23] whereas the number of cases of GRFomas is unclear. The relative frequency of these tumors is insulinomas, nonfunctional PETs, and gastrinomas occurring approximately with equal frequency, 2 to 8 times as common as VIPomas and 17 to 30 times as common as glucagonomas. [2], [10], [11] Somatostatinomas were equal in frequency to glucagonomas in some studies, but less common in others. [2], [10], [11] In various series PETs had an incidence equal to, [11] or 50%, [24] of that seen with carcinoid tumors. In autopsy studies, PETs occur in 0.5% to 1.5% of cases; [7], [11], [25], [26] however, in less than 1 of 1000 cases was a functioning PET thought to occur. [7], [11], [25] In surgical studies nonfunctioning PETs are reported to comprise 15% to 33% of all PETs removed, [1], [10], [27], [28] and [29] and in a large pathology series to account for 36% of all PETs. [6] In addition to the established PET listed in Table 97-1, it has been proposed [30] that PETs secreting calcitonin cause a distinct syndrome with diarrhea. However, too few cases are described to include this syndrome. Furthermore, with other causes of hypercalcitonemia, such as with medullary thyroid cancer, only 25% to 42% of patients develop diarrhea and studies suggest it is not secondary to the increased calcitonin levels per se, but due to a motility disorder of which the causative factor(s) is unknown. Therefore, until more patients are studied it remains unclear if this should be considered a specific PET syndrome. [30], [31], [32] and [33]

PATHOLOGY AND TUMOR BIOLOGY

PETs share a number of pathological features. [5] These tumors frequently contain ductular structures [5], [6] and produce hormones not normally produced in the adult pancreas. Therefore they are thought to originate from an immature stem cell. [5], [6] Because endocrine cells bud off from ductules during ontogenesis of the pancreas and ductular structures are present in these tumors, it has been suggested these cells may originate from ducts. [34] The tumors are thought to originate from cells that are part of the diffuse neuroendocrine cell system. [5], [6], [35], [36] These cells share cytochemical properties and these tumors, together with carcinoid tumors, medullary carcinoma of the thyroid, melanomas, and pheochromocytomas, [5], [6], [36], [37], [38] and [39] have been called APUDomas (an acronym for *a*mine *p*recursor *u*ptake and *d*ecarboxylation). [2], [5], [6], [36], [37] and [38] The tumors are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm (Fig. 97-1). Mitotic figures are uncommon. Ultrastructurally, the tumors demonstrate electron dense granules which contain various peptides, amines, neuron-specific enolase, synaptophysin, and chromogranin A and C. [2], [5], [6], [38] PETs are frequently multihormonal when examined by immunocytochemical studies. [5], [6], [12], [27], [40], [41] In various series more than 50% of all PETs contained more than one hormone by immunocytochemistry. [5], [6], [12], [40], [41] and [42] In insulinomas, for example, glucagon has been identified by immunocytochemical methods in 0% to 44%, somatostatin in 0% to 18%, gastrin in 3% to 11%, PP in 18% to 39%, and ACTH-like immunoreactivity in 11%. [27], [38] Particularly common are PP cells which have been identified in 22% to 39% of insulinomas, 0% to 67% of glucagonomas, and 50% to 75% of VIPomas. [27] In some cases numerous hormones are released into the circulation whereas in others only one peptide may be detectable. [27], [40], [41] At present it is not apparent why

patients with a given PET syndrome present only with a syndrome characteristic of hypersecretion of only one of these peptides; even though the tumor contains multiple peptides. Possible explanations include that only one of the peptides produced is released, only one is released in sufficient quantity to cause symptoms, only one peptide produced is biologically active, or all the peptides are released but some have antagonistic physiological actions. [43]

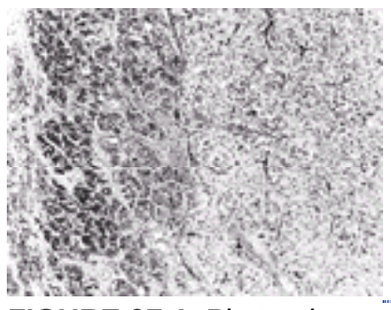

FIGURE 97-1. Photomicrograph of an insulinoma. This insulinoma (**right**) demonstrates a typical histological pattern seen with pancreatic endocrine tumors (PETs) with monotonous sheets of small round cells with uniform nuclei and cytoplasm. The tumor is well marginated and interfaces with the normal pancreas (**left**) by a distinct margin. Hematoxylin and eosin stain, original magnification ×125.

In addition to producing and frequently releasing multiple gastrointestinal peptides, PETs produce a number of products that are characteristic of neuroendocrine differentiation and are used to identify these tumors. These general markers are neuron-specific enolase, chromogranins (A,B,C), synaptophysin, epitope Leu-7, protein gene product (PGP)-9.5, and the alpha or beta subunit of human chorionic gonadotropin (a-hCG, ß-hCG). [3], [11], [44], [45] and [46] Chromogranins are acidic glycoproteins that are present in almost all endocrine or neuronal tissue. [3], [5], [44] Chromogranin is released into the plasma in patients with PETs or carcinoid tumors, [24], [44], [45], [47], [48] and [49] and elevated plasma levels of chromogranin A, B, or C are reported in more than 90% of such patients. [3], [24], [44], [45], [49] Increased plasma levels of a-hCG and ß-hCG also occur in PETs and have been reported by some to be suggestive of malignancy; however, this remains controversial. [2], [3], [12], [27], [45], [46] Neuron-specific enolase (NSE), the r-r dimer of the glycolytic enzyme enolase, occurs in the cytoplasm of most neuroendocrine cells, is present in most PETs as well as carcinoids and other APUDomas, [5], [36], [39] and is frequently released into the plasma and can be used as a tumor marker. [45], [50] Synaptophysin is a calcium-binding vesicle membrane glycoprotein that is synthesized independently of the other neuroendocrine proteins. [11], [39] The presence of chromogranin immunoreactivity in the tumor is the most generally used marker to identify a pancreatic tumor as endocrine in origin. [5]

Because patients with PETs are now living longer with increasingly effective therapy, the development of a secondary symptomatic PET syndrome may become more common. [40], [41] One study suggests a secondary symptomatic PET syndrome is common, occurring in 7.5% of patients with a mean follow-up of 19 months, [40] whereas another study suggests it is uncommon, occurring in only 2% of patients with gastrinoma with a mean follow-up of 11 years. [41] Because of the frequent presence of multiple peptides by immunocytochemistry in the PET, it has become increasingly difficult, if not impossible in most cases, to determine by immunocytochemistry, which of the hormones found in the tumor are clinically important in a patient. [6], [12], [38] Therefore, a functional PET syndrome should only be diagnosed if the clinical symptoms are present and plasma elevations are documented, and not on the basis of immunohistochemical results only.

In general, histological classification of PETs has failed to predict the growth pattern of the tumor or determine whether it is malignant. [6], [12], [38] Furthermore, there is no definite correlation between the histological pattern and the type of clinical syndrome the tumor is associated with. [12], [38], [51] Therefore, at present malignancy can only be unequivocally established in those patients who are demonstrated to have metastatic tumor that has spread either to lymph nodes or the liver, gross invasion or infiltration into adjacent organs, or clear blood vessel invasion. [5], [6], [12], [38] Because of this it is not completely established what percentage of PETs are malignant. The benign nature can only be established by long-term follow-up. In general, 5% to 10% of insulinomas are reported as malignant, whereas in various series 50% to 90% of the other tumors are reported as malignant. [2], [7], [12], [16], [17], [20], [23], [38], [51], [52]

The size of the tumor is usually not related to the severity of the hormonally induced symptoms; however in general, there is a correlation of size with the occurrence of malignancy. [6], [7], [8] and [9], [42], [51], [53] Whereas insulinomas, like gastrinomas, are generally small (<2 cm), glucagonomas and the other PETs are larger at the time of detection (frequently >5 cm). [12], [16], [17], [20], [23], [51], [52] The majority of the primary PETs are solitary and encapsulated when not associated with the multiple endocrine neoplasia type I (MEN I) (discussed subsequently). [5], [6] When metastatic spread occurs it is usually to regional lymph nodes first and later to the liver. Late in the course of the disease, metastases to bone may also occur. [8], [54]

PETs may occur either in a nonfamilial form (sporadic) or be associated with an inherited syndrome. [55], [56], [57] and [58] Inherited syndromes associated with PETs include MEN I [58], [59], [60] and [61] and three phakomatoses (von Recklinghausen's disease, von Hippel-Lindau syndrome, tuberous sclerosis). [11], [55], [56], [57] and [58] MEN I or Wermer syndrome is an autosomal dominant disorder characterized by tumors or hyperplasia of multiple endocrine organs with hypercalcemia due to hyperparathyroidism being the most common abnormality (i.e., occurring in 97% of patients). [57], [59], [60] Nonfunctional PETs are the second most frequent abnormality, occurring in 80% to 100% of patients. [60] Functional PETs occur in 80% of patients with MEN I. [59], [60] and [61] The incidence of gastrinomas, insulinomas, glucagonomas, and VIPomas in MEN I is 54%, 21%, 3%, and 1%, respectively. [60] Pituitary and adrenal cortical adenomas also occur but are less common. [60], [61] In MEN I, the chromosome defect mapped to chromosome 11q13, [59] and a study [62] using positional cloning identified the *MEN-I* gene in this region. The *MEN-I* gene contains 10 exons and encodes a unique ubiquitously expressed 610-amino acid protein, called menin, a nuclear protein that interacts with the AP1 transcriptional factor, Jun D [59] and with SMAD3, a protein important in mediating the cell growth inhibition mediated by transforming growth factor-ß (TGF-ß). [63] Numerous studies suggest that the *MEN-I* gene is a tumor suppressor gene, functioning in a similar manner to that suggested by Knudson for retinoblastoma. [58], [59], [64] In such a circumstance, the affected individual inherits one altered copy of the responsible gene from an affected parent, and then acquires a mutation on the remaining normal allele. Studies [58], [65], [66] suggest a similar double acquired loss of the *MEN-I* gene may be important in sporadic (noninherited) PETs because 32% to 38% of these have loss of heterozygosity at the 11q13 locus. [58], [66] Furthermore, 27% to 39% of sporadic PETs have mutations in the *MEN-I* gene, suggesting some sporadic PETs have similar pathogenesis to PETs in patients with MEN I. [58], [66] The exact percentage of patients with PETs who have MEN I varies in different series and with different tumors from less than 5% to 25%. [12] MEN I is present in 20% to 25% of patients with gastrinomas, [12], [67] 4% to 6% with insulinomas, [52], [60] 13% to 17% with glucagonomas, [15], [16] 6% to 11% with VIPomas, [17], [68] 7% with somatostatinomas, [23] and 33% with GRFomas. [20] The recognition that the PET can be part of the MEN-I syndrome is important because multiple PETs are frequently present. [6], [12] Furthermore, screening of family members for various features of the syndrome is indicated. [12], [59], [60] and [61]

Almost all insulinomas either occur in the pancreas (see Table 97-1) or are attached to it, [52], [69], [70] and [71] although rarely an aberrant insulinoma may be found in carcinoid tumors in the duodenum, ileum, lung, or mesentery. [52], [69] Multiple insulinomas occur in only 10% to 13% of cases and in these patients the presence of MEN I should be suspected. [51], [52] Glucagonomas occur almost entirely within the pancreas, usually in the pancreatic body and tail. [6], [14], [15] and [16], [51], [72] In contrast to insulinomas or gastrinomas, the majority of glucagonomas are usually large (3–10 cm) at the time of diagnosis. [14], [15] and [16], [51], [72] VIPomas in adults are almost all pancreatic in location (i.e., >90%); however, occasionally the VIPoma syndrome is reported in association with a pheochromocytoma or carcinoid tumor of the intestine. [17], [18] and [19] In children, the VIPoma syndrome is often due to a ganglioneuroma or ganglioneuroblastoma. [19], [73], [74] VIPomas are usually large tumors. [17], [19] Somatostatinomas, similar to gastrinomas, frequently are found in extrapancreatic locations (see Table 97-1). [12], [20], [21], [23] In various reviews, [20], [23] 47% to 56% of somatostatinomas are in the pancreas, usually in the pancreatic head and 44% to 52% are extrapancreatic, usually in the small intestine (duodenum or jejunum). Similar to glucagonomas or VIPomas, somatostatinomas tend to be large (mean size = 5 cm). [21], [23], [75] Nonfunctioning PETs and PPomas occur in the pancreas, and are usually greater than 5 cm in diameter. [1], [4], [6], [29] Other less common functioning PETs such as those associated with acromegaly (GRFomas), [21], [76], [77] carcinoid syndrome, [78], [79] paraneoplastic hypercalcemia, [27], [80], [81] and [82] or Cushing syndrome, [27], [83], [84] and [85] are usually large tumors within the pancreas.

In addition to the MEN-I syndrome, some studies report PETs in patients with von Recklinghausen's disease, [22], [55], [86] von Hippel-Lindau syndrome, [55], [87] and tuberous sclerosis. [55], [88], [89] Duodenal somatostatinomas have been reported in a number of patients with von Recklinghausen's disease [22], [23], [55], [90] as well as

Zollinger-Ellison syndrome. [86] In von Hippel-Lindau syndrome, 10% to 17% of patients have a PET, which is usually nonfunctional, but occasional insulinomas and VIPomas are described. [55] Somatostatinomas have also been reported in von Hippel-Lindau syndrome. [91] Three patients with tuberous sclerosis were reported with insulinomas and one was reported with a nonfunctioning PET. [88], [89]

The molecular pathogenesis of PETs, until recently, was largely unknown. [55], [56], [58] In contrast to most common nonendocrine tumors (pancreatic, colonic, gastric adenocarcinomas, etc.), alterations in neither common tumor suppressor genes (retinoblastoma gene, *p53* gene) nor common oncogenes (i.e., *jun, src, ras, fos, myc,* etc.) are generally present in PETs or the closely related carcinoid tumor, [55], [57], [58] suggesting they are not generally important in their molecular pathogenesis. Studies suggest alterations in the *MEN-I* gene, as discussed previously in this section, in the *p16/MTS1* tumor suppressor gene, *DP64/SMAD 4* gene, amplification of the *HER-2/neu* protooncogene, and loss of an unknown tumor suppressor gene on chromosome 1 or 3p could also be important. [7], [55], [57], [58], [92], [93] Mutations in the *MEN-I* gene occur in one third of sporadic PETs, [58], [66] and alterations in the *p16/MTS1* gene in 50% to 92% of PETs, [92], [93] suggesting these are particularly important. Whether the presence of these alterations carries a worse prognosis is unclear.

CLINICAL FEATURES AND DIAGNOSIS

In each PET syndrome except nonfunctioning tumors, early symptoms are caused by the excessive hormone release, whereas late symptoms are primarily due to the metastatic spread of the tumor per se (cachexia, pain, bleeding).

Insulinoma

Insulinomas are endocrine tumors that originate in the pancreas, secrete excessive amounts of insulin, and cause a distinct syndrome characterized by symptoms due to hypoglycemia.

Insulinomas rarely occur in adolescence. The average age of presentation in most series is between 40 and 50 years of age, with 60% of the insulinomas occurring in women. [51], [52], [70], [71], [94], [95]

The clinical manifestations of insulinomas are due to the hypoglycemia secondary to the excess unregulated insulin secretion by the tumor. The symptoms are typically associated with fasting (i.e., the attacks characteristically occur before breakfast, when a meal is delayed, or hours postprandially). The majority of patients have symptoms of central nervous system dysfunction secondary to hypoglycemia (neuroglycopenic symptoms) which include headaches, confusion, lightheadedness, visual disturbances, irrational behavior, drowsiness, or even confusion resulting in coma. Patients with insulinomas misdiagnosed as psychiatric or neurological problems have been reported. [11] The majority of patients also have symptoms due to catecholamine excess secondary to the hypoglycemia such as sweating, tremor, palpitations, and irritability. [51], [94] The average time from onset of symptoms to diagnosis is 3 years, although some studies suggest this to be decreasing. [94], [95]

The presence of an insulinoma should be suspected in all patients with hypoglycemia, especially patients with a history of fasting hypoglycemia or with a family history of MEN I. Fasting hypoglycemia can be mediated by a number of different conditions (Table 97-2). [51], [70], [96], [97] and [98] It should be remembered that insulinoma is only one cause of fasting hypoglycemia and other causes should also be suspected such as inadvertent or deliberate administration of insulin, ingestion of oral hypoglycemia agents, alcoholism with severe liver disease or malnutrition, or other extrapancreatic tumors (see Table 97-2). The diagnosis of insulinoma requires the demonstration of hypoglycemia combined with an inappropriate elevation of plasma insulin concentration and ultimately a PET.

I. Mediated by endogenous insulin or insulin-like factors
  A. Pancreatic islet disease (insulinoma, hyperplasia, nesidioblastosis)
  B. Spontaneous autoimmune antiinsulin antibody syndrome
  C. Autoantibodies to insulin receptor
  D. Noninsulin tumor-associated hypoglycemia
II. Reduced Hepatic Glucose Output
  A. Deficient gluconeogenesis or glycogen storage
  B. Hormonal deficiencies (e.g., adrenal insufficiency)
  C. Enzymatic defects (e.g., glucose-6 phosphatase deficiency)
  D. Ethanol consumption and poor nutrition
  E. Severe liver disease
III. Drugs or Other Pharmacological Causes
  A. Sulfonylureas or biguanides
  B. Insulin administration
  C. Ingestion of akee fruits (hypoglycin)
  D. Other drugs (aspirin, pentamidine, haloperidol, quinine)

Modified from refs. 51, 70, 98.

TABLE 97-2 Causes of Fasting Hypoglycemia

The key to establishing the diagnosis is suspecting the symptoms could be due to hypoglycemia, and Whipple's triad, [99] described in 1938, was long used to diagnose insulinomas. This triad consisted of hypoglycemic symptoms, detecting hypoglycemia (<50 mg/dL), and relief of symptoms with glucose ingestion. Unfortunately the symptoms are not specific for insulinoma [100] and were present in only 43% of cases of insulinomas in a large review of 1085 cases. [52] A fast with monitoring of plasma insulin, glucose, C-peptide, and proinsulin values is now the study usually used to establish the diagnosis of insulinoma. [70], [71], [94], [98] A 72-hour fast in the hospital (with free access to water) is usually used, [51], [98] although one study proposes a 48-hour fast is sufficient. [101] The blood studies mentioned should be monitored at regular intervals (2–4 h) and more frequently if blood sugar decreases to less than 50 mg/dL. If at any point the patient becomes symptomatic, repeat serum levels of the blood studies should be obtained before administering glucose. The test is terminated for neuroglycopenic symptoms or for persistent glucose levels less than 40 mg/dL. Over 90% of insulinomas reported have been detected in this fashion and 70% to 80% of patients will develop hypoglycemia during the first 24 hours of fasting and 98% will develop the condition by 48 hours. [51], [94], [95] In normal nonobese subjects, serum insulin concentrations decrease to less than 6 µU/mL when blood glucose decreases to 40 mg/dL or less and the ratio of serum insulin to glucose remains less than 0.3 (in mg/dL). [51], [95], [97], [98] An insulinoma is considered present if serum insulin concentrations remain constant or increase during hypoglycemia. One set of proposed criteria are:

- documented glucose levels near or below 40 mg/dL (2.2 mM)
- concomitant insulin levels greater than 6 µU/mL (43 pmol/L);
- elevated C-peptide levels (greater than 0.2 nmol/mL in a patient without elevated sulfonylureas in the plasma). [70]

Some add a requirement for a serum proinsulin =5 pmol/L [71], [102] or the insulin/glucose ratio more than 0.3 [51], [98] In one study all 114 patients with insulinoma operated on between 1980 and 1995 had a positive fast, [70] whereas in another review all 132 patients with insulinomas fulfilled the biochemical criteria, but 4 of 132 patients (3%) did not become symptomatic. [103] In the very small percentage of patients with a negative test (i.e., serum insulin concentrations decreasing to less than 6 µU/mL with hypoglycemia), yet insulinoma is still suspected, additional tests (i.e., various provocative tests) may have to be used. [27], [51], [70], [97], [98], [103]

The diagnosis of insulinoma can be difficult because an inappropriately elevated serum insulin concentration associated with hypoglycemia can be observed in a number of different conditions (see Table 97-2). [104] In addition to insulinomas, ß-cell hyperplasia or nesidioblastosis, factitious or inadvertent administration of excessive insulin or oral hypoglycemia agents and autoantibodies against insulin or the insulin receptor can also cause those findings (see Table 97-2). [51], [98], [104] ß-Cell hyperplasia or nesidioblastosis consisting of a proliferation of insulin-producing cells is a leading cause of hyperinsulinism in newborns and has also occasionally been reported in adults. [98], [105] Of these varying causes of hypoglycemia and hyperinsulinemia (see Table 97-2), surreptitious use of insulin or sulfonylureas is the most difficult to distinguish from a patient with insulinoma. [97], [98], [102], [106] To differentiate these conditions a combination of studies consisting of the determination of serum concentrations of proinsulin, C-peptide, antibodies to insulin, and sulfonylurea need to be done. [97], [98], [102], [106]

Insulin is synthesized as proinsulin, which consists of a single chain molecule containing both a 21-amino acid a-chain and a 30-amino acid ß-chain connected by a 33-amino acid connecting peptide (C-peptide). [107], [108] Insulin and C-peptide are liberated in equimolar amounts, and because proinsulin or its intermediate are also found in granules, it is also detected in small quantities in the serum with insulin. [98], [107], [108] Normal subjects have less than 25% of the serum insulin as proinsulin.

Serum proinsulin has been reported to be elevated in at least 80% to 90% of patients with insulinoma. [97], [98], [108] Since high proinsulin values are not found in other hypoglycemic disorders (elevated levels can occur in cirrhotics and patients with type-2 diabetes), an elevated value is very helpful in the diagnosis of insulinoma. However, a normal level does not exclude the diagnosis. In insulinoma the characteristic findings are either a normal or elevated serum concentration of C-peptide, antibodies to insulin are not present, and sulfonylurea is not detected in the blood. [97] In a typical patient with surreptitious use of insulin the C-peptide level is decreased, proinsulin is normal or decreased, antibodies to insulin may be present, and serum sulfonylurea determinations are negative. [97], [98], [104] In patients with surreptitious use of sulfonylureas, the serum concentration of proinsulin is usually normal, antibodies to insulin are not present, and sulfonylurea is detected in the serum or the urine. [97], [98] It is important to remember that the methods usually used for measuring second generation sulfonylureas are insensitive. [71]

VIPoma

The VIPoma syndrome is due to an endocrine tumor usually located in the pancreas that secretes excessive amounts of vasoactive intestinal polypeptide (VIP) which causes a distinct syndrome characterized by fasting, large volume diarrhea, hypokalemia, and hypochlorhydria (Table 97-3).

SIGN/SYMPTOM	FREQUENCY (%)
Secretory diarrhea	89–100
Hypokalemia	67–100
Weight loss	33–72
Dehydration	44–95
Hypochlorhydria	34–76
Hyperglycemia	20–50
Hypercalcemia	25–50
Flushing	13–28
Dilated, atonic gallbladder	Unknown

From refs. 17, 19, 68, 115, 131.

TABLE 97-3 Clinical Features of the Vasoactive Intestinal Polypeptide Syndrome

The VIPoma syndrome is also called the Verner-Morrison syndrome because of its original description by these two authors in two patients with profuse watery diarrhea, hypokalemia, and dehydration with a non-ß-cell pancreatic islet cell tumor. [109] It has also been termed pancreatic cholera [110] and the WDHA syndrome [111] (for the *w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria that some patients develop). [18], [19], [74] While early in the presentation the diarrhea may be episodic or intermittent, characteristically the diarrhea is large in volume (>1 L/d), secretory in nature, and persists during fasting (see Table 97-3). [18], [19], [27] The diarrhea fluid frequently is described as having the appearance of weak tea. An increased net secretion of sodium and chloride into the small intestine has been demonstrated in these patients. [112], [113] The sum of fecal sodium and potassium concentrations multiplied by two will equal the osmolality, thus there is no osmotic gap. [19] In general these patients are reported not to develop steatorrhea (only 16% do so [19]) or have abdominal cramping pain, but some studies suggest pain may be more common than once was typically reported. [19], [27], [68] Studies assessing malabsorption are usually normal with a normal fecal fat excretion in 84%, normal D-xylose in 94%, and normal Schilling's test in 87%. [19] The increased fecal loss frequently leads to dehydration (see Table 97-3). [19], [68] Hypokalemia is present in most patients (see Table 97-3) [17], [18], [19], [68], [114], [115] and is the result of the large losses of potassium in the diarrhea fluid. Hypochlorhydria rather than achlorhydria is found in 28% to 76% of patients with VIPoma syndrome (see Table 97-3). [18], [68], [114], [115] This has been attributed to the inhibitory effect of VIP on gastric acid secretion. [18], [18], [27] Flushing is seen in 13% to 28% of patients with the VIPoma syndrome [17], [18], [68], [114], [116] and has been attributed to the vasodilatory effects of VIP (see Table 97-3). [18], [117] The fact that prolonged infusion with VIP in humans results in a gradual decrease in flushing suggests the development of tachyphylaxis. [11] This phenomenon has been used to explain why only a minority of patients develop flushing. [18] Hyperglycemia is noted in 20% to 50% of patients with VIPomas [19], [68] and it has been attributed [18] to the glycogenolytic effect of VIP on the liver (see Table 97-3). [118] Hypercalcemia also is reported in 25% to 76% of patients with VIPoma. [18], [19], [27], [68] At present the mechanism of hypercalcemia in most cases is not established; however, it seems to be related to the tumor itself because it is relieved by complete tumor removal. [19] Only 6% to 11% of patients with VIPomas have a history of MEN I, which is why MEN I is rarely the cause of the hypercalcemia. [17], [19], [68]

Beside VIP a number of substances, [18], [119] including secretin, [11] gastric inhibitory polypeptide, [120] pancreatic polypeptide, [121] and prostaglandins [122] are reported to cause diarrheagenic secretion in some patients. Controversy arose in early studies whether VIP was the sole cause of the diarrhea in WDHA because it was not found to be elevated in all patients by different investigators and exogenous VIP infusions for 1 or 2 hours did not cause diarrhea in humans. [123] However, in more recent studies, only VIP has been found to be elevated consistently in patients with the WDHA syndrome. [18], [73], [119], [124], [125] Furthermore, continuous infusion of VIP for 10 hours in normal subjects to achieve plasma VIP concentrations similar to those seen in patients with WDHA produced profuse watery diarrhea within 6 to 7 hours. [124], [126] The diarrhea produced in these patients is similar to that seen in patients with WDHA. The ability of VIP to cause intestinal secretion is consistent with its known mechanism of action. VIP has been shown to cause net chloride secretion associated with increased short circuit current, to bind to specific receptors on intestinal epithelial cells, and to activate adenylate cyclase and increase cyclic AMP in intestinal cells. [27], [127] Occasionally patients with the WDHA syndrome have normal plasma concentrations of VIP. [18] Another VIP-related peptide, peptide histidine isoleucine (PHI), is reported to be elevated in the plasma of patients with WDHA. [19], [27], [128], [129] Tumor tissue obtained from patients with the WDHA syndrome also demonstrated PHI-like immunoreactivity which was produced by the same cells as VIP. [19], [27], [128], [129] Furthermore, analysis of a WDHA tumor demonstrated that VIP and PHI sequences are in the same gene. [127], [129] PHI infusions also caused intestinal secretion although PHI was 32-fold less potent than VIP [130] and therefore, even though PHI was reported to coexist in 22 of 24 VIPomas, [128] because of the low potency, it remains to be proven whether PHI is contributing to the diarrheal state. [19]

The definite diagnosis of VIPoma requires the establishment of a secretory diarrhea, demonstration of elevated serum concentrations of VIP, and identification of a PET. The likely possibility that VIPoma and not some other cause is responsible for the diarrhea may be suggested by measuring the stool volume. [18], [19], [27] In 70% to 80% of patients with VIPomas the stool output is greater than 3 L/d, [19], [131] in 100% of 52 patients it was more than 1000 L/d. [19] When the stool output is less than 700 mL/d the diagnosis of VIPoma is excluded. [18] In addition the diarrhea in patients with VIPomas persists during fasting [18], [19] and the sum of the concentration of stool sodium and potassium multiplied by two equals the isotonicity. [19]

A number of diseases can cause chronic secretory diarrheas with this volume and need to be differentiated from VIPomas. [32] The diarrheas due to midgut carcinoids in the carcinoid syndrome or medullary thyroid carcinoma are primarily due to motility disturbances and rarely reach this volume. [19], [32] However, high-volume fasting diarrhea occurs in patients with Zollinger-Ellison syndrome [12], [32], [67] and diffuse islet-cell hyperplasia, [19] as well as among patients with surreptitious use of laxatives or the pseudopancreatic cholera syndrome. [19], [73], [132] The serum gastrin concentration is elevated in patients with Zollinger-Ellison syndrome but not in patients with VIPoma. Furthermore, with effective treatment of the gastric hypersecretion the diarrhea stops in patients with Zollinger-Ellison syndrome. [12], [32], [67], [133]

To differentiate patients with VIPoma from those with pseudopancreatic cholera syndrome or laxative abuse a reliable VIP radioimmunoassay is required. [18], [19], [73] The normal fasting plasma VIP concentration in a number of laboratories is 0 to 190 pg/mL. [18], [73], [119] It is best that the fasting plasma VIP concentration be determined at the time when diarrhea is present because occasionally between diarrhea periods in some patients with VIPoma, VIP levels may be normal. [18] The mean concentration of plasma VIP in one series of 29 patients with the VIPoma syndrome was 956 pg/mL with a range of 225 to 1850 pg/mL. [18], [27] In another series [74] of 52 cases of VIPoma the mean value was 702 pg/mL with a range from 159 to 2530 pg/mL. In two reviews, [17], [68] 94% to 100% of patients with VIPoma had elevated plasma VIP levels. Normal plasma VIP levels are reported to occur in 12% of cases with a pancreatic tumor and in 82% of cases with pancreatic islet-cell hyperplasia. [19] In most recent studies plasma VIP levels are not elevated in patients with laxative abuse. [18], [19], [73], [114], [119], [120] Patients with chronic secretory diarrhea due to chronic laxative abuse can be difficult to detect, but should be suspected if plasma VIP levels are normal or a laxative screen is positive. [134] Because of the difficulty in diagnosing laxative abuse, a laxative screen should be performed in any patient with unexplained chronic diarrhea. [135]

Elevated plasma VIP levels should not be the sole basis for the diagnosis of a VIPoma. [18], [136] Other conditions including prolonged fasting, inflammatory bowel disease, small bowel resection, radiation enteritis, and chronic renal failure can occasionally elevate plasma VIP levels. [18], [136] In one study of 193 patients with chronic diarrhea, [136] eight different gastrointestinal hormones (motilin, PP, neurotensin, somatostatin, substance P, VIP, gastrin-releasing peptide, and calcitonin) were assessed and 45% of the patients had one or more elevated levels; however, no patient had a PET. This study shows false-positive elevated plasma levels for those hormones reported to cause diarrhea, including VIP, are not uncommon and therefore tests need to be ordered selectively and carefully interpreted in light of other

clinical and laboratory findings to establish a correct diagnosis. [136]

Glucagonoma

Glucagonomas are endocrine tumors of the pancreas that secrete excessive amounts of glucagon and cause a distinct syndrome characterized by dermatitis, glucose intolerance, weight loss, and anemia (Table 97-4).

SIGN/SYMPTOM	FREQUENCY (%)
Dermatitis (migratory necrolytic erythema)	64–90
Hypoaminoacidemia	41–100
Glucose intolerance or diabetes mellitus	38–90
Weight loss	56–96
Anemia	33–85
Diarrhea	14–29
Thromboembolism	12–35
Glossitis, cheilitis	14–40
Psychiatric disturbance	0–17

from refs. 13–16, 72, 141–143, 152.

TABLE 97-4 Clinical Features of the Glucagonoma Syndrome

The first description of what we know as the glucagonoma syndrome was reported in 1942 [137] in a patient with a skin rash associated with pancreatic cancer. McGavran and colleagues, in 1966, reported the first well-described case of a patient with the glucagonoma syndrome. [138] The patient had elevated immunoreactive glucagon in plasma, diabetes mellitus, a skin rash, and a PET. In 1973, Wilkinson [139] introduced the term *necrolytic migratory erythema* for the skin rash associated with PETs. Mallinson and colleagues in 1974 [140] specifically established the association of glucagonomas with the skin rash when they reported nine cases with the clinical glucagonoma syndrome consisting of dermatitis, diabetes mellitus, unexplained weight loss, hypoaminoacidemia, anemia, and a glucagon-producing tumor of the pancreas.

The peak incidence for the glucagonoma syndrome is 45 to 70 years of age; the syndrome has not been described in children. [13], [14], [15] and [16], [51], [72] The characteristic skin rash associated with the glucagonoma syndrome, called necrolytic migratory erythema is present in the vast majority of cases (see Table 97-4). [14], [15] and [16], [72], [139], [141], [142] and [143] The skin lesion starts as an annular erythema at intertriginous and periorificial sites. It is normally found on the buttocks, groin, perineum, and thighs. The erythema subsequently becomes raised and the central parts form superficial bullae. The top of the bulbous lesion frequently detaches, leaving eroded areas that become crusted (Fig. 97-2; see also Color Fig. 97-2). Lesions frequently become confluent. The extent and the severity of the lesions may wax and wane. Healing in 2 or 3 weeks results in hyperpigmentation (see Fig. 97-2). Histologically, early skin lesions demonstrate a superficial spongiosis and necrosis and subcutaneous blister formation. [139], [141], [142] and [143] The pathogenic mechanism by which the glucagonoma syndrome produces this characteristic skin rash is unclear. It is not established that the skin rash is associated with the hyperglucagonemia because numerous patients have been given large doses of glucagon for long periods of time without developing the characteristic rash. [141] Glucagon-induced hypoaminoacidemia may be one mechanism because correction of the hypoaminoacidemia has been shown to eliminate the dermatitis without changing plasma glucagon concentrations. [141], [144], [145] The resemblance of the lesions to those seen with zinc deficiency have resulted in trials of therapy with zinc, with some responses. [15] However, resolution of the rash has been reported following simple hydration with glucose and saline; [141], [146] therefore, it is not known that either hypoaminoacidemia or zinc deficiency are necessarily causative in all patients. A number of other clinical features are also characteristic of the glucagonoma syndrome (see Table 97-4). Angular cheilitis (see Fig. 97-2) is a common feature as is nail dystrophy and thinning of the hair. [14], [15] Some patients develop a painful glossitis (see Table 97-4).

FIGURE 97-2. (See Color Fig. 97-2) Migratory necrolytic erythema involving the face in a patient with metastatic glucagonoma. These typical skin lesions usually start on the extremities or intertriginous or periorificial sites. The lesions initially are erythematous and scaly, later become raised and bullous, and finally become crusty as is evident in this patient. Healing results in hyperpigmentation. Angular cheilitis, a common feature in patients with glucagonoma, is also present in a mild form in this patient. The patient also demonstrates loss of the buccal fat pad and temporal muscle wasting indicative of the generalized wasting these patients characteristically develop.

Hypoaminoacidemia occurs in most patients and, as originally pointed out by Mallinson, the levels may vary with the intensity of the disease. [16], [140], [141] The hypoaminoacidemia is thought secondary to the hyperglucagonemia because glucagon infusions have been demonstrated to have a controlling influence on amino acid metabolism by altering gluconeogenesis. [141], [147] It has been demonstrated in human subjects that glucagon deficiency caused by either suppression with somatostatin or total pancreatectomy increases plasma amino acid concentrations. [27], [148], [149] On the other hand, the administration of glucagon decreases plasma amino acid concentrations. [149] Metabolic studies [150], [151] in patients show an increase in amino acid catabolism, a 15% increase in whole body lipolysis, and a 15% increase in hepatic glucose production; the energy expenditure, as well as rate of protein breakdown, were normal.

Diabetes mellitus and glucose intolerance occur frequently in patients with the glucagonoma syndrome (see Table 97-4). [13], [16], [141], [143], [152] In one study [14] however diabetes was present in only 38% of patients at presentation and developed in an additional 38% as the glucagonoma progressed. The relationship of the hyperglucagonemia to the diabetes mellitus or glucose intolerance remains unclear. Glucagon levels in patients with glucagonomas do not correlate well with the degree of glucose intolerance. [51], [141], [142] and [143], [152] Furthermore, various treatments have resulted in definite changes in plasma glucagon concentrations but have not produced correlated changes in blood glucose. For example, tumor resection and normalization of blood glucose may not result in the correction of the glucose intolerance. [51], [72], [141] The somatostatin analog, octreotide, may depress plasma glucagon levels, but frequently does not improve the diabetes. [11], [14], [15], [153] In some patients however, removal of the glucagon-producing tumor has improved glucose tolerance. [140], [141] Whether or not glucagon causes glucose intolerance appears to depend to a large degree on the patient's insulin reserve. If it is intact, hyperglucagonemia is present without glucose intolerance. [14], [51], [141], [152]

Weight loss is a common feature of patients with the glucagonoma syndrome and it may be profound (see Table 97-4, Fig. 97-2). [13], [14], [15] and [16], [51], [72], [141], [142] and [143] A number of observations suggest weight loss is a specific feature of the glucagonoma syndrome. Weight loss is prominent in patients with small tumors as well as those with metastatic tumors. It is not seen early in other PETs unless malabsorption is present, suggesting the cachexia is an intrinsic feature of the glucagonoma syndrome. [141] The weight loss has been attributed to the catabolic effects of glucagon. [141], [151] However, in an experimental study [154] in which glucagonomas from a pluripotent rat islet tumor were transplanted into normal animals, severe anorexia and adipsia developed. Studies show bilateral vagotomy had no effect on the

development of anorexia, that the satiety peptides, cocaine and amphetamine-regulated transcript (CART) or leptin, are unlikely to be the mediators, and that the unknown mediator can override the potent appetite-stimulatory effect of neuropeptide (NPY). [155], [156] These results [154] suggest that the anorectic effects of glucagonoma are due to the production of a novel substance by the glucagonoma and not due to glucagon per se because other transplanted glucagonomas producing similar levels of plasma glucagon elevation do not cause anorexia. [154]

Thromboembolic phenomena are more common in patients with the glucagonoma syndrome (see Table 97-4). [13], [14] and [15], [51], [72], [141], [142] and [143] Both deep vein thrombosis and pulmonary emboli have been reported to occur in a significant number of cases and have been the cause of death in some patients. [13], [51], [141], [142] and [143] Glucagon is not known to affect coagulation parameters, however the pathophysiology of the thromboembolic events in glucagonoma has not been systematically studied. A normochromic, normocytic anemia is also reported to be a frequent finding in patients with glucagonomas (see Table 97-4). [14], [15] and [16], [51], [72], [141], [142] Serum iron, serum vitamin B_{12}, and serum folate concentrations are usually normal, and the anemia does not respond to therapy with any of these agents. It, however, does respond to resection of the tumor. [141], [157], [158] and [159] Further evidence that the anemia may be due to glucagon excess is that prolonged therapy with a long-acting glucagon preparation decreases erythropoiesis in rats and mice. [159] Psychiatric disturbances, particularly depression, have been reported in a number of patients with the glucagonoma syndrome, however the exact frequency or even whether they are more common in patients with glucagonoma has not been established (see Table 97-4). [14], [15], [72], [137], [139], [141]

Glucagonoma is usually suspected in patients with chronic unexplained and therapy-resistant dermatitis or elevated sedimentation rates and is associated with glucose intolerance, thromboembolic phenomenon, or the MEN-I syndrome (see Table 97-4). [11], [15], [141], [142] and [143], [152] Diagnosis rests on demonstrating a pathological elevation of the plasma glucagon concentration. In almost all patients with glucagonoma the plasma glucagon concentration is elevated (>150 pg/mL), [16], [141], [142], [152] with a mean value of 2110 ± 334 pg/mL (±1SEM) in 23 patients with proven glucagonoma in one study. The highest value in a patient without glucagonoma was 409 ± 29 pg/mL. In a review of 58 published cases of glucagonoma, plasma glucagon levels exceeded 1000 pg/mL in 90%, were between 500 and 1000 pg/mL in 7%, and less than 500 in 3%. [13], [72] In a study from the Mayo Clinic of 21 cases, [14] 48% of patients had values greater than 1000 pg/mL and 86% of patients had values greater than 500 pg/mL. It has been suggested that a plasma glucagon concentration of more than 1000 pg/mL is diagnostic of glucagonoma [141] because other causes of elevated plasma glucagon levels do not cause this degree of elevation. In this study 3 of 21 patients (14%) had plasma glucagon levels less than 500. [14] A high degree of suspicion for the disease therefore should be maintained, especially in patients with small tumors or MEN I. [15] Other conditions that are associated with increased plasma glucagon concentrations include renal insufficiency, acute pancreatitis, hypercorticism, hepatic insufficiency, severe stress (trauma, exercise, bacteremia, diabetic ketoacidosis), prolonged fasting, familial hyperglucagonemia, or other PETs. [15], [16], [51], [72], [142], [152], [160], [161] In two studies, one involving 71 patients with fasting hyperglucagonoma at least two times the upper limit of normal (i.e., >120), [152] and the other [16] with 407 cases of glucagonoma from the literature, only 21% and 57% of the patients included, respectively, had a clinical glucagonoma syndrome. Therefore, hyperglucagonemia without the glucagonoma syndrome is not necessarily uncommon. In one series [152] the hyperglucagonemia occurred with polyfunctional PETs in 69% of the cases, especially with patients with Zollinger-Ellison syndrome, insulinomas, and carcinoid tumors. In almost all of these cases the hyperglucagonemia was not associated with the glucagonoma syndrome. In general, in these nonglucagonoma conditions causing hypergastrinemia, the plasma glucagon is not elevated above 500 pg/mL except in patients with cirrhosis. [51], [72], [142] For the occasional patient with glucagonoma with a fasting plasma glucagon concentration less than 1000 pg/mL that may overlap with other conditions, there is no proven provocative test that will clearly distinguish these conditions. [51], [72] Usually, however, these nonglucagonoma conditions can be excluded on clinical grounds. In various series from 0% to 20% of patients with glucagonomas had MEN I. [13], [14] and [15], [142], [143] These patients can be difficult to diagnose because they have minimal symptoms early in their disease course. [15] It is important to remember that necrolytic migratory erythema [162] can be observed in patients without an associated glucagonoma. The most common conditions this is reported to occur in are celiac disease, malabsorptive conditions, cirrhosis, malignancies, and pancreatitis. [162]

Somatostatinomas

Somatostatinomas are endocrine tumors of the pancreas or intestine that secrete excessive amounts of somatostatin which causes a distinct syndrome characterized by diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea (Table 97-5).

SIGN/SYMPTOM	FREQUENCY (%)		
	Somatostatinoma *Pancreatic*	*Intestinal*	Somatostatinoma *Syndrome**
Diabetes mellitus	90–95	21	95
Gallbladder disease	90–94	43	68
Diarrhea	60–97	10–40	37
Steatorrhea	83	12	47
Hypochlorhydria	86	17	26
Weight loss	30–90	20–45	68

*Somatostatinoma refers to a pancreatic endocrine tumor which shows somatostatin-like immunoreactivity and may occur without (89%) or with (11%) the somatostatinoma syndrome which is due to somatostatin secretion by the tumor.[21,22]

Modified from refs. 20, 21, 23.

TABLE 97-5 Clinical Features of the Somatostatinoma Syndrome

In 1977 the first two cases of somatostatinomas were independently reported. [163], [164] On the basis of these reports and the known actions of somatostatin, it was proposed that the clinical somatostatinoma syndrome consisted of mild diabetes mellitus, gallbladder disease, weight loss, and anemia. [165] Diarrhea, steatorrhea, and hypochlorhydria became additional features as other cases have been described (see Table 97-5). [75], [166], [167]

There is no general agreement on the definition of what is a somatostatinoma. In the literature this term is generally used to indicate a PET possessing somatostatin-like immunoreactivity and it may (11% to 45%), or may not (55% to 89%), be associated with clinical symptoms due to ectopic release of somatostatin. [21], [22] and [23] In this chapter the term *somatostatinoma syndrome* will be used to indicate a somatostatin-producing PET associated with clinical features due to ectopic somatostatin release (see Table 97-5), and the term *somatostatinoma* will be used to include a PET containing somatostatin immunoreactivity.

Somatostatin is a tetradecapeptide originally isolated and purified from ovine hypothalamic tissue. [168] It inhibits the release of almost all other hormones, and has direct effects on a number of gastrointestinal functions including being a potent inhibitor of basal and pentagastrin- or meal-stimulated acid secretion, cholecystokinin-stimulated pancreatic enzyme secretion, and intestinal absorption of amino acids. [168], [169] A number of studies have suggested that somatostatin has a paracrine effect on antral gastrin release. [168] Somatostatin also has marked effects on gut motility and transit time. [168], [169]

Somatostatinomas primarily occur in the pancreas (46% to 75%) or in the upper small intestine (25% to 54%). [20], [21], [23], [75] In the pancreas 62% to 78% of the somatostatinomas occur in the pancreatic head. [20], [23], [75] Tumors not in the pancreas occur in the duodenum (43% to 90%), ampullary area (48%), jejunum (5%), or cystic duct area. [20], [23] Most somatostatinomas (>96%) are solitary and vary from less than 1 cm to 10 cm in diameter with a mean of 4 to 5 cm. [23], [75] Pancreatic tumors are larger than duodenal tumors (5 cm vs. 2 cm) ($P < 0.0001$), [23] and are more malignant than intestinal tumors (92% vs. 6%) in one study, [20] but not in another [23] (i.e., both 50%). With duodenal somatostatinoma the occurrence of lymph node metastases correlates with primary tumor size. [170] Electron microscopic studies show typical D-cell secretory granules in 52% to 89% of the tumors. [20], [23], [170]

The mean age of patients with pancreatic somatostatinomas or intestinal somatostatinomas is 50 years with a range of 30 to 84 years. [20], [75] In one series, [20] in the patients with pancreatic somatostatinomas there was a 2:1 female predominance whereas 60% of the patients with intestinal somatostatinoma are male; [20] however, in another review somatostatinomas occurred with equal frequency in both genders. [23]

In assessing the symptoms and signs due to somatostatinomas it is important to differentiate between those due to the PET per se, which are similar to any PET (pain, icterus, weight loss, hepatomegaly, abdominal tumor, etc.) from those that are due to the increased somatostatin secreted by the PET. In one large literature review of 173 cases of somatostatinomas, [23] only 18 cases (11%) were associated with the somatostatinoma syndrome (see Table 97-5). In one study [23], 93% of

patients with somatostatinomas had symptoms or signs of the condition; the most frequent being abdominal pain (40%), weight loss (26%), icterus (23%), abdominal tumor (12%), diarrhea (18%), nausea/vomiting (16%), and hepatomegaly (10%). Diabetes mellitus or glucose intolerance occurs in 63% to 90% of patients with somatostatinomas. [20], [21], [75] However, diabetes mellitus occurred in 90% to 95% of the patients with pancreatic somatostatinomas and only 21% of those with intestinal somatostatinomas (see Table 97-5). [20] The diabetes is usually mild and severe hypoglycemia and ketosis, although reported, are uncommon. [21], [27], [167] The development of diabetes mellitus or glucose intolerance is secondary to the ability of somatostatin to inhibit insulin and glucagon release [20], [21], [168] and the replacement of functional islet tissue by tumor. [75] This latter factor may be responsible for explaining why diabetes mellitus is more common in patients with pancreatic than intestinal somatostatinomas (see Table 97-5) [20] In patients with the somatostatinoma syndrome, 95% had diabetes mellitus (see Table 97-5). [23]

Gallbladder (cholelithiasis) disease is reported in 65% to 90% in patients with somatostatinomas. [20], [21], [75] It is reported in 90% to 94% of patients with pancreatic somatostatinoma and 43% of patients with intestinal somatostatinoma (see Table 97-5). [20] Cholelithiasis was present in 68% of patients with the somatostatinoma syndrome (see Table 97-5). [23] The high incidence of gallbladder disease in patients with somatostatinomas and the lack of occurrence in patients with other PETs suggests a causative association between the gallbladder disease and somatostatinoma. This conclusion is supported by studies which demonstrate that somatostatin analogs inhibit gallbladder emptying, alter the motility of the sphincter of Oddi, alter hepatic bile secretion, and have effects on the bile composition. [21], [168], [169], [171], [172] and [173] It is also supported by studies of patients with acromegaly or PETs treated long-term with octreotide. [169], [174], [175] The latter studies [169], [171], [175] demonstrate that 13% to 66% of patients treated long-term with octreotide develop gallstones.

Diarrhea and steatorrhea were reported in 36% to 90% of patients in various studies. [20], [21], [23], [75] The diarrhea characteristically consists of 3 to 10 foul-smelling stools per day and the steatorrhea varies from 20 to 76 g/d. [20], [75] Diarrhea and steatorrhea are much less common in patients with intestinal (10% to 40%) rather than pancreatic somatostatinomas (60% to 97%) (see Table 97-5). [20], [23] In some, but not all cases, the severity of the diarrhea and steatorrhea correlates with the size and degree of metastatic spread of the tumor and improves with tumor resection. [75] Somatostatin has been shown to inhibit pancreatic enzyme and fluid secretion as well as gallbladder motility. [168], [169] In addition somatostatin also inhibits intestinal absorption of lipid, [176] D-xylose, vitamin B_{12}, and folate. These biologic actions of somatostatin may be responsible for the maldigestion, steatorrhea, and diarrhea observed in these patients. [75] The fact that patients with intestinal somatostatinomas have less diarrhea or steatorrhea has been attributed to their lower plasma somatostatin levels or the lack of local effects of the somatostatinoma within the pancreas (See Table 97-5). [20] Diarrhea is present in 37% and steatorrhea in 47% of patients with the somatostatinoma syndrome (see Table 97-5). [23]

Hypochlorhydria was found in 33% of patients in one study, [75] in 53% of patients in a second study, [20] and 70% in a third study. [23] Hypochlorhydria occurred in 86% of patients with pancreatic somatostatinoma and 17% of patients with intestinal somatostatinoma (see Table 97-5). [20] Hypochlorhydria was present in 26% of patients with the somatostatinoma syndrome (see Table 97-5). [23] Infusion of somatostatin has been shown to inhibit gastric secretion in normal human subjects as well as basal and food-stimulated gastrin release. [168] As with the glucagonoma syndrome, weight loss is reported to be common in patients with somatostatinomas. [21] Weight loss was reported in 32% to 90% of patients with pancreatic tumors and in 20% to 45% of patients with intestinal tumors [23], [75] (see Table 97-5), with weight loss ranging from 9 to 21 kg. Weight loss was reported in 68% of patients with somatostatinoma syndrome (see Table 97-5). [23] The weight loss may be secondary to the diarrhea and malabsorption. Other less common features reported in patients with somatostatinoma include mild to moderate anemia in 15% to 67% of patients with somatostatinomas, [23], [75] and in 21% of patients with the somatostatin syndrome. [23] Also, the occurrence of various associated endocrine disorders is reported in patients with somatostatinomas. [75] In one study, four patients were reported to have hypoglycemic episodes with normal or elevated plasma insulin concentrations and were iagnosed as having insulinomas. [75] In two patients with elevated plasma insulin concentrations the tumors did not contain increased amounts of insulin, only somatostatin. Tumor tissue was not available from the other two cases; however, immunocytochemical studies demonstrated mostly D-cells (somatostatin-producing cells) with some ß-cells (insulin-producing) in one patient and 20% to 30% D-cells with 30% to 40% ß-cells in another patient. [75]

The diagnosis of somatostatinoma has been applied to numerous PETs in the literature based only on immunohistochemical results which, in most cases (55% to 89%), is not associated with the somatostatinoma syndrome due to ectopic somatostatin release. [21], [22] and [23] The diagnosis of the somatostatinoma syndrome requires the demonstration of increased concentrations of somatostatin-like immunoreactivity (SLI) in the resected tumor and the plasma as well as at least some features of the appropriate clinical syndrome (see Table 97-5). The establishment of SLI only in a resected tumor is not sufficient for the diagnosis of the somatostatinoma syndrome. Minimal increases in plasma/SLI levels need to be interpreted with caution because they can occur in nonendocrine disorders. [21] Furthermore, while plasma SLI levels are frequently elevated with pancreatic tumors, in small intestinal somatostatinomas the SLI levels are frequently normal. [21], [22] SLI is frequently detected as a subpopulation of cells in a variety of PETs, especially nonfunctional tumors. [21], [177] High plasma SLI levels have been reported with endocrine tumors outside of the pancreas or intestine, as with small cell lung cancer, bronchial oat cell carcinoma, medullary thyroid carcinoma, pheochromocytomas, and other catecholamine-producing extra-abdominal paragangliomas. [21] It is likely in the future that the syndrome will be diagnosed earlier because of the increased clinical awareness of the somatostatinoma syndrome (see Table 97-5) and the greater availability of reliable assays for the determination of SLI in blood. Presently these assays are complicated by the need for extraction of the plasma and are not widely available.

The diagnosis of somatostatinoma at a time when plasma SLI concentrations are only marginally elevated and the tumor has not yet metastasized will require the development of reliable provocative tests. Tolbutamide and arginine have been reported to stimulate plasma SLI increases; [75], [178] however, arginine is a well established stimulant for normal D-cells and thus is unlikely to differentiate normal from supranormal secretion. [75] Furthermore even though tolbutamide stimulates SLI increases in animals, [178] it is reported not to cause changes in plasma SLI concentrations in normal human volunteers. [179] Until an adequate provocative test is developed, if the somatostatinoma syndrome is to be diagnosed earlier, it may be necessary to determine plasma SLI concentrations on all patients with diabetes mellitus without a family history and with any other clinical features of the somatostatinoma syndrome, or all patients with unexplained diarrhea. [166]

In most studies somatostatinomas have been found more or less by accident. [75] Because most somatostatinomas (i.e., 89%) [23] do not produce the somatostatinoma syndrome and the most common presenting symptoms are nonspecific (abdominal pain, weight loss, icterus, diarrhea, nausea/vomiting), [23] the correct diagnosis is rarely suspected prior to the discovery of a PET at laparotomy for cholecystectomy, during imaging studies for nonspecific complaints, or after a biopsy for metastatic liver disease discovered during a workup for nonspecific gastrointestinal symptoms. [20], [21], [23], [75] The presence of psammoma bodies in a duodenal tumor should particularly raise the suspicion that the tumor could be a somatostatinoma. [21], [23], [180] These lesions are found in approximately one half of duodenal somatostatinomas, [21], [22] and [23] but are uncommonly found (i.e., 2% to 5%) in pancreatic somatostatinomas or in other types of duodenal carcinoids or duodenal gastrinomas. [21], [180] Duodenal somatostatinomas are increasingly associated with von Recklinghausen's disease. [21], [22], [55] Duodenal somatostatinomas in patients with von Recklinghausen's disease are similar to duodenal somatostatinomas in patients with sporadic duodenal somatostatinomas in that they are rarely associated with symptoms of the somatostatinoma syndrome (i.e., 2%), infrequently cause elevated plasma SLI levels, often contain psammoma bodies (37% to 66%), [22], [23] and are less likely to be malignant (30% duodenal vs. 70% for pancreatic somatostatinomas). [22], [23]

GRFomas

GRFomas are endocrine tumors that frequently originate in the pancreas but also occur in other extra-pancreatic sites and secrete excessive amounts of growth hormone-releasing factor (GRF) that causes acromegaly.

Tumors releasing growth hormone-releasing factor (GRFomas) were described in 1982. [181], [182] Growth hormone-releasing factor is a 44-amino acid peptide originally isolated from human PETs causing acromegaly and is structurally similar to vasoactive intestinal polypeptide. [21], [181] The true frequency of this syndrome is still not established but a review in 1997 included 40 cases. [77] In one immunocytochemical study [183] of PETs, 4 of 9 (44%) contained GRF-like immunoreactivity, although only one patient had acromegaly. In another study [184] 6 of 24 (25%) PETs, of which 16 were associated with various clinical syndromes (8 with insulinoma; 5, gastrinoma; 2, VIPoma-2; 1, Cushing syndrome), were found to have GRF-immunoreactive material. None of these patients had clinical acromegaly. GRFomas occur in the pancreas in 29% to 30% of cases; 47% to 54% occur in lung tumors with the majority in the right lung; 8% to 10% occur in the small intestine; and up to 13% occur in other sites including adrenal gland, foregut, and retroperitoneum (see Table 97-1). [21], [77], [185], [186] The patients were 15 to 66 years of age with an average age of 38 to 39 years. [77], [185], [186] A female predominance (78%) is seen with pancreatic GRFomas as well as all GRFomas (73%). [77], [185], [186] The clinical features can be divided into three categories: acromegalic features due to ectopically released GRF causing excess growth hormone secretion; clinical features due to hormones other than GRF co-released, such as gastrin causing Zollinger-Ellison syndrome or ACTH causing Cushing syndrome; and local symptoms due to mass effect of the hormone. [21], [185], [186] The mean duration from symptom onset to diagnosis is 5 to 6 years. [185], [186] The acromegalic features of GRFomas are indistinguishable from those of classical acromegaly. [21], [185], [186] Patients usually have a large pancreatic tumor (>6 cm; range 1–25 cm) and in 33% to 39% of cases it is metastatic at the time of

diagnosis. [77], [185] The majority of pancreatic GRFomas occur in the pancreatic tail. [77], [186] In one series [185] metastatic disease was present in 30% of the patients with pancreatic GRFomas and two of the three patients with intestinal GRFomas. [186] No relationship between the presence or absence of metastases, tumor size, or plasma GRF level was found. [186] Multiple pancreatic GRFomas occurred in 30% in one series, [186] usually in patients with MEN I. [21] Forty percent of the patients with pancreatic GRFomas have associated Zollinger-Ellison syndrome; 40% have Cushing syndrome, and 33% have associated MEN-I syndrome. [27], [186]

GRFomas are usually suspected in a patient with acromegaly and an elevated growth hormone level with hepatic metastases or with abdominal complaints. [21], [76], [181], [182], [185], [186] Pancreatic GRFomas are often associated with a gastrinoma and Zollinger-Ellison syndrome or Cushing syndrome. Therefore, any patient with Cushing syndrome or peptic ulcer symptoms, diarrhea, a pancreatic mass, or with symptoms suggestive of chronic esophageal reflux who presents with acromegalic features, should be suspected of having a GRFoma. Furthermore, pancreatic GRFomas have occurred in a number of patients with the MEN-I syndrome. Any patient with acromegaly with hyperparathyroidism or a family history of MEN-1 should also be suspected of having a GRFoma. The diagnosis should be suspected in any patient with acromegaly without a pituitary adenoma, with acromegaly associated with hyperprolactinemia which is seen in 70% of GRFomas, with paradoxical growth hormone response to thyroid-stimulating hormone (TSH), or during an oral glucose tolerance test. [21], [77], [185], [186] A GRFoma is an uncommon cause of acromegaly. In one study [187] of 177 unselected patients, none had acromegaly. The diagnosis is confirmed by performing a plasma assay for GRF and for growth hormone. [21], [76], [77], [185], [186] Elevated plasma levels of growth hormone (usually >5 µg/L in men and 10 µg/L in women) and an elevated plasma GRF confirm the diagnosis. A recent review proposes an empirical diagnostic threshold value for GRFomas of 300 pg/mL for the plasma GRF level. [21] Healthy subjects have GRF levels less than 50 to 100 pg/mL [77] and patients with pituitary adenomas causing acromegaly have plasma GRF levels less than 200 pg/mL. [21], [187] In addition to growth hormone and GRF, in patients with GRFomas plasma levels of insulin-like growth factor 1 (IGF-1) are elevated similar to patients with acromegaly due to a pituitary adenoma. [185]

Nonfunctioning PETs

Nonfunctioning PETs are endocrine tumors that originate in the pancreas and either do not secrete any peptide or their secreted products do not cause clinical symptoms. The symptoms that occur are due to the effects of the tumor per se.

Nonfunctioning PETs differ from the PETs in their clinical presentation, as their symptoms are entirely due to the tumor per se and not to the secreted products. [1], [6], [20], [28], [29] Nonfunctional PETs frequently release peptides which cause no clinical symptoms including chromogranin A (69% to 100%), chromogranin B (100%), pancreatic polypeptide (50% to 100%), a-hCG (40%), ß-hCG (20%), synaptophysin, and neuron-specific enolase; some release neurotensin. [1], [3], [20], [43], [45], [50] Immunocytochemically, these tumors often contain multiple peptides. [1], [38] In one study of 30 such tumors, [38] 50% had immunoreactivity for insulin, 30% for glucagon, 40% to 75% for PP, 13% for somatostatin, and 13% for none of these. Nonfunctional PETs are usually solitary, large tumors (72% >5 cm in one study [188]) and occur primarily in the pancreatic head (14 were in the head, two were in the body, and three were in the tail in one study [188]). Nonfunctioning PETs are frequently diagnosed after the patient presents with symptoms or signs of metastatic tumor in the liver (cachexia, abdominal pain, hepatomegaly) and a liver biopsy is performed which reveals metastatic endocrine tumor. [1], [20], [28], [29] Infusions of PP into animals has been shown to have numerous effects including inhibition of pancreatic secretion, a relaxant effect on the gallbladder, weak inhibition of pentagastrin-stimulated acid secretion, and various stimulating effects on gastrointestinal motility. [189] At present it is unclear why patients with PETs with very high plasma concentrations of PP do not have symptoms due to the increased PP per se. Typically the patient with a nonfunctioning PET is 40 to 60 years of age. [1], [20], [28], [29] They occur equally in men and women. [1], [28], [29], [188] Patients with nonfunctioning PETs frequently present with abdominal pain (36% to 56%), 28% to 40% with jaundice, 24% to 46% with weight loss, 8% to 40% with abdominal masses, and in 16% of the tumors were found incidentally at surgery in asymptomatic patients. [29], [188] In most series, [1], [28], [29], [190] but not all, [191], [192] more than 60% (range, 64%–92%) of patients with nonfunctioning PETs have metastatic disease at the time of diagnosis. [1], [20], [29], [188] The median delay in time from first symptoms to diagnosis varies from 0.5 to 2.7 years. [1]

Nonfunctioning PETs are usually not differentiated from any other malignant tumor of the pancreas prior to histological studies. [1], [20] In one series [28] the diagnosis of a nonfunctioning PET was not made in a single patient prior to surgery. Furthermore, 20% of the patients were asymptomatic and the tumors were found incidentally during other operative procedures. [28] Any patient with a long survival (>5 years) previously diagnosed as having metastatic pancreatic adenocarcinoma should be suspected of possibly having a nonfunctioning PET. An elevated plasma chromogranin A or B level (69% to 100%), PP (50% to 100%), a-hCG (40%), ß-hCG (20%), neuron-specific enolase (31%), or positive somatostatin receptor scintigraphy (SRS) is strong evidence to suggest that a pancreatic mass is a PET. [1], [3], [20], [45], [50], [193], [194] In 53 patients with adenocarcinoma of the pancreas, none had elevated plasma levels of PP. [20] However, elevated levels of PP do not establish the diagnosis of a PPoma even when a pancreatic mass is present because plasma PP levels are increased in 22% to 71% of patients with functional PETs [1], [41], [195], [196] as well as in nonpancreatic carcinoid tumors. In one study [196] plasma PP levels were greater than 1000 pg/mL in 32% of patients with gastrinomas, 21% with insulinomas, 57% with glucagonomas, 74% with VIPomas, 33% with somatostatinomas, and 45% with carcinoid tumors. Furthermore, plasma PP elevations can occur with renal failure, older age, postbowel resection, alcohol abuse, certain infections or inflammatory conditions, acute diarrhea, diabetes, pancreatitis, or with eating. [196] To improve the specificity an atropine suppression test has been proposed. [196] In a study of 48 patients with elevated plasma PP levels, atropine (1 mg IM) did not suppress the levels in any of 18 patients with PETs, but did suppress it in all patients without PETs. In another study of 28 pancreatic ductular cancers [193] none were positive with SRS whereas 65% of proven PETs were positive. Furthermore, 42% of long-term survivors of pancreatic adenocarcinoma (>3 years) were positive by SRS, suggesting they were really PETs that had been misdiagnosed. [193] In a study of 61 nonfunctional PETs, [192] 56 (92%) were well differentiated, 5 (8%) poorly differentiated, and 34 (56%) demonstrated metastases. The presence of vascular or perineural invasion, a K_i 67 proliferative index greater than 2%, a mitotic rate =2, size =4 cm, capsular penetration, nuclear atypia, lack of progesterone receptors, and presence of calcitonin all correlated with malignancy. [192] These factors had prognostic significance for survival. [192] At present there are no data that suggest that nonfunctioning PETs producing PP or other peptides differ in biologic behavior from tumors not producing these peptides. [190]

Other Tumors (Cushing Syndrome, etc.)

Cushing syndrome associated with a PET (ACTHoma) is usually [83], [164], [197], [198] and [199] recognized in patients with another symptomatic PET. In various studies 4% to 16% of all cases of ectopic Cushing syndrome were due to PETs secreting adrenocortico- tropic hormone (ACTH). [84] Cushing syndrome occurs in 19% of patients with MEN I with Zollinger-Ellison syndrome, is due to pituitary production of ACTH, and the disease in these patients is usually mild. [83] Cushing syndrome occurs in 4% to 5% of patients with sporadic Zollinger-Ellison syndrome. [8], [83], [197], [198] and [199] In patients with the sporadic form of Zollinger-Ellison syndrome, the symptoms of Cushing syndrome are severe, usually occur in patients with metastatic disease, and the Cushing syndrome is due to ectopic production of ACTH. [83], [198], [199] In one study [198] each patient with ectopic Cushing syndrome resulting from a PET had metastatic disease in the liver, although rare patients with nonmetastatic disease with Zollinger-Ellison syndrome with Cushing syndrome due to ACTH release by the gastrinoma are reported. [85] These patients usually respond poorly to chemotherapy. [83] In one prospective study [8] the development of Cushing syndrome in patients with gastrinomas was an independent predictor of poor survival, with patients living a mean of only 1.7 years after its onset. [83] The occurrence of Cushing syndrome only as a clinical manifestation of a PET is uncommon. [200]

Paraneoplastic hypercalcemia due to a PET releasing PTH-related peptide (PTHrP), a PTH-like immunoreactive material, or an unknown hypercalcemic substance has been reported rarely. [80], [81], [201], [202] In most, [80], [201], [202] and [203] but not all, [80], [117] cases describing paraneoplastic hypercalcemia with a PET [201], [202] and [203] the tumors are large and are metastatic to the liver at the time of diagnosis. In a review [80] of 23 cases of PETs associated with hypercalcemia, 30% occurred in patients with VIPomas. The tumors were generally large (7–18 cm) and in 7 of 8 patients PTHrP was demonstrated immunohistochemically. [80]

It has been proposed that there is a neurotensinoma syndrome associated with PETs. [20], [27], [43], [204], [205] and [206] Neurotensin is a 13-amino acid peptide first extracted from bovine brain and subsequently also isolated from the human gastrointestinal tract. [207] Neurotensin has a number of pharmacological effects including hypotension, tachycardia, cyanosis, stimulating pancreatic protein and bicarbonate secretion, affecting intestinal motility, and stimulating jejunal and ileal fluid and electrolyte secretion. [207] The clinical features of the patients described with neurotensinomas with PET include diarrhea with hypokalemia, weight loss, and in some cases diabetes, cyanosis, hypotension, and flushing. [20] In the six cases included in one review, [20] three were cured by tumor resection and three responded to streptozotocin treatment. [20], [27], [204], [205] and [206] Others [41], [204] have raised the question of whether a specific neurotensinoma syndrome actually exists. In one study [204] of 180 patients with functional PETs an elevated plasma neurotensin level was found in six patients with VIPomas and the clinical symptoms of those patients did not differ from those without an elevated plasma neurotensin level. In a second study, [41] 19% of patients with Zollinger-Ellison syndrome were found to have an elevated plasma neurotensin level and their symptoms did not differ from those without an elevated plasma neurotensin level, therefore it is not apparent that a distinct

neurotensinoma syndrome exists.

PETs causing the carcinoid syndrome can occur. [78], [79] These tumors are characteristically malignant (68% to 88%) and are large. [56], [78], [79] Pancreatic PETs [24] are foregut carcinoids which may lack dihydroxyphenylalanine (DOPA) decarboxylase, the enzyme that converts 5-hydroxytryptophan to serotonin (5-hydroxytryptomine); [24] however, 84% of patients with pancreatic PETs associated with the carcinoid syndrome have increased urinary 5-hydroxyindule acetic acid (5-HIAA) levels which can be used for their detection. [56]

TUMOR LOCALIZATION

The techniques used for tumor localization and the rationale for using various localization methods is similar for all the PETs. Tumor localization studies need to be undertaken for a number of reasons once the proper radioimmunoassays and functional studies establish the particular type of PET. For appropriate management of the patient the tumor's location and extent must be established. [208], [209] The only possible long-term cure of these syndromes is by surgical excision. To establish whether the tumor is potentially resectable, tumor localization studies are essential. In all cases except insulinoma, the majority, if not all of these tumors if followed long enough, may be malignant, and therefore if metastatic spread is not present at the time of diagnosis, an attempt should be made to surgically cure these patients. Gastrinomas and insulinomas frequently present as small tumors. [42], [52], [210] Up to 50% of PETs that occur frequently extrapancreatically, such as gastrinomas, [12], [42], [210], [211] and 10% to 20% of PETs that occur almost entirely within the pancreas, such as insulinomas, [51], [95] are not found at surgery. Therefore, detailed localization studies may help the surgeon in finding the tumor. The tumor can also be multiple with multifocal tumors reported to occur in 10% of insulinomas [51], [98] and up to 50% of some PETs such as gastrinomas. [12], [211] Furthermore, except for insulinoma, the other PETs are frequently diagnosed only after metastatic spread to the liver has occurred. [12], [16], [17], [20], [23], [51], [75], [141] To determine whether treatment should be started for the metastatic disease and to assess the results of such treatment, tumor localization methods are essential. [2], [12], [212], [213] and [214]

Abdominal ultrasound, [2], [12], [208], [215], [216], [217], [218], [219] and [220] computed tomography (CT scan) (Fig. 97-3, Fig. 97-4, Fig. 97-8, Fig. 97-9), [2], [12], [208], [215], [216], [217] and [218], [220], [221], [222], [223], [224] and [225] selective abdominal angiography (Fig. 97-5, Fig. 97-6), [2], [12], [208], [218], [220], [223], [226] magnetic resonance imaging (MRI) (see Fig. 97-4, Fig. 97-7), [2], [208], [215], [216], [225], [227], [228] radiolabeled SRS (Fig. 97-7, Fig. 97-8), [215], [221], [229], [230], [231], [232], [233], [234] and [235] endoscopic ultrasound (see Fig. 97-9), [215], [221], [222], [235], [236], [237], [238] and [239] selective venous sampling for hormones from portal venous tributaries using a transhepatic approach (i.e., portal venous sampling, PVS) (Fig. 97-10), [12], [140], [240], [241], [242] and [243] hepatic venous sampling for hormones after intraarterial injection of secretin (gastrinomas) or calcium (insulinomas) (see Fig. 97-10), [243], [244] and [245] and intraoperative ultrasonography (Fig. 97-11) [216], [228], [246], [247] have all been reported to be useful for localizing PETs.

FIGURE 97-3. Computed tomographic (CT) scan in a patient with an insulinoma. The insulinoma is in the pancreatic tail (*arrow*). The splenic vein courses around the tumor. The CT scan with intravenous contrast will localize 17% to 40% of insulinomas.

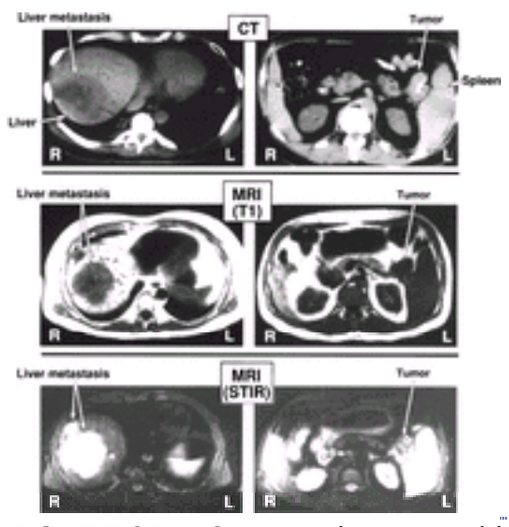

FIGURE 97-4. Computed tomographic (CT) scan (**top panels**), magnetic resonance imaging (MRI) T-1 weighted image (**middle panels**), and a short inversion time-inversion recovery (STIR) MRI (**bottom panels**) in a patient with a pancreatic endocrine tumor (PET) metastatic to the liver producing parathyroid hormone-related peptide (PTHrP) causing hypercalcemia. In the left panels the CT scan (**top**) demonstrates a solitary, large metastasis in the right lobe of the liver (*arrow*) which is not well outlined and on the T-1 (**middle**) and the STIR (**bottom**) MRIs two metastases are clearly seen (*arrow*) in the right lobe of the liver. In the **right panels** more caudal views show the primary tumor in the pancreatic tail. The CT scan (**top, right**) demonstrates clearly the 4-cm pancreatic tail tumor with central calcification, whereas it is less well seen on the MRI T-1 (**middle**) and STIR images (**right**). This figure demonstrates that metastases from PETs are often much more easily identified on MRI, especially the STIR images, because the tumor has a characteristically bright appearance. [12], [364] In contrast the primary tumor is frequently seen better on the CT scan.

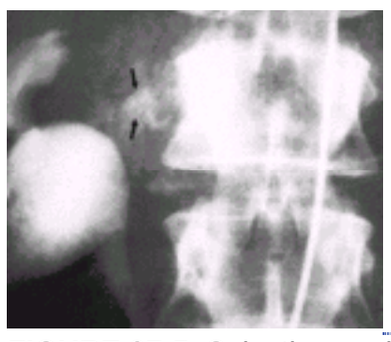

FIGURE 97-5. Selective angiographic localization of the pancreatic endocrine tumor (PET) in a patient with insulinoma. The insulinoma (1 cm) is localized in the pancreatic head by a selective celiac artery injection. Insulinomas, as other PETs, are characteristically hypervascular as demonstrated in the insulinoma in this patient. Because of this hypervascularity even small pancreatic primary lesions are frequently only seen on angiography. Angiography localizes 60% of insulinomas and 68% of the primary tumors in other PET syndromes.

FIGURE 97-6. Selective common hepatic artery injection in a patient with metastatic insulinoma. The primary insulinoma is in the pancreatic head (*double arrows*) and two hepatic metastases are located in the liver (*small arrows*). Tumors are malignant in only 10% to 15% of patients with insulinomas, whereas in other pancreatic endocrine tumors (PETs) the majority are malignant. For the conventional localization methods (ultrasound, computed tomography scan, magnetic resonance imaging [MRI], angiography), angiography and MRI are the most sensitive modalities for localizing liver metastases (see Table 97-6). (Courtesy of Dr. Jeffrey A. Norton, University of California, San Francisco.)

TABLE 97-6 Studies Assessing the Ability of Various Modalities to Localize Insulinomas and Other Pancreatic Endocrine Tumors

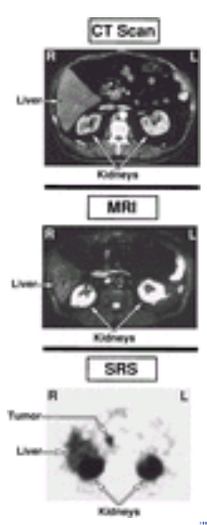

FIGURE 97-7. Comparison of the ability of computed tomography (CT) scan, magnetic resonance imaging (MRI), and somatostatin receptor scintigraphy (SRS) to localize a pancreatic endocrine tumor (PET). This patient previously had a duodenal PET secreting chromogranin A and gastrin resected and underwent reexamination when the serum chromogranin A level increased 1-year postresection. Neither the CT scan (**top**) nor the MRI (**middle**) demonstrated a lesion, whereas the SRS demonstrated a tumor in the pancreatic head area. At surgery a 1.5-cm pancreatic head lymph node containing tumor was found and resected. This study demonstrates the greater sensitivity of SRS for localizing all noninsulinoma PETs [169], [230], [231], [232] and [233] and why it is now the initial imaging study of choice in these patients.

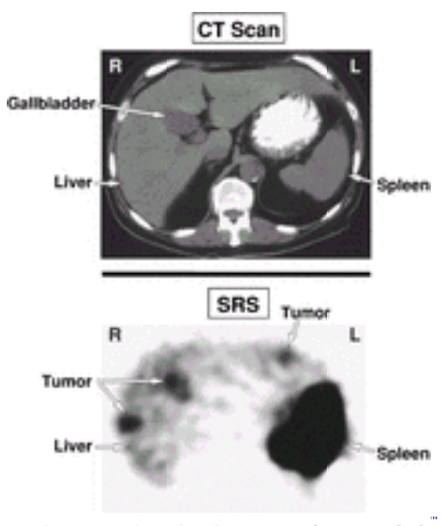

FIGURE 97-8. Comparison of the ability of computed tomography (CT) scan and somatostatin receptor scintigraphy (SRS) to localize metastatic pancreatic endocrine tumor (PET). This patient had right upper quadrant pain with an elevated serum chromogranin level and gastrin level. The CT scan (**top**), magnetic resonance imaging, ultrasound, and angiography were negative; however, the SRS (**bottom**) showed three liver metastases. A percutaneous biopsy demonstrated metastatic PET. This study demonstrates the greater sensitivity of SRS for detecting metastatic disease, both in the liver and other distant sites, in patients with malignant PETs. [169], [230], [231], [232] and [233], [251], [255], [258]

FIGURE 97-9. Endoscopic ultrasound of a patient with an insulinoma. This image of the head of the pancreas was taken using a 12-MHz probe at the level of the duodenal bulb. It shows a 1.3 × 0.7 cm sharply demarcated relatively hypoechoic nodule (*arrow*) which was an insulinoma that was later enucleated at surgery. The splenic vein is seen below the tumor in the 5 o'clock position. The patient was a 29-year-old woman with clinical history and laboratory values diagnostic of insulinoma, but with negative dynamic computed tomography and selective angiography studies. This result shows the sensitivity of endoscopic ultrasound for localizing even small, intrapancreatic endocrine tumors. (Courtesy of Dr. Charles J. Lightdale, Director of Clinical Gastroenterology, Columbia-Presbyterian Medical Center, New York, NY.)

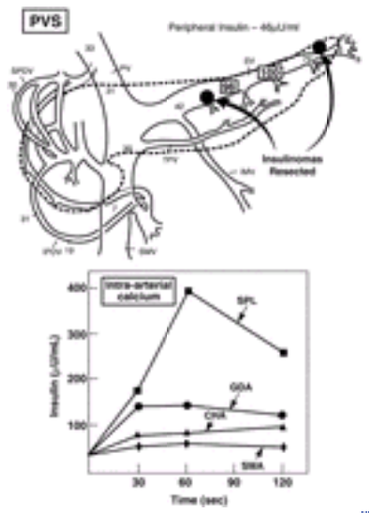

FIGURE 97-10. Functional location of an insulinoma by selective venous sampling for insulin concentrations in portal venous tributaries (**top**) or by selective hepatic venous sampling for insulin concentrations after selective intraarterial calcium injections (**bottom**) in a patient with multiple insulinomas in the setting of multiple endocrine neoplasia type I (MEN I). In the **top panel** a sampling catheter was passed across the liver and venous samples obtained from the indicated locations and simultaneous peripheral venous samples were obtained which were assayed for insulin concentration. The step-up to 100 μU/mL is seen in the midsplenic vein, suggesting a tumor in the pancreatic body or tail. (Abbreviations: *PV,* portal vein; *SMV,* superior mesenteric vein; *SPDV,* superior pancreaticoduodenal vein; *IPDV,* inferior pancreaticoduodenal vein; *IMV,* inferior mesenteric vein; *TPV,* transverse pancreatic vein; *SV,* splenic vein.) In the **bottom panel** calcium gluconate (0.01 mEq Ca^{2+}/kg) [244] was selectively injected into the indicated arteries and hepatic venous samples obtained prior to injection and at 30, 60, and 120 seconds postinjection and analyzed for insulin concentration. There was a marked increase after the splenic artery injection (*SPL*), whereas after injection into the gastroduodenal artery (*GDA*), common hepatic artery (*CHA*), and superior mesenteric artery (*SMA*) there was a much smaller increase. Two insulinomas were found at surgery (see location by *arrows* in **top panel**) in the pancreatic body and tail, which is in the area localized by the portal venous sampling (PVS) as well as the area supplied by the splenic artery. The intraarterial calcium method is more sensitive than PVS [243], [244] and has the advantage of requiring less expertise, can be done at the time of angiography, and therefore, a separate procedure is not required. In some studies [244] the intraarterial calcium is the most sensitive modality for localizing small insulinomas. [Courtesy of Dr. John Doppman, NIH.]

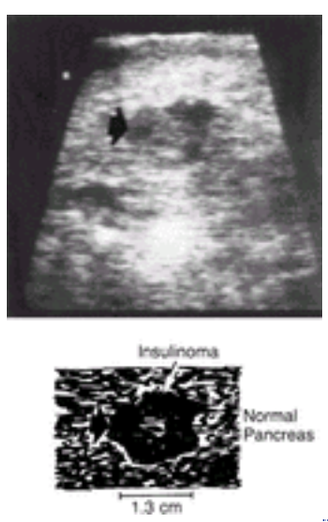

FIGURE 97-11. Intraoperative ultrasound localization of an insulinoma. **Top:** An intraoperative ultrasound image of an insulinoma (*arrow*). The image was taken with a 10-MHz transducer. **Bottom:** A drawing of the ultrasound image showing a tumor (*arrow*). A 1.3-cm, nonpalpable insulinoma was found at surgery in the pancreatic head. Studies [216], [228] demonstrate intraoperative ultrasound will localize 88% of insulinomas. In this patient the use of intraoperative ultrasound guided the successful enucleation of this tumor which could not be identified at surgery by any other means. (Courtesy of Dr. Jeffrey A. Norton, University of California, San Francisco.)

Small PETs (<1 cm) have been the most difficult to localize. The ability of conventional imaging studies (ultrasound, CT scanning, MRI scanning, and selective angiography) to image a PET have been shown to be dependent on the size of the tumor. [224], [226], [227] and [228] For example, using any of the imaging modalities (ultrasound, CT scanning, selective angiography, or MRI) less than 10% of tumors smaller than 1 cm, 30% to 40% of tumors 1 to 3 cm, and 70% to 80% of tumors larger than 3 cm were detected. [12], [248] Therefore most VIPomas, glucagonomas, and somatostatinomas which are usually clinically suspected only when the tumor is large (frequently >4 cm), will be detected. One study demonstrates that small PETs (gastrinomas) (<1 cm) also were less frequently detected than large tumors by SRS. [231] Table 97-6 summarizes the results of studies on the ability of the various modalities to localize insulinomas which are characteristically small (<1 cm), as are most duodenal gastrinomas at the time of clinical presentation compared to other PETs which are frequently larger. [15], [16], [17] and [18], [23], [70], [195] The results with insulinomas are presented separately, not only because of their smaller size at presentation, but also because they are almost exclusively within the pancreas, whereas gastrinomas, VIPomas (in children), and somatostatinomas can frequently be extrapancreatic. [16], [17], [23], [52], [69], [231], [249] Ultrasound, CT scanning (see Fig. 97-3), and MRI (10% to 30%) are relatively insensitive, whereas selective abdominal angiography 60% (see Fig. 97-5, Fig. 97-6), selective PVS for insulin 80% (see Fig. 97-10), intraoperative ultrasound 89% (see Fig. 97-11), endoscopic ultrasound 82% (see Fig. 97-9), and hepatic venous sampling for insulin after calcium injection 94% (see Fig. 97-10) are sensitive methods to localize insulinomas. Insulinomas differ from other PETs in that they possess a low density of somatostatin receptors that bind octreotide with high affinity (subtypes 2 and 5, sst_2, sst_5). This makes SRS much less sensitive in localizing insulinomas (i.e., 25%, see Table 97-6). [209], [232], [233] Results for localization of other PETs except insulinomas are listed in Table 97-6 and compared to the values for insulinomas. These results are primarily based on studies of gastrinomas because the other PETs are uncommon, and frequently the patients with these tumors present with advanced metastatic disease so that routine surgical exploration is not performed.

Similar localization data involving large numbers of patients are not available with other PETs within the pancreas. However, because VIPomas, GRFomas, and

glucagonomas are almost entirely intrapancreatic it is likely that similar results to those for insulinomas of similar size will be obtained except for the SRS, which will be higher in these tumors. For somatostatinomas, which are frequently extrapancreatic, it is likely that results similar to those obtained with gastrinomas will be found. Ultrasound and MRI are relatively insensitive at localizing noninsulinoma PET primaries (24% to 25%); however, CT localizes 50%, angiography finds 68%, [12], [208], [226] selective venous sampling for gastrin 70%, [208], [240], [243] intraoperative ultrasound 91%, [208], [216], [246] endoscopic ultrasound 70%, [208], [236] and SRS 70%. [215], [230], [234], [235], [250], [251]

All PETs are hypervascular and therefore angiography is frequently the most sensitive conventional imaging modality. [208], [226], [230] Figure 97-5 and Figure 97-6 show the typical hypervascular appearance of both a primary PET (insulinoma) (see Fig. 97-5) and hepatic metastases from a malignant insulinoma (see Fig. 97-6).

Two newer localization methods that are being increasingly used in patients with PETs are SRS and endoscopic ultrasonography (see Table 97-6). PETs, in addition to a number of other neuroendocrine tumors (carcinoids, medullary thyroid cancer, pituitary adenomas, small cell lung cancer, paragangliomas) and other nonendocrine tumors (lymphomas [Hodgkin's disease, non-Hodgkin's lymphoma], central nervous system tumors [meningiomas, astrocytomas], breast cancer, prostate cancer) and granulomatosis diseases (sarcoidosis, tuberculosis, Wegener's granulomatosis), frequently possess high densities of somatostatin receptors which can be used for localization studies with radiolabeled somatostatin analogs. [169], [232], [233] For SRS, both [^{111}In-DTPA-DPhe [1]]octreotide and [iodine 123 (^{123}I)-Tyr [3]]octreotide have been used [169], [233] and in the United States the former agent is now increasingly used for tumor localization studies. [^{111}In-DTPA-DPhe [1]]octreotide has the advantage over [^{123}I-Tyr [3]]octreotide in that it is primarily excreted in urine instead of bile, allowing better visualization of right upper quadrant masses; has a larger half-life (2.8 days vs. 13.2 hours) allowing longer scanning time and is easier to label. [169], [233], [252] In vitro autoradiographic studies demonstrate 100% of gastrinomas, glucagonomas, nonfunctional PETs, 61% to 67% of insulinomas, 88% to 96% of carcinoids, and 0% of pancreatic adenocarcinomas bind radiolabeled octreotide. [230], [232], [233] Cloning studies demonstrate that there are five subtypes of somatostatin receptors and that radiolabeled octreotide binds with high affinity with somatostatin receptor subtypes 2 and 5 to subtype 3 with intermediate affinity and to subtypes 1 and 4 with low affinities. [169], [253] The overexpression of somatostatin receptors seen on autoradiography in PETs is consistent with the results of SRS in various studies. SRS visualizes a tumor in 87% to 96% of patients with a carcinoid tumor, 73% to 100% with a gastrinoma, 46% to 61% with an insulinoma, 82% to 89% with a nonfunctional PET, 100% with a glucagonoma, and 50% to 80% with a VIPoma in two reviews consisting of 477 patients. [232], [233] In a comparative study [230] of conventional modalities and SRS in 80 patients with gastrinomas, SRS identified a possible primary tumor in 58% and was superior ($P < 0.001$) to angiography (28%), MRI (30%), CT scan (31%), or ultrasound (9%). It was equal to the combination of all conventional imaging studies combined (48%). Furthermore, SRS [230] only identified a primary tumor in 20% of patients. Another study [231] confirms the greater sensitivity of SRS over conventional imaging studies, but it demonstrates that SRS can also frequently miss (>50%) PETs under 1 cm in diameter. The former study [230] concluded that SRS was now the imaging study of choice to localize noninsulinoma PETs. Figure 97-7 demonstrates the increased sensitivity of SRS over the CT scan or MRI in detecting tumor recurrence in a lymph node in a patient with a malignant PET. A number of additional studies have compared the ability of SRS and other imaging studies to localize tumors in patients with insulinomas [215], [221], [222], [238] and other PETs. [215], [230], [234], [235], [238], [254] In these studies SRS localized an insulinoma in 10% of patients and a gastrinoma in 71% to 81% of patients, whereas CT scan, ultrasound, and MRI detected 20% of insulinomas and a primary tumor in 38% of patients with other PETs.

Three studies [251], [255], [256] and [257] have examined the ability of SRS to alter clinical management in patients with PETs, which is the most important test of its potential use. In one study [255] involving 40 patients with gastroenteropancreatic tumors, SRS altered clinical management in 28% of patients; in the other two studies [251], [256] involving 122 and 85 patients, it altered management in 47% and 24%, respectively, of cases. SRS altered management primarily by clarifying equivocal lesions seen on conventional imaging studies, being the only modality to identify liver metastases, a primary tumor, or distant metastases which altered management. [251], [255], [256] and [257] One particularly important category of clarifying lesions was in regard to small hemangiomas of the liver (<2 cm). [258] These have a prevalence of 7.3% to 15% in autopsy studies, appear indistinguishable from small liver metastases from PETs on MRI or angiography, and cannot be distinguished easily by red blood cell (RBC) scanning or any imaging modality. [258] In one study [258] SRS was positive in 93% of patients with small liver metastases (mean 1.3 cm) from PETs and negative in all small hepatic hemangiomas (mean 1.3 cm). SRS had a significantly better sensitivity, accuracy, and positive and negative predictive value than any other modality for identifying the liver metastases (see Fig. 97-8). [258]

Numerous studies demonstrate that endoscopic ultrasound (EUS) is a sensitive method to detect PETs, especially if intrapancreatic (see Fig. 97-9). [215], [221], [222], [235], [237], [238] and [239] In ten different studies, endoscopic ultrasound localized an insulinoma in 57% to 92% of patients, [215], [221], [222], [236], [239] and was almost equally sensitive to calcium provocative testing (i.e., 88%), [239] whereas CT scan only localized a tumor in 0% to 20%, and SRS in 12% to 14%. Similarly, EUS localized a gastrinoma overall in 40% to 100% of patients, [239] a pancreatic gastrinoma in 75% to 100% of cases in four studies, [215], [222], [237] but a duodenal gastrinoma in 0% to 67% in four studies. [215], [235], [237], [238] Therefore, EUS was particularly sensitive for localizing PETs within the pancreas and with insulinomas is more sensitive than SRS, whereas with other PETs in the pancreas it is at least equal in sensitivity to SRS. [215], [221], [239] Figure 97-9 shows the ability of EUS to localize an insulinoma in a patient. EUS requires considerable expertise to obtain optimum results, whereas SRS can be performed in most radiology departments. However, to obtain optimum results with SRS, single photon emission computed tomography (SPECT) scanning is needed. [232], [234] Some studies suggest SRS in combination with EUS in patients with gastrinomas is more sensitive than either alone. [235], [259] Neither the EUS nor the SRS localize many small extrapancreatic PETs, especially duodenal gastrinomas. [210], [231], [234], [235] SRS has the advantage over EUS of allowing total body at one time, therefore it is especially useful for identifying distant metastases. With both EUS and SRS false-positive results can be obtained; however, the exact rate is not well defined. SRS can be positive in thyroid disorders, breast disease, lymphomas, granulomatosis diseases (sarcoid, tuberculosis, etc.) due to gallbladder filling, wound infections, accessory spleen, various arthritides, and other neuroendocrine tumors besides PETs, such as gastric carcinoids. [169], [233], [260], [261] In a prospective study, [261] SRS had a false-positive rate of 12% for localizing a gastrinoma; however, when the clinical context was carefully considered, the percentage in which false-positive SRS results altered clinical management was 3%. There are no comparable studies on the false-positive rate of EUS for small PETs, especially those that are extrapancreatic in location.

For metastatic disease to the liver, SRS is more sensitive than conventional imaging studies (see Table 97-6). [169], [230], [234], [251], [255], [258] This is shown in Figure 97-8 for a patient presenting with right upper quadrant pain with an elevated serum chromogranin level but normal CT scan (see Fig. 97-8) as well as other conventional imaging (MRI, angiography, ultrasound). The SRS demonstrated three liver metastases that were proven to be metastatic PETs. In a comparative study [230] of 24 patients with proven hepatic metastases and gastrinomas, SRS was positive in 92% of the patients which was significantly better than ultrasound (46%), CT scanning (42%), angiography (62%), and was equal to MRI (71%). The combination of all conventional imaging studies was equal to SRS alone (83% vs. 92%, respectively).

Functional localization by venous sampling for hormonal gradients from various portal venous sites or peripheral veins has been used for both insulinomas and other PETs (see Fig. 97-10). [12], [140], [240], [241], [242] and [243] This procedure requires considerable expertise and was associated with complications in 20% of the patients in one large study. [241] A simplified method has been developed that has replaced direct venous sampling from portal venous tributaries and does not require a transhepatic catheterization. Studies [210], [245], [262] demonstrated that gastrinomas can be functionally localized by measuring hepatic venous samples for gastrin gradients after selective intraarterial injection of secretin. This method was more sensitive than PVS, required less expertise, and had lower morbidity. A similar procedure has been developed for localizing insulinomas [244], [263] using calcium gluconate (0.01–0.025 mEq Ca^{2+}/kg). In one comparative study [244] in patients with insulinomas the intraarterial study with selective hepatic venous sampling for insulin levels was positive in 88% of the patients, ultrasound in 9%, CT scan in 17%, MRI in 43%, angiography in 36%, and PVS in 67%. Calcium infusions may also stimulate the release of hormones from other PETs, so this approach may be useful in these tumors. [264], [265] and [266] A typical result is shown in Figure 97-10 where a much larger increase in insulin concentration in the hepatic vein is seen after the splenic arterial injection; at surgery insulinomas were found in the pancreatic tail in the area supplied by this artery.

Intraoperative ultrasound can be a valuable aid in localizing PETs at the time of surgery (Fig. 97-11). [216], [228], [246], [247] Intraoperative ultrasound is particularly useful for localizing small intrapancreatic PETs, but is less sensitive for extrapancreatic tumor. [216], [246] Intraoperative ultrasound may also suggest whether the PET is malignant, define the proximity of a PET to the pancreatic duct, and further define the anatomy of a nodule palpated at surgery. [216], [228], [246], [247] The use of intraoperative ultrasound at surgery will be discussed further in the treatment section under "Surgical."

Bone metastases have been described in patients with advanced PETs. [54] In a one study [54] of 115 patients with gastrinomas, bone scanning, MRI of the spine, and SRS were compared in their ability to identify bone metastases. Eight patients (7%) were shown to have bone metastases and SRS and MRI had the highest sensitivity and specificity. [54] Bone scanning [54] had a low specificity and was less sensitive than SRS or MRI of the spine. Bone metastases occurred in 31% of the patients with liver metastases, only occurred in patients with liver metastases, were usually in the axial skeleton initially, and their detection changed management in all cases. [54] Figure 97-12 shows an example of the ability of SRS to image the entire skeleton at one time and localize bone metastases in a patient with a malignant

PET. In this patient (see Fig. 97-12) SRS detected more spinal metastases than MRI, demonstrating its high sensitivity.

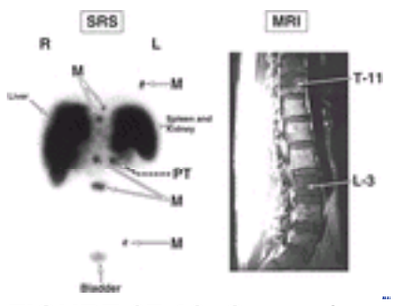

FIGURE 97-12. Comparison of the ability of somatostatin receptor scintigraphy (SRS) and magnetic resonance imaging (MRI) to localize bone metastases in a patient with a malignant pancreatic tail pancreatic endocrine tumor (PET) secreting glucagon and gastrin. In this patient with back pain, MRI demonstrated T-11 and L-3 metastases (**right panel,** *arrows*) whereas SRS (**left panel**) demonstrated numerous metastases (*M*) in the thoracic and lumbar spine, ribs, and right pelvis. The primary tumor (*PT*) is shown on SRS (*broad dotted arrow*). This patient's results show the high sensitivity of SRS for localizing bone metastases and its ability to allow a complete body scan at one time.

Figure 97-13 summarizes the currently recommended approach to a patient with a PET that is not an insulinoma. In such a patient both the location of the primary tumor and possible occurrence of liver or distant metastases need to be assessed. Because of its increased sensitivity and ability to image the entire body in one study, the SRS is recommended as the initial study with SPECT imaging. If the SRS is positive for liver metastases, the extent and number of lobes need to be established to determine whether surgical resection of all tumor that can imaged is possible as discussed in the next section, "Treatment." If diffuse metastases are present, a CT or ultrasound-guided percutaneous liver biopsy should be done (see Fig. 97-13). Because it is difficult to evaluate increases in tumor size by SRS, an MRI or CT scan should be performed to evaluate changes in the size of liver metastases with time. [212] If no metastases are present and no primary tumor is seen, endoscopic ultrasound should be performed by an experienced endoscopist. If a primary tumor is still not seen, a selective angiogram should be performed and the use of intraarterial calcium with determination of hepatic venous hormonal gradients considered (see Fig. 97-10, Fig. 97-13).

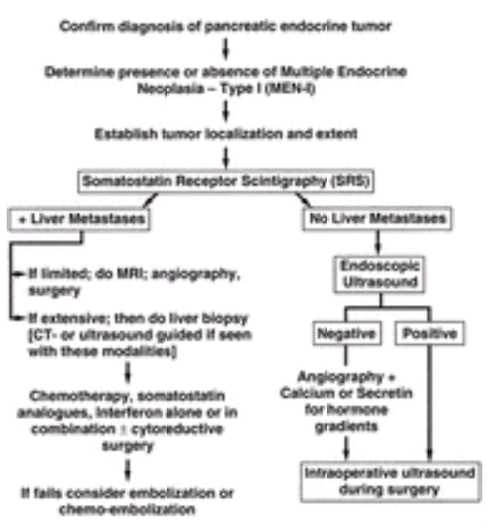

FIGURE 97-13. Algorithm summarizing the approach to tumor localization in a patient with a pancreatic endocrine tumor (PET) that is not an insulinoma. Because of its increased sensitivity for detecting the primary and metastatic disease both in the liver and distant sites [169, 230, 233, 251, 255] and its ability to cover all body areas in one study, somatostatin receptor scintigraphy (SRS) with single photon emission computed tomography (SPECT) imaging is the initial localization method of choice. SRS will localize greater than 90% of patients with liver metastases. [169, 230, 233, 251, 255] If no liver metastases are seen, endoscopic ultrasound (EUS) is the most sensitive method to localize the pancreatic primary. [236, 259] If the EUS is negative, selective angiography with intraarterial injection of calcium (insulinoma, somatostatinoma, glucagonoma) and sampling of hormonal levels in hepatic venous samples should be done. At surgery intraoperative ultrasound should always be used because it will identify lesions not seen by other methods. [216] Up to 15% of patients with metastatic disease in the liver may have resectable disease and should be considered for surgery. [213, 214, 272, 276]

TREATMENT

All patients with functioning PETs have two problems that are interrelated but often have to be dealt with separately. Acutely the symptoms due to the hormone excess state must be controlled, and ultimately the tumor itself must be dealt with. Although excision of the PET would solve both clinical problems, this is frequently not possible either because there is metastatic disease at the time of diagnosis, the primary PET cannot be found at surgery, or curative resection is not achieved. Furthermore, the clinical condition of the patient may have deteriorated because of complications of the hormone excess state necessitating treatment prior to surgery. [2, 247]

Even with the increased ability to control the symptoms of the hormone excess state with various medical therapies, a number of factors suggest that all patients with PETs should be considered for possible surgical resection of the tumor. First, even though only 5% to 15% of insulinomas are reported as malignant, with the other PETs at least 50% are malignant and in many reports this percentage of patients or higher have metastases at the time of diagnosis. [2, 267] For example, in various studies up to 90% of all gastrinomas, [12, 42, 268] 90% to 100% of nonfunctional PETs, [1, 28, 269, 270] 82% of glucagonomas, [13] and 50% to 60% of VIPomas [18, 19] were malignant. Furthermore, although in some studies large tumors are more likely to be malignant, [7, 8, 51, 53, 271] metastases occasionally occur with small tumors; therefore, the fact that no tumor is found on the initial imaging studies or that the tumor is small does not establish that metastatic disease will not occur. Although a number of patients with metastatic glucagonomas, [51, 72, 141] gastrinomas, [7, 8, 12, 53] and somatostatinomas [13, 21, 75] have been reported to have long-term survivals, recent detailed studies with PETs, such as gastrinoma in which there has been very effective therapy for the gastric hypersecretion for a more than 15 years, suggest that long-term prognosis is much worse in patients with advanced disease than originally thought. [7, 8, 12, 72, 271, 272] Results from the study primarily of patients with gastrinomas have provided a number of insights into prognostic factors and determinants of survival in these patients which are likely also important with other less common PETs because of their similar biologic behavior, histopathology, growth patterns, and metastatic pattern (Table 97-7). [7, 8, 42, 53, 212, 271] These studies demonstrate that various PETs in different patients frequently grow at very different rates. [7, 8, 17, 53, 212, 271, 273] In approximately 75% of patients with gastrinomas the tumor demonstrated either no growth or indolent growth and in 25% it demonstrates aggressive growth. [8, 53] Furthermore, even in patients with liver metastases, aggressive growth occurred in less than 50%, however, all the deaths occurred in this subgroup of patients. [212]

I. Clinical Features	
	Female gender
	Absence of MEN-1 syndrome
II. Laboratory Features	
	Increased chromogranin A in some studies
	Increased gastrin level in gastrinomas
	Lack of progesterone receptors
III. Tumor Extent/Size	
	Presence of liver metastases
	Increased extent of liver metastases
	Presence of lymph node metastases
	Presence of bone metastases
	Primary tumor site
	Primary tumor size (≥3 cm—worse prognosis)
IV. Tumor Behavior	
	Growth of liver metastases
	Incomplete tumor resection
	Nonfunctional tumor
	Development of ectopic Cushing syndrome
	Increased depth of tumor invasion
V. Histological Features	
	High nuclear atypia
	Poor tumor differentiation
	High growth indices [high K_i 67 index (>2%), Proliferating cell nuclear antigen expression]
	Capsular invasion
	Vascular or perineural invasion
VI. Other	
	Flow cytometric features (i.e., aneuploidy)
	Ha-Ras oncogene or *p53* overexpression

Data are from refs. 7, 8, 53, 169, 192, 271, 274.

TABLE 97-7 Prognostic Factors in Pancreatic Endocrine Tumors for Decreased Survival

The presence or absence of liver metastases either initially, or the development of liver metastases during follow-up, is the single most important prognostic factor (Fig. 97-14). [8] , [17] , [53] , [271] For example, in one study [8] the 15-year survival in patients with liver metastases present during initial assessment was 26%, whereas in patients without liver metastases it was 96%. The extent of liver metastases (one lobe, two lobes, diffuse) (see Fig. 97-14), presence of lymph node metastases, bone metastases, a large primary tumor size, primary location (pancreatic worse prognosis than duodenal gastrinoma), various histological features, tumor marker levels (chromogranin A, specific hormone such as gastrin level), and flow cytometric features are all important prognostic factors (see Table 97-7, Fig. 97-14). [2] , [7] , [8] , [53] , [169] , [192] , [271] , [274] Studies demonstrate that survival is directly related to tumor extent. In patients with primary tumors so small that no tumor was found at the time of surgery, the 5- or 10-year survival was 90% to 100%. [12] , [72] , [272] In patients with complete tumor resection the 5- or 10-year survival was also 90% to 100%. In patients whose tumors are incompletely resected or who have developed a recurrence postoperatively, the 5-year survival varied from 14% to 76% and 10-year survival was 20%. In patients with unresectable PETs, such as gastrinomas metastatic to the liver, the 5-year survival varied from 20% to 75% and the 10-year survival in one study was 30% (see Fig. 97-14). [12] , [72] , [272] These data suggest that once metastatic disease occurs the prognosis is significantly decreased. An important study [275] demonstrated for the first time that resection of the primary tumor (i.e., gastrinomas) significantly decreases the rate of development of liver metastases. In this study [275] survival was also almost significantly improved ($P = 0.08$). Furthermore, because therapy for advanced disease is in many cases only partially effective, [2] , [12] , [211] , [213] it is important to attempt to resect the PET while still localized. Unlike gastrinoma, the long-term medical therapy of the other various PETs is not well established and it is not known what percentage of patients will not respond to medical treatment. Therefore, in functional PET syndromes not including gastrinomas, cytoreductive surgery may be helpful because it may improve symptom control. [141] , [213] , [214] , [276] , [277] Lastly, the long-term toxicity of most medical therapies except for gastrinomas is not well established.

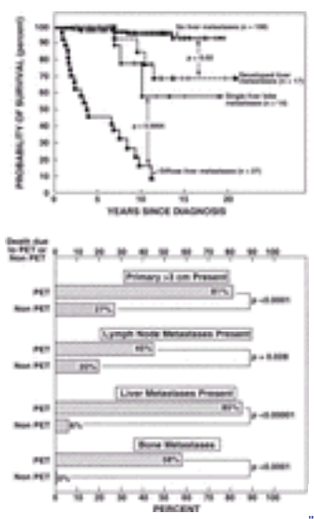

FIGURE 97-14. Effect of the extent or development of liver metastases from a pancreatic endocrine tumor (PET) (**top panel**), presence or absence of lymph node or bone metastases or PET primary size on disease-related survival. In the bottom panel, the percentages of patients with a PET-related (n = 33) or non–PET-related (n = 34) death with the indicated tumor size or metastases are shown. Data are from 158 patients and are modified from refs. [8] (**top**) and 42 (**bottom**). These results demonstrate that the presence of liver, bone, or lymph node metastases, a large primary PET size, and increased extent of liver metastases are all important predictors of a tumor-related death.

Nonmetastatic Disease

Medical Treatment

General considerations. The initial management of patients with insulinomas and the long-term management of those patients with insulinomas who are not surgically cured, is directed at controlling the hypoglycemia. The simplest form of nonsurgical control is dietary management. Frequent small meals may alleviate symptoms. [70] , [98] In severe cases intravenous glucose combined with various drug therapies may be required. In general, 10% dextrose should be avoided because of the electrolyte imbalances generated by the combination of elevated serum concentrations of glucose and hyperinsulinemia. [98] Some investigators have used slowly absorbed nutrients to maintain normal blood sugars prior to surgery. This may be preferable to diazoxide because of reports of sudden hypotension in some patients receiving diazoxide prior to surgery. [278] However, diazoxide (150–800 mg/d) has been used successfully to manage patients with insulinoma prior to surgery as well as in long-term treatment. [70] , [98] , [279] Diazoxide is a benzothiadiazide that has a plasma half-life of 28 hours and a peak hyperglycemic effect 12 hours after an oral dose or 4 hours after an intravenous dose. Its hyperglycemic action is attributed to directly inhibiting insulin release by adrenergic stimulation and by enhancing glycogenolysis. [51] , [70] The main side effects of diazoxide are sodium retention (47%) gastrointestinal symptoms such as nausea, and occasionally, hirsutism. [51] , [70] , [98] , [279] Sodium retention can be minimized by administration of diazoxide with a diuretic and restricting sodium intake. The gastrointestinal side effects can be decreased by taking the drug with meals. [51] , [98] Diazoxide is primarily excreted by the kidneys and is known to displace various protein bound drugs and increase their free concentrations in the serum. [98] Diazoxide therapy should be initiated with low doses and increased to a maximum of 600 to 800 mg/day in two or three divided doses as tolerated or until symptoms are controlled. In general approximately 50% to 60% of patients will respond. [51] , [70] , [98] , [279] , [280] Patients have been treated for up to 22 years with diazoxide, [279] demonstrating it can be effective long term. The calcium channel blocker verapamil [70] , [281] , [282] and diphenylhydantoin [283] have also been used to control hypoglycemia, with some success in some patients when diazoxide has failed. The long-acting somatostatin analog, octreotide (Sandostatin) has been shown to be effective in 36% of patients for the acute and long-term control of hypoglycemia in patients with insulinoma. [27] , [116] , [153] , [169] This will be discussed further in the next section. In the initial management of patients with VIPomas the most important issue is to replace the large volumes of fluid and electrolytes lost, and correct the hypokalemia and acidosis [18] , [19] This is particularly important because acutely a common cause of death in these patients is renal failure associated with hypokalemia and hypokalemic nephropathy. [18] Drug therapy previously included the use of high doses of prednisone (60–100 mg/d) [18] which decreased diarrhea in 40% to 50% of patients, [18] , [18] and clonidine, [284] angiotensin II, [285] norepinephrine, [285] , [286] indomethacin, [287] , [288] lithium carbo-nate, [289] phenothiazines, [290] , [291] propanolol, [27] metoclopra-mide, [292] lidamidine, [293] and loperamide, [293] all of which decreased the diarrhea in a small number of patients. These agents primarily enhanced sodium absorption in the proximal small intestine or inhibited intestinal secretion. [18] Newer studies demonstrate that the long-acting somatostatin analog octreotide is now the drug of choice and will control diarrhea in 87% of all patients with VIPomas. [27] , [169] This will be considered in detail in the following section. In patients with glucagonoma a migratory necrolytic erythema rash may be severe. Some studies suggest that correction of the hypoaminoacidemia with parenteral amino acids and normalization of the plasma amino acid levels will improve the rash. [72] , [144] , [145] However, another study noted disappearance of the rash after surgical resection of the glucagonoma but not dietary normalization of the plasma amino acids. [146] Octreotide [116] , [153] , [169] improves symptoms in 84% of patients with

glucagonomas and its use is discussed in detail in the next section.

Medical therapy with octreotide. As pointed out earlier, somatostatin has been shown to inhibit the release of a number of hormones in both animals and in human volunteers, as well as to have direct actions on a number of target organs including inhibition of gastric and pancreatic secretion, intestinal absorption, and gastrointestinal motility. [168], [169] Administration of natural somatostatin by continuous infusion to a number of patients with functioning PETs demonstrated symptomatic improvement in patients with VIPomas, insulinomas, gastrinomas, and glucagonomas. [27], [43], [116], [169] However, natural somatostatin has a very short half-life ($t_{0.5}$ 2–3 min) [11], [169] and, therefore, has limited therapeutic efficacy because it has to be given by continuous intravenous infusion. The synthetic octapeptide analog of somatostatin, octreotide acetate (Sandostatin), has a half-life ($t_{0.5}$ 100 min) 33 times longer than somatostatin and thus can be administered 2 to 4 times a day. [116], [169], [294], [295] In the rat, it was 70-fold more potent than somatostatin at inhibiting growth hormone release, 3-fold more potent than native somatostatin at inhibiting insulin release, 23-fold more potent at inhibiting glucagon release, and 80-fold more potent than native somatostatin at inhibiting acid secretion. [169], [294], [295] Octreotide is usually started at a dose of 50 to 150 µg bid to tid subcutaneously given by self-administration and the dose increased if it is not effective. Doses up to 750 µg tid have been used in patients with the carcinoid syndrome and PETs. [116], [153], [169] There have been reports in small numbers of cases where intermittent subcutaneous administration of octreotide was ineffective or only partially effective and the continuous infusion of octreotide was more effective. [169], [296], [297] One long-term study [298] reported on 7 patients with various PETs treated for a median period of 20 months (range 13–54 months) in which octreotide was initially effective in all. Worsening of symptoms and rising plasma hormone concentrations occurred over a median period of 5 months after starting therapy and was initially reversed by increasing the octreotide dose. After a median of 13 months (range 5–34 months) symptoms returned and were no longer responsive to higher doses of octreotide. In 55 patients with insulinoma drawn from various series, [169] octreotide improved some symptoms in 31% and plasma insulin concentrations decreased in 41%. However 65% of the patients received octreotide for less than 1 week because most went to curative surgery. Octreotide also decreases growth hormone secretion and plasma glucagon levels and it may worsen hypoglycemia. Reduction in hypoglycemia attacks was noted only occasionally. [299] Octreotide was given for more than 1 month in 10 patients. In short-term studies octreotide appears to benefit 36% of patients with insulinoma, however the true percentage of patients with insulinomas that continue to respond to octreotide is not clear. [153] Five subtypes of somatostatin receptors exist and octreotide has high affinity for subtypes 2 and 5, intermediate affinity for sst_3, and low affinity for sst_1 and sst_4. [169], [253] The response rate of insulinomas to octreotide is likely lower than other PETs because they frequently possess low densities of somatostatin receptors, whereas the other PETs possess high densities of high affinity sst_2 and sst_5 in 80% to 90% of cases. [169], [232], [253], [300], [301] This finding may also explain why insulinomas appear to be less responsive to octreotide than glucagonomas, VIPomas, gastrinomas, or GRFomas, and are imaged less frequently by SRS. [169], [232], [233], [300] Octreotide improved diarrhea in 27 of 31 patients (87%) with VIPomas in one review [169] and plasma VIP concentrations decreased in 87% of the patients, which is similar to the 78% to 90% response rate in other reports. [17], [19], [116], [153], [169] In one review [169] tumor size was evaluated in 18 patients with VIPomas and a decrease in size occurred in 4 patients. All patients demonstrated a decrease in diarrhea within the first 24 hours but in 3 patients the effect lasted only a few days. [116] Octreotide was given for more than 1 month in 90% of the patients and remained effective for more than 6 months in 50% of all patients. However, some patients developed decreased responsiveness to octreotide with time and the dose had to be increased. In 87% of patients there was a decrease in the VIP plasma level with octreotide treatment although in many cases it did not return to within the normal range. [169], [302], [303] In up to 25% of patients the diarrhea may respond without a decrease in plasma VIP levels. [153] The apparent discrepancy in response and plasma hormone levels may be partially explained by the fact that multiple forms of VIP occur in the plasma and after octreotide treatment only the native peptide may disappear, which may represent a small fraction of the total VIP immunoreactivity and, therefore, no change in plasma VIP is detected. [303] An example of such a patient is shown in Figure 97-15. This patient [302] had severe secretory diarrhea of 5816 ± 185 g/d with daily losses of 616 mmol of sodium and 348 mmol of potassium, and required 3 L/d of fluid with 462 mmol of sodium and 400 mmol of potassium to maintain serum potassium at 3.4 mmol/L and bicarbonate at 15 to 24 mmol/L (see Fig. 97-15). Octreotide, 100 µg twice a day, was started and stool output fell to 292±55 g/d, with fecal loss of 5 mmol of sodium and 25 mmol of potassium. Serum potassium and bicarbonate levels rose. This VIPoma was secreting VIP, motilin, PP, and neurotensin which, with octreotide treatment, decreased 94% for PP, 76% for VIP, 88% for neurotensin, and 70% for motilin (see Fig. 97-15). [302] This patient's diarrhea was controlled for 3 months at which time she died of respiratory failure. [302] The cost effectiveness of long-term octreotide treatment in patients with VIPomas has been studied. [304] It was concluded that long-term octreotide treatment decreases medical costs for a patient with VIPoma by 50%. [304]

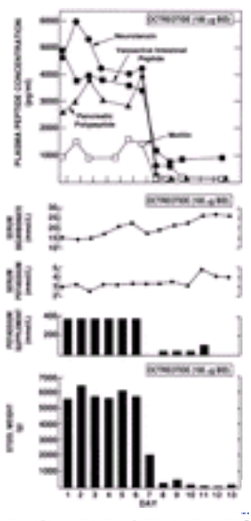

FIGURE 97-15. Effect of octreotide treatment on hormonal levels, stool volume, serum electrolytes and potassium replacement in a patient with a metastatic VIPoma. This patient [302], [303] had a VIPoma secreting vasoactive intestinal polypeptide (VIP), neurotensin, pancreatic polypeptide (PP), and motilin. Values for the different parameters for 6 days prior to and 7 days after receiving octreotide 100 µg bid SC are shown. The hormone levels all decreased by more than 70%, the need for bicarbonate and potassium supplementation were decreased by 94%, and stool weight decreased by more than 95% (5816 ± 185 g/d to 292 ± 55 g/d). The patient was maintained for 3 months on octreotide, remaining asymptomatic until death of unrelated causes.

In 32 patients with glucagonoma, octreotide improved the skin rash in 24 patients and reduced plasma glucagon concentrations in 78% of patients. [14], [15], [27], [43], [72], [116], [153], [157], [169] Weight loss, pain, and diarrhea improved in patients with these symptoms, but octreotide may not improve the diabetes mellitus. [14], [72], [157] Octreotide usually does not decrease tumor size, decreasing the tumor size in only 8% of cases in one study [14] and only 4% of cases in the literature. [14], [169] Decreases in plasma glucagon concentration occur in 80% to 90% of patients but do not always parallel the improvements in the rash. [72], [116], [153] Octreotide was administered for more than 1 month in 94% of patients and remained effective for more than 6 months in 75% of all patients. In one study [14] the duration of treatment ranged from 2 months to 3.5 years. Bromocriptine, a dopamine agonist, is effective in patients with classic acromegaly; however, it only reduces GRF levels in 25% of patients with GRFomas. [77] Octreotide has become the agent of choice for GRFomas. [21], [77], [169], [185] Octreotide reduces symptoms of both growth hormone excess and growth hormone-releasing hormone (GHRH) plasma concentrations in patients with GRFomas. [21], [77], [153], [169], [305] In most patients reported with GRFomas, octreotide improved symptoms and reduced the GHRH levels in all patients, [21], [77], [169], [185] although in one study [306] /SUP>continuous infusion was required. Eight of the nine patients received treatment with octreotide for more than 6 months. [153], [169], [305] Pituitary shrinkage occurred with octreotide treatment in some studies. [185] In GRFomas, the suppression of growth hormone secretion is mainly due to a suppressive effect at the pituitary level because plasma GRF levels do not become undetectable. [77] A small number of patients with somatostatinomas were treated with octreotide. [153], [307] In three of four treated patients plasma somatostatin-like immunoreactivity levels decreased and symptoms due to the somatostatinoma syndrome (diarrhea and diabetes) were improved in two patients. [307] Long-term treatment with octreotide has a number of unresolved issues. Many patients require increasing doses of octreotide with time and some patients require very high doses. [153], [169], [308] When the octreotide was stopped and restarted in a small number of patients, the symptoms were controlled at a lower dose of octreotide, [153] whereas other patients did not respond. Furthermore, it is unclear why, in some cases, intermittent subcutaneous (SC) injections are not effective, whereas continuous low-dose subcutaneous infusions are effective. It is also unclear if intermittent SC octreotide injections are not effective, whether the sustained release preparations (octreotide–long-acting release [LAR], lanreotide-slow release [SR]) [309] will be effective. In addition to reducing the ectopic release of hormone, octreotide also decreases growth rate in a significant proportion of PETs and decreases tumor size in a small percentage of patients. [2], [153], [169], [273], [310] This will be discussed later in the chapter but it is not established that the dose of octreotide is the same for both effects. With short-term treatment side effects have been recorded in approximately 50% of patients treated with octreotide but have rarely been serious enough to stop therapy. [116], [153], [169] Most patients only experience some pain or discomfort at the SC injection site (9%). [116] The most common other side effects are gastrointestinal and include nausea (15%), vomiting (1%), constipation, crampy abdominal pain, and diarrhea (13%) which may improve with time. [153] Steatorrhea can occur with octreotide. [169] At low doses of octreotide steatorrhea is usually mild and transient, however at high doses gross steatorrhea can occur. [311] Dunne and colleagues [116] reported 13% of patients developed diarrhea, 6% fatty stools, and 8% loose stools; in nine patients elevated fecal fat levels were demonstrated. Octreotide rarely has to be stopped because of steatorrhea. Octreotide occasionally may impair glucose tolerance and unmask diabetes mellitus. [312] Occasional postprandial hyperglycemia has been reported. [153] Reactions were graded as mild in 48%, moderate in 38%, and severe in 15%. [116] Most of the side effects were short-lived and did not result in stopping octreotide treatment. During long-term treatment a number of studies have assessed the safety and adverse effects of octreotide,

especially on gallstone formation and gallbladder function, particularly in patients with acromegaly. [169], [171], [174], [175], [313] In one study [174] of 103 acromegalic patients treated with octreotide (SC) for a mean of 30 months, 66% of patients developed an adverse event the first year and 46% the second. Most were related to the gastrointestinal tract including diarrhea (58%), abdominal discomfort (44%), loose stools (36%), nausea (30%), flatulence (13%), and constipation (9%). With continued treatment the adverse events usually disappeared and only 5% of patients discontinued treatment because of adverse events. In various studies in acromegalic patients the incidence of gallstones ranges from 5% to 80% with a mean of 29%. [169], [171], [174], [313] In one study [175] of 33 patients with carcinoid syndrome or PETs treated long-term with octreotide, the overall incidence of cholelithiasis and/or gallbladder sludge was 52%. Seven percent of the patients had symptomatic disease and required an emergency cholecystectomy. The incidence of cholelithiasis varied with octreotide dose, [175] being 35% in patients on low dose (150 µg tid) and 61% with high dose (500 µg tid). The incidence of acute cholecystitis was 12% in the low-dose group and 5% in the high-dose group. [175] Eleven percent of patients underwent elective cholecystectomy. Long-term treatment can also alter glucose tolerance significantly in some patients, which indicates glucose levels should be monitored. [169] Long-term treatment with synthetic somatostatin analogs has been greatly simplified by the availability of sustained-release forms. [58], [169], [172], [309], [314], [315], [316], [317] and [318] Both a long-acting octreotide formulation (octreotide LAR [30 mg IM every month], available in the U.S. and Europe) and a slow-releasing lanreotide (lanreotide SR [30 mg IM every 10–24 days], available in Europe) are now being used for the treatment of acromegaly, carcinoid syndrome, and PETs. [169], [172], [309], [314], [315], [316], [317] and [318] Following a 30-mg IM injection of octreotide-LAR, a plasma level of 1 mg/mL is achieved and maintained for more than 25 days, indicating this formulation can be given monthly. [309] The principal side effects of octreotide-LAR are similar to that discussed for the shorter-acting formulation and include pain at the injection site and gastrointestinal symptoms (usually mild and frequently transient—pain, cramping, diarrhea). [309], [314], [315], [319], [320] Octreotide-LAR and lanreotide-SR impair gallbladder emptying [172], [173] and octreotide-LAR has been shown to inhibit CCK release. [173] In various studies long-term treatment with octreotide is reported not to increase the incidence of gallstones (at 12 mos), [316] or to cause 15% to develop asymptomatic biliary sludge, but none developed gallstones (up to 3 y). [318] Lanreotide-SR is reported to cause new gallstones in 10% to 26% of patients. [314], [317], [321]

Surgical All patients with PETs should undergo exploratory laparotomy for possible cure. [2], [210], [216], [247], [277], [322] Exceptions are patients with unresectable metastatic disease or the occasional patient whose symptoms are well controlled by medical management yet who also has a concurrent medical problem that would make the risks of surgery prohibitive. It is particularly important that the surgery only be done by a surgeon with experience in operating on patients with PETs. [12], [98] Even very experienced general surgeons and many endocrine surgeons have little experience with these rare tumors and therefore will frequently miss small tumors, perform unnecessary major resections, or failure to perform the appropriate resection to palliate symptoms. As outlined previously (see Fig. 97-13), prior to surgery all patients should undergo localization studies and if the tumor localization or extent is still unclear, then functional localization studies (selective hormone sampling of portal venous tributaries) or calcium infusion with hepatic venous sampling (insulinomas, somatostatinomas, VIPomas) should be considered. Even if localization studies are negative, provided metastatic disease or a prohibitive concurrent illness are not present, the patient should undergo exploratory laparotomy. [2], [12], [210], [216], [231], [247], [277] The surgical approach has been reviewed, [210], [223], [277] and is guided by the tumor location. At exploration the liver should be carefully examined for evidence of metastatic disease. In the case of PETs that are frequently extrapancreatic in location the entire abdomen, especially the proximal small intestine, should be carefully explored to locate extrapancreatic tumors. [210], [223] An extended Kocker maneuver should be performed to allow thorough examination of the pancreatic head area. The entire pancreas must be carefully explored, even if one PET is found, because there may be multiple tumors. [98] A detailed exploration for multiple endocrine tumors is particularly important in those patients with MEN I. [12], [323] Isolated small insulinomas should be removed by enucleation because they are rarely malignant. Isolated noninsulinoma PETs in the pancreatic body or tail should be removed either by enucleation or en bloc by distal pancreatectomy because they are occasionally malignant. [210], [216], [223], [247] Pancreatic head and proximal pancreatic body tumors require enucleation with careful dissection to avoid damage to the main pancreatic duct and its attendant morbidity. If at surgery an isolated hepatic metastasis is found and can be removed without increased risk, then it should be excised with negative margins. [2], [223] Aggressive surgery such as a proximal cephalic pancreaticoduodenectomy (Whipple operation) at present is indicated only in carefully selected patients because it has not been established that the increased risk of morbidity may not outweigh the potential benefit in most patients. [2], [12], [210] Pneumococcal vaccine (Pneumovax) should be administered preoperatively to lower the risk of postsplenectomy sepsis. At the time of surgery the use of intraoperative ultrasound may be helpful and is recommended. [12], [216], [282], [283] Studies show this technique will identify a certain number of PETs that would not otherwise be identified and therefore should be used routinely (see Fig. 97-11). [2], [12], [216], [228], [246], [247], [324] In seven studies [216] intraoperative ultrasound localized 89 of 101 (88%) insulinomas. Intraoperative ultrasound changed operative management in 10% of all cases of gastrinomas [246] either by localizing additional tumors or by determining a tumor was malignant. Intraoperative ultrasound is particularly helpful for intrapancreatic lesions. [216] In one study [246] intraoperative ultrasound localized 96% (22 of 23) of pancreatic gastrinomas and in a review of four studies [216] it localized 91% of 34 pancreatic gastrinomas. However, it is less sensitive for localizing duodenal tumors, localizing only 30% of duodenal gastrinomas in two studies. [246] In 12 consecutive patients with occult insulinomas not visualized by any conventional imaging study, [228] intraoperative ultrasound identified 10 of 11 (91%) of the insulinomas that were correctly identified including 5 pancreatic head insulinomas not identified by palpation. The use of intraoperative ultrasound not only localizes primary tumors not detected by other modalities, it reduces complications like fistulae, pancreatitis, and pseudocysts by allowing better definition of the anatomy prior to a procedure. [216] At the time of surgery in patients with insulinomas there have been occasional reports of hypoglycemia during manipulation of the tumor. Use of the artificial pancreas (Biostator) has documented an increased glucose requirement during resection of the insulinoma. [325] A number of centers document successful tumor removal by demonstrating rebound hyperglycemia. However, a study has shown that rebound hyperglycemia did not occur in 23% patients with successful tumor excision [326] and therefore, its use is not recommended. In most studies 75% to 98% of patients with insulinomas will be cured by surgery. [51], [52], [70], [98], [103], [218], [223], [277] With glucagonomas there have been a number of reports of successful excision of the tumor [11], [43], [72], [141], [327], [328] and in many cases follow-up has been significantly long enough to suggest cure. However, at least 50% to 95% of the patients with glucagonomas have metastases at the time of diagnosis and a significant additional percentage at the time of surgery. [14], [16], [72], [141] A number of cases of glucagonomas have shown recurrence during long-term follow-up, despite what appeared to initially have been a complete resection of all tumor. [141] Therefore, the true long-term cure rate is not established. With VIPomas, somatostatinomas, GRFomas, and PPomas many patients present with metastatic disease and, while curative resections do occur, the exact percentage of patients cured by surgical excision of the tumor has not been adequately studied. [4], [29], [68], [277] If the patient is found to have more extensive disease with either local invasion or metastases or at time of surgery or metastatic disease prior to surgery, then the question of debulking or cytoreductive surgery often arises, especially if the patient has a functional PET syndrome. [213], [214], [272], [276], [277], [329] This will be dealt with more extensively in the following section “Metastatic Disease.”

Metastatic Disease

Metastatic PETs have been characterized as slow growing. [7], [11] In fact, until recently there was very little data on the rate of growth of untreated metastatic disease in patients with PETs because many patients required antitumor therapy to control symptoms. Three studies [8], [212], [273] provide some insights into the natural history of metastatic disease. One study [212] of 19 patients with proven metastatic gastrinoma in the liver provides some important insights into the natural history. In 26% of these patients the tumor demonstrated no growth over a 29-month period, 32% had slow growth (1% to 50% volume increase/mo) and 42% had rapid growth (>50% volume increase/mo). [212] These results agree with another study [273] which demonstrated that 78% of patients with metastatic neuroendocrine tumor to the liver had progressive disease over a 6-month period. The third study [8] showed that 50% of patients with gastrinomas die from tumor-related causes, with the extent of metastatic disease and presence of bone metastases being important prognostic factors. These studies demonstrate that in most patients metastatic PETs continue to increase in size and in approximately 50% the growth is rapid. [212] Survival studies also support these findings. [8], [212] In one study [212] 62% of patients with liver metastases with rapid growth died and none of the patients with liver metastases showed either no growth or slow growth over a mean follow-up period of 5.5 years. No clinical or laboratory parameter correlated with growth rate; however, the growth rate was highly predictive of death from the tumor. [212] In one recent study [328] involving 85 patients with various functional PETs, none of the patients without metastatic disease died (follow-up 3–18 years, median 8 years). However, for the 41 patients with metastatic disease, 66% died from tumor progression with an overall 5- and 10-year survival rate of 54% and 28%, respectively. In patients with metastatic disease not to the liver (primarily lymph nodes), [328] the 5-year survival was significantly better ($P < 0.001$) (90%) than those with hepatic metastases at diagnosis (23%). The 5- and 10-year survival rates [328] for patients with malignant insulinomas is 50% to 88% and 50% to 75%, gastrinomas 47% to 53% and 18% to 30%, glucagonomas 52% to 60%, and VIPomas 20% to 88% and 25%, respectively. [16], [17], [52], [68], [328] The natural history of metastatic VIPomas, glucagonomas, somatostatinomas, or insulinomas is not completely clear because until recently effective therapy for the hormone excess state did not exist in most cases and patients frequently died of resulting complications from the hormone hypersecretion. However, with the availability of the long-acting somatostatin analog octreotide, this may change. Excellent long-term survival data are now available for patients with gastrinomas, for which effective therapy has existed for more than 20 years (see Fig. 97-14). [8], [12], [53], [210], [211] Overall, the 5- and 10-year survival rates are 74% and 60%, respectively, in 6 series, [12], [53] whereas for patients with a tumor completely resected it is 100% and 90%, [53] with a primary tumor so small that no tumor was found at surgery it is 95% and 84%, [12], [53] for patients in whom the tumor was resected but they are not cured or had a recurrence it is 75% and 56%, respectively, [53] and in patients with unresectable tumors it is 44% and 33%, respectively. These data clearly demonstrate that overall survival correlates with the extent of the disease. Furthermore, two large studies [8], [53] of 185 patients demonstrates the single most important determinant of long-term survival in patients with gastrinoma is the presence of liver metastases. Moreover, of patients with metastatic disease who subsequently died, 50% to 70% of the deaths were due to tumor progression. [8], [12] At present there are no data to suggest that the other metastatic PETs will differ in their natural history from gastrinoma and, in fact, the study of survival of patients with other PETs [328] previously cited suggests a similar natural history. This conclusion is further supported by the fact that similar percentages of patients with each noninsulinoma PET have metastatic or malignant disease, suggesting that their malignant potential is similar as are growth patterns. [18], [20], [51], [141] Therefore, most authorities would agree that treatment directed at the metastatic disease is indicated. [2], [330], [331] Disagreement occurs over the type of therapy, the efficacy of the therapy, and when therapy should begin. Chemotherapy, [12], [211], [270], [330], [332], [333], [334], [335], [336], [337], [338], [339], [340], [341], [342], [343], [344], [345], [346], [347], [348], [349], [350], [351], [352] and [353] possible cytoreductive surgery, [12], [213], [214], [272], [276], [354], [355], [356] and [357] hepatic arterial embolization (for functional tumors metastatic to the liver with or without chemotherapy [chemoembolization]), [337], [358], [359] interferon, [360], [361], [362], [363], [364], [365], [366] and [367] the use of the long-acting somatostatin analogs, [153], [273], [310], [360], [368], [369], [370], [371], [372] and [373] liver transplantation, [56], [374], [375], [376], [377], [378] and [379] and somatostatin receptor-mediated

radiotherapy [58], [380], [381] and [382] have all been reported to have positive effects on metastatic PET growth. Each will be considered in subsequent sections.

Chemotherapy A number of different chemotherapeutic regimens have been evaluated in patients with metastatic PETs (Table 97-8). In most studies, because of their rare occurrence, chemotherapy for PETs has been considered together as a group or in other cases included in series with metastatic carcinoid tumors. [2], [12], [270], [343], [348], [351] Although some studies [270], [334], [343] report no difference in responsiveness to chemotherapeutic agents between different types of PETs, it has been pointed out that the sample size of the various tumors included in these studies was too small to establish that each type of PET responds equally to chemotherapy. [12], [342] In fact, some clinical observations suggest there may be significant differences in their responsiveness. For example, in some studies as many as 90% of metastatic VIPomas are reported to respond to streptozotocin, often with a complete response. [16] In contrast, only 5% in one prospective study [340] and 40% in another prospective study [342] of patients with metastatic gastrinomas increasing in size prior to treatment responded to streptozotocin plus 5-fluorouracil (5-FU) with or without doxorubicin and in no case was there a complete response. Furthermore, a high proportion of metastatic glucagonomas are reported to respond to dimethyltrizenoimidazole carboxamide (DTIC) including several complete remissions in some studies, [2], [156], [333], [383], [384] and [385] whereas in other PETs, DTIC had a low response rate (i.e., 6%; see Table 97-8).

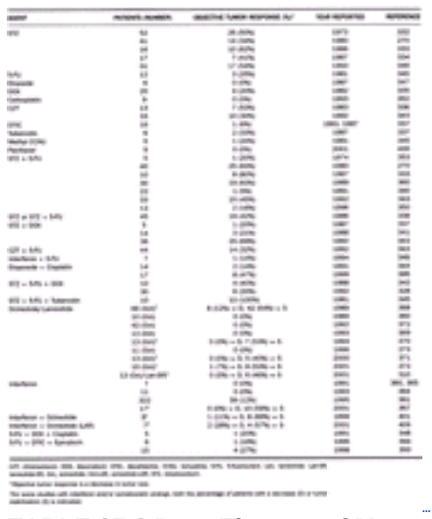

TABLE 97-8 Drug Therapy of Metastatic Pancreatic Endocrine Tumors

In almost all studies, streptozotocin is used either alone or in combination with 5-FU and/or doxorubicin. [2] Streptozotocin is a nitro-urea antibiotic originally isolated from a *Streptomyces*. [386], [387] In early studies it was observed to induce diabetes mellitus. [388] The first report of clinical effectiveness of streptozotocin in a PET was in 1968. [389] Since then it has been generally used in the treatment of PETs either alone or in combination with other agents (see Table 97-8). In various series streptozotocin alone has been reported to cause objective remissions in 34% to 62% of PETs and other single-agent therapy has been relatively ineffective with 5-FU, etoposide, doxorubicin, carboplatin, methyl CCNU, tubercidin, and DTIC giving an objective response in 0% to 33% (see Table 97-8). Chlorozotocin (CZT), a chloroethyl analog of streptozotocin, was discovered in 1976. [389] Compared to streptozotocin, CZT is reported to have only mild to moderate gastrointestinal toxicity and myelosuppression is the dose-limiting side effect, [390], [391] Furthermore, it has the practical advantage of only having to be administered in a single intravenous dose during each course of chemotherapy. CZT alone in two studies had a response rate of 30% to 53%, which is similar to streptozotocin alone (see Table 97-8). Streptozotocin with 5-FU or doxorubicin or both has been reported to cause objective responses in 5% to 80% of patients with a mean response rate of 43% in the different reports (see Table 97-8). The current chemotherapeutic agents of choice for metastatic PETs are the combination of streptozotocin and doxorubicin. [343] This recommendation is based on an Eastern Cooperative Oncology Group (ECOG) comparative study [343] of streptozotocin and doxorubicin versus streptozotocin plus 5-FU or CZT in 105 patients with metastatic PETs. Streptozotocin and doxorubicin had a 69% response rate and this was significantly higher than the 45% response rate with streptozotocin and 5-FU or 30% response rate with CZT alone. Furthermore, streptozotocin [343] plus doxorubicin had a significant advantage in terms of survival ($P = 0.0004$). A previous prospective study [270] done by the ECOG had also demonstrated the superiority of double-agent therapy over streptozotocin alone, with streptozotocin plus 5-FU having a higher response rate of 63% compared to 40% with streptozotocin alone in patients with metastatic PETs. At present it is not clear why the response rate in some more recent prospective studies [340], [342], [350] is significantly lower than the response rate reported in these two studies. In three more recent prospective studies with streptozotocin with 5-FU with or without doxorubicin in patients with metastatic gastrinomas or PETs to the liver, response rates of 5%, 16%, and 40% were reported. [340], [342], [350] In no study were there any complete responders and in one study there was no difference in survival between responders and nonresponders. [342] At present it is not clear whether this difference in response rates from those previously reported with PETs is due to either differences in the tumors themselves or to differences in extent of metastatic disease. The use of both streptozotocin and CZT is associated with significant side effects. In prospective studies 74% to 100% of patients experienced nausea/vomiting and 20% to 40% developed renal toxicity with increased serum creatinine, proteinuria, or both. Nausea and vomiting are frequently severe but now can be controlled in almost every patient with 5-hydroxytryptamine receptor antagonists such as ondansetron. [2], [392] These side effects are reversible in most cases including the early renal effects; however, in the 1992 ECOG study, [343] nine patients developed chronic renal failure and seven patients required dialysis. Serum creatinine and urine protein must be assessed prior to each cycle of chemotherapy. [270], [342] Various triple-drug combinations with or without streptozotocin have been tried in small numbers of patients with variable response rates including streptozotocin with 5-FU and doxorubicin [328], [342] or with tubercidin, [345] 5-FU, doxorubicin, and cisplatin, and 5-FU with DTIC and epirubicin (see Table 97-8). [348], [393], [394] In one study the combination of etoposide and cisplatin [344] was used in 13 patients with metastatic carcinoid tumors, 14 patients with metastatic PETs, and 18 patients with anaplastic tumors (see Table 97-8). None of the carcinoid tumors, 14% of the PETs, and 67% of the anaplastic neuroendocrine tumors demonstrated a partial to complete regression. [344] Two subsequent studies [395], [396] confirmed the effectiveness of this combination in undifferentiated or poorly differentiated carcinoids or PETs, with a 54% and 42% response rate. Most experts agree that chemotherapy, chemoembolization, hormonal therapy, or interferon is only indicated in patients with extensive metastatic disease (usually to the liver) [2], [12], [211], [213], [330], [333], [338], [358] and is not indicated for treatment of the primary tumor when surgery is not curative. There is no agreement, however, about when chemotherapy, chemoembolization, hormonal therapy, or interferon should be begun. [2], [12], [211] Some groups recommend treatment only when the patient develops symptoms due to the PET, [270] whereas others recommend it only when the tumor is demonstrated to be increasing in size. [2], [12], [342]

Other Treatments of Metastatic Disease

Interferon. Because of the toxicity and relatively poor response rates of chemotherapy in patients with extensive metastaticPETs, other approaches have been investigated. Interferon (human leukocyte, a-interferon) is reported to be effective in controlling symptoms in a number of patients with PETs and carcinoid tumors. [349], [361], [362], [365], [397], [398] One review [399] analyzed results from 383 patients from 13 studies of patients with various neuroendocrine tumors (carcinoid tumors, PETs) treated with interferon (a-2a recombinant, a-2b recombinant, a-2c recombinant, natural leukocyte a-IFN). A biochemical response (decreased tumor plasma or serum marker) occurred in 44%, decreased tumor size in 11%, [399] and tumor stabilization in 35%. Of the 58 patients with PETs in another review of 322 patients, [361] 51% had a biochemical response and 12% had a decrease in tumor size occurring with a mean duration of treatment of 20 months (range, 2–96 months). [361] Patients with VIPomas had a higher response rate (83%, 10 of 12) than other PETs. Twenty-eight of the 58 patients had received chemotherapy prior to treatment with interferon and their biochemical response rate was not different from those without previous chemotherapy (55% vs. 44%). [361] Disease stabilization occurred in 14 of 58 (24%) patients with a mean duration of 16 months. In a number of studies a-interferon treatment rarely resulted in a decrease in size of either a malignant PET (see Table 97-8) or carcinoid tumor (0–12%); however, in a number of studies interferon treatment inhibited further tumor growth in 24% to 80% of patients with metastatic neuroendocrine tumors (see Table 97-8). [361], [399] These studies suggest a-interferon as a primary tumoricidal agent is minimally effective; however, it has tumoristatic activity in a significant percentage of patients. [361], [364] Another study [400] reports a-interferon can stimulate an increase in bcl-2 expression in neuroendocrine tumors (NETs) (i.e., carcinoids and PETs) and this effect may stabilize the cells at G_0 and contribute to this tumoristatic effect. Whether a-interferon treatment extends survival is unknown. Interferon has also been used in combination with a number of agents, such as 5-FU, [349] but it is not clear that this increases its antitumor effect (see Table 97-8). Also, a-interferon is increasingly being used in combination with somatostatin analogs [401], [402] (see Table 97-8). This is discussed in the following section.

Somatostatin analogs. A number of studies in animals have demonstrated that somatostatin analogs can inhibit the growth of various tumors under various experimental conditions. [169] Studies demonstrate that except for insulinomas, more than 90% of PETs possess somatostatin receptors. [232], [233], [403] In one review of cases reported up to 1988, [368] hormonal therapy with the long-acting somatostatin analog octreotide was reported to cause a decrease in tumor size in 12% of patients with NETs (see Table 97-8). In more recent studies 0% to 8% of patients were reported to experience decrease in NET size. [58], [273], [319], [370], [372], [398], [404], [405], [406] and [407] However, disease stabilization is reported in 25% to 88% of patients with metastatic NETs treated with somatostatin analogs. [315], [319], [320], [406], [407] These results demonstrate that octreotide, similar to interferon, has minimal tumoricidal activity alone in PETs. However, in a significant number of patients it stabilizes the disease, preventing additional progression, but it remains unclear whether it causes stabilization for a significant period of time to increase survival. Tumor stabilization is also reported with depot-sustained release formulations of somatostatin analogs. [319], [320], [405] A study [408] demonstrates somatostatin analogs can induce apoptosis in NETs and this may be an important factor in its tumoristatic effects.

The combination of somatostatin (either SC or long-acting forms) with a-interferon is reported to cause disease stabilization in 57% to 89% of patients with malignant NETs, some of whom did not previously respond to either agent alone (see Table 97-8). [401] , [409]

Hepatic artery embolization/chemoembolization. Hepatic artery embolization with or without postocclusion chemotherapy (streptozotocin, doxorubicin, 5-FU, or DTIC) has been used successfully in patients with various PETs. [2] , [337] , [358] , [359] , [410] , [411] , [412] , [413] , [414] , [415] , [416] and [417] Because the liver derives only 20% to 25% of its blood supply from the hepatic artery and 75% to 80% from the portal vein, and because most PETs are vascular with an arterial supply, hepatic artery embolization can be used if the portal vein is patent to treat metastatic disease to the liver. In some studies 60% to 100% of patients with metastatic NETs have symptomatic improvement and 33% to 80% have an objective response. [11] , [413] , [416] , [418] Chemoembolization with doxorubicin in iodized oil combined with gelatin or sponge particles, or with streptozotocin, 5-FU, cisplatin, or mitomycin C is reported to improve symptoms in 68% to 100% of patients and to decrease tumor size and/or hormone levels in 37% to 100% of patients. [350] , [412] , [415] , [416] , [417] , [418] , [419] and [420] Mean duration of objective responses lasts from 6 to 42 months. [412] , [416] , [418] This procedure is not without significant side effects. In the literature [410] the mortality overall for this procedure is less than 3% of cases, but pain develops in almost 100%, fever and leukocytosis are seen in at least 50% of patients, and 5% to 15% are reported to have severe complications including hepatic failure, bleeding, infection, or acute renal failure. [358] , [419] In almost all patients some abdominal pain, nausea, vomiting, and fever occur, which lasts up to 10 days. [58] , [412] , [416] , [420] Furthermore, in patients with metastatic PETs, in up to 31% of patients with metastatic gastrinoma to the liver, metastases to bone can occur, [54] suggesting that procedures directed at the liver, such as embolization, may be of limited value to control metastatic spread in some patients with extensive disease. However, in a patient with a hormonal syndrome that cannot be controlled by other therapies, this procedure may be helpful. [2] , [24] Hepatic artery embolization has been combined with treatment with a-interferon [11] , [24] , [421] in patients with metastatic carcinoid tumors, which closely resemble PETs in responsiveness and histology. Five of seven patients (71%) one year after the treatment continued to demonstrate a decrease in the metastatic disease in the liver, whereas with interferon alone (n = 10) only 10% demonstrated a decrease. In another study [421] involving 36 patients with metastatic carcinoid tumors, interferon alone resulted in a 24% response rate (decrease in 5-HIAA secretion) and survival rate was 40% after 5 years. In contrast [421] with interferon and hepatic artery embolization, the response rate was 60% and 5-year survival rate was 75%.

Cytoreductive surgery. The systematic removal of all resectable tumor (i.e., cytoreductive or debulking surgery) may prolong the life expectancy of some patients with some functional PETs. [2] , [11] , [12] , [29] , [213] , [214] , [272] , [276] , [277] , [322] , [354] , [355] Systematic removal of all resectable disease has been reported to help control symptoms in patients with malignant insulin-omas, [277] , [328] , [422] glucagonomas, [19] , [51] , [141] , [277] VIPomas, [18] , [19] , [277] GRFomas, [21] somatostatinomas, [277] and nonfunctional PETs [1] , [29] and has led to the suggestion that resection should be performed if possible, if extensive tumor is identified at the time of surgery and resection can be done without increased risk. No studies have evaluated cytoreductive surgery in a controlled, prospective manner. It is important to distinguish between the possible benefit of such surgery in patients who are asymptomatic (nonfunctional tumors) or have symptoms well controlled (gastrinomas, effective medical control of other tumors), from patients in whom symptoms are not controlled. In the former group cytoreductive surgery is performed to extend survival, but no controlled studies have established its usefulness. In the latter case there are numerous examples previously cited with each of the symptomatic PETs where cytoreductive surgery improved symptoms. A number of studies [214] , [276] , [329] , [423] and two reviews [213] , [416] have provided data regarding this approach. It is important to remember that surgical removal of all visible tumor is only possible in a very small proportion of all patients with PETs with metastatic disease (9% in one study, [423] 5% and 15% in two others [214] , [272]). In one study [214] of 80% of cases with metastatic disease deemed possibly surgically resectable, the tumor was completely excised at surgery and survival was 79% at 5 years with a mean follow-up of 3 years. In this study [214] patients with extensive metastatic disease postresection had a 5-year survival equal to that of patients with inoperable tumors of 28%, whereas patients with limited metastatic disease at surgery had a significantly prolonged survival ($P = 0.019$). In another study [276] 36 extended hepatectomies or hepatic lobectomies and 38 nonanatomic liver resections were performed in patients with advanced disease with malignant NETs. Perioperative mortality was 2.7%, morbidity 24%, and 4-year survival was 73%, with 90% of patients having symptomatic improvement. [276] Norton and colleagues [272] reported the successful resection of all metastatic disease in 5 of 20 (25%) patients with metastatic gastrinomas with extensive disease, including two patients who maintained normal fasting gastrins postresection. The conclusion of each of these studies [213] , [214] , [272] , [276] , [329] was that resection of metastatic disease should be considered in selected patients with metastatic NETs if all gross disease can be resected safely. It is important to remember, however, that this approach is only possible in approximately 10% of patients. It has not been systemically evaluated, and it remains unclear whether patients identified with metastatic disease by localization studies prior to surgery and with symptoms well controlled by medical management will benefit long-term by debulking surgery. In fact one review [355] injects a note of caution in the use of aggressive cytoreductive surgery, pointing out that this surgery can be associated with a high complication rate and that many of these patients survive a prolonged period of time even with advanced disease. In this review [355] the authors recommend cytoreductive surgery be performed in patients with metastatic PETs only if the PET is potentially fully resectable. If it is not fully resectable at surgery, they recommend refraining from performing a partial resection.

Liver transplantation. Liver transplantation is increasingly being used in patients with metastatic NETs (PETs and carcinoid tumors). [11] , [56] , [58] , [374] , [375] , [376] , [377] , [378] and [379] , [424] , [425] The use of hepatic transplantation for many metastatic tumors, such as colorectal carcinoma, cholangiocarcinoma, or metastatic sarcomas, has been largely abandoned because of early recurrence. [378] However, because of their more indolent biologic behavior, patients with metastatic NETs are considered more likely to benefit from liver transplantation. [378] , [424] The reports are generally confined to small numbers of patients with limited follow-up. [56] , [374] , [375] and [376] , [424] In a review [424] of reports of liver transplantation in patients with malignant NETs (n = 103) (48 PETs, 43 carcinoids), the 5-year survival rate was 45%. Occasional long-term cures are reported. [424] , [425] It was concluded that liver transplantation may be justified in younger patients with metastatic disease confined to the liver. [424]

Somatostatin receptor-mediated radiotherapy. The presence of high densities of somatostatin receptors on almost all NETs (PETs and carcinoids), [169] , [232] , [233] , [300] which is now widely used to localize these tumors, [169] , [232] , [233] , [257] is now being investigated as a means of possible antitumor treatment using radiolabeled analogs. [58] , [380] , [381] and [382] , [426] , [427] Both [^{111}In-DTPA ^{0}]octreotide, which emits conversion and auger electrons as well as somatostatin analogs usually coupled by a DOTA group (1, 4, 7, 10,-tetraazacyclododecane-N, N', N'', N''' tetraacetic acid) to yttrium 90 (^{90}Y), which strongly emits ß-particles, or lutetium 177 (^{177}Lu) which is a ß- and ?-emitter, are reported to have antitumor effects in animal studies and small studies in humans. [381] , [382] , [426] , [427] , [428] , [429] , [430] , [431] , [432] , [433] and [434] Of 20 patients [380] with advanced NETs who received at least 20 Gbq of [^{111}In-DTPA ^{0}]octreotide, in 14 patients (70%) either a decrease (30%) or tumor stabilization (40%) occurred. In two reports involving 20 patients and 39 patients with various malignant tumors including NETs, [430] , [434] administration of a ^{90}Y-labeled octreotide analog resulted in 80% to 86% showing a tumor growth response with 21% to 25% demonstrating a decrease in size and 49% to 55% tumor stabilization. Renal toxicity occurred in 3% to 5%. [430] , [434] Lutetium 177-DOTA-Tyr ^{3}-octreotide was used in 26 patients mostly with metastatic NETs, who received at least 300 mCi. [433] Eighty-eight percent demonstrated tumor stabilization (54%) or a decrease in size (34%). Although the use of ^{111}In-, ^{90}Y-, or ^{177}Lu-or labeled somatostatin analogs represents an exciting new approach to target tumor cytotoxicity, at present, too few patients with NETs have been treated to assess either its toxicity or efficacy.

CHAPTER 98

David C. Whitcomb

HEREDITARY DISEASES OF THE PANCREAS

GENETIC PREDISPOSITION TO PANCREATIC DISEASE

Determining genetic predisposition to pancreatic disorders was recently recognized as one of the most important areas of research and clinical practice related to the pancreas. The importance of this rapidly developing field centers on the recognition that most patients with idiopathic pancreatitis have a strong genetic predisposition and that other forms of pancreatic disease, including alcoholic pancreatitis, appear to be strongly influenced by gene-environment interactions. [1] A number of pancreatic disorders are now known to be associated with germ-line mutations (Table 98-1). The focus of this chapter is on the genetic factors underlying various types of pancreatic disease, with application of these findings to major disorders. In addition, the management of disease-specific problems is addressed.

TABLE 98-1 Pancreatic Disorders Associated with Germline Mutations

Definitions and Nomenclature

Clear understanding of the relationship between gene mutations and pancreatic disease requires use of several specific terms. Key terms for this discussion include hereditary pancreatitis, familial pancreatitis, mutation, DNA sequence variation, polymorphism, gene, modifier gene, monogenic and polygenic traits or disorders, orthologous genes, and synteny. In addition, the primary nomenclature systems are reviewed (see Online Links at the end of this chapter for up-to-date information on nomenclature).

Hereditary pancreatitis specifically refers to otherwise unexplained pancreatitis in an individual from a family in which the pancreatitis phenotype appears to be inherited through a disease-causing gene mutation expressed in an autosomal dominant pattern. [2], [3] *Familial pancreatitis* refers to pancreatitis from *any* cause that occurs in a family with an incidence that is greater than would be expected by chance alone, given the size of the family and incidence of pancreatitis within a defined population. Familial pancreatitis may or may not be caused by a genetic defect. Hereditary pancreatitis therefore defines a narrow, specific term, whereas familial pancreatitis is a broad, general term that encompasses hereditary pancreatitis. These distinctions are especially important from prognostic and genetic counseling perspectives because of the very high risk and clear clinical course of hereditary pancreatitis.

The term *mutation* refers to an event, wherein a DNA base or bases are substituted, inserted, or deleted, resulting in a new genomic DNA base sequence, or the process by which a gene undergoes a structural change. [4] The term mutation can also be used to describe a modified gene resulting from a mutation. [4] The result of a mutation is *DNA sequence variation*. A *polymorphism* refers to the existence of two or more genetically different classes (e.g., DNA sequence variances) in the same interbreeding population. [4] A *s*ingle genomic DNA *n*ucleotide *p*olymorphism is *SNP* (pronounced “snip”). The terms polymorphism and mutation are often used with more specific intent. For example, the term *polymorphism* may refer to commonly observed DNA sequence variation (e.g., seen in greater than 1% of a population), and the term *mutation* is commonly used to describe a DNA sequence variation that is disease-associated.

The location of a genomic DNA sequence variation is usually communicated using the nucleotide number of a reference sequence with the change following the number. For example, the cationic trypsinogen R122H mutation could be designated by the GenBank accession number (U66061, 133283G>A), or preferably an official National Center for Biotechnology Information (NCBI) Reference Sequences (see RefSeq http://www.ncbi.nlm.nih.gov/LocusLink/refseq.html) for mRNA (NM_002769, 367G>A), or a genomic contig (NT_007769, 133283G>A).

A *gene* is a DNA segment that contributes to phenotype, function, or both. [5] If there is an absence of demonstrated function, a gene may be characterized by sequence, transcription, or homology, [5] homology meaning similar structure, function, or both. [6] Human gene mutations are preferably described using the HUGO Mutation Database nomenclature. [7] (see HGMD, Human Gene Mutation Database: http://www.uwcm.ac.uk/uwcm/mg/hgmd0.htm). In this system, the location of a specific DNA sequence variation in a gene is determined using the reference sequence, and then numbering the sequential nucleotides of the gene beginning at the A of the ATG of the initiator Met codon. The designation of the position of a nucleotide change is as above with the caveat that a “g.” should precede the designation for genomic sequence and “c.” for cDNA. Deletions are designated by “del” after the nucleotide number (e.g., 1997delT) and insertions by “ins” after the nucleotide interval number (e.g., 1997-1998insT). [7] For amino acid nomenclature, the single-letter amino acid symbol is preferred, and the format is R122H (arginine at codon 122 substituted by histidine). The “wild-type” amino acid is given before and the mutation-associated amino acid after the codon number. Therefore, there is no confusion as to the significance of G, C, T and A in the nomenclature. [7] For intronic variations, the “IVS” designation is used. For example, IVS4+1G>T denotes the G to T substitution at nucleotide +1 of intron 4, and IVS4-2A>C denotes the A to C substitution at nucleotide -2 of intron 4. [7] For further details, see the “Recommendations for a Nomenclature System for Human Gene Mutations.” [7]

A *monogenic* disorder means that the genetic disorder occurs through mutations in a single gene. A monogenic disease could be either dominant or recessive. A *modifier gene* refers to the co-inheritance of another mutated gene that alone is not disease causing, but confers unique phenotypic features to a genetic disorder

(see the later section “ Meconium Ileus”). Polygenic disorders result from the combined action of mutant alleles from more than one gene when neither of the mutant genes alone is disease causing.

When similar genetic information is compared between species (e.g., mice and humans) several additional terms are used. The term *orthologus* means the same or homologous gene sequences in different species (e.g., rat versus human cationic trypsinogen), whereas the term *synteny* properly refers to the gene loci on the same chromosome in different species. [8] However, the term syntenic region is often used to compare regions of similar gene content between species when they are located within different chromosomal regions (e.g., the *trypsinogen gene cluster* on human chromosome 7, mouse chromosome 6, and rat chromosome 4).

Classification and Organization of Genetic Information

The explosion of information on genes and genetics spawned the creation of a number of important resources. Online Mendelian Inheritance in Man (OMIM) is a computerized database of human genes and genetic disorders supported by the NCBI, National Library of Medicine, National Institutes of Health. OMIM focuses primarily on inherited, or heritable, genetic diseases and serves as a phenotypic companion to the human genome project. [9]

The UniGene system was created by the NCBI to consolidate all of the redundant expressed sequences tags (short DNA sequences derived from reverse transcription of RNA extracted from various tissues). The system was designed to partition automatically all GenBank sequences, including expressed sequences tags, into a nonredundant set of gene-oriented clusters. Each UniGene cluster contains sequences that represent a unique gene and is linked to related information, such as the tissue types in which the gene is expressed. Each gene is identified by a unique descriptive name and UniGene symbol and number, which are coordinated with other genetics databases. In this chapter, the common names for genes or proteins are often used. If the common name of a gene (e.g., trypsinogen) and the UniGene name and symbol differ (e.g., protease, serine 1; *PRSS1*), then both are given with the initial use in the text.

Clinically Important Genetic Mutations

Mutations in three different genes clearly predispose to most gene-associated exocrine pancreas disorders in humans. The genes include the cationic trypsinogen (protease, serine, 1; *PRSS1*) gene, the pancreatic secretory trypsin inhibitor (serine protease inhibitor, Kazal-type, 1; *SPINK1*) gene, and the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. Although the mechanism and inheritance pattern of the disease-associated mutations in these genes are markedly different, they all cause *common* and *clinically significant* pancreatic disorders.

Determining whether a mutation is clinically important requires understanding of several interacting factors. [3] These factors include the *severity* of the mutation, the *prevalence* of the mutation in specific populations, and the *physiologic function* of the wild-type gene. The severity of a mutation reflects a change in the function of the encoded protein by altering the amount or location of expression, the protein function, the regulatory elements, or the ability to interact properly with other factors. [3] In general, more severe mutations are more likely to cause disease in an individual patient. The prevalence of a mutation in a population (or DNA sequence variation) also determines clinical importance. One can envision a large variety of very severe gene mutations that would disrupt the function of key proteins, but if they are never seen in patients, then they are of little clinical importance. [3] The physiologic function of the gene product also plays a critical role in determining whether the mutation is clinically important. In other words, does the gene play a pivotal role in a critical process? Are there adaptive or redundant mechanisms in place to lessen the impact of a mutation? Does the gene product play a key role in development, regulation, protection, or repair? Does the disease appear as an autosomal dominant, autosomal recessive, or complex genetic pattern, and does it require environmental factor or mutations in a second gene in order to become clinically evident? Indeed, growing experience with gene knock-out mice reveals that the importance and independence of many genes must be reconsidered. Thus, clinically important mutations must be determined by identifying mutations in well-characterized patient populations combined with adequately sized genetic epidemiology studies. In the following sections on pancreatic disease, recent data on the severity and prevalence of known mutations and on the physiologic role of the gene product are presented.

MAJOR GENE MUTATION–ASSOCIATED PANCREATIC DISORDERS

Cationic Trypsinogen (PRSS1) Gene Mutation–Associated Pancreatitis

Cationic Trypsinogen The first pancreatitis-associated mutation in the cationic trypsinogen gene (*PRSS1* OMIM *276000) was discovered in 1996 through efforts to identify the cause of hereditary pancreatitis. [10] The role of trypsin in pancreatic physiology and the protective mechanisms employed by the pancreas to control prematurely activated trypsin are covered as a background to understanding mutation-associated pathophysiologic mechanisms predisposing to pancreatitis.
Physiology of trypsin. Cationic trypsinogen is the most abundant of three trypsinogen isoforms synthesized in the pancreas and represents about 23% of total pancreatic secretory proteins in humans. [11] The other two isoforms, anionic trypsinogen (protease, serine, 2; *PRSS2;* OMIM *601564) and mesotrypsinogen (protease, serine, 3; *PRSS3*) make up about 16% and less than 0.5% of the total pancreatic secretory protein by weight, respectively. [11], [12] The specific amino acid targets for trypsin are the arginine (symbol Arg or R) or lysine (symbol Lys or K) residues within the target peptides or proteins. Trypsinogen becomes enzymatically active *trypsin* after the intestinal brush-border brush enzyme enterokinase or another active trypsin molecule cleaves the 8–amino acid N-terminal peptide fragment called *trypsinogen activation peptide* (TAP) (Fig. 98-1). Trypsin activates not only trypsinogen but also the other pancreatic digestive proenzymes in an activation cascade. These pancreatic digestive enzymes digest the major, complex nutrient molecules within a meal. The pancreatic enzymes are then destroyed, usually before the mid-ileum.

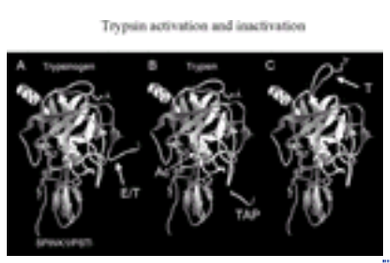

FIGURE 98-1. Trypsin activation and inactivation. This figure shows three variations of the trypsin-SPINK1 complex. **A:** Trypsinogen is the top portion of the complex with arginine 122 (extending from the loop at the top). The *arrow* shows the site of the TAP portion of the trypsinogen molecule where either enterokinase (E) or trypsin (T) can cleave this peptide and activate trypsinogen to trypsin. **B:** Trypsin is generated when TAP is released and the molecule undergoes conformational changes to become active (Ac, active site). **C:** The side chain containing the critical R122 site can be attacked by another trypsin (T) when it is in a susceptible conformation (From ref. [14]).

Pancreatic acinar cell protection from trypsin. Because of the efficiency of the activation cascade and the destructive potential of pancreatic digestive enzymes unleashed in the wrong location, it is imperative that trypsin activity within the pancreas be severely limited. The pancreatic acinar cells synthesize pancreatic secretory trypsin inhibitor (*SPINK1*) (see Fig. 98-1), which is regulated as an acute-phase reactant. [13] *SPINK1* provides the first line of defense against prematurely activated trypsin within the pancreas. [10] A second protective mechanism is trypsin self-destruction or autolysis beginning at arginine 122 of the trypsin primary amino acid chain (see Fig. 98-1). The autolysis site is often inaccessible to hydrolysis, especially with elevated calcium, so that it cannot be attacked by a second trypsin. [14], [15] Thus, trypsin both activates trypsinogen by cleaving TAP and later inactivates trypsin by cleaving the side chain at R122. Additional protective mechanisms are also operational. [12], [16]
Pancreatitis-Associated Trypsinogen Mutations Several mutations have been identified within the cationic trypsinogen gene that cause acute and chronic pancreatitis. [17] The number of mutations is limited and the type of mutations specific because they cause pancreatitis by altering the protein through a gain-of-function mechanism by enhancing the activation of trypsinogen or preventing inactivation of trypsin. [18] Gain-of-function mutations often result in an autosomal dominant inheritance pattern because only one of the two alleles must be affected to express the abnormal phenotype; that is, half of the protein is out of control. Loss-of-function mutations are usually autosomal recessive because both copies of the gene product must be *lost* to cause the disease phenotype (e.g., cystic fibrosis). In the case of hereditary pancreatitis, most families have identifiable gain-of-function mutation in the cationic trypsinogen gene, with R122H and N29I being the most prevalent. These two mutations represent the causative mutation in about two thirds of the families with classical hereditary pancreatitis [19] and currently are the only mutations for which genetic testing is recommended. [20] (Table 98-2 and Table 98-3).

1. Recurrent (two or more) attacks of acute pancreatitis for which there is no explanation (anatomic anomalies, ampullary or main pancreatic strictures, trauma, viral infection, gallstones, alcohol, drugs, hyperlipidaemia, etc.)
2. Unexplained (idiopathic) chronic pancreatitis
3. A family history of pancreatitis in first-degree (parent, sibling, child), second-degree, (aunt, uncle, niece, nephew), or third-degree (grandparent, first cousin) relative
4. An unexplained episode of documented pancreatitis occurring in a child that has required hospitalization and where there is significant concern that hereditary pancreatitis should be excluded
5. For a patient with pancreatitis eligible for an Ethics Committee– or Institutional Review Board (IRB)–approved research protocol

Modified from ref. 20.

TABLE 98-2 Indications for Genetic Testing for *PRSS1* Mutations

Before genetic testing, the patient should understand:
1. Why the test has been suggested and the need for documented informed consent
2. The implications of finding a pancreatitis-related mutation in the *PRSS1* gene for the health and medical care of that patient
3. How their genetic test result will be communicated to them and who else will be informed of their result (i.e., the clinician that has requested that test, other involved pancreatic specialists, the family doctor, hospital medical records, insurance carrier)
4. The availability of genetic counseling after the test result is known
5. The pancreatic cancer risk and the possible adverse health and life insurance and employment consequences for the patient (if not safeguarded against by state or national legislation)
6. The implications of a positive genetic test result for their relatives
7. Whether or not they wish for their test sample to be used for any research project and by what (anonymized) route this will occur

Modified from ref. 20.

TABLE 98-3 Pregenetic Test Patient Information for *PRSS1* Mutations

Clinical Characteristics of Hereditary Pancreatitis About two thirds of the families with hereditary pancreatitis appear to have cationic trypsinogen mutations, and one third have unidentified mutations. [19] The clinical phenotype of the trypsinogen-associated mutations and noncationic trypsinogen associated mutations are similar, and thus the topic is addressed here.

Hereditary pancreatitis disease phenotype. Hereditary pancreatitis is a genetic disorder with high disease penetrance; about 80% of individuals with a cationic trypsinogen R122H or N29I genotype in most studies develop pancreatitis at some time in their life (80% disease penetrance). The reason for the incomplete penetrance is unknown and appears to be independent of major environmental factors or modifier genes. [21] The clinical presentation is usually recurrent episodes of acute pancreatitis beginning in childhood (median age of onset, 10 years), although the range is from infancy to the fifth or sixth decade of life. [22] Episodes of acute pancreatitis are similar to acute pancreatitis from other causes and may vary from mild abdominal discomfort to severe life-threatening episodes with pancreatic necrosis, splenic vein thrombosis, pseudocyst formation, and death. However, in some patients, an episode of acute pancreatitis may be prolonged. Half of the patients with episodes of acute pancreatitis progress to chronic pancreatitis. [19], [23] Patients with hereditary pancreatitis-associated chronic pancreatitis suffer from all of the common complications of alcoholic and idiopathic chronic pancreatitis, including unrelenting pain, parenchymal and ductal calcifications, duct distortion, fibrosis, maldigestion, and diabetes mellitus. [22], [24], [25], [26], [27] and [28] These features make hereditary pancreatitis indistinguishable from other causes of acute and chronic pancreatitis except for the relatively early age of onset, the autosomal dominant inheritance pattern, and the lack of other identifiable etiologies. [18] A high incidence of pancreatic cancer is another striking feature of hereditary pancreatitis, beginning 30 to 40 years after the onset of pancreatitis. [29], [30] The estimated accumulated risk for pancreatic cancer to age 70 in these families is about 40 percent. [28], [29], [30], [31] and [32] A remarkable gene-environment interaction is related to tobacco smoking. The age- and sex-adjusted odds ratio is doubled by tobacco smoking, and the median age of diagnosis of pancreatic cancer is 20 years earlier in the smokers. [29], [30] Thus, the evidence is very strong for a connection between hereditary pancreatitis and pancreatic cancer.

Diagnosis of hereditary pancreatitis. The diagnosis of hereditary pancreatitis remains an area of controversy. Reasons include lack of consensus on a precise definition and that the implications of this diagnosis will persist throughout life. Furthermore, the diagnosis has implications for future descendants and other family members and may affect social and reproductive choices, employment, and insurability. [33], [34] and [35] Before genetic testing, the diagnosis of hereditary pancreatitis was based solely on evaluation of the patient's extended family and exclusion of other causes of pancreatitis. [36] Genetic testing offers a new and powerful tool because it is highly accurate, provides precise risk assessment, and can detect or exclude the likelihood of pancreatitis *before* symptoms develop. [33] Furthermore, genetic testing can detect hereditary pancreatitis–associated mutations in individuals without a clear family history of pancreatic disease. Indeed, the cationic trypsinogen mutations N29I and R122H have been detected in families that appear to have autosomal dominant, autosomal recessive, or familial patterns or patients with idiopathic (sporadic) pancreatitis. [19] Therefore, it is currently our practice to diagnose patients with hereditary pancreatitis only if they have a clear family history or have unexplained pancreatitis or recurrent pancreatitis-like pain with confirmed cationic trypsinogen R122H, N29I, or equivalent mutations.

Genetic testing for cationic trypsinogen mutations. Genetic testing should be approached with caution. [33], [34] The results of genetic testing are highly accurate but may have broad implications for the patient's future health, family, employment, and insurability. The clinician must therefore understand the implications of testing, be prepared to provide pretest and posttest counseling to the patient (or refer the patient to a genetic counselor), and ensure that informed consent is obtained before testing. [33] Genetic testing is now available for the cationic trypsinogen R122H and N29I mutations [1] through an approved laboratory (in the United States an approved laboratory would require a Clinical Laboratory Improvement Act license [33], [35]). Guidelines for testing have recently been adopted by an expert consensus conference group [20] and are summarized in Table 98-2 and Table 98-3. The primary indications for cationic trypsinogen mutation testing include recurrent idiopathic acute pancreatitis, idiopathic chronic pancreatitis, verification of a clinical suspicion in a family member of a kindred with known mutations, to help a patient understand or validate his or her condition, and to assist individuals in making lifestyle decisions (e.g., reproduction, diet, smoking) based on the known risk for pancreatitis and potentially pancreatic cancer. [1], [29], [33] Genetic testing is also used in children with unexplained pancreatitis or episodes of pancreatitis-like pain when there is significant concern about the possibility of hereditary pancreatitis. Indeed, identification of an established pancreatitis-associated gene mutation can be valuable in expediting an expensive and prolonged evaluation of recurrent pancreatitis in children and precludes further evaluation of elusive causes of pancreatitis in adults. The positive and negative predictive values of a genetic test in identifying specific mutations are almost perfect with properly applied modern techniques. [33], [35] Interpretation of test results and explanation of their meaning to the patient continue to be a central issue because positive or negative test results have lifelong implications for the patient as well as the patient's extended family. A positive test result in a clinically *unaffected* person is interpreted as conferring a significant increased risk for pancreatitis, with this risk possibly diminishing with age. A negative test result in a family with a known mutation essentially eliminates the risk for this genetic form of pancreatitis. If a mutation has not been previously identified in the family, then a negative test result in an unaffected person is considered noninformative because one cannot distinguish whether the tested individual is free from genetic risk or has inherited a different pancreatitis predisposing gene mutation. [1] The genetic testing of children raises unique issues. [20] Unlike an adult patient, a child legally cannot provide informed consent. Thus, the decision for a child is essentially left to the parents or legal guardian. For children 7 years and older, a parent or legal guardian may provide consent for genetic testing, although these older children should provide assent, or agreement to the testing. The testing of purely asymptomatic children is strongly discouraged because there is no clear medical benefit in identifying carriers at a young age. [20], [33] Testing for the purpose of intervention with diet, medication, or surveillance for complications of a genetic disorder (e.g., undertaking repeated colonoscopies for patients with the familial adenomatous polyposis syndrome) has been advocated. [37] In hereditary pancreatitis families, alcohol, emotional stress, and fatty foods have been reported to precipitate pancreatitis attacks, [25] and smoking increases the risk for both pancreatitis [38], [39] and [40] and pancreatic cancer. [30] Testing for the purpose of encouraging mutation-positive older children to avoid these excesses is advocated by some caregivers. However, avoidance of fatty foods, alcohol, and tobacco represents excellent general medical advice and therefore provides no compelling reason for genetic testing. [33] In either case, the personal desires of older children to postpone testing or to proceed with testing to relieve their own anxieties and learn more about their own personal health must also be carefully considered. Ownership of test results in children must be addressed. [1]

Treatment of hereditary pancreatitis. No specific treatment exists for the prevention or treatment of hereditary pancreatitis. However, some patients report that vitamins, antioxidants, or digestive enzyme supplements are helpful. [41] Symptomatic improvement was documented in a controlled trial of three children given antioxidants, vitamins, and selenium. [42] Symptomatic treatment for pancreatic duct obstruction or other sources of pain is also helpful and should be handled in a manner similar to other forms of pancreatitis. [43] Definitive recommendations for specific treatments await clinical evidence from well-designed trials. [41] A major concern for patients with hereditary pancreatitis is pancreatic cancer. Tobacco smoking appears to be the most important independent risk factor [29], [30] and should be strongly discouraged. Unfortunately, no good screening test exists for the early diagnosis of pancreatic cancer in high-risk groups. [32], [44] A recent consensus conference concluded that at the present time, screening for pancreatic cancer should be performed in high-risk individuals within multicenter Institutional Review Board–approved protocols. [45] If a patient in a high-risk group is to undergo an attempted curative resection of the pancreas for a suspected tumor, the whole pancreas should be removed. [45]

Pancreatic Secretory Trypsin Inhibitor (SPINK1) Gene Mutation–Associated Pancreatitis

An association between mutations in the *SPINK1* gene and idiopathic chronic pancreatitis in children was first described in 2000. [46] The predominant *SPINK1* mutation was N34S, which is present in about 1% to 2% of the general population. *SPINK1* mutations are commonly associated with familial pancreatitis and idiopathic pancreatitis developing before the age of 20 years. [47] *SPINK1* mutations are also associated with other forms of alcoholic pancreatitis (6%) [48] and occur in a high percentage of patients with fibrocalculous pancreatic diabetes, a subtype of tropical pancreatitis. [49], [50] *SPINK1* mutations are seen to a lesser extent in tropical calcific pancreatitis [51] and even in early-onset non–insulin-dependent diabetes mellitus in Bangladesh. [51]

Physiology of the Pancreatic Secretory Trypsin Inhibitor, *SPINK1* *SPINK1* appears to play a major role in protecting the pancreas from prematurely activated trypsinogen. [12] The *SPINK1* gene codes for a 56–amino acid mature peptide (see Fig. 98-1) that is synthesized in pancreatic acinar cells as well as other sites. [12] *SPINK1* normally inhibits trypsin by directly blocking the active catalytic site. A lysine target substrate, or "bait," for active trypsin is located at the apex of the substrate-inhibitor binding loop. The lysine fits into trypsin's specificity pocket, and *SPINK1* forms a stable complex with a covalent bond between the catalytic serine residue of the enzyme and the lysine carboxyl group of the reactive site of the trypsin inhibitor. [12] The binding is reversible, and *SPINK1* is also slowly digested by trypsin. [12] *SPINK1* inhibits anionic trypsin (*PRSS2*) but not mesotrypsin (*PRSS3*). [12] It has been estimated that the pancreas contains enough inhibitors to neutralize about 20% of total potential trypsin activity, [12] although this ratio probably varies depending on physiologic conditions. Because *SPINK1* and trypsinogen are both synthesized within the acinar cells, it is likely that *SPINK1* provides the first line of defense against prematurely activated trypsinogen (Fig. 98-2). Therefore, a *loss* of *SPINK1* function should hypothetically increase the chance of free trypsin activity inside the pancreas by allowing active trypsin to overcome more easily the first line of defense. [46], [47]

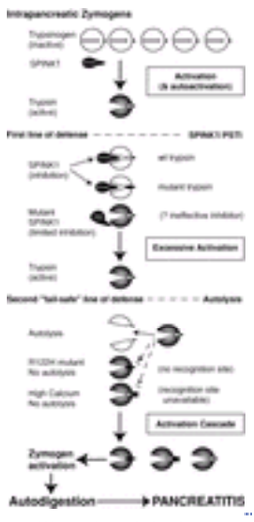

FIGURE 98-2. Mechanistic model of trypsinogen activation and inactivation within the pancreas. Tyrpsinogen (inactive) and *SPINK1* (also known as pancreatic secretory trypsin inhibitor, or *PSTI*) are synthesized together within the pancreatic acinar cells at a 5:1 ratio (*top*). Trypsinogen activation occurs within the acinar cell and threatens to initiate the zymogen activation cascade, leading to pancreatic autodigestion and pancreatitis. The first line of defense is trypsin inhibition by *SPINK1/PSTI*. *SPINK1* effectively inhibits up to 20% of potential trypsin (including mutant trypsin). If there is excessive trypsin activation (>20%) or ineffective inhibition by mutant *SPINK1*, then free trypsin activity rises and again threatens to initiate the activation cascade. The second line of defense is trypsin autolysis. This process begins with hydrolysis of the side chain connecting the two globular domains of trypsin at arginine 117 (R117 using the chymotrypsinogen numbering system [208]) coded for by codon 122 (codon numbering system [7]). Autolysis fails in hereditary pancreatitis with R122H mutation and possibly others, or under high calcium conditions. As free trypsin levels rise, the zymogen activation cascade is activated, leading to pancreatic autodigestion and acute pancreatitis. In hereditary pancreatitis and possibly other conditions, repeated attacks of acute pancreatitis lead to chronic pancreatitis. [209] (From ref. [1].)

Pancreatitis-Associated *SPINK1* Gene Mutations Based on the likely physiologic role of *SPINK1* in protecting the pancreas from active trypsin, it is predicted that pancreatitis-associated *SPINK1* mutations would be loss-of-function mutations. Therefore, a large number of disease-associated mutations are possible. The *SPINK1* N34S is the most commonly identified mutation in nearly all control populations, with prevalence of up to about 2% of control population (about 1% alleles frequency). [46], [47], [52], [53] This means that the *SPINK1* N34S mutation is *many* times more prevalent than chronic pancreatitis (1 in 16,000 or 0.006% of the population) and especially more common than idiopathic chronic pancreatitis in children. Patients with idiopathic pancreatitis may have *SPINK1* genotypes that are heterozygous, compound heterozygous, or homozygous for *SPINK1* mutations without a clear difference in age of onset or disease severity. [47] Therefore, the common *SPINK1* N345S mutation acts as an important *risk factor* or susceptibility factor for pancreatitis, potentiating the harmful effects of other genetic or environmental insults to the pancreas that actually initiate episodes of pancreatitis. [47], [54], [55]

Clinical Characteristics of Patients with *SPINK1* Mutations

Clinical phenotypes of patients with SPINK1 mutations. Unlike patients with cationic trypsinogen mutations, patients with *SPINK1* mutations and pancreatic disease do not have a single phenotype. [54] The highest incidence of *SPINK1* mutations is in patients with idiopathic chronic pancreatitis beginning before the age of 20 years. [47], [56] Depending on the regional population, between 15% and 25% of children have identifiable *SPINK1* mutations (usually N34S), [46], [47], [56] whereas in adults with idiopathic chronic pancreatitis or alcoholic chronic pancreatitis, the prevalence is about 5% to 10%. [47], [56]

Clinical presentation. A single clinical presentation for patients with *SPINK1* mutations has not been fully defined. The age of onset is usually younger than 20 years. In the United States, children may present with recurrent attacks of acute pancreatitis or with abdominal pain that is eventually determined to be due to chronic pancreatitis. In the Indian subcontinent, the first symptom may be diabetes associated with fibrocalculous pancreatic diabetes (see earlier). The number of attacks of pancreatitis and number of hospitalizations reported by patients with *SPINK1* mutations are similar to reports of patients with hereditary pancreatitis, with nearly 90% hospitalized more than once and 60% hospitalized more than 5 times. Review of the cases from the University of Pittsburgh database suggest that pancreatic calcifications are present at diagnosis in 16% of patients, pseudocysts in 19%, and dilated ducts in 26%. Insulin-dependent diabetes mellitus was also present in 13% of patients with pancreatitis associated with *SPINK1* mutations. These data suggest that the clinical characteristic of these patients is similar to other types of idiopathic chronic pancreatitis.

Genetic testing for SPINK1 mutations. Testing for *SPINK1* mutations in individuals with early-onset chronic pancreatitis may provide important information on predisposing causes of pancreatitis for the concerned patient. [1] However, most experts do not advocate genetic testing for *SPINK1* mutations at this time. [20] Furthermore, because fewer than 1% of patients with a heterozygous *SPINK1* mutation alone are likely to develop pancreatitis, the major reasons are lacking to do *presymptomatic* testing. If genetic testing is performed, appropriate pretest and posttest genetic counseling must be provided.

Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Gene Mutation–Associated Diseases, Including Cystic Fibrosis and Pancreatitis

The *CFTR* gene (OMIM *602421) was discovered during the search for the cause of cystic fibrosis (CF). CF (OMIM #219700) has been the most common lethal genetic defect of white populations. CF is caused by severe mutations in the *CFTR* gene located on chromosome 7q32 and is inherited as an autosomal recessive disorder. [57]

Physiology of *CFTR* The *CFTR* gene contains more than 4300 nucleotides, divided into 24 exons that code for a single protein of 1480 amino acids. [57] The protein forms an anion channel for chloride and, to a lesser degree, bicarbonate. CFTR has 12 membrane-spanning regions divided into 2 membrane-spanning domains, 2 nucleotide-binding folds, and a regulatory domain (R domain) that is activated by cyclic adenosine monophosphate (cAMP). *CFTR* also regulates other ion channels in the same cell, including the amiloride-sensitive epithelial sodium channel. [58], [59] In the pancreas, the *CFTR* channel is located on the apical (lumenal) membrane of the pancreatic duct cell. [60] Binding of secretin to secretin receptors or vasoactive intestinal polypeptide receptor [61] on the basolateral membrane of the duct cells results in elevation of cAMP. cAMP activates protein kinase A (PKA) which, in the presence of ATP, interacts with the R domain of *CFTR* to open the *CFTR* anion channel. Opening of the *CFTR* channel results in efflux of intracellular chloride and depolarization of the duct cell. [62] *CFTR* activation is tightly linked to pancreatic bicarbonate secretion. [63] With cell depolarization, bicarbonate and sodium enter the duct cell through the basolateral sodium-bicarbonate cotransporter. [62], [64], [65] It is believed that bicarbonate secretion occurs on the apical side through a chloride-bicarbonate exchanger, [66] although *CFTR* is also permeable to bicarbonate with a Cl^- to HCO_3^- permeability ratio of 5:1, [67] and other bicarbonate channels probably exist. [67] *CFTR* also plays a key role in chloride and bicarbonate secretion in the

airways, intestine, bile ducts, and other organs.

***CFTR* Mutations in Typical and Atypical Cystic Fibrosis** Major mutations in *both* of the *CFTR* alleles result in complete loss of *CFTR* function and typical CF. The effects on cell and organ function include inability to hydrate mucus and other macromolecules adequately, leading to accumulation of viscid material and inspissated glands. This results in progressive organ destruction of the respiratory system and pancreas and to dysfunction of the liver, intestine, sweat glands, and other sites where epithelial cell secretion plays an important physiologic role. About 1000 mutations and sequence variations have been identified in the human *CFTR* gene. About 70% of white patients with CF have a 3—base pair deletion of the phenylalanine-coding codon 508 (?F508). [71] African Americans may have their own set of common CF mutations that originate from the native African population, including the 3120+1G>A mutation, which occurs with a frequency of 12.3% in a representative population. [68] Although there are many reported *CFTR* mutations, about 70 specific mutations represent more than 90% of all CF-causing mutations. [69]

Classification of CFTR mutations. The mutations in the *CFTR* gene have been classified based on their functional impact on the CFTR protein. Mutations affecting synthesis (class 1), maturation and trafficking (class 2), or activation (class 3) yield little or no functional protein and are considered severe mutations. [58, 70] Mutations that alter conductance (class 4) and protein abundance (class 5) and diminish, but do not eliminate, *CFTR* function are considered mild mutations and are often associated with pancreatic sufficiency or atypical CF. [58, 70] In most cases, so-called mild mutations are clinically mild only in regard to the severity of the pancreatic involvement, not overall disease severity or longevity. Some mutations affect the ability of *CFTR* to regulate other channels (class 6). [58] Finally, there are numerous silent mutations (no amino acid base change), intronic and exonic polymorphisms, and sequence variations with unknown significance. In general, the *less* severe mutation dictates the phenotype of autosomal recessive disorders such as CF and thus determines the phenotypic classification. Class 4 and 5 mutations deserve special mention because preservation of some *CFTR* function alters the eventual disease phenotype. For example, patients who have one or two mild *CFTR* mutations, such as R117H, R334W, R347P, A455E, or P574H, and therefore retain more than 1% *CFTR* function, are pancreatic sufficient. [71] If less than 1% of *CFTR* function exists, then the patient will develop typical CF with pancreatic insufficiency [69, 72] (Table 98-4). Sweat chloride becomes abnormal when less than 5% of function is preserved. With 5% of *CFTR* function or less, the patient also becomes susceptible to progressive pulmonary infection, even though the patient may maintain pancreatic sufficiency. Other features of CF, such as congenital bilateral absence of the vas deferens (CBAVD) with azoospermia, nasal polyps, or recurrent pancreatitis may occur any time *CFTR* function falls below 10% of normal.

PERCENTAGE OF NORMAL CFTR FUNCTIONS*	MANIFESTATIONS OF CYSTIC FIBROSIS
<1	Pancreatic exocrine deficiency (plus manifestations listed below)
<4–5	Progressive pulmonary infection (plus manifestations listed below)
<5	Clinically demonstrable sweat abnormality (plus manifestations listed below)
<10	Congenital absence of the vas deferens
10–49	No known abnormality
50–100	No known abnormality (this range represents the levels in asymptomatic heterozygotes and normal persons)

*The percentage of normal CFTR function is approximate.
Modified from ref. 69.

TABLE 98-4 Relation between the Amount of Functional *CFTR* Produced and the Phenotype

Some *CFTR* mutations may modify other *CFTR* mutations. Examples include the R553Q-?F508/?F508 phenotype, which partially reverses the ?F508 phenotype, or the R117H-intron 8 5T allele (*in cis*), which confers tissue-specific variations in expression of the mild R117H mutant CFTR protein. [58] Thus, a variety of genotype-phenotype combinations exists, and these can be broadly categorized based on the overall functional level of *CFTR*.

Other germline mutations that modify the cystic fibrosis genotype. Recent animal model and clinical epidemiologic evidence demonstrate that mutations in genes other then *CFTR* strongly influence the clinical features of CF. [73] The risk for meconium ileus was localized to a chromosomal region in mice, [74] which is syntenic to a locus on human chromosome 19 that was determined to be associated with meconium ileus in humans. [75] Other modifier gene mutations increase the risk for liver disease in CF patients. [73] The risk for liver disease appears to be independent of *CFTR* genotype, is associated with meconium ileus, [76] and is also associated with mutations in some protease inhibitors, [77] including a $_1$-antitrypsin. [73] The risk for pulmonary disease may also be influenced by modifier genes. For example, an a $_1$-antitrypsin enhancer polymorphism appears to be a genetic modifier of pulmonary outcome in CF. [78] Various combinations of *CFTR* mutations, modifier genes, and environmental factors also result in atypical CF features, including chronic pancreatitis, CBAVD with male infertility, disseminated bronchiectasis, chronic sinusitis, or other disorders without typical pancreatic and pulmonary manifestations of CF. [58, 79, 80]

Clinical Characteristics of Cystic Fibrosis The incidence of CF is 1 in 3200 white American newborns, 1 in 15,000 African American newborns, and 1 in 31,000 Asian American newborns. [81] On the other hand, CF is very rare in Japanese, with only 34 patients identified in a national survey of CF in Japan conducted in 1999. [82] CF is diagnosed within the first year of life in more than 70% of patients and in more than 85% by age of 5 years, but 8% remain undiagnosed until after the age of 10 years. [81] Presenting features during infancy include meconium ileus, maldigestion and malabsorption with frequent foul stools, recurrent pneumonia, failure to thrive, and rectal prolapse. When an infant presents with pancreatic insufficiency or meconium ileus, the etiology is usually CF caused by two severe *CFTR* mutations. Pulmonary function is normal at birth in patients with CF but later accounts for much of the morbidity and almost all of the mortality associated with CF. A number of factors other than the *CFTR* genotype contribute to the severity of lung disease, including chronic infection with *Pseudomonas aeruginosa,* nutritional status, environmental factors such as exposure to second-hand smoke, [83] and probably the effects of unidentified modifier genes. In older patients, the presenting symptoms of CF may include various pulmonary symptoms, nasal polyps, male infertility, liver disease, recurrent acute pancreatitis, or chronic pancreatitis, although the prevalence of *CFTR* mutations in patients with these common disorders is much lower than the prevalence of *CFTR* mutations in infants with pancreatic insufficiency or meconium ileus. A careful family history may also provide important clues to the diagnosis of CF. Features of CF that are commonly present at the time of diagnosis are given in Table 98-5.

FEATURE	PERCENT
Acute or persistent respiratory symptoms	50.5
Failure to thrive, malnutrition	42.9
Steatorrhea, abnormal stools	35.0
Meconium ileus, intestinal obstruction	18.8
Family history	16.8
Electrolyte imbalance	5.4
Rectal prolapse	3.4
Neonatal screening	2.3
Nasal polyps, sinus disease	2.0
Genotype	1.2
Hepatobiliary disease	0.9
Prenatal diagnosis	0.8
Other	1.2
Unknown	1.9

*Not mutually exclusive.

TABLE 98-5 Presenting Features in 20,096 Patients with Cystic Fibrosis

Organ-Specific Effects of *CFTR* Mutations

The pancreas in cystic fibrosis

Pancreatic pathology. Eighty-five to 90% of patients with CF have exocrine pancreatic dysfunction. [84] This illustrates the central role of *CFTR* in human pancreatic physiology compared with the *CFTR* knock-out mouse, which has relatively mild pancreatic changes. [85] In humans, pancreatic insufficiency may become increasingly evident in early life because pancreatic function is progressively lost. [86] In patients with typical CF, the pancreas becomes shrunken, cystic, fibrotic, and fatty. The histological appearance resembles other forms of chronic pancreatitis except for the inspissated secretions in the pancreatic ducts. Acinar cell atrophy, ductular hyperplasia, mild inflammatory changes, and progressive fibrosis gradually replace the pancreatic lobules. The islets of Langerhans are spared in most cases until late in the process and appear concentrated in the shrinking pancreas. [87] Radiographically, the appearance of the pancreas in CF can be quite variable. Ultrasonography, magnetic resonance imaging (MRI), and computed tomography (CT) scanning can document the progression of the chronic pancreatitis. Radiographically, the pancreas can appear normal, with incomplete or complete lipomatosis, as a cystic pancreas, macrocystic pancreas, or atrophic pancreas. [88, 89] and [90] The greatest sensitivity is provided either by MRI or CT scanning, but even with these methods, the correlation of abnormalities with the degree of exocrine dysfunction is poor. [88]

Exocrine pancreas dysfunction in cystic fibrosis. The progressive pancreatic damage occurring in patients with CF often begins in utero. On the other hand, the pancreas of an infant with severe *CFTR* mutations may appear normal. [86, 91] One of the first signs of pancreatic pathology in infants is hypertrypsinemia [92, 93] related to destruction of the pancreatic parenchyma. Pancreatic function progressively deteriorates and, in most cases, ends in complete pancreatic insufficiency. Pancreatic insufficiency in CF is usually suspected after observing abnormal stools and heralds complete pancreatic exocrine failure. Patients with retained pancreatic function may develop recurrent pancreatitis. Pancreatitis tends to be more problematic in older patients, with the reported incidence among patients older than 30 years being about 2.4%. [94, 95] In addition to pancreatic exocrine dysfunction, about one third of adults with CF have glucose intolerance, and about 10% develop cystic

fibrosis–related diabetes mellitus (CFRD) [96], [97] because the islets of Langerhans are destroyed. [98] CFRD remains a major problem, and a consensus conference report on diagnosis and management has recently been published. [99]

Recurrent acute and chronic pancreatitis associated with CFTR mutations. As noted earlier, compound heterozygous *CFTR* mutations with *CFTR* ^{SEVERE}/*CFTR* ^{MILD} genotype may have the CF phenotype with abnormal sweat chloride levels and pulmonary disease, while maintaining adequate pancreatic function for digestion. [71], [100] These patients are susceptible to acute pancreatitis. [95] Recent evidence suggests that many patients diagnosed with idiopathic chronic pancreatitis may harbor a combination of one severe mutation, such as ?F508, plus a milder mutation, such as *CFTR* R117H, which allows enough *CFTR* activity for most organs to function. [101] However, this combination of severe (class 1 to 3) and mild (class 4 to 5) *CFTR* mutations clearly predisposed individuals to recurrent acute and chronic pancreatitis. [101], [102] The diagnosis may be difficult in these cases because many mild *CFTR* mutations are not included in commercial *CFTR* testing (see later). Confirmation of diminished *CFTR* function should be done with nasal bioelectric potential difference measurements.

Pancreatic cancer risk. There is growing evidence that chronic pancreatitis from any cause is a risk factor for the development of pancreatic cancer. [103] Recent reports suggest an increased incidence of both pancreatic and intestinal cancers among CF patients compared with control populations. [104], [105] Cancers tended to occur in the third decade of life and often involved the esophagus, small and large intestines, stomach, liver, biliary tract, pancreas, and rectum. [105] Issues of prevention and screening likely will arise as more CF patients survive well into adulthood. However, at this time, there are no data on effective screening modalities for patients with chronic pancreatitis and high risk for pancreatic cancer. [45]

Gastrointestinal track disorders in cystic fibrosis. Patients with CF suffer from a wide variety of gastrointestinal problems extending from the esophagus to the rectum. [106], [107] The most common problems include gastroesophageal reflux and regurgitation, meconium ileus, distal intestinal obstruction syndrome, constipation, and rectal prolapse. The risk for gastrointestinal bleeding is increased because of unbuffered gastric acid, liver disease, and vitamin deficiencies. Symptoms of altered bowel habits, nausea and vomiting, heartburn, gastroesophageal reflux, bloating, flatus, constipation, and abdominal pain are common. [106]

Gastroesophageal reflux. Symptoms of gastroesophageal reflux occur in 20% of patients with CF. [108], [109] and [110] Esophagitis has been documented in up to 50% of patients with significant respiratory problems. [110], [111] Barrett esophagus has also been seen in a number of patients. [112] The reasons for reflux and esophagitis in CF are many, including excessive stomach acid and impaired acid buffering, body positioning during postural drainage of pulmonary secretions, diminished intrathoracic pressure related to lung disease, increased dietary requirements, and others. Treatment is identical to gastroesophageal reflux without CF.

Small intestinal complications of cystic fibrosis. The lumenal surface of the intestine is covered by a massive epithelial surface area. These cells express *CFTR,* and ion transport is affected by *CFTR* mutations. [61], [113], [114] The importance of *CFTR* in gut function is especially evident in mouse models, in which nearly all mice die of intestinal pathology unless there is specific intervention. [85] The CF knock-out mouse intestinal pathology parallels much of human intestinal pathology, including abnormal electrophysiologic profiles, goblet cell hyperplasia, mucin accumulation, crypt dilation, and intestinal obstruction similar to human meconium ileus. [85] Abnormal duodenal bicarbonate secretion is seen in CF patients, which partially explains the lower postprandial pH in the proximal duodenum of these patients compared with normal controls. [115], [116] and [117] Decreased activity of certain cytoplasmic peptide hydrolases in intestinal mucosa and reduced uptake of phenylalanine, isoleucine, and glycine have been found in patients with CF in comparison with control subjects, [118] but xylose absorption remains normal. [119] The small intestinal epithelial cells express a wide variety of ion channels, including non- *CFTR* chloride channels. On the other hand, a number of other transport abnormalities are also present, and may include other ion channels that are regulated by *CFTR*. [59] The variety of chloride channels in the colon is limited compared with the small intestine and respiratory system, [120] so that the defect in colonic function closely relates to the *CFTR* genotype. The loss of pancreatic digestive enzymes and resulting maldigestion aggravates the intestinal pathobiology. The lumen of mucosal glands in the small intestine of patients with CF often contains inspissated secretions. The changes may increase with age. The most severe alterations in the intestinal glands of the small bowel are usually found in patients with meconium ileus. [121] Mucus in CF is more abundant, stains more intensely, and contains more weak acid groups and protein than normally seen. [87] On radiographic examination, the duodenal folds usually appear thickened with nodular filling defects, mucosal smudging, dilations, and redundancy. [122] Radiographically, similar changes occur in the more distal small bowel, including thickening and distortion of jejunal folds and variable dilation of intestinal loops from the jejunum to the rectum. [123]

Meconium ileus. Clinically, the most severe complication of CF in the intestine is meconium ileus. However, distal intestinal obstruction syndrome, intussusception, rectal prolapse, and malabsorption also present common and significant problems. Meconium ileus is the presenting symptom in 10% to 20% of infants with CF and appears to be related to both *CFTR* genotype [100], [124] and a modifier gene on human chromosome 19. [75] The meconium is characterized by a striking decrease in the content of water and the presence of undegraded serum proteins, intestinal disaccharidases, and some lysosomal enzymes. The role of diminished pancreatic enzymes remains controversial because pancreatic involvement may be mild or normal in infants with meconium ileus. [91] Meconium ileus rarely occurs in infants without CF. The focal point of meconium ileus is the distal ileum, which appears narrowed, beaded, and filled with pellets of inspissated meconium. [125] Proximally, the ileal wall is hypertrophied and may become dilated with sticky, dark green-black meconium. Distally, the colon is unused. In addition, meconium ileus may be complicated by volvulus, atresia, or meconium peritonitis. [87] Meconium ileus classically manifests with signs of intestinal obstruction within 48 hours of birth in an infant who is otherwise well. In simple meconium ileus, no meconium passes, and there is progressive abdominal distention and, eventually, bilious vomiting. Dilated, firm, rubbery loops of bowel are visible and palpable through the abdominal wall, particularly in the right lower quadrant, and rectal examination is tight, productive of only a small mucous plug or a small amount of sticky meconium. [87] The complications of “complicated” meconium ileus involve volvulus, ileal atresia, a ruptured viscus, meconium peritonitis, or a combination of these.

Distal intestinal obstruction syndrome and constipation. The distal intestinal obstruction syndrome differs from meconium ileus and may reflect accumulation of undigested food residues, abnormal motility, dilation of the bowel, and dehydration. The distal intestinal obstruction syndrome may affect 3% to 10% of patients with CF. [107], [126], [127] Intussusception of the ileocolic region is a common complication of the distal intestinal obstruction syndrome. [107], [128] Distal intestinal obstruction syndrome may even be the presenting symptom of the disease. Symptoms include abdominal pain caused by constipation or fecal impaction, palpable cecal masses that may eventually pass spontaneously, and complete obstruction of the bowel by firm, putty-like fecal material in the terminal ileum, right colon, or both. [126], [129] The plain radiograph of the abdomen characteristically shows the proximal colon and distal small bowel packed with bubbly-appearing fecal material.

Rectal prolapse. Significant rectal prolapse occurs in 1% to 2% of patients with CF, [130] although it has been seen in up to 18% of patients in some large studies. [131] Onset of rectal prolapse is usually in the first 3 years of life, is often the presenting symptom of CF, and is usually recurrent. [131] A sweat test has been advocated for any child who has had even a single episode of rectal prolapse. [131] Medical management is almost always successful, and adequate replacement of pancreatic enzymes usually results in rapid improvement. However, up to 10% of patients with significant rectal prolapse may require surgical correction.

Liver disorders in cystic fibrosis. Liver abnormalities are frequently observed in patients with CF, but the frequency and severity appear to be decreasing. About 15% of patients have a liver-related problem. However, with modern medical management and emphasis on nutrition, less than 5% develop significant liver injury. [94], [132], [133] The three predominant forms of liver disease in CF include neonatal cholestasis, manifesting with or without meconium ileus or intestinal atresia [134]; fatty liver syndrome; and cirrhosis manifested by portal hypertension or liver failure. Clinical findings include palpable liver (11%), elevated levels of liver enzymes (2.4%), abnormal serum albumin levels (7.4%), cirrhosis with portal hypertension (2.5%), fatty liver (7%), neonatal liver disease (6%), and palpable spleen (2.2%). [130] Asymptomatic hypertransaminasemia or abnormal ultrasonographic findings may be the only manifestations of liver disease, although detection of hepatomegaly or splenomegaly remains a critical component of the physical examination. Esophageal varices or ascites can also be manifestations of hepatic involvement in CF. These may precede evidence of functional impairment (hepatocellular failure) by years. The prevalence of liver abnormalities in CF patients with pancreatic sufficiency is markedly lower. Most patients with mild liver abnormalities do not progress to liver failure, and the abnormal liver injury test results seen in infants may spontaneously resolve. [133] About 10% of patients develop some degree of cirrhosis, and this usually occurs before or during puberty. [133] A familial tendency to develop cirrhosis has been seen [135] and may be associated with one or more modifier genes (see earlier). Other risk factors include neonatal liver disease, pancreatic insufficiency, and possibly human leukocyte antigen class [135], [136] and meconium ileus. [76] Malnutrition and essential fatty acid deficiency may also predispose patients to hepatic steatosis, [133] but nutritional status does not appear to be a major risk factor for liver disease. [137] Histologically, the liver of infants may contain excessive biliary mucus associated with mild periportal inflammation and early fibrosis. Cholestasis from excessive biliary mucus with mild periportal changes may develop and persist for some time. Later in life, focal biliary fibrosis, characterized by inspissated granular eosinophilic material in ductules, bile duct proliferation, chronic inflammatory infiltrates, and variable fibrosis, may develop. Occasionally, the focal lesions coalesce and progress to multilobular biliary cirrhosis. [138] Bile acid metabolism is disturbed in patients with CF and exocrine pancreatic insufficiency. [139], [140] and [141] Fecal losses are high and may approach those of patients with ileal resection. Pancreatic enzyme replacement reduces fecal bile acid excretion and corrects steatorrhea and azotorrhea. The fractional turnover rate of the bile acid pool is increased and the total bile acid pool size diminished in the absence of pancreatic enzymes, [141] whereas the biliary lipid composition and saturation index approach those of patients with cholelithiasis. [140] Treatment with pancreatic supplements returns abnormal values toward normal. Patients with hepatomegaly and abnormal liver test results, with or without abdominal pain, should undergo an assessment of the status of the liver and biliary system. After routine laboratory screening, an ultrasound examination, MRI, or other imaging study may be warranted. Liver biopsy in patients with CF should be undertaken when indicated by the clinical course.

Malnutrition in Cystic Fibrosis Malnutrition occurs in CF through diminished nutrient intake, maldigestion, malabsorption, altered energy utilization, and increased energy expenditure. Intake may be diminished because of abdominal pain, severe gastroesophageal reflux, anorexia, and vomiting or regurgitation and aggravated by depression, physical fatigue, smell and taste aversion, or an altered body image. [142] Maldigestion and malabsorption occur because of pancreatic insufficiency, inadequate bile salt secretion, excess intestinal mucus, infectious enteritis, bacterial overgrowth of the small bowel, and other small bowel pathology. [143] Altered energy utilization is primarily related to diabetes mellitus and liver disease. Increased energy expenditure frequently accompanies severe respiratory disease and is

accentuated by chronic infections, fever, increased respiratory effort, and bronchodilator medications. [142] Severe respiratory symptoms are also associated with anorexia, nausea, and vomiting, which further aggravate the malnutrition cycle. The risk for undernutrition and malnutrition in patients with CF and pancreatic insufficiency is therefore high and potentiates the morbidity and mortality from CF-related problems. [144], [145], [146] and [147]

Diagnosis and Treatment of Cystic Fibrosis

Diagnosis of typical and atypical cystic fibrosis. Once the possibility of CF is considered, the final diagnosis should be confirmed or excluded in a timely fashion and with a high degree of accuracy. This will help prevent unnecessary testing, provide appropriate therapeutic interventions and prognostic and genetic counseling, and ensure access to specialized medical services. On the other hand, the diagnosis should not be taken lightly or made prematurely because it has implications for daily physiologic therapy, medications, special meals, insurance, and employment. Furthermore, a "diagnosis" of CF is difficult to undo. Clinical confirmation of the diagnosis rests on demonstration of elevated concentrations of chloride in sweat (chloride concentration at least 80 mmol/L) [69], [148] or demonstration of an abnormal nasal bioelectric response in specific testing protocols, [69], [149], [150] reflecting abnormal *CFTR* function. When performed correctly, these tests are reliable. However, both false-positive and false-negative sweat test results are seen in newborns, in patients with malnutrition, in the presence of some medications, or if inadequate sweat is obtained. [69] Thus, most experts insist on utilization of standardized methods performed at CF centers that perform the test frequently. A Cystic Fibrosis Foundation consensus panel recently recommended that the diagnosis of CF could be made by the presence of one or more characteristic clinical features, a history of CF in a sibling, or a positive newborn screening test result with confirmation by laboratory evidence of *CFTR* dysfunction. [81] Furthermore, they recommended that either sweat chloride or nasal bioelectrical responses should be abnormal on 2 separate days before the diagnosis is confirmed by one of these methods. [81] Nasal potential difference measurement is difficult to perform, very labor intensive, and available only in a few centers, but it can be especially helpful in cases of atypical CF or borderline features. [69], [101], [151] Genetic testing is also commercially available to confirm the clinical diagnosis (two disease-causing mutations must be identified), but these results cannot always be interpreted apart from the clinical context and functional testing, especially in cases with atypical presentation, because between 2% and 15% of patients with CF may have one or two unidentified mutant alleles.

Treatment. The treatment of CF should be initiated early and should be aggressive, especially in young patients. The effects of delayed diagnosis and inadequate treatment may be long lasting and irreversible in some cases. Therefore, vigilance is warranted.

Pancreatic enzyme replacement therapy. The treatment for pancreatic digestive enzyme deficiency is enzyme replacement. [152], [153] and [154] However, the timing, amount, and other cofactors play important roles in proper delivery of enzyme supplements aimed at restoring digestive function. [155] Enzymes are given with all protein- and fat-containing foods and milk products, including predigested formulas and breast milk. Microspheres, minimicrospheres, or microtables are preferable to granules because the acid-resistant enteric coating protects the enzyme from acid degradation in the stomach and protects against the mouth and perianal excoriation that was previously seen with raw, uncoated enzyme powders. [156], [157] Enzymes should be taken about 15 minutes before each meal or snack. For prolonged meals, additional enzymes should be taken also during the meal. Parents and adults should be taught to adjust the enzyme dosage according to the anticipated amount of fat in a meal. Generic enzymes may not be bioequivalent to proprietary enzymes. [158] Therefore, apparent treatment failure should include investigation of the brand of enzymes that were dispensed. Another cause of failure is destruction of the digestive enzymes by gastric acid. Although enteric coating of pancreatic enzymes may protect pancreatic enzymes in the stomach, the intestines remain more acidic (1 to 2 pH units) in patients with *CFTR* mutations than those with other types of pancreatitis because of loss of duodenal bicarbonate secretion. [115], [116] In the past, treatment of the gastric and intestinal acidity included the use of sodium bicarbonate (baking soda) and histamine-2 receptor antagonists. However, the availability, efficiency, and safety of the proton pump inhibitors have resulted in widespread use of these products. Enteric-coated products remain effective when used with proton pump inhibitors. The dose of enzymes is usually calculated according to lipase content. A usual dose of pancreatic enzymes contains 1000 to 2500 units lipase/kg/meal. Adequacy of treatment is typically determined on clinical grounds. Frequent, bulky, fatty stools, excessive bloating and flatus, excessive appetite, and inadequate growth velocity are signs of inadequate treatment. Calculation of a coefficient of fat absorption is used for clinical studies, but rarely in clinical practice. Although the human fecal elastase-1 test accurately predicts pancreatic insufficiency, [159], [160] and [161] it is of no value in determining the adequacy of enzyme replacement because it is specific for *human* elastase.

Treatment of meconium ileus and distal intestinal obstruction syndromes. Treatment of complicated meconium ileus is surgical. There is a very low operative mortality rate, and long-term survival approaches 100% for uncomplicated meconium ileus. [124], [162] Nonoperative relief of uncomplicated meconium ileus may be possible with diatrizoate (Gastrografin) enemas. [107], [124] A diagnostic barium enema usually precedes therapeutic Gastrografin enemas in children, [91], [124], [163] but a Gastrografin enema can be used directly in adult patients with distal intestinal obstruction syndrome. Infants with CF and meconium ileus who survive beyond 6 months of age have the same prognosis as any patient with CF and do not tend to have more severe disease. [124] The treatment of distal intestinal obstruction syndrome is primarily medical. A stepwise approach with therapeutic trials of more than one modality should be used in each patient before a consideration of surgery. [125] Vigorous medical therapy includes regular oral doses of pancreatic enzymes and stool softeners, oral or rectal administration of 10% *N*-acetylcysteine, and Gastrografin enemas. Maintenance treatment with oral doses of *N*-acetylcysteine, increased doses of pancreatic enzymes, and lactulose has been successfully used to prevent recurrent episodes of the syndrome. Treatment of this disorder with balanced intestinal lavage solutions has also proved helpful. [127], [164] New polyethylene glycol preparations without electrolytes (e.g., MiraLax) also appear to be safe, effective, and well tolerated in adults [165] and children, [166] although its utility in CF has not yet been established.

Treatment of liver complications. The treatment of symptomatic liver disease in CF is a challenge and usually requires a team approach. Treatment of cholestasis is probably best accomplished with ursodeoxycholic acid (20 mg/kg/day), although controlled clinical trials have not confirmed as yet that ursodeoxycholic acid can prevent the progression of liver disease. In patients with cirrhosis, infections (spontaneous bacterial peritonitis and cholangitis) necessitate treatment with appropriate antibiotics. Encephalopathy is extremely uncommon in the cirrhosis of CF but should be treated with protein restriction, lactulose, or neomycin, especially in preparation for liver transplantation. Endoscopic screening should be considered for patients with evidence of cirrhosis to diagnose complications of portal hypertension, including gastropathy and gastric and esophageal varices. Gastrointestinal bleeding should be treated vigorously upon diagnosis. Endoscopic banding or sclerotherapy of bleeding esophageal varices is the most effective and rapid form of therapy. Adrenergic beta-blockers (e.g., propranolol, atenolol) have not yet been widely used in patients with CF liver disease. If severe lung disease is not a contraindication for surgery and the clinical status of the patient is acceptable, end-stage liver disease in CF is an indication for liver transplantation. [167] In rare cases, combined liver-lung transplantation may be indicated, but few such procedures have been reported. [168]

Assessment and treatment of malnutrition. Maintenance of adequate nutrition remains one of the most important challenges in treating patients with CF. The key concepts for nutritional management include proper assessment of nutritional requirements, taking into consideration age, height, weight, and anthropometrics and severity of lung disease as well as anorexia, pancreatic insufficiency, other intralumenal phase abnormalities, and mucosal dysfunction. [142], [169], [170] The physician must therefore determine whether the patient has inadequate nutritional intake and the degree of maldigestion, malabsorption, altered energy requirements, or other medical complications such as diabetes mellitus or liver disease. If the nutritional targets of maintaining or gaining weight are missed, or biochemical evidence of malnutrition emerges, then a detailed evaluation is warranted. Nutritional targets begin with determination of the patient's ideal weight compared with his or her actual weight. Further adjustments are made for age, growth patterns, specific nutritional deficiencies, and other factors. For adult patients, the body mass index (BMI) is used to assess appropriate weight, calculated as weight in kilograms divided by height in square meters. [156] In pediatric patients, the BMI percentile should be used [156] (see appropriate charts on the Center for Disease Control website at http://www.cdc.gov/growthcharts). The older method was to calculate the percentage ideal body weight (IBW), calculated as the actual weight divided by ideal weight-for-height multiplied by 100. [170], [171] The percentage IBW should also be recorded if this method was used before development or use of the BMI percentile charts. [156] /SUP>If the patient is losing weight or a child appears to develop a weight plateau but maintains weight above 90% of IBW, [156] or if the BMI is between the 10th and 25th BMI percentile, he or she is at risk for nutritional failure. Nutritional failure occurs when weight plateaus for more than 3 months in children younger than 5 years of age or for more than 6 months in children older than 5 years of age, or when the percentage IBW is less than 90% or the BMI percentile is less than 10th percentile. [156] Inquiry about reproductive health, including menstrual regularity in females, may also provide clues as to nutritional health. The optimal dietary intake for a patient with CF is greater than the recommended daily allowance of healthy children and adults. Ideally, a normal diet for age should be encouraged, except that fat intake should achieve 35% to 40% of calories, balanced with adequate pancreatic replacement therapy. [106], [156] However, a daily intake between 110% and 149% of the standard Recommended Daily Allowance (RDA) for age is needed for calories and protein to promote normal growth, and children with end-stage lung disease may require in excess of 150% of the RDA. [156], [172] Nutritional intervention begins with addition of high-calorie foods to the usual diet and use of nutritional supplements. [156] When this fails, enteral feedings should be started. This may be achieved through nasogastric tubes, gastrostomy, or jejunostomy tubes. The presence and severity of gastroesophageal reflux disease symptoms may influence the decision on route. Standard formulas are usually well tolerated. Nocturnal infusion is encouraged to promote normal eating patterns during the day. Initially, 30% to 50% of the estimated caloric needs should be provided overnight. Very-low-fat, elementary formulas may be used without enzyme supplements for patients with enteral feeding tube and should be given by continuous infusion. [156] Pancreatic enzyme supplements taken orally in the usual premeal dose are recommended before all nocturnal enteral feedings. Patients with enteral feedings should be monitored for carbohydrate intolerance by measuring blood glucose levels 2 to 3 hours into the feeding and at the end of the feeding on at least 2 separate nights. Insulin may be required to prevent hyperglycemia, and the dosage may need to be adjusted during illness, steroid use, or other changes in health status. All patients with CF should receive a multivitamin preparation daily, and many require vitamin A, E, K, and D supplements. [170]

Clinical practice guidelines for cystic fibrosis management. Advances in medical treatment and nutrition have markedly improved the prognosis of patients with CF, with more than half of all patients living beyond 30 years of age. [130], [173] The treatment necessary to surpass this milestone requires attention to a wide range of issues involving multiple organ systems, nutritional challenges, developmental problems, social issues, and other considerations. These are usually best met by well-coordinated multidisciplinary teams. Care guidelines have been defined and refined within the numerous CF centers, which typically focus on infant and pediatric patients. In many cases, the pediatric CF specialists continue to care for adult patients with CF. However, there is growing

consensus among experts that these patients should transition to physicians specializing in adult patient care sometime between the age of 18 and 21 years, depending on the medical condition, the emotional maturity of the patient, and the readiness of the family. [174] Adult patients with CF suffer from the same matrix of problems recognized in the pediatric population, plus additional problems. These medical problems include pancreatitis, adequate nutrition, cirrhosis with portal hypertension, diabetes with its long-term complications, osteopenia, and reproductive issues. [97], [175], [176] and [177] Gallbladder disease, peptic ulcer disease, pancreatitis, and cirrhosis with portal hypertension are more common in adults than in children. [130], [178] Furthermore, pulmonary disease is more severe in adults than in children, and malnutrition remains a prominent problem in about 35% of adults with CF. [130] Increasingly, these patients will require evaluation for potential malignancies of the digestive tract and evaluation for liver disease or other complications that will necessitate the specialized attention of a gastroenterologist. The complexity and severity of these problems requires the coordinated care of a multidisciplinary team that is typically headed by pulmonologists and includes gastroenterologists, endocrinologists, urologists, and the allied health care of nurses, dietitians, respiratory and physical therapists, and social workers. [174] The adult patient should be seen at least four times a year, with annual investigation of nutritional status (including vitamin levels), liver function, and other disease-related screening tests (e.g., oral glucose tolerance test hemoglobin A1c). Routine clinical visits should include qualitative dietary history; assessment of appetite, eating, and related behavioral patterns; and supplemental feeding practice since the last visit, including enteral and parenteral nutrition. [174] The nutritional assessment may be expedited with assistance of a qualified registered dietitian or others with skills in obtaining a 3-day quantitative dietary record and assessment of energy balance. Measurement of mid-arm circumference and triceps skin-fold thickness provides clinical information on both lean body mass and subcutaneous fat stores. Standardized techniques and equipment should be used for body measurements, and special training is recommended to ensure accuracy and consistency. [156] The pulmonary problems are beyond the scope of this chapter and require the attention of a pulmonologist with experience in CF. Also, CFRD should be managed by the endocrinologists. If the CF-related training and experience of an adult medical specialists is limited, then a CF Care Center Director or other pediatrician with more extensive experience with CF should remain on the multidisciplinary team, or referrals should be made to centers with more experience in adult CF medicine. [174]

RARE SYNDROMES WITH MAJOR PANCREATIC MANIFESTATIONS

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (SDS, OMIM *260400) remains the second most frequently recognized cause of pancreatic insufficiency in children, representing about 3% of causes of pancreatic dysfunction. [86] SDS is an autosomal recessive disorder [179] with a disease gene at the centromere of chromosome 7. [180], [181] Rather than being a pancreas-destroying disease like CF and hereditary pancreatitis, the pancreas in patients with SDS appears to have fatty replacement of acinar cells. [182], [183] The parotid gland amylase secretion may also be defective, suggesting that the acinar cell dysfunction is generalized. [184]

SDS is characterized by exocrine pancreatic insufficiency with normal sweat electrolytes and significant hematologic abnormalities. [185], [186] and [187] Skeletal defects, including short ribs with broadened anterior ends and metaphyseal dyschondroplasia on the femoral head, short stature, myelodysplastic syndromes, and acute leukemias, are common. [185], [186] Other abnormalities include elevated liver enzymes, hepatomegaly, and developmental delay.

The pancreatic insufficiency associate with SDS is quite variable and differs from CF because it improves with time in up to 50% of patients. [86], [185], [186], [188] The lesion appears to be a developmental failure of the acinar cells because enzyme secretion is drastically reduced, whereas duct cell function is normal. [86] Pancreatic insufficiency can be diagnosed with fecal fat measurements, pancreatic function testing for lipase levels, low immunoreactive serum trypsinogen levels, or imaging studies such as MRI or CT that reveal lipomatous pancreas. The treatment of pancreatic insufficiency is supportive, including pancreatic enzyme replacement.

Cyclic neutropenia is the most common hematologic disorder, but other cellularity can be involved. [185], [186], [188] The cyclic neutropenia leads to recurrent infections, especially respiratory problems. The human granulocyte colony-stimulating factor has been successfully used in patients with SDS with severe neutropenia and frequent infections. [186], [189] This seems to control the neutropenia, even when weekly doses are given. The dose should be the minimum necessary to achieve control of infection. [186] The problem with this treatment is that there are no clear guidelines for the duration of use or for whether it is advisable in the presence of cytogenetic alterations. [186]

Another major problem in SDS patients is myelodysplastic syndrome and eventually acute myeloid leukemia. [185], [186], [190], [191] Although the prevalence has not been established, acute myeloid leukemia is reported to occur in 0% to 30% of patients. [179], [185], [186], [191] Some specific abnormalities are common, especially isochromosome 7q10. [180] Allogenic bone marrow transplantation should be considered for patients who develop leukemia. [186], [192], [193] and [194]

Johanson-Blizzard Syndrome

Johanson-Blizzard syndrome (OMIM *243800) is a very rare autosomal recessive syndrome of unknown etiology. Johanson-Blizzard syndrome [195] is also known as nasal alar hypoplasia, hypothyroidism, pancreatic achylia, and congenital deafness syndrome. [9] It is characterized by pancreatic insufficiency and growth retardation with lipomatous transformation of the pancreas. Histologically, the pancreatic ducts and islets are preserved but are surrounded by connective tissue and a total absence of acini. Pancreatic ductal function remains normal. [196] Additional features include thyroid dysfunction, cardiac anomalies, genitourinary malformations, midline ectodermal scalp defects, dental anomalies, and imperforate or anterior anus. [195], [197] On the other hand, there may be milder forms presenting with isolated pancreatic enzyme deficiencies. [197] The treatment of the exocrine pancreas deficiencies is similar to other forms of pancreatic insufficiency.

Pearson Marrow-Pancreas Syndrome

Pearson marrow-pancreas syndrome (OMIM #557000) is a rare, autosomal dominant mitochondrial DNA (mtDNA) breakage syndrome. [198], [199] Clinical features include pancreatic insufficiency, sideroblastic anemia, and diabetes mellitus. The pancreatic insufficiency appears to be due to pancreatic fibrosis. [200] The molecular defect in Pearson marrow-pancreas syndrome was initially identified as a 4977–base pair deletion of mtDNA, although a variety of mtDNA defects have been discovered. [201], [202] and [203] The clinical features and severity of disease appear to correlate with the proportion of abnormal mtDNA, and multiple organ systems may be involved.

RARE DEVELOPMENTAL ABNORMALITIES

A variety of congenital abnormalities of the pancreas have been observed, reflecting defective embryogenesis. Pancreatic divisum, annular pancreas, common channel syndrome, choledochal cysts, heterotopic pancreatic tissue, and annular pancreas are included in this group, but the genetics is not well understood.

Pancreatic agenesis is extremely rare and is probably caused by a homozygous nucleotide deletion in the *PDX1* gene, resulting in premature termination of the *PDX1* gene production. [204] The clinical features include intrauterine growth retardation, insulin-dependent diabetes, and pancreatic exocrine insufficiency. Serum C-peptide and glucagon are undetectable, and the pancreas is absent on imaging studies. Survival into childhood is possible with proper diagnosis and insulin and enzymatic supplementation. [204], [205] Pancreatic hypoplasia is thought to be a variant of pancreatic agenesis, and isolated agenesis of the dorsal or ventral pancreas has also been observed. Agenesis of the dorsal pancreas [206] and ventral pancreas [207] has occasionally been seen, but the cause is unknown.

Acknowledgements

This work was supported by NIH DK54709, a Veterans Administration Merit Review Award, the Lustgarten Foundation, the National Pancreas Foundation, and the Cystic Fibrosis Foundation. I thank Drs. Preston Campbell, Alexander Schneider, Asif Khalid, and Amit Rastogi and the Cystic Fibrosis Foundation for assistance in preparing this manuscript.

CHAPTER 99

Diane M. Simeone

GALLBLADDER AND BILIARY TRACT: ANATOMY AND STRUCTURAL ANOMALIES

The extrahepatic biliary tract has a great number of anomalies and variations, with a wide range of anatomic variations also seen in the vascular structures surrounding the extrahepatic biliary tree. Increasing use of diagnostic and interventional radiology as well as therapeutic endoscopy has made it essential for a wide variety of physicians to become familiar with the anatomy of the extrahepatic biliary tract. This review of anatomy and anomalies of the extrahepatic bilary tree will assist surgeons, gastroenterologists, and radiologists in understanding and recognizing the anomalies they may encounter.

EMBRYOLOGICAL DEVELOPMENT

The biliary tract develops from the primitive gastrointestinal tract, in the distal foregut, as a ventral sacculation; it is first apparent at week 5 of gestation, or when the embryo is 3-mm long (Fig. 99-1A). This sacculation grows and extends into the ventral mesentery, dividing into two buds: the cranial bud develops into the liver and intrahepatic bile ducts and the caudal bud develops into the gallbladder and cystic duct (Fig. 99-1B). The base of the diverticulum ultimately becomes the common bile duct. Another small bud develops from the proximal aspect of the caudal bud and grows inferiorly, ultimately developing into the ventral pancreas (see Fig. 99-1A, Fig. 99-1B).

FIGURE 99-1. Embryology of the developing biliary tract. **A:** At the 3-mm stage of the embryo, the ventral bud enters the mesogastrium and soon divides into a cranial and a caudal bud. A smaller caudad bud represents the origin of the ventral pancreas. **B:** As the embryo reaches 5 mm, the cranial bud, which will form the liver and intrahepatic biliary tract, moves toward the septum transversum, pulling the caudal bud, which will form the gallbladder and extrahepatic bile ducts. **C:** When the embryo reaches 7 mm, the right and left lobe of the liver occupy the position under the septum transversum. The ventral pancreas and the extrahepatic biliary tract are visible. As the ventral pancreas rotates to reach the dorsal pancreas, it pulls the lower end of the common bile duct with it. **D:** At the 12-mm embryonic stage, the ventral pancreas has rotated, and the anatomic relations between the bile ducts and the gastrointestinal tract have assumed their mature forms.

The cranial bud divides into two smaller buds that grow upward toward the septum transversum (future diaphragm). These eventually become the right and left lobes of the liver. The caudal bud is carried superiorly by the growth of the cranial bud and stops at the undersurface of the cranial bud to become the gallbladder and cystic duct (Fig. 99-1C). Rarely, continued advancement of the caudal bud too far superiorly will result in an intrahepatic gallbladder, which is almost always embedded within the right lobe of the liver.

As the cranial and caudal buds are advancing, the ventral pancreatic bud rotates 180 degrees from right to left, allowing it to fuse with the dorsal pancreatic bud to form the complete pancreas. Fusion of the two parts of the pancreas occurs during week 7 of gestation. Because the lower end of the common bile duct is attached to the ventral pancreatic bud, the rotation results in fusion of the junction of the common bile duct and the duodenum on the posteromedial duodenal wall, posterior to the dorsal pancreatic duct (Fig. 99-1D).

The ventral sacculation from which the biliary tract arises is originally composed of a solid cord of endodermal cells and contains no lumen. Beginning at week 7 of gestation, vacuolization begins to occur and a completely open lumen is formed in the gallbladder, cystic duct, hepatic ducts, and common bile duct within 1 week. By the third month of gestation, bile flow is demonstrable through the canalized biliary tract into the duodenum. [1]

ANATOMY OF THE GALLBLADDER

Gross Anatomy

The gallbladder is a pear-shaped sac that is located along the inferior surface of the liver in the line of division of the anatomic left and right lobes; it lies in a depression known as the gallbladder fossa (Fig. 99-2). The adult gland is typically 7 to 10 cm in length and has an average capacity of 30 mL. The gallbladder is intimately attached to the liver by loose connective tissue, which contains small veins and lymphatics that connect between the gallbladder and liver. Occasionally, one or more small accessory ducts from the liver traverse this connective tissue to enter the gallbladder directly. Inadequate ligation of an accessory duct may account for the occasional bile leak that occurs after cholecystectomy.

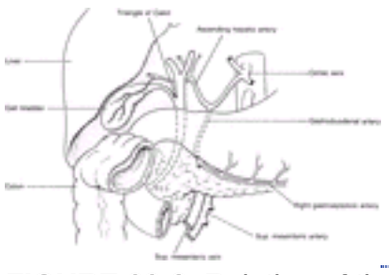

FIGURE 99-2. Relation of the gallbladder and the extrahepatic biliary tract to the liver, duodenum, colon, and pancreas.

The remainder of the gallbladder not in direct contact with liver is covered by peritoneum reflected from the liver. The gallbladder is divided into four anatomic areas: fundus, body, infundibulum, and neck. The fundus is the rounded end of the gallbladder that normally extends 0.5 to 1 cm beyond the liver margin and is covered with peritoneum. The fundus rests on the duodenum and hepatic flexure of the colon (see Fig. 99-2) and is in direct contact with the anterior abdominal wall, usually near the lateral border of the right rectus abdominus muscle at approximately the level of the ninth costal cartilage; however, its position may vary. The fundus may occasionally possess a kink, known as a phrygian cap deformity, which has no pathological significance.

The fundus merges imperceptibly into the body, the largest part of the gallbladder, and the segment that is closely attached to the liver on one side. This intimate contact is responsible for early direct spread of gallbladder carcinoma into the liver. The infundibulum represents a transitional region between the body and neck. It is notable because occasionally a shallow diverticulum may be present on the inferior surface of the infundibulum, referred to as a Hartmann pouch. Gallstones may become impacted within the Hartmann pouch, causing cystic duct obstruction and thus acute cholecystitis.

The neck is a short (usually 5–7 mm) region that tapers into the cystic duct. The neck occupies the deepest part of the gallbladder fossa and lies in the free border of the hepatoduodenal ligament.

Arterial Blood Supply

The blood supply to the gallbladder is usually from a single cystic artery that arises from the right hepatic artery, traverses the triangle of Calot, and divides into two branches close to the gallbladder wall [2] (Fig. 99-3A). One branch runs along the peritoneal surface of the gallbladder and the other branch in the gallbladder fossa between the gallbladder and liver. When the cystic artery arises from the right hepatic artery, its course is often parallel and medial to the cystic duct. Double or accessory cystic arteries have been reported in up to 20% of people. Variations in the site of origin and course of the cystic artery are common. The cystic artery typically arises from the right hepatic artery (95%), but also may arise from the left hepatic artery, the common hepatic artery, an aberrant right hepatic artery that arises from the superior mesenteric artery, the gastroduodenal artery, the superior mesenteric artery, or celiac axis directly (see Fig. 99-3). The cystic artery may be short or long, and may pass either behind the hepatic duct (84%) or may cross the hepatic duct anteriorly.

FIGURE 99-3. Common variations in the origin of the cystic artery. **A:** It originates most commonly from the right hepatic artery; it traverses the triangle of Calot, and, upon reaching the gallbladder, it divides into two main branches. **B:** Occasionally the two branches come off the right hepatic artery independently. The cystic artery may cross the hepatic duct anteriorly (**C**), come off the left hepatic artery (**D**), or, more rarely, come directly from the celiac axis (**E**). (From Lindner H. Embryology and anatomy of the biliary tree. In: Way LW, Pellegrini CA, eds. Surgery of the gallbladder and bile ducts. Philadelphia: WB Saunders, 1987.)

The cystic artery, when it originates from the right hepatic artery, may closely parallel the right hepatic artery for a distance before reaching the gallbladder. In 5% to 10% of cases, the cystic artery does not arise from the right hepatic artery until just before it enters the right lobe of the liver, thus creating a very short (only a few millimeters) cystic artery. Failure to recognize this may lead to inadvertent ligation of the right hepatic artery during cholecystectomy.

Venous and Lymphatic Drainage

The gallbladder lacks a major cystic vein but rather drains through a network of small veins. These veins run either from the hepatic surface of the gallbladder directly to the liver or run toward the cystic duct and join venous collaterals from the common bile duct before ultimately draining into the portal vein.

The lymphatic drainage of the gallbladder parallels the venous drainage pattern. Lymph flows directly from the gallbladder to the liver or may drain toward the cystic duct into a single node or group of nodes. From these lymph nodes, lymph may ultimately drain into several nodes along the surface of the portal vein and common bile duct.

Nerve Supply

The gallbladder is innervated by branches of both the sympathetic and parasympathetic nervous systems, which pass through the celiac plexus. Preganglionic sympathetic nerves arise from the T8 and T9 levels. Postganglionic sympathetic nerves originate at the celiac plexus and travel along the hepatic artery and portal vein to the gallbladder. Parasympathetic nerves arise from branches of the vagal trunks. Unlike the branches of the posterior vagal trunk that pass through the celiac plexus, branches of the anterior vagal trunk reach the gallbladder by way of the gastrohepatic ligament (Fig. 99-4). Visceral pain caused by gallbladder wall distention or inflammation is conducted through afferent sympathetic fibers and is referred to the epigastric, right subcostal, or right scapular regions. The nerve supply to the common bile duct is the same as for the gallbladder.

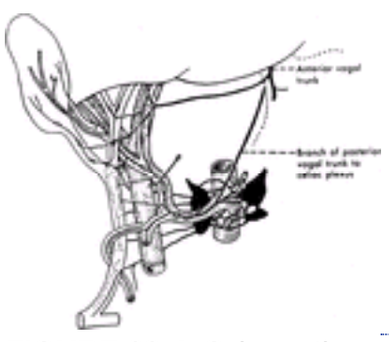

FIGURE 99-4. Schematic representation of the innervation of the gallbladder and extrahepatic biliary tract. The nerves originate from both vagi and from the celiac axis. They reach the biliary tract, traveling along the walls of the hepatic artery, except for the direct vagal branches of the anterior vagus, which cross through the gastrohepatic ligament.

Although gallbladder contractility is primarily mediated by cholecystokinin (CCK), innervation of the gallbladder also modulates gallbladder contractility. Vagal activity contributes to normal gallbladder tone and enhances the ability of subthreshold doses of CCK to promote gallbladder mobility. [3] Sympathetic fibers enhance gallbladder relaxation. In addition to the classic parasympathetic and sympathetic nervous systems, a large number of peptide-containing neurons exist within the gallbladder. The peptides identified thus far by immunocytochemical techniques include CCK, [4] vasoactive intestinal polypeptide, [4] gastrin-releasing peptide, [5] neuropeptide Y, [6] pituitary adenylate cyclase–activating polypeptide (PACAP), [7] calcitonin gene–related peptide (CGRP), [7] and substance P. [7] The physiologcial functions of these peptidergic nerves within the gallbladder remain to be elucidated.

Histology and Ultrastructure

The gallbladder has five layers: epithelium, lamina propria, muscularis, perimuscular connective tissue layer, and serosa. The mucosa, lined with a simple columnar epithelium, consists of many folds that increase the efficiency of the gallbladder in concentrating bile. The apical surface of the epithelium is covered with abundant microvilli. The basal surface of the epithelium is in contact with the lamina propria, which is rich in loose connective tissue, elastic fibers, blood vessels, and lymphatics. The muscularis is an arrangement of circular, longitudinal, and oblique fibers without any well developed layers. Ganglia may be found between the muscle fibers of the muscularis. The subserosa contains loosely arranged collagen and elastic fibers, as well as larger blood vessels and lymphatics. This thick subserosal layer attaches the gallbladder to the liver. Dissection during cholecystectomy usually takes place between the subserosa and serosa, which in normal circumstances is an avascular plane. The serosa is absent on the surface of the gallbladder that is in direct contact with the liver. Mucus is secreted into the gallbladder from tubular alveolar glands found in the mucosa lining the infundibulum and neck of the gallbladder.

At the ultrastructural level, the gallbladder epithelium is well suited for its physiological role of concentrating bile. The columnar epithelial cells have basally located nuclei and apices covered with numerous microvilli that protrude into the gallbladder lumen. Numerous mitochondria are present within the epithelial cells, which facilitate the active process of bile concentration. Epithelial cells are tightly joined together along their lateral membranes by tight junctions, which separate the gallbladder lumen from the intercellular spaces. During active bile concentration, the intercellular spaces become distended with water and electrolytes. Water extracted during this process passes into a rich capillary network in the lamina propria.

ANATOMY OF THE EXTRAHEPATIC BILIARY DUCTS

Hepatic Ducts

The common hepatic duct is formed by the union of the right and left hepatic ducts. In 95% of cases, this union takes place outside the liver, just below the level of the porta hepatis. In 5% of cases, the left and right hepatic ducts join within the substance of the liver. The lengths of the right and left hepatic ducts vary from 0.5 to 2.5 cm in length, with the left hepatic duct usually longer than the right. The ducts may join at a wide or acute angle, depending on their extrahepatic length; however, they usually join about 1 cm below the porta hepatis to form the common hepatic duct. The confluence of the right and left hepatic ducts lies anterior to the portal venous bifurcation, usually overlying the origin of the right branch of the portal vein. An accessory right hepatic duct is present in 10% of people. The common hepatic duct passes downward in the superior portion of the hepatoduodenal ligament and lies anterior to the portal vein and to the right of the hepatic artery (Fig. 99-5). In cases when the cystic duct inserts on the right hepatic duct or at the junction of the union of the right and left hepatic ducts, there is no common hepatic duct. The length of the common hepatic duct varies from 2 to 6.5 cm. It joins the cystic duct to form the common bile duct.

FIGURE 99-5. Schematic representation of the hilum of the liver. The right anterior and posterior hepatic ducts join to form the right hepatic duct. This duct and the left duct join outside the liver capsule to form the common hepatic duct. The left duct is usually longer and more superficial than the right. The triangle of Calot, with the right hepatic artery and the cystic artery, is also clearly displayed. (From Lindner H. Embryology and anatomy of the biliary tree. In: Way LW, Pellegrini CA, eds. Surgery of the gallbladder and bile ducts. Philadelphia: WB Saunders, 1987.)

The course of the right hepatic artery is variable in relation with the right hepatic duct and common hepatic duct. Usually the right hepatic artery passes posterior to the common hepatic duct near the junction of the right and left hepatic ducts (64%). In 24% of people, the right hepatic artery or the cystic artery may pass anterior to the common hepatic duct. In the remaining patients (12%), the right hepatic artery arises from the superior mesenteric artery and runs parallel and to the right of the common bile duct and posterior to the cystic duct. Because of the inconstant location of the right hepatic artery and its close proximity to the cystic artery, the right hepatic artery may be mistaken for the cystic artery and is particularly vulnerable to injury during biliary tract surgery.

The triangle of Calot, originally described in 1891, is bounded superiorly by the hilum of the liver, on the right by the cystic duct, and on the left by the common hepatic duct [8] (see Fig. 99-5). Dissection of the triangle of Calot during cholecystectomy must be carried out with care because many important structures run through this triangle: the right hepatic artery, the cystic artery, 90% of accessory hepatic ducts, and 95% of aberrant right hepatic arteries. In cases when there is a replaced right hepatic artery originating from the superior mesenteric artery, the vessel travels toward the liver in a position posterolateral to the common bile duct and just behind the cystic duct. Here it is vulnerable to injury. Complete dissection of the triangle of Calot, with separation of the base of the gallbladder from the liver bed, allowing identification of the only two structures that should be emanating from the gallbladder, the cystic duct and cystic artery, is critical to avoid injury during cholecystectomy.

Cystic Duct

The cystic duct arises from the neck of the gallbladder and joins the common hepatic duct. Its lumen usually measures 1–3 mm, but it may occasionally be as large as 10 mm, allowing larger gallstones to enter the common bile duct. While the cystic duct typically joins the common hepatic duct directly (70%), the site of the cystic duct junction with the extrahepatic biliary tree may vary from the right hepatic duct down to the level of the ampulla (Fig. 99-6 and Fig. 99-7). Thus the length of the cystic duct may vary from 0.5 to 8 cm. The cystic duct may join the right hepatic duct, may run parallel to the common hepatic duct for a distance with connective tissue ensheathing both ducts, and, in some instances, may not enter the common hepatic duct until passing behind the duodenum. Additionally, the cystic duct may spiral around the common hepatic duct, passing either dorsal or ventral to the common hepatic duct before joining it. These anatomic variations may lead to bile duct injury during cholecystectomy, especially if dissection is carried out to clearly define the union of the cystic duct and common bile duct, a practice that is unnecessary during cholecystectomy.

FIGURE 99-6. Endoscopic retrograde cholangiopancreatogram demonstrating an anomalous junction of the cystic duct with an accessory right hepatic duct.

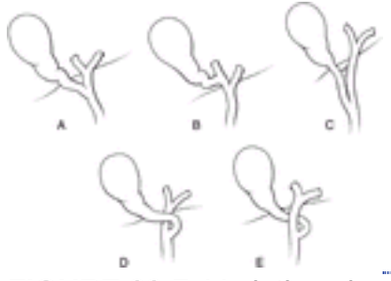

FIGURE 99-7. Variations in cystic duct anatomy. **A:** Cystic duct joins common hepatic duct directly (most common). **B:** Cystic duct joins the right hepatic duct. **C:** Low junction of cystic duct with common hepatic duct. **D:** Anterior spiral of cystic duct before joining common hepatic duct. **E:** Posterior spiral of cystic duct before joining common hepatic duct.

Within the cystic duct, the mucosa forms a series of 5 to 10 crescent-shaped folds, known as the spiral valves of Heister. They span the length of the cystic duct and project into the cystic duct lumen. These valves serve to prevent excessive distention or collapse of the gallbladder with changes in cystic duct pressure and may function to block passage of gallstones into the common bile duct. They may make catheterization during intraoperative cholangiogram difficult.

Common Bile Duct

Union of the cystic duct and common hepatic duct forms the common bile duct. Its length is approximately 7.5 cm, but can vary depending on the relative lengths of the cystic and common hepatic ducts. The mean diameter of the common bile duct is about 6 mm, but it may dilate significantly in the face of distal obstruction. The common bile duct is divided into four anatomic segments: supraduodenal, retroduodenal, pancreatic, and intraduodenal. The supraduodenal segment is usually 2.5 cm in length and is located in the right border of the hepatoduodenal ligament. It lies anterior to the portal vein and to the right of the ascending common hepatic artery. This anatomic relationship allows the surgeon to compress these three structures between an index finger inserted through the foramen of Winslow into the lesser sac and a thumb placed anteriorly across the hepatoduodenal ligament. This maneuver is referred to as the Pringle maneuver and allows rapid occlusion of the blood supply to the liver, which is useful for controlling major liver hemorrhage.

The retroduodenal segment lies posterior to the first part of the duodenum and is about 2.5 to 4 cm long. As it runs to the inferior surface of the duodenum, it moves right to left, lying just to the right of the gastroduodenal artery. The retroduodenal common bile duct is loosely attached to the duodenum by a thin layer of areolar tissue. Because of the close relationship of this portion of the common bile duct and the duodenal bulb, it may occasionally be involved in the inflammatory process of a posterior penetrating duodenal ulcer and may be inadvertently injured during antrectomy.

The pancreatic segment of the common bile duct extends from the lower border of the first part of the duodenum to the posteromedial wall of the second portion of the duodenum where the duct penetrates the duodenal wall. It may be entirely retropancreatic, or it may lie within the substance of the head of the pancreas. Obstruction of this segment of the common bile duct is common with cancers of the pancreatic head, which often initially present with painless jaundice.

The common bile duct then turns 90 degrees to the right to enter the posteromedial wall of the descending duodenum. The final, or intraduodenal, segment of the common bile duct is about 2 cm long and travels obliquely through the duodenal wall with the main pancreatic duct. The common bile duct may join the main pancreatic duct outside the duodenum, or the ducts may form a common channel as they traverse through the duodenal wall, in both of these cases opening through a single ostium on the major ampulla of Vater. This site is typically 7 to 10 cm from the pylorus. From the inside of the duodenal lumen, the termination of the ampulla appears as a small, protruding, nipple-like structure marked by a longitudinal duodenal fold. In 29% of cases, a septum persists between the two ducts, and the ducts empty on the papilla as separate ostia.

Ampulla of Vater

Union of the common bile duct and the main pancreatic duct forms the ampulla of Vater. The length of the ampulla is variable, and if there is no junction of the common bile duct and main pancreatic duct, there is no true ampulla of Vater. Rienhoff and Pickrell [9] studied the pancreatic duct system in 250 autopsy specimens. They found an ampulla longer than 2 mm in 46% of cases (range from 3 to 14 mm), an ampulla less than 2 mm in 32% of cases, and no junction of the pancreatic and bile ducts in 29% of cases.

The common bile duct narrows significantly as it passes through the wall of the duodenum, and the ampulla narrows before it enters the duodenal lumen. These narrowings are frequent sites for stones to lodge and cause either biliary or pancreatic obstruction. Additionally, these are potential sites of injury when instrumented during common bile duct exploration.

Sphincter of Oddi

The intraduodenal segment of the common bile duct and the ampulla is surrounded by a sheath of smooth muscle fibers referred to collectively as the sphincter of Oddi. The sphincter of Oddi is a unique group of muscle fibers that arise from the bile duct wall and manometric studies have verified that the sphincter acts independently of the duodenal musculature. The resting pressure of the sphincter of Oddi is approximately 13 mm Hg above duodenal pressure. [10] Regulation of bile flow is primarily controlled by the sphincter of Oddi. Relaxation of the sphincter occurs with CCK stimulation and is facilitated by parasympathetic stimulation. Sympathetic stimulation causes increased sphincter tone.

The preampullary portion of the common bile duct is invested in a sheath of ircular muscle referred to as the sphincter choledochus (sphincter of Boyden) (Fig. 99-8). The distal main pancreatic duct may have a short sphincter called the sphincter pancreaticus. If present, the sphincter pancreaticus and sphincter choledochus may intertwine in a figure-of-eight manner. The smooth muscle sheath surrounding the ampulla is called the sphincter of the ampulla; if there is no ampulla, the distal sphincter is simply called the sphincter of the papilla. During endoscopic sphincterotomy, the sphincter of Oddi is divided using electrocautery to relieve common bile duct obstruction from a common duct stone.

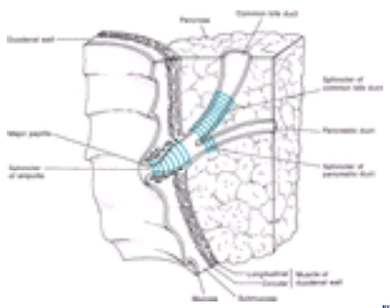

FIGURE 99-8. The muscular apparatus at the terminal end of the common bile duct. The bile duct is closely associated with the pancreatic duct, and they both enter the medial wall of the duodenum tangentially. Each duct has its own sphincter, which is poorly developed in the pancreatic duct.

Arterial Blood Supply

The arterial blood supply to the extrahepatic bile ducts is segmental. Because of the segmental nature of the blood supply, extensive mobilization of the extrahepatic bile ducts may lead to ischemic injury and development of postoperative biliary stricture and thus should be avoided. [11] The hepatic ducts and the supraduodenal portion of the common bile duct are nourished by small arterial branches from the cystic artery (Fig. 99-9). The retroduodenal portion of the common bile duct is supplied by branches of the retroduodenal and posterior superior pancreaticoduodenal arteries The pancreatic and intraduodenal segments of the common bile duct are supplied by both the anterior and posterior superior pancreaticoduodenal arteries.

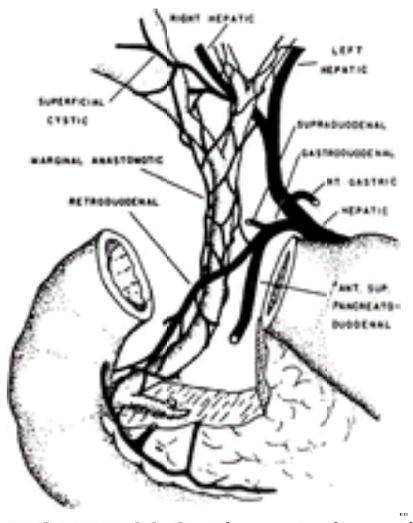

FIGURE 99-9. The extrahepatic biliary tract is supplied by a rich vascular net of vessels from the hepatic and gastroduodenal arteries. The relationship between the hepatic arteries and the extrahepatic biliary tree is evident.

Venous and Lymphatic Drainage

The veins of the hepatic ducts and proximal common bile duct, like those from the gallbladder and cystic duct, enter the liver directly. Veins from the lower portion of the common bile duct drain into the portal vein. The lymphatic drainage from the hepatic ducts and upper common bile duct flows superiorly along the course of the common bile duct to lymph nodes in the porta hepatis. Some lymphatic drainage arising from the inferior portion of the common bile duct may reach the deep pancreatic nodes near the origin of the superior mesenteric artery. All lymphatic drainage ultimately reaches the celiac lymph nodes.

Histology and Ultrastructure

The mucosa of the extrahepatic bile ducts contains columnar epithelium surrounded by a layer of connective tissue. The epithelium contains many mucous glands. Muscle fibers in the hepatic ducts and proximal common bile duct are relatively few and discontinuous, and may be arranged in either a longitudinal or circular direction. As the common bile duct approaches the duodenum, it begins to develop a more substantial muscle layer, which merges into the sphincter of Oddi complex, where distinct bundles of muscle fibers are evident.

CONGENITAL VARIATIONS AND MALFORMATIONS

Gallbladder and Cystic Duct

Congenital anomalies of the gallbladder may be classified into three different categories: anomalies of number, anomalies of form, and anomalies of position. Duplication of the gallbladder is thought to occur in approximately one of every 4000 human gallbladders. [12] With complete duplication, the gallbladders are separate, and the cystic ducts may join one another before entering the common duct or each cystic duct may enter separately. Partial duplications can result in bilobed gallbladders (Fig. 99-10A), in which the two gallbladder cavities are separate at the fundus but joined at the neck and drain via a common cystic duct. Gallbladders may also be septate (divided by a partial or complete septum) with septa present in either a longitudinal or transverse direction, the latter referred to as an hourglass gallbladder (Fig. 99-10B). Septate gallbladders are thought to be a result of incomplete vacuolization of the solid endodermal cord during development. None of these abnormalities of the gallbladder by themselves have clinical significance unless they are involved in a pathological process.

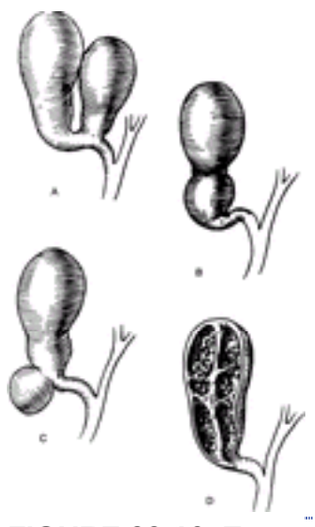

FIGURE 99-10. Two gallbladders (**A**), a bilobed gallbladder (**B**), a diverticulum at the neck (**C**), and a septated gallbladder (**D**) are all anatomic variations that relate to the embryological development of the biliary tract. (From Lindner H. Embryology and anatomy of the biliary tree. In: Way LW, Pellegrini CA, eds. Surgery of the gallbladder and bile ducts. Philadelphia: WB Saunders, 1987.)

Lack of development of the gallbladder bud results in agenesis of the gallbladder. Most cases are associated with extrahepatic biliary atresia. [13] In the absence of associated biliary atresia, an intrahepatic gallbladder or left-sided gallbladder must be ruled out before the diagnosis is made.

Abnormal migration of the caudal bud (future gallbladder and cystic duct) of the ventral diverticulum during development may cause an anomalous gallbladder position. If the caudal bud advances beyond the cranial bud (future liver), it may become buried in the liver substance, creating an intrahepatic gallbladder. These are usually identified by ultrasonography prior to cholecystectomy and may make cholecystectomy slightly more difficult. If the caudal bud lags behind the cranial bud, a floating gallbladder is created. A floating gallbladder is a gallbladder that is completely covered with peritoneum; it is usually suspended from the liver by a mesentery. A floating gallbladder is at a higher risk for torsion. Left-sided gallbladders are rare, but they have been described in the setting of situs inversus (all abdominal viscera are reversed right for left) or in the setting in which the gallbladder alone is transposed. [12] The gallbladder has also been found in other unusual locations such as the falciform ligament, [14] the abdominal wall, [15] and the retroperitoneum. [16] Regardless of the anomalous position of the gallbladder, it is important to realize that in almost all cases the cystic duct will inevitably join the common bile duct in a relatively normal position.

Abnormal development of the gallbladder bud may also cause anomalies in the cystic duct. Double cystic ducts may drain a single, nonseptated gallbladder and join the biliary system at the common bile duct or right hepatic duct. There may be absence of the cystic duct, and, in this case, the neck of the gallbladder drains directly into the common bile duct. Failure to recognize this anomaly has resulted in excision of a segment of the common bile duct during cholecystectomy in which the common bile duct has been mistakenly identified as the cystic duct. Liberal use of intraoperative cholangiography has been emphasized when intraoperative anatomy is confusing or anomalies are present.

Hepatic Ducts and Common Bile Duct

True accessory hepatic ducts result from the development of an extra bud from the biliary anlage during development. Accessory ducts are much more common on the right than the left. They may drain directly into the gallbladder, the right or left hepatic ducts, the cystic duct, or the common bile duct. Accessory hepatic ducts are present in about 10% of individuals. Cystohepatic ducts that drain bile directly from the liver to the gallbladder are rare. Aberrant hepatic ducts, unlike true accessory ducts, result from an extrahepatic course of a duct that is normally contained within the liver parenchyma. Accessory ducts provide a second drainage route from a region of the liver, in contrast to an aberrant duct, which represents the only drainage to a particular region of the liver, but lies in an unusual location. Almost all aberrant hepatic ducts represent the right anterior segmental duct, which joins the right posterior segmental duct outside the liver. This extrahepatic union occurs in about 10% of cases and may result in mistaken identification of the right anterior segment duct as the cystic duct during cholecystectomy, with inadvertent ligation. [17] Both aberrant and true accessory hepatic ducts are at equal risk for injury during cholecystectomy.

Anomalies in the common bile duct do exist but are quite uncommon. The common bile duct may contain two lumens but appears to be single externally. The common bile duct may be completely duplicated, with one duct draining the right lobe of the liver and one duct draining the left lobe. Duplicated ducts usually empty separately into the duodenum. [18], [19] Rarely, the common bile duct may open into the gastrointestinal tract at an ectopic site. The common bile duct has been reported to drain into the stomach [20] and the duodenal bulb, [21] as well as the distal duodenum. [22], [23]

Biliary Atresia

Biliary atresia is defined as the obliteration of the extrahepatic and/or intrahepatic bile ducts, with many different variations described (Fig. 99-11). The incidence of biliary atresia is 1 per 15,000 births. Ten to 15 percent of patients with biliary atresia have associated anomalies of the inferior vena cava (absence), portal vein (preduodenal portal vein), intestine (intestinal malrotation), and spleen (polysplenia). [24] Most patients have a form of biliary atresia with complete obstruction of the gallbladder and extrahepatic bile ducts, whereas 10% to 15% of patients have obstruction of the proximal hepatic ducts with patency of the gallbladder and distal common bile duct. Only 1% to 2% of patients have proximal hepatic duct patency.

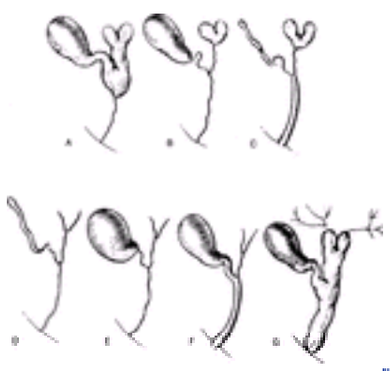

FIGURE 99-11. The different forms of biliary atresia. Biliary atresia may be partial, affecting the intra- or extrahepatic portions of the biliary tract, or it may be a complete process (**D**). (From Lindner H. Embryology and anatomy of the biliary tree. In: Way LW, Pellegrini CA, eds. Surgery of the gallbladder and bile ducts. Philadelphia: WB Saunders, 1987.)

In biliary atresia, the bile ducts are replaced by dense fibrotic tissue containing evidence of both an acute and chronic inflammatory process. [25] Typically, there is obliteration of the entire extrahepatic biliary tract, including the gallbladder. Extrahepatic biliary atresia frequently extends into the intrahepatic bile ducts, probably as an end result of a destructive process leading to fibrosis and obliteration of the biliary tree, with development of secondary biliary cirrhosis. [26] If left untreated, the typical course is one of progressive hepatic insufficiency, with an average survival of 12 to 19 months. [27]

The pathogenesis of biliary atresia is not known. Existing data seem to contradict the theory that failure of recanalization of the bile ducts during development is the cause. Data accumulated from the surgical experience using portoenterostomy have provided some insight into the disease process. Early establishment of bile drainage, typically before 60 days, can reverse the liver injury and is associated with long-term survival, while delay in establishing bile drainage until after 120 days is often associated with progression of cirrhosis and a poor outcome. In addition, infants who develop biliary atresia are rarely jaundiced at birth and frequently have bile-stained meconium; biliary atresia has rarely been demonstrated in autopsy studies of fetuses. [28] These observations suggest that biliary atresia is a dynamic process targeting the extrahepatic bile ducts, with progressive destruction rather than a static process. While the events that initiate this destructive process are unknown, experimental data suggest that neonatal Reovirus type 3 or other infectious stimuli may be causative agents. [29], [30] and [31]

The clinical presentation of biliary atresia is progressive neonatal jaundice with an onset in the first few weeks of life. Jaundice usually becomes visible in the first 2 to 4 weeks of life. Biliary atresia must be differentiated from neonatal physiologcial jaundice, as well as congenital infectious causes, such as Cytomegalovirus and rubella, and genetic diseases, including a1-antitrypsin deficiency.

Technetium 99m–iminoacetic acid (^{99m}Tc-IDA) hepatobiliary scanning is the imaging test of choice for biliary atresia, especially when preceded by a 5- to 7-day course of phenobarbital to increase bilirubin conjugation and excretion. The sensitivity of the test for biliary atresia is 100%, with a specificity of 94%. [32] An abdominal ultrasound should also be performed as a standard part of the evaluation of the jaundiced infant and is helpful to evaluate the possibility of other sources of biliary obstruction. Liver biopsy is nondiagnostic in up to 25% of patients and is often unnecessary to make a diagnosis.

Because of the near 100% mortality associated with medical management of biliary atresia, surgical therapy has become the treatment of choice. The standard operation, hepatic portoenterostomy, termed the Kasai procedure, was first described by Kasai in 1959 [33] following his original observation of residual microscopic bile channels in the fibrous tissue of the porta hepatis in patients with biliary atresia. The Kasai procedure consists of exploratory laparotomy with excision of the occluded extrahepatic biliary system and a Roux-en- enteric anastomosis to the transected fibrotic cord at that level of the porta hepatis where microscopic bile ducts have

been documented by frozen section. Primary hepatic transplantation is reserved for patients with a delayed diagnosis and advanced cirrhosis at presentation or patients with failed Kasai procedures. [34]

Most series report a 40% to 60% 5-year survival rate following portoenterostomy. [35], [36] In general, one third have good long-term results with minimal or no liver dysfunction and normal growth and development, one third do poorly and are dependent on immediate liver transplantation for survival, and one third have slow, progressive liver dysfunction over a period of months to years and subsequently need liver transplantation. Although the failure rate is fairly high, the fact that one third of patients will do well and never require transplantation and another subset will experience normal growth for a period of years before potentially requiring transplantation, in addition to the shortage of transplantable organs, has prompted centers to use the Kasai procedure as first-line therapy for biliary atresia. [37], [38] and [39]

Choledochal Cyst

CHAPTER 100

Sum P. Lee and Cynthia W. Ko

GALLSTONES

Autopsy studies of Egyptian and Chinese mummies have shown that gallbladder stones have existed for more than 35 centuries. Today, over 20 million Americans have gallstones, and more than 700,000 cholecystectomies are performed annually in the United States. [1] Gallstone-related symptoms and complications are among the most common gastroenterologic disorders requiring hospitalization, at an estimated annual cost of almost $6.5 billion. [2] This chapter summarizes the pathogenesis, clinical manifestations, and evolving treatment of gallstones.

EPIDEMIOLOGY

Gallstones are classified as cholesterol stones and pigment stones. In most Western countries, more than 75% of gallstones are the cholesterol type. The prevalence of gallstones varies widely in different countries and among different ethnic groups in the same country. Epidemiologic and animal studies have implicated genetic factors to account for this wide variation. [3], [4] Animal models are being developed that may help this line of investigation. [5] In addition, lifestyle factors, such as diet, obesity, weight loss, and low levels of physical activity have been implicated. [6], [7], [8], [9] and [10] Gallstone prevalence increases with age, and gallstones are more prevalent in females of any age group. [1]

Because the disease is nonfatal and often asymptomatic, the diagnosis of gallstones is not always made before death. Autopsy studies correlating with clinical information suggest that approximately two thirds of the population with gallstones are asymptomatic. [11] Methods most commonly used to determine gallstone prevalence include autopsy studies, determination of cholecystectomy rates, and ultrasonography. A Danish screening ultrasound survey showed new gallstone formation in 3% of the population older than 40 years of age in each 5-year period. [12]

The wide scatter in gallstone prevalence among different nations and ethnic groups is strong evidence that genetic factors are involved in gallstone formation. Those with the highest rates of gallstone formation are the Pima Indians of North America, Chileans, and Caucasians in the United States. [3], [11], [13] Next are the populations of Sweden, Germany, and Austria, followed by New Zealand, Great Britain, Norway, Ireland, and Greece. [14], [15], [16], [17] and [18] At the bottom of this list are the Asian populations in Singapore and Thailand. [19], [20]

The type of gallstone also varies among cultures. In developed countries, cholesterol gallstones are most common and usually occur in the gallbladder. In Africa and Asia, where the prevalence of gallstones is low, pigment gallstones are most common, and stones also can be found in the bile ducts.

Progressive increases in the rate of gallstones during the 20th century support a role for lifestyles and dietary factors in the pathogenesis of gallstones. Cholecystectomy rates partly reflect the provision of medical services, and autopsy gallstone rates may vary even within a country during a given time period. Nevertheless, several studies have shown increases in the prevalence of gallstones over time. [17], [21], [22] and [23] Post–World War II westernization in Japan is one example. Since the late 1940s, the prevalence of gallstones in Tokyo has more than doubled, and there has been a change from pigment to cholesterol gallstones. [22] In Saudi Arabia over a 10-year period, the frequency of cholecystectomy has increased sharply, a rise not matched by the increase in population, use of medical services, or number of other surgical procedures. A shift to a more Western diet has been suggested as a possible explanation. [24]

ETIOLOGY

Pathogenesis of Cholesterol Gallstones

The total body pool of cholesterol is supplied by de novo synthesis from acylcoenzyme A (acyl-CoA) and dietary absorption. [25], [26] Most of this pool is solubilized and secreted unmodified in bile or converted to bile acids (Fig. 100-1). Approximately 20% of biliary cholesterol comes from new hepatic synthesis. [27], [28] The remainder originates from a preformed pool within the liver. [29], [30] Important contributors into this pool include hydrolysis of cholesteryl ester stores, dietary sources such as chylomicrons, and direct hepatic and extrahepatic synthesis of the lipoproteins high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL). Total hepatic cholesterol is tightly regulated within a narrow range. [31], [32] The association of gallstones with serum cholesterol levels is not straightforward; although gallstones may be linked to decreased serum HDL cholesterol and increased serum triglyceride levels, no such association has been found for total serum cholesterol levels. [33], [34]

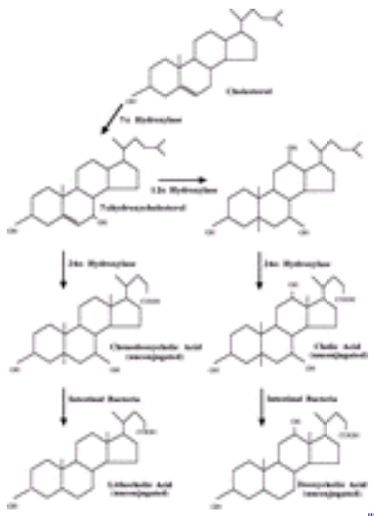

FIGURE 100-1. Schematic representation of bile acid synthesis and metabolism. The initial step in bile acid synthesis is hydroxylation of cholesterol by the enzyme 7a-hydroxylase. Further conversion of this metabolite by 12a-hydroxylase and 26a-hydroxylase results in synthesis of the primary bile acids, cholic acid, and chenodeoxycholic acid. Following conjugation with glycine or taurine, secretion, and transport to the intestine, bacteria metabolize the primary bile acids to the secondary bile acids, lithocholic acid and deoxycholic acid.

Various defective metabolic states can disrupt this regulatory balance, resulting in absolute biliary cholesterol hypersecretion or relative bile acid hyposecretion. Both defects can coexist, as in the case of the Pima Indians. [35]

Several mechanisms may be operative in biliary cholesterol hypersecretion. [36], [37], [38], [39] and [40] Nonobese gallstone patients may have higher intracellular levels of total and free cholesterol, suggesting enhanced intracellular cholesterol transport. [41] Clinical situations associated with excessive secretion of biliary cholesterol include obesity, aging, drug effects, and hormonal therapy. [42] Table 100-1 summarizes some of these examples and the proposed underlying pathogenesis. Recent animal studies have indicated that there are specific genes that determine the incidence of cholesterol stone formation in mice fed a lithogenic diet. [4] For example, the *Lith1* gene is associated with gallstone disease in a dominant fashion. [5] Further work has identified the bile-salt–export pump as a candidate protein for the *Lith1* gene. [43] Other candidate genes associated with gallstones in mice include HMG CoA reductase, canalicular multispecific organic anion transporter (*Cmoat*), intracellular lipid transporters (*Pctp* and *Fabp6*), lipoprotein lipase, and lecithin-cholesterol acyltransferase. [4] Although the human homologs to these animal genes are still being identified, the *ApoE4* genotype has been linked to an increased incidence of cholesterol gallstones in humans. [44], [45] and [46] ApoE, a lipid transfer protein, is reported to be associated with stones with high cholesterol content, [45] faster dissolution when treated with ursodeoxycholic acid, and higher recurrence rates after lithotripsy. [46] ApoE may have a role in regulation of biliary cholesterol secretion. [47] The role of apoE, and its interactions with dietary factors, deserves further study in humans.

CLINICAL EXAMPLES	PATHOGENESIS
Obesity, hyperlipoproteinemia	Increased hydroxymethylglutaryl-coenzyme A activity leading to increased mevalonic acid and cholesterol synthesis
Progesterone, oral contraceptives, clofibrate	Inhibition of hepatic acyl-coenzyme A cholesterol acyltransferase activity leading to decreased conversion of cholesterol to cholesteryl ester stores
Estrogens	Increased lipoprotein receptors B and E leading to increased hepatic cholesterol uptake; inhibition of 12α-hydroxylase leading to decreased synthesis of chenodeoxycholic acid
Selected nonobese Japanese	Increased hepatic intracellular transport of cholesterol
Selected nonobese Caucasians	Reduced activity of 7α-hydroxylase leading to a defect in conversion of cholesterol to bile acids; increased enterohepatic cycling of bile acids, leading to increased biliary deoxycholate levels
Age	Age-related decrease (?) in 7α-hydroxylase activity
Marked weight reduction	Mobilization of tissue cholesterol

TABLE 100-1 Risk Factors Associated With Cholesterol Hypersecretion in Bile

Alternatively, biliary supersaturation may occur with relative bile acid hyposecretion [48], [49] and [50] (Table 100-2). A diminished bile acid pool and secretion rate may result from excessive intestinal losses or decreased production. In nonobese patients with cholesterol gallstones, cholic acid and chenodeoxycholic acid pools are reduced, and deoxycholic acid is often increased in bile. [50] Conversion of cholic acid to deoxycholic acid, possibly in the small intestine or by colonic bacteria, may account for these changes. [51], [52] With an expanded deoxycholate pool in bile, biliary cholesterol secretion rises. [53]

CLINICAL EXAMPLES	PATHOGENESIS
Ileal disease, bypass, or resection	Impaired bile acid absorption or excessive losses
Cerebrotendinous xanthomatosis	Inherited 26-hydroxylase deficiency leading to incomplete oxidation of the cholesterol side chain and decreased bile acid production
Congenital 12-hydroxylase deficiency	Decreased cholate and deoxycholate synthesis
Selected nonobese Caucasians	Excessive feedback suppression of bile acid synthesis leading to a decreased pool, hepatic return, and secretion
Primary biliary cirrhosis Chronic cholestasis	Decreased bile acid secretion

TABLE 100-2 Risk Factors Associated With Relative Bile Acid Hyposecretion

Cholesterol Solubilization

Free cholesterol is virtually insoluble in aqueous solution. Bile acids, because of their unique amphipathic properties, are able to solubilize cholesterol and phospholipids in mixed micelles. [54], [55] Phase equilibrium diagrams can be constructed to characterize cholesterol solubility in a defined milieu of various lipid concentrations. Using these data, the Cholesterol Saturation Index (CSI) can be calculated. [56] CSI is the ratio of the actual amount of cholesterol in a given bile sample to the maximal cholesterol carrying capacity of that sample determined in vitro. Bile that has a CSI greater than 1 is considered supersaturated. Supersaturated bile that does not form cholesterol crystals is called metastable.

In addition to classic micelle packaging, cholesterol can be solubilized with phospholipid (principally phosphatidylcholine) as unilamellar vesicles ranging in size from 40 to 100 nm. [57], [58], [59] and [60] Vesicles consist of a bilayer of phospholipid interdigitated with cholesterol, without associated bile acids. These vesicles are thought to be assembled within the hepatocyte and then transported to the biliary canaliculus. [61] Vesicles comprise a separate and distinct carriage system that probably represents the major mode of cholesterol transport from the hepatocyte.

Bile acid secretion is the primary driving force behind the biliary secretion of cholesterol and phospholipid. [62], [63] As bile acids are actively secreted against a gradient

into the canaliculus, they induce the subsequent secretion of cholesterol-phospholipid vesicles into bile. Hydrophobic bile acids are more effective in provoking lipid secretion, although the maximum rate of biliary lipid secretion is similar for all bile acids. [64] Within the canaliculus, the bile acid concentration rises, reaching a micellar concentration that allows conversion to mixed micellar carriers. This interchange continues in a dynamic fashion within the ductules, ducts, and gallbladder. [65] The relative percentage of cholesterol transported in the micellar fraction can vary dramatically, depending on the physiological conditions. For example, at low bile acid secretion rates, as with fasting, the predominant form of cholesterol carriage in hepatic bile is vesicular. [57], [58] Conversely, the higher bile acid concentration in the gallbladder favors a shift toward micelle formation [57], [58] (Fig. 100-1 and Fig. 100-2).

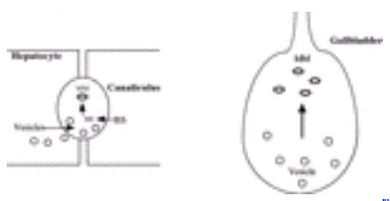

FIGURE 100-2. Schematic representation of biliary lipid secretion. At the biliary canalicular membrane of the hepatocyte, vesicles of cholesterol and phospholipids are secreted. Bile salts (*BS*) are also secreted by a different mechanism. Inside the canaliculus, mixed micelles (*MM*) of bile salts, cholesterol, and phospholipids are formed when bile salts reach a critical micellar concentration. As bile is further concentrated in the gallbladder, more vesicles are converted to mixed micelles. Mixed micelles transfer more phospholipid than cholesterol in solubilizing biliary lipids. Vesicles in the gallbladder are relatively depleted in phospholipid and enriched in cholesterol. These vesicles are more unstable and prone to nucleation.

Nucleation of Cholesterol Crystals

An early and indispensable step in cholesterol gallstone formation is nucleation, the emergence of solid cholesterol crystals in saturated bile (Fig. 100-3). Antecedent vesicular fusion and aggregation may be crucial for crystal generation. Nucleation of crystals results in a diminution of vesicular cholesterol without effect on micellar cholesterol. [57] Under video-enhanced microscopy, crystals appeared to originate from aggregated vesicles. [66], [67] and [68] Thus, cholesterol in vesicles may be more unstable and prone to precipitate than that in mixed micelles.

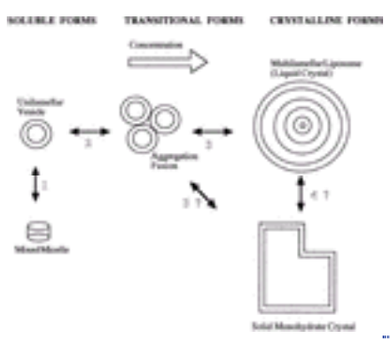

FIGURE 100-3. Schematic representation of cholesterol nucleation. In bile, cholesterol exists in two soluble forms, vesicles and mixed micelles. These forms are in dynamic equilibrium (*1*) depending on the total bile salt and lipid concentration. With concentration, vesicles are depleted of phospholipid and enriched in cholesterol, resulting in a tendency for vesicles to aggregate and fuse (*2*). Pronucleators may also cause vesicular fusion. The fused vesicles lead to formation of multilamellar liposomes or liquid crystals (*3*). Cholesterol separates from the liquid to the solid crystalline form during nucleation (*4*). Whether vesicles can nucleate into solid cholesterol crystals is unclear.

Vesicles in bile do not represent a homogeneous population. Gallbladder bile vesicles are likely to participate in nucleation; vesicles in hepatic bile are much more resistant to nucleation. The discrepancy in their behavior partly is caused by the difference in their relative cholesterol-to-phospholipid content. Vesicles that have increased ratios of cholesterol to phospholipid aggregate, fuse, and nucleate more readily. [68] The concentrated bile acids within the gallbladder may preferentially remove vesicular phospholipid over cholesterol during the dynamic shift to the micellar phase. The remaining vesicles are relatively cholesterol enriched and prone to nucleation. Conversely, hepatic vesicles have lower cholesterol-to-phospholipid contents and are therefore more stable.

Many people secrete supersaturated bile without developing gallstones. [69] Gallbladder bile taken from patients with cholesterol stones nucleates more rapidly than equally saturated bile from controls. Together, these observations suggest that factors in addition to cholesterol supersaturation must be involved in nucleation. Considerable efforts have been made to identify specific nucleating factors. Biliary proteins have generated the most attention, as total biliary protein content is increased in bile with cholesterol crystals compared with samples without crystals. [70]

Burnstein and colleagues provided the first major evidence for a potent pronucleating agent in bile. [71] A small-molecular-weight glycoprotein in bile binds to concanavalin A and exhibits promoting abilities. [72], [73] Hepatic bile from patients with cholesterol gallstones contained proteins associated with vesicles; when purified, these vesicles had potent cholesterol-nucleating activity. [74] A small, pigment-associated, anionic protein appears to be important in the regulation of calcium salts and in cholesterol precipitation in bile. [75], [76] and [77] Other putative pronucleators include a $_1$-acid glycoprotein aminopeptidase N, immunoglobulins G and M, haptoglobin, fibronectin, and a $_1$-antichymotrypsin. [78], [79], [80], [81], [82], [83], [84] and [85] However, the role of these proteins in vivo remains controversial. [86], [87] and [88] In contrast to these proteins, other biliary protein fractions, such as apolipoproteins AI and AII, a biliary glycoprotein heterodimer, and immunoglobulin A (IgA) inhibit in vitro nucleation assays. [89], [90], [91] and [92]

Other research has focused on the role of gallbladder mucin, a high-molecular-weight glycoprotein that is the major organic constituent of gallbladder mucus. It consists of a polypeptide core with multiple oligosaccharide side chains. These peptide cores also contain hydrophobic domains that bind pigment, cholesterol, and phospholipid, entrapping vesicles and micelles in its binding sites. [93], [94] With this close contact, membrane fusion and mixing can occur with formation of multilamellar vesicles. Addition of mucin to supersaturated bile will greatly accelerate cholesterol crystal nucleation. [88], [95] Mucin may become incorporated into the core of the growing gallstone, providing an architectural framework for crystal growth and stone formation. [96] Thus, mucin can act as a pronucleator. [97] Mucus hypersecretion before stone formation appears to be a universal antecedent in a number of animal models of lithogenesis. [98], [99] The stimulus for mucin hypersecretion is not clear, although prostaglandins may play a role. For example, the hypersecretory response can be inhibited by the administration of large doses of oral aspirin in the human gallbladder, [100] and aspirin ingestion can completely abolish subsequent formation of cholesterol crystals and gallstones. [101] However, inhibition of prostaglandin synthesis with indomethacin did not prevent mucin hypersecretion in a prairie dog model. [102], [103] Although prostaglandin activity may play a role in the pathogenesis of mucin hypersecretion, the role of other factors such as lithogenic bile or hydrophobic bile salts awaits study. [104], [105] and [106] More recently, oxy- sterols have been identified in bile of patients with pigment gallstones, [107] and the presence of these oxysterols may also affect mucin secretion. [108] The gallbladder can also secrete in response to gastrointestinal peptides such as secretin, assisting the emptying of precipitate. [109]

Calcium complexes are also important, as they are present in the central matrices of many, if not all, cholesterol stones, where they may serve as potential nidi for cholesterol crystallization. [110], [111], [112] and [113] Calcium has been shown to bind to mixed micelles, simple micelles, and simple vesicles in vitro, potentially explaining its role in cholesterol crystal nucleation. [114] Calcium may also regulate gallbladder secretion of electrolytes and glycoproteins. [115], [116] Various studies have found conflicting data about levels of biliary calcium in gallstone patients. [117], [118] and [119] Free and total calcium increased in the bile in obese patients who developed

gallstones during weight reduction. [120]

Role of the Gallbladder

The importance of the gallbladder in cholesterol gallstone pathogenesis must be emphasized. Cholecystectomy essentially cures recurrent de novo cholesterol stone formation. Gallbladder mucosal function plays an important role in this pathogenic process. The gallbladder can absorb excess water and electrolyte and concentrate bile. [121] It also normally secretes hydrogen ions and mucin. Sodium and chloride ion fluxes are altered in an animal model of lithogenesis. [122]

Alterations of lipid metabolism in gallbladder epithelium that might increase cholesterol content have also been studied. Hydroxymethylglutaryl-CoA reductase activity, governing cholesterol synthesis, is lower in the gallbladder mucosa than in hepatic tissue, and acyl-CoA:cholesterol acyltransferase (ACAT) activity catalyzing the esterification of cholesterol is several times higher than in the liver. [123] A study also suggests that normal human gallbladders can absorb phospholipids and cholesterol from bile in vitro, resulting in bile becoming less lithogenic. [124] In contrast, gallbladders from patients with cholesterol stones were less able to absorb cholesterol and phospholipids, resulting in potentially more lithogenic bile. This impaired ability to absorb biliary lipids may be an additional pathogenetic factor for gallstones.

In addition to epithelial cell function, gallbladder motility is of vital importance. Gallbladder stasis is a risk factor for lithogenesis, as mucin gels to accumulate with prolonged bile storage. The viscosity of these gels may interfere with mechanical emptying. Increased cholesterol nucleation and crystal growth as well as enzymatic and nonenzymatic hydrolysis of bilirubin conjugates could occur with prolonged stasis. The resulting unconjugated bilirubin may precipitate with calcium.

Altered gallbladder contractility before cholesterol stone formation has been shown in a lithogenic animal model. [125] In humans, prolonged total parenteral nutrition (TPN) induces gallbladder hypomotility and profound stasis, predisposing to subsequent biliary sludge and possible stone development. [126] High spinal cord injury is linked to gallbladder stasis and gallstone formation. [127], [128] Pregnancy, oral contraceptives, obesity, diabetes mellitus, and octreotide therapy are also associated with impaired emptying and cholelithiasis. [129], [130] Hormonal influences and prostaglandins are postulated mediators of gallbladder contractility. [131]

Biliary Sludge

Precipitates in bile have been called by many names—biliary sludge, microlithiasis, and pseudolithiasis. Sludge is best diagnosed by microscopic examination of a fresh sample of gallbladder bile. [132] Sludge also can be seen ultrasonographically as low-amplitude echoes without postacoustic shadow that layer with gravity. [133], [134] In certain clinical conditions, sludge may evolve into cholelithiasis.

Biochemically, sludge is composed of calcium bilirubinate granules and cholesterol monohydrate crystals embedded in a mucus gel. Ceftriaxone may precipitate as a calcium salt that appears ultrasonographically as sludge. [135] These calcium precipitates, with cholesterol crystals 50 µm or more in diameter, produce the characteristic ultrasonic echoes in sludge. The deformable mucin gel accounts for its unique layering and flow characteristics. [134]

In a prospective study of patients receiving prolonged TPN, 6% of the patients developed sludge during the initial 3 weeks. By 4 to 6 weeks, 50% of the patients had sludge, and after 6 weeks, its appearance was universal. [136] Stones developed in 43% during follow-up. Significantly, sludge resolved with reinstitution of oral feedings in all the patients by the end of 4 weeks. Although stasis was undoubtedly the major factor in sludge formation, these patients represented a medically ill population with complicating metabolic derangements.

Gallbladder sludge may also appear spontaneously in selected individuals. The clinical outcome of a group of patients who presented with upper abdominal pain and had sludge documented on initial ultrasound examination was examined. [134] In approximately 18%, the sludge resolved over a 2-year period. It had a disappearing and reappearing course in about 60%. Gallstones also developed in 14%. Another retrospective study demonstrated similar findings. [137] In most, sludge disappeared spontaneously after 2 months. omplications including stones or acute acalculous cholecystitis developed in 19.6%. These collective cohorts may represent patients with de novo cholesterol stone formation who have been detected at an early stage.

One scenario of cholesterol lithogenesis begins first as a defect in the hepatic secretion of biliary lipids, resulting in cholesterol supersaturation of bile. Gallbladder mucin hypersecretion and stasis develop, perhaps through the action of chemical mediators. As the bile is progressively concentrated, the vesicular fraction becomes relatively cholesterol enriched. These vesicles aggregate and fuse. When the balance of the opposing promoting and inhibitory factors favors nucleation, cholesterol crystals form. The crystals formed are retained within the gallbladder, where they grow and conglomerate with mucin glycoprotein and other constituents such as calcium and bilirubin. Continued stasis and impaired emptying of cholesterol precipitates lead to macroscopic stone formation.

Pathogenesis of Pigment Gallstones

Chemical Composition and Chemical Associations Pigment gallstones are subclassified into brown and black types, which differ in morphology, pathogenesis, and clinical associations (Table 100-3). In contrast to cholesterol gallstones, ethnic origin is not an important determinant of pigment gallstones. Black pigment stones can occur in persons with no predisposing factors. In the United States, black pigment gallstones are found in the gallbladder and are not associated with bacterial infection.

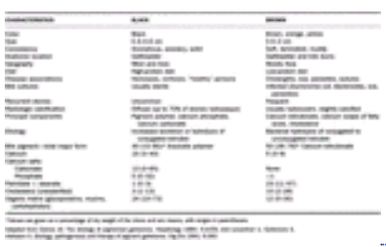

TABLE 100-3 Clinical Associations and Compositions of Black and Brown Pigment Gallstones

Factors associated with the formation of black pigment stones include chronic hemolysis (e.g. sickle cell disease), thalassemia, cardiac valvular prosthesis, advancing age, long-term TPN, and cirrhosis. [138], [139], [140] and [141] Black pigment stones seldom coexist with cholesterol stones in the same gallbladder. A calcium-regulatory protein that may mediate calcium precipitation has been isolated from black pigment stones. [142] In Asia, brown pigment stones are often found in the bile ducts and are strongly associated with bacterial infection. [143] There is a high incidence of infection with *Escherichia coli,* with the bacterial presence within stones easily demonstrated. [144], [145] and [146] Biliary secretory IgA is decreased. [147] Infected bile exhibits high bacterial ß-glucuronidase activity, often associated with a juxtapapillary duodenal diverticulum. [148], [149]

Deconjugation of Bilirubin Bilirubin, a tetrapyrrole-like cholesterol, is insoluble in water. After glucuronidation, bilirubin is secreted, mostly as the diglucuronide (75%–80%) or the monoglucuronide (20%), with a small amount of unconjugated bilirubin (3%). Because black and brown pigment stones contain calcium-bilirubin salts, the pathogenesis of pigment stones involves the deconjugation and precipitation of bilirubin. In patients with chronic hemolysis, there is a tenfold increase in the excretion of conjugated bilirubin in hepatic bile. [150] In an animal model of ileal resection, bilirubin circulates enterohepatically during the early postsurgical period, with increases in biliary levels of this molecule. [151] In patients with Crohn's ileitis or who had undergone ileal resection, concentrations of conjugated and unconjugated bilirubin were increased compared to patients with Crohn's or ulcerative colitis. In these studies, it has been hypothesized that unconjugated bilirubin is absorbed from the colon in the presence of ileal disease. These findings may help explain the increased incidence of pigment stones in patients with ileal disease. Bile acid mixed micelles and an acidic milieu promote bilirubin solubilization. The role of biliary ß-glucuronidase in the pathogenesis of pigment gallstones has been controversial. Studies employing molecular genetic techniques have implicated bacterial infection in producing brown pigment stones. [152], [153] It has been hypothesized that bacterial ß-glucuronidase hydrolysis of conjugated bilirubin into insoluble bilirubin leads to infection-related brown pigment stones. However, this hypothesis does not seem to be relevant to black pigment gallstones. [154] ß-Glucuronidase activity in uninfected bile has been demonstrated, suggesting that this enzyme may also originate in the epithelium. [155], [156] In support of this, a study showed that gallbladder bile from patients with pigment, cholesterol, or mixed gallstones has a higher proportion of bilirubin monoglucuronide than that of controls. [157] However, another risk factor, gallbladder stasis, must be present for precipitates of calcium bilirubinate to form.

Stasis, similar to the scenario described for cholesterol nucleation, can provide an opportunity for nonenzymatic hydrolysis of bilirubin diglucuronide and subsequent precipitation. [158], [159] Prolonged TPN, with attendant gallbladder stasis, can result in the formation of gallbladder sludge and black pigment stones. [136], [160] The gallbladder may contribute to pigment gallstone formation in other ways. Calcium homeostasis is intimately linked to black and brown pigment gallstones, because both kinds contain predominantly calcium bilirubinate. Hepatic bile is supersaturated with calcium carbonate. The gallbladder epithelium can acidify bile, increasing the solubility of calcium carbonate. Inability of an inflamed gallbladder to acidify bile may contribute to pigment gallstone formation. Gallbladder epithelium secretes a matrix of mucous glycoprotein into bile that binds to bilirubin and other hydrophobic lipids and is contained in black and brown pigment gallstones. [93] A working hypothesis can be made of pigment gallstone formation. Bilirubin excretion is increased. Gallbladder stasis or bile infection allows the hydrolysis of bilirubin diglucuronide to less soluble forms. Inability of an inflamed gallbladder mucosa to acidify bile perturbs calcium and bilirubin olubility. Mucus secreted by the gallbladder epithelium buffers hydrogen ions and decreases acidity enabling calcium carbonate, phosphate, and bilirubin to precipitate. For reasons poorly understood, the calcium bilirubinate in brown pigment stones remains in the monomeric form, but undergoes significant cross-linking to become polymeric and crystalline in black pigment stones.

CLINICAL MANIFESTATIONS

Biliary Colic

Approximately one third of patients with gallstones are symptomatic. Biliary colic is the main complaint in 70% to 80% of symptomatic patients. This is a visceral pain of tonic spasm resulting from transient obstruction of the cystic duct by a stone. Implicit in the term biliary colic is the fact that the gallbladder mucosa does not show features of acute inflammation. The pain of biliary colic is thought to be caused by functional spasms around an obstructed cystic duct; pain of acute cholecystitis is caused by gallbladder wall inflammation.

Although sometimes quite variable, biliary pain often has specific characteristics. The pain is episodic and severe, and it is located in the epigastrium or less frequently in the right upper quadrant, left upper quadrant, the precordium, and the lower abdomen. [161], [162] The pain may be precipitated by eating a large meal, but often no single food is the lone culprit. Pain may develop without any precipitating events.

Typically, the pain has a sudden onset and rises steeply in intensity over a 15-minute interval to a steady plateau lasting as long as 3 hours. Resolution of pain is slower. Pain lasting more than 6 hours should raise the suspicion of cholecystitis. The pain may radiate to the interscapular region or, rarely, to the right shoulder tip. Vomiting and diaphoresis are not uncommon. The patient is usually restless and unable to find a comfortable position. Residual tenderness in the upper abdomen may persist after an attack. The interval between attacks is unpredictable and may last weeks, months, or years.

True biliary colic should be differentiated from nonspecific dyspepsia. Flatulence, pyrosis, aerophagia, vague abdominal discomfort, and fatty food intolerance are common complaints of many patients, whether or not they have cholelithiasis. [163] Whether patients with gallstones experience increased distress from fatty foods has been difficult to prove.

The ability to differentiate true biliary pain from nonspecific abdominal symptoms significantly impacts the success of treating gallstone disease. For example, a cholecystectomy performed for gallstone-induced biliary colic is usually curative, but symptoms often persist if it is done for patients with nonspecific dyspepsia and cholelithiasis. [164], [165] It is worthwhile to clarify prevalent misunderstandings about biliary pain. First, biliary colic is a misnomer, because the pain is steady, not intermittent or fluctuating. Second, the pain is primarily epigastric. It is inappropriate to interpret pain not located in the right upper quadrant as atypical of gallstone symptoms. Third, fat intolerance is not a feature of biliary colic. Fourth, despite the availability of many imaging techniques to demonstrate the presence of gallstones, the diagnosis of biliary colic is ultimately based on clinical judgment.

Acute Cholecystitis

The most common cause of acute cholecystitis is obstruction of the cystic duct by gallstones, resulting in acute inflammation of the gallbladder. Approximately 90% of cases are associated with cholelithiasis. Obstruction likely damages the gallbladder mucosa, initiating an inflammatory reaction involving prostaglandins and other chemical mediators. [166], [167] Hydrolysis of biliary lipids such as lecithin and reabsorption of bile salts may also play a role. [168], [169] Although bacteria are commonly found in the gallbladder bile of patients with acute cholecystitis, this is probably a secondary event. [170], [171] Secondary bacterial infection can progress to empyema.

Most patients with acute cholecystitis have had previous attacks of biliary pain. The pain of acute cholecystitis typically lasts longer than 3 hours and, at the end of 3 hours, shifts from the epigastrium to the right upper quadrant with the emergence of localized tenderness. With time, the intensity of pain may diminish, but tenderness increases. Vomiting is common. Fever is common, but is rarely higher than 101°F. The sequence of clinical features represents visceral pain of ductal impaction by stones, proceeding to gallbladder inflammation with parietal pain.

In older adults, presenting signs and symptoms may be especially mild. On physical examination, the Murphy sign, an abrupt arrest in inspiration secondary to pain elicited during direct palpation of the right upper quadrant, may be present. In 30% to 40% of patients, a palpable mass may be present, consisting of the gallbladder and perhaps adherent omentum. Fifteen percent of patients with acute cholecystitis will be jaundiced, even without choledocholithiasis and obstruction. The pathogenesis may involve edema and compression around the inflamed cystic duct. Pyogenic or amebic liver abscesses are in the differential diagnosis.

Chronic Cholecystitis

Patients with chronic cholecystitis usually have gallstones and have had repeated attacks of biliary pain or acute cholecystitis. This results in a thickened and fibrotic gallbladder, which shows evaginated mucosal pouches (Rokitansky-Aschoff sinuses) on histological examination. It is uncommon for the gallbladder to be palpable during an attack of pain. The patient may have fewer symptoms referable to the gallbladder but may present with associated gallstone complications such as recurrent pancreatitis, choledocholithiasis, and cholangitis.

Choledocholithiasis and Cholangitis

Gallstones passing into the common bile duct from the gallbladder may proceed to the duodenum if the stone is small. They may also remain in the common bile duct and give rise to complications. The majority of stones in the common duct have the same composition as those in the gallbladder. However, some are softer and more brownish because of deposits of calcium bilirubinate and other calcium salts, including fatty acid complexes. [139] Common duct stones are frequently associated with infected bile, which may or may not be clinically apparent.

Choledocholithiasis is one of many causes of obstructive or “surgical” jaundice, which must be differentiated from hepatocellular or “medical” jaundice. Obstruction of the passage of bile results in jaundice and pruritus. The pathogenesis of pruritus is unclear, although retention of bile salts with irritation of sensory nerve endings or retention of endogenous opiate agonists have been proposed as mechanisms. Sometimes pruritus can be the predominant or incapacitating symptom. With biliary obstruction, the feces may be hypocholic or acholic. Light-colored or clay-colored stools are uncommon in bile duct obstruction resulting from gallstones because the obstruction is rarely complete, but are more commonly observed with malignant strictures of the common bile duct.

Unlike malignant obstruction of the common bile duct, a palpable and nontender gallbladder due to cholelithiasis is uncommon. The biliary obstruction is usually incomplete, and the gallbladder itself is likely to be fibrotic, scarred, and nondistensible secondary to chronic cholecystitis. However, the exceptions to this rule (Courvoisier law) are substantial, with frequent false-positive and false-negative results.

Obstruction of the common bile duct also causes increased intraductal pressure, inhibiting bile flow and causing the reflux of bile from the canaliculus into the sinusoids. The normal pressure in the common bile duct is 10 to 15 cm H_2O; with obstruction, the pressure can rise to above 40 cm H_2O. [172], [173] This also distends the biliary tree. Dilation of the extrahepatic and intrahepatic bile ducts is a valuable sign of common bile duct obstruction and is best seen using ultrasonography or computed tomography (CT) scan. Clinically, the only manifestations may be mild hepatomegaly or right upper quadrant tenderness.

With prolonged biliary obstruction, secondary hepatic parenchymal damage may set in. With increased fibrogenesis induced by bile duct obstruction, secondary biliary cirrhosis may occur. The propensity for developing cirrhosis varies with the completeness and duration of obstruction. The average time for choledocholithiasis

to result in secondary biliary cirrhosis is about 5 years. [174] Patients may present with portal hypertension or hepatic failure. Patients with incomplete obstruction more commonly present with variceal bleeding, and those with complete obstruction with hepatic failure. [175] Even if the patient has cirrhosis, every effort should be made to relieve the obstruction, since reversal of portal hypertension and secondary biliary cirrhosis have been reported. [176]

A common complication of choledocholithiasis is cholangitis. For bacterial infection to occur, obstruction or bile stasis is always present, although obstruction is not always associated with overt bacterial infection. For example, cholangitis is extremely common in choledocholithiasis, not uncommon in sclerosing cholangitis, and relatively uncommon (10%–15%) in malignant bile duct strictures.

The typical clinical picture, occurring in 70% of cases, consists of biliary pain, jaundice, and chills and rigors (Charcot triad). Pain, usually characteristic of biliary colic, occurs in 90% of patients. Bacteremia with chills and fever occurs in 95%. Clinical jaundice is present in 80%. Clinical signs are nonspecific, with mild hepatomegaly, tenderness, and occasionally rebound tenderness. [177] Depending on the progress of the illness, shock, multiple liver abscesses, or multi-organ failure may result. In contrast, for many patients, cholangitis is a short and self-limited illness complicating choledocholithiasis or sclerosing cholangitis.

Blood cultures are often positive and reflect the organisms infecting the bile ducts. The most commonly found organisms are *E. coli, Klebsiella, Pseudomonas,* and enterococci. Co-infection with anaerobes occurs in 15%. [178], [179] and [180]

Acute pancreatitis may be precipitated by the passage of stones or sludge in the common bile duct, and sludge or microscopic stones may account for a significant proportion of cases of idiopathic pancreatitis. [132], [181]

DIFFERENTIAL DIAGNOSIS

Clinical Signs and Symptoms

The clinical symptoms and signs of biliary tract disorders are not highly specific. The patient's history, physical findings, and laboratory data should be carefully examined. A clinical impression of biliary colic should be confirmed by imaging studies. Because gallstones are found commonly and may coexist with other disorders, the finding of gallstones does not exclude other diseases contributing to or complicating the patient's clinical picture. Disorders of other visceral organs, including the upper gastrointestinal tract, colon, kidneys, and pancreas, should be excluded by appropriate diagnostic tests. Extra-abdominal disorders that may produce a similar clinical picture include angina pectoris, dissecting aortic aneurysm, spinal neuralgia, pleuritis, pericarditis, and uncommon metabolic disorders such as hereditary angioedema (C1 esterase inhibitor deficiency) and acute intermittent porphyria.

In addition to pain, patients with acute cholecystitis usually present with symptoms and signs of local inflammation (e.g., right upper quadrant mass, tenderness) and systemic toxicity (e.g., fever, leukocytosis). The differential diagnosis includes other causes of intra-abdominal inflammation or infection. Acute appendicitis can cause a difficult diagnostic problem. The periumbilical pain shifting to the right lower quadrant with an inflamed mass may be confused with biliary colic with an inflamed gallbladder. A gallbladder can be low lying or an appendix can be subhepatic. Fever and leukocytosis are features of both. Ultrasonography or hepatobiliary scintigraphy may be helpful.

It may be difficult to differentiate acute pancreatitis from cholecystitis because the two conditions produce tenderness in an overlapping area. Gallstones may cause acute pancreatitis, and cholecystitis and pancreatitis therefore may coexist. Acute cholecystitis alone can be associated with hyperamylasemia, but pancreatitis often has higher enzyme levels. Biliary scintigraphy and imaging techniques such as ultrasound and CT scans are helpful diagnostically.

Perforated peptic ulcer usually produces more dramatic pain and peritoneal signs. Plain abdominal x-ray films or CT scans often show free intra-abdominal air. If free air cannot be visualized and ulcer perforation is still suspected, an urgent radiographic study with water-soluble contrast should demonstrate the perforation.

Diagnostic Studies

Laboratory Tests In uncomplicated biliary colic, there are usually no accompanying changes in hematologic and biochemical tests. In acute cholecystitis, leukocytosis with a "left shift" is usually seen, but this does not differentiate it from other intra-abdominal infections. The amylase level may be elevated because of transient obstruction of the pancreatic duct by a common duct stone. Edema and inflammation of the gallbladder can partially obstruct the common bile duct, causing mild elevation of the serum aminotransferases and alkaline phosphatase. Elevation of serum bilirubin can also be associated with the enzyme level changes, especially if the common hepatic duct or common bile duct is involved in the inflammatory reaction. Bilirubin elevation is proportional to the degree of obstruction. Bile canalicular and ductular cells produce alkaline phosphatase, the elevation of which does not depend on the magnitude or cause of obstruction. Abdominal pain, fever, and jaundice are often the presenting features of choledocholithiasis. In such cases, the bilirubin level is usually between 2 and 10 mg/dL, and the alkaline phosphatase is less than five times normal. If the level of bilirubin is above 15 mg/dL, a neoplastic obstruction should be strongly suspected. A cholangiogram should be obtained to define the cause and level of obstruction if ductal dilation is documented by ultrasonography or CT scans.

Radiologic Studies Plain abdominal films are often obtained. They are rarely useful in biliary colic because only 13% to 17% of gallstones contain sufficient calcium to be radiopaque. In acute cholecystitis, x-ray films are obtained to exclude other intra-abdominal causes of abdominal pain, fever, and leukocytosis, such as perforated ulcer or intestinal obstruction. Occasionally, when emphysematous cholecystitis is present, intramural gas outlining the gallbladder can be seen, but ultrasonography is a better source to show this. Ultrasonography has high specificity and sensitivity for the diagnosis of gallstones and should be a routine examination in the evaluation for gallstone disease. Stones appear as high-amplitude echoes with postacoustic shadow (Fig. 100-4). Other findings include thickening of the gallbladder wall (>2 mm), intramural gas, and a pericholecystic collection of fluid. The latter two suggest active gallbladder inflammation or infection. Biliary sludge may also be found and is common in extrahepatic biliary obstruction. In the absence of distal obstruction, sludge can be associated with abdominal pain (i.e., biliary colic), acute cholecystitis, or pancreatitis and should be regarded as part of the spectrum of gallstone disease. [133], [134] Dilation of intrahepatic or extrahepatic bile ducts suggests distal obstruction. However, a diagnosis of choledocholithiasis is not excluded by the absence of sonographic demonstration of a stone. [182]

FIGURE 100-4. Ultrasound scan showing gallstones. The stones generate high-amplitude echoes and are large and dense enough to constitute substantial acoustic impedance in the path of the ultrasound beam. Hence, there is a void behind the stone, known as the postacoustic shadow. Some edema of the gallbladder wall is also seen, suggesting acute cholecystitis.

Hepatobiliary scintigraphy can confirm or exclude the diagnosis of acute cholecystitis with a high degree of sensitivity and specificity. After a 2- to 4-hour fast, the patient is given an intravenous injection of a technetium 99 (^{99m}Tc)-labeled iminodiacetic acid derivative (IDA agent), which is excreted into the bile ducts and is sequentially imaged under a gamma camera. Several ^{99m}Tc-IDA compounds have been developed and differ with respect to their degree of hepatic uptake and time to reach a peak concentration in bile. In a normal study, images of the gallbladder, common bile duct, and small bowel appear by 30 to 45 minutes. A normal ^{99m}Tc-IDA scan virtually rules out the diagnosis of acute cholecystitis in a patient who presents with abdominal pain. Failure to visualize the gallbladder by 90 minutes despite adequate views of the liver, common bile duct, and small bowel strongly suggests acute obstructive disease. False positives can result from either nonfasting or prolonged fasting states. Chronic cholecystitis is another cause of false-positive results. Delayed repeat scanning after 4 or more hours decreases the false-positive rate and provides sensitivity and specificity values of approximately 97% and 90%, respectively. Administration of low-dose morphine at 1 hour may obviate the need for delayed repeat scans. Morphine may be used as an adjunct to scintigraphy, as it causes contraction of the sphincter of Oddi, increasing common bile duct pressure and enhancing filling of the cystic duct. Hepatobiliary scintigraphy cannot provide anatomic information and cannot directly identify gallstones. Oral cholecystography is seldom used nowadays as a primary diagnostic test for the detection of gallstones or acute cholecystitis. The study involves the administration of

oral contrast tablets such as iopanoic acid the night before. The contrast is absorbed from the small bowel, conjugated and excreted by the liver, and concentrated within the gallbladder. The following morning, abdominal x-rays are obtained. Extrabiliary conditions such as small bowel disease, hepatic dysfunction, or prolonged fasting can all lead to gallbladder nonvisualization. [183], [184] Inadequate gallbladder visualization can occur in 15% to 50% of patients after a single dose. The chief advantage of oral cholecystography over ultrasound is its ability to assess the patency of the cystic duct and gallbladder function, which may be useful if medical therapy of gallstones is being considered. Moreover, the size, number, and degree of calcification of stones can be accurately determined. CT can also be used in the detection of cholelithiasis. Although superior to ultrasound in other clinical situations, CT is not as reliable in diagnosing gallbladder stones. However, CT is useful in demonstrating dilated bile ducts and mass lesions and can be considered the test of choice if clinical suspicion of a tumor (e.g., pancreatic cancer) obstructing the common bile duct is strong. When a more definitive view of the biliary system is needed, cholangiography should be performed by endoscopic retrograde cholangiopancreatography (ERCP) or through a percutaneous transhepatic cholangiography (PTC) (Fig. 100-5). The selection of either approach depends on the expertise at a particular institution and on the level and nature of the suspected lesion. In general, ERCP is used to demonstrate the lower limit of an obstruction and has the advantage of the ability to sample tissue. PTC demonstrates the upper limit of an obstructive lesion or a proximal obstruction better. Both tests have a risk of introducing infection in the presence of obstruction.

FIGURE 100-5. Endoscopic retrograde cholangiogram shows a stone within the common bile duct and a small stone or debris in the cystic duct. (Courtesy of Scott Schulte, M.D.)

Magnetic resonance (MR) cholangiography, a promising new technique for imaging the biliary tree, has been shown to be over 90% sensitive and specific for the diagnosis of bile duct stones, when compared to ERCP. [185], [186] and [187] It also has the advantage of being noninvasive and potentially allowing diagnostic imaging without the risks of PTC or ERCP. Helical CT has also been studied, and found to have sensitivity and specificity of 80% to 85%. [188], [189] Addition of an oral contrast agent for CT cholangiography may provide sensitivities and specificities comparable to MR cholangiography. [190] With the availability of many tests, the future challenge to the clinician will be to avoid unnecessary or redundant investigations.

CLINICAL COURSE AND COMPLICATIONS

Natural History of Asymptomatic Gallstones

It is estimated that 60% to 80% of all gallstones are asymptomatic at a given time. [191], [192] and [193] The rate with which gallstones develop varies. In patients on TPN or obese persons with rapid weight loss, the interval can be weeks. In Pima Indians, the progression from cholesterol supersaturated bile to formation of gallstones occurs in 5 to 10 years. [194] When gallstones do form, the risk factors for developing symptoms are unknown. However, the rate at which stones give rise to symptoms and complications is relatively small. In contrast, once gallstones start to cause biliary-specific symptoms, the risk of continuing problems is relatively high.

Studies by Wenckert and Robertson [195] and Lund [196] followed a total of 1307 patients with gallstones as long as 20 years and concluded that 50% of patients remained asymptomatic, 30% had biliary colic, and 20% had complications. Some have cited such data as indicating prophylactic cholecystectomy for all patients with gallstones, regardless of the severity of symptoms. However, the patients in these studies, although asymptomatic at the time of entry to the follow-up study, had previously been hospitalized for symptoms related to gallbladder disease.

Gracie and colleagues [197] followed a cohort of 123 asymptomatic persons with gallstones found by oral cholecystography. These 110 men and 13 women (average age, 54 years) were followed for 11 to 24 years. New-onset biliary colic developed at a rate of 2% per year for the first 5 years, but the cumulative incidence over time plateaued, such that the total incidence was 15% at 10 years and 18% at 15 and 20 years. Three patients (2%) developed complications. All were preceded by repeated attacks of biliary colic and all had uneventful cholecystectomies. No deaths related to gallbladder disease occurred in this cohort.

The Rome Group for Epidemiology and Prevention of Cholelithiasis (GREPCO) study has reported follow-up of 161 patients with gallstones. [198] For patients who were initially asymptomatic, biliary colic developed in 11.9% at 2 years, 16.5% at 4 years, and 25.8% at 10 years. The subjects were also followed for development of complications of gallstones, including cholecystitis, pancreatitis, and biliary obstruction. After 10 years, 3% of those who were initially asymptomatic developed complications. One patient of this group developed an adenocarcinoma of the gallbladder.

A 20-year population-based survey of mortality in Pima Indians with and without gallstones was reported. [199] The overall age- and sex-adjusted death rate was higher in those with a history of gallstones, with a ratio of 1:9. The death rate attributed to malignancies was 6.6 times higher in those with gallstones. Of the 20 fatal malignancies in patients with gallstones, 11 were cancers of the gastrointestinal tract, of which 6 were malignancies of the gallbladder or bile ducts.

These studies highlight the question of whether a link between gallstones and malignancies exists. A statistical association between colon cancer and gallstones has been reported, although this may represent selection bias because patients with colon cancer are more likely to have their gallbladders evaluated. [200] Increased rates of gallbladder carcinoma or carcinoma of the extrahepatic bile ducts in patients with gallstones have been found in an autopsy series and in a case-control study. [201], [202] This issue deserves further study.

Natural History of Symptomatic Gallstones

Once an episode of biliary colic has occurred, there is a high risk of repeated attacks of pain. Cohort studies following symptomatic gallstone patients indicate that 58% to 72% of patients have ongoing symptoms and complications. [196], [203] More than 90% of complications, such as cholecystitis, cholangitis, and pancreatitis, are preceded by attacks of pain. The most serious complications are gangrene and perforation of the gallbladder, occurring in about 10% of cases of acute cholecystitis.

When the gallbladder perforates, the outcome depends on the anatomic relation with the neighboring structures. It can localize to form an abscess; it can be a free perforation with peritonitis; or it can communicate with another hollow viscus as a fistula. A localized perforation with confined spillage sealed off by omentum and adherent adjacent viscera is the most common form of perforation. A pericholecystic abscess is formed. This should be suspected when acute cholecystitis is slow to resolve, especially with a second episode of fever, right-sided abdominal pain, or the appearance of a right upper abdominal mass. Ultrasonography and CT may show the pericholecystic abscess, but this is not dependable. If the degree of clinical suspicion is high, the diagnosis should be confirmed at surgery. This is especially so in older patients or patients on long-term steroid treatment in whom fever and the inflammatory response may be minimal.

In 1% to 2% of perforations, especially in the fundus of the gallbladder, free perforation occurs and carries a mortality rate of at least 30%. Bile and purulent peritonitis are almost always associated with persistent or progressive abdominal pain. When the suspicion is raised, no test can establish the diagnosis without further delaying intervention and causing additional tissue injury. Antibiotics should be given and emergency surgery performed.

When the gallbladder perforates into the adjacent intestine, an attack of acute cholecystitis often subsides as the inflamed organ is decompressed. In descending

order of frequency, the duodenum, hepatic flexure of the colon, stomach, and jejunum are the sites of the cholecystoenteric fistula. If the gallstones are completely discharged and are small enough to pass rectally, an uncomplicated cholecystoenteric fistula results. However, if stones are still present in the gallbladder or in the common bile duct, chronic symptoms may arise.

When a fistula develops and the gallstone is too large to traverse the intestine, it causes obstruction. In such cases, the diameter of the stone is greater than 2.5 cm and the site of obstruction is usually in the small intestine, most commonly at the ileocecal valve. Gallstone ileus sometimes has a prior history of acute cholecystitis, but most of the stones erode slowly through the gallbladder, and the symptoms may be minimal, especially in older patients. Gallstone ileus should always be considered in an older patient with intestinal obstruction. [204], [205] Plain abdominal x-ray films may show air in the biliary tree, and barium studies often reveal the site of communication. The gallbladder does not opacify with oral cholecystography. Ultrasound scans can detect air in the biliary tree but not the site of the fistula. CT scans are less useful in detecting gallstones and fistulae, although they may show air in the biliary tree.

TREATMENT

Because gallstones are common and often asymptomatic, the treatment of gallstones should consider the patient's clinical presentation (Fig. 100-6). For asymptomatic gallstones, before active treatment is instituted, the following questions should be considered: What is the rate at which new-onset symptoms emerge? If symptoms develop, what is the risk of these evolving to complications, and what is the risk of morbidity and mortality from such complications? What is the risk of prophylactic treatment? What are the short- and long-term costs of prophylactic treatment compared with no or delayed treatment?

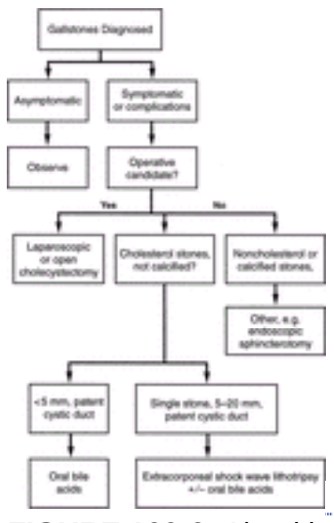

FIGURE 100-6. Algorithm for management of biliary sludge and gallstones.

The fractional and cumulative risk of developing symptoms is not great (2%–5% per year). Complications develop after the emergence of symptoms. Risk-benefit analyses of elective cholecystectomy have shown no advantage to aggressive prophylactic cholecystectomy for asymptomatic gallstone patients. Once complications develop, cholecystectomy is a safe procedure with a mortality rate of 0.1% to 0.2% for open procedures. [206], [207] The surgical mortality rate of 0.9% to 1.8% is higher for patients older than 60 years of age. [208], [209] The mortality rate for laparoscopic cholecystectomy appears comparable. [210] With common bile duct exploration, the mortality rate is approximately two to three times higher.

Generally, the indications for cholecystectomy should not change, and asymptomatic patients do not need to undergo surgery despite the widespread availability of laparoscopic cholecystectomy. However, in certain subsets of patients, it may be prudent to make exceptions and proceed with a prophylactic cholecystectomy. These groups include children, patients with sickle cell disease, and the morbidly obese. [211], [212] In the latter group, a cholecystectomy is recommended if the patient undergoes bariatric surgery such as a gastric bypass. [213] Patients who are immunosuppressed on a long-term basis may represent another group, as signs of acute cholecystitis may be "masked." A calcified or "porcelain" gallbladder is associated with a higher risk of cancer. [214] It is also agreed that patients with choledocholithiasis, even if asymptomatic, should undergo surgery. This is reinforced by postmortem studies, which showed, even in asymptomatic patients, ductal stones contributed significantly to death. [215], [216]

Patients with diabetes mellitus are a controversial group. It has been stated that diabetics have a higher risk of complications, morbidity, and mortality from gallstones. However, they may have an increased operative risk with elective and emergency cholecystectomy, largely because of concomitant cardiovascular disease. [217], [218] The issue of prophylactic cholecystectomy in diabetics continues to be debated.

Symptomatic gallstones should be treated. Options include surgery, dissolution, or fragmentation of symptomatic gallstones (Table 100-4).

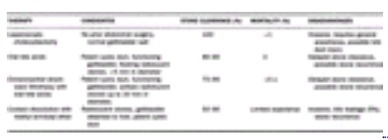

TABLE 100-4 Therapeutic Options for Symptomatic Gallbladder Stones

Surgical Treatment

Cholecystectomy is the only definitive treatment. Elective cholecystectomy is usually simple, safe, and curative; is indicated for most patients with symptoms; and is the first choice when complications ensue. Nonsurgical modalities of treatment are less favored with the advent of laparoscopic cholecystectomy.

Laparoscopic Cholecystectomy

In 1901, Georg Kelling reported laparoscopic examination of the abdominal cavity using a cystoscope in a dog. [219] Technical advances, such as the Veress needle used to induce pneumoperitoneum, was introduced in 1928 and is still in use today. [220] Laparoscopic techniques were first routinely incorporated into surgical practice by gynecologists in the 1960s. With the introduction of videolaparoscopy in the 1980s, general surgeons began to use the technique to perform cholecystectomies. [221]

Laparoscopic cholecystectomy was first performed in France in 1987. [222] The procedure has since gained remarkably rapid widespread use and acceptance in Europe and the United States, becoming the standard of care for the treatment of symptomatic cholelithiasis and acute or chronic cholecystitis. In fact, the overall rate of cholecystectomy increased rapidly with the introduction of the laparoscopic approach, possibly due to a wider patient and physician acceptance of this method of treating gallstones. [223] There is also some evidence that the indications for cholecystectomy have broadened since introduction of the laparoscopic approach. [224] This rapid increase, however, has shown signs of leveling off or diminishing. [225] Due in part to the rapid acceptance of the procedure by patients and physicians, there have been few randomized, controlled trials comparing laparoscopic with open cholecystectomy. [226], [227] However, early publications compiling results for more than 5000 patients have documented its safety and efficacy. [228] Retrospective comparative studies have shown that laparoscopic cholecystectomy produced fewer complications, shorter hospital stays, more rapid returns to normal activities, and minimal use of postoperative analgesia. [229], [230] and [231] Additionally, overall mortality

appears to be reduced. [225]

The technique involves general anesthesia with endotracheal intubation. A pneumoperitoneum is established, and the laparoscope with video camera attached is inserted through an umbilical incision. Accessory trocars and cannulas are inserted through separate sites. The gallbladder, cystic duct, and artery are identified. An intraoperative cholangiogram can be performed by cannulation of the cystic duct. This allows for the detection of common bile duct stones and delineation of the ductal anatomy. The blood supply to the gallbladder is identified and controlled, and then the cystic duct is ligated. The gallbladder is dissected from the underlying liver bed, using electrocautery or laser energy. The gallbladder is removed through the incision site. Stones may need to be mechanically crushed within the gallbladder before removal. Stones spilled into the peritoneal cavity are retrieved. [232]

The primary indication for laparoscopic cholecystectomy is identical to that for open cholecystectomy: symptomatic cholelithiasis. Absolute contraindications include an inability to tolerate general anesthesia and uncontrolled coagulopathy. Relative contraindications include scarring or inflammation, precluding access to the gallbladder using the transperitoneal approach, and diffuse peritonitis. As surgeons have accumulated more experience, the technique has been applied to a variety of patients. The procedure has been successfully performed in anticoagulated patients, obese patients, children, and pregnant women prior to the third trimester. [233], [234], [235] and [236]

Examination of the results of large series illustrates the pertinent aspects of the procedure. A representative analysis of 1518 laparoscopic cholecystectomies performed at academic and private hospitals has been published. [237] In 4.7% of the patients, the procedure was converted to open cholecystectomy, most often because of difficulties in identifying anatomy due to inflammation or bile duct injury. Of the 1518 patients in this series, 96.5% had ultrasound examinations before surgery to document cholelithiasis, and preoperative cholangiography was performed in 4.2% of patients. Some surgeons routinely used intraoperative cholangiography and others used it selectively or not at all. Intraoperative cholangiograms were obtained in 29.3% of patients, with a failure rate of 23.3%.

Complications, including delayed discharge, undesired change in therapy, readmission, biliary injury or leakage, infection, hemorrhage, or conversion to open cholecystectomy, occurred in 5.1% of cases. Superficial wound infection was the most common complication. Injuries to the common bile duct or the hepatic duct occurred in 0.5%. Similar to other groups, the rate of bile duct injury was higher early in a given surgeon's experience with the procedure, illustrating the steep learning curve associated with the procedure. The mean hospital stay was 1.2 days, with a range of 6 hours to 30 days. One patient died. [210], [228]

Several aspects of laparoscopic cholecystectomy are currently being investigated. This includes debates about the selection of patients for preoperative or intraoperative cholangiography. Some argue for routine operative cholangiography to look for unsuspected common bile duct stones and to identify ductal anatomy, anomalies, and injuries. Intraoperative cholangiography is usually safe and successful. [238] Others argue for a more selective approach. Preoperative clinical and ultrasonographic assessment can be used to predict the likelihood of common duct stones. A history of jaundice or pancreatitis, dilated common bile ducts on ultrasound, and elevated levels of bilirubin, aminotransferases, or alkaline phosphatase can be used as an indication for preoperative ERCP with possible sphincterotomy or intraoperative cholangiogram. [229], [239] Preoperative ERCP and sphincterotomy does not interfere with laparoscopic cholecystectomy or increase the operative complication rate. [240] Statistical models to predict which patients have choledocholithiasis, and therefore might benefit from preoperative ERCP or intraoperative cholangiogram, have been developed. [241], [242]

If unsuspected choledocholithiasis is discovered intraoperatively, several options are available. The surgeon may convert to an open procedure and carry out a common bile duct exploration with transcystic duct retrieval of stones. Bile duct exploration can also be carried out using laparoscopic or endoscopic techniques. [243] Another common option is postoperative ERCP with sphincterotomy. In experienced hands, laparoscopic bile duct exploration appears to have high success rates (75%–91%). [244], [245] It also has the potential advantages of using only one procedure for treatment of these patients and avoiding the delay inherent in postoperative ERCP. For those patients in whom the procedure is not successful, postoperative ERCP with sphincterotomy remains an option. The modalities of therapy in this area are evolving rapidly, and it is not yet clear which of these techniques will ultimately prove most efficacious and cost-effective. The perioperative approach to common bile duct stones should depend on local availability and expertise.

A serious direct complication of laparoscopic cholecystectomy is injury to the common bile or hepatic ducts. This may result from misidentification of the common duct for the cystic duct, resection of part of the common and hepatic ducts, or associated right hepatic arterial injury. The estimated incidence of bile duct injury varies from 0.3% to 2.7%. [246] In contrast, biliary tract injuries are estimated to occur in 0.25% to 0.5% of open cholecystectomies. [247] The major risk factor for bile duct injury is the experience of the surgeon. Bile duct injuries appear to be much more common early in a surgeon's experience with the technique. Other risk factors appear to be the presence of aberrant biliary tree anatomy and the presence of local acute or chronic inflammation. [246] There does not appear to be a correlation between the incidence of bile duct injury and the frequency of operative cholangiography. [210] Bile leaks may also develop due to displacement of the operative clips on the cystic duct.

Bile duct injury leads to two clinical manifestations: bile leakage into the peritoneum, with resulting abdominal pain and bile peritonitis, and biliary obstruction due to partial or complete hepatic or common duct obstruction from ductal ligation or stricture. Patients can present 3 to 7 days after surgery with fever, abdominal pain, anorexia, ileus, ascites, nausea, or jaundice. Patients with late-onset stricture may present months later with jaundice. Biliary scintigraphy using ^{99m}Tc-IDA can be used to diagnose bile leakage and may show activity in the right paracolic gutter. [248] ERCP with stent placement or sphincterotomy can be used both diagnostically and therapeutically. ERCP appears to be the treatment of choice for less severe lesions, such as minor lacerations of the common bile duct. [246], [249] ERCP may also be used to treat bile leakage due to displaced cystic duct clips. Lesions in the proximal biliary tree may be more amenable to percutaneous transhepatic approaches. [250] Surgical repair may be necessary in some patients, such as those with transected common bile ducts. [246], [250], [251] and [252] Intra-abdominal bile collections may need to be drained percutaneously.

These results bring up certain issues that merit further elaboration. The management of patients with acute cholecystitis, and in particular, the timing of surgery has been controversial. Although laparoscopic cholecystectomy has been performed successfully in acute cholecystitis, this group of patients has a higher incidence of common bile duct stones, and the procedure is technically more difficult and often lasts longer. [253] In this setting, intraoperative cholangiograms may be more difficult to obtain and bile duct injuries more common. Two randomized trials comparing early (<3 days) versus delayed (4–6 weeks) surgery for acute cholecystitis showed no benefit to delaying surgery. [254], [255] Although patients in the early surgery group had longer operating times, they had similar rates of conversion to open cholecystectomy and shorter hospital stays. Thus, early operation for acute cholecystitis may be beneficial.

If the operative field is not adequately visualized or variant anatomy is encountered, conversion to an open cholecystectomy should be undertaken. Conversion to an open procedure should not be considered a complication. In most series, conversion rates are higher with emergency operations. Reported rates range from 1.5% to 15%, with most reporting rates around 5%. [210] With experience, the operative conversion rate appears to fall.

The cost-effectiveness of laparoscopy has been examined. Although the direct operating room and recovery room costs are higher for laparoscopic cholecystectomy, the shortened length of hospital stay leads to a net savings. [256], [257] More rapid return to normal activity may lead to indirect cost savings. Not all such studies have demonstrated a cost savings, however. [229] In fact, with the higher rate of cholecystectomy in the laparoscopic era, the costs in the United States of treating gallstone disease may actually increase.

Although laparoscopic cholecystectomy has replaced open cholecystectomy as the standard of care for gallstones, many patients still present with complications of gallstone disease. Glasgow and colleagues [258] found that 1.3 per 1000 people underwent cholecystectomy for symptomatic gallstone disease in California in 1996. Of these, 56% had biliary colic, and the remainder more severe complications such as acute cholecystitis, gallstone pancreatitis, or cholangitis. Patients presenting with biliary colic were more likely to undergo laparoscopic surgery electively, while those with the more severe complications were more likely to require an emergency or open procedure. In many patients, surgery was significantly delayed after the development of initial symptoms. Patients being treated for complicated gallstone disease had significantly longer hospital stay and costs.

Many studies suggest that laparoscopic cholecystectomy has become common and that indications for the procedure are widening. [224] Cholecystectomy may be performed in some whose symptoms are not clearly biliary in origin. In contrast, some patients with symptomatic gallstones may not receive surgery in a timely fashion. Thus, there is evidence for both underuse and overuse of laparoscopic cholecystectomy. Future work might center upon clarification of the appropriate indications for surgery, as well as ensuring timely recognition and treatment of gallstone symptoms.

Endoscopic Treatment

Stones may be removed from the common bile duct by means of ERCP with sphincterotomy. In the postoperative period, endoscopic and radiographic techniques may be used to extract stones through a T-tube tract. Stones may be extracted or fragmented with the help of a choledochoscope. In all of these modalities, the gallbladder is left in situ, allowing the possibility of recurrent stone formation. Some small studies have shown that patients undergoing sphincterotomy alone for treatment of their gallstone disease have a much higher rate of future biliary complications than patients undergoing open cholecystectomy. [259]

Medical Dissolution

With the advent of laparoscopic cholecystectomy, medical therapy for gallstone disease has fallen somewhat out of favor. These therapies are now limited to patients who are not candidates for laparoscopic or open cholecystectomy.

Oral Bile Acid Litholysis Two bile acids, chenodeoxycholic acid (3a,7a-dihydroxycholanoic acid; CDCA) and its 7ß epimer (3a,7ß-dihydroxycholanoic acid), ursodeoxycholic acid (UDCA), have been used for gallstone dissolution. [260], [261], [262], [263], [264] and [265] These two bile acids induce the secretion of undersaturated hepatic bile, and do not increase the absolute amount of bile acids secreted. The biologic effects of administration of CDCA and UDCA include suppression of de novo hepatic cholesterol synthesis by inhibiting hydroxymethylglutaryl-CoA reductase and enhancement of the activity of 7a-hydroxylase, leading to an increase in bile acid synthesis. [266], [267] Intestinal absorption or reabsorption of cholesterol is down-regulated. [268] Because CDCA has more associated side effects and a lower success rate in dissolving gallstones, UDCA, the major bile acid of the Himalayan black bear, is now the bile acid of choice for gallstone dissolution. UDCA is a remarkably safe compound. The usual dose is 8 to 12 mg/kg/d. The proper selection of patients is a main factor affecting the success of bile acid therapy. The selection criteria include gallstones predominantly consisting of cholesterol; pigment stones or calcified stones are excluded. Small stones that are buoyant in an oral cholecystogram examination have a 90% chance of dissolution. Stones should have a large surface area in relation to the mass, and those with a diameter larger than 1.5 cm are not suitable. Oral cholecystogram or hepatobiliary scanning can be used to document the patency of the cystic duct.
Contact Solvents Solvents can be delivered directly to dissolve gallstones when a catheter can be used to access them. Several cholesterol solvents are available, although none is a simple, safe, and effective method of treating gallstones. The most commonly used agent is methyl- *tert*-butyl ether (MTBE). To dissolve gallstones, the gallbladder is punctured by percutaneous transhepatic approach. A catheter is inserted into the lumen of the gallbladder, and MTBE is introduced and withdrawn from the catheter. [269], [270] Dissolution can be achieved within a few hours. [271] In well-selected patients in specialized centers, this method is effective (90% success rate) and safe. Complications include those caused by the percutaneous puncture procedure and side effects if the MTBE drains into the duodenum (e.g., hemolytic anemia, erosive, or hemorrhagic duodenitis, aspiration pneumonia, somnolence). Small cholesterol gallstones without a thick calcified rim are suitable for this therapy. Calcified or pigment gallstones, cirrhosis of the liver with portal hypertension, and coagulopathy are contraindications.
Extracorporeal Shock Wave Lithotripsy Energy generated externally can be directed to fragment gallstones. This method of treatment combines two approaches: oral bile acid therapy and fragmentation of gallstones. Extracorporeal shock wave lithotripsy (ESWL) requires accurate localization of the gallstones within the gallbladder, usually achieved by three-dimensional ultrasonography. This spatial localization is fed into a computer, which directs the energy to focus sharply on the gallstone. The source of energy varies with different methods. The energy waves, traveling in phases of compression and rarefaction, converge on the gallstone without causing tissue damage because no acoustic impedance occurs. Acoustic impedance and differential tensile forces develop, causing surface disintegration or cavitation. Fragmentation of a gallstone into small fragments (<3 mm) results from successful ESWL. These fragments can be discharged into the duodenum spontaneously or can be rapidly dissolved by UDCA. Depending on the type of lithotriptor, it takes one to several sessions of ESWL before optimal fragmentation can be achieved. UDCA, usually given before and concurrently with ESWL, is continued for several months until stones have completely disappeared. [272] If patients are properly selected, ESWL is effective and safe. Outpatient treatment has been reported. [273] Selection criteria of patients for ESWL are similar to those listed for oral bile acid therapy. Early reports indicated a promising success rate of more than 90% with single, small cholesterol stones. [274], [275] However, larger stones and multiple stones have a lower fragmentation rate of 34% to 71%. [276] The best results are obtained with small, single stones. [277] About 20% of patients developed biliary colic for several weeks after ESWL (25% of these patients required cholecystectomy), and 1% had pancreatitis. [274], [275] and [276] Other side effects include local discomfort, petechiae or bruising, transient noncontraction of the gallbladder, and microscopic hematuria. ESWL is currently not used in the United States for uncomplicated gallbladder stones. However, problematic common bile duct stones not cleared by ERCP with sphincterotomy may be amenable to a combined approach using ESWL. [278]

Rational Approach to Treating Symptomatic Gallstones

Surgery remains the definitive curative method of gallstone treatment. The advent of laparoscopic cholecystectomy and its widespread acceptance has revolutionized surgical treatment of gallstones. Laparoscopic cholecystectomy is now regarded as the treatment of choice for symptomatic gallstones. For patients unable or unwilling to pursue this route, nonsurgical methods such as oral bile acid therapy or lithotripsy are available (Fig. 100-6).

When stones are removed and the gallbladder is left behind, stones may recur. With oral bile acid therapy, the cumulative recurrence rate is about 15% in 2 years and 50% in 10 years. [279], [280] Patients with multiple stones have higher recurrence rates than those who have solitary stones. The long-term recurrence rate after ESWL is also high, 15% at 1 year and 60% at 5.5 years. [46] One of the major challenges of nonsurgical treatment modalities of gallstones is preventing recurrence. It is not generally agreed whether long-term, low-dose UDCA can protect against recurrence. Cholecystectomy is curative for gallbladder stones.

To our knowledge, no formal cost comparison has been made between surgical and nonsurgical treatment. Surgery has a high immediate cost and low long-term cost. Nonsurgical means of treatment may have a low immediate cost but high long-term cost because of recurrent or persistent disease. In selecting patients for nonsurgical treatment, a diagnosis of gallstones by ultrasonography is insufficient. The physician must also determine gallstone composition and gallbladder function. Regular monitoring by ultrasonography during nonsurgical treatment may be necessary. These additional tests increase cost.

In approaching a patient with symptomatic gallstones, an elective cholecystectomy remains the gold standard. However, for those who cannot or will not have surgery, there are other alternatives. One of the nonsurgical methods may be selected if the patient satisfies all the criteria and if expertise is available.

ACALCULOUS CHOLECYSTITIS

Acute cholecystitis can present as an acalculous disorder. Acalculous cholecystitis represents 5% to 10% of the patients with acute cholecystitis and may be increasing in frequency. [281], [282] This entity is distinct from gallstone-related disease in that it usually occurs in the setting of major surgery, critical illness, trauma, or burn-related injury. The patients tend to be predominantly male and older than 50 years of age. Many of them are on TPN, and bile inspissation or sludge formation may occur. Hypotension and sympathetic vasoconstriction may contribute, predisposing the patient to ischemic injury as well. Extensive small vessel occlusion has been shown in cholecystectomy specimens from these patients. [283] Another postulated risk factor is mechanical ventilation with positive end-expiratory pressure (PEEP). [281] PEEP may decrease portal perfusion and increase resistance in the common bile duct, with subsequent stasis. [284], [285] The pathogenesis of acalculous cholecystitis probably involves some combination of bile stasis, chemical inflammation, and mucosal ischemia. Gallbladder ischemia may be the only predisposing factor found in many cases. Bacterial infection, usually by gram-negative bacteria and anaerobes, appears to occur secondarily.

P>In acalculous cholecystitis, complications such as gallbladder gangrene and perforation, emphysematous cholecystitis, or empyema, may develop more rapidly than in calculous cholecystitis. [281] One retrospective study revealed that 70% of patients had gangrene, empyema, or perforation of the gallbladder evident at the time of surgical exploration. [286] This increased complication rate occurring in the setting of advanced age and other illnesses contributes to the higher mortality rate associated with this disorder. For these reasons, it is important to suspect and pursue an early diagnosis. It should be suspected in patients who are critically ill with signs of sepsis, but with no obvious source. Findings on physical examination and laboratory studies are not necessarily helpful. Potential diagnostic modalities include ultrasonography, CT, hepatobiliary scintigraphy, and laparoscopy.

Ultrasonography is usually the initial modality chosen. Criteria for acalculous cholecystitis include a thickened gallbladder wall (>4 mm), pericholecystic fluid, subserosal edema without ascites, intramural gas, sloughed mucosal membranes, or a sonographic Murphy sign. Reported sensitivity rates range from 67% to 92%, with specificity over 90%. [287] Experience with CT is also favorable. Diagnostic criteria are similar to ultrasonography. Its reported sensitivity and specificity are in excess of 95% when compared with findings at the time of surgery. [287] Another advantage of CT is the ability to look for other intra-abdominal pathology. Results with hepatobiliary scintigraphy are variable, with reported sensitivity rates ranging from 68% to 91% and frequent false-positive results. Adjunctive use of morphine to enhance gallbladder filling may improve the accuracy of this test. [288] Patients in whom the diagnosis is uncertain or with generalized peritonitis may benefit from

diagnostic laparoscopy or exploratory laparotomy. In small series of patients, diagnostic laparoscopy appears to be accurate and safe. [289], [290] Some suggest empiric percutaneous cholecystostomy if the diagnosis is suspected but cannot be confirmed with other modalities. [291]

Rare causes of acute cholecystitis include specific infections, such as *Salmonella* or *Candida* infection. [292], [293] Cytomegalovirus and *Cryptosporidium* can infect the biliary system and produce cholecystitis and cholangitis in severely immunocompromised patients, such as those with acquired immunodeficiency syndrome (AIDS) or after marrow transplantation. [294], [295] In patients with AIDS, infection with microsporidia such as *Enterocytozoon bieneusi, Pneumocystis carinii,* and *Isospora belli* have been documented. [296] However, acute calculous cholecystitis may also occur in these patients. No specific symptoms can differentiate these two, and patients may have coexisting gallstones and opportunistic infection. In these patients, acalculous cholecystitis probably represents part of the spectrum of AIDS-related cholangiopathy.

Once a diagnosis of acalculous cholecystitis is made, the gallbladder must be drained or removed. Choosing the treatment modality may be difficult as patients often have severe co-morbid conditions. Options now include percutaneous or surgical cholecystostomy, surgical cholecystectomy, or endoscopic transpapillary cholecystotomy. [291], [297], [298] and [299] Percutaneous cholecystostomy has been gaining favor recently. Its advantages include the use of local anesthesia and the ability to be performed at the bedside. Also, percutaneous cholecystostomy can be the definitive therapy in acalculous cholecystitis. The overall success rate is 63% to 94% with a low complication rate of approximately 10%. [300] Complications include liver laceration, hemorrhage, infection, hemobilia, bile leak, bile peritonitis, and catheter dislodgment. Other disadvantages of cholecystostomy include a limited ability to look for other causes of sepsis and potentially inadequate drainage in cases of pericholecystic abscess, gangrene, or gallbladder perforation. Surgical cholecystostomy or cholecystectomy are the traditional therapies, but patients may be poor operative candidates. Endoscopic transpapillary drainage has been reported in small series and needs to be further studied before it can be recommended for general use.

RECURRENT PYOGENIC CHOLANGITIS

Recurrent pyogenic cholangitis, also known as Oriental cholangiohepatitis or hepatolithiasis, is a syndrome primarily seen in southeast Asian populations such as Taiwan, China, Japan, and Korea. Patients present clinically with recurrent attacks of abdominal pain, fever, and jaundice. Previous reports found this entity to be among the leading causes of acute abdominal emergencies in Hong Kong. [301] The prevalence of intrahepatic stones is likely decreasing in many parts of Asia. [302] Primary intrahepatic stones are generally calcium bilirubinate or mixed stones. Intrahepatic calcium bilirubinate stones contain less bilirubin and more cholesterol than pigment stones in the extrahepatic bile ducts. [303] The pathogenesis of these stones is complex, and likely involves a combination of bile infection, malnutrition or dietary factors, biliary stasis, and possibly parasitic infestation. It is generally believed that bacterially mediated hydrolysis of bilirubin by ß-glucuronidase is crucial to formation of pigment stones. This leads to formation of unconjugated bilirubin, which can precipitate as calcium bilirubinate. The ß-glucuronidase enzyme often originates from *E. coli* or other bacteria in the biliary tree. There has been a debate about whether bacterial infection precedes or is a sequela of stone formation. However, in at least some patients with bilirubinate stones, bile infection precedes stone formation. [148] ß-Glucuronidase can be inhibited by glucarolactone, whose levels are decreased in patients with a low protein and low fat diet. [304] It has therefore been suggested that dietary factors contribute to formation of intrahepatic stones. The role of infection by parasites such as *Ascaris lumbricoides* or *Clonorchis sinensis* has been controversial. The parasites or their ova have been found as nidi for intrahepatic stones in earlier studies. [303] However, infection with these parasites is widespread, but recurrent pyogenic cholangitis is uncommon outside southeast Asia. Even within endemic countries, there is not a direct correlation between the prevalence of parasitic infection and the occurrence of this syndrome. These lines of evidence suggest that factors in addition to parasites are important for the development of these stones.

Recurrent pyogenic cholangitis frequently presents in patients under 50 years of age. Men and women are affected equally. It is more common with lower socioeconomic status and malnutrition. Symptoms occur when the stones cause partial or complete biliary obstruction, either with or without associated infection. Many patients will present with epigastric or right upper quadrant pain or discomfort. Acute cholangitis, with fever, right upper quadrant pain, and jaundice, is also common. Physical examination may show right upper quadrant tenderness, hepatomegaly, or an enlarged gallbladder. Laboratory results are generally consistent with the degree of biliary obstruction and infection. In advanced cases, biliary cirrhosis and its sequelae may develop.

Recurrent pyogenic cholangitis is often diagnosed clinically in endemic areas. Delineating the extent and location of stones and strictures is essential to planning further treatment. Abdominal plain films are rarely useful as the stones are usually radiolucent. CT scan may be useful to assess ductal dilation. Percutaneous or endoscopic retrograde cholangiography may provide the most accurate information. The left intrahepatic duct is preferentially involved. Frequent findings on cholangiography include stones, biliary strictures, and ductal dilation. The intrahepatic ducts may also appear “pruned” with decreased arborization. [305] Histologically, increased fibrous tissue around the portal tracts may be found with bile ductular proliferation.

Surgery is the primary method of treatment for this syndrome. The role of endoscopic treatment is relatively limited because of the difficulty in treating intrahepatic strictures and stones. Surgery should aim to remove as many stones as possible and to achieve adequate drainage of obstructed ducts. [305] In rare cases, hepatic resection can be undertaken if the stones and strictures are localized. If strictures cannot be managed operatively, many surgeons will create a Roux-en-choledochojejunostomy with the end of the loop left in the subcutaneous abdominal wall tissue. [306] This allows easier access for later endoscopic or interventional radiologic treatment.

Interventional radiology techniques are also important in management of recurrent pyogenic cholangitis. If percutaneous transhepatic drainage can be established, cholangioscopy can be used to direct attempts at electrohydraulic or laser lithotripsy, stricture dilation, and stone clearance. [307] Solvents such as MTBE are ineffective, because the stones are not cholesterol stones. Surgical and interventional radiologic techniques to achieve adequate drainage and stone clearance will be required by many patients.

CHAPTER 101

Jayant A. Talwalkar and Russell H. Wiesner

PRIMARY SCLEROSING CHOLANGITIS AND OTHER CHOLANGIOPATHIES

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. Histological characteristics include the presence of portal tract inflammation, periductal fibrosis, and loss of small bile ducts. Disease progression is almost universal among subjects, resulting in biliary cirrhosis and hepatic failure. Immunologic and genetic alterations have been cited as factors in its pathogenesis. [1], [2] Understanding the natural history of PSC has become important because of the success of liver transplantation as an effective therapeutic modality.

EPIDEMIOLOGY

With the increasing availability of endoscopic retrograde cholangiography (ERCP), a growing body of knowledge about the clinicopathologic features of PSC has emerged. Fifty to 70% of affected individuals are of male gender, with an average age of 40 years at diagnosis. [3], [4], [5], [6], [7], [8], [9] and [10] The male predominance seen in PSC has not been observed in inflammatory bowel disease (IBD) or similar autoimmune liver diseases as primary biliary cirrhosis (PBC) and autoimmune hepatitis (AIH). However, a significant proportion of female subjects have been reported among select cohorts. [8], [9] The suggestion of a reduced survival outcome from PSC in female subjects, however, has yet to be confirmed. [9]

The close association between PSC and IBD is well established. Among northern Europeans, 70% to 80% of PSC patients have chronic ulcerative colitis (UC). [11], [12], [13] and [14] Lower prevalence rates of IBD in PSC, however, have been noted elsewhere. [15], [16] These wide variations appear related to influences not explained by clinical practice. The use of surveillance colonoscopy with mucosal biopsy assessment, although improving the detection of subclinical IBD, is nonetheless required if accurate prevalence estimates for IBD in PSC are to be determined. No meaningful difference in PSC-related survival, however, has been observed among patients with or without IBD. [9] Ulcerative pancolitis or colonic involvement alone by Crohn's disease imparts the greatest risk for PSC. [10], [11] Conversely, about 2.4% to 4% of patients with UC [10], [12], [13] and [14] and 1.4% to 3.4% with Crohn's disease [11], [14] have or develop PSC. From descriptions in the general population, an estimated prevalence rate of 13 to 140 cases of PSC per 1 million population exists. [10] The only population-based epidemiologic investigation of PSC revealed annual incidence and cross-sectional prevalence rates of 1.3 and 8.5 per 100,000 population. [17] Geographic areas outside of Norway, however, have reported PSC at lower rates with less well-defined methods. [18] The accuracy of prevalence data is limited by several factors, including the failure to identify asymptomatic patients, those with fluctuations in liver biochemical parameters such as serum bilirubin, and those without coexisting IBD. From an estimated prevalence rate of 40 to 225 cases per 100,000 United States population for UC, the prevalence of PSC is estimated between 2 and 11 cases per 100,000 population with UC.

Although a negative relationship between smoking history and UC activity is well established, [19] similar investigations in PSC have also been conducted. By comparing UC patients with age- and gender-matched controls, a lower prevalence rate of PSC (4.9%) was observed among individuals who smoked compared with nonsmoking controls (26.1%). The coexistence of UC could not support this finding. [20]

PATHOGENESIS

Immune Mediated

Immune System Alterations Immunologic and genetic alterations have been cited as factors in the pathogenesis of PSC as well as disease progression. Cellular immune abnormalities have been described focusing primarily on the significance of lymphocyte function in PSC. CD4 lymphocyte recognition of antigens found on biliary epithelia is hypothesized to initiate the immune-mediated histological damage seen in PSC. [21], [25] T-cell reactivity studies have demonstrated activation of both suppressor and cytotoxic lymphocyte populations with exposure to major histocompatibility complex (MHC) antigens in vitro. [25] Recent investigations suggest that hepatic T cells in PSC have oligoclonal restriction different from populations in peripheral blood. [22] Conflicting results exist, however, regarding the significance of altered circulating CD8 and CD4 T lymphocytes as both reductions and elevations in their ratios have been observed. [23] Increased numbers of hepatic B-cell lymphocytes reported among PSC patients with advanced histological disease is not recognized with earlier stages of disease, suggesting that cellular infiltration may be a secondary phenomena related to chronicity. [24] Historically, there have been no accepted animal models that characterize PSC. Orth and colleagues [26] described a bacteria-free rat model of sclerosing cholangitis derived from the injection of 2,4,6-trinitrobenzesulphonic acid into bile ducts. The cholangiographic pattern in these animals was consistent with PSC as well. The presence of CD3-positive T-cell infiltrates and increased bile duct expression of class II MHC molecules was also consistent with PSC observed in humans. Further studies are required to validate the model's reproducibility. A number of clinical investigations have also confirmed the presence of numerous humoral immune markers in the sera of patients with PSC. Non–organ-specific markers such as immunoglobulin G and M, antinuclear antibody (ANA), and anti–smooth muscle antibody (ASMA) are often seen in low but detectable titers. [2], [28] Their relevance in the pathogenesis of PSC may occur among patients displaying clinical features of AIH and PSC. Elevated levels of circulating immune complex molecules have also been reported in up to 80% of PSC cases and other HLA-B8–and HLA-DR3–associated immune-mediated diseases. [27], [28] Selected cross-reactive antibody species among patients with UC and PSC are not seen in cases of PSC alone, suggesting a shared mechanism for immune-mediated damage. [29] Perinuclear antineutrophil cytoplasmic antibody (pANCA) has been reported in 26% to 85% of PSC subjects and in 70% of UC patients without PSC. [30], [31] and [32] The antigenic and subsequent pathogenic role of pANCA, however, is unknown. [33] Seropositivity for ANCA in PSC has been reported with extensive involvement of the biliary tree, hepatic dysfunction, and severe cholestasis. [34]
Genetics An increased prevalence of HLA-A1, -B8, and -DR3 alleles in PSC has been described but remains nonspecific given their occurrence in other organ-specific autoimmune diseases. [35] Greater than expected frequencies of the HLA-DRw52a antigen and HLA-DRB3*0101 were initially reported among 100% of patients undergoing liver transplantation at a U.S. center. [36] Subsequent investigations have not supported the DRw52a allele as an important susceptibility marker for disease development. [37] HLA-DRB3*0101 appears to be the most common susceptibility locus in 55% to 65% of PSC patients [21] and may be universal in end-stage liver disease from PSC. [13] In Scandinavia, however, the HLA alleles DRB1*0301 and DRB1*1301 have been reported as the primary susceptibility loci in PSC. [38] Of potential significance is the reported association between HLA-DRB3*0101 and reduced survival among subjects with PSC. [37] Rapid disease progression has also been suggested with the existence of HLA-DR4, in which a protective effect was once previously proposed. [39] A multicenter investigation found the HLA-DR3,DQ2 heterozygous genotype associated with more rapid disease progression in PSC, whereas a protective effect resulted from HLA-DQ6. [41] Although controversial in nature, these findings remain to be confirmed among larger populations to verify the predictive effect of HLA alleles on disease outcome in PSC. A number of non-MHC candidate genes may be related to the immune dysregulation in PSC. Serum cytokines, including interleukin-1 (IL-1) and IL-10, have been examined as inflammatory response mediators in PSC. No association between IL-1 and IL-10 gene polymorphisms with susceptibility or resistance to PSC has been observed. [40], [45] Class I MHC chain A (*MICA*) and B (*MICB*) genes have also been studied in PSC. *MICA5.1* (90% versus 74%) and *MICB24* (58% versus 29%) were significantly increased among PSC patients compared with controls. [42] The frequency of PSC patients carrying all four alleles was also significantly greater than controls (49% versus 18%). Among two independent PSC populations, [43] the MICA*008 allele was more common in PSC than controls (66% versus 48%), whereas the MICA*002 allele had a protective effect from PSC. The influence of a matrix metalloproteinase-3 functional polymorphism has also been reported in PSC. [44] Although reductions in allele 6A homozygosity were observed in PSC compared to controls, the development of portal hypertension was significantly associated with 5A homozygosity in PSC.

Non–Immune Mediated

The primary target of immune-mediated injury in PSC is the biliary epithelium. Increased expression of class II MHC molecules on biliary epithelium in PSC to support their role as antigen-presenting cells remains controversial.

The strong association between PSC and IBD has suggested that an infectious etiology may be present in specific individuals. [46] Alterations in diseased bowel mucosa facilitating portal bacteremia may be responsible. Increased serum levels of tumor necrosis factor (TNF) have been observed in animal models from portal bacteremia, resulting in activated hepatic Kupffer cells. [47] Clinical findings in humans, however, are noted for the relative lack of significant colonic inflammation in patients with PSC and after total proctocolectomy for refractory UC. [48] As with PBC, the role of *Helicobacter* species infection in developing PSC has been examined. The significance of an increased rate of *Helicobacter* species DNA in patients with PSC (especially those with UC) compared with noncholestatic liver disease requires further study. [49] An increased rate of a-Hemolytic streptococci from explanted liver tissue [50] and bile [51] have also been found in PSC patients. Among PSC patients with or without previous ERCP, a-hemolytic streptococci were the most frequent isolate despite similar positive culture rates. The impact of a-hemolytic streptococci on etiopathogenesis or disease progression in PSC, however, remains unknown. Viral infections such as cytomegalovirus among immunocompromised hosts can result in PSC-like changes. [52]

Immunodeficiency syndromes have been identified with cholangiographic changes suggestive of PSC including familial immunodeficiency syndrome, X-linked immunodeficiency, angioimmunoblastic lymphadenopathy, and acquired immunodeficiency syndrome (AIDS). [53]

Bile acid metabolite hepatotoxicity has been observed in animal models after chenodeoxycholic acid breakdown to lithocholic acid by bacterial 7-a-dehydroxylation in the colon. No major bile acid abnormalities among human subjects with PSC have been identified. [54]

Biliary tree injury resulting from hepatic artery chemoembolization with fluorodeoxyuridine, 5-fluorouracil, and mitomycin can yield cholangiographic features compatible with PSC. [55] Direct toxicity or ischemia to bile ducts is hypothesized.

CLINICAL MANIFESTATIONS

Asymptomatic elevations in serum liver biochemistries or the development of symptoms such as fatigue (75%) and pruritus (70%) are observed with the diagnosis of PSC (Table 101-1). Jaundice (65%) and weight loss (40%) are less common and should raise the suspicion of advanced disease or a complication related to PSC. [1], [2], [4], [8] The average duration of symptoms before diagnosis is 2 years. Fever and abdominal pain in a patient with PSC are highly suggestive of bacterial cholangitis, which can manifest at initial presentation. [56] A previous history of IBD and elevated serum liver biochemistries often prompts investigations to exclude PSC. Among patients with refractory UC requiring total proctocolectomy, it has been shown that PSC may still develop. [48]

FINDING	PREVALENCE (%)
Symptom	
Fatigue	75
Pruritus	70
Jaundice	65
Weight loss	40
Fever	35
Asymptomatic	10
Sign	
Hepatomegaly	55
Jaundice	50

TABLE 101-1 Symptoms and Signs at Initial Presentation in Primary Sclerosing Cholangitis

Asymptomatic Disease

Although symptomatic PSC is commonly associated with jaundice or pruritus, an increasing number of asymptomatic cases are being identified. Asymptomatic patients have represented between 15% and 25% of most reported observational cohorts examined. [4], [5] and [6], [9], [57] Recent reports, however, have observed prevalence rates of greater than 40% for asymptomatic PSC. [8]

Progression of liver disease can also occur among asymptomatic patients, yet existing data are conflicting. Over a 6-year period, advancing liver disease was noted among 34 (76%) of 45 asymptomatic subjects with a 31% rate of liver transplantation or death. Minimal histological abnormalities (stage I or II) on liver biopsy with no cases of cirrhosis were found in most subjects at study entry. The estimated median survival rate for asymptomatic patients without liver failure was 75% at 7 years versus 96% for comparable age- and sex-matched healthy controls. [57] Among 13 (31%) of 42 PSC patients who were asymptomatic at initial presentation, Helzberg and colleagues [4] reported that 11 individuals remained symptom free for a mean duration of 37 months, resulting in an overall survival rate of 75% at 9 years. No significant decompensation occurred over a 4.4 year period among 27 asymptomatic subjects. [3]

Despite a silent or subclinical presentation at diagnosis, there is evidence to support that asymptomatic PSC becomes symptomatic. Fatigue, pruritus, jaundice, or abdominal discomfort develop in 60% of cases. [4], [5] and [6], [8] The similar frequencies in clinical deterioration among asymptomatic and symptomatic patients, however, emphasizes the lack of predictive ability associated with subjective complaints at diagnosis. [4], [6] Differences in criteria for defining the asymptomatic state may also explain the discrepancy in published results. Fatigue and weight loss have been reported in up to 30% and 24% of asymptomatic subjects, respectively. In addition, advanced histological features have been demonstrated in 30% to 43% of subjects considered asymptomatic at diagnosis. [3], [57]

Symptomatic Disease

Most subjects in reported investigations have been described as symptomatic based on findings at diagnosis. [3], [4], [5], [6], [7], [8] and [9] Helzberg and colleagues [4] first reported an 18% mortality rate among patients with PSC over a mean follow-up period of 56 months. All deaths occurred in symptomatic individuals. A similar mortality rate of 14% over 51 months has been observed with a reduced median survival for symptomatic individuals as well (112 months versus 144 for the entire cohort). [8] Two larger series, however, have provided evidence to suggest a more aggressive disease course for symptomatic PSC. Among 174 PSC subjects followed at the Mayo Clinic, [5] a 41% combined rate for liver failure, cholangiocarcinoma, and need for transplantation was observed over 6.25 years of follow-up. Median survival for the entire cohort was 11.9 years. For symptomatic patients with PSC, the median survival was reduced to between 8 and 9 years. Similar results were reported from Kings College, [6] where a median survival of 12 years among 126 subjects over a 6.9 year period of follow-up was observed.

Biochemical Features

Serum hepatic biochemical parameters usually reflect a cholestatic profile. Alkaline phosphatase values often predominate, with elevations up to three times the upper limit of normal in nearly 95% of cases. [1], [2], [3], [4], [5], [6], [7], [8] and [9] Serum alanine and aspartate transaminase levels can also be found between two and three times the upper limit of normal. [3], [4], [8], [9], [56] Of note, serum total bilirubin is normal in 60% of individuals. [1], [2], [56] Increased levels of total bilirubin, which often fluctuate in PSC, are worrisome for advanced disease when persistent elevations occur. No significant differences in serum liver biochemistry profiles have been seen among asymptomatic and symptomatic individuals at diagnosis. [57] Normal serum albumin and prothrombin time levels reflecting hepatic synthetic function are found in most cases at diagnosis. [3], [4], [5], [6], [7], [8] and [9]

Serologic Features

Serum immunoglobulin levels and autoantibodies are associated with PSC. Elevations in IgG and IgM in up to 40% and 60% of individuals are observed. [2], [7] ANA and smooth muscle antibody ASMA can also be detected but are in lower titers compared to AIH. [2], [7], [58] Antimitochondrial antibodies (AMAs) are exceedingly rare in PSC. [5], [58] pANCAs are detected in the serum of PSC patients at rates between 30% and 80% [30], [31] but lack specificity because they are also observed in PBC, AIH, and UC. [31], [59] Angulo and colleagues [60] have observed a greater rate of seropositivity for ANA, anticardiolipin, antithyroperoxidase, pANCA, and rheumatoid factor among PSC patients compared with control subjects. Ninety-seven percent of PSC patients were found to have one or more autoantibodies, whereas 81% were found with three or more. The presence or absence of IBD was not significantly associated with autoantibody history.

Radiographic Features

Cholangiography The diagnosis of PSC is made by cholangiography. Both ERCP and percutaneous transhepatic cholangiography (PTC) have been employed in a nonoperative setting. PSC commonly affects the entire biliary tree in a heterogeneous manner. Intrahepatic duct involvement is nearly universal among patients with PSC. [61] Only 20% of patients have hilar duct involvement with sparing of the remaining extrahepatic duct. Segmental fibrosis of both intrahepatic and extrahepatic ducts with subsequent saccular dilation of normal intervening areas results in the characteristic beads-on-a-string appearance seen in PSC (Fig. 101-1). Bile duct strictures are of varying lengths but can be up to several centimeters. The serrated appearance of bile duct walls and occasional diverticulum are also identified in extrahepatic portions of the biliary tree in 25% of cases. [62]

FIGURE 101-1. Cholangiographic features in primary sclerosing cholangitis. Multifocal strictures with intervening saccular dilation (beads-on-a-string appearance) of both intrahepatic and extrahepatic bile ducts are shown.

The initial use of magnetic resonance cholangiopancreatography (MRCP) for suspected PSC has been increasingly recognized. [63], [64] Among 23 of 73 patients identified with PSC, [63] an overall diagnostic accuracy of 90% for MRCP compared with 97% for invasive cholangiography was reported. Similar conclusions were observed among 34 subjects with PSC in an independent study. [64] Advantages of MRCP over invasive cholangiography include visualization of bile ducts proximal to obstructed areas and hepatic parenchymal assessment to exclude features of cirrhosis and portal hypertension. The inclusion of subjects with advanced PSC and overestimation of stricture length by MRCP have been observed as potential biases in both investigations.

Cross-Sectional Imaging Computed tomography (CT) [65], [66] and [67] and magnetic resonance imaging (MRI) [67], [68] and [69] have been used in the evaluation of PSC. Radiologic features of PSC detected by cross-sectional imaging include segmental dilation of intrahepatic bile ducts which tapers toward the hilum. [65] Gallstones have been identified in up to 25% of patients with PSC, whereas asymmetric thickening of the gallbladder wall independent of cholelithiasis may also be observed. [66] Marked hypertrophy of the right and caudate hepatic lobes with simultaneous atrophy in the remaining liver is often seen in cirrhotic-stage PSC. [67] As observed for other etiologies of cirrhosis, the presence of confluent hepatic fibrosis and regenerative nodule formation may be confusing for hepatocellular carcinoma. With MRI, the presence of abnormal T2-weighted signal intensity from periportal areas is common and correlates with fibrosis. [68] Enlarged areas (greater than 1.5 cm) of abnormal T2 signal within portal areas are considered suspicious for cholangiocarcinoma. [69]

Histological Features

Liver biopsy is required for staging disease severity and determining prognosis in PSC. Periductal fibrosis with inflammation, bile duct proliferation alternating with obliteration, and ductopenia constitute the main histological findings. [70] Fibroobliterative cholangiopathy, which is considered the most diagnostic finding on liver biopsy PSC, is present in only 10% of all cases. [71] However, similar findings may occur in varying stages of other conditions, such as PBC, AIH, or chronic extrahepatic bile duct obstruction. The histological abnormalities in PSC are classified into four stages. Stage I (portal stage) is associated with a nonspecific inflammation confined to the limiting plate that surrounds the portal tract. Fibrosis is usually not seen at this stage. Stage II (periportal stage) is associated with inflammation extending beyond the limiting plate with expansion of the portal tracts. Fibrosis is seen involving portal and periportal areas. Stage III (septal stage) is characterized by septal or bridging fibrosis spanning portal tracts in conjunction with bridging necrosis (Fig. 101-2). Stage IV, or cirrhosis, is when complete septal fibrosis in association with nodular regeneration is present. [70]

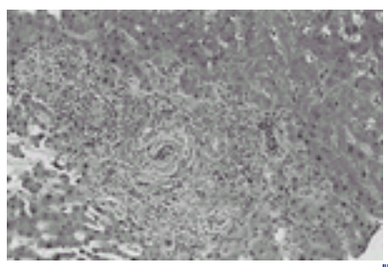

FIGURE 101-2. Histologic features of primary sclerosing cholangitis. Portal tract expansion with chronic nonspecific inflammation, edema, and periportal fibrosis consistent with stage II disease is shown.

DIFFERENTIAL DIAGNOSIS

The identification of serum hepatic biochemical elevations consistent with cholestasis in a male patient with concurrent IBD is strongly suggestive of PSC (Table 101-2). Excluding structural causes for biliary obstruction including choledocholithiasis by ultrasonography or cross-sectional imaging is required. Cholangiography by direct or cross-sectional imaging methods that reveals the typical features of PSC is considered the gold standard for diagnosis. Although liver biopsy is not mandatory for confirming the existence of PSC, it is helpful for staging and excluding other causes of chronic cholestasis.

Extrahepatic biliary tract obstruction
Choledocholithiasis
Strictures
Malignancy
Primary biliary cirrhosis
Autoimmune hepatitis
Pyogenic hepatic abscesses
Fungal cholangitis
Acquired immunodeficiency syndrome cholangiopathy
Choledochal cyst
Cystic fibrosis
Cirrhosis
Intrahepatic hepatocellular carcinoma
Cholangitis glandularis proliferans
Eosinophilic cholangitis

TABLE 101-2 Differential Diagnosis of Primary Sclerosing Cholangitis

PBC more commonly affects women than men (9:1 ratio) and is rarely associated with IBD. The diagnosis is confirmed by elevated serum titers of AMA. Early histological involvement is characterized by lymphoplasmacytic portal infiltration or granulomatous inflammation (florid duct lesion). [72] AMA-negative PBC or autoimmune cholangitis is clinically similar to PSC in the absence of cholangiography. With normal biliary tree visualization, a liver biopsy is required to distinguish this condition from small duct PSC, in which involvement with ductular fibrosis is more prominent. [73]

AIH is distinguished from PSC by (1) predominant elevations in serum aminotransferase levels compared with alkaline phosphatase and bilirubin; (2) the presence of elevated serum ANA or ASMA titers; (3) extensive interface or lobular lymphoplasmacytic inflammation; and (4) normal cholangiography. [74] In children, the initial presentation of PSC often resembles AIH; thus, cholangiography is necessary for accurate diagnosis. [75] Overlap syndromes between AIH and PSC among pediatric and adult populations have been recognized in 2% to 20% of cases based on various definitions. [58], [76], [77] Cholangiography in these patients, however, must demonstrate features of PSC before consideration of an overlap state is made. Potential benefit from corticosteroid therapy among select individuals may be attained.

The development of pyogenic hepatic abscesses with invasion of adjacent bile ducts can result in irregularities reminiscent of PSC. [78] Frequent attacks of ascending cholangitis in a native of Southeast Asia are consistent with the diagnosis of recurrent pyogenic cholangitis (oriental cholangiohepatitis). Cholangiography is noted for dilation of intrahepatic and extrahepatic ducts, decreased arborization with tapering of peripheral ducts (arrowhead sign), and straightening of the intrahepatic ducts from periductal fibrosis. [79] Systemic fungal infection may colonize or invade the biliary tree, resulting in cholangiographic features similar to PSC. [80] AIDS cholangiopathy presents with striking elevations in serum alkaline phosphatase with or without symptoms of jaundice and abdominal pain. Extrahepatic bile duct dilation and papillary stenosis are most commonly observed. Thickened bile duct walls rather than saccular dilatations in AIDS cholangiopathy distinguish this entity from PSC. [81]

Choledochal cyst involvement of intrahepatic bile ducts can also resemble PSC. Ultrasonography usually shows marked areas of ductal dilation, and cholangiography is almost invariably diagnostic. [82] Cystic fibrosis, which involves intrahepatic bile duct cystic dilation, can produce a cholangiogram typical of PSC. [83]

Diffuse abnormalities of the biliary tree without discrete extrahepatic stricturing may also be observed with conditions such as cirrhosis and intrahepatic hepatocellular carcinoma. In cirrhosis, the presence of distal duct tapering is noted when cholangiography is performed. Cross-sectional imaging and liver biopsy (if indicated) will confirm the presence of hepatic neoplasia when suspected. Biliary duct changes similar to that in cirrhosis are also observed if cholangiography is performed. [84]

Cholangitis glandularis proliferans [85] (a rare disorder similar to adenomyomatosis of the gallbladder) and eosinophilic cholangitis [86] can present with nonstricturing intrahepatic duct dilation resembling PSC.

ASSOCIATED CONDITIONS

An increased prevalence for concurrent autoimmune disorders has been recognized in PSC (Table 101-3) but remains less common than in PBC. UC remains the most commonly associated autoimmune disorder in PSC (70% to 80%) [2], [5], [6], [7] and [8], [10], [11], [12], [13] and [14] with colonic involvement from Crohn's disease in 5% to 8% of cases. [11], [14] Other diseases include pancreatitis (10% to 25%), [87], [89] diabetes mellitus (5% to 15%), [88] and autoimmune thyroid disease (3% to 5%). [88] Rare associations include Sicca syndrome, [89] immune thrombocytopenic purpura, [90] mediastinal or retroperitoneal fibrosis, [91], [92] pseudotumor orbit, [92] Peyronie disease, [93] rheumatoid arthritis, [94] ankylosing spondylitis, [95] Hodgkin disease, [96] membranous nephropathy, [97] glomerulonephritis, [98] autoimmune hemolytic anemia, [99] celiac disease, [100], [101] histiocytosis X, [102] hypereosinophilia, [86] focal nodular hyperplasia, [103] and Down syndrome. [104]

DISEASE	PREVALENCE (%)
Ulcerative colitis	70–80
Crohn's colitis	5–8
Pancreatitis	10–25
Diabetes mellitus	5–15
Autoimmune thyroid disease	3–5

TABLE 101-3 Selected Extrahepatic Autoimmune Diseases Associated with Primary Sclerosing Cholangitis

DISEASE-RELATED COMPLICATIONS

Fatigue

The frequency of reported fatigue by individuals with PSC averages between 60% and 70%. [56], [68] Its level of intensity appears independent of histological and cholangiographic disease severity. [1], [2], [3], [4], [5], [6], [7] and [8] Reported fatigue has been associated with reductions in health-related quality of life in PSC. [105] Knowledge of the exact mechanism responsible for fatigue in PSC remains unknown.

Pruritus

In PSC, the prevalence of pruritus ranges from 40% to 60% on average in reported observational cohort studies. [1], [2], [3], [4], [5], [6], [7] and [8] Proposed mechanisms of action have included bile salt retention with skin deposition [106] and the accumulation of endogenous opioid ligands and receptors within the central nervous system. [107] As with fatigue, the severity of pruritus in PSC appears to be independent of histological stage, although extrahepatic stricturing can influence symptom intensity. [1], [2], [3], [4], [5], [6], [7] and [8]

A number of medical therapies have been evaluated for symptom relief of pruritus. Initial therapy with antihistamines is often associated with residual sedation and only limited success. [72] Cholestyramine (a bile acid–binding resin) may decrease the intensity of pruritus but is rarely met with complete symptom resolution. [108] Among subjects with intact gallbladders, the use of 4 g before or after breakfast is thought to maximize bile acid sequestration and symptom alleviation. Divided doses over 24 hours in subjects after cholecystectomy are more effective than once- or twice-daily dosing. Administration of cholestyramine several hours apart from other medications is recommended to prevent elimination without gastrointestinal absorption.

Hepatic enzyme inducers, including phenobarbital [109] and rifampin, [110], [111] and [112] have been associated with improvements in bile acid flow experimentally and in the treatment of pruritus. Excessive sedation at higher doses has limited the clinical utility of phenobarbital. [109] Rifampin in doses of 300 to 600 mg/d is associated with a rapid onset of action and symptom relief in PSC. [110] Although well-tolerated, this medication is also associated with cholestatic liver injury and bone marrow aplasia in up to 10% of cases. [111] Ursodeoxycholic acid (UDCA) at doses of 13 to 15 mg/kg/d has not been shown to be effective in the treatment of pruritus. [112] Other therapeutic options used for pruritus in PSC, including oral naltrexone, [113] activated charcoal hemoperfusion, [114] and plasmapheresis, [115] have been sporadically applied with good results. Among patients with intractable pruritus refractory to medical therapy, liver transplantation is the only existing therapeutic option. [72]

Metabolic Bone Disease

Metabolic bone disease in PSC is related to osteopenia rather than osteomalacia (defective bone mineralization) among North American patients. [116] Decreased bone formation (osteoporosis) rather than increased resorption is thought to be an important mechanism in the pathogenesis of bone disease. [117] Calcium and vitamin D metabolism is usually abnormal among anicteric patients with PSC. [118] The recognition of improved bone mineral density about 6 months after liver transplantation also suggests the presence of an unidentified substance creating osteopenia. [121] About 50% of PSC patients have osteopenia (i.e., a Z score of less than -1.0 by lumbar spine bone mineral densitometry), whereas osteoporosis (i.e., a Z score of less than -2.5) is less common than in PBC (10% versus 35%). [119], [120] As many as 50% of liver transplant recipients have bone mineral densities below the fracture threshold. [121] Reasons for this difference compared to PBC include a greater proportion of male patients with higher baseline bone mass and a slower rate of bone loss compared with women. Osteoporosis in PSC should be suspected among postmenopausal women and individuals with advanced age, a long duration of IBD, and the presence of advanced hepatic disease. [119], [120]

Ensuring adequate intake of calcium (1000 to 1200 mg/d) with weight-bearing activity is recommended as an initial treatment for all individuals. Measurement of serum vitamin D levels is also an essential part of the preventative management in PSC. The presence of vitamin D deficiency is variable among patients with metabolic bone disease. Oral replacement therapy is indicated if measured serum levels are reduced compared with local normal values. The 25-hydroxylation of vitamin D is intact among PSC patients; therefore, vitamin D can be used rather than 1,25-dihydroxyvitamin D or 25-hydroxyvitamin D. Dosing is generally between 25,000 and 50,000 IU two to three times per week. The efficacy of bisphosphonate (alendronate, etidronate) therapy in PSC remains unknown. No benefit from calcitonin was observed compared with placebo among PSC patients after liver transplantation. [121]

Steatorrhea

Impairment in bile acid delivery resulting in insufficient critical micellar concentrations in the small intestine is the most common cause of steatorrhea with advanced hepatic disease from PSC. [1] The coexistence of celiac disease with PSC has been reported in an increasing number of patients. [100], [101] Exocrine pancreatic insufficiency has also been observed as a cause of steatorrhea related to overall glandular dysfunction, which may be associated with chronic pancreatitis. [87], [89] Determining the exact cause is important because specific therapeutic options can be employed for symptom relief. In patients with decreased bile acid concentrations, the oral replacement of medium-chain triglycerides for long-chain compounds is usually of benefit. Adherence to a gluten-free diet and pancreatic enzyme replacement therapy are recommended for patients affected by celiac disease and pancreatic insufficiency, respectively.

Micronutrient Deficiency

Malabsorption of fat-soluble vitamins is common with advanced hepatic disease from PSC. Intrahepatic cholestasis and impaired bile acid delivery to the small intestine are putative causes. Vitamin A deficiency, observed in 20% to 50% of cases, is often clinically asymptomatic. When symptomatic, the presence of night blindness is observed and should be corrected by oral replacement therapy with 25,000 to 50,000 IU two to three times a week. As discussed previously, vitamin D deficiency can occur and is the next most common fat-soluble vitamin deficiency in 15% to 50% of cases. [118]

Vitamin E deficiency is a rare occurrence in PSC. When present, it may be associated with ataxia from neuropathic involvement of the posterior vertebral columns of the spinal cord. Oral replacement therapy with 400 IU daily is indicated in asymptomatic patients. [122]

Vitamin K deficiency is most commonly related to severe cholestasis, cholestyramine treatment for pruritus, or significant hepatic dysfunction from end-stage PSC. The initiation of water-soluble oral vitamin K, 5 mg daily, with repeat measurement of prothrombin time is effective in determining the extent of malabsorption. If correction of prothrombin time is encountered, daily oral doses between 5 mg and 10 mg per day should be initiated.

Biliary Calculi

Biliary calculi have been reported in up to 40% of patients with PSC. [1], [2], [56], [66] Cholelithiasis is common and often requires cholecystectomy when symptomatic biliary colic occurs in nonadvanced hepatic disease. [66] Choledocholithiasis is reported at frequencies of 5% to 15% and more commonly among symptomatic individuals with biliary strictures. Most calculi are pigmented in nature and involve both central and peripheral bile ducts. [123] Symptoms, including intractable abdominal pain or recurrent bacterial cholangitis, have been successfully treated by endoscopic [124], [125] or percutaneous [126] methods to provide biliary decompression and stone extraction. Biliary surgery, including stone extraction and bilioenteric anastomosis, [126], [127] may be required only in cases refractory to endoscopic and percutaneous approaches.

Dominant Stricture

Dominant strictures or stenoses occur in 15% to 20% of PSC patients. [128] Clinical manifestations include a sudden increase in serum alkaline phosphatase or bilirubin in the asymptomatic patient, progressive jaundice, and bacterial cholangitis. [1], [2], [56] Cholangiography is required to determine the nature and extent of existing strictures. [128] Balloon dilation of identified stenoses by endoscopic [124] or percutaneous [128] approaches often provides significant clinical improvement. For cases with incomplete response to balloon dilation alone, the use of endoscopic stents for 3 to 6 months to prevent recurrent stricture formation has been advocated. [129], [130] Reports of infectious complications, however, have raised questions about the efficacy of this approach. [131] Cytologic brushings with pinch biopsies of all dominant strictures is required to help exclude the presence of cholangiocarcinoma. [132]

Bacterial Cholangitis

Bacterial cholangitis in PSC is most commonly associated with a previous history of biliary tract surgery, [56] bile duct calculi, [123] or ductal obstruction from a dominant stricture. [128] Once suspected, empiric broad-spectrum intravenous antibiotic therapy should be initiated. Cholangiography (with ERCP if possible) should then be considered to exclude obstruction and provide biliary decompression. The use of prophylactic antibiotic therapy (oral fluoroquinolone, trimethoprim-sulfamethoxazole), especially in the setting of short-term biliary stent placement, may reduce the risk for recurrent cholangitis. Recurrent episodes of bacterial cholangitis in PSC can be an indication for liver transplantation. [56]

Cholangiocarcinoma

A measurable proportion of subjects with PSC will develop cholangiocarcinoma as a complication of disease. Prevalence rates appear to vary between 4% and 20% in most reported series. [3], [5], [6], [7], [8] and [9], [133] Between 30% and 45% of individuals with PSC are diagnosed with cholangiocarcinoma at the time of liver transplantation [134], [135], [136], [137], [138], [139], [140], [141] and [142] and autopsy. [3], [143], [144] PSC may be simultaneously present in 30% to 50% of cases of diagnosed cholangiocarcinoma. The anatomic distribution of cholangiocarcinoma in PSC primarily involves the hilum (75% of cases), intrahepatic ducts (16%), and gallbladder (8%). [145]

Risk factors for cholangiocarcinoma in PSC remain incompletely understood. No association with stage of hepatic disease in PSC is observed, with coexisting cirrhosis affecting only 20% of patients with cholangiocarcinoma. [145], [146] Advanced age and longer duration of IBD [144] have also been cited. Formal epidemiologic investigations (case-control) have been performed in two independent populations. [147], [148] Previous or current cigarette smoking has been suggested to be associated with cholangiocarcinoma in only one study. [148] The presence of colorectal dysplasia and carcinoma in patients with PSC and UC has been noted as a possible risk factor for cholangiocarcinoma. [143]

The presence of oncogenic mutations, inactivation of tumor suppressor genes, and apoptosis have been postulated as mechanisms for developing cholangiocarcinoma in PSC. K- *ras* mutations found in the biliary secretions of PSC patients have been associated with cholangiocarcinoma, [149], [150] yet this remains a nonspecific finding. Aberrations of the *p53* tumor suppressor gene occur in 30% to 80% of PSC cases complicated by cholangiocarcinoma [151] but are often seen as a late finding. Chromosomal loss of 9p21 and *p16* tumor suppressor gene inactivation have also been reported. [152] The recognition of biliary dysplasia as a precursor to cholangiocarcinoma has been inconsistently suggested. [153], [154]

The diagnosis of cholangiocarcinoma in PSC remains challenging despite recent technological advances. Using the Mayo PSC model among 48 subjects undergoing liver transplantation, the incidence of biliary tract malignancy was significantly associated with model risk scores higher than 4.4 independent of clinical status. [155] Subsequent investigations to confirm this observation have not been performed. Marked bile duct dilation in association with a polypoid structure larger than 1 cm on cholangiography has been reported in association with cholangiocarcinoma. The distinction between benign and malignant biliary strictures with less prominent findings, however, remains difficult. Comparisons between ultrasound, CT, and MRI have also demonstrated inadequate ability to distinguish between PSC patients with and without cholangiocarcinoma. [156] Emerging techniques such as positron emission testing, which show initial promise, require further examination. [157]

Serum tumor markers, including carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA), have been employed for the early detection and diagnosis of cholangiocarcinoma. CA 19-9 levels higher than 100 U were found to have a sensitivity of 89% and specificity of 86% for detecting cholangiocarcinoma in PSC. [158] The combination of both markers (CA 19-9 + CEA × 40) exceeding values of 400 U was reported to have an 86% diagnostic accuracy despite a sensitivity of 67%. [159] Similar results using this formula were reported in an independent study. [160] The prospective evaluation of four tumor markers (CA 19-9, CEA, CA 50, and CA 242) among 75 patients failed to achieve high test performance characteristics for predicting cholangiocarcinoma. [146] Serum CA 19-9 levels of more than 100 U/mL for detecting cholangiocarcinoma among PSC patients have recently been noted with further limitations in diagnostic sensitivity (52%) and specificity (76%). [161]

The performance of endoscopic biopsy and cytologic brushing for the diagnosis of cholangiocarcinoma is noted for good specificity but poor sensitivity. [132], [162] Among 47 patients with dominant strictures identified at ERCP, a 60% sensitivity and 89% specificity using biopsy and brushings was observed. [132] False positivity with cellular atypia from chronic inflammation may also occur. [162] DNA aneuploidy detection by flow cytometry has been reported in 80% of individuals with cholangiocarcinoma versus 12% with benign strictures. [163]

Therapeutic options for cholangiocarcinoma in the setting of PSC are limited. For extrahepatic biliary resection in PSC, operative complication and morality rates exceed 30% and 6%, respectively, in the absence of bile duct cancer. [164] Highly selected patients, however, may derive benefits from surgical resection. [165] Curative attempts with liver transplantation to date have resulted in poor outcomes from residual tumor at surgical margins and local hepatic lymph node involvement. [136], [139], [141], [142] However, the presence of cholangiocarcinoma in situ (tumor smaller than 1 cm) found incidentally at liver transplantation has been associated with long-term survival rates similar to those of patients with PSC alone. [138], [166] To improve outcomes after liver transplantation, the implementation of preoperative radiation and chemotherapy in highly selected patients with unresectable cholangiocarcinoma and PSC has yielded a short-term (less than 5-year) survival of greater than 80% at the Mayo Clinic. [167]

Portal Hypertension

The development of biliary cirrhosis from progressive PSC can result in the typical complications of portal hypertension associated with other chronic liver diseases. These include ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, esophagogastric variceal bleeding, portal hypertensive gastropathy, hepatorenal syndrome, and hepatopulmonary syndrome. A unique complication is peristomal variceal bleeding, which occurs among patients with IBD who have undergone proctocolectomy with ileostomy formation. [168] Newer surgical techniques, including ileal pouch–anal anastomosis at the time of proctocolectomy, are indicated among patients with identified PSC to prevent this complication. [169] Pharmacological (ß-blocker) and endoscopic (sclerotherapy) therapies are without long-term efficacy. [168] Transjugular intrahepatic portosystemic shunt placement has been shown to be effective in treating uncontrolled bleeding and preventing further episodes. [170]

Colonic Dysplasia and Carcinoma

The association between an increased risk for colonic dysplasia or carcinoma and PSC in the setting of UC has gained interest in recent times and remains controversial. Decreased bile acid secretion and increases in secondary bile acid exposure to colonic mucosa are considered potential mechanisms. [171] In addition, a greater proportion of right-sided colon neoplasia has been observed in UC patients with PSC versus UC alone. [172], [173] and [174] Absolute cumulative risks for colorectal dysplasia and carcinoma of 5% (at 10 years), 31% (20 years), and 50% (25 years) have been observed in patients with PSC and UC, compared with 2%, 5%, and 10% risks for UC alone, respectively. [143] Other studies, however, have failed to confirm a significant risk from PSC for colonic dysplasia and carcinoma. [175], [176] Given the potential association between bile acid exposure and colorectal neoplasia, the use of UDCA was strongly associated with a decreased risk for colonic dysplasia among 59 PSC patients undergoing colonoscopic surveillance for UC. This association remained after adjustment for duration and severity of PSC. A younger age at IBD onset, however, was also associated with an increased dysplasia risk. [177] Confirmation of findings in a controlled trial setting is warranted. Annual surveillance colonoscopy with biopsy is recommended in patients with PSC and UC, especially after liver transplantation among patients with UC in the absence of

proctocolectomy. [135], [178], [179] and [180]

DISEASE-MODIFYING THERAPIES

Liver transplantation is the only effective treatment for end-stage hepatic disease resulting from PSC. Because of the variable nature of disease progression, the development of randomized clinical trials for assessment of therapies has been difficult. As a result, there is no effective medical therapy identified for the treatment of PSC (Table 101-4).

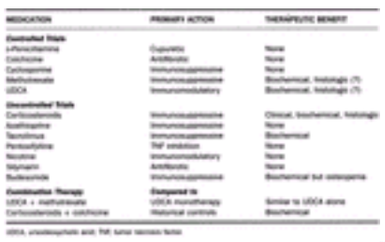

TABLE 101-4 Medical Therapies Evaluated in Primary Sclerosing Cholangitis

Medical Therapy

D-Penicillamine An increase in hepatic copper found among patients with chronic cholestatic liver disease including PSC provided the rationale for examining D-penicillamine. Among 70 patients randomized to active drug or placebo, there was no reported benefit in terms of biochemical improvement, histological stabilization, or survival free of liver transplantation after 3 years of follow-up. Major toxicities, including renal disease, resulted in drug discontinuation among 20% of subjects. [181]

Colchicine A randomized controlled trial of 84 subjects with PSC (44 given colchicine 1 g/d, 40 placebo) revealed no differences in biochemical, histological, or survival between groups after 36 months of follow-up. [182] Combination therapy with prednisolone and colchicine has been associated only with initial biochemical improvement after 24 months of treatment. [183]

Corticosteroids The report of beneficial results from corticosteroid use has only been demonstrated in uncontrolled trials. Patients with early-stage histological disease may have symptomatic and biochemical improvement. [184] The use of oral budesonide, a systemic corticosteroid with significant first-pass hepatic metabolism and reduced toxicity, in 21 PSC patients was associated with improved hepatic biochemistries alone at the expense of worsening osteopenia in a pilot investigation. [185] The use of prednisone or budesonide in combination with UDCA was not associated with significant clinical or biochemical improvement in a double-blinded, randomized controlled trial. [186] A combination of prednisone, azathioprine, and UDCA in 15 patients was noted for significant biochemical and histological improvement. These results were also observed among individuals with partial biochemical responses to UDCA. [187] Case reports detailing beneficial effects from topical corticosteroid therapy by endoscopic delivery through a nasobiliary drain were complicated by an increased rate of bacterial cholangitis. [188], [189]

Azathioprine No randomized controlled trial for azathioprine monotherapy has been reported to date. Open-label pilot studies are noted for mixed results using biochemical parameter responses. [190], [191]

Cyclosporine A single randomized controlled trial of cyclosporine among 34 patients [192] was noted for the absence of significant symptomatic, biochemical, or histological improvement. Toxicity from cyclosporine, including hypertension and renal insufficiency, was minimal.

Methotrexate Data from a double-blind, randomized controlled trial comparing oral pulse methotrexate (15 mg/wk) with placebo among 24 patients [193] is noted only for reductions in serum alkaline phosphatase. No improvements in total bilirubin, histology, or survival were observed. Early-stage histological disease was associated with possible symptom and biochemical improvement. [194] Combination therapy with methotrexate and UDCA in 19 patients was associated with toxicity (from methotrexate) without biochemical improvement when compared to UDCA alone in 9 patients. [195]

Ursodeoxycholic Acid The mechanism of action attributed to UDCA in the treatment of chronic cholestatic liver disease is multifaceted. In addition to suppressing cytotoxic endogenous bile acid secretion, [196] there is evidence to suggest that UDCA is associated with membrane stabilization [197] and reduced aberrant HLA type I expression on hepatocytes. [198] Improved mitochondrial dysfunction induced by hydrophobic bile acids, decreased cytokine production, and inhibition of apoptosis have also been recently identified in association with UDCA. [199] Early investigations suggested a beneficial effect from UDCA on PSC. [200], [201] Three randomized, controlled trials comparing UDCA with placebo, however, did not show significant improvements in histology or survival despite biochemical parameter response. [202], [203] and [204] Two recent investigations of high-dose UDCA (25 to 30 mg/kg/d) reported improvements in biochemical, [205], [206] cholangiographic, and histological parameters [206] when compared with standard doses. Results from placebo-controlled studies examining high-dose UDCA in PSC are awaited.

Novel Therapies Pilot investigations of oral nicotine [207] and pirfenidone [208] have failed to demonstrate improvements in serum hepatic biochemistries or Mayo PSC risk score. Despite properties of anti-TNF attenuation, the use of oral pentoxifylline was not associated with clinical or biochemical improvement among 20 patients with PSC. [209] No investigation of parenteral anti-TNF antibody use in PSC has been reported to date. Tacrolimus (FK506), a calcineurin-based inhibitor with pharmacological properties similar to cyclosporine, has been associated with significant improvements in biochemical profiles among all 10 subjects in an open-label pilot trial. Mean serum aminotransferase levels among these patients, however, were up to 5-fold greater than normal values, which is not seen in patients with typical PSC. No effect on histology based on limited follow-up was also observed. [210] The nucleoside analog cladribine usually was associated with progression of histological fibrosis despite improvements in periportal inflammation among four PSC patients after 24 months of follow-up. [211]

Endoscopic Therapy

Endoscopic therapy in PSC has been successful in alleviating cholestasis aggravated by mechanical biliary obstruction. Controversy remains, however, regarding the safety and efficacy of ERCP based on the limited numbers of patients reported and variety of endoscopic methods used. Among PSC patients undergoing diagnostic ERCP, a 2% complication rate has been reported compared with 14% among patients with jaundice or cholangitis. [212] With advances in technology and endoscopic development, a number of options for therapeutic intervention are possible, including endoscopic sphincterotomy, hydrostatic balloon dilation, nasobiliary tube (NBT) drainage, and biliary stent placement. The current use of endoscopic dilation with sphincterotomy or stenting is associated with clinical response rates from 70% to 90%. [125], [213]

Among 53 patients requiring ERCP for the evaluation of biliary obstruction, [124] a technical success rate of 88% was observed with 15 subjects (28%) experiencing procedure-related complications. Twenty-eight patients (56%) reported symptomatic improvement after ERCP for a median of 31 months. No change in cholangiographic findings, however, was seen in more than 50% of cases. In the largest series reported to date of 106 PSC patients, [214] dominant stenoses were observed in 43 instances over a median follow-up of 5 years. Most of these stenoses were treated using balloon dilation. Complications included pancreatitis (5.2%), cholangitis (3.3%), and bile duct perforation (0.5%). Survival after balloon dilation of the first recognized stenosis was significantly better when compared with predicted survival using the Mayo multicenter prognostic model.

NBT placement for drainage and saline irrigation has been employed to prevent recurrent biliary obstruction. [188], [189] Among 12 asymptomatic patients with high-grade strictures treated initially by hydrostatic balloon dilation followed by NBT irrigation, [215] an improvement in clinical, biochemical, and cholangiographic features was documented in 75% of cases over 23 months. One patient had no change in clinical status from unresponsive disease. Progressive disease in 3 subjects required treatment by liver transplantation. Further use of NBT irrigation among symptomatic patients has not been reported.

A retrospective examination of 25 symptomatic patients treated by biliary stent placement is noted for an endoscopic success rate of 84%. [129] Clinical and biochemical improvement in all cases was noted after 6 months. Additional procedures for stent exchange was associated with a complication rate of 14% over a 29-month period. During follow-up, only 12 patients (57%) remained asymptomatic with normal hepatic biochemistries. The use of short-term stenting (mean, 11 days) of dominant strictures among 32 patients has been associated with an 83% improvement rate from symptomatic cholestasis (fatigue, pruritus) and biochemical improvement over 4 years. [130] Reintervention rates at 1 year (80%) and 3 years (60%) were observed. A recent investigation advocating the use of aggressive stricture dilation, stenting, or

both, combined with UDCA therapy, in PSC was based on results in an uncontrolled trial setting. [216]

Biliary Reconstructive Surgery

Among pre-cirrhotic patients with extrahepatic biliary strictures refractory to endoscopic and percutaneous therapy, the use of intraoperative resection has been performed successfully. [164], [217], [218] and [219] Common sites of involvement in this setting include the common bile duct (CBD) and perihilar regions. Early reports involving 17 of 22 patients undergoing choledochoenteric anastomosis noted good to excellent results in 13 cases (76%). [217] Transhepatic stenting was employed in 6 cases. An overall survival rate of 82% at 52 months after surgery was observed. Among 31 patients undergoing extrahepatic bile duct resection and long-term stenting, [218], [219] excellent results among 26 pre-cirrhotic individuals were reported. A 20% survival rate over 5 years, however, was noted in patients with cirrhosis.

Comparisons between operative and nonoperative therapies have been reported involving 104 patients treated surgically (n = 54) or using endoscopic balloon dilation (n = 35) and percutaneous stenting (n = 19). [164] In this retrospective investigation, no differences in procedure-related morbidity and mortality were recorded. Improvements in serum bilirubin up to 3 years after resection were significantly better compared with nonoperative therapies. Among 40 patients with cirrhosis at surgical resection, an overall 5-year survival rate of 85% (including liver transplantation in 21 patients) was noted. Transplant-free survival, however, was 78% at 5 years among subjects without decompensated cirrhosis undergoing resection. A 59% overall and 46% transplant-free 5-year survival rate, respectively, was observed among medically treated individuals. Cholangiocarcinoma in 9% of medically treated patients was reported, in contrast to no cases among surgical patients.

Concerns regarding operative bile duct resection complicating the performance of liver transplantation have been raised. [134], [136], [139], [140], [141] and [142] The association between prior bile duct surgery and poor outcomes, including decreased survival, however, has not been conclusively determined. [135], [138] Among select individuals with PSC, a history of prior surgery has been associated with longer operative procedure times, [134], [135], [164] greater intraoperative blood loss, [134], [135] and [136] and increased risks for biliary complications after transplantation. [134], [135], [137]

Liver Transplantation

Among patients with end-stage liver disease from PSC, the current treatment of choice is liver transplantation. PSC is the fourth most common indication for liver transplantation in the United States, accounting for nearly 10% of all procedures. Indications for liver transplantation are similar to other hepatic diseases, including complications from portal hypertension (ascites, variceal bleeding, encephalopathy). Significant impairments in health-related quality of life from fatigue, pruritus, and painful osseous fractures may also be considerations for liver transplantation. Unusual circumstances prompting liver transplantation referral in PSC include recurrent cholangitis despite medical therapy, severe extrahepatic biliary obstruction among individuals with advanced hepatic disease precluding operative repair, and uncontrolled peristomal variceal bleeding. Reports from single centers performing liver transplantation for PSC are noted for patient survival rates of 90% to 97% at 1 year and 83% to 88% at 5 years (Table 101-5). Improvements in operative technique and immunosuppression management have greatly contributed to improvements in patient survival. Long-term graft survival, however, has been affected by a higher incidence of rejection (acute cellular and chronic ductopenic) and hepatic artery thrombosis. [220]

TABLE 101-5 Patient Survival after Liver Transplantation for Primary Sclerosing Cholangitis

Among patients with coexistent UC undergoing liver transplantation, it has been recognized that gastrointestinal symptoms may improve with the initiation of immunosuppressive therapy. Exacerbations of UC, however, are reported in up to 30% to 50% of patients, with some individuals requiring proctocolectomy for disease control. [221], [222] and [223] An increased prevalence of pouchitis among PSC patients after liver transplantation compared with UC patients who undergo transplantation for other hepatic disease states has also been reported. [224] Patients with intact colons appear to be at increased risk for colorectal neoplasia after liver transplantation. [135], [178], [179] and [180], [225] Among 198 post–liver transplantation patients with IBD, [225] a 7% prevalence rate for colorectal cancer was observed in most cases diagnosed within 30 months of liver transplantation. Duration of IBD greater than 9 years was noted in 93% of cases in this series. The cumulative risk for colorectal cancer among individuals transplanted for PSC at the Mayo Clinic [178] was calculated at 1% per year. The cumulative incidence for colonic dysplasia, however, was increased to 15% at 5 years and 21% at 8 years.

An increasing body of evidence suggests that PSC is a recurrent disease after liver transplantation in select patients. [225], [226], [227] and [228] Quantifying the prevalence rate for recurrent PSC, however, has been limited by the absence of uniform diagnostic criteria that exclude known causes of biliary tract dysfunction including ABO incompatibility, chronic ductopenic rejection, early and late hepatic artery thrombosis, and prolonged cold ischemic time. Among 120 PSC patients undergoing liver transplantation at the Mayo Clinic, [228] 24 (20%) developed evidence of recurrent PSC using strict criteria. Cholangiography was diagnostic for recurrent PSC in 92% of cases, whereas 46% of liver biopsy results were compatible with recurrence. An independent study found prevalence rates of recurrent disease closer to 10%. [225] The identification of sustained elevations in serum alkaline phosphatase levels (more than two times the upper limit of normal) beyond 2 years from liver transplantation appears associated with an increased risk for disease recurrence. [228]

NATURAL HISTORY AND PROGNOSIS

Most published investigations to date support the contention that PSC is a progressive disease which can ultimately lead to liver failure or death. A median survival of 9 to 12 years in the absence of liver transplantation appears independent of geographic and environmental influences [3], [4], [5] and [6], [9], [10] Subsets of patients with PSC, however, appear to follow different patterns of disease progression. Because of this significant variation in natural history, the use of mathematical prognostic models has allowed for improvements in estimating risks for disease progression and PSC-related survival independent of liver transplantation.

Subject age, serum total bilirubin, hemoglobin, a history of IBD, and histological stage on liver biopsy were observed as independent predictors of death among PSC patients at the Mayo Clinic. [5] A similar prognostic index including subject age, hepatomegaly, splenomegaly, elevated serum alkaline phosphatase, and advanced histological stage has also been reported. [6] To address variations among independent populations, a multicenter prognostic model was developed using 426 patients from five centers. [229] Subject age, serum bilirubin, splenomegaly, and histological stage emerged as independent predictors of death in PSC. More recently, a revised version of the original Mayo PSC model has eliminated histological stage in favor of variceal bleeding history, avoiding the need for invasive liver biopsy in estimating prognosis. [230]

Examination of the Child-Turcotte-Pugh (CTP) classification as a prognostic model in PSC has yielded mixed results. [231], [232] Significant differences in 7-year survival have been demonstrated among CTP class A (89.8%), class B (68%), and class C (24.9%) patients with PSC. [231] Subject age and CTP classification were independent predictors of mortality. A subsequent investigation of 147 patients, [232] however, was noted for limitations in predicting survival among CTP class B and C patients. CTP classification was not observed as an independent predictor of death in this cohort, in contrast to the Mayo PSC risk score.

Attempts at defining the optimal timing for liver transplantation in PSC have examined the application of existing prognostic models. Among 216 PSC patients who underwent liver transplantation between 1981 and 1990, [139] a dramatic survival benefit was observed compared with predicted survival using the Mayo PSC model (73% versus 28% at 5 years; $p < 0.001$). Long-term survival between subjects grouped by risk score, however, was similar. The occurrence of cholangiocarcinoma was associated with a significant decline in survival independent of pretransplantation Mayo risk score. The presence of ascites, previous upper abdominal surgery, elevated serum creatinine, IBD, and history of biliary tree malignancy have been described as predictors of reduced posttransplantation survival as well. [233]

Additional investigations surrounding outcomes after liver transplantation in PSC have focused on health-related quality of life and resource use. [234], [235] and [236] Among

436 patients with cholestatic liver disease including PSC (n = 208), the independent predictors of postoperative morbidity were subject age, renal failure (defined as serum creatinine higher than 2 mg/dL), Child-Pugh classification, and United Network of Organ Sharing status. [234] Increased resource use based on hospital charges has been associated with a Karnofsky score of less than 40, poor nutritional status, and renal failure. [235] A subsequent multicenter investigation, however, demonstrated that the CTP classification is a significantly better predictor of clinical and economic outcomes than the Mayo risk score. [236]

VARIANT SYNDROMES

Small Duct Primary Sclerosing Cholangitis

A subset of patients with typical features of PSC may have normal-appearing intrahepatic and extrahepatic bile ducts by cholangiography. [237], [238] The diagnosis of small duct PSC is based on (1) serum biochemical profile consistent with cholestatic liver disease; (2) the presence of IBD; (3) normal cholangiogram; and (4) appropriate findings on liver histology. Characteristic features described by liver histology assessment include mild portal mononuclear inflammation, ductular proliferation, and nonsuppurative fibrous obliterative cholangitis. [238] Fibrous-obliterative cholangitis, although considered pathognomic for PSC, occurs in only 10% to 40% of cases. [70] Granulomatous cholangitis (more commonly seen in primary biliary cirrhosis) is seen in 8% of cases. [1] Disease progression is characterized by periportal fibrosis, ductopenia, and eventual biliary cirrhosis. [70] Previously described as part of *pericholangitis*, the prevalence of small duct PSC is estimated between 15% and 35% among adults with UC. [237], [238] As many as 33% of patients with eventual large duct PSC are identified with normal cholangiograms during the course of disease despite histological evidence for PSC. Isolated small duct involvement at diagnosis with eventual recognition of large duct PSC occurs in 40% of cases. [237] Although uncommon, the progression to end-stage liver disease requiring hepatic transplantation has been associated with small duct PSC. [139] Specific reference to small duct PSC in terms of medical therapy has not been widespread given its rare occurrence. The natural history of small duct PSC appears to reflect outcomes related to large duct PSC. [237], [238] Cholangiocarcinoma has been rarely observed among patients with small duct PSC. [239]

Autoimmune Hepatitis–Primary Sclerosing Cholangitis Overlap Syndrome

Patients with PSC and clinical features reminiscent of AIH are classified as having an *overlap syndrome* between the two conditions. [240], [241], [242] and [243] Greater than expected serum aminotransferase elevations (5 to 10 times) and increased titers of serum autoantibodies, including ANA, ASMA, and pANCA, are observed in most cases. [241], [242] and [243] The presence of typical biliary stricturing and dilation seen with PSC is often accompanied by increased lymphoplasmacytic portal or periportal infiltrates on liver biopsy consistent with AIH. In PSC, the presence of overlap with AIH was previously thought to range between 35% and 54% using the original International Autoimmune Hepatitis Group (IAHG) scoring system criteria. [240] Using the revised IAHG scoring system, a decrease in prevalence of AIH-PSC overlap between 1.4% and 11% has been reported. [241], [242] In contrast, van Buuren and colleagues observed similar prevalence rates of AIH-PSC overlap based on either conventional diagnostic criteria (23%) or the revised IAHG scoring system (19.5%). [243] Empiric immunosuppressive therapy for potential benefit among patients with AIH-PSC overlap has been recommended. [240]

Idiopathic Adulthood Ductopenia

Idiopathic adulthood ductopenia (IAD) is a syndrome described by the presence of (1) biochemical parameters consistent with cholestasis; (2) histological evidence of ductopenia involving more than 50% of bile ducts; (3) no evidence for the diagnoses of PSC and IBD; and (4) the exclusion of other known etiologies for cholestasis, including PBC and drug-induced hepatotoxicity. [244] Variation in extent of bile duct loss likely reflects a spectrum in natural history. [238] Other diagnostic possibilities include an unidentified chronic viral cholangitis, small duct PSC in the absence of IBD after colonoscopic investigation, or advanced AMA-negative PBC with resulting ductopenia. [244]

Among 29 reported cases of IAD, [238], [244] a median age of 27 years (range, 15 to 67 years) at diagnosis is observed. Male-to-female gender distribution is estimated at 2:1. Jaundice and pruritus are seen at initial presentation in 33% of cases. Disease progression reported among 10 patients occurred over a median duration of 4 years (range, 5 months to 15 years). Seven of 23 (30%) patients with follow-up greater than 6.5 years died from liver disease, whereas 4 patients required liver transplantation. Corticosteroid or UDCA therapy was associated with clinical improvement in 3 of 4 cases. Among subjects with features similar to IAD despite less than 50% bile duct loss, [245] a benign course in 3 of 24 individuals using sequential liver biopsies over 12 years was reported. Four of 5 patients treated with UDCA had normalization of serum liver biochemical parameters.

ACQUIRED IMMUNODEFICIENCY SYNDROME CHOLANGIOPATHY

Epidemiology

Biliary tract disease in AIDS (AIDS cholangiopathy) was first described soon after the identification of the human immunodeficiency virus (HIV). [246] AIDS cholangiopathy describes a syndrome that resembles sclerosing cholangitis associated with papillary stenosis. [247], [248] Pathogens involved with the development of AIDS cholangiopathy do not appear to affect patients who are immunocompromised for other reasons. The mean age of affected patients is reported at 36.5 years, with a preexisting diagnosis of AIDS for 1 to 2 years before symptomatic biliary tract involvement. [248], [249] CD4 T-cell counts of less than 50/mm ^{3} have also been associated with the risk for AIDS cholangiopathy and significant mortality within 1 year of infection. [249]

Pathogenesis

Infection of the biliary or duodenal epithelium is the primary cause of ductal abnormalities in AIDS cholangiopathy. Among pathogens identified, *Cryptosporidium* species are the most common identifiable etiology and often found without coexistent infection. [247], [248], [250], [251] Among 82 HIV-infected patients exposed to cryptosporidia in a water-borne outbreak, [250] the development of abdominal pain associated with biliary tract disease occurred in 29% of cases and was confirmed by cholangiography in 40%. Simultaneous bouts of new onset diarrhea from cryptosporidia were also reported. If undetected by blood or stool cultures, the next most common organisms are *Microsporidia* species. [252], [253] Other recognized infections include cytomegalovirus (CMV), [254] *Enterocytozoon bieneusi*, [255] *Septata intestinalis*, [256], [257] *Mycobacterium avium–intracellulare*, [258] *Isospora belli*, [259] and possibly HIV infection itself. [258] Hepatic CMV inclusions have been observed in 5% to 44% of patients at autopsy. Among AIDS patients with CMV and cholestatic liver disease, as many as one third have bile duct abnormalities. [254] Ultimately, as many as 50% of patients with AIDS cholangiopathy have no identifiable opportunistic infection. [248], [252], [254], [256] Malignancies such as lymphoma [260] and Kaposi sarcoma [260] have been associated with cholangitis but rarely present as a cholangiopathy. Histological findings in AIDS cholangiopathy observed on bile duct and liver biopsy include moderate to severe inflammation and fibrosis. [261]

Clinical Manifestations

The most common presentation is epigastric or right upper quadrant abdominal pain (64% to 88%) with fever (20% to 65%). Jaundice, however, is distinctly uncommon. Diarrhea is also present in most cases related to small intestinal involvement with the characteristic pathogens. Superimposed bacterial cholangitis is a rare complication. [248], [249], [262] Serum liver biochemistries are noted for elevations in alkaline phosphatase greater than three to five times the upper limit of normal in more than 75% of cases. Milder increases in serum transaminases (less than threefold) are also noted. Normal biochemical parameters have also been observed in 20% of instances with cholangiographic abnormalities. [248], [249], [252], [263] Ultrasonography or CT imaging can detect biliary duct dilatation (intrahepatic or extrahepatic) in most instances. [264], [265] Cholangiography is required for the diagnosis of AIDS cholangiopathy. Left-sided biliary duct system involvement is observed with an increase in intrahepatic duct involvement with saccular dilatations, debris, and pruning. Irregular stricturing of the entire CBD with wall thickening in the absence of dilation is common. [248], [262], [265] The most common characteristic biliary tree manifestation is papillary stenosis with intrahepatic sclerosing cholangitis in 50% of cases. Other variations include intrahepatic and extrahepatic sclerosing cholangitis without papillary stenosis, papillary stenosis alone, intrahepatic sclerosing cholangitis alone, or long (more than 1 cm) extrahepatic strictures. [248], [267], [268] Among individuals with severe pain and associated cholangitis, the identification of papillary stenosis is nearly universal. [248], [263], [269] The presence of isolated CBD strictures should raise the suspicion for primary lymphoma [260] or pancreatic disease. [262]

Differential Diagnosis

The differential diagnosis includes choledocholithiasis, acalculous cholecystitis, periampullary tumors including pancreatic and bile duct cancer, and PSC. Choledocholithiasis will also produce intrahepatic duct dilation above the level of obstruction where biliary duct dilation is distinctly uncommon in AIDS cholangiopathy. The presence of elongated stricturing with intrahepatic and peripheral bile duct dilation is more often observed with periampullary carcinoma but can resemble findings when papillary stenosis alone is present. Direct visualization and biopsy of the ampulla is required to exclude carcinoma. Global duct narrowing, diffuse stricturing, and intrahepatic stone formation characterize PSC. The finding of concomitant IBD also suggests PSC, even in subjects with AIDS.

Treatment

Treatment is directed at identified pathogens as well as biliary tree abnormalities. Antimicrobial therapy against *Cryptosporidia* species with trimethoprim-sulfamethoxazole is indicated, especially among patients with coexistent diarrheal symptoms. [251] Effective treatment against *Microsporidia* species remains elusive. [253] Ganciclovir for CMV [254], [267] and multidrug regimens against *M avium–intracellulare* [258] should also be provided. Albendazole for *S intestinalis* infection has been shown to result in symptom improvement when present. [256] Successful therapy for malignancy-related cholangiopathy with reversal of biliary tract abnormalities has been reported with B-cell non-Hodgkin lymphoma in anecdotal instances. [260] There is no indication for prophylactic treatment in patients unaffected by AIDS cholangiopathy.

Symptomatic patients with a high degree of suspicion for biliary tract disease require cholangiography by ERCP. [247], [248], [262] For patients with papillary stenosis alone, endoscopic sphincterotomy has been associated with improvement in abdominal symptoms. [249], [267], [269] Often, there is little to no change in serum hepatic biochemical parameters in most cases. [262] A continued rise in serum alkaline phosphatase levels, however, suggests the presence of intrahepatic duct involvement as well. [248], [262] The performance of balloon dilation or stent placement in cases of papillary stenosis is without dramatic benefit over sphincterotomy. [262] UDCA therapy for symptomatic disease is not highly efficacious. [270] A diagnosis of acalculous cholecystitis requires cholecystectomy. [271]

POSTTRANSPLANTATION CHOLANGIOPATHIES

Bone Marrow Transplantation

Epidemiology The most frequent etiologies of cholangiopathy within the first 80 days of bone marrow transplantation (BMT) include acute graft-versus-host disease (GVHD), cholangitis lenta, and drug-induced cholestasis. [272], [273] Chronic GVHD is the most common cause beyond 80 days. [273] Risk factors for developing cholestatic-mediated injury after BMT have been identified. The use of conditioning therapies before BMT, including combinations of irradiation and immunosuppressive agents, has most often been associated with hepatic venoocclusive disease (VOD). [274], [275] and [276] Allogeneic donor stem cell recipients are considered to be at increased risk for acute and chronic GVHD. [273] Related sibling donors with identical HLA typing impart the lowest risk for acute or chronic GVHD among all donor source types. [277] The use of immunosuppressive agents for acute GVHD prophylaxis is also associated with an increased risk for cholestatic injury. [272], [278] Antimicrobial prophylaxis against viral and fungal infections in the post-BMT period, [272], [279] although reducing the risk for hepatobiliary infections, may also contribute associated toxicities resulting in liver injury.

Pathogenesis A number of pathophysiologic mechanisms have been implicated in BMT-related cholangiopathies. In cholangitis lenta, the release of bacterial cell wall components, [280] as well as proinflammatory cytokines including IL-1, IL-6, and TNF-a, results in bile flow impairment. [281] Biliary epithelial cells, zone 1 hepatocytes, and periductular glands have been recognized as intrahepatic targets for donor-derived lymphoid cells in acute GVHD. [282] Cell death mediated by apoptosis has also been observed, yet exact mechanisms for this process after BMT are not well understood. [283] Abnormalities in cellular and humoral immunity have been implicated in chronic GVHD. [272] Impaired bile salt and bilirubin transport is associated with hepatotoxicity from cyclosporine. [284] Bile canaliculi injury, hepatocyte necrosis, and elevated serum hepatic biochemistries are observed with supratherapeutic blood levels of cyclosporine. [272], [285] Intrahepatic thromboses of terminal venules and central veins are observed in conjunction with clinical manifestations of VOD. [274]

Clinical Manifestations Acute GVHD occurs exclusively among recipients of allogenic bone marrow and stem cell infusions. The development of a skin rash, evidence for gastrointestinal dysfunction (including nausea and diarrhea), and elevated serum hepatic enzymes are typical manifestations. Hepatic GVHD may also occur independently of skin and the gut manifestations but is uncommon. Average time to onset is about 15 to 21 days after BMT. A delay in time to onset for acute GVHD has been reported with the use of immunosuppressive prophylaxis and non-HLA mismatched grafts. Increases in serum aminotransferase and alkaline phosphatase levels (2- to 10-fold each) with hyperbilirubinemia are characteristic. Decompensated liver disease (ascites, coagulopathy) is uncommon in the early stages of acute GVHD. A rapid increase in hyperbilirubinemia may suggest concomitant sepsis, cholangitis lenta, or VOD. [272] Liver biopsy is often required in this setting for diagnosis. Histological findings of acute GVHD include bile duct epithelial cell necrosis and apoptosis, mild to moderate hepatocyte necrosis, and cholestasis. Ductopenia has been reported in severe cases. [286] The probability of developing chronic GVHD from acute GVHD is estimated at 50% or higher. Progressive hepatic GVHD has been reported as an independent predictor of mortality after BMT. Clinical evidence of portal hypertension is often noted in the absence of histological cirrhosis. [272] Cholangitis lenta is associated with fever and mild hyperbilirubinemia in the early posttransplantation phase and the use of immunosuppressive treatment for acute GVHD. The time interval for developing a preceding infection may be days to weeks. Elevations in serum alkaline phosphatase may be observed, but isolated hyperbilirubinemia is the most common biochemical finding. Total bilirubin levels can reach values as high as 15 mg/dL, and yet hepatic synthetic function is generally intact. Liver histology is noted for cholestasis within pericentral canaliculi and periportal areas in the absence of significant portal inflammation from immunosuppression. [272], [280] Drug-induced cholestasis can occur by idiosyncratic (cyclosporine) [287] or dose-dependent (methotrexate) [272] mechanisms. Among 38 patients receiving cyclosporine at 3 mg/kg/d, [288] an increase in serum bilirubin levels was reported compared with patients given 1.5 mg/kg/d despite therapeutic serum trough levels (less than 400 ng/mL). In doses up to 20 mg/kg/d, most patients treated for acute leukemia developed jaundice and hyperbilirubinemia, which resolved after drug cessation in 2 to 5 days. [289] Azathioprine [290] and fluconazole [291] may be associated with hepatocyte necrosis yet more commonly result in asymptomatic serum aminotransferase elevations. Antibiotics, including amoxicillin–clavulanic acid, [292] flucloxacillin, [293] and trimethoprim-sulfamethoxazole, [294] have been reported in association with cholestatic hepatitis and chronic liver disease in rare instances. Ceftriaxone has been implicated in the pathogenesis of cholelithiasis. [295] Cholestasis is also observed after chronic total parenteral nutrition (TPN). Elevated serum liver biochemistries, including total bilirubin, serum aminotransferases, and alkaline phosphatase, can be attributed to TPN. The association between prolonged TPN and liver failure, however, remains quite rare. Reversal of liver biochemical abnormalities often occurs after TPN discontinuation and resumption of oral intake. Other associated complications in the presence or absence of chronic TPN administration include biliary sludge, cholelithiasis, and acalculous cholecystitis. [296] Chronic GVHD of the liver has been associated with the rapid onset of bile duct destruction and subacute development of intrahepatic cholestasis. It may occur de novo or result from prior acute GVHD. The estimated time to onset after BMT ranges between 40 and 50 days. Hepatic involvement occurs in up to 80% of cases. Biochemical features typically include progressive elevations in serum alkaline phosphatase (as high as 15 times normal) and hyperbilirubinemia. Rapid-onset chronic GVHD may present with elevated serum aminotransferases during tapering of immunosuppressive medications. [272], [273] Histological features on liver biopsy include ductopenia, lymphoplasmacytic portal inflammation, periportal fibrosis, and cholestasis. In select cases, a paucity of bile ducts may be observed (vanishing bile duct syndrome). [272], [286] The development of jaundice, hepatomegaly, and weight gain over 5% of ideal body weight is consistent with the diagnosis of VOD. The average time of onset after BMT is between 15 and 30 days. Persistent jaundice after an episode of acute GVHD can also be from VOD in the setting of fluid retention. Biochemical features include isolated hyperbilirubinemia as the most common presentation. [272], [274], [297] Ultrasonography is commonly negative for biliary tract obstruction or hepatic vein thrombosis. Most patients with VOD have mild involvement and eventual spontaneous resolution. Progressive VOD is associated with liver failure in select cases. [297]

Treatment Prevention of acute GVHD is the most important aspect of treatment because eventual multiple organ involvement is often fatal. Conventional prophylactic strategies have included combination pharmacological therapy with corticosteroids, [272], [276] cyclosporine, [272], [276] methotrexate, [272], [276], [278] tacrolimus, [278] or antilymphocyte antibodies. [278] Depletion of donor T lymphocytes by elution or monoclonal antibody therapy is associated with reductions in the incidence and severity of acute GVHD. Reports of Epstein-Barr virus–associated lymphoproliferative disorder from depletion and elution techniques, however, have also been noted. [302] Systemic corticosteroid therapy (prednisone, 2 mg/kg/d) is the treatment of choice in acute GVHD with hepatic involvement. [298] Treatment failures (defined as persistent skin and gut symptoms) are managed with increasing corticosteroid doses (4 to 8 mg/kg/d) [299] and the addition of tacrolimus [301] or antithymocyte globulin. [300] Empiric treatment of cholestasis-associated pruritus with UDCA may be of benefit in select cases. [303] No specific therapy exists for cholangitis lenta. Treatment of the underlying infection often results in a reduction of hepatic biochemical elevations and improvement in bile flow. [280] Discontinuation of potential offending agents is the initial step in treating drug-induced cholestasis. Improvements in cholestasis and serum hepatic biochemistries occur within 5 to 7 days of cyclosporine discontinuation. [272], [289] Dose reduction of cyclosporine or substitution with other anti–T-lymphocyte agents is recommended in the presence of acute GVHD to minimize worsening bile duct injury. [272] The use of immunosuppressive therapy including prednisone and cyclosporine is required for the treatment of chronic GVHD. Salvage therapy options include tacrolimus, thalidomide, or sirolimus. [272], [273] Empiric UDCA to modulate symptoms from intrahepatic cholestasis may result in serum hepatic biochemical improvement. [303] Mild to moderate cases of VOD are treated by supportive measures. Diuretic therapy may be useful in patents with symptomatic

fluid overload. [272], [274], [297] For severe cases of VOD, the use of thrombolytic therapy has been shown to improve hyperbilirubinemia in up to 30% of patients. The risk for significant hemorrhage among patients with preexisting thrombocytopenia, including a fatality rate approaching 15%, is associated with thrombolytic therapy. [297], [304] Transjugular intrahepatic portosystemic shunt placement to improve sinusoidal portal hypertension has been associated with an increased mortality rate in patients with severe VOD. [305]

Liver Transplantation

Cholangiopathies associated with liver transplantation can involve either intrahepatic or extrahepatic bile ducts. The two most common forms of surgical biliary anastomoses performed in liver transplantation are choledochocholedochostomy and choledochojejunostomy. Factors involved in choosing one type of anastomosis over another include underlying hepatic disease and size match between recipient and donor organ.

Epidemiology Intrahepatic cholangiopathies after liver transplantation primarily involve the biliary epithelium. One condition in liver transplantation associated with bile duct injury is chronic allograft rejection. Histological criteria for chronic allograft rejection include the loss of intralobular bile ducts in 50% or more identified portal tracts. [306] Recurrent allograft PSC occurs in up to 20% of cases in which strict criteria are applied to exclude other potential causes of intrahepatic biliary disease. [226], [227] and [228] Features of biliary obstruction including cholangitis and fibroobliterative lesions have been reported in allograft biopsies of PSC patients. [228] Extrahepatic cholangiopathies after liver transplantation include anastomotic strictures, hilar strictures, ischemic-type bile duct strictures, bile leaks, choledocholithiasis, and sphincter of Oddi dysfunction. The overall incidence of biliary complications ranges from 9% to 15%, and complications usually develop 2 to 6 months after liver transplantation. Anastomotic strictures occur in 3% to 7% of cases and may be early or late. [306], [307], [308] and [309] Hilar strictures after liver transplantation are associated with local ischemia or hepatic artery thrombosis. Prolonged cold ischemia time and ABO incompatibility have also been reported as risk factors. [310], [311] Bile leaks occur in up to 25% of liver transplantation recipients. [307], [308] Sites of injury include the biliary anastomosis, T-tube insertion site, reduced-size parenchymal graft cut edge, or unrecognized collateral bile duct. [307] Bile leaks associated with the choledochojejunostomy anastomosis occur at the reconstruction site in the early posttransplantation period. [309] T-tube removal in association with choledochocholedochostomy anastomosis is reported to constitute more than 50% of all bile leaks. [307], [308] The finding of choledocholithiasis after liver transplantation is generally associated with a biliary stricture. [307] Sphincter of Oddi dysfunction has been recognized after choledochocholedochostomy reconstruction. Cholangiography is noted for a dilated CBD tapering to its origin. [307], [308]

Clinical Manifestations Patients with intrahepatic or extrahepatic cholangiopathies after liver transplantation often present with asymptomatic elevations in serum alkaline phosphatase or total bilirubin. Mild elevations in serum transaminases can occur as well. Alternatively, the presence of fever or right upper quadrant abdominal pain may be consistent with bacterial cholangitis. [307], [308] and [309] Jaundice and pruritus are uncommon but can be associated with chronic ductopenic rejection. [306] Imaging studies with ultrasound or CT are sensitive for the detection of intrahepatic duct dilation. Examination of hepatic arterial blood flow by Doppler ultrasonography is mandatory in the setting of biliary stricture to exclude thrombosis and stenosis. [310], [311] If a T tube is present, cholangiography is performed to determine the location and extent of biliary strictures when suspected. [307], [308] and [309] ERCP has developed into the initial method of cholangiography in liver transplantation patients for diagnostic and therapeutic interventions. [312] The use of PTC may be indicated when distal bile duct dilation is not significant or evidence for a proximal biliary obstruction above the bifurcation is observed by imaging studies. [307], [314] Histological examination of the allograft by liver biopsy is warranted if cholangiography is unremarkable. [306]

Treatment Ensuring adequate immunosuppression in the presence of chronic ductopenic rejection is mandatory. Conversion from cyclosporine to tacrolimus (FK506) is often recommended because resulting bile flow impairment and cholestasis reduces effective gastrointestinal absorption of cyclosporine. [306] Treatment options for recurrent PSC deal primarily with stricture dilation with or without long-term biliary tube stenting. [228] Hepatic retransplantation in this population is the only available definitive solution if allograft failure ensues. [228], [313] Surgical conversion to a choledochojejunostomy for biliary strictures associated with the choledochocholedochostomy anastomosis was previously considered the treatment of choice after liver transplantation. [307], [309] Recent advances in endoscopic and radiologic techniques have demonstrated satisfactory results from balloon dilation, stenting, or both. Patients who fail to respond after these nonoperative measures may then be considered candidates for biliary anastomosis reconstruction. The use of expandable metal stents may also be considered in subjects who are poor candidates for surgery after liver transplantation. [312], [314], [315] Focal areas of stricturing in association with indwelling T tubes, often related to postoperative edema, usually resolves with observation. [307] The correction of aberrant hepatic artery flow (by angioplasty or surgical revision) may be beneficial to prevent further bile duct injury and diffuse stricturing in the early postoperative period. Hilar strictures are difficult to manage by operative intervention based on previous manipulation of the porta hepatis. Interventions with balloon dilation and percutaneous indwelling stent placement are often required. Problems with recurrent biliary obstruction from debris and mucosal sloughing (especially when ischemic cholangiopathy is present) require frequent biliary stent manipulations and changes. [315] The efficacy of bilateral endoscopically placed stents (polyurethane and expandable metal) compared to percutaneous drainage is unknown. Diffuse biliary stricturing can initially be managed with nonoperative methods, including balloon dilation followed by stenting of dominant strictures. [307], [315] Similar to hilar strictures, the occurrence of stent occlusion has limited the long-term success of this strategy. [315] No benefit with UDCA or prophylactic antibiotic therapy for the prevention of biliary stricturing has been shown. Hepatic retransplantation in eligible candidates is often required for definitive therapy. [313] The management of choledocholithiasis is similar to non–liver transplantation scenarios with the use of balloon dilation and stone removal by ERCP or PTC. Endoscopic sphincterotomy may or may not be required. [307], [312] Sphincter of Oddi dysfunction, when confirmed using accepted criteria, is also treated by endoscopic sphincterotomy despite the absence of abnormal manometric findings. [307]

IATROGENIC CHOLANGIOPATHIES

Operative Bile Duct Injury

Epidemiology Operative bile duct injury is most commonly associated with cholecystectomy (90% of instances). The incidence of bile duct injury with open cholecystectomy is estimated between 0.1% and 0.2%, which includes minor duct (of Luschka) injuries. [316] Initial reports of bile duct injury from laparoscopic cholecystectomy in 1% to 2% of cases have now been reduced to frequencies equivalent to those of open cholecystectomy given the accumulation in clinical experience. [317] Risk factors for bile duct injury include limited operative experience, acute or chronic inflammation involving the biliary tree and gallbladder fossa, and aberrant anatomy. [318] A classification system for bile duct injuries has been proposed by Strasberg and colleagues. [318] Type A injuries affect the minor ducts without the loss of biliary tree continuity, including the cystic duct and gallbladder fossa. Type B and C injuries involve aberrant right hepatic duct injuries. Occlusion of the cystic duct in this scenario is termed a type B injury, whereas complete cystic duct transection is termed a type C lesion. Type D injuries involve incomplete lacerations of the primary bile ducts (common bile, common hepatic, left and right hepatic). Evolution of these lesions to type E injuries can occur. Type E injuries include five variations with lesions located between the common hepatic duct and above the bifurcation. Type A, D, and E bile duct injuries are most often reported.

Clinical Manifestations The timing and extent of injury often determine clinical presentation. Bile duct injuries are often not recognized at the time of surgery. The median time to symptoms is 5 to 7 days but may be weeks. Fever, abdominal pain, and wound drainage can be observed. Jaundice may represent distal CBD occlusion or transection. A minor proportion of patients are asymptomatic at presentation. Imaging studies, such as hepatobiliary scintigraphy (HIDA scan), can document the existence of bile leakage in 90% to 95% of cases. Identification and localization of bile duct injuries by cholangiography is required before repair. [317], [318] Late complications, including biloma formation and biliary stricture, may occur. [319]

Treatment Endoscopic or percutaneous methods to treat bile duct injuries have been employed with success. These measures are effective in the treatment of active bile leaks as well as benign postoperative drainage strictures. Endoscopic sphincterotomy with or without NBT or stent placement is equally effective for bile leak closure. Removal of stents in 3 to 4 months with repeat cholangiography to document bile leak closure is recommended. The disconnection between distal and proximal bile duct systems requires PTC for diagnosis and therapy. [320] Injuries noted at surgery require immediate repair. Techniques include suturing of linear lacerations, end-to-end anastomosis, formation, and Roux-en- biliary reconstruction. Damage involving the common hepatic duct bifurcation is treated with biliary-enteric reconstructive techniques. Facilitation of surgical repair can be provided by preoperative stent placement. Continued stent placement for up to 3 to 6 months is advised. [320] Long-term results from surgical bile duct repair are good and associated with the nature and extent of injury, type of surgical reconstruction performed, and center experience. [319]

Secondary Sclerosing Cholangitis

The development of cholangiographic changes similar to PSC have been reported as secondary phenomena resulting from complications of therapeutic interventions. The most well-known cause of secondary sclerosing cholangitis (SSC) is related to hepatic artery infusion with floxuridine (FUDR). Prevalence rates for FUDR-associated SSC remain unchanged between 17% and 56%. Involvement of the common hepatic duct bifurcation with sparing of the CBD is characteristic. The arterial supply of extrahepatic bile ducts is derived primarily from the gastroduodenal arcade, which is often excluded from hepatic artery infusion. Ischemia, rather than direct FUDR toxicity to biliary epithelium, appears to be the underlying mechanism of action. [321] Although injury appears to be contained within the biliary system,

liver failure associated with FUDR-induced SSC is related to coexistent obstructive vasculopathy. [320] The injection of 20% formaldehyde with sodium chloride or ethanol for the treatment of hydatid disease has also been associated with SSC. [322] Direct sclerosant-type effects on biliary epithelia is the proposed mechanism of action.

MISCELLANEOUS CHOLANGIOPATHIES

Biliary Stricture from Chronic Pancreatitis

Epidemiology Biliary strictures from pancreatic disease occur based on anatomic proximity between the distal CBD and posterior pancreas. The presence of fixed structures, including pancreatic cysts and masses, are associated with extrinsic CBD compression. Biliary stenosis associated with the inflammation of acute and chronic pancreatitis is usually transient. Chronic biliary obstruction is noted among 4% to 10% of patients with alcoholic pancreatitis. Biliary stricture after operative therapy for chronic pancreatitis is observed between 60% to 70% of cases. [323], [324]
Clinical Manifestations In chronic pancreatitis, there are no specific clinical features that suggest the presence of biliary obstruction. Serum hepatic biochemistries are noted for elevations in serum alkaline phosphatase without similar degrees of hyperbilirubinemia. Mild serum aminotransferase (78%) and amylase (47%) elevations can occur as well. Among patients with postoperative bile duct strictures, as many as 80% of cases are identified within the first postoperative year. Late manifestations may occur years after initial surgery. [323], [324] Among 987 patients with benign postoperative biliary strictures followed over 25 years, the most common symptoms at presentation were fever (64%), abdominal pain (49%), and jaundice (44%). Elevations in serum alkaline phosphatase and bilirubin occurred in 50% of cases. [325]
Diagnosis Ultrasonography and cross-sectional imaging techniques (CT, MRI) are useful for documenting biliary dilatation or biloma formation in select cases. Cholangiography (ERCP or PTC) can define both location and extent of stricture involvement. [323], [324] Smooth, long stricturing of the distal CBD between 2 and 4 cm in length is most characteristic. Hepatic histology can also identify biliary obstruction in 80% of cases involving chronic alcoholic pancreatitis with cirrhosis occurring in 29% of patients. [324]
Course and Complications Complications associated with biliary stricture from chronic pancreatitis include cholangitis, choledocholithiasis, and secondary biliary cirrhosis. As many as 20% of reported patients have developed biliary cirrhosis or liver failure after biliary stricture formation from operative injury. [324]
Treatment In cases of biliary stricturing from chronic pancreatitis, the optimal management has yet to be defined. Surgical decompression is employed for high-grade obstruction complicated by jaundice or cholangitis. [325] Endoscopic approaches with stricture dilation and stenting have been more recently performed. Nearly 25% of patients experience stricture regression after stenting for up to 3 months, whereas incomplete responders require operative decompression. [326] Among patients with abnormal serum hepatic biochemistries and no symptoms, the pursuit of operative therapy is controversial. Liver biopsy features of progressive biliary fibrosis favor surgical decompression.

Biliary Fistulas

Spontaneous Enteric Biliary Fistula

Epidemiology. Prevalence rates between 0.5% and 5% after biliary tract operations have been reported. Gallstones are responsible for 90% of cases, followed by peptic ulcer disease (6%) and trauma (4%). Cholecystoduodenal (75%), cholecystocolonic (15%), and cholecystogastric (6%) fistulas are the most frequent sites of tract formation. Cholecystoduodenal fistulas from gallstones almost exclusively involve the periampullary area. Fistulas may be obstructive or nonobstructive. The female-to-male ratio for developing both fistula types is 2:1 to 3:1. Gallbladder carcinoma has been associated with enteric biliary fistulas in 15% of cases. [327]
Clinical manifestations. Nonobstructive fistulas are often diagnosed as incidental findings at cholecystectomy or cholangiography. Consequences of these fistulas include ascending cholangitis, weight loss, and bleeding. Obstructive fistulas present with symptoms reminiscent of bowel obstruction, which may be complete or partial. [327] Gallstone ileus can present with acute small bowel obstruction from gallstones of diameters greater than 25 mm. The ileocecal area is the most common site of obstruction (75%), followed by the jejunum (20%). Abdominal x-ray findings of pneumobilia are observed in only 30% of enteric biliary fistulas. Biliary reflux of oral contrast is more suggestive of biliary fistula. [328]
Treatment. The treatment of choice when possible is surgical. For gallstone ileus, the performance of cholecystectomy, fistula excision, and operative cholangiography to exclude choledocholithiasis is recommended. Mortality rates approaching 20% in previous reports have now been reduced below 5%. [328]
Operative Biliary Fistula Most commonly observed in association with bile duct injury after cholecystectomy, the development of a cutaneous or internal bilioperitoneal fistula occurs in 33% of postoperative cases. Hepatobiliary scintigraphy (i.e., HIDA scan) can detect bile leaks and fistulas with greater than 90% sensitivity. Cholangiography may ultimately be required for diagnosis confirmation. Endoscopic therapy with NBT placement or stents has been successful in selected cases. Treatment failures require surgical intervention. [329]
Bronchobiliary Fistula The overall prevalence rates of bronchobiliary fistula are unknown but range between 4% and 10.5% among patients with hepatic and subphrenic abscesses, respectively. Other etiologies responsible for bronchobiliary fistula formation include blunt abdominal trauma, bile duct stenosis, choledocholithiasis, and congenital causes. Clinical manifestations include bilioptysis, jaundice, and cholangitis. The diagnosis has been made by cholangiography and hepatobiliary scintigraphy. The treatment of choice is surgical. [330]
Miscellaneous Biliary Fistula Vascular fistulas with the biliary tree may occur and include both arterial and venous systems. Causes include trauma, infection, or iatrogenic (operative, transjugular intrahepatic portosystemic shunt) complications. Hemobilia is the most common sign at presentation. Biliobiliary fistulas involving the gallbladder, cystic duct, or secondary biliary radicle with the main biliary tree can also occur. Compression by stone impaction in the cystic duct or gallbladder neck (Mirizzi syndrome) may result in erosion through the CBD, resulting in fistula formation. [331]

CHAPTER 102

Shelly C. Lu and Khaldoun A. Debian

CYSTIC DISEASES OF THE BILIARY TRACT

Cystic dilations occur throughout the biliary system. Most common are cystic dilations of the common bile duct (CBD) (i.e., choledochal cysts), but cystic dilations involving the intrahepatic ducts alone or in combination with other cystic abnormalities of the extrahepatic ducts are increasingly recognized. The terminology and classification are tremendously confused. The term *choledochal cyst* has commonly referred to all cystic abnormalities of the biliary tree; however, this term is best restricted to only cystic abnormalities of the CBD. Despite the many variations of these cystic abnormalities, some underlying features unify them.

EPIDEMIOLOGY

Biliary cysts are rare, with about 4000 cases reported worldwide. [1] The incidence of biliary cysts is much higher in Japan, where one half to two thirds of all reported cases have originated. [1], [2] and [3] The Japanese incidence (1 in 13,000 births) is about 150 times more common than in the West (1 in 2,000,000 births). [3] The incidence is much higher among women, with a female-to-male ratio of 3:1 or 4:1. Between 40% and 60% of patients are diagnosed before 10 years of age, 52% to 76% before 20 years of age, and 83% to 90% before 30 years of age. [1], [2], [3] and [4] This is mainly a disease of children and young adults.

CLASSIFICATION

Todani and associates [5] proposed the most complete and practical classification that recognizes five types of bile ducts cysts (Fig. 02-1).

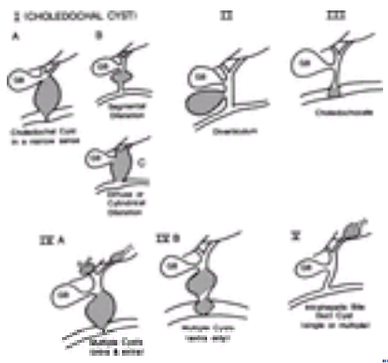

FIGURE 102-1. Todani's classification of biliary cysts based on location. *Hatched areas* represent cystic dilations.

Type I cysts include choledochal cysts in a narrow sense, segmental choledochal dilations, and diffuse or cylindrical dilations. Seventy-five to 85% of cases are type I.
Type II or diverticulum cysts are found anywhere in the extrahepatic ducts and make up 2% to 3% of reported cases.
Type III or choledochocele cysts, also rare, represent 1.4% to 5.6% of reported cases. In 1989, Sarris and Tsang [6] reviewed 48 cases in the English literature and proposed a further anatomic classification of choledochoceles. In type A, the ampulla opens into the choledochocele, which communicates with the duodenum through another small opening. Type A choledochoceles can be further subclassified into A1, in which the pancreatic duct and CBD share a common opening into the cyst (33% of cases); A2, in which the openings are distinct (4% of cases); and A3, in which the choledochocele is small and entirely intramural (25% of cases). In type B, the ampulla opens directly into the duodenum, with the choledochocele communicating only with the distal CBD (21% of cases). This scheme is useful because of important therapeutic implications.
Type IV cysts are also subclassified. Type IVA multiple cysts in the intrahepatic and extrahepatic ducts account for 18% to 20% of reported cases. [3] Type IVB multiple cysts occur only in the extrahepatic duct and are much less common.
Type V intrahepatic bile duct cyst (single or multiple) are also quite rare. They probably represent Caroli disease as originally described.

Serena and colleagues [7] proposed a type VI biliary cyst, which is cystic dilation of the cystic duct with otherwise normal intrahepatic and extrahepatic ductal systems. Three cases of type VI cysts have been described in the literature up to 1999. [8]

Anatomically based classification is of great practical importance in planning surgical management. Other classifications emphasize clinical presentation rather than ductal anatomy.

PATHOGENESIS

The cause of biliary cysts has been disputed. The major debate concerns whether cysts are congenital or acquired. The possibility of genetic factors has also been raised. First, this disease is much more common in Japanese than in Europeans. Familial occurrence has been reported in one pair each of mother and daughter, mother and son, father and daughter, and a pair of sisters. However, a study of a pair of monozygotic twins showed discordance for both anomalous pancreaticobiliary junction and biliary cyst. [9] Thus, this is not compatible with single gene control.

Many early investigators, including Douglas and Alonzo-Lej, favored the congenital malformation theory. [10] Several observations support this theory. First, biliary cysts appear in all age groups, and antenatal diagnosis has been reported as early as 15 weeks' gestation, making a congenital origin likely. There are also many associated anomalies of the biliary system, such as double CBD, double gallbladder, multiseptate gallbladder, biliary atresia, congenital hepatic fibrosis, and annular pancreas. [11] In addition, many cysts fail to shrink after decompressive surgery, suggesting inherently abnormal ductal wall development. [2]

Of the theories proposing acquired cysts, that of Babbitt and associates [12] has received the most attention. They proposed that choledochal cysts develop because of an anomalous arrangement of the distal pancreaticobiliary tree. In all seven of their patients with choledochal cysts, they found that the CBD entered the pancreatic duct at a right angle at an abnormally long distance (more than 2 cm) from the ampulla of Vater (Fig. 102-2). This abnormal anatomy impaired normal sphincteric function at the pancreaticobiliary junction. Because the maximal secretory pressure of the pancreas is 30 to 50 cm H_2O and that of the liver is 25 to 30 cm H_2O, pancreatic juice flows into the bile duct in the absence of a sphincter mechanism. This anomaly is associated with recurrent cholangitis, edema, fibrosis, obstruction of

the bile ducts, and carcinoma. These complications are believed to result from chronic reflux of pancreatic juice and subsequent activation in bile of various pancreatic proteinases and lipases. In support of this are findings of high levels of amylase that are frequently found in the cyst fluid and the demonstration that pancreatic juice in the CBD of animals with an anomalous arrangement can cause cystic dilation of the CBD. [4], [13] Although amylase has been found in the cyst fluid, this enzyme probably does not play a pathogenetic role. Amylase is not detectable in the duodenal fluid of newborns and infants, but trypsin activity is the same in newborns and older children. [14] In addition to increased amylase activity in bile, Shimada and colleagues [15] also showed markedly increased concentration and proportion of lysophosphatidylcholine in bile (especially in gallbladder) of patients with anomalous pancreaticobiliary ductal junction, most of whom had biliary cyst. This was due to increased hydrolysis of phosphatidylcholine, a normal component of bile, by increased activity of phospholipase A_2. Because lysophosphatidylcholine is cytotoxic, this may play a role in the pathogenesis of biliary cyst by adversely affecting an already weakened bile duct wall and in the later development of malignant degeneration.

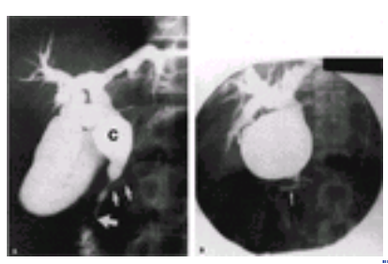

FIGURE 102-2. Choledochal cyst—anomalous ductal relationship. **A:** Cystic enlargement of the common bile duct (*C*) with associated dilation of the common hepatic and intrahepatic ducts. The abnormal junction of the pancreatic duct (*small arrows*) and common bile duct and long common channel (*large arrow*) is displayed. **B:** A large cyst involves the common hepatic and common bile duct accompanied by intrahepatic ductal dilation. A long common channel (*arrow*) results from the abnormally high junction with the pancreatic duct.

Anomalous pancreaticobiliary ductal anatomy occurs in 65% to 80% of patients with choledochal cysts. [10] The anomalous pancreaticobiliary ductal union is not unique to patients with biliary cysts; it is also associated with biliary malignancies (especially gallbladder carcinoma) and abnormal pancreatic ducts. [16] In a large study of 1325 patients examined with direct cholangiography for symptoms suggestive of hepatobiliary and pancreatic disease, 29 patients had the anomaly (2.2%), of whom 21 patients had associated choledochal cyst. Surprisingly, the frequencies of gallbladder carcinoma in patients with the anomaly were 50% and 5% in the absence or presence of associated choledochal cyst, respectively. None of the patients with gallbladder carcinoma had gallstones. The overall frequency of carcinoma of the biliary tract was 14% in patients with choledochal cyst and 50% in those without. This striking difference led the authors to recommend prophylactic cholecystectomy in patients with anomalous pancreaticobiliary ductal junction. [17] Similar findings have been reported by Sugiyama and Atomi. [18] Based on these studies, the authors concurred with the recommendation of prophylactic cholecystectomy.

Many investigators emphasized that cystic dilation results from a combination of two factors: segmental weakness of the duct wall and distal obstruction. [19] The weakness of the wall and the distal obstruction may be congenital or acquired. Several animal experiments support the importance of distal obstruction. [2], [20] Ligation of the distal CBD in adult rabbits, rats, and dogs gives rise to diffuse dilation of the intrahepatic and extrahepatic ducts. This also occurs in neonatal lambs. [20] After CBD ligation, all six studied lambs developed choledochal cysts, and all four adult sheep developed isolated dilation of the gallbladder.

The etiologic importance of these distal ductal abnormalities is unclear. The animal experiments may not be applicable to humans. The distal obstruction theory also would not explain solely intrahepatic duct cysts. Not all choledochal cysts have demonstrable distal obstruction.

The infantile form of choledochal cysts appears in some cases to result from an obliterative process similar to that producing biliary atresia. Twenty-four (13%) of 188 patients with biliary cysts were also found to have biliary atresia. [21] However, well-documented cases of acquired biliary cysts in adults have appeared, including seven attributed to recurrent attacks of pancreatitis. [22] More recent studies suggest many other factors may also be involved. One is the finding of abnormal sphincter of Oddi pressure in patients with choledochal cysts. [23] Other studies have added viral infection and genetic mutations to possible causes of choledochal cysts. [24], [25] and [26] Tyler and coworkers found reovirus in 13 of 23 tissues from patients with extrahepatic biliary atresia and 7 of 9 tissues from patients with choledochal cysts, prevalences that were much higher than in patients with other hepatobiliary diseases (21%) or autopsy cases (12%). [24] This is intriguing because reovirus can produce a disease in weanling mice with similar pathological features to human choledochal cysts. [24] However, the number of patients with choledochal cysts examined was small, and causality remains to be established. Two cases of choledochal cysts in association with rare genetic syndromes have been described recently. [25], [26] One was in association with familial adenomatous polyposis syndrome [25] and the other in association with Simpson-Golabi-Behmnel syndrome. [26] These investigators raised the possibility that mutations in their respective genes may have contributed to the development of the choledochal cyst.

Two recent studies advanced our understanding of the pathogenesis of Caroli syndrome (type V biliary cysts in association with congenital hepatic fibrosis; see section on Clinical Presentations). First is the identification of impaired protein *N*-glycosylation due to phosphomannose isomerase deficiency as a cause of congenital hepatic fibrosis, a disorder of ductal plate malformation often associated with type V cysts. [27], [28] These patients often present with protein-losing enteropathy, which responds to D-mannose treatment. [28] Whether the hepatobiliary abnormalities will improve is unknown. These recent findings also suggest that normal protein glycosylation is important in the formation of ductal plates. Another advance is the development of a novel animal model with features of polycystic kidney, multiple intrahepatic bile duct dilations, and congenital hepatic fibrosis. [29] These animals exhibit increased proliferative and decreased apoptotic activities in the biliary epithelial cells during development as compared with controls, suggesting that the remodeling defect in immature bile ducts associated with the imbalance of cell kinetics might play a role in the development of the hepatobiliary abnormalities. [29] This animal model should provide important insights into the pathogenesis of this syndrome.

It is clear that many factors are important in the pathogenesis of biliary cysts, which encompass a wide spectrum of lesions.

CLINICAL PRESENTATIONS

Type I or Choledochal Cysts

Patients with choledochal cysts present with two typical clinical constellations determined mostly by the patient's age at presentation. [2] In infancy, jaundice with or without acholic stools is the most common finding, occurring in as many as 80% of patients. [2] The presentation is often indistinguishable from biliary atresia, which is sometimes associated with choledochal cysts. [21] Pain may or may not be a factor, but vomiting and failure to thrive have been reported in as many as 50% of patients. [2] Hepatomegaly is often found, and 30% to 60% of patients have a palpable abdominal mass. [2] The mass is usually in the right hypochondrium; is soft, elastic, round, and mobile laterally; and may follow the movements of the diaphragm. [5] The classic clinical triad of pain, jaundice, and a palpable abdominal mass has been found only in 11% to 63% of large series. [2] Frequently, biliary cirrhosis and portal hypertension complicate the management. [21]

The noninfantile form (patients older than 2 years of age) covers a wide age range, with the oldest patient reported in the eighth decade. Asymptomatic patients have been described. [30] Chronic and intermittent pain appears to be the most common presenting symptom, reported in 50% to 96% of patients. [31] Intermittent jaundice and recurrent cholangitis are also common, reported in 34% to 55%. Abdominal mass is much less common; it occurs in about 10% to 20% of cases. The classic triad of pain, jaundice, and a palpable mass has been reported in 3% to 13% of patients. [31] Cirrhosis and portal hypertension are less often encountered. Recurrent pancreatitis has been reported only in the noninfantile form, although whether there is actual pancreatic inflammation is debatable. [32] When these patients present with painful attacks, they often show slight elevation of serum bilirubin levels and an increase in the degree of the choledochal dilation, possibly caused by biliary obstruction. The terms *fictitious pancreatitis* and *pseudopancreatitis* have been applied to these patients. [32] One possible explanation is that amylase in the biliary tract has ready access to the bloodstream. This would also explain why hyperamylasemia is almost never observed in patients younger than 1 year of age with choledochal

cysts: the amylase levels are usually very low in bile because acinar growth of the pancreas is not complete until 1 to 2 years of age. [32]

The other presentation that has been reported only in patients older than 10 years of age is that of carcinoma associated with choledochal cysts. [33]

Type II or Diverticulum Cysts

More than 50 cases of type II or diverticulum cysts have been reported in the world literature, representing 2% to 3% of large series. [31], [34] Presenting symptoms generally reflect the compression of nearby structures by the cyst.

Type III or Choledochocele Cysts

About 125 cases of choledochocele have been reported. [31], [35], [36] and [37] More than 73% of reported patients were older than 20 years of age, unlike with type I cysts, which are found in 60% of the patients with biliary cysts younger than 10 years of age. [36] There is also less female preponderance, with a female-to-male ratio of 1.4:1. [36] Common presenting symptoms include intermittent episodes of abdominal pain and obstructive jaundice. Abdominal mass is not found. Pancreatitis is much more common in choledochocele than in any other type of biliary cyst and is reported in 30% to 70% of these patients, presumably caused by reflux of bile or obstruction. [37] Stones in the cele or the CBD are also much more common, reported in 25% to 35% of these patients, in contrast to only 8% in type I cysts. [31], [37] Rarely, intestinal (duodenojejunal) intussusception may be the presenting feature of choledochocele. [35]

Type IV and V Cysts or Caroli Disease

Caroli and associates [38] originally described this disease as a congenital malformation of intrahepatic bile ducts, characterized by segmental cystic dilation of the intrahepatic ducts; increased incidence of biliary lithiasis, cholangitis, and liver abscesses; absence of cirrhosis and portal hypertension; and association of renal tubular ectasia or similar renal cystic disease.

After the first report, Caroli [39] recognized that two distinct disease entities are associated with intrahepatic duct cysts: the simple type, which was his original description, and the periportal fibrosis type. The simple type is associated with medullary sponge kidney in 60% to 80% of the cases. The periportal fibrosis type is also known as *Caroli syndrome*. In addition to intrahepatic cystic dilation, congenital hepatic fibrosis, cirrhosis, portal hypertension, and esophageal varices are frequently seen. Hepatic function is usually well preserved in the periportal fibrosis type; the major clinical manifestations are recurrent cholangitis, liver abscess formation, and portal hypertension. It is often associated with the renal abnormalities of autosomal recessive polycystic kidney disease. [27]

It is now apparent that Caroli disease, including the simple and periportal-fibrosis types, represents only part of the spectrum of cystic disease of the intrahepatic ducts. In an excellent review by Barros and associates [40] of 46 well-documented cases with hepatic histopathology and biliary tree studies available, only 13% of patients had the simple type. Thirty-five percent had the periportal-fibrosis type, 22% had intrahepatic and extrahepatic cystic dilation (i.e., type IVA of Todani's classification), and 30% had all three abnormalities: cystic dilation of the intrahepatic and extrahepatic bile ducts and congenital hepatic fibrosis.

The term *congenital hepatic fibrosis* refers to a unique congenital liver histology characterized by bland portal fibrosis, hyperproliferation of interlobular bile ducts within the portal areas with variable shapes and sizes of bile ducts, and preservation of normal lobular architecture. [40] The prevalence of biliary cysts in patients with congenital hepatic fibrosis probably has been underestimated because most patients did not have cholangiographic studies performed.

The aforementioned forms of intrahepatic biliary cystic disease should be differentiated from polycystic liver disease because of significant dissimilarities. Polycystic liver disease is an autosomal dominant genetic defect, but the manner of inheritance of Caroli disease remains poorly defined. [27] Polycystic liver cysts are large, contain serous fluid, and do not communicate with the biliary tree. Caroli disease cysts communicate with the biliary tree. Portal hypertension is rare in polycystic liver disease. The prognosis for polycystic liver disease patients is determined by the effect of cystic disease on the kidneys and not the liver. [41] The incidence of malignant transformation in the intrahepatic parenchymal cysts of polycystic liver disease is 1.3%, compared with 7% in Caroli disease. [42]

Until 1984, 162 cases of Caroli disease had been reported. [42] Males and females are equally affected, unlike the female predominance in choledochal cysts. Symptoms usually appear in early adult life, with recurrent episodes of fever, chills, and abdominal pain due to cholangitis. More than 80% of patients present before 30 years of age. Biliary lithiasis is found in 34% of these patients and may predispose to recurrent cholangitis. [40] Occasionally, the disease is diagnosed later in life, with the sequelae of portal hypertension, most commonly bleeding esophageal varices. [39], [42]

DIAGNOSIS

Diagnosis of biliary cysts requires a high index of suspicion. The major reason for missed diagnosis is that biliary cysts are usually not included in the differential diagnosis of recurrent abdominal pain, pancreatitis, obstructive jaundice, or cholangitis. Most patients do not present with the classic triad of pain, jaundice, and abdominal mass. Biochemical tests only reflect the degree of biliary obstruction and infection. Correct diagnosis depends on the use of imaging studies.

Ultrasonography is the best screening method for type I, II, IV, and V cysts. [1], [2] More than 17 cases of antenatal diagnosis of choledochal cyst by means of ultrasonography have been reported. [43] When a choledochal cyst is suspected on prenatal ultrasonography, repeat ultrasonography is indicated immediately after birth so that expeditious treatment can be provided. The major drawback to ultrasonography is that it provides little anatomic or functional information.

Hepatobiliary scintigraphy has been advocated as a sensitive, noninvasive tool for the diagnosis of choledochal cyst. This technique is useful for all except type III cysts. [44] The characteristic findings are biliary tract dilation and tracer retention after 24 hours. [44] It provides information about excretory patterns and has therefore been recommended by many for postoperative patient follow-up.

Ultrasonography and scintigraphy are complementary and provide a sound basis for preoperative diagnosis in patients younger than 2 years of age. For older patients, computed tomography has been advocated by some to be superior to ultrasound. [44], [45] Until recently, percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) have been regarded as providing the best detailed examinations. PTC is especially useful in defining complex anatomic cysts of the intrahepatic ducts, but ERCP provides the best visualization of the distal portion of the biliary tree, especially the relation of the biliary and pancreatic ducts. [2] This notion has been challenged in recent years by improvements made in magnetic resonance imaging. [46], [47] Several studies have shown that magnetic resonance cholangiopancreatography (MRCP) is as good as ERCP in the evaluation of biliary cysts, especially in adults. [46], [47] Because MRCP is noninvasive and not operator dependent, it is likely to replace ERCP and PTC as the imaging study of choice in patients with biliary cysts.

ERCP is likely to remain useful in the diagnosis of type III cysts (i.e., choledochoceles). The typical features are the "clubbed" appearance of the distal CBD and a round, cystlike, contrast-filled structure in the terminal CBD, which often protrudes into the duodenal lumen. Emptying of contrast material is often delayed. Choledochoceles are easily differentiated from duodenal diverticula and duodenal duplication cysts by filling during cholangiography but not during upper gastrointestinal contrast studies (Fig. 102-3). Duodenal diverticula fill on upper gastrointestinal series but not on cholangiography. Duplication cysts do not fill with either method. [48]

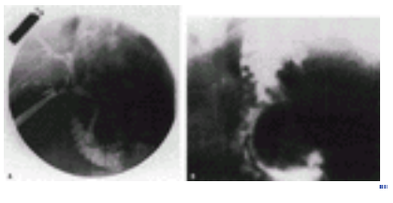

FIGURE 102-3. Choledochocele—type III cyst. **A:** Cholangiography reveals a club-shaped enlargement of the distal common bile duct bulging into the duodenum. **B:** Upper gastrointestinal series reveals a smoothly rounded filling defect in the second portion of the duodenum.

Oral cholecystography and intravenous cholangiography are of no use in diagnosing biliary cysts. [3], [31] Other nonspecific findings include a mass displacing the gas shadows on plain abdominal radiographs and displacement of antrum, usually anteroinferiorly and to the left, on upper gastrointestinal series.

The definitive diagnosis of biliary cyst and its classification is secured by intraoperative cholangiography at the time of operative intervention. Delineation of the precise anatomy is critical in preventing injury, especially to the pancreatic duct because of the high frequency of the anomalous union and in providing the best operative management possible. [2]

PATHOLOGY

The wall of the cyst is usually thickened because of productive fibrosis and inflammation. In histology, dense connective tissue, with fibrocollagenous and sometimes smooth muscle and elastic elements, is seen. There is no epithelial lining, but islets of cylindrical or columnar epithelium may be preserved. A case of biliary papillomatosis arising in a choledochal cyst wall was reported. [49] Duodenal mucosa covers choledochoceles externally, but the internal surface of choledochoceles is variably lined by duodenal mucosa (63% of cases), bile duct mucosa (21% of cases), or unclassified glandular epithelium (13%). [50]

Liver biopsy is abnormal in 60% of patients with biliary cysts, demonstrating biliary cirrhosis, portal fibrosis, or evidence of biliary atresia. Other abnormal findings include liver abscesses, especially in cases of Caroli disease, and sludge or stones in the CBD. In newborn patients with biliary cysts, the histology is usually normal or shows mild bile duct proliferation consistent with biliary obstruction. [10]

TREATMENT

Biliary cyst treatment is surgical, and primary cyst excision is the procedure of choice. [5] Internal drainage procedures, such as choledochoduodenostomy and Roux-en- choledochojejunostomy, were widely employed, especially in Western countries. [2], [22] There are three major drawbacks to internal drainage procedures compared with cyst excision. First, the morbidity rate is much higher, up to 88% with internal drainage procedures compared with 2% to 8% with cyst excision. [21] The usual complications are recurrent pain, jaundice, stricture formation, and cholangitis. These appear to be more common after choledochoduodenostomy than after Roux-en- choledochojejunostomy. [2], [21] The second drawback is the need for reoperation because of the high complication rate. In large series, 13% to 70% of patients have required reoperation after internal drainage, but a 0% to 10% reoperation rate was reported after cyst excision. [21], [51] The third drawback is the risk for malignant transformation, which is not diminished after an internal drainage procedure (see the section on Clinical Course and Complications). Patients who develop biliary carcinoma after excision of choledochal cyst are extremely rare; only three were reported up to 1984. [52] The fundamental reason for poor outcome after internal drainage is that diseased tissue remains and is used for biliary reconstruction. The cyst wall is inherently inflamed and fibrous, precluding normal healing. Biliary stasis persists and predisposes to recurrent cholangitis, stone, and stricture formation.

The aforementioned techniques are applicable to choledochal cysts (i.e., types I and IV cysts involving the CBD). Type II cysts should be excised. Treatment of type III cysts depends on the anatomy (see Fig. 102-1). Sarris and Tsang [6] recommend excision of the duodenal lumenal portion of the cyst, leaving the medial portion containing the ampulla intact as the preferred treatment in most cases of type IIIA cysts (i.e., A1 and A2). Transduodenal sphincteroplasty and ERCP with papillotomy have been advocated as treatment for type IIIA3 cysts. Type IIIB cysts should be treated by excision and sphincteroplasty. The malignant potential of choledochocele appears to be very low. [36], [37] However, Schimple and colleagues [53] pointed out that carcinoma has only been reported in choledochoceles that were lined by biliary or undifferentiated epithelium internally (up to 20% in some reports). They advocate complete excision of the choledochocele by separation and reinsertion of the common bile duct and pancreatic duct into the duodenal wall if the choledochocele is lined by biliary or undifferentiated epithelium, whereas sphincteroplasty should be reserved only for those lined by duodenal epithelium.

Intrahepatic cyst (i.e., type IVA or V) treatment depends on the degree of involvement. When segmental cystic disease is confined to one lobe (more often the left lobe), lobectomy is usually curative. [42], [54] If both lobes are involved, some have advocated establishing a permanent-access hepaticojejunostomy after partial hepatectomy to allow easy biliary tree access when necessary. [54] It is uncertain how effective this approach will be. If extrahepatic cysts coexist with intrahepatic cysts (type IVA), they should be excised as previously described. Chronic antibiotic therapy in multilobar Caroli disease may have some benefit. Ultimately, if attacks of cholangitis are frequent and quality of life poor, hepatic transplantation may be a therapeutic option. A summary of the recommended surgical treatments is given in Table 102-1.

TYPE OF BILIARY CYST	SUGGESTED TREATMENT
I	
A	Cyst excision with Roux-en-Y hepaticojejunostomy or jejunal interposition hepaticoduodenostomy
B	
C	Choledochojejunostomy or sphincteroplasty if excision is impossible
II	Excision if possible
III	
A_1	Excision
A_2	
A_3*	Sphincteroplasty or endoscopic retrograde cholangiopancreatography with papillotomy
III B	Excision and sphincteroplasty
IV	
A	Extrahepatic cyst excision with biliary reconstruction as in IA and IB. Lobectomy if intrahepatic cyst is confined to one lobe, or permanent access hepatocojejunostomy if intrahepatic cysts are diffuse. Transplantation in selected cases.
B	Cyst excision as in IA, IB
V	Hepatic resection for localized disease or permanent access hepaticojejunostomy for diffuse disease. Transplantation may be an option.

* Complete excision of the choledochocele by separation and reinsertion of the common bile duct and pancreatic duct into the duodenal wall if the choledochocele is lined by biliary or undifferentiated epithelium.

TABLE 102-1 Suggested Treatment for Biliary Cysts

Cholecystectomy should be performed at the time of cyst excision because continuous free bile flow minimizes the risk for reflux and cholangitis and because the gallbladder has shown clinical and histological evidence of cholecystitis in patients in whom secondary operations have been necessary, and the gallbladder is predisposed to malignant change in patients with biliary cysts. [55]

If the definitive surgical procedure is successful, the prognosis is generally excellent. Reversal of cirrhosis has even been reported. [56]

CLINICAL COURSE AND COMPLICATIONS

Complications of biliary cysts include recurrent cholangitis before treatment and after internal drainage procedures, stone formation, stenosis and stricture, pancreatitis, biliary cirrhosis, portal hypertension due to cirrhosis or portal vein thrombosis, liver abscess, especially in Caroli disease, and cyst rupture. [6], [21], [57] Pregnancy can precipitate or aggravate symptoms of choledochal cyst, specifically cyst rupture. Twenty-six cases have been reported to rupture during pregnancy or labor. [58] Pregnant women with symptomatic choledochal cyst should avoid labor by having cesarean sections as soon as the fetus is mature.

The most feared complication is malignancy. [55], [59] Carcinoma afflicts predominantly adults. The youngest patient with carcinoma during initial choledochal cyst surgery was 10 years of age. [59] The mean age for detecting carcinoma after enteric drainage was 35 years, with a mean interval of 10 years after the enteric drainage procedure. [59] The mean age for detecting carcinoma at the initial surgery for biliary cyst was 50 years; this is two decades earlier than the mean age for bile duct

carcinoma in the general population. [59] Even though the overall incidence of biliary carcinoma in association with biliary cysts is 2.5%, it is actually 14% to 18% in the adult patients (older than 20 years of age) and 50% by 50 years of age. [2], [33], [59] In contrast, the overall incidence of biliary carcinoma is 0.012% to 0.48% in the general population. [60] The female-to-male ratio is 2.5:1, slightly less than that seen with choledochal cysts.

Carcinomas occur not only in the cyst wall but also in the remainder of the hepatobiliary and pancreatic tree. Of 154 cases of carcinoma in cases of biliary cysts, only 58% were actually in the cyst wall, 40% were gallbladder, 1.3% were pancreatic, and 0.6% were intrahepatic carcinomas. [59]

The pathogenesis of malignant change in biliary cysts is unknown. Stones are not thought to be important because they are found only in 13.8% of patients [59] (Fig. 102-4). Adenocarcinoma is the most common type, constituting 70% to 84% of all types. Other histological types are squamous (4% to 9%) and undifferentiated or anaplastic (7% to 21%), and one case of small cell carcinoma was reported. [59]

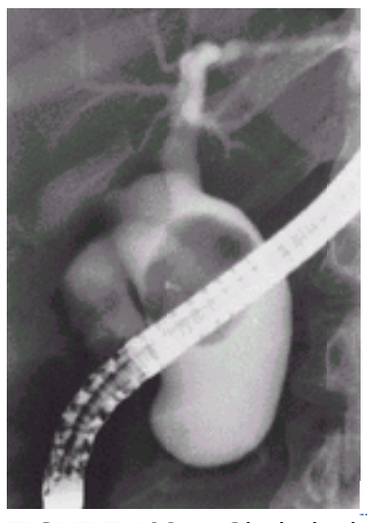

FIGURE 102-4. Choledochal cyst—type IA. Endoscopic retrograde cholangiogram shows cystic dilation of the common bile duct with a very large filling defect due to a calculus. Stones are uncommon complications of biliary cysts, reported in only 13.8% of cases (Courtesy of Dr. Hartley Cohen, USC School of Medicine, Los Angeles.)

Isolated intrahepatic cysts (i.e., Caroli disease) are also associated with a higher incidence of carcinoma. Overall, 7% of patients with Caroli disease were found to have cholangiocarcinoma, with no female predominance. [61] The average age at the time of diagnosis of carcinoma was 51 years. [61]

The prognosis of carcinoma related to biliary cysts is dismal. Almost all patients die soon after diagnosis. [59], [61] One preventive therapy is total cyst excision during the initial operation. However, cyst excision does not completely eliminate the future risk for carcinoma because the rest of the pancreaticobiliary tree appears to also be predisposed to malignant change.

CHAPTER 103

Jeffrey A. Drebin and Steven M. Strasberg

TUMORS OF THE BILIARY TRACT

CHOLANGIOCARCINOMA

Cholangiocarcinoma is cancer of biliary epithelium. It may arise from intrahepatic or extrahepatic bile ducts. Sporadic cholangiocarcinoma is quite uncommon, but cholangiocarcinoma has a high incidence in the presence of certain benign conditions. Information on cholangiocarcinoma is mostly derived from small case series gathered over many years and therefore tends to be descriptive. Consequently, claims for the best form of investigation or treatment must be interpreted cautiously.

Classifications

There are several suggested classifications. Clinically, intrahepatic and extrahepatic cholangiocarcinomas are distinct entities (Table 103-1) but are linked by cell of origin and etiologic factors. Intrahepatic cholangiocarcinoma arises from small ducts or ductules and presents as an intrahepatic mass, the differential diagnosis of which usually is other intrahepatic tumors such as hepatomas. Extrahepatic cholangiocarcinoma arises from large ducts and usually presents as biliary tract obstruction. The extrahepatic tumors may be further subdivided into upper duct tumors (also called perihilar, hilar, or Klatskin tumors) and lower duct tumors. [1] The division into upper and lower duct cholangiocarcinomas is logically based on staging and treatment considerations. Lower duct tumors are similar to other periampullary tumors, such as adenocarcinomas of the head of the pancreas, in terms of diagnosis and treatment.

NAME	SYNONYMS
Intrahepatic	Small duct, intraparenchymal, peripheral[a]
Extrahepatic—upper duct	Hilar cholangiocarcinoma, perihilar cholangiocarcinoma, Klatskin tumor, proximal[a] bile duct cancer
Extrahepatic—lower duct	Distal[a] bile duct cancer

Note: The classification is the authors'. Intrahepatic and extrahepatic are the main division in the classification per the TNM system. Extrahepatic tumors are divided into two rather than three anatomic zones per ref. 1.

[a] These terms are undesirable, particularly "proximal" and "distal." Distal means away from the center of the body and proximal means near. Note that in pancreatic terminology, distal refers to the part of the duct farthest away from the termination in the duodenum; whereas in biliary terminology, the opposite is true. The terms are properly applied to limbs, and their use in biliary-pancreatic terminology should be abandoned.

TABLE 103-1 Classification of Cholangiocarcinoma

Extrahepatic cholangiocarcinoma has been classified, for staging purposes, by a classification introduced and modified by Bismuth [2] into four types based on the level of ductal involvement (Fig. 103-1). Cholangiocarcinomas are also classified by the TNM system, [3] which groups intrahepatic cholangiocarcinomas with other intrahepatic malignancies and considers extrahepatic cholangiocarcinomas as a separate group (Table 103-2). A potentially useful modification of the staging system for intrahepatic cholangiocarcinomas has recently been proposed. [4]

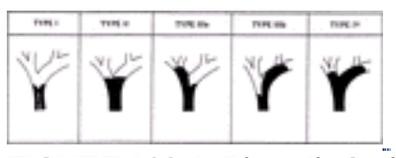

FIGURE 103-1. Bismuth-Corlette classification of hilar cholangiocarcinomas.

TABLE 103-2 TNM Classification for Cholangiocarcinoma and Gallbladder Carcinoma

Incidence, Etiology, and Pathogenesis

The true incidence of bile duct carcinoma is difficult to determine because reports of incidence and survival statistics from these cancers are usually included with liver and gallbladder cancers or pancreatic carcinomas. Recent reports suggest that rates of intrahepatic cholangiocarcinoma may be increasing in Great Britain [5] and the United States. [6] The incidence peaks at about 65 years of age, and the tumor is more common in men than women.

Sporadic cholangiocarcinoma is very uncommon. The tumor usually arises in association with an underlying condition. Underlying conditions are of two types: those that have a high frequency in localized populations, such as parasitic infestation with *Opisthorchis viverrini* in Northeast Thailand; and those that have a much lower frequency but a more global distribution, such as primary sclerosing cholangitis (PSC) (Table 103-3). In Northeast Thailand, liver fluke–associated cholangiocarcinoma is a leading cause of death, [7] whereas in the United States, cholangiocarcinoma accounts for less than 1% of malignancies. The diverse predisposing causes of cholangiocarcinoma usually result in chronic inflammation of the biliary tract.

Predisposing causes with a high incidence in localized areas of the world
Infestation with *Opisthorchis viverrini* in Northeast Thailand
Infestation with *Chlonorchis sinensis* in China
Intrahepatic stones
Predisposing causes with a low but more global incidence
Primary sclerosing cholangitis
Choledochal cysts
Thorotrast[*]
Ulcerative colitis

[*]A number of other agents have been claimed to be associated with cholangiocarcinoma, but the evidence is weak.

TABLE 103-3 Predisposing Causes of Cholangiocarcinoma

Opisthorchis species– and *Chlonorchis* species–related cholangiocarcinoma are caused by eating raw fish [7] containing the larval stage of flukes. Because eating raw fish is more common among males in affected populations, liver fluke–associated cholangiocarcinoma is more common in males. The risk for cholangiocarcinoma in people infested with *Opisthorchis* species is related to the degree of infestation, as measured by stool egg count. [8] Infestation is associated with increased nitrate levels in body fluids, which is reversible upon treatment with praziquantel. [9] There is suggestive evidence from human [9] and animal [10] studies that *N*-nitroso compounds may be the carcinogens involved. Liver fluke infestation is also associated with development of intrahepatic stones. Intrahepatic gallstones are also associated with an increased risk for cholangiocarcinoma. [11] Cholangiocarcinoma may develop even after stone removal, if bile duct fibrosis induced by the stone disease leads to stasis and infection. [11]

Cholangiocarcinoma occurs in about 10% of patients with PSC. [12] Also, cholangiocarcinoma occurs 10 times more frequently in patients with chronic ulcerative colitis than in the general population. [13] PSC and ulcerative colitis often coexist; in such patients, as might be expected, the incidence of cholangiocarcinoma is even higher. [14] Cholangiocarcinoma also occurs in about 10% of patients with untreated choledochal cyst disease. [15], [16] Malignancy of the bile ducts and gallbladder in patients with choledochal cysts appears to be related to the presence of an anomalously high pancreatic duct–bile duct junction. This is discussed in the section on Carcinoma of the Gallbladder. Thorotrast-related cholangiocarcinoma is now largely a disease of the past because the agent has not been used since about 1940.

Molecular Genetics Studies in recent decades have shown that cancer results from the accumulation of multiple genetic abnormalities in a single cell. [17] This process of multistep carcinogenesis involves genes that control cell cycle progression and apoptotic cell death. Many of the specific genetic events responsible for neoplastic transformation in colon and pancreatic malignancies have been identified. [18], [19] Relatively less is known about the events responsible for neoplastic transformation in the biliary tract. The *erbB2* oncogene (also called the *HER2* oncogene or the *neu* oncogene) encodes a cell surface protein that interacts with several distinct cellular receptors, including the receptor for epidermal growth factor. [20] Overexpression of *erbB2* has been identified in tumors of the breast, ovary, stomach, pancreas, lung, and prostate. Several studies have examined expression of *erbB2* in cholangiocarcinomas. [21], [22] and [23] Although an early report suggested that expression of *erbB2* was present in less than 10% of cholangiocarcinomas, [21] studies from several other laboratories have identified *erbB2* expression in 67% to 73% of cholangiocarcinomas. [22], [23] Overexpression of the epidermal growth factor receptor has also been identified in some cholangiocarcinomas. [24] The *ras* genes constitute a distinct family of oncogenes that transduce proliferative signals from cellular receptors to the cell interior. [25] One member of this family, termed K- *ras* has been shown to be mutated in a significant fraction of colon, pancreas, and lung carcinomas. Several studies have demonstrated K- *ras* expression in cholangiocarcinomas. [24], [26], [27] and [28] Point mutations involving this gene may occur in more than half of all cholangiocarcinomas. [27], [28] Several other genes, including the *myc* gene [29] and *p53* gene, [30] have been studied in cholangiocarcinomas. These genes encode proteins that reside in the cell nucleus and control transcription of growth regulatory genes. Expression of the *myc* gene appears to be an almost universal feature of cholangiocarcinomas, [23] whereas *p53* expression has been identified in 50% to 80% of cholangiocarcinomas. [30], [31], [32] and [33] The studies cited here have just begun to characterize the genetic events responsible for the development of cholangiocarcinoma. It is interesting that the genes that have been linked to cholangiocarcinoma thus far, particularly *erbB2* K- *ras* and *p53* also appear to be involved in a high percentage of pancreatic carcinomas. [19] It is possible that this reflects exposure to common carcinogens in the biliary and pancreatic epithelium.

Pathology

Malignant tumors of the bile ducts are almost exclusively epithelial tumors (carcinomas). Tompkins and associates [34] reported that the distribution of extrahepatic bile duct cancers is 49% in the upper third, 25% in the middle third, 19% in the lower third of the duct; 7% of these cancers were diffuse. The Johns Hopkins group reported a distribution of 6% intrahepatic; 67% extrahepatic, upper duct (“perihilar”); and 27% extrahepatic, lower duct (“distal”). [1] It must be stressed that all such figures arising from surgical case series are heavily influenced by referral patterns and may not be representative of the disease generally.

Grossly, extrahepatic bile duct cancers can be divided into three types: polypoid or nodular masses, sclerosing, and diffusely infiltrating. Some cancers may present as only a thickening of the bile duct wall, which appears to be involved in dense fibrous scar. Polypoid or papillary cancers have the best prognosis.

Histological variants of adenocarcinomas of the bile duct include well-differentiated, pleomorphic, giant cell, adenosquamous, oat cell, and colloid carcinoma. Bile duct cancers have a tendency to spread along the bile duct. The longitudinal extent of cancers along the bile duct is often difficult to determine by gross examination. Shimada and colleagues [35] examined 29 cases by histological examination after resection and found that the mean distance of microscopic invasion beyond the gross margin was 16.8 mm toward the liver and 6.5 mm toward the duodenum.

Histological diagnosis of malignant bile duct cancers may be difficult at times. Well-differentiated cancers with little invasion are difficult to differentiate from the bile duct involved in scar formation or PSC. Cancers arising in the upper duct tend to be better differentiated with more sclerotic stroma that contains chronic inflammatory cells. [36] Perineural invasion (i.e., malignant cells within nerve sheaths), a prominent feature of bile duct cancers, is not present in PSC and is the single most important diagnostic criterion of malignancy. Other problems in differential diagnosis occur with cancers of the lower bile duct that involve the ampulla, duodenum, and pancreas. Because all of these sites may give rise to malignant tumors with similar characteristics, it may be difficult to determine site of origin conclusively. An important point is that bile duct cancers, as opposed to pancreatic adenocarcinomas, are somewhat less likely to metastasize widely. As a result, aggressive treatment of bile duct tumors is associated with a somewhat more favorable outcome.

Hilar tumors often arise in one of the main bile ducts and produce asymptomatic obstruction of that duct before progressing to obstruct the other main duct, which leads to jaundice. Unilateral obstruction results in atrophy of the affected side of the liver and hypertrophy of the other side. This phenomenon will also occur if there is unilateral portal vein occlusion. The clinical importance of atrophy has been emphasized by Blumgart and Stain. [37] Atrophy may result in axial rotation of structures in the hepatoduodenal ligament. For instance, with atrophy of the left hemiliver and hypertrophy of the right, the structures rotate in a clockwise direction when viewed from below, which hides the hepatic artery, rotates the bile duct to the left, and exposes the portal vein on the right side of the hepatoduodenal ligament in the usual

position of the bile duct. The effect of atrophy must be taken into account when adding liver resection to extrahepatic duct resections for cholangiocarcinoma.

Cholangiocarcinomas must also be differentiated from benign inflammatory tumors, [38] also called *hepatic inflammatory pseudotumors* and *benign fibrosing disease*. [39] These inflammatory masses mimic extrahepatic and intrahepatic cholangiocarcinomas but consist of chronic inflammatory cells and fibrosis. Benign inflammatory tumors appear to occur most frequently in extrahepatic upper ducts but also occur intrahepatically, [40] and less commonly in lower ducts. In a recent series of upper duct "tumors," this inflammation accounted for 13% of cases. [39] The failure to appreciate this diagnosis may lead to inappropriate therapies, such as long-term stenting or hepatic resection.

Bile duct cancers usually spread by direct extension to involve adjacent organs and tissues. Upper duct cancers may directly invade the liver. Cancers in the common bile duct or cystic duct may directly invade the gallbladder. Regional lymph node metastases are common, liver metastases distant from the primary occur occasionally, but distant metastases are unusual.

Intrahepatic cholangiocarcinomas grossly may be well or poorly demarcated, single or multiple. Mucin production, fibrosis between the acini of tumor tissue, and a more overtly glandular pattern are the main differentiating characteristics from hepatoma. Immunohistochemical staining for specific cytokeratins may also be helpful. Unlike hepatomas, some cholangiocarcinomas stain positively for CA 19-9 or carcinoembryonic antigen (CEA). It may be very difficult to distinguish between a liver metastasis of colonic or pulmonary origin and an intrahepatic cholangiocarcinoma.

Clinical Presentation

Extrahepatic upper duct and extrahepatic lower duct tumors are not usually separable on the basis of presenting symptoms. Most patients present with painless jaundice and its clinical constellation of dark urine, light stool, and pruritus. Nonspecific gastrointestinal symptoms such as anorexia and nausea, as well as mild weight loss and fatigue, are not unusual. Mild abdominal pain without jaundice may be the sole presenting symptom in upper duct cholangiocarcinoma; many patients with upper duct cholangiocarcinoma have had recent cholecystectomy, presumably because it was believed that gallstones were the source of these symptoms. Cholangitis is uncommon unless the biliary tree is instrumented. On examination, patients are usually jaundiced, and in the case of tumors arising below the insertion of the cystic duct, the gallbladder may be palpable.

Laboratory tests suggest extrahepatic biliary obstruction. Characteristically, the bilirubin rises over several weeks to a level of 20 mg/dL if the jaundice is unrelieved and the direct reacting fraction accounts for more than 50% of the total bilirubin. Marked elevation of serum alkaline phosphatase and ?-GT levels and mild elevation of transaminase levels are also usual.

Cholangiocarcinoma in patients with PSC is often associated with deterioration in clinical status and liver function tests. However, these signs are unreliable and late markers of cholangiocarcinoma. Cholangiocarcinoma may be present without any change in traditional liver function tests. [41] Furthermore, screening of patients at risk, such as those with PSC, using computed tomography (CT) scanning, ultrasound, and even endoscopic retrograde cholangiopancreatography (ERCP) is ineffective. [42] CA 19-9 is emerging as a better diagnostic marker. The Mayo group has reported that a cutoff of 100 IU was 89% sensitive and 86% specific for cholangiocarcinoma in PSC. [43] The King's College group recommend the use of an index that incorporates both CEA and CA 19-9 values and that has attained similar sensitivities for cholangiocarcinoma in PSC. [42] Bile CEA levels are reportedly elevated in cholangiocarcinoma, but not in benign diseases, other than intrahepatic stones. [44]

Intrahepatic cholangiocarcinomas characteristically present with nonspecific right upper quadrant pain. Other symptoms include weight loss and nausea. An intrahepatic cholangiocarcinoma may occasionally be critically situated in the central area of the liver and, as a result, may cause jaundice owing to obstruction of the main ducts by external pressure.

Diagnosis and Staging

Extrahepatic, Lower Duct Tumors The most common cause of painless jaundice or jaundice with mild pain in the cancer age group is pancreatic carcinoma. Consequently, both lower and upper duct cholangiocarcinomas are often initially suspected to be pancreatic carcinoma. The question of which is the best initial investigation of painless jaundice is controversial. Ultrasound, ERCP, and CT scan have all been advocated. Ultrasound has the advantages of low cost and lack of invasiveness, and it is the best test for detection of choledocholithiasis and cholecystolithiasis. In young patients with any pain or in older patients with pain that has characteristics of biliary colic, ultrasound is probably still the best first examination. Conversely, in the typical patient with painless jaundice, CT scan may be the best initial investigation. This is so because in most instances, when a periampullary mass is detected without evidence of metastatic spread, CT scan is the only investigation needed before proceeding to surgery or staging laparoscopy with ultrasound. When no mass is present on CT scan, a diagnostic ERCP is performed to determine the site and type of biliary obstruction.
Staging laparoscopy with ultrasound. Preoperative staging of the tumor is also of great importance. Ideally, staging locates and sizes all tumors in the body. The immediate goal of staging for the surgeon is to determine whether the tumor has spread beyond the limits of operative resection; this may be due to distant metastases or to the local extent of the tumor. For staging purposes in lower duct cholangiocarcinoma, *local extent* means the macroscopic limits of the tumor in relation to the portal vein and superior mesenteric artery. The value of staging laparoscopy with ultrasound in hepatobiliary-pancreatic malignancies has recently become evident. The importance of laparoscopy in staging hepatobiliary-pancreatic malignancy was demonstrated by Warshaw's group [45] and by John and associates. [46] We have found that additional staging information, proving that resection for cure was not possible, was obtained by this technique in 22 of 50 patients with hepatobiliary-pancreatic malignancies, who had been completely evaluated by conventional studies. [47] Of the remaining 28 patients, 26 were actually resectable for cure at the time of surgery. Staging lap- aroscopy permits evaluation of the peritoneal surfaces without laparotomy, and frequently metastatic implants are found. Laparoscopic ultrasound can detect vascular and distant nodal invasion, which makes the tumor inoperable [47] (Fig. 103-2). Others have found endoscopic ultrasonography useful in determining the extent of tumor involvement. [48] The role of positron emission tomographic scanning in staging cholangiocarcinoma is still investigational. [49], [50]

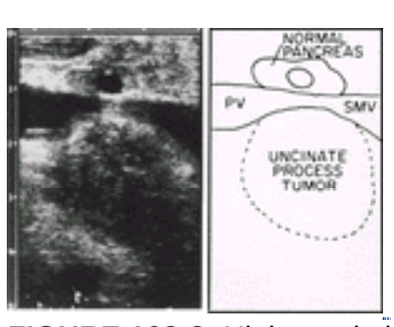

FIGURE 103-2. High-resolution laparoscopic ultrasound image demonstrating a 2.5- to 3-cm inhomogeneous hypoechoic mass in the uncinate process consistent with a pancreatic cancer. The tumor abuts the superior mesenteric vein (*SMV*) and portal vein (*PV*) posteriorly behind the neck of the pancreas, which itself appears to be normal. No evidence of actual vascular invasion is seen. At laparotomy, this adenocarcinoma was resected. (From ref. [47].)

Extrahepatic Upper Duct Tumors Altemeier and colleagues [51] and Klatskin [52] wrote classic papers on perihilar cholangiocarcinoma in an era in which the biliary tree was inaccessible to preoperative imaging. Consequently, both stressed the difficulty of diagnosing this tumor. Today, there are many imaging techniques that can display the tumor or its effects on adjacent vessels, including transabdominal ultrasound, CT scan, CT with angioportography, magnetic resonance imaging (MRI), percutaneous cholangiography (PTC), ERCP, positron emission tomography, angiography, endoscopic ultrasound, and laparoscopy with laparoscopic ultrasound examination. Diagnosis is usually based on history and imaging characteristics. Any patient who has a perihilar stricture, without evidence of ductal disease elsewhere in the biliary tree suggestive of PSC, and who has not had previous biliary surgery that might have resulted in stricture, is considered to have upper duct cholangiocarcinoma. Inflammatory pseudotumor is not ruled out by these considerations, and a confident diagnosis depends on pathological examination of tissue obtained at surgery or cytologic brushings obtained by ERCP or PTC. In a recent report covering 74 patients with biliary and pancreatic strictures, the sensitivity and specificity of brush cytology were 56% and 100%, and the positive predictive value was 100%. [53] Therefore, brush cytology is diagnostic and very useful when positive but of little value when negative. Because perihilar tumors are less accessible than lower duct or pancreatic neoplasms, it is unlikely that a sensitivity of 50% is being achieved in these tumors. Mucobilia on ERCP is an uncommon finding but highly suggestive of a papillary cholangiocarcinoma, which may be intrahepatic or

extrahepatic. [54] Fine-needle aspiration (FNA) is also useful if the mass can be seen on ultrasound examination or on CT scan. Another technique that we have used with success is to direct the biopsy needle at a stent placed through the site of duct narrowing. Staging is also of great importance in upper duct tumors. For staging purposes, *local extent* means the macroscopic limits of the tumor in relation to the biliary tree, especially the upper level of the stricture, and whether and to what degree invasion of adjacent vessels has occurred. The upper level of the stricture provides the information for the Bismuth stage. Blumgart [37] has described the indicators of unresectable bile duct cancers: bilateral intrahepatic bile duct spread, involvement of the main trunk of the portal vein, involvement of both branches of the portal vein or bilateral involvement of the hepatic artery and portal vein, or a combination of vascular involvement on one side of the liver with extensive bile duct involvement on the other. With vascular replacement, it may be possible to resect some cholangiocarcinomas previously considered unresectable. The local extent of the disease along the biliary tree has usually been determined by direct cholangiography—either ERCP or PTC (Fig. 103-3). Because the upper margin of disease is of most interest in these tumors, PTC has been generally favored over ERCP. However, today, ERCP has progressed to the point that a complete picture of the biliary tree can often be obtained even when the obstruction is complete. Magnetic resonance cholangiography is a new, less invasive method of evaluation of the biliary extent of perihilar cholangiocarcinoma. Although promising, it is too early to determine whether it will routinely provide the detail obtained by direct cholangiography (Fig. 103-4).

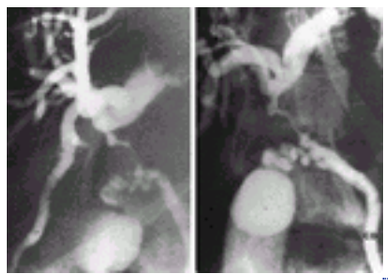

FIGURE 103-3. Cholangiogram shows a Klatskin tumor. The intrahepatic bile ducts are dilated and the size of the common bile duct (*CD*) is normal.

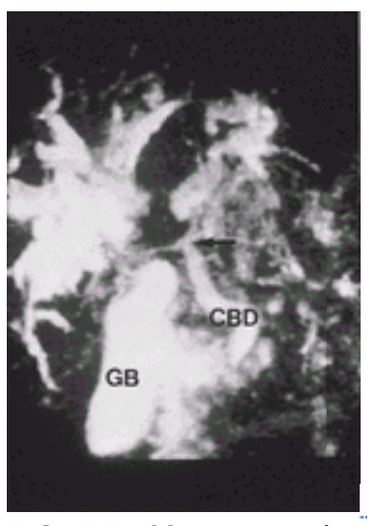

FIGURE 103-4. Magnetic resonance cholangiogram showing extrahepatic and intrahepatic biliary tract. Narrowing of bile duct produced by a hilar tumor is shown (*arrow*). GB, gallbladder; CBD, common bile duct. (Courtesy of Dr. Joseph T. Ferrucci, Department of Radiology, Boston University School of Medicine.)

Vascular invasion has been assessed by angiography, color-flow Doppler ultrasound, and MRI. Angiography is the gold standard for assessing vascular involvement but is also the most invasive. Our preference is for color-flow Doppler ultrasound because the tumor and its extravascular extent, as well as its effect on vessels, are seen in real time, and multiple detailed views of the tumor and its relationships may be obtained. Vascular deviation without narrowing is not evidence of unresectability. Color-flow Doppler ultrasound is very dependent on the skill of the ultrasonographer and on equipment. It has been claimed that Doppler ultrasound is effective in evaluating portal vein involvement (Fig. 103-5) but less so in examining the hepatic artery. [55]

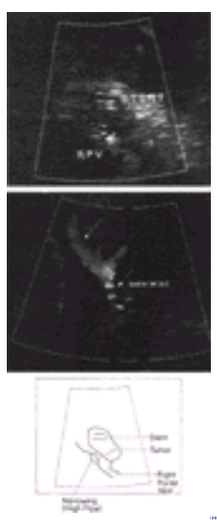

FIGURE 103-5. Flow Doppler ultrasonograms showing encasement of right portal vein by tumor. A stent that had been placed through the tumor can also be seen. Note that in the area of vein encasement, the color is yellow and blue, indicating higher-velocity flows than the red areas, in which the vein is not compressed.

Additional information on local extent of disease in or around the biliary tree can be obtained by laparoscopy with laparoscopic ultrasound, which permits close contact between the ultrasound probe and the tumor. [47] The best position for the probe is often the anterior surface of the liver, looking through a 2- to 4-cm thickness of liver into the porta hepatis. Using this method, we have been able to identify tumor extending along the intrahepatic ducts above the level that was evident by the upper level of the biliary stricture identified on direct cholangiography. Vascular encasement and lymph node involvement may be detected (Fig. 103-6). Bilateral biliary involvement to the point that all four sectional ducts [47] are involved precludes curative resection.

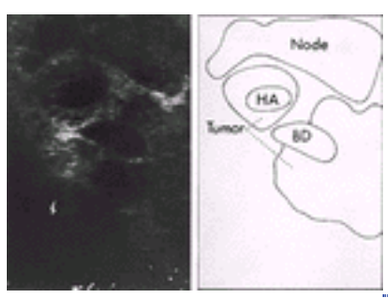

FIGURE 103-6. Laparoscopic ultrasonogram showing encasement of the hepatic artery (*HA*) and bile duct (*BD*). An enlarged lymph node that contains tumor is also seen.

Several factors preclude dogmatic statements regarding selection and order of investigation in extrahepatic upper duct cholangiocarcinoma. There are no good comparative studies examining this issue; there are so many potentially valuable investigations, and further developments in imaging are occurring so rapidly that it is

unlikely that good data will be realized; equipment and expertise vary from center to center; patients are often referred with several studies already completed; upper duct cholangiocarcinoma is often at presentation not distinguishable from lower duct cholangiocarcinoma or other malignancies causing complete obstruction of the lower duct, and consequently, initial investigation cannot be directed specifically to the perihilar region. The important considerations are that a combination of investigations must be used to achieve the goals of staging—evaluating the local extent of disease and whether it is metastatic—and that clinicians have a variety of algorithms to choose from to achieve staging. Our approach is given below.

Summary of our present algorithm for staging in extrahepatic cholangiocarcinoma. In the typical case of painless jaundice, a CT scan is obtained first. If there is a periampullary mass, the next step is staging laparoscopy with ultrasound unless therapeutic decompression of the biliary tree by ERCP or percutaneous stenting is indicated (see later). If no mass is seen, ERCP with brushings is performed when ductal dilation extends into the lower bile duct or when there is no ductal dilation. Either ERCP or PTC cholangiography with brushings is performed when only intrahepatic ducts are dilated, suggesting an upper ductal lesion. In the case of lower duct lesions, detection of a single stricture by ERCP is taken as evidence of a periampullary cancer, possibly cholangiocarcinoma, and the next investigation is staging laparoscopy with ultrasound. In the case of upper duct strictures, compatible with hilar cholangiocarcinoma, the next step is to evaluate vascular involvement by color-flow Doppler ultrasound; FNA is done at this time. In some cases, MRI is useful to assess liver invasion or vascular involvement not clearly identified on CT or flow Doppler ultrasound. Staging laparoscopy with ultrasound then follows for those patients who are still potentially resectable. The utility of staging laparoscopy in the operative assessment of extrahepatic cholangiocarcinomas has been recently validated in a large series from the Memorial Sloan Kettering Cancer Center. [56]

Intrahepatic Tumors Intrahepatic cholangiocarcinoma is in the differential diagnosis of the intrahepatic mass. Except for events such as mucobilia or tumor embolizing into the extrahepatic bile ducts, an event that may cause pain, jaundice, or even pancreatitis [57] (Fig. 103-7), intrahepatic cholangiocarcinoma does not produce highly characteristic findings. On axial imaging, the tumor may be single or multiple. Neither CT or MRI appears superior in characterizing these rare lesions. [58] On CT scan, the lesion is usually irregular or unencapsulated and of low attenuation with only mild enhancement seen with contrast. [58] The tumors are low attenuation on CT angioportography. [59] On T1-weighted MRI, the intrahepatic cholangiocarcinoma is usually of low intensity, but on T2-weighted images, they are of high intensity. [58], [60] Local vascular invasion is often seen by CT, MRI, [60] or angiography, [61] and ductal dilation is often present peripheral to the tumor. Centripetal filling in after gadolinium administration has been noted. [60] Liver biopsy is useful when focal nodular hyperplasia is likely on the basis of imaging studies, or the tumor is inoperable because of metastatic spread or extent in the liver. Otherwise, in potentially resectable cases, the next investigation after axial imaging by either CT or MRI is staging laparoscopy with ultrasound as for other hepatic masses. [46], [47]

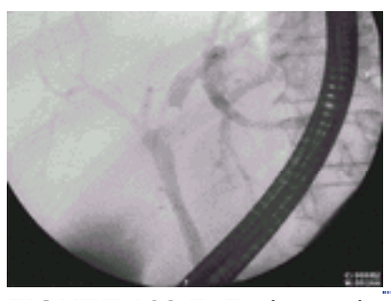

FIGURE 103-7. Endoscopic retrograde cholangiogram showing a bullet-shaped filling defect in the left hepatic duct. At surgery, this was found to be a tumor embolus from an intrahepatic cholangiocarcinoma. This patient presented with pancreatitis, presumably caused by such an embolus.

Preoperative decompression of the biliary tree in jaundiced patients. Three randomized studies have shown that jaundiced patients do not benefit from preoperative decompression of the biliary tree. [62], [63] and [64] However, these studies were performed in an era in which the most common surgical procedure performed after preoperative decompression was palliative surgical bypass of the biliary tree—a relatively short procedure associated with limited morbidity. No study has examined the potential benefit of preoperative decompression when the following operative procedure is either pancreaticoduodenectomy or liver resection. A recent study found that operative morbidity was greater in patients with hilar cholangiocarcinoma who had an aspartate aminotransferase level of more than 90 IU than in patients with lower levels. [65] Until definitive studies are available, preoperative decompression is still an option to be considered. In our opinion, it should be done if hemihepa- tectomy for cholangiocarcinoma is planned in a jaundiced patient or if a pancreaticoduodenectomy is to be done in a patient with longstanding or severe jaundice. Other preoperative preparations include correction of vitamin K deficiency and bowel preparation.

Treatment

Lower Duct Tumors Lower duct cholangiocarcinoma is one of the four types of periampullary tumors treated by pancreaticoduodenectomy, the others being pancreatic, ampullary, and duodenal cancers. The extent of the procedure is the same as that used for pancreatic carcinoma and will not be described in detail in this chapter. The procedure has reached a “near-zero” mortality rate in expert hands at tertiary care centers specializing in hepatobiliary-pancreatic surgery. [66] Often, the tissue of origin of the tumor, that is, whether pancreatic, ampullary, or bile duct in origin, is uncertain until after the specimen is examined pathologically, and even then, doubt can remain. The main complication of this procedure is a fistula from the pancreatic-jejunal anastomosis, which occurs in 5% to 10% of patients. [66] Biliary fistulas occur in about 2% of patients. Patients rarely die from these complications today because of improvements in diagnostic and interventional radiology, intensive care, and treatment of infection. [66] Resection of part of the stomach is no longer required for lower duct cholangiocarcinoma, although there is little or no difference in short-term outcome or quality of life [67] between the pylorus-preserving and standard types of pancreaticoduodenectomy. Many patients require pancreatic enzyme replacement after this procedure, but few become diabetic. Palliative treatment of unresectable lower duct tumors is by stenting and a combination of chemotherapy and radiation. The only randomized trial of surgical bypass versus endoscopic intubation favored the latter. [68] When unresectability is determined only after open exploration has been performed, a double bypass is performed to decompress the biliary tree and bypass the duodenum, which may become obstructed. Palliative resection of periampullary tumors may be unavoidable because the full extent of the tumor may not be detectable until the procedure is nearing completion; however, compared with upper duct tumors, this is an uncommon problem. Palliative resections for visceral cancers is an accepted procedure, for example, for colonic and gastric cancers, but has been avoided for periampullary tumors because of the risk of the procedure. Recently, however, an argument has been made in favor of palliative resection because the procedure can be now done with little risk. [69]

Upper Duct Tumors The goals of surgical resection are to remove the tumor with negative resection margins. This may be accomplished with or without an associated hepatic resection depending on the extent of the tumor. In some cases, it will be known preoperatively or by intraoperative staging with ultrasound that a liver resection will be required because the disease will have spread into the liver on one side. At other times, the need for a liver resection becomes apparent only intraoperatively, after exploration, or after the extrahepatic bile ducts are resected and microscopic disease is discovered on one side at the highest possible point of extrahepatic resection. Unfortunately, it is also at this point in the operation, when because of the discovery of bilateral microscopic involvement, it becomes clear that a curative resection has not been accomplished and is not possible. The same considerations apply to the discovery of microscopic involvement of vessels. Operative management is further complicated by the fact that frozen-section diagnosis of the presence or absence of tumor at the resection margin may be very difficult in these fibrotic cancers. A description of the operative technique is beyond the purposes of this text; however, the principal steps in the operation are as follows. The bile duct is divided at the level of the pancreas and a negative margin confirmed by frozen section. The bile duct and gallbladder are dissected off and away from the portal vein and hepatic arteries, leaving the latter structures bare; that is, all nodes and soft tissue are taken with the specimen. The bile ducts and surrounding tissue are freed to above the bifurcation where the tumor is situated, until macroscopically normal ductal tissue is encountered in the right and left bile ducts. These ducts are divided and frozen sections obtained. Coring out of liver tissue in the porta may permit excision to the level of the first branches of the right and left bile ducts. If the tumor has grown too far up one side to perform an extrahepatic resection, the bile duct is divided on the side to be retained, and the liver, bile ducts, and vascular structures are removed on the other side. Reconstruction is by a Roux-en- limb, 60 cm in length, to avoid reflux of intestinal contents into the biliary tree. Cholangiocarcinoma commonly invades caudate bile ducts, and caudate resection is routinely performed by some surgeons for upper duct cholangiocarcinoma. This area must be carefully evaluated at surgery and caudate resection performed if there is any question of caudate invasion. The important trends in surgery of upper duct cholangiocarcinoma are that a higher percentage of upper duct tumors are being resected, [70] largely owing to the more common use of liver resection, [71] vascular resection and reconstruction are becoming more common, and surgical morbidity and mortality are decreasing. Mortality is 5% or less. [72], [73] and [74] Because liver resection combined with hilar duct resection is performed for more advanced disease, comparisons between local resection and local resection plus liver resection for outcomes, such as percentage of procedures obtaining negative margins and survival, are meaningless. The results of surgical resection depend highly on whether negative resection margins are achieved. [65], [75], [76], [77], [78] and [79] There are almost no 5-year survivors when resection margins are positive. [65], [79], [80] Other negative prognostic variables are tumor stage, [78] nodal disease, [54], [78] tumor grade, [65], [80] bilirubin concentration, [65], [80] and absence of mucobilia. [54] When negative margins are obtained, the 5-year survival rate varies from 11% to 43% in recent series. [1], [65], [78], [79] and [80] Again, it must be stressed that these results are in small numbers of highly selected patients. The median survival of patients with tumor-free margin is 3 to 3.4 years, compared with a median survival of 1 to 1.2 years for patients with disease at the resection margins. Palliation of unresectable upper duct tumors may be by percutaneous [81] or endoscopic intubation or by surgical bypass. There have been no randomized trials. Metallic stents have extended the functional period of stents. Plastic stents typically clog at 3 to 4 months, whereas metal stents last 8 [82] to 10 [83] months. Surgical treatment is by biliary enteric bypass, usually employing the duct to segment III, the so-called Bismuth-Corlette procedure. [84] Bypass to

right-sided ducts is more difficult and less successful. Surgical implantation of large-bore tubes through the tumor has been used in the past but is rarely employed now.[85, 86] Both surgical bypass and internal stenting have proponents.[70, 78, 87] Stenting has the advantage of initial low morbidity and the disadvantages of occasional failure to clear jaundice, bouts of cholangitis, and the need for repeated procedures to deal with stent obstruction. With improvement in techniques of stenting, one may expect resolution of jaundice in 80% of patients, with a 10% major morbidity rate, a 30-day mortality rate of about 5%, and a median survival of 8 months.[88] Surgical bypass requires a major open surgical procedure and has corresponding early morbidity,[70] but the complete clearance of jaundice is usual, and cholangitis is uncommon. There are many nonrandomized comparisons of these techniques, but all are contaminated by patient selection and consequently are of little value in determining which technique is superior. For instance, greater success in clearing jaundice by surgical bypass may partly reflect an earlier stage of disease. Patient selection is probably quite appropriate in this disease. Younger, healthier patients, in whom bypass to segment III will decompress 40% to 50% of the liver, probably should have surgical decompression; whereas older patients, especially those with intercurrent disease or in whom decompression will provide biliary drainage from less than 40% of liver mass, should be treated by nonsurgical means.[89] Radiation therapy has been used alone or in combination with other techniques. Its value is unclear because most series are small and no randomized comparisons exist. External-beam irradiation was successful in clearing jaundice in 10 of 11 patients in a recent report; no other decompressive measures were used.[90] Brachytherapy has been applied through percutaneous tubes, with a median survival of 23 months.[91] The combination of surgery and radiotherapy was reported to provide a median survival of 14 months in unresectable or recurrent disease.[92] Another series reported no benefit to radiation.[93]

Intrahepatic Tumors The principles of treatment are as for other malignant intrahepatic hepatic lesions.[94] The tumor must be resected with a margin of normal tissue to obtain microscopically free resection margins (a 1-cm tumor-free resection margin is the goal) yet leave enough normally functioning liver tissue behind for the patient to have adequate liver function in the postoperative period. The size of the resection may vary from a single segment or less to resection of three of the four hepatic sections.[95] Like upper duct tumors, results depend on whether negative resection margins are achieved. There are few case series that separate out these uncommon tumors from other cholangiocarcinomas. One recent series obtained a 5-year survival rate of 44%[1] in 18 patients, whereas another reported a 32% 2-year survival rate in 19 patients.[96] Liver transplantation has been performed for intrahepatic and upper duct cholangiocarcinoma, but the results have been disappointing. In Klintmalm's series, only 3 of 14 patients (21%) lived more than 28 months after the procedure,[97] whereas Shimoda's series of 25 patients reported a 3-year survival of 32%.[98] Although these are not poor results for a visceral cancer, they must be evaluated with the knowledge that many patients with end-stage chronic liver disease are dying while on a waiting list for liver transplantation, and the comparative survival rate in this group of patients would be expected to be about 90%. In general, liver transplantation is not a treatment for this disease at the present time.[78, 97]

BENIGN BILE DUCT TUMORS

Benign tumors are uncommon. Most information comes from case reports. The clinical presentation is similar to that of choledocholithiasis: pain, jaundice, and less commonly, cholangitis or pancreatitis. Adenomas are the most common benign tumors of the bile ducts. They may be single, multiple, tubular, papillary, or mixed. Multicentricity has been reported but is uncommon. Cystadenoma and granular cell tumors are rare benign tumors of the extrahepatic bile ducts. Cystadenomas are similar to and may coexist with cystadenomas of the liver and pancreas.[99] Granular cell tumors are unusual, occur most commonly in black women, and may be associated with granular cell tumors at other sites.[100, 101] The malignant potential of these lesions is unknown. Reported benign mesenchymal tumors include fibromas, lipomas, leiomyomas, and neurilemomas.

Papillomatosis is a rare condition in which multiple papillary lesions involving a large amount of the bile duct mucosa may be encountered. Because malignant transformation or progression to invasive carcinoma has been reported, papillomatosis of the bile duct mucosa should be considered a premalignant lesion.[102, 103] This lesion should be treated by complete excision if possible; if not, regrowth is common.

CARCINOMA OF THE GALLBLADDER

Carcinoma of the gallbladder is the fifth most common malignancy of the gastrointestinal tract.[104] Like information on cholangiocarcinoma, studies of gallbladder cancer tend to be small case series covering many years, and claims for the best orm of investigation or treatment must be cautiously interpreted. Cancers arising from gallbladder mucosa appear to behave in a fashion similar to other adenocarcinomas of the gastrointestinal tract; premalignant to invasive malignant changes can be found, metastatic spread occurs by lymphatic and vascular routes, diagnosis is often delayed, and survival is related to stage. Interestingly, at the population level, mortality is also inversely related to cholecystectomy rates.[105]

Incidence

The highest incidence of gallbladder cancer occurs in Chileans and Bolivians.[106] Gallbladder cancer is the fourth leading cause of all cancer deaths in Chile; mortality from gallbladder cancer (5.2%) in Chile is the highest in the world.[107] Other commonly affected population groups include Native Americans, Hispanic American women, Latin American women, Japanese women in Japan, African Zimbabwian women, European immigrant women in Israel, and northern Europeans.[108] In contrast to the general population of the United States, in whom the incidence is low at about 3 per 100,000, gallbladder cancer is the most common gastrointestinal malignancy in Native Americans. Low rates of gallbladder cancer occur among Nigerians, New Zealand Maoris, and Chinese natives and immigrants.[108]

Cancer of the gallbladder in the United States is a disease of elderly people, with the greatest incidence occurring after 65 years of age. It is three times more common in women than in men, and it is more common in whites than in blacks. Genetic differences are exceedingly important. In North America, the highest incidence of gallbladder cancer occurs among Native Americans and Mexican Americans. In North and South America, gallbladder cancer is related to Indian rather than Spanish heritage because the incidence of gallbladder cancer in Spain, Cuba, and Puerto Rico is low. In Mexico, mestizos (people of mixed ancestry) have the highest incidence, whereas in Bolivia, there appears to be a difference based on tribal origin (language).[109]

Etiology

Etiologic factors that appear to be or have been claimed to be important for the development of gallbladder cancer include genetic characteristics, gallstone disease, bile composition, calcification of the gallbladder wall, anomalous junction of the biliary and pancreatic ducts, congenital biliary cysts, some infections, environmental carcinogens, and drugs. Geographic differences may reflect racial and genetic differences, although cultural differences possibly play a role. A progression from dysplasia to early cancer to metastatic cancer has been observed,[110] the progression from dysplasia to cancer taking about 15 years.

Gallstone disease is associated with gallbladder cancer, but the mechanism is unknown. Most reports of the relationship between gallstones and gallbladder cancer have come from operative or autopsy studies; however, a prospective cohort study of patients with gallstones found that gallstones did increase the risk for gallbladder cancer, but the actual incidence was very low (9 per 10,000 per person-years), and the absolute number of cases of gallbladder cancer (5 of 2583 people) in this population was low.[111] The incidence of gallbladder cancer in patients with cholecystolithiasis ranges between 0.5% and 3%.[112] Cholecystolithiasis is present in 70% to 90% of patients with gallbladder cancer. Duration of gallstones, patient age, size of gallstones, and possible carcinogenic effects of gallstones, such as from the chemical composition or bacteria within the stones, may be important,[113] although in a recent study, patients with cancers did not have larger stones, nor were their stones of higher cholesterol content.[109]

Duration of cholecystolithiasis appears to be a crucial factor for the development of cancer. Patients who have had cholecystolithiasis for longer than 40 years have a significantly higher incidence of gallbladder cancer than those who have had gallstones for a shorter time. Glenn and Hays[114] suggested that 1% of patients older than 65 years of age with gallstones would develop gallbladder cancer. This more likely reflects the duration of stone disease rather than an effect of age. However, the possibility of cancer is not an indication for cholecystectomy in a patient with asymptomatic stones. In many countries, gallbladder cancer is unknown, which is probably related to the rate of cholecystectomies performed for asymptomatic gallstones or early in the course of patients with symptomatic stones.

Little is known about the pathophysiology of gallbladder cancer in patients with cholecystolithiasis. Chronic irritation of gallbladder mucosa by stones, followed by repeated episodes of epithelial repair over a period of years, may lead to malignant transformation. The chemical composition of stones or bile may be related to development of gallbladder cancer. Indeed, because bile from high endemic areas is more mutagenic than that from low endemic areas,[115] there is probably some factor excreted by the liver into bile that contributes to malignant transformation. Cholesterol stones are the most common type associated with gallbladder cancer. Bile acids can act as co-carcinogens, and there is a structural similarity to the known carcinogen, methylcholanthrene. In the most comprehensive analysis yet, Strom and colleagues[109] performed a case-control study in Mexico and Bolivia that compared patients with gallbladder cancer, patients with gallstones, and patients with no

biliary tract disease. Their prior hypotheses that patients with tumor would have increased levels of lithocholate was not confirmed, but bile glycoursodeoxycholate levels were unexpectedly elevated in the patients with cancer. This paper must be read to appreciate the difficulty of doing and interpreting such a combined epidemiologic and biochemical study. For instance, the authors were unsure at the end of their study whether their unexpected findings in bile acid composition were a cause or effect of the tumor. There are no conclusive data linking bile composition of bile acids to carcinoma of the gallbladder. Because bile is the main route of excretion of dietary or chemical metabolites with molecular weight of more than 500, there are a very large number of potentially carcinogenic compounds.

A number of recent studies from Japan have linked anomalous pancreatic-biliary duct junction (APBJ) to gallbladder and extrahepatic bile duct cancer. [116], [117] and [118] There is a much higher incidence of biliary tract cancer in patients with APBJ. About 2% of Japanese patients examined had APBJ. About 75% of these cases were associated with a choledochal cyst, the rest having normal-caliber bile ducts. In those associated with choledochal cyst, cancer may arise in the extrahepatic duct or gallbladder, whereas in those without ductal dilation, the cancer seems almost always to occur in the gallbladder. [116], [117] Cancer of intrahepatic ducts does not appear associated with APBJ. Patients with APBJ get cancer at a younger age than patients with sporadic gallbladder cancer. [117] Pediatric patients with APBJ frequently have epithelial hyperplasia of the gallbladder. [119] The nonmalignant areas of the gallbladder of patients with APBJ-associated gallbladder cancer show increased hyperplastic changes in the gallbladder mucosa compared with patients with sporadic gallbladder cancer. [120] In a cat model, side-to-side biliary-pancreatic anastomosis produced hyperplastic changes in the gallbladder within 6 months. [121]

Another factor that has been associated with gallbladder cancer is partial or complete calcification of the gallbladder wall (porcelain gallbladder). Although an incidence of coexistent gallbladder malignancy of up to 25% has been claimed in patients with porcelain gallbladder, recent data suggest that this is less common. [122] Others have questioned whether porcelain gallbladder is linked to gallbladder carcinoma at all. [123] *Salmonella typhi* carriage; exposure to toxic environmental factors in the automotive, rubber, textile, and metal industries [36], [106], [124]; previous gastric operations [125]; and elevated body mass index [109] have been associated with gallbladder cancer.

Molecular Genetics There are relatively few studies examining the molecular events in carcinoma of the gallbladder. As in cholangiocarcinomas, the *erbB2* oncoprotein is expressed in a significant fraction of gallbladder cancers. [126] Furthermore, transgenic mice that express *erbB2* in the gallbladder epithelium develop gallbladder carcinomas. [127] Data regarding the expression of *ras* and *myc* genes in gallbladder cancer are conflicting, [126], [128], [129] but it appears that the expression of these genes is substantially less than in cholangiocarcinomas. Similarly, point mutations involving the K- *ras* gene appear to be less common in gallbladder cancer than in cholangiocarcinomas. [129] Several studies have identified *p53* expression in gallbladder cancers; about two thirds of such tumors express *p53*. [33], [130] Such overexpression is not seen in adenomas.

Pathology

As noted, there is a progression from dysplasia to carcinoma in situ to invasive cancer in the gallbladder epithelium that appears to take about 15 years. [110] Premalignant lesions are associated with gallbladder cancer, and it is thought that chronic inflammation may play a role in development of premalignant lesions. [36] Two types of metaplasia, intestinal and squamous, have been found in patients with gallbladder cancer. The relation of intestinal metaplasia to subsequent development of gallbladder cancer has not been determined. Squamous metaplasia, in which squamous epithelium replaces the normal gallbladder epithelium, is a rare premalignant lesion that has been found with squamous cell cancer of the gallbladder. Cholecystitis follicularis, a rare type of inflammation, has been reported in a few cases of gallbladder cancer, but its premalignant potential is unclear. [36]

The classification of malignant lesions of the gallbladder is shown in Table 103-4. Sixty percent of cancers of the gallbladder are found in the fundus, 30% in the body, and 10% in the neck. They may be isolated or involve the entire gallbladder through intramural spread, analogous to linitis plastica of the stomach.

TABLE 103-4 Malignant Neoplasms of the Gallbladder

Most malignant neoplasms of the gallbladder are adenocarcinomas, which behave in a manner similar to adenocarcinomas arising from other epithelial tissues. They originate as mucosal lesions, and as growth progresses, they invade the wall of the gallbladder. The anatomy of the gallbladder wall partly explains the advanced stage of disease at which most patients with gallbladder cancer present. The lack of a well-defined muscularis leads to early entry of invasive gallbladder cancer into the perimuscular connective tissue. Lymphatic, neural, and hematogenous invasion occurs earlier with gallbladder cancer than with cancers of the gut.

Gallbladder cancer frequently extends beyond the gallbladder to involve the liver and the extrahepatic biliary tree. Most patients with liver involvement have direct extension of the disease; fewer than 10% of patients have liver metastasis without full-thickness invasion of the gallbladder wall. The routes of lymphatic drainage of the gallbladder have been studied in an attempt to rationalize aggressive surgery for cancer of the gallbladder. Uesaka and colleagues [131] injected a carbon particle suspension into the primary drainage nodes—the cystic and peri- choledochal nodes. The main route of drainage was on the right side of the bile duct to the superior retropancreatic node and from there directly to the paraaortic nodes or indirectly to the paraaortic nodes through posterior pancreatic nodes. Drainage to the left side of the bile duct to the celiac nodes and drainage upward to the hilar nodes and into segment IV of the liver were much less common modes of drainage. Lymph node metastasis to the cystic, pericholedochal, peripancreatic, and celiac nodes occurs early; more than 50% of patients are found to have lymph node metastases at the time of diagnosis. Direct invasion of the duodenum and the colon also occur. Intraperitoneal spread, Krukenberg tumors (i.e., ovarian metastases), and hematogenous dissemination occur.

A uniform staging system for gallbladder cancer has not been widely applied. Nevin and colleagues [132] developed the first clinically useful staging system. The TNM system, described by the American Joint Committee on Cancer, is the preferred staging system. [3] Survival of patients with gallbladder cancer is related to stage and histological type of cancer. Lymph node involvement is rare in stage T1 tumors [132], [133]; that is, lymph node involvement almost never occurs until the muscularis has been penetrated. After that lymph node involvement is common, occurring in about 50% of stage II patients and in 70% to 80% of patients in stage III and IV. [132], [133] There is a close correlation between lymph node involvement and prognosis. [134], [135] and [136] Most long-term survivors are patients with well-differentiated tumors that were minimally invasive. These are usually found incidentally at or immediately after cholecystectomy (Fig. 103-8).

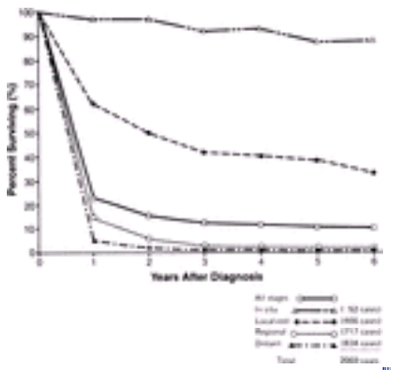

FIGURE 103-8. Gallbladder cancer survival rates by stage in all races and genders from 1973 to 1981. (From ref. [36].)

Clinical Presentation

Signs and symptoms of gallbladder cancer are nonspecific. This explains the delay in diagnosis in most patients with gallbladder cancer. In TNM stage I and II symptoms often mimic those of cholelithiasis and cholecystitis. [137] Indeed, in early stages, the cause of symptoms may be the associated cholelithiasis. Pain is the most common initial complaint; it may be dull and aching, colicky, sharp, constant, or intermittent, and it may or may not radiate to the back. Other symptoms include nausea, vomiting, and anorexia. In later TNM stages, weight loss, jaundice, hepatomegaly, a palpable mass, or ascites may develop. Jaundice develops in 30% to 60% of patients and is a poor prognostic sign because it is caused by extension of the tumor beyond the gallbladder, with obstruction of the extrahepatic bile ducts; 85% of patients with jaundice have unresectable tumors. [112] The patients may also have obstruction of the duodenum or colon. Malignant cholecystoenteric fistula may be the first indication of gallbladder cancer.

Diagnosis and Staging

In most cases, the diagnosis is not made preoperatively [112]; this is true even in recent series. [138] Laboratory findings are not diagnostic but are related to abnormalities associated with bile duct obstruction. Patients frequently have increased alkaline phosphatase and bilirubin levels. Blood levels of CEA or CA 19-9, another tumor marker, may also be elevated. These findings are not diagnostic because they may have other causes.

Diagnostic techniques include oral cholecystography, ultrasonography, CT scanning, and possibly MRI. The most widely employed diagnostic study for biliary tract disease is ultrasound. Findings on ultrasonography that are suggestive, but not diagnostic, of gallbladder cancer include thickening of the wall, a mass projecting into the lumen, calcification of the gallbladder, multiple masses or a fixed mass in the gallbladder, a mass extending into the liver, or an extracholecystic mass. In a comparison of patients with unsuspected gallbladder cancer and patients with benign gallbladder disease, it was found that solitary stone, displaced stone, intralumenal mass, and invasive mass were more commonly associated with cancer. [139] A report of mucosal thickening should also be viewed with suspicion. CT scanning may help in the diagnosis but is of limited help in staging the disease except in estimating the extent of hepatic invasion [140] (Fig. 103-9).

FIGURE 103-9. Computed tomography scan of patient with carcinoma of the gallbladder (*GB*) showing invasion of hepatic parenchyma (*arrow*).

Gallbladder polyps may be malignant but are rarely so when smaller than 1 cm in diameter. In a recent series of 103 patients with gallbladder polyps, none was malignant if less than 1 cm in diameter, but 23% of polyps larger than 1 cm were malignant. [141] In another series, 88% of polyps larger than 1 cm in diameter were malignant, and polyps larger than 1.8 cm were more likely to contain a more advanced stage of cancer. [142] FNA appears to be an accurate way of distinguishing between polyps due to cholesterolosis and neoplastic polyps, [143] especially when the polyps are larger than 1 cm in diameter [144]; however, it is much less accurate in determining whether a neoplastic polyp is an adenoma or carcinoma. [144] Duplex Doppler ultrasound imaging of blood flow within a neoplastic polyp may also be useful in distinguishing these lesions from cholesterol polyps.

Many of the staging considerations are similar to those discussed under cholangiocarcinoma. Staging laparoscopy with ultrasound appears to have many of the same advantages for staging of gallbladder cancer that it has for other hepatobiliary malignancies. [46], [47], [145]

Treatment

Both treatment and prognosis of gallbladder cancer depend on stage of disease. [132] Unfortunately, most cancers are diagnosed when symptomatic, and at that time, the stage of disease is usually TNM III or IV. [135], [146] Because most patients in advanced stages are not resectable, the stage distribution at the time of open surgery has been more heavily weighted to later stages than the stage distribution of patients actually resected for cure. For instance, in a German series of 81 operated patients, the TMN stage distribution (I to IV) was 7%, 12%, 15%, and 66%, [135] whereas the stage distribution of 106 radically resected cases in a Japanese series was 14%, 43%, 24%, and 19%. [133] It is to be hoped that staging laparoscopy with ultrasound will alleviate this disparity and reduce the number of patients having open exploration without resection. Of the 106 patients in the Japanese series, curative resection was achieved in 74. Most of the noncurative resections were in patients with stage IVb cancer. [133] In a recent American series containing 149 patients, 58 cancers were explored, and of those, 23 were resected for cure. [135] As previously noted, these types of figures may not be representative of the broad population of patients contracting the disease.

There are no established principles of treatment because no definite trials establishing these exist. At best, there are rational guidelines based on the facts that T1 lesions rarely have metastasized to lymph nodes but T2 to T4 lesions have usually done so [132], [133] and that radical surgery achieving negative tumor margins has resulted in acceptable results in more advanced disease. [147] There are several levels of resection. In increasing order of magnitude they are (1) extraserosal cholecystectomy or cholecystectomy with wedge resection of the liver, (2) extraserosal cholecystectomy combined with portal lymph node dissection and sometimes extrahepatic bile duct resection, (3) liver resection with cholecystectomy and lymph node dissection and sometimes extrahepatic bile duct resection, and (4) the most radical—liver resection with cholecystectomy and lymph node dissection combined with pancreaticoduodenectomy.

Beginning with the earliest stages, the recommendation for treatment may be summarized as follows. When gallbladder cancer is suspected, an open procedure should be performed. If there is no evidence of spread outside the gallbladder, an extraserosal cholecystectomy should be done. An extraserosal cholecystectomy excises the gallbladder on a deeper plane than a standard cholecystectomy, so that the gallbladder and all connective tissue down to actual liver tissue are removed. This can be done laparoscopically; however, it is our opinion that it should not be attempted because gallbladder perforation and bile spillage are more common in the laparoscopic technique. The negative consequences of tumor implantation or incomplete excision far outweigh any benefit of minimally invasive surgery. The excised specimen should be inked. If resection margins are negative and if the tumor has not penetrated the muscularis (T1 lesion), the procedure is considered to be complete. If margins are positive or if the muscularis has been penetrated, then resection of segments 4b and 5 and a lymph node dissection are performed. If the cystic duct resection margin is positive, then, in addition, the extrahepatic bile duct is excised to clear margins.

When there is obvious penetration to the serosal layer on the deep surface of the gallbladder by intraoperative ultrasound or palpation, then resection of the gallbladder with segments 4b and 5 and a lymph node dissection with or without extrahepatic bile duct resection is the recommended procedure. Sometimes, because of the local depth of penetration into the liver, a more extensive liver resection is required. Stated otherwise, a cholecystectomy is usually sufficient for T1 lesions and usually results in cure. For T2 to T4 lesions, the extent of resection depends on the route of direct extension, whether into the liver or bile duct; a lymph node dissection is always done.

Results in recent case series [133], [135], [147], [148] appear to show marked improvement over classic reports. Mortality is infrequent, even for major resections, but there is a complication rate of about 25%, including minor complications. Exact comparisons among series are not possible because different operations have often been done for the same disease stage. For long-term survival, a curative resection with negative margins must be obtained. If negative resection margins are achieved, 5-year survival rates according to stage are about as follows: stage I, 90%; stage II, 80%; stage III, 40%; and stage IV, 15%. Prognosis in stage IV appears best when the tumor is placed in this category because of local hepatic invasion, rather than because of lymph node involvement. [135] Lymph node involvement is an ominous sign, [135] although 5-year survivors have been reported in some series. [133], [148] Based on the pattern of lymph node drainage, a pancreaticoduodenectomy has been performed for T2 to T4 disease. [149] However, the results have still been poor in advanced stages.

Palliation of gallbladder cancer mainly requires treatment of obstructive jaundice. The considerations are the same as for cholangiocarcinoma, except that percutaneous or endoscopic means of decompression are preferable in this rapidly progressive state. Chemotherapy is experimental and of no proven benefit. [150] Although some gallbladder cancers may be radiosensitive, [151] radiation therapy provides little survival benefit because of the extent of tumor at the time of diagnosis. Palliation of jaundice has been reported, and intraoperative irradiation may be beneficial. [152], [153] Although these types of treatments should be considered, their role has not been defined.

Incidental Gallbladder Cancer at Laparoscopic Cholecystectomy Gallbladder cancer may be an incidental finding at laparoscopic cholecystectomy, as it was at open cholecystectomy in the past; the incidence ranges from 0.3% to 1%. The difference in the present era is that port-site implantation may occur. [154], [155] Port-site implantation may simply be due to contact between the malignancy and the tissues at the perimeter of the port site at the time of gallbladder extraction. However, positive-pressure pneumoperitoneum appears to be another factor. [156] Preoperative suspicion should be raised by the ultrasonographic findings listed previously. Extraction of the gallbladder in a plastic bag is prudent when these signs exist or when there is evidence of gallbladder wall thickening at surgery. Every gallbladder should be inspected at the time of extraction and questionable areas resected for biopsy. If a cancer is discovered, it should be treated at that time using the principles stated previously. The tissue surrounding the trocar ports should also be excised as part of the treatment because seeding may have occurred. Early reoperation is the approach of choice when the tumor is discovered on later pathological examination, when surgery at the time of the initial procedure could not proceed because of uncertainty of diagnosis or degree of penetration of the tumor, or when the surgeon believes that the proposed procedure must be discussed with the patient. Stage I gallbladder carcinomas that have clear resection margins probably require no further surgical treatment.

BENIGN TUMORS OF THE GALLBLADDER

Benign tumors of the gallbladder are uncommon and infrequently symptomatic. Benign epithelial tumors include adenomas and mixed tumors. Adenomas may be tubular, papillary, or mixed. One third are multiple, and fewer than 50% are associated with stones. Benign tumors may be symptomatic, causing biliary colic, presumably as a result of shedding of tumor, which temporarily obstructs the cystic duct. Treatment is laparoscopic cholecystectomy when the mass is symptomatic and less than 1 cm in diameter. Cholecystectomy is performed for either symptomatic or asymptomatic tumors when the mass is larger than 1 cm in diameter because of the possibility of malignancy and for the same reason the procedure is performed open. FNA may permit the diagnosis of cholesterolosis, in which case surgery is necessary only if symptomatic and laparoscopic surgery may be performed. (see earlier).

Other problems with which benign tumors of the gallbladder are confused are much more common than benign tumors of the gallbladder. These include cholesterolosis and adenomyomatosis. The former is a disease of unknown etiology in which cholesterol accumulates focally, segmentally, or diffusely in the gallbladder. Focal cholesterolosis may present as a polyp and be confused with a tumor. Adenomyomatosis goes by a variety of other names as well. It is a condition in which there is nonneoplastic ingrowth of gallbladder glands into the wall of the gallbladder and even penetration of the wall. The cause is unknown. It may be focal or diffuse. When focal, the site is usually in the fundus, producing the characteristic fundal adenomyoma. When diffuse, it produces wall thickening. Both types may be confused with malignancy. There are characteristic changes on ultrasound and contrast cholangiography, which help differentiate the process form cancer. Benign mesenchymal tumors are rare and include leiomyoma, hemangioma, and lipoma.

CHAPTER 104

Glen A. Lehman and Stuart Sherman

SPHINCTER OF ODDI DYSFUNCTION (POSTCHOLECYSTECTOMY SYNDROME)

Sphincter of Oddi dysfunction (SOD) is a major consideration in patients with postcholecystectomy syndrome, which may be broadly defined as persistence or recurrence of upper abdominal symptoms, especially right upper quadrant pain, after cholecystectomy. If the cholecystectomy was done for vague or nonspecific symptoms, which were in reality not pancreatobiliary in origin, persistence of symptoms is not surprising. If, however, the cholecystectomy was done for clinically apparent biliary colic or cholelithiasis, then recurrence of symptoms is of more concern for organic disease, such as common duct stones or SOD. Common duct stones are discussed in Chapter 102. This chapter focuses primarily on the discussion of SOD.

DEFINITIONS

We assume that patients with postcholecystectomy syndrome, upper abdominal pain suggestive of biliary colic, undergo appropriate invasive and noninvasive evaluation to rule out common duct stones, tumors, or strictures near the cholecystectomy site. The residual group of patients has a high frequency of SOD. SOD refers to benign, noncalculous obstruction to flow of bile or pancreatic juice through the pancreaticobiliary junction, that is, the sphincter of Oddi (SO). [1] SOD may be manifested clinically by pancreaticobiliary pain, pancreatitis, or deranged liver function tests. SO dyskinesia refers to a motor abnormality of the SO, which causes a hypertonic sphincter. In contrast, SO stenosis refers to a structural alteration of the sphincter, probably from an inflammatory process, with subsequent fibrosis. Because it is often impossible to distinguish patients with SO dyskinesia from those with SO stenosis, the term SOD has been used to incorporate both groups of patients. In an attempt to deal with this overlap in etiology, and also to determine the appropriate use of SO manometry (SOM), a clinical classification system has been developed for patients with suspected SOD [2] (Hogan-Geenen SOD classification system; Table 104-1) based on clinical history, laboratory results, and endoscopic retrograde cholangiopancreatography (ERCP) findings. A variety of less accurate terms—such as papillary stenosis, ampullary stenosis, biliary dyskinesia, and postcholecystectomy syndrome—are listed in the medical literature to describe this entity. The latter term is somewhat of a misnomer because SOD may clearly occur with an intact gallbladder.

TABLE 104-1 Hogan-Geenen Sphincter of Oddi Classification System Related to the Frequency of Abnormal Sphincter of Oddi Manometry and Pain Relief by Biliary Sphincterotomy

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY

The SO is a small complex of smooth muscles surrounding the terminal common bile duct, the main (ventral) pancreatic duct of Wirsung, and the common channel (ampulla of Vater), when present. It has both circular and figure-of-eight components. The high-pressure zone generated by the sphincter is variably 4 to 10 mm in length. Its roles appear to be to regulate the flow of bile and pancreatic exocrine juice and to prevent duodenum-to-duct reflux (i.e., to maintain sterile intraductal environment). The SO possesses both a variable basal pressure and phasic contractile activity. The former appears to be the predominant mechanism for regulating outflow of pancreaticobiliary secretion into the intestine. Although phasic SO contractions may aid in regulating bile and pancreatic juice flow, their primary role appears to be maintaining a sterile intraductal milieu. Sphincter regulation is under both neural and hormonal control. Phasic wave frequency of the sphincter is closely tied to the migrating motor complex (MMC) of the duodenum. Phase III of the MMC is associated with the most rapid phasic wave activity of the sphincter. Innervation of the bile duct does not appear to be essential because sphincter function has been reported to be preserved after liver transplantation. [3] Although regulatory processes vary among species, cholecystokinin and secretin appear to be most important in causing sphincter relaxation, whereas nonadrenergic, noncholinergic neurons, which at least in part transmit vasoactive intestinal peptide and nitric oxide, also relax the sphincter. [4] The role of cholecystectomy in altering these neural pathways needs further definition.

Wedge specimens of the SO obtained at surgical sphincteroplasty from SOD patients show evidence of inflammation, muscular hypertrophy, fibrosis, or adenomyosis within the papillary zone in about 60% of patients. [5] In the remaining 40% with normal histology, a motor disorder is suggested. Less commonly, infections with cytomegalovirus or *Cryptosporidium* species, as may occur in patients with acquired immunodeficiency syndrome, or *Strongyloides* species have caused SOD.

It is suspected that SOD causes pain by impeding the flow of bile and pancreatic juice resulting in ductal hypertension. Alternatively, ischemia arising from spastic contractions and hypersensitivity of the papilla has been proposed.

EPIDEMIOLOGY AND FREQUENCY

SOD may occur in pediatric or adult patients of any age; however, patients with SOD are typically middle-aged women. Although SOD most commonly occurs after cholecystectomy, it may be present with the gallbladder in situ. In a survey of functional gastrointestinal disorders, SOD appeared to have a relevant impact on quality

of life because it was highly associated with work absenteeism, disability, and health care use. [6]

The frequency of manometrically documented SOD in patients before cholecystectomy has received limited study. Guelrud and colleagues [7] studied 121 patients with symptomatic gallstones and a normal common bile duct diameter (by transcutaneous ultrasound) by SOM before cholecystectomy. An elevated basal sphincter pressure was found in 14 patients (11.6%). SOD was diagnosed in 4.1% of patients with a normal serum alkaline phosphatase level (4 of 96) and in 40% with an elevated serum alkaline phosphatase level (10 of 25). Ruffolo and associates [8] evaluated 81 patients with symptoms suggestive of biliary disease but normal ERCP and no gallbladder stones on transcutaneous ultrasound by scintigraphic gallbladder ejection fraction and endoscopic SOM. Fifty-three percent of patients had SOD, and 49% had an abnormal gallbladder ejection fraction. SOD occurred with a similar frequency in patients with an abnormal gallbladder ejection fraction (50%) and a normal ejection fraction (57%).

Postcholecystectomy pain, resembling the patient's preoperative biliary colic, occurs in at least 10% to 20% of patients. [9] The frequency of diagnosing SOD in reported series varies considerably with the patient selection criteria, the definition of SOD, and the diagnostic tools employed. In a British report, SOD was diagnosed in 41 (9%) of 451 consecutive patients being evaluated for postcholecystectomy pain. [10] Roberts-Thomson and Toouli [11] evaluated 431 similar patients and found SOD in 47 (11%). In a subpopulation of such patients with a normal ERCP (except dilated ducts in 28%) and recurrent pain of more than 3 months duration, SOD was diagnosed in 68%. Sherman and colleagues [12] used SOM to evaluate 115 patients with pancreaticobiliary pain with and without liver function test abnormalities. Patients with bile duct stones and tumors were excluded from analysis. Fifty-nine of 115 patients (51%) showed abnormal basal SO pressure greater than 40 mm Hg. These patients were further categorized by the Hogan-Geenen SOD classification system (see Table 104-1). The frequencies of abnormal manometry of a single sphincter segment were 86%, 55%, and 28% in type I, II, and III patients, respectively. These abnormal manometric frequencies are very similar to those reported by others for type I and type II patients. [13], [14] In type III patients, the finding of an abnormal basal sphincter pressure has varied from 12% to 55%. As noted, patient selection factors may be one explanation for this great variability. When both the pancreatic and biliary portions of the sphincter are studied, the detection rate for SOD increases.

Dysfunction may occur in the pancreatic duct portion of the SO and cause recurrent pancreatitis. Manometrically documented SOD has been reported in 15% to 59% of patients with recurrent pancreatitis, previously labeled as idiopathic. [15]

TYPICAL CLINICAL PRESENTATION

Abdominal pain is the most common presenting symptom of patients with SOD. The pain is usually epigastric or right upper quadrant, may be disabling, and lasts for minutes to hours. In some patients, the pain is continuous with episodic exacerbations. It may radiate to the back or shoulder and be accompanied by nausea and vomiting. Food or narcotics may precipitate the pain. The pain may begin several years after a cholecystectomy was performed for a gallbladder dysmotility or stone disease and is similar in character to the pain leading to the cholecystectomy. Alternatively, patients may have continued pain that was not relieved by a cholecystectomy. Jaundice, fever, or chills are rarely observed. Physical examination is characterized only by mild epigastric or right upper quadrant tenderness. The pain is not relieved by trial medications for acid-peptic disease or irritable bowel syndrome. Laboratory abnormalities consisting of transient elevation of liver function tests, typically during episodes of pain, are present in less than 50% of patients. [12] After initial evaluation, patients are commonly categorized according to the Hogan-Geenen SOD classification system (see Table 104-1). Patients with SOD may present with typical pancreatic pain (epigastric or left upper quadrant radiating to the back) and recurrent pancreatitis.

Clinical Evaluation

The diagnostic approach to suspected SOD may be influenced by the presence of key clinical features. However, the clinical manifestations of functional abnormalities of the SO may not always be easily distinguishable from those caused by organic ones (e.g., common bile duct stones) or other functional nonpancreaticobiliary disorders (e.g., irritable bowel syndrome).

General Initial Evaluation

Evaluation of patients with suspected SOD (i.e., patients with upper abdominal pain with characteristics suggestive of a pancreatobiliary origin) should be initiated with standard serum liver chemistries, serum amylase or lipase, abdominal ultrasonography, or computed tomography (CT) scans. The serum enzyme studies should be drawn during bouts of pain, if possible. Mild elevations (less than two times the upper limits of normal) are frequent in SOD, whereas greater abnormalities are more suggestive of stones, tumors, and liver parenchymal disease. CT scans and abdominal ultrasounds are usually normal, but occasionally a dilated bile duct or pancreatic duct may be found (particularly in patients with type I SOD). Standard evaluation and treatment of other, more common upper gastrointestinal conditions, such as peptic ulcer disease and gastroesophageal reflux, should be done simultaneously. In the absence of mass lesions, stones, or response to acid suppression therapeutic trials, the suspicion for sphincter disease is increased.

DIAGNOSTIC METHODS (NONINVASIVE)

Because SOM (considered by most authorities to be the gold standard for diagnosing SOD) is difficult to perform, invasive, not widely available, and associated with a relatively high complication rate, several noninvasive and provocative tests have been designed in an attempt to identify patients with SOD.

Morphine-Prostigmin Provocative Test

Morphine has been shown to cause SO contraction, as assessed manometrically. Prostigmin (neostigmine), 1 mg subcutaneously, is added as a vigorous cholinergic secretory stimulant to morphine (10 mg, subcutaneously) to make this challenge test. The morphine-prostigmin test, historically, had been used extensively to diagnose SOD. Reproduction of the patient's typical pain associated with a fourfold increase in aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, amylase, or lipase levels constitutes a positive response. The usefulness of this test is limited by its low sensitivity and specificity in predicting the presence of SOD and its poor correlation with outcome after sphincter ablation. This test has largely been replaced by tests believed to be more sensitive.

Ultrasonographic Assessment of Extrahepatic Bile Duct and Main Pancreatic Duct Diameter after Secretory Stimulation

After a lipid-rich meal or cholecystokinin administration, the gallbladder contracts, bile flow from the hepatocytes increases, and the SO relaxes, resulting in bile entry into the duodenum. Similarly, after a lipid-rich meal or secretin administration, pancreatic exocrine juice flow is stimulated, and the SO relaxes. If the SO is dysfunctional and causes obstruction to flow, the common bile duct or main pancreatic duct may dilate under secretory pressure. This can be monitored by transcutaneous ultrasonography. Sphincter and terminal duct obstruction from other causes (stones, tumors, strictures) may similarly cause ductal dilation and need to be excluded. Pain provocation should also be oted if present. Limited studies comparing these noninvasive tests with SOM or outcome after sphincter ablation [16], [17], [18] and [19] show only modest correlation.

Quantitative Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy assesses bile flow through the biliary tract. Impairment to bile flow from sphincter disease, tumors, or stones (as well as parenchymal liver disease) results in impaired radionuclide flow. The precise criteria to define a positive (abnormal) study remain controversial, but duodenal arrival time greater than 20 minutes and hilum-to-duodenum time greater than 10 minutes are most widely used. [20], [21] Most studies are flawed by lack of correlation with SOM or outcome after sphincter ablation. Thomas and colleagues [22] recently reported that the use of morphine during nuclear scintigraphy increased sensitivity to 83% and specificity to 81% when compared with abnormal basal sphincter manometry. Overall, it appears that patients with dilated bile ducts and high-grade obstruction are likely to have a positive scintigraphic study. Esber and colleagues [23] found that patients with lower-grade obstruction (Hogan-Geenen classification types II and III) generally have normal scintigraphy, even if done after cholecystokinin provocation.

In the absence of more definitive data, we conclude that noninvasive testing for SOD has a relatively low or undefined sensitivity and specificity and is, therefore, not recommended for general clinical use, except in situations in which more definitive testing (manometry) is unsuccessful or unavailable.

DIAGNOSTIC METHODS (INVASIVE)

Because of their associated risks, invasive testing with ERCP and manometry should be reserved for patients with clinically significant or disabling symptoms. In general, invasive assessment of patients for SOD is not recommended unless definitive therapy (sphincter ablation) is planned if abnormal sphincter function is found.

Cholangiography

Cholangiography is essential to rule out stones, tumors, or other obstructing processes of the biliary tree that may cause symptoms identical to those of SOD. Once such lesions are ruled out by a good-quality cholangiographic study, ducts that are dilated or drain slowly suggest obstruction at the level of the sphincter. A variety of methods to obtain a cholangiogram are available. For noninvasive imaging, magnetic resonance cholangiography is most promising, but quality varies greatly from center to center. Software development continues, and quality of images continues to evolve. Direct cholangiography can be obtained by percutaneous methods, intraoperative methods, or more conventionally, ERCP. Although some controversy exists, extrahepatic ducts that are greater than 12 mm in diameter (postcholecystectomy) when corrected for magnification, are considered dilated. Drainage of contrast is influenced by drugs that affect the rate of bile flow and relaxation or contraction of the SO. Such drugs must be avoided to obtain accurate drainage times. Because the extrahepatic bile duct angulates from anterior (the hilum) to posterior (the papilla), the patient must be supine to assess gravitational drainage through the sphincter. Although definitive normal supine drainage times have not been well defined, [24] a postcholecystectomy biliary tree that fails to empty all contrast media by 45 minutes is generally considered abnormal.

Endoscopic evaluation of the papilla and peripapillary area can yield important information that can influence the diagnosis and treatment of patients with suspected SOD. Occasionally, ampullary cancer may simulate SOD. The endoscopist should do tissue sampling of the papilla (preferably after sphincterotomy) in suspicious cases. [25]

Radiographic features of the pancreatic duct are also important to assess in the patient with suspected SOD. Dilation of the pancreatic duct (more than 6 mm in the pancreatic head, and more than 5 mm in the body) and delayed contrast drainage time (9 minutes in the prone position) may give indirect evidence for the presence of SOD.

Sphincter of Oddi Manometry

The most definitive development in our understanding of the pressure dynamics of the SO came with the advent of SOM. SOM is the only available method to measure SO motor activity directly. Although SOM can be performed intraoperatively and percutaneously, it is most commonly done in the ERCP setting. SOM is considered by most authorities to be the gold standard for evaluating patients for sphincter dysfunction. [26], [27] The use of manometry to detect motility disorders of the SO is similar to its use in other parts of the gastrointestinal tract. Unlike other areas of the gut, SOM is more technically demanding and hazardous. Questions remain as to whether these short-term observations (2- to 10-minute recordings per pull-through) reflect the 24-hour pathophysiology of the sphincter. Despite some problems, SOM is gaining more widespread clinical application.

Technique and Indications SOM is usually performed at the time of ERCP. All drugs that relax (anticholinergics, nitrates, calcium-channel blockers, and glucagon) or stimulate (narcotics or cholinergic agents) the sphincter should be avoided for at least 8 to 12 hours before manometry and during the manometric session. Data indicate that benzodiazepines do not affect the sphincter pressure and therefore are acceptable sedation for SOM. Meperidine, at a dose of 1 mg/kg, does not affect the basal sphincter pressure (although it does increase the phasic wave frequency). [28] Because the basal sphincter pressure is generally the only manometric criterion used to diagnose SOD and determine therapy, it was suggested that meperidine could be used to facilitate conscious sedation for manometry. If glucagon must be used to achieve cannulation, an 8- to 10-minute (at least) waiting period is required to restore the sphincter to its basal condition. Size 5-French catheters should be used because virtually all standards have been established with these catheters. Triple-lumen catheters are state of the art and are available from several manufacturers. A variety of catheter types can be used. Catheters with a long intraductal tip may help secure the catheter within the bile duct, but such a long nose is commonly a hindrance if pancreatic manometry is desired. Over-the-wire (monorail) catheters can be passed after first securing one's position within the duct with a guidewire. Whether this guidewire influences basal sphincter pressure is unknown. Some triple-lumen catheters accommodate a 0.018-inch diameter guidewire passed through the entire length of the catheter and can be used to facilitate cannulation or maintain position in the duct. A recent study in our unit showed that stiffer-shafted nitinol-core guidewires used for this purpose commonly increase basal sphincter pressure by 50% to 100%. To avoid these artifacts, such wires need to be avoided, or very-soft-core guidewires must be used. Guidewire-tipped catheters are being evaluated. Aspiration catheters in which one recording port is sacrificed to permit both end and side hole aspiration of intraductal juice are highly recommended for pancreatic manometry [29] (Fig. 104-1). Most centers prefer to perfuse the catheters at 0.25 mL/channel using a low-compliance pump. Lower perfusion rates give accurate basal sphincter pressures but not accurate phasic wave information. A new water-perfused sleeve system, similar to that used in the lower esophageal sphincter, awaits more definitive trial in the sphincter of Oddi. [30] The perfusate is generally distilled water, although physiologic saline needs further evaluation.

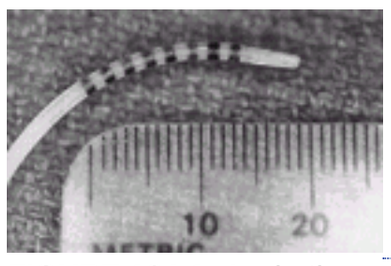

FIGURE 104-1. Aspiration manometry catheter: 5-French manometry catheter (Wilson Cook Model No. SOM-21-S-Lehman, Wilson Cook, Winston-Salem, North Carolina), which allows for aspiration from end and side holes while pressures are accurately recorded from the two remaining ports.

SOM requires selective cannulation of the bile duct or pancreatic duct. The duct entered can be identified by gently aspirating on any port (Fig. 104-2 and Color Fig. 104-2). The appearance of yellow fluid in the endoscopic view indicates entry into the bile duct. Clear aspirate indicates that the pancreatic duct was entered. A small amount of dilute contrast can be injected, but this may hinder accurate intraductal pressure measurements and offers no advantage over aspiration. One must be certain that the catheter is not impacted against the wall of the duct to ensure accurate pressure measurements. Once deep cannulation is achieved and the patient acceptably sedated, the catheter is withdrawn across the sphincter at 1- to 2-mm intervals by standard station pull-through technique. Ideally, both the pancreatic and bile ducts should be studied. Data indicate that an abnormal basal sphincter pressure may be confined to one side of the sphincter in 35% to 65% of patients with abnormal manometry. [31], [32], [33] and [34] Thus, one sphincter may be dysfunctional whereas the other normal. Raddawi and colleagues [31] reported that an abnormal basal sphincter was more likely to be confined to the pancreatic duct segment in patients with pancreatitis and to the bile duct segment in patients with biliary-type pain and elevated liver function tests.

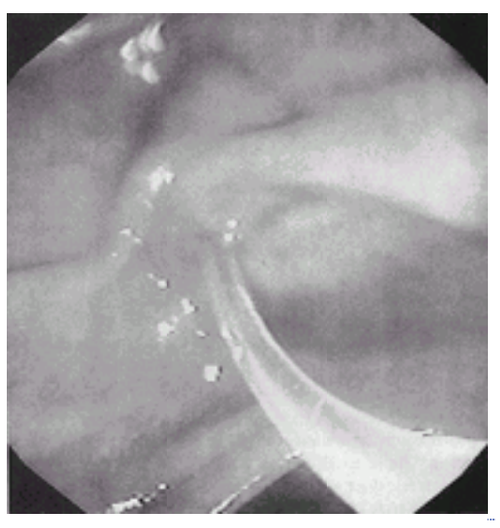

FIGURE 104-2. (See Color Fig. 104-2.) The duct entered during sphincter of Oddi manometry can be identified by aspirating the catheter. Dark-colored fluid (*top right*) signifies entry into the bile duct, whereas clear fluid indicates pancreatic duct entry.

Abnormalities of the basal sphincter pressure should ideally be observed for at least 1 minute in each lead and be seen on two or more separate pull-throughs. From a practical clinical standpoint, we settle for one pull-through (from each duct) if the readings are clearly normal or abnormal. During standard station pull-through technique, it is necessary to establish good communication between the endoscopist and the manometrist who is reading the tracing as it rolls off the recorder. This permits optimal positioning of the catheter to achieve interpretable tracings. Alternatively, electronic manometry systems with a television screen can be mounted near the endoscopic image screen to permit the endoscopist to view the manometry tracing during endoscopy. Once the baseline study is done, agents to relax or stimulate the sphincter can be given (e.g., cholecystokinin) and manometric or pain response monitored. The value of these provocative maneuvers for everyday use needs further study before widespread application is recommended. Criteria for interpretation of an SO tracing are relatively standard; however, they may vary somewhat from center to center. Some areas where there may be disagreement in interpretation include the required duration of basal SO pressure elevation, the number of leads in which basal pressure elevation is required, and the role of averaging pressures from the three (or two in an aspirating catheter) recording ports. [2] Our recommended method for reading the manometry tracings is first to define the zero duodenal baseline before and after the pull-through. Alternatively, intraduodenal pressure can be continuously recorded from a separate intraduodenal catheter attached to the endoscope. Identify the highest basal pressure (Fig. 104-3) that is sustained for at least 30 seconds. Take the four lowest amplitude points in that zone and take the mean of these readings as the basal sphincter pressure for that lead for that pull-through. Average the basal sphincter pressure for all interpretable observations and take this as the final basal sphincter pressure. The amplitude of phasic wave contractions is measured from the beginning of the slope of the pressure increase from the basal pressure to the peak of the contraction wave. Four representative waves are taken for each lead and the mean pressure determined. The number of phasic waves per minute and the duration of the phasic waves can also be determined. Most authorities read only the basal sphincter pressure as an indicator of pathology of the SO. However, data from Kalloo and colleagues [35] suggest that intraductal biliary pressure, which is easier to measure than SO pressure, correlates with SO basal pressure. In this study, intrabiliary pressure was significantly higher in patients with SOD than those with normal SO pressure (20 versus 10 mm Hg; $p < 0.01$). This study needs to be confirmed but supports the theory that increased intrabiliary pressure is a cause of pain in SOD.

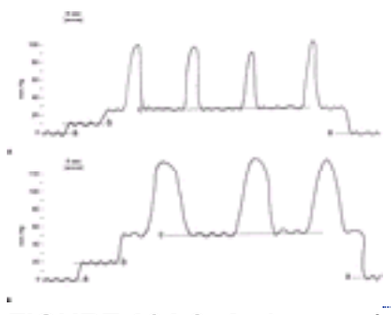

FIGURE 104-3. A: A normal station pull-through of one lead at sphincter of Oddi manometry. The study has been abbreviated to fit onto one page. *(a)* Baseline duodenal 0 reference. *(b)* Intraductal (biliary) pressure of 10 mm Hg (normal). *(c)* Basal biliary sphincter pressure of 28 mm Hg (normal). Phasic waves are about 70 mm Hg in amplitude and less than 6 seconds' duration (normal). **B:** An abnormal station pull-through of one lead at sphincter of Oddi manometry. *(a)* Baseline duodenal 0 reference. *(b)* Intraductal biliary pressure of 20 mm Hg (abnormal). *(c)* Basal biliary sphincter pressure of 52 mm Hg (abnormal). Phasic waves are about 70 mm Hg in amplitude (normal) but have an abnormal duration of 10 to 12 seconds.

The best study establishing normal values for SOM was reported by Guelrud and associates. [36] Fifty asymptomatic control patients were evaluated and repeated on two occasions in 10 subjects. This study established normal values for intraductal pressure, basal sphincter pressure, and phasic wave parameters (Table 104-2). Moreover, the reproducibility of SOM was confirmed. Various authorities interchangeably use 35 mm Hg and 40 mm Hg as the upper limit of normal for mean basal SO pressure.

Basal sphincter pressure*	>35 mm Hg
Basal ductal pressure	>13 mm Hg
Phasic contractions	
Amplitude	>220 mm Hg
Duration	>8 s
Frequency	>10/min

Values were obtained by adding 3 standard deviations to the mean (mean obtained by averaging the results on 2–3 station pull-throughs). Data combine pancreatic and biliary studies.

* Basal pressures determined by (1) reading the peak basal pressure (i.e., highest single lead as obtained using a 3-lumen catheter); (2) obtaining the mean of these peak pressures from multiple station pull-throughs.

From ref. 36.

TABLE 104-2 Suggested Standard for Abnormal Values for Endoscopic Sphincter of Oddi Manometry Obtained from 50 Volunteers without Abdominal Symptoms

Several studies have indicated that pancreatitis is the most common major complication after SOM. [29] Using standard perfused catheters, pancreatitis rates as high as 31% have been reported. Such high complication rates have initially limited more widespread use of SOM. These data also emphasize that manometric evaluation of the pancreatic duct, particularly in patients with chronic pancreatitis, is associated with a high complication rate. Rolny and associates [37] reported an 11% incidence of pancreatitis after pancreatic duct manometry. Twenty-six percent of chronic pancreatitis patients undergoing SOM developed pancreatitis. A variety of methods to decrease the incidence of postmanometry pancreatitis have been proposed. These include (1) using an aspiration catheter; (2) performing gravity drainage of the pancreatic duct after manometry; (3) decreasing the perfusion rate to 0.05 to 0.1 mL/lumen/min; (4) limiting pancreatic duct manometry time to less than 2 minutes (or avoiding pancreatic manometry); (5) using the microtransducer (nonperfused) system [38]; and (6) placing a pancreatic stent after manometry or sphincterotomy. In a prospective randomized study, Sherman and colleagues [29] found that the aspirating catheter (this catheter allows for aspiration of the perfused fluid from end and side holes while accurately recording pressure from the two remaining side ports) reduced the frequency of pancreatic duct manometry-induced pancreatitis from 31% to 4%. The reduction in pancreatitis with the use of this catheter in the pancreatic duct and the very low incidence of pancreatitis after bile duct manometry lend support to the notion that increased pancreatic duct hydrostatic pressure is a major cause of this complication. Thus, when the pancreatic duct sphincter is studied by SOM, aspiration of pancreatic juice is strongly recommended. In a prospective randomized trial, Tarnasky and associates [39] showed that stenting the pancreatic duct decreased post-ERCP pancreatitis from 26% to 6% in a group of patients with pancreatic sphincter hypertension undergoing biliary sphincterotomy alone. This observation, however, was not confirmed by another study. [40] SOM is recommended in patients with idiopathic pancreatitis or unexplained disabling pancreaticobiliary pain with or without hepatic enzyme abnormalities. An attempt is made to study both sphincters, but clinical decisions can be made when the first sphincter evaluated is abnormal. An ERCP is usually performed (if an adequate study is not available) immediately after the SOM to exclude other potential causes for the patient's symptoms. Indications for the use of SOM have also been developed according to the Hogan-Geenen SOD classification system (see Table 104-1). In type I patients, there is a general consensus that a structural disorder of the sphincter (i.e., sphincter stenosis) exists. Although SOM may be useful in documenting SOD, it is not an essential diagnostic study before endoscopic or surgical sphincter ablation. In fact, sometimes SOM may produce misleading results in this group of patients. Such patients uniformly benefit from sphincter ablation regardless of the SOM results (see section " Stent Trial as a Diagnostic Test"). Type II patients demonstrate SO motor dysfunction in 50% to 65% of cases. [41] In this group of patients, SOM is highly recommended because the results of the study predict outcome from sphincter ablation. Type III patients have pancreaticobiliary pain without other objective evidence of sphincter outflow obstruction. SOM is mandatory to confirm the presence of SOD. Although not well studied, it appears that the results of SOM may predict outcome from sphincter ablation in these patients.

Stent Trial as a Diagnostic Test

Placement of a pancreatic or biliary stent on a trial basis in hope of achieving pain relief and predicting the response to more definitive therapy, that is, sphincter ablation, has received only limited application. Pancreatic stent trials, especially in patients with normal pancreatic ducts, are strongly discouraged because serious ductal and parenchymal injury may occur if stents are left in place for more than a few days. [42] Goff [43] reported a biliary stent trial in 21 type II and III SOD patients with normal biliary manometry. Size 7-French stents were left in place for at least 2 months if symptoms resolved and removed sooner if they were judged ineffective. Relief of pain with the stent was predictive of long-term pain relief after biliary sphincterotomy. Unfortunately, 38% of the patients developed pancreatitis (14% were graded severe) after stent placement. Because of this high rate of complications, biliary stent trials are strongly discouraged.

THERAPY FOR SPHINCTER OF ODDI DYSFUNCTION

Therapy for SOD is evolving. Historically, most emphasis has been placed on definitive intervention, that is, surgical sphincteroplasty or endoscopic sphincterotomy. This appears appropriate for patients with high-grade obstruction (type I as per Hogan-Geenen criteria). In patients with lesser degrees of obstruction, the clinician must carefully weigh the risks and benefits before recommending invasive therapy. Most reports indicate that SOD patients have a complication rate from endoscopic sphincterotomy of at least twice that of patients with ductal stones. [40], [44]

Medical Therapy

Medical therapy for documented or suspected SOD has received only limited study. Because the SO is a smooth muscle structure, it is reasonable to assume that drugs that relax smooth muscle might be an effective treatment for SOD. Sublingual nifedipine and nitrates have been shown to reduce the basal sphincter pressures in asymptomatic volunteers and symptomatic patients with SOD. [1], [45] Khuroo and colleagues [46] evaluated the clinical benefit of nifedipine in a placebo-controlled crossover trial. Twenty-one of 28 patients (75%) with manometrically documented SOD had a reduction in pain scores, emergency room visits, and use of oral analgesics during short-term follow-up. In a similar study, Sand and associates [47] found that 9 of 12 (75%) type II SOD (suspected; SOM was not done) patients improved with nifedipine. Although medical therapy may be an attractive initial approach in patients with SOD, several drawbacks exist. [1] First, medication side effects may be seen in up to one third of patients. Second, smooth muscle relaxants are unlikely to be of any benefit in patients with the structural form of SOD (i.e., SO stenosis), and the response is incomplete in patients with a primary motor abnormality of the SO (i.e., SO dyskinesia). Finally, long-term outcome from medical therapy has not been reported. Nevertheless, because of the relative safety of medical therapy and the benign (although painful) character of SOD, this approach should be considered in all type III and less severely symptomatic type II SOD patients before considering more aggressive sphincter ablation therapy. Guelrud and colleagues [48] have demonstrated that transcutaneous electrical nerve stimulation lowers the basal sphincter pressure in SOD patients by a mean of 38% but generally not into the normal range. This stimulation was associated with an increase in serum vasoactive intestinal peptide levels.

Surgical Therapy

Surgery was the traditional therapy of SOD. The surgical approach, most commonly, is a transduodenal biliary sphincteroplasty with a transampullary septoplasty (pancreatic septoplasty). Sixty to 70% of patients were reported to have benefited from this therapy during a 1- to 10-year follow-up. [49], [50] Patients with an elevated basal sphincter pressure, determined by intraoperative SOM, were more likely to improve from surgical sphincter ablation than those with a normal basal pressure. [50] Some reports have suggested that patients with biliary-type pain have a better outcome than patients with idiopathic pancreatitis whereas others suggested no difference. [49], [50] However, most studies found that symptom improvement after surgical sphincter ablation alone was relatively uncommon in patients with established chronic pancreatitis. [50]

The surgical approach for SOD has largely been replaced by endoscopic therapy. Patient tolerance, cost of care, morbidity, mortality, and cosmetic results are some of the factors that favor an initial endoscopic approach. Surgical therapy is reserved for patients with restenosis after endoscopic sphincterotomy and when endoscopic evaluation or therapy is not available or technically feasible (e.g., Roux-en- gastrojejunostomy).

Endoscopic Therapy

Endoscopic Sphincterotomy Endoscopic sphincterotomy is the standard therapy for patients with SOD. Most data on endoscopic sphincterotomy relate to biliary sphincter ablation alone. Clinical improvement after therapy has been reported to occur in 55% to 95% of patients (see Table 104-1). These variable outcomes are reflective of the different criteria used to document SOD, the degree of obstruction (type I biliary patients appear to have a better outcome than type II and III), the methods of data collection (retrospective versus prospective), and the techniques used to determine benefit. Rolny and colleagues [51] studied 17 type I postcholecystectomy biliary patients by SOM. In this series, 65% had an abnormal SOM (although not specifically stated, it appears that the biliary sphincter was studied alone). Nevertheless, during a mean follow-up interval of 2.3 years, all patients benefited from biliary sphincterotomy. The results of this study suggested that because type I biliary patients invariably benefit from biliary sphincterotomy, SOM in this patient group is not only unnecessary but also possibly misleading. The results of this study, however, have never been validated at another center. Although most of the studies reporting efficacy of endoscopic therapy in SOD have been retrospective, two notable randomized trials have been reported. In a landmark study by Geenen and associates, [49], [52] postcholecystectomy, type II, biliary patients were randomized to biliary sphincterotomy or sham sphincterotomy. SOM was performed in all patients but not used as a criterion for randomization. During a 4-year follow-up, 95% of patients with an elevated basal sphincter benefited from sphincterotomy. In contrast, only 30% to 40% of patients with an elevated sphincter pressure treated by sham sphincterotomy, or with a normal sphincter pressure treated by endoscopic sphincterotomy or sham sphincterotomy, benefited from this therapy. The two important findings of this study were that SOM predicted the outcome from endoscopic sphincterotomy and that endoscopic sphincterotomy offered long-term benefit in type II biliary patients with SOD. Confirming data were seen in a 2-year follow-up study by Toouli and colleagues. [53] Sherman and associates [54] reported their preliminary results of a randomized study comparing endoscopic sphincterotomy and surgical biliary sphincteroplasty with pancreatic septoplasty (with or without cholecystectomy) to sham sphincterotomy for type II and III biliary patients with manometrically documented SOD. The results are shown in Table 104-3A and Table 104-3B. During a 3-year follow-up period, 69% of patients undergoing endoscopic or surgical sphincter ablation improved, compared with 24% in the sham sphincterotomy group ($p = 0.009$). There was a trend for type II patients to benefit more frequently from sphincter ablation than type III patients: 13 of 16 (81%) versus 11 of 19 (58%) ($p = 0.14$). Evidence is now accumulating that the addition of a pancreatic sphincterotomy to an endoscopic biliary sphincterotomy in such patients may improve the outcome. Long-term outcome studies, preferably in randomized trials, are awaited.

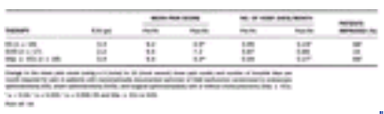

TABLE 104-3A Randomized Controlled Trial for Sphincter of Oddi Dysfunction: Outcome of Therapies

SOD TYPE*	NO. OF PATIENTS IMPROVED/TOTAL NO. OF PATIENTS		
	ES	S-ES	Slp ± CCx
Type II	5/6 (83%)†	1/7 (14%)	8/10 (80%)†
Type III	8/13 (62%)	3/10 (30%)	3/6 (50%)

*SOD type based on Hogan-Geenen SOD Classification System.
†$p < 0.02$; ES and Slp ± CCx vs S-ES.
From ref. 54.

TABLE 104-3B Clinical Benefit Correlated with Sphincter of Oddi Dysfunction (SOD) Type

These results clearly indicate that the response rate and enthusiasm for sphincter ablation must be correlated with patient presentation and balanced against the high complication rates reported for endoscopic therapy of SOD. Most studies indicate that patients undergoing endoscopic sphincterotomy for SOD have complication rates two to three times higher than patients undergoing endoscopic sphincterotomy for ductal stones. [44] Pancreatitis is the most common complication, occurring in up to 20% of patients. At least in one study, the frequency of complications appears to be dependent on the bile duct diameter. [40], [55] Endoscopic techniques are being developed (e.g., pancreatic duct stenting before combined pancreaticobiliary sphincterotomy) to limit such complications. [39]

Balloon Dilation and Stenting

Balloon dilation of strictures in the gastrointestinal tract has become commonplace. In an attempt to be less invasive and possibly preserve sphincter function, adaptation of this technique to treat SOD has been described. Unfortunately, because of the unacceptably high complication rates, primarily pancreatitis, this technology has little role in the management of SOD. [56] Similarly, although biliary stenting might offer short-term symptom benefit in patients with SOD and predict outcome from sphincter ablation, it too has unacceptably high complication rates and cannot be advocated in this setting [43] (see previous section, “ Stent Trial as a Diagnostic Test”).

Botulinum Toxin Injection

Botulinum toxin, a potent inhibitor of acetylcholine release from nerve endings, has been successfully applied to smooth muscle disorders of the gastrointestinal tract such as achalasia. In a preliminary clinical trial, toxin injection into the SO resulted in a 50% reduction in the basal biliary sphincter pressure and improved bile flow. [57] This reduction in pressure may be accompanied by symptom improvement in some patients. A small series of patients [38] showed an excellent correlation between pain resolution with botulinum toxin injection into the major papilla and symptom resolution with subsequent biliary sphincterotomy. Such an approach requires two endoscopies to achieve symptom relief. Further studies are needed before recommending this technique.

SPHINCTER OF ODDI DYSFUNCTION IN RECURRENT PANCREATITIS

SOD has been manometrically documented in 15% to 59% of patients with recurrent pancreatitis, previously labeled as idiopathic. [15] Biliary sphincterotomy alone has been reported to prevent further pancreatitis episodes in more than 50% of such patients. From a scientific, but not practical, viewpoint, care must be taken to separate out subtle biliary pancreatitis, [58] which will similarly respond to biliary sphincterotomy. The value of ERCP, SOM, and sphincter ablation therapy was studied in 51 patients with idiopathic pancreatitis. [59] Twenty-four (47.1%) had an elevated basal sphincter pressure. Thirty were treated by biliary sphincterotomy ($n = 20$), or surgical sphincteroplasty with septoplasty ($n = 10$). Fifteen of 18 patients (83%) with an elevated basal sphincter pressure had long-term benefit (mean follow-up, 38 months) from sphincter ablation therapy (including 10 of 11 treated by biliary sphincterotomy), in contrast to only 4 of 12 (33.3%; $p < 0.05$) with a normal basal sphincter pressure (including 4 of 9 treated by biliary sphincterotomy). Guelrud and colleagues, [60] however, found that severance of the pancreatic sphincter was necessary to resolve the pancreatitis. In this series, 69 patients with idiopathic pancreatitis caused by SOD underwent treatment by standard biliary sphinctero- tomy ($n = 18$), biliary sphincterotomy with pancreatic sphincter balloon dilation ($n = 24$), biliary sphincterotomy followed by pancreatic sphincterotomy in separate sessions ($n = 13$), or combined pancreatic and biliary sphincterotomy in the same session ($n = 14$). Eighty-one percent of patients undergoing pancreatic and biliary sphincterotomy had resolution of their pancreatitis, compared with 28% of patients undergoing biliary sphincterotomy alone ($p < 0.005$). These data are consistent with the theory that many such patients who benefit from biliary sphincterotomy alone have subtle gallstone pancreatitis. The results of Guelrud and colleagues [60] also support the anatomic findings of separate biliary and pancreatic sphincters, and the manometry findings of residual pancreatic sphincter hypertension in more than 50% of persistently symptomatic patients who undergo biliary sphincterotomy alone. The best method to treat residual pancreatic sphincter stenosis (after biliary sphincterotomy) awaits further study. Patients with idiopathic pancreatitis who fail to respond to biliary sphincterotomy alone should have their pancreatic sphincter reevaluated and be considered for sphincter ablation if residual high pressure is found.

FAILURE TO ACHIEVE SYMPTOMATIC IMPROVEMENT AFTER BILIARY SPHINCTEROTOMY

Table 104-4 lists several potential explanations as to why patients may fail to achieve symptom relief after biliary sphincterotomy is performed for well-documented SOD. First, the biliary sphincterotomy may have been inadequate, or restenosis may have occurred. Although the biliary sphincter is commonly not totally ablated, [61] Manoukian and associates [62] indicate that clinically significant biliary restenosis occurs relatively infrequently. If no cutting space remains in such a patient, balloon dilation to 8 to 10 mm may suffice, but long-term outcome from such therapy is unknown.

1. Residual or recurrent biliary sphincter dysfunction
2. Pancreatic sphincter (major papilla) dysfunction
3. Chronic pancreatitis—subtle, pancreatogram normal
4. Other obstructive pancreatobiliary pathology (stones, strictures, tumor, pancreas divisum)
5. Nonpancreatobiliary disease—especially gut motor disorders or visceral hypersensitivity.

TABLE 104-4 Causes for Failure to Achieve Symptom Relief after Biliary Sphincterotomy for Sphincter of Oddi Dysfunction

Second, the importance of pancreatic sphincter ablation is being increasingly recognized, as noted in the data preliminarily reported by Guelrud and colleagues. [60] Soffer and Johlin [63] reported that 25 of 26 patients (mostly type II), who failed to respond to biliary sphincterotomy, had elevated pancreatic sphincter pressure. Pancreatic sphincter therapy was performed with overall symptomatic improvement in two thirds of patients.

Third, patients may fail to respond to sphincterotomy because they have chronic pancreatitis. These patients may or may not have abnormal pancreatograms. Intraductal pancreatic juice aspiration, after secretin stimulation, may help make this diagnosis. [64], [65] Endoscopic ultrasound may show parenchymal and ductular changes of the pancreas in some of these patients, suggesting chronic pancreatitis. [66], [67]

Fourth, some patients may have pain from altered gut motility or hyperalgesia [68] of the stomach, small bowel, or colon (irritable bowel or pseudoobstruction variants). There is increasing evidence that upper gastrointestinal motility disorders [69], [70] and visceral hyperalgesia [71] may masquerade as pancreatobiliary-type pain (i.e., discrete right upper quadrant pain). Multiple preliminary studies show disordered duodenal motility in such patients. [69], [70] This area needs further study to determine the frequency, significance, or coexistence of these motor disorders associated with SOD.

SUMMARY

Our knowledge of SOD and the manometric techniques available to assist in this diagnosis are evolving. Successful endoscopic SOM requires good general ERCP skills and careful attention to the main details listed previously. If SOD is suspected in a type III or mild to moderate pain level type II patient, medical therapy should generally be tried. If medical therapy fails or is bypassed, ERCP and manometric evaluation are recommended. The role of less invasive studies remains uncertain owing to undefined sensitivity and specificity. Sphincter ablation is generally warranted in symptomatic type I patients and type II and III patients with abnormal manometry. The symptom relief rate varies from 55% to 95%, depending on the patient presentation and selection. Initial nonresponders may require thorough pancreatic sphincter and pancreatic parenchymal evaluation. More studies are needed to evaluate this complex issue. SOD patients have relatively high complication rates after invasive studies or therapy. Thorough review of the risk-to-benefit ratio with individual patients is mandatory.

CHAPTER 105

Gary C. Kanel

ANATOMY, MICROSCOPIC STRUCTURE, AND CELL TYPES OF THE LIVER

The liver is a unique organ having a wide range of both structural and physiologic functions. Understanding the arrangements of all the individual components of the liver on both gross and light microscopic examination assisted by electron microscopic and immunoenzymatic features allows a better understanding of liver histopathology and pathophysiology. Study of the embryologic evolution of the hepatic and hepatobiliary elements also assists in understanding many of the key concepts in developmental abnormalities seen in a wide variety of both pediatric and adult liver diseases. This chapter outlines the gross and microscopic characteristics of the liver and briefly addresses liver function, with an introductory presentation of embryologic development.

EMBRYOLOGY

The hepatic primordium anlage first appears toward the end of the third week of gestation and is seen as a hollow midline outgrowth stalk (hepatic diverticulum) of the endodermal epithelium at the distal aspect of the foregut (future duodenal loop). [1], [2], [3], [4] and [5] By the fourth week, the diverticulum enlarges by way of proliferation of the endodermal cell strands (hepatoblasts) and projects cranially into the mesoderm of the septum transversum (the mesodermal plate between the pericardial cavity and the yolk sac stalk), eventually giving rise to the hepatic parenchyma and intrahepatic duct structures (Fig. 105-1). The cephalic end ultimately develops into the right and left hepatic lobes. The stalk between the diverticulum and foregut narrows, forming the extrahepatic biliary system and gallbladder. The proliferating endodermal cells initially form solid cords, which then anastomose and form isolated vesicles and cribriform tubules with centrally located lumenal structures (biliary canaliculi). The cords eventually become confluent and form channels that subdivide the cords by small capillaries, which co-mingle with the developing vitelline and umbilical veins. These channels ultimately form the hepatic sinusoids. The individual hepatoblasts develop into the mature hepatocyte, with those cells immediately adjacent to the portal mesenchyme becoming the ductal plates. [6] The rapid growth rate of the hepatic cords allows sheets several cells thick, termed *muralium multiplex* to develop; these persist until birth, after which the cell sheets narrow to two cells (*muralium duplex*) and eventually evolve into a one cell thick trabecular cord (*muralium simplex*) by 5 years of age. [7], [8]

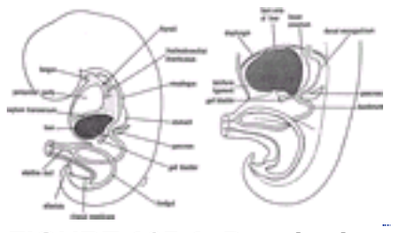

FIGURE 105-1. Developing Embryo. The drawing to the *left* represents a 9-mm embryo, estimated at about 36 days' gestation. The liver is derived from the hepatic diverticulum (midline outgrowth stalk of the distal foregut) and projects cranially into the septum transversum and caudally into the abdominal wall. The drawing to the *right* represents an embryo that is slightly older, with the falciform ligament noted between the hepatic parenchyma and the anterior abdominal wall. (From ref. [3].)

The mesoderm of the septum transversum initially surrounds the liver and is in continuity with the lesser curvature of the stomach, duodenum, and ventral body wall. The mesoderm becomes stretched between the liver and lesser curvature, forming the lesser omentum, and between the diaphragm and ventral abdominal wall, forming the falciform, coronary, and triangular ligaments. A portion also develops into the hepatic (Glisson) capsule. The developing hepatic artery and vagus nerve branch follow the mesoderm along and adjacent to the portal vein. The mesoderm on the liver surface also is in continuity with the peritoneum, whereas that portion in contact with the future diaphragm remains uncovered ("bare area"). The mesoderm is the main focus for the development of hematopoiesis, which begins at about 6 weeks and becomes most active during the sixth and seventh months, then rapidly regresses owing to developing bone marrow activity. The hematopoiesis is responsible for the prominent liver size in the fetus (up to 10% body weight by week 10, with the liver occupying most of the abdominal cavity) but regresses at birth so that only a few islands of hematopoietic cells are noted. The liver then weights about 5% of body weight. Hematopoiesis is usually absent by 4 weeks of age. Initially, the enlarged fetal liver has symmetric right and left lobes; with time, however, the growth rate diminishes but affects the left lobe more than the right, causing the size difference seen at birth. The caudate and quadrate lobes develop as subdivisions of the right lobe.

The *vascular network* is originally derived from the development of both the vitelline and umbilical veins and occurs at the same time as proliferation of the hepatoblasts. The cords and vessels anastomose, forming the hepatic sinusoids. The sinusoidal plexus initially receives blood through the vitelline vein and is drained into the sinus venosus, but by the fifth week, the right and left umbilical veins also supply blood to the sinusoidal plexus. By the fifth week, most of the major vessels are identified and include the right and left umbilical vein, the transverse portal sinus, and the ductus venosus, which shunts the blood directly from the umbilical vein into the inferior vena cava. At this time, the left umbilical vein becomes the main source of blood flow, with the right umbilical vein becoming atrophic by the fifth week. The portal vein develops from the vitelline vein and then subdivides into the right and left branches. The hepatic and portal vein branches divide the parenchyma into lobules and acini. The left umbilical vein blood flow has three major branching routes: (1) through the sinusoidal plexus of the left half of the liver, (2) through the sinusoidal plexus of the right half of the liver by retrograde flow from connections with the left branch of the portal vein, and (3) through the ductus venosus. At birth, a sphincter mechanism closes the ductus venosus, causing cessation of blood flow through the umbilical vein, with the liver now receiving blood from the left branch of the portal vein. The resultant closed segment of the umbilical vein then becomes the umbilicus, and the fibrotic ductus venosus becomes the ligamentum venosum.

The *biliary apparatus* develops from membranous infolding occurring between the junctional complexes between individual hepatoblasts and appears initially as intercellular spaces with no distinct wall. The biliary canaliculi are first seen at week 6, with bile synthesis occurring by week 9 and bile secretion by week 12. The hepatoblasts immediately adjacent to the mesenchyme of the portal tracts form the ductal plate, which is two layered; by 3 months, a lumen is seen within the ductal plate, with formation of double-layered tubular structures. Invasion of these cells into the portal mesenchyme occurs, forming an anastomosing network of portal duct structures. These ducts are not fully developed at term, [9] after which remodeling forms the true interlobular bile ducts that assume their major role as a linkage between the canalicular biliary apparatus and the extrahepatic biliary tree. This biliary network is fed by a hypervascular complex of arterioles and capillaries formed from the peribiliary plexus. The immature structures at birth may persist for up to 1 months. The extrahepatic biliary tree develops from the stalk of the original hepatic outgrowth.

The individual cell functions become apparent at different but early times in the embryologic development. [7], [10], [11] The alpha-fetoprotein, which is in high quantities at birth, initially is present by 1 month's gestation. Glycogen may be seen by 2 months, with glycogen synthesis becoming most apparent by 3 months; at birth, the amount of glycogen rapidly diminishes owing to rapid and active glycogenolysis. Fatty change within the hepatocyte also parallels that of glycogenesis. Hemosiderin is usually visible in early stages and becomes most marked as intrahepatic hematopoiesis decreases; it then gradually decreases but may still be seen at birth in the

periportal hepatocytes. The perisinusoidal cells and Kupffer cells appear by 3 months' gestation.

GROSS ANATOMY

The liver takes up the majority of the right upper abdominal cavity and extends from the right lateral aspect of the abdomen 15 to 20 cm transversely toward the xiphoid. [1], [12], [13] and [14] The weight of the adult liver varies from 1200 to 1800 g, dependent on the overall body size, and constitutes about 1.8% to 3.1% of the total body weight; however, at birth, the liver is larger compared to adjacent thoracic and abdominal viscera and constitutes about 5% to 6% of the body weight. [1], [15], [16] The liver anatomically has four lobes: right, left, caudate, and quadrate. The right lobe accounts for one half to two thirds the total liver volume; however, functionally, the right and left lobes are of about equal size and are divided by a line extending from the inferior vena cava superiorly to the middle of the gallbladder fossa inferiorly. A total of eight functional segments are present, each demarcated by the vascular and biliary drainage [1], [7], [12], [17], [18] and [19] (Fig. 105-2): the lateral (segments VI and VII) and medial (segments V and VIII) divisions of the right lobe, the medial (segment IV) and lateral (segments II and III) divisions of the left lobe, and the caudate lobe (segment I), the latter a "watershed" area of the right and left lobe vasculature.

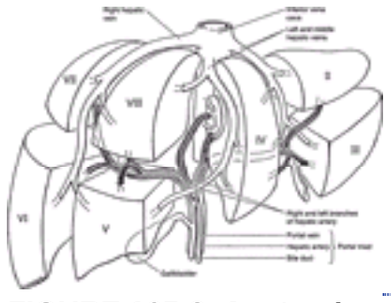

FIGURE 105-2. Anatomic and Functional Subdivisions. The liver is divided into eight functional anatomic segments, each having its own vascular flow and biliary drainage. These include the right lateral (segments VI and VII) and medial (segments V and VIII) divisions, the left medial (segment IV) and lateral (segments II and III) divisions, and the caudate lobe (segment I). (From Moore KL, Dalley II AF. Clinically oriented anatomy. 4th ed. Philadelphia: Lippincott Williams & Wilkins, 1999.)

The hepatoduodenal ligament connects the liver to the superior aspect of the duodenum and supports the hilar vessels and duct structures. The transverse fissure separates anteriorly the right lobe from the caudate lobe, whereas the umbilical fissure is located to the left of the quadrate lobe, which itself is bordered on the right by the gallbladder. The peritoneal layers forming the falciform ligament, which extends between the liver and the anterior abdominal wall, separate to form the superior layer of the coronary ligament and the left triangular ligament. The ligamentum teres is located along the lower edge of the falciform ligament and contains the obliterated umbilical vein remnant. The total surface area of the liver is structured by direct continuity with the surrounding abdominal organs, ligaments, and fascia.

The *portal vein* is the main route of vascular drainage of the gastrointestinal tract and is formed through the merger of the superior mesenteric and splenic veins. It also receives blood from the coronary and cystic veins. The portal vein is located along the hepatoduodenal ligament posterior to the hepatic artery and common bile duct and ends at the porta hepatis at the main lobar fissure, dividing into the right and left main branches. The right branch divides early into anterior and posterior segments, whereas the left branch divides into two segments: the *pars transversus* which extends to the left in the porta hepatis, and the *pars umbilicus* which descends into the umbilical fossa in line with the left segmental fissure. The caudate lobe veins arise from both the right and left main portal vein branches (Fig. 105-3).

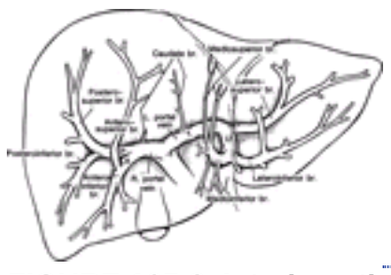

FIGURE 105-3. Intrahepatic Branches of the Portal Vein. T, pars transversus; U, embryonic ductus venosus; P, posterior segment; A, anterior segment. (From Skandalakis LJ, Colborn GL, Gray SW, et al. Surcical anatomy of the liver and extrahepatic biliary tract. In: Nyhus LM, Baker RJ, eds. Mastery of surgery. 2nd ed. Boston: Little, Brown, 1992.)

The *hepatic vein* is composed of three major tributaries (right, middle, left), each having intrahepatic branches. The middle and left hepatic eins often converge to form a single outflow vessel before draining into the inferior vena cava, whereas the right hepatic vein opens through a separate ostium. The caudate lobe drains directly into the inferior vena cava.

The *hepatic artery* is a branch of the celiac artery and ascends along the hepatoduodenal ligament and eventually divides into the right and left main branches. The right hepatic artery is usually seen behind the common hepatic duct after giving rise to the cystic artery, and it eventually divides into the anterior and posterior segmental branches. The left hepatic artery obliquely passes upward and to the left in the porta hepatis, eventually dividing into the medial and lateral segmental branches. The quadrate lobe is fed by a middle hepatic artery branch, whereas the caudate lobe is fed by both right and left hepatic artery branches.

The *biliary system* originally arises from the bile canaliculi and can grossly be demonstrated in the larger interlobular branches. The biliary drainage of the right lobe is derived from anterior and posterior segmental branches that merge to form the right hepatic duct. Lateral and medial segmental branches merge to form the left hepatic duct that drains the left lobe. The caudate lobe is drained from three duct branches directly into the right and left hepatic ducts (Fig. 105-4). The smaller ducts do not have a distinct wall, but the larger septal branches demonstrate a thin wall secondary to periductal collagen fibers and can more easily be demonstrated on gross inspection. The bile duct structures are directly fed by the hepatic artery and its branches, which parallel the ducts as they course through the various hepatic segments.

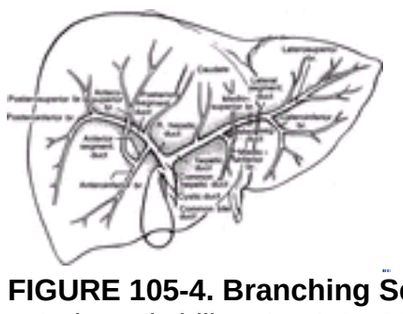

FIGURE 105-4. Branching Segments of the Intrahepatic Bile Ducts. (From Skandalakis LJ, Colborn GL, Gray SW, et al. Surgical anatomy of the liver and extrahepatic biliary tract. In: Nyhus LM, Baker RJ, eds. Mastery of surgery. 2nd ed. Boston: Little, Brown, 1992.)

The *lymphatic channels* provide both sympathetic and parasympathetic innervation and are divided into *deep* and *superficial* branches. The deep lymphatic branch parallels the portal and hepatic vein branches, whereas the superficial lymphatic structures arise from the Glisson's capsule and drain through the adjacent falciform ligament, diaphragm, esophagus, and hilar lymph nodes. [1], [20]

The *nerve supply* parallels the main hepatic artery and portal vein and is divided into *parasympathetic* and *sympathetic* fibers. The former are preganglionic and derived from the vagus nerve, whereas the latter are postganglionic and receive their nerve supply from T7 through T10. The nerve supply enters the hepatic hilum through both anterior and posterior routes and feeds the arteries and bile ducts through sympathetic innervation. The nerve fibers branch through the main portal tracts, with smaller unmyelinated branches feeding the periportal hepatocytes. In addition, many of the nerve fibers terminate on endothelial cells lining the smallest arterioles and along Kupffer cells, stellate (fat-storing) cells, and hepatocytes. [21]

MICROANATOMY

Normal Histology

Architecture The basic architectural arrangement of the portal structures, sinusoids, and outflow vessels is evenly spaced throughout all lobes of the liver and is best assessed under low- and medium-power microscopy. [22], [23] Although the portal inflammatory and cellular components and the size of the liver cell plates vary, dependent on the developmental stage of the liver, the architectural framework can be seen in fetal liver as well. Although the architecture may at times be difficult to assess when acute liver injury is present, upon recovery, the arrangements universally return to normal; on the other hand, distortion of the architecture seen in advanced chronic liver disease is for the most part irreversible.

Portal Tracts The portal tracts are often referred to as *portal triads;* this term is misleading in that more than three components are present. The *interlobular bile ducts* number from one to two per portal structure, although in infants, the ducts early on appear to be slightly less frequent. The ducts are usually seen immediately adjacent to the *hepatic arterioles* which are responsible for their blood supply. The hepatic arterioles are usually singly present. The *portal venules* similarly are a single structure, although transverse cuts of the portal tracts in biopsy material can mistakenly appear as if two or more ducts and vessels are present. True increase in portal venules and lymphatics are characteristic of portal hypertension and are usually seen in conjunction with portal fibrosis or cirrhosis. The *fibrous tissue* that supports the major portal components varies in amount, dependent on the distance of the portal tract from the hepatic hilum, and errantly can be felt to be "fibrotic" when the biopsy specimen is taken toward the hilum. The infiltrating *cellular inflammatory components* within the fibrous tissue consist of scattered lymphocytes, which are scanty but often present to some degree even in normal livers.

Parenchyma In adults, the hepatic lobules constitute about 80% of the total hepatic volume and are composed predominantly of *liver cell cords* one cell thick made up of polyhedral hepatocytes. The adjacent sinusoids are lined by both *endothelial cells* and *Kupffer cells*. The perisinusoidal space is located between the endothelial cells and hepatocytes. *Stellate cells* and *collagen fibers* are also present along the perisinusoidal space, but on routine hematoxylin and eosin staining of normal liver tissue, these structures are usually inconspicuous. The sinusoids drain from the portal venule and hepatic arterioles into the terminal hepatic venules (Fig. 105-5).

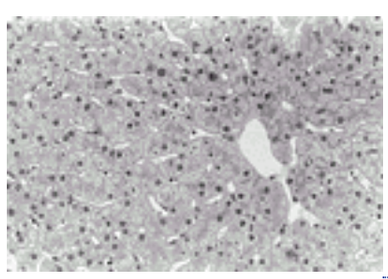

FIGURE 105-5. Parenchyma. The liver cell plates are one cell thick and are composed of polyhedral hepatocytes with centrally placed nuclei. These cells are bordered by sinusoids lined by both Kupffer and endothelial cells. The sinusoids directly drain into the terminal hepatic (central) venules.

Parenchymal Cellular Components

Hepatocyte The *hepatocyte* composes about two thirds of the total number of cells within the liver and about four fifths of the total liver volume. [1], [24], [25] and [26] The cells on the average measure from 25 to 40 µm in diameter, dependent on their zonal location and patient age, and are polyhedral and multifaceted. The cells in the adult are arranged in cords that are one cell thick and have three distinct cell boundaries: *sinusoidal lateral* (intercellular), and *canalicular* membranes. [7], [24] The *sinusoidal* or basolateral surface area constitutes about 60% to 70% of the total surface area. Microvilli measuring about 0.5 µm in length can be seen along the surface extending into the perisinusoidal spaces. The *lateral* membranes lie between adjacent hepatocytes and constitute about 15% of the surface area. They are divided into a number of junctional subunits. [1], [24] The *gap junctions* represent the two adjacent membranes having a distinct 2- to 4-µm gap, whereby communication between cells for transport of metabolites occurs by way of projected particles ("bobbins") directed from each cellular membrane. No microvilli are seen. The *desmosomes* are attached to the intermediate filaments and play a role in the resilience of the cell membrane. The *intermediate junctions* are attached to various cytokeratin filaments that also aid in cellular resilience. The *tight junctions* are zones of contacted membranes and represent a permeability barrier to macromolecules. The *canalicular* membranes constitute about 15% of the membrane surface area, lie toward the center of the intercellular junction, and represent the origin of biliary drainage (Fig. 105-6 and Fig. 105-7). They are lined by microvilli and measure in diameter from 0.5 µm in the perivenular zone (zone 3 of Rappaport) to 2.5 µm in the periportal zone (zone 1).

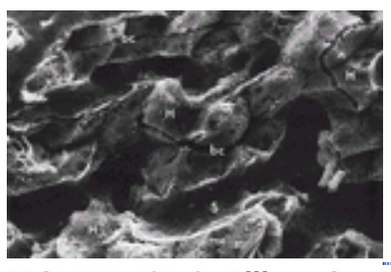

FIGURE 105-6. Biliary Canaliculi. By scanning electron microscopy, the liver cell plates and adjacent sinusoids (*S*) are seen with the bile canalicular (*bc*) network located between the adjacent hepatocytes (*H*). (From ref. [24].)

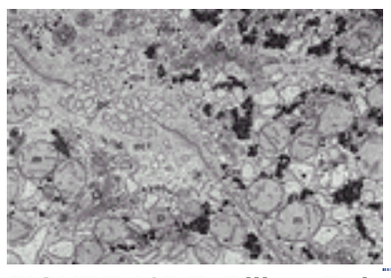

FIGURE 105-7. Biliary Pole. By electron microscopy, the bile canaliculi (*bc*) can be seen to the left of the field, surrounded by microvilli (*mv*) and pericanalicular ectoplasm (*ect*). Golgi complexes (*G*), vesicles (*ves*), mitochrondria (*m*), peroxisomes (*p*), and lysosomes (*lys*) can also be seen in the adjacent liver cell cytoplasm. (From ref. [24].)

Nucleus. The liver cell *nucleus* is centrally located within the hepatocytes, measures about 10 µm in diameter, and contains clumped chromatin and nucleoli. [24], [27] The nuclear membrane is composed of two envelopes separated by a narrow zone. These membranes have numerous apertures or pores that provide

cytoplasm-nuclear communication. The outer membrane often is lined by ribosomes, which are in direct communication with adjacent rough endoplasmic reticulum fibers. The intranuclear chromatin fibers are composed of *heterochromatin* which is round to irregular dense metabolically inactive granules, and *euchromatin* which actively transcribes RNA. [24] Anywhere from one to six nucleoli can be seen, their number and size in direct proportion to their degree of activity (ribosomal RNA function). The hepatocyte usually contains one nucleus, although bilobed forms may also be seen that are more often identified in the elderly population. Mitotic figures are infrequent but may also be prominent in instances of active liver cell regeneration (e.g., resolving acute viral hepatitis). Various nuclear inclusions may be identified [24], [28], [29] and include glycogen (frequently seen in diabetic patients), lipid, and cytoplasmic invaginations (pseudoinclusions, or nuclear membrane irregularities).

Cytoplasm. The liver cell *cytoplasm* constitutes about 90% of the volume of the hepatocytes and contains numerous functionally important organelles (Fig. 105-8). The cytoplasm and intracellular components vary in size, ultrastructure, and function, dependent on the zonal location of the hepatocytes (see " Functional Components: Liver Cell Heterogeneity" and Table 105-1 and Table 105-2). The superstructure is maintained by the cytoskeleton of the hepatocyte and includes three major subdivisions: the microfilaments, microtubules, and intermediate filaments. [7], [24], [30], [31] and [32]

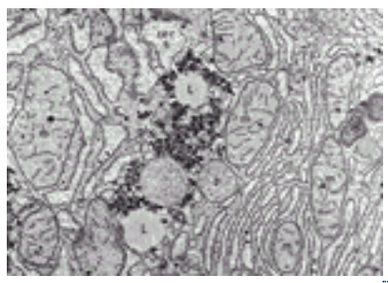

FIGURE 105-8. Liver Cell Cytoplasm). As seen by electron microscopy, the cytoplasm is composed of rough endoplasmic reticulum (*rer*), mitochondria (*m*), glycogen (*gly*), lipid droplets (*L*), and peroxisomes (*p*). (From ref. [24].)

TABLE 105-1 Liver Cell Structural Zonal Variations

ZONE 3 (PERIVENULAR)	ZONE 1 (PERIPORTAL)
Glycolysis	Gluconeogenesis
Glycogen synthesis from glucose	Glycogen synthesis from lactate
Lipogenesis	β Oxidation of fatty acids
Removal of ammonia from blood by glutamine	Amino acid catabolism
Detoxification, biotransformation of the majority of drugs and toxins*	Urea synthesis
Ketogenesis	Cholesterol synthesis
Bile acid synthesis	Bile acid secretion
Bile salt–independent fraction of bile formation; bile acid uptake (sodium independent)	Bile salt–dependent fraction of bile formation; bile acid uptake (sodium dependent)
Glucuronidation	
Mixed-function oxidase	
Increase in Kupffer cell phagocytic activity	

* Note that certain drugs and toxins (e.g., allyl formate, phosphorus) are metabolized and may cause liver cell injury in zone 1 because of different pathophysiologic mechanisms.

TABLE 105-2 Liver Cell Functional Zonal Variations

The *mitochondria* are one of the most prominent intracellular organelles, [7], [24] averaging up to 2200 per hepatocyte. They have numerous critical functions that include oxidative phosphorylation and fatty acid oxidation and contain components essential for the urea and citric acid cycles. They are larger in the perivenular zone but more numerous in the periportal zones and generally maintain a constant volume within each hepatocyte. They are oval to oblong in shape, and measure anywhere from 0.4 to 3.5 µm in diameter. They may be divided into outer and inner membranes separated by a gap. The *endoplasmic reticulum* [24], [33] is composed of a convoluted network of cisternae, saccules, tubules, and vesicles that are distributed throughout the liver cell cytoplasm and constitute about 15% of the cytoplasmic volume. It is divided into two components, the *rough endoplasmic reticulum* and *smooth endoplasmic reticulum.* The rough endoplasmic reticulum is seen predominantly surrounding the nucleus and biliary channels, whereas the smooth endoplasmic reticulum forms a meshwork of small tubules that are devoid of ribosomes and often communicate with the Golgi apparatus. The *Golgi apparatus* [7], [24], [33], [34] is composed of highly polarized parallel flattened dilated saccules or vesicles, is about 1 µm in diameter, and is most often present adjacent to the liver cell nucleus and biliary canaliculi. Anywhere from 40 to 60 Golgi can be seen within the cytoplasm. The Golgi function includes production of secretory vacuoles for transportation and excretion of synthesized proteins into the sinusoids, bile secretion, incorporation of carbohydrates to proteins, and membrane synthesis and repair. *Lysosomes* [7], [24], [35], [36] appear as electron-dense pleomorphic single-membrane–bound vesicles containing various enzymes, such as acid phosphatase, esterases, proteases, and lipases; they are most frequently identified adjacent to the canalicular membrane. They are divided into *primary* and *secondary* lysosomes, which are actively involved in phagocytosis and eventual degradation of various cellular components. *Peroxisomes* are single-membrane intracellular organelles, also termed *microbodies* that vary in size from 0.2 to 1.3 µm. [7], [24], [37], [38] They are round to oval, exhibit a finely granular homogeneous matrix, contain various oxidases and catalases, and primarily function in the oxidation and degradation of numerous substrates with formation of hydrogen peroxides. They are also involved in oxidation of long-chain fatty acids. There are various *intracellular components* readily seen by light microscopy that contribute to the function and appearance of the liver cell. [22], [23] *Lipochrome* pigment appears as fine to coarse brown granules and is derived from increase in lysosomal activity and intracellular condensation of various cellular remnants. Two other intracellular pigments that can resemble lipochrome include bile and hemosiderin. *Bile* is present as clumped green to green-yellow globules that stain positively with the Hall stain for bilirubin. Usually, the presence of intracellular bile is also accompanied by intracanalicular bile. *Hemosiderin* pigment is coarsely granular and golden brown, is best highlighted by the Perl iron stain, and represents red blood cell degradation remnants. Intracellular *lipids* appear as clear, distinct, rounded vacuoles and are composed predominantly of neutral triglycerides. The size of the fat droplets varies, with the extremely small variants (termed *microvesicular* or "foamy") often difficult to assess on routine light microscopy unless thin 1-µm sections are prepared or fat stains (oil red O) on frozen sections are performed. Intracellular *glycogen* is distributed throughout the cytoplasm but is more frequently seen adjacent to the smooth endoplasmic reticulum. Glycogen is easily demonstrated by periodic acid-Schiff stain on frozen-section material. Nuclear glycogen, when abundant, gives the nucleus a clear appearance and may be seen in a number of liver diseases, including diabetes and Wilson disease.

Kupffer Cell The *Kupffer cells* are sinusoid lining cells that function as tissue macrophages; they represent more than 75% of fixed macrophages throughout the body and take up about one third of the hepatic sinusoidal cell volume. [7], [24], [39], [40], [41] and [42] Although originally derived from the circulation, they eventually rest along the sinusoidal borders and maintain the ability to divide. Kupffer cells have oval to elongated nuclei and abundant pyramidal stellate cytoplasm that contains numerous lysosomes; they measure up to 9 µm in length (Fig. 105-9). They overlie but do not form junctional complexes with the smaller endothelial cells. Kupffer cells may be identified, however, in gaps between adjacent endothelial cells, with cytoplasmic processes extending through endothelial fenestrations. Their primary functions relate to phagocytosis and eventual clearance of particulate material, clearance of endotoxins and degenerating cellular components, synthesis and catabolism of lipids, clearance of senescent erythrocytes, sequestration of antigens, and clearance of immune complexes.

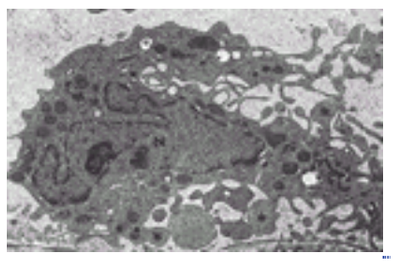

FIGURE 105-9. Kupffer Cell. By electron microscopy, the Kupffer cell exhibits a cleft nucleus (*N*), pseudopodia (*), and numerous lysosomes (*lys*). (From ref. [24].)

Endothelial Cell The *endothelial cells* are flattened, elongated sinusoidal cells ranging in size from 50 to 80 nm; they represent almost one half of the sinusoidal cell volume [24], [39], [42], [43] and [44] (Fig. 105-10). Numerous cytoplasmic projections and clustered fenestrae or gaps that range in size from 0.1 to 0.2 µm are present. These fenestrae function as a filtration barrier. The individual cells are loosely attached. A main function of the endothelial cell relates to filtering of the sinusoidal blood of various molecules, enabling substances such as glycoproteins and polysaccharides direct contact with the hepatocyte, but excluding and protecting the liver cell from numerous larger cellular components and various soluble compounds by (1) receptor-mediated endocytosis (ligand binding to coated pits on the cell surface), (2) pinocytosis (trapping of extracellular fluid droplets), and (3) phagocytosis (plasma membrane encircling and internalizing particles). [45]

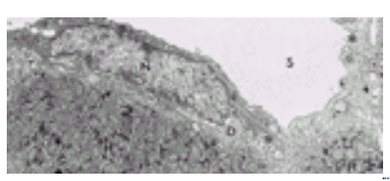

FIGURE 105-10. Endothelial Cell. This photomicrograph by electron microscopy of a sinusoid (*S*) shows an endothelial cell with an elongated nucleus (*N*) and scanty cytoplasm (*). The space of Disse (*D*) and adjacent cytoplasm of two hepatocytes (*H*) are noted. (From ref. [24].)

Stellate (Perisinusoidal) Cell Also termed *fat-storing cells* and *Ito cells* the *stellate cells* are located within the perisinusoidal liver cell recesses along the space of Disse [24], [39], [42], [46], [47] and [48] (Fig. 105-11) and constitute about one fifth of the sinusoidal cell volume. These cells range in size from 2 to 10 µm in diameter and contain small star-shaped nuclei without prominent nucleoli. The cytoplasm often contains variably sized lipid droplets, which contain a high concentration of vitamin A (retinoyl palmitate) that can easily be demonstrated as intensely green on frozen sections by rapidly fading fluorescence when excited at 328-nm wavelength. [45] Besides being the major source of vitamin A storage, the cells synthesize extracellular matrix by way of cytokine activation and resultant transformation to myofibroblasts in response to liver injury, with enhancement of protein and collagen synthesis. [49], [50]

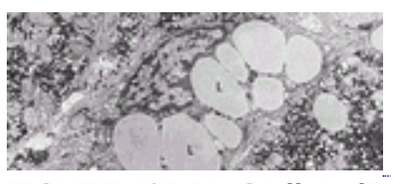

FIGURE 105-11. Stellate (Perisinusoidal) Cell. These cells, also termed *Ito* cells (*IC*), are seen by electron microscopy along the perisinusoidal recesses and characteristically demonstrate cytoplasmic lipid droplets (*L*) containing vitamin A. Adjacent hepatocytes (*H*) are noted. (From ref. [24].)

Pit Cell Also termed *liver-associated lymphocytes* and *large granular lymphocytes pit cells* are nonparenchymal T cells distributed within the sinusoidal lumen in loose contact with the endothelial or Kupffer cells; they occasionally can be seen within portal tracts. [45], [51], [52], [53] and [54] These cells function as natural lymphocyte-activated killer cells. They are often called pit cells because of the resemblance of the cytoplasmic granules to grape seeds. [1], [55] These cells are often seen in direct contact with the endothelium in response to various immunologic mechanisms and can be targeted in viral hepatitis, acute posttransplantation cellular rejection, and various primary and metastatic neoplastic processes. [7], [45]

Stroma (Extracellular Matrix) The *stroma* constitutes about 10% of the liver volume and overall supports the basic hepatic architectural arrangement, produces intercellular cohesion and communication, and effects cellular differentiation. The Glisson's capsule, composed of dense hypocellular collagen, encapsulates the liver and extends at the hilum into the hepatic parenchyma, forming the tensile structure of the portal tracts. Extension within the sinusoids into the space of Disse as reticulin fibers maintains the intralobular framework. Five basic types of collagen are seen, with types I and III representing more than 95% of the total collagen. Type I represents mature collagen strands, whereas type III represents new collagen (reticulin fibers). Type IV is present in the basal lamina (membrane) around small vascular structures and ducts and represents about 1% of the total hepatic collagen. The noncollagenous proteins are numerous matrix glycoproteins and include (1) *laminin* the major glycoprotein component within the basement membranes; (2) *fibronectin* synthesized by peri- sinusoidal cells and responsible for collagen adhesion; and (3) *elastin* which stabilizes blood vessel walls. Collagen deposition is often triggered by activation of the stellate cells in certain instances of liver cell necrosis and impaired or delayed regeneration of hepatocytes.

Biliary Network

The main function of the *biliary tract* is to transport bile synthesized in the hepatocyte into the gastrointestinal tract by way of the extrahepatic biliary network. In addition, the transport proteins synthesized by biliary epithelium and located within the microvilli aid in both (1) the secretion of bicarbonate-rich fluid and (2) the reabsorption of various fluids and solutes that overall enhance bile flow. [56] It can be divided into its structural components, [57] the smallest of which are the *biliary canaliculi*. These are located along the intercellular spaces between hepatocytes, range in size from 0.5 to 1 µm in diameter, and are lined by microvilli. The canaliculi have numerous anastomotic connections and may undergo contractions secondary to actin, myosin, and tropomyosin, [58] enabling and enhancing forward bile flow.

The canaliculi that enter the portal tracts are called the *terminal ductules periportal cholangioles* or *canals of Hering*. These duct structures are derived from hepatocytes located at the limiting plate and form communication with the interlobular bile ducts. The ducts at this point develop a basement membrane and have both liver cell and ductal ultrastructural and histochemical features. Although in the normal liver, these ducts are usually inconspicuous on routine light microscopy, their prominent proliferation (*duct transformation duct metaplasia*) is most apparent in instances of severe liver cell necrosis that extends to and involves the periportal hepatocytes.

The *interlobular bile ducts* range in size from 15 to 20 µm in diameter within the smaller portal structures and are lined by a single layer of cuboidal cells having discrete round nuclei, usually inconspicuous nucleoli, and scanty eosinophilic cytoplasm. The duct cytoplasm contains sparse mitochondria, free ribosomes, and abundant intermediate cytokeratin filaments. The lumenal surface contains numerous pinocytotic vacuoles. Adjoining duct epithelium shows complex interdigitations. The lumenal surface also contains microvilli. A basement membrane is apparent and easily demonstrated on periodic acid-Schiff stain. Although the smaller ducts have no apparent wall, the larger interlobular ducts, which measure up to 100 µm in diameter, develop a small periductal fibrous sheath. Anastomoses of the smaller interlobular ducts is frequent. The main blood supply is the smaller branches of the hepatic artery and the peribiliary plexus, which run in parallel with the duct structures. These ducts express class I major histocompatible antigens, with cytokine-mediated class II expression in instances of liver allograft rejection and certain chronic biliary tract diseases that attack ducts, such as primary biliary cirrhosis.

The larger *interlobar and septal ducts* measure more than 100 µm in diameter, have a fibrous wall, and are lined by a single layer of cuboidal to columnar epithelium with nuclei located toward the basement membrane. Some degree of periductal fibrous tissue is common but should not be confused with the distinct periductal concentric collagenosis seen in instances of long-term bile duct obstruction.

The interlobar and septal ducts lead into the *segmental ducts* that measure up to 800 µm in diameter, which eventually form the major *hilar ducts* that measure up to 1.5 mm in diameter. The hilar ducts ultimately branch into the main right and left hepatic ducts. The hilar ducts are lined by columnar mucus-secreting epithelium, have a distinct fibromuscular wall, and are associated with both intramural and extramural seromucinous peribiliary glands, which communicate with the bile duct lumen. The same type of peribiliary glands are demonstrated around the intrahepatic large bile ducts as well. [59]

Vascular Network

The major blood vessels that supply the liver are the *portal vein* and *hepatic artery*. The *portal vein* sequentially develops interlobar, segmental, interlobular veins and preterminal branches, with the terminal portal venules measuring about 20 to 30 µm in diameter and seen in the smaller triangular portal tracts. The vascular inflow from the portal veins is controlled by various sphincters. The *hepatic artery* branches accompany the portal vein and divide within the smaller portal tracts into two segments: (1) the *periportal plexus* which branches around the portal vein and drains into the sinusoids, and (2) the *peribiliary plexus* which provides blood supply to the accompanying interlobular bile ducts by way of small capillaries that are layered around the ducts. Various connections are seen between the small arterioles and the sinusoids that are most prominent in the periportal zone (zone 1 of Rappaport). The arterial flow is dependant on both sphincters and contractile mechanisms that define the degree of arterial versus portal venous blood flow, with the arterial flow varying inversely with the portal venous circulation.

The *hepatic acinus* can be divided into three segments: simple, complex, and acinar agglomerate. The *simple acinus* is the smallest functional parenchymal unit and centers around the preterminal portal venules, hepatic arteriole, and terminal bile ductules (Fig. 105-12). The acinus is divided into three zones (zones of Rappaport): (1) *periportal* (zone 1), which includes the limiting plate; (2) *midzone* (zone 2); and (3) *perivenular* (zone 3), with the terminal hepatic venule at its outer lateral margin. There is no discrete demarcation separating these zones from one another. The watershed areas occur at the periphery of the acini where blood can be derived from the smallest arteriolar branches and portal venules from adjacent acini. Biliary drainage runs parallel to the vascular sinusoidal circulation. The *complex acinus* is derived from three adjacent simple acini fed by a preterminal portal vein and arterial branches. A small aggregate or sleeve of liver cells (*acinuli*) directly surrounds the preterminal branch. The *acinar agglomerate* is composed of about four complex acini and is fed by a portal venous branch measuring 300 to 1200 µm in diameter.

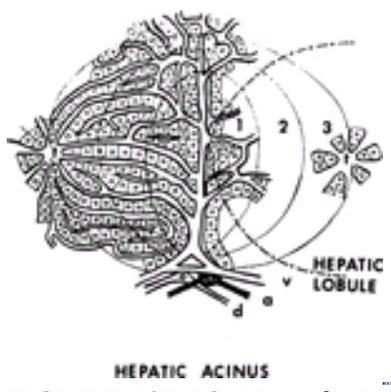

FIGURE 105-12. Hepatic Acinus. This drawing represents a *simple* acinus and its relationship with the preterminal portal venule (*v*), small hepatic arteriole (*a*), and ductule (*d*) and is divided into three zones (zones of Rappaport) with the terminal hepatic venule (*t*) located along its outer margins. (From Sternberg SS. Histology for pathologists. New York: Raven Press, 1992.)

The *space of Disse* lies between the hepatocyte and the endothelial cells, measures 0.2 to 1.0 µm in width, and forms a space that is not appreciated on routine light microscopy on biopsy material but that can sometimes be seen in autopsy livers secondary to liver cell shrinkage from autolysis. Numerous microvilli can be seen projecting from the liver cell membrane into the space of Disse. The discontinuity of the adjacent endothelial cells enables plasma to have easy permeability to the liver cell membranes. The space of Disse contains reticulin fibers, which can best be appreciated on special reticulin stains and which are easily seen on electron microscopy. The stellate or perisinusoidal cells (Ito cells) also protrude into this space. The sinusoids eventually drain into the terminal hepatic venules, which have no fibrous wall. These vessels then drain into the terminal hepatic veins and into the sublobular intercalated veins; they then exit the liver from the three main hepatic vein branches into the inferior vena cava.

Most *hepatic lymph* is derived from the space of Disse, whereas about 10% comes from capillary leakage from the peribiliary plexus. Its main function is to drain excess proteinaceous fluid from the interstitial hepatic spaces. [1, 60] The hepatic lymph drainage within the space of Disse travels into the smallest lymphatic vessels within the portal tracts by way of “endothelial massaging” by circulating erythrocytes and leukocytes within the sinusoids. The terminal branches form plexuses lined by endothelial cells and are accentuated around the hepatic arterioles in the smaller portal structures, although lymphatics are also seen adjacent to portal veins and bile duct tributaries in larger portal tracts. Small branches can also be seen along the hepatic venous outflow branches. A lymphatic plexus is also identified within the Glisson’s capsule and communicates with the intrahepatic lymphatics through anastomotic channels. Most lymphatics leave the liver at the porta hepatis, although lymphatic drainage is prominent through the Glisson’s capsule in instances when the hepatic venous drainage is impaired (e.g., acute and chronic hepatic venous outflow obstruction, cirrhosis). The larger lymphatic channels have an identifiable wall and are valved.

Neural Network

The *nerve fibers* are composed of both parasympathetic and sympathetic branches and release neurotransmitters from the intrasinusoidal fibers that contribute to modulation of liver cell function. Small nerve segments can be seen within the larger portal tracts, but smaller unmyelinated fibers can be discerned by way of electron microscopy and immunohistochemical studies within the space of Disse.

Functional Components: Liver Cell Heterogeneity

The hepatocytes within the various parenchymal zones have many different specialized physiologic functions that often parallel the light microscopy, ultrastructural features, and enzyme distribution patterns [1, 21, 61, 62, 63, 64, 65] and [66] (see Table 105-1 and Table 105-2). These functions are manifestations of (1) the nutrient and hormonal gradients delivered to the various zones, (2) the sinusoidal vascular perfusion and oxygen concentration gradients, (3) the availability of innumerable substrates and cofactors, and (4) the expression of various enzyme activities through gene expression and local (zonal) genetic variations. As a consequence, functional and morphologic zonal liver cell changes and injury are end-stage manifestations of modifications, alterations, and impairment of many of these critical and complex parameters.

CHAPTER 106

Marc G. Ghany and T. Jake Liang

ACUTE VIRAL HEPATITIS

Five viral agents have been associated with acute hepatitis. These viruses were denominated A, B, C, D, and E in order of their discovery. They are a genetically diverse group of viruses linked by their tropism for the liver, their primary site of replication. They all cause an acute hepatitis, which can range in clinical severity from an asymptomatic illness to fulminant hepatitis. Hepatitis B, C, and D viruses have the propensity to progress to chronic hepatitis. These hepatotrophic viruses account for 90% to 95% of all cases of acute viral hepatitis in the United States. [1] Data from the Centers for Disease Control and Prevention (CDC) Sentinel Counties Study of acute viral hepatitis indicated that hepatitis A virus (HAV) was the cause for almost half the reported cases, hepatitis B virus (HBV) a third, hepatitis C virus (HCV) 15%, and the remainder to non-A, non-C viruses. [2] In the United States, acute viral hepatitis has a low case fatality rate, 1% to 2%, but is associated with substantial morbidity. Death from end-stage liver disease, a long-term consequence of acute viral hepatitis, ranks in the top 10 of all causes of mortality in the United States.

Other viruses from the families *Arenaviridae* (e.g., Lassa fever virus), *Bunyaviridae* (e.g., Rift Valley fever and Hanta viruses), *Flaviviridae* (e.g., yellow fever and dengue viruses), *Filoviridae* (e.g., Marburg and Ebola viruses), and *Herpesviridae* may cause hepatitis as part of a systemic illness but are not considered primary hepatotrophic viruses.

EPIDEMIOLOGY

Overview

The hepatotrophic viruses are found worldwide, and there are distinct geographic regions where each virus is highly endemic. The global distribution of each virus is closely linked to its mode of transmission. Enterically transmitted viruses, HAV and hepatitis E virus (HEV), are more common in regions of the world that lack proper sanitation and have limited access to fresh water. In contrast, parenterally transmitted viruses, HBV, HCV and hepatitis D virus (HDV), predominate in areas of the world where social or customary practices facilitate their transmission, explaining the high rate of HCV infection in injection drug users in the United States and HDV in the South American Indians of the Amazon basin. Despite the institution of public health measures to educate the general public on transmission risks, the number of cases of acute viral hepatitis has not declined substantially in recent years. This may be partly because risk factors for acute viral hepatitis have not been identified in 30% to 40% of cases. [1] If elimination of infection is the ultimate goal, further studies on the various modes of transmission are necessary.

Hepatitis A Virus

Prevalence HAV infection occurs worldwide. The prevalence of antibody to hepatitis A (anti-HAV) correlates inversely with the socioeconomic status and the prevailing standard of hygiene of a region. In highly endemic areas, the prevalence of anti-HAV is almost universal by 5 years of age, whereas in industrialized nations, it is generally less than 5% for all age groups sampled. This finding has important public health implications. Outbreaks of HAV infection are more common in low-prevalence areas because of a susceptible population and rare in endemic areas because of natural herd immunity. This explains the cyclic epidemics observed every 10 to 15 years in areas of intermediate prevalence, such as the United States. Additionally, a paradoxical increase in the number of cases of clinical hepatitis is observed in low- and intermediate-prevalence areas owing to a greater number of adult infections. About one third of the U.S. population has serologic evidence of past HAV infection. Prevalence was found to increase with age according to data obtained from the Third National Health and Nutrition Examination Survey (NHANES-III, 1988–1994). [3] This finding can be explained by infections that occurred during childhood when sanitary conditions were poorer than present-day standards and travel to endemic regions by adults. The age-adjusted prevalence of anti-HAV was highest in Mexican Americans (70%) and lowest in non-Hispanic whites (23%). This difference is probably related to socioeconomic factors rather than racial susceptibility to infection. The incidence of acute HAV infection in the United States has remained fairly constant over the past several decades.

Transmission HAV is transmitted primarily by the fecal-oral route through person-to-person contact or ingestion of contaminated food or water. Viral titers are highest in stool and can reach 10^8 virions per milliliter. [4] This is because HAV lacks a lipid envelope and is readily secreted by hepatocytes into bile and the intestinal tract. [5] The virus is detected in stool during the incubation period, and the viral titer peaks 2 weeks before the onset of symptoms. [6] Therefore, the highest period of infectivity is before the onset of symptoms. In most cases, viremia becomes undetectable after the peak of the alanine aminotransferase (ALT) level. [7] However, experimental

transmission studies performed in human volunteers and chimpanzees revealed that viremia may persist for long periods during the convalescent phase of the illness. [6], [7] and [8] This suggests that blood obtained during the convalescent phase may be potentially infectious. Furthermore, the virus could be demonstrated by reverse transcriptase polymerase chain reaction (RT-PCR) in convalescent stool and may be a source of infection in sporadic cases. Viral titers in serum are about twofold less than those of stool; therefore, parenteral spread is not a significant route of transmission. Transmission has been reported occasionally in blood transfusion recipients, patients who require clotting factors, and injection drug users who share needles. [9], [10] and [11] Transmission has not been associated with saliva, semen, or urine. [4] Sexual transmission of hepatitis is reported in both heterosexuals and homosexuals. Outbreaks in homosexual men seem to be related oral-anal contact during the sexual encounter. [12], [13] Nosocomial spread from undiagnosed cases has been reported. [14] In the United States, the highest rates of spread are reported in household contacts, in intimate contacts of an index case, and in child day-care centers (person-to-person spread). [15] Data from the Viral Hepatitis Surveillance Program at the CDC in 1995 showed that contact with another person with hepatitis A was overall the most frequently identified risk factor. Attendees or employees of day-care centers accounted for 10% to 15% of cases. However, nearly 50% of cases in both 1994 and 1995 reported no known risk factor. [15] It has been suggested that transmission from an asymptomatic infant or child may account for most of the adult cases of HAV infection. [16] Outbreaks of HAV have been associated with ingestion of shellfish, [17], [18] raw onions, [19] salads, [20] and frozen strawberries, [21] but these account for a small number of cases overall.

Hepatitis B Virus

Prevalence Hepatitis B occurs worldwide; the areas of highest prevalence are China, Southeast Asia, sub-Saharan Africa, and Alaska. Almost 50% of the world's population live in these regions, where the prevalence of hepatitis B surface antigen (HBsAg), a serologic marker of chronic infection, can exceed 8%. [22] Another 40% of the world's population live in areas with intermediate prevalence, 3% to 5%, such as Japan and India. In low-prevalence areas such as the United States, Western Europe, and Australia, the rate of HBsAg positivity is 0.1% to 2%. In endemic areas, most infections occur in children, whereas in areas of low seroprevalence, most infections occur in adults. The prevalence of HBsAg was found to increase with age in the U.S. population and is highest in people aged 20 to 29 years, probably reflecting transmission through injection drug use or sexual exposure. [23] Certain U.S. populations, such as Eskimos, have higher rates of HBsAg positivity. [24] The incidence of acute HBV infection has declined dramatically in the United States, primarily owing to the use of the hepatitis B vaccine in high- risk groups, behavioral changes as a result of the human immuno- deficiency virus (HIV) epidemic, and federal regulations introduced to limit nosocomial spread.
Transmission Hepatitis B is transmitted primarily by the percutaneous route. Not surprisingly, the highest titers of virus are seen in serum and blood; intermediate titers are seen in semen, vaginal fluid, and saliva; and lowest titers are observed in tears, urine, feces, and breast milk. The infectivity of other body fluids is 100- to 1000-fold less compared with blood. Transfusion of blood products used to be the major route of transmission before the introduction of blood screening in 1985. Studies of multitransfused hemophiliac patients before 1985 indicated that 40% to 50% had markers of previous or active HBV infection. [25] Transfusion-related HBV infection has been virtually eliminated by screening of blood donors. The transmission of hepatitis B varies in endemic and nonendemic regions. In the United States and Western Europe, areas of low endemicity, injection drug use and sexual exposure to an acute case or chronic carrier are the major modes of transmission. Data from the CDC Viral Hepatitis Surveillance Program showed that sexual exposure was the predominant risk factor in the United States; 26% of cases reported sexual contact with a person known to have HBV. Injection drug use was the next most common (13%). The risk for sexual transmission was directly related to number of lifetime sexual partners, paid sex, and prior history of sexually transmitted diseases. The risk for transmission appears to be greater from men to women. In contrast, in endemic regions, perinatal (vertical transmission) and person-to-person spread (horizontal transmission) are more common modes of spread. Perinatal spread is responsible for the high rate of infection seen in China and Southeast Asia. [26] Perinatal spread is more efficient if the mother is HBeAg positive. Fetal exposure to blood during passage through the birth canal is thought to be the cause of infection rather than transplacental spread. In sub-Saharan Africa, another highly endemic area, the major route of spread is horizontal transmission, occurring in young children between the ages of 4 and 6 years, presumably through close physical contact or intrafamilial spread. The reason for the lower rate of vertical transmission in the African population may be due to the low prevalence of hepatitis B e antigen (HBeAg) in the serum of females of childbearing potential. [27] Health care workers were at major risk for exposure in the 1980s; however, widespread use of the hepatitis B vaccine has reduced the incidence of acute hepatitis markedly, from 9% in 1985 to 0.8% in 1994–95. [28] Nosocomial infection continues to remain a source of infection, and transmission has been reported from physician to patient, from contaminated multiuse vials and medical instruments, in hemodialysis units, and through organ transplantation, especially in the case of antibody to hepatitis B core antigen (anti-HBc)–positive donors after orthotopic liver transplantation (OLT).

Hepatitis C Virus

Prevalence HCV infection occurs worldwide, and it is estimated that 3% of the world's population is infected based on blood donor studies. [29], [30] The geographic prevalence of antibody to HCV (anti-HCV) is fairly consistent throughout the world, ranging from 0.5% to 2%. However, the prevalence of HCV is disproportionately high in Egypt and Japan. In Egypt, this has been explained by the use of mass parenteral therapy for schistosomiasis with reusable glass syringes during the period between 1961 and 1985 and in Japan through the use of blood transfusions during the Second World War. [31], [32] and [33]. Data from the NHANES-III study found a prevalence of anti-HCV of 1.8% in the general U.S. population. [34] Prevalence was higher in African Americans and Hispanics. Groups with higher prevalence than the general population included hemophiliacs, injection drug users, patients receiving hemodialysis, and people attending sexually transmitted disease clinics. Currently, injection drug users are at highest risk for acute HCV infection. Since 1989, the incidence of acute HCV infection has been on the decline, primarily owing to screening of the blood supply and a decrease in injection drug use.
Transmission HCV is transmitted by percutaneous, sexual, and perinatal routes. The highest viral titers are seen in blood and serum. Before the introduction of blood-screening procedures (anti-HBc and ALT levels were used as surrogate markers for non-A, non-B hepatitis beginning in 1985 until they were replaced by anti-HCV testing in 1991), transfusion of blood or blood products was a major source of infection, accounting for up to 20% of cases of infection. HCV is efficiently transmitted by blood. Sixty to 95% of hemophiliacs who received clotting factor before 1985 tested positive for anti-HCV. [35], [36] With the introduction of screening measures, the risk for acquiring hepatitis C through blood transfusion in the United States is now estimated to be 1:400,000. [37] Transmission of HCV through the blood supply still occurs in countries where testing for HCV is not routinely performed. Injection drug use is a highly efficient means of transmission and now the major route of transmission of HCV in the United States. The prevalence of anti-HCV in active injection drug users who share needles is 70% after 1 year and greater than 90% after 8 years. Prevalence of anti-HCV in this group has been shown to be associated with duration of injection drug use and sharing needles with a long-time drug user. Intranasal cocaine use has been suggested as a mode of transmission. [38] A cross-sectional study of volunteer blood donors in the United States reported that a history of intranasal cocaine use was independently associated with anti-HCV positivity. [38] HCV can be transmitted sexually. Epidemiologic case-control and cross-sectional studies report independent associations between HCV infection and exposure to an infected sex partner, increasing number of sex partners, failure to use a condom, and sexual activities involving trauma. [34], [39] The presence of other sexually transmitted diseases (e.g., herpes and syphilis) has been shown to facilitate the transmission of HCV. The rate of sexual transmission from an infected case to a partner is low in monogamous relationships, 1.5%, but increases with duration of the partnership and averages 3% to 5%. [40], [41] The rate of sexual transmission is the same for heterosexual and homosexual relationships. Overall, sexual transmission accounts for a relatively small percentage of acute cases, less than 10%. Perinatal transmission occurs but is low and is significantly lower compared with HBV. The rate of transmission is estimated to be 3% to 5% for mothers not infected with HIV-1 and increases to 12% to 14% in HIV-1–positive women. [42], [43] Perinatal transmission of HCV was shown to correlate with viral level; thus, the higher viral loads in HIV-positive women may account for their higher rate of perinatal transmission. [44], [45] Transmission of HCV through breast-feeding has not been reported. [46] It was suggested that cesarean section may be associated with a lower rate of perinatal transmission. [47] Mother-to-child transmission occurs but is uncommon. [41], [48] Nosocomial transmission of HCV occurs but is not a major cause of new infections. [49], [50] Transmission through contaminated multidose vials, through endoscopes, from physician to patient, and through surgical procedures were identified as potential sources of infection. [51], [52], [53] and [54] Needle-stick injury is a risk factor for health care workers (see later).

Hepatitis D Virus

Prevalence HDV, the infectious agent of delta hepatitis, is found throughout the world. Its prevalence mimics that of HBsAg owing to its dependency on HBV for its life cycle. [55] However, there are areas where there is discordance between the prevalence of HDV and HBV, such as in China, where the rate of HBV infection is high but HDV low. The reason for this is unknown. HDV is endemic in the southern Mediterranean, Amazon basin, and tropical and subtropical Africa. It is estimated that about 5% of HBsAg carriers are infected with HDV. Prevalence of HDV is low in the United States. [56] Recent studies indicate that the seroprevalence of HDV in southern Europe is declining. Studies in Italy confirmed a decrease in incidence of acute cases from 3.1 per 100,000 population in 1987 to 1.2 per 100,000 population in 1992. [57], [58] This decline was attributed to the introduction of hepatitis B vaccination programs and a decrease in injection drug use. [57]
Transmission Hepatitis D is transmitted in a similar fashion to hepatitis B. The single most important factor influencing transmission of HDV is the HBsAg status of an individual. HDV cannot be transmitted in the absence of HBsAg. Exposure to blood and blood products used to be the major route of transmission, but this has been virtually eliminated by screening of blood for HBV. [55] In developed countries, injection drug use and sexual transmission are the major routes of spread. The mode of spread in populations from Africa and the Amazon Basin is not well understood, but tribal practices that expose individuals to blood or sexual exposure may play a role. Perinatal transmission is rare.

Hepatitis E Virus

Prevalence HEV is the major causative agent of enteric non-A, non-B hepatitis and the primary cause of sporadic hepatitis in the developing world. [59], [60] HEV is found worldwide, and the highest prevalence is found in areas of the world where there is inadequate sanitation. It is endemic in Southeast and Central Asia. Epidemics of HEV infection, usually involving many thousands of people, occur in endemic areas. In endemic areas, the prevalence of antibody appears to increase with age; about 5% of children younger than 10 years old have antibody to HEV, but 10% to 40% of adults are seropositive. [61], [62] This suggests that HEV infection does not occur frequently in children in endemic areas. This discrepancy may be in part due to the sensitivity of the test used for serologic testing. The prevalence of anti-HEV in the United States is low.

Transmission Hepatitis E is transmitted by the fecal-oral route. Highest attack rates are seen in individuals aged 15 to 40 years. [62] In endemic areas, consumption of contaminated water accounts for most new cases of HEV. Person-to-person spread is rare, and secondary attack rates appear to be distinctly uncommon, occurring in 0.7% to 2.2% of household contacts of hepatitis E, compared with rates of 50% to 75% in susceptible household contacts of hepatitis A. [62] There is no evidence for parenteral or sexual transmission. Vertical transmission is known to occur but accounts for only a small number of cases. [63] HEV is responsible for sporadic outbreaks of hepatitis. However, the reservoir of HEV during sporadic outbreaks is unclear. Recent data based on the detection of HEV in the feces of domestic swine in Nepal and the United States and anti-HEV in the sera of pigs, cattle, sheep, and rodents suggests that HEV may be a zoonosis. [64], [65] and [66] Cases of HEV infection in the United States are rare and usually associated with a history of travel to an endemic area. Infection has been reported without a history of travel, lending support to the zoonosis theory.

VIROLOGY

The five known hepatitis viruses, A to E, belong to completely different virus families. Although all of them can cause acute hepatitis, only HBV, HCV, and HDV infection can lead to chronic infection. The virologic characteristics of each virus are summarized in Table 106-1 and described in detail in this section.

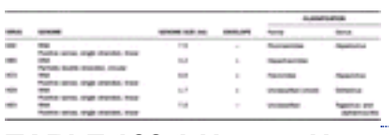

TABLE 106-1 Human Hepatitis Viruses

Hepatitis A Virus

HAV is classified in the *Hepatovirus* genus in the *Picornaviridae* family. It has one serotype but multiple genotypes. The virus is nonenveloped and stable to acid and heat treatment. The HAV has a linear, positive-sense, single-stranded RNA genome of about 7.5 kilobases (kb). The genome has a protein covalently attached to its 5' end and a poly A tail at the 3' end. [67] The genome is organized similarly to other picornaviruses in that it codes for a single polyprotein of about 2235 amino acids [68] (Fig. 106-1). The polyprotein is divided into three main functional domains from the 5' end, P1, P2, and P3. Individual proteins are cleaved from the functional domains, with P1 encoding the viral capsid proteins, whereas P2 and P3 encode the nonstructural proteins. The 5' untranslated region (UTR) is the most conserved segment of the genome [69] and contains an internal ribosomal entry site that functions to initiate protein synthesis from two in-frame AUG codons. [70] Mutations in this region appear to enhance the adaptation of virus growth in cell culture but do not appear to affect in vivo virulence. [71]

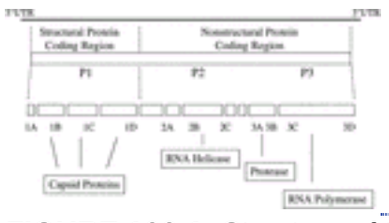

FIGURE 106-1. Structure of the hepatitis A virus and genetic organization. The *top line* represents the hepatitis A virus RNA genome. Translation of the genome yields the polyprotein; the *lower diagram* illustrates the three regions of the polyprotein and the individual protein products.

Cleavage within the P1, P2, and P3 domains of the polyprotein gives rise to the individual viral proteins. Four capsid proteins, designated 1A to 1D, are encoded in P1, with the P2 and P3 regions encoding proteins 2A to 2C and 3A to 3D, respectively. The 3B protein covalently attaches to the 5' terminus of the genome and serves as the primer for replication. [67] The functions of 2A, 2B, and 3A are unclear. The 3C is probably a serine proteinase [72] involved in cleavage of the polyprotein. 3D is the putative viral RNA polymerase. [73]

The replication process of HAV has been inferred from studies of other picornaviruses. [74] Entry of the virus into the host is mediated by a cell surface receptor, which has been recently proposed to be a mucin-like class 1 integral membrane glycoprotein. [75] Viral entry is followed by uncoating and initiation of viral protein synthesis. [76] Viral RNA synthesis proceeds from negative to plus strand and occurs in the cytoplasm. Viral assembly follows a sequence similar to that of picornaviruses in a cellular membrane compartment. [77]

Hepatitis B Virus

HBV has been classified into seven genotypes, A to G, based on sequence divergence. [78], [79] Three types of viral particles are visualized in infectious sera under electron microscopy. Two of the viral particles are smaller spherical structures with a diameter of 20 nm and filaments of variable length with a width of 20 nm, both of which vastly outnumber the Dane particles in infectious serum. [80] The spheres and filaments are composed of HBsAg and host-derived lipids and are noninfectious owing to the absence of nucleic acid. [81] The infectious HBV virion (Dane particle) has a 42-nm spherical, double-shelled structure, consisting of a lipid envelope containing HBsAg that surrounds an inner nucleocapsid. The HBcAg complexes with viral-encoded polymerase and viral DNA genome to form the nucleocapsid. [82] The genome of HBV is a partially double-stranded circular DNA of about 3.2 kilobase pairs. The viral polymerase is covalently attached to the 5' end of the minus strand. [83]

The viral genome encodes four overlapping open reading frames (ORFs) (Fig. 106-2). The S ORF encodes the viral surface envelope proteins, the HBsAg, and comprises the pre-S1, pre-S2, and S regions. The core gene consists of precore and core regions. Multiple in-frame translation initiation codons are a feature of the *S* and *C* genes, which give rise to functionally distinct proteins. HBeAg and the viral nucleocapsid HBcAg are translated from initiation at the precore and core regions, respectively (Fig. 106-3). The core protein has the intrinsic property to self-assemble into a capsid-like structure and contains a highly basic cluster of amino acids at its C terminus with RNA-binding activity. [84] The precore ORF codes for a signal peptide that directs the translation product to the endoplasmic reticulum, where the protein is further processed to form the secreted HBeAg. The role that HBeAg serves is still unknown because mutations inactivating the precore region do not appear to affect viral replication. [85] One speculative role for HBeAg is an immune tolerogen, whose function is to promote persistent infection. [86] The polymerase (pol) is a large protein (about 800 amino acids) and is functionally divided into three domains: the terminal protein domain (TP), which is involved in encapsidation and initiation of minus-strand synthesis; the reverse transcriptase domain, which catalyzes genome synthesis; and the RNase H domain, which degrades pregenomic RNA and facilitates replication. The HBX is a 16.5-kd protein and has been attributed with multiple functions, including signal transduction, direct transcriptional activation, DNA repair, and inhibition of protein degradation. [87], [88] and [89] The mechanism of this activity and the biologic function of HBX in the viral life cycle remain largely unknown.

However, it is well established that HBX plays an essential role in HBV infection in vivo [90], [91] and may contribute to the oncogenic potential of HBV. [92]

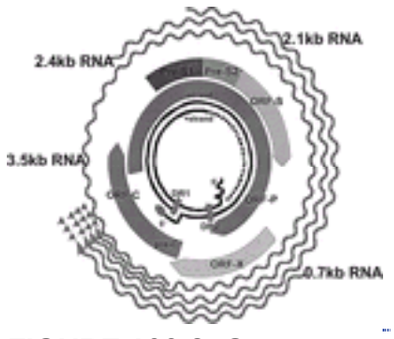

FIGURE 106-2. Genome structure and organization of hepatitis B virus. The hepatitis B virus open reading frames: pre-C and C (precore and core proteins), P (polymerase protein), pre-S1, pre-S2, and S (L, M, and S surface envelope proteins), and X protein are shown. The viral genome structure is composed of the full length (-)-DNA strand and variable length (+)-DNA strand (*solid* followed by *dashed line*). The pol protein is covalently attached to the 5' of the (-) strand and a capped oligoribonucleotide (*angulated line*) to the (+) strand. Direct repeats 1 and 2 (*small rectangular boxes*) are shown on the genome. The *outer lines* represent the four transcripts all terminating at a common polyadenylation site.

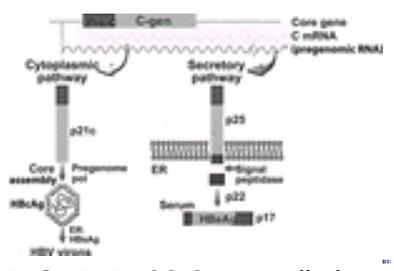

FIGURE 106-3. Two distinct processing pathways of *HBV* core gene. Two species of core RNAs are transcribed from the core gene. One starts before the pre-C and the other in the middle of the pre-C region. The former codes for the pre-C/C protein and is directed to the secretory pathway through the signal peptide sequence in the pre-C. After further proteolytic cleavage in the endoplasmic reticulum, HBeAg is formed and secreted. The latter RNA codes for the core protein, which is involved in the nucleocapsid assembly.

Other functionally important elements within the HBV genome include two direct repeats (DR1 and DR2) in the 5' ends of the minus and plus strands, which are required for strand-specific synthesis during replication. [93] Two enhancer elements, designated as En I and En II, confer liver-specific expression of viral gene products. [94] A glucocorticoid-responsive sequence within the S domain, [95] a polyadenylation signal within the core gene, [96] and a posttranscriptional regulatory element overlapping En I and part of HBX ORF have been described. [97]

The HBV replication pathway has been studied in great detail and is summarized in Fig. 106-4. The initial phase of HBV infection involves the attachment of mature virions onto host cell membranes, likely involving the pre-S domain of the surface protein. [98] Various cellular factors have been proposed to be the viral receptors, but only the carboxypeptidase D has been shown to play an essential role in viral entry for the duck HBV. [99] Mechanisms of viral disassembly and intracellular transport of viral genome into the nucleus are not well understood and probably involve modification of nucleocapsid core protein. [100] After entry of viral genome into the nucleus, the single-stranded gap region in the viral genome is repaired by the viral pol protein, and the viral DNA is circularized to the covalently closed circular form. [100] This form of HBV DNA serves as the template for transcription of several genomic and subgenomic RNAs. Structurally, the transcripts are unspliced, polyadenylated, and possess a 5' cap structure. The 3.5-kb genomic transcripts consist of two species with different 5' ends: the pregenomic and the precore RNAs. The pregenomic RNA (pgRNA) serves as the template for reverse transcription and the mRNA for core and polymerase; the precore RNA directs the translation of the precore gene product. [101] The polymerase is initiated at the pol start codon of the pgRNA, probably as a result of a ribosomal scanning mechanism. [102] The large HBsAg (LHBsAg) protein is translated from the 2.4-kb subgenomic RNA, the middle (M) and small HBsAg (SHBsAg) proteins from the 2.1-kb RNA, and the HBX protein from the 0.7-kb RNA.

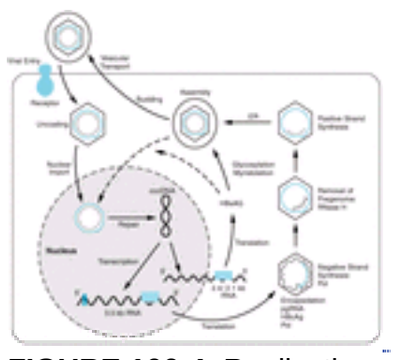

FIGURE 106-4. Replication of hepatitis B virus. Infectious virions probably attach to hepatocytes through the pre-S1 domain of the L protein. Upon entering, the nucleocapsid is delivered to the nucleus, and the viral genome is repaired to the covalently closed circular form (cccDNA). Viral transcripts are translated in the cytoplasm, and the core and polymerase proteins interact with the genomic length RNA to form the nucleocapsids. Reverse transcription occurs, and the mature virions are assembled in the endoplasmic reticulum, where they acquire the surface proteins. The virion is then secreted through vesicular transport. The encapsidation signal (dark box) and posttranscriptional regulatory element (light box) on the *HBV* transcripts are shown as *rectangular boxes*.

The S protein accounts for most *S* gene products, with the L protein constituting 1% to 2% and the M protein 5% to 15%. Each surface protein has a glycosylation site in the S domain. Additional modifications of the M and L proteins occur at the pre-S2 domain with an N-linked oligosaccharide and a myristic acid at the amino-terminal glycine residue of the pre-S1 domain. [103] The distribution of the three envelope glycoproteins varies among the types of viral particles, with little M and L protein in the 20-nm particles but relatively more L protein in the Dane particles.

Assembly of HBV begins with encapsidation of the genome. The packaging signal is a *cis*-acting element referred to as epsilon, which contains a stem-loop structure. [104] The terminal protein of the pol interacts with the epsilon and in concert with the core protein forms the nucleocapsid. [105] After encapsidation, the pol mediates the reverse transcription of the pgRNA to minus-strand DNA and subsequent positive-strand synthesis. The circular form of the DNA is completed through several complicated steps of strand transfer. [106] The nucleocapsid then interacts with the envelope proteins in the endoplasmic reticulum to assemble into mature virions.

Hepatitis C Virus

HCV is an enveloped virus and has been classified into six genotypes, 1 to 6. The virus circulates predominantly in complex with immunoglobulins and lipoproteins. [107], [108] It is a member of the *Flaviviridae* family and has a positive-sense, single-stranded RNA genome about 9.6 kb in length with a single large ORF and highly conserved UTRs at the 5' and 3' ends [109], [110] and [111] (Fig. 106-5). The 5' UTR contains an internal ribosomal entry site that mediates translation. [110] The 3' UTR has a

variable length with a 5' to 3' sequence followed by a polypyrimidine tract and finally by a highly conserved 98 nucleotide sequence. [111] The 3' UTR is also predicted to have extensive secondary structures that probably play a role in viral replication. In the large ORF, the structural genes for core and two envelope glycoproteins, E1 and E2, are located at the N-terminal end and the nonstructural genes NS2, NS3, NS4A, NS4B, NS5A, and NS5B at the C-terminal end.

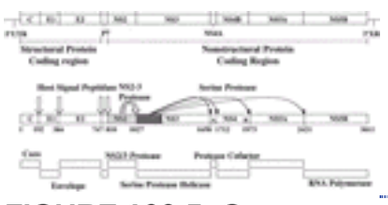

FIGURE 106-5. Genome organization of hepatitis C virus. The 5' and 3' untranslated regions (UTR) flanking a polyprotein open reading frame are shown at the *top*. Numbering refers to nucleotide positions of genes, based on the sequence of an *HCV* genotype 1a infectious clone. The middle panel shows HCV polyprotein processing with cleavage sites of host signal peptidase (*open arrows*), NS2-3 protease (*gray arrow*), and NS3 serine protease (*thin arrows*). Numbering denotes amino acid position upstream of cleavage sites. The processed HCV proteins are shown at the bottom.

The HCV polyprotein of about 3000 amino acids is processed co- and posttranslationally by cellular and viral proteases to produce the individual gene products. [112], [113] Cellular proteases in the endoplasmic reticulum catalyze the cleavage of the structural proteins, whereas viral encoded proteases cleave the nonstructural proteins. [114]

The highly conserved core protein is the putative viral nucleocapsid and encompasses the first 191 amino acids of the polyprotein. The E1 and E2 are envelope glycoproteins with C-terminal hydrophobic transmembrane domains. [115] The 27 N-terminal amino acids of E2 have been designated the hypervariable region 1, owing to significant amino acid variations among all isolates. [116] Studies have suggested that sequence variations of the hypervariable region 1 result from immune pressure as a mechanism to evade host immune response.

The NS2 region encodes a metalloproteinase that requires cell membrane and N-terminal NS3 for efficient function. [117] The NS2-3 protease mediates autocatalytic cleavage between the NS2 and NS3 (Fig. 106-5). The NS3 region encodes a multifunctional protein with an N-terminal serine protease and a C-terminal RNA helicase and nucleotide triphosphatase (NTPase). [118] The NS3 protease, distinct from NS2-3 protease activity, is involved in processing the downstream polyprotein. [119] The NS4A interacts with and acts as a cofactor for the NS3 protease. [120] The crystal structure of NS3 protease has a trypsin-like structure but becomes more chymotrypsin-like when co-crystalized with NS4A. [121] The function of NS4B is unknown. The NS5A may play a role in sensitivity to interferon. [122] The NS5B is the RNA-dependent RNA polymerase that mediates viral replication. Similar to replication of other *Flaviviridae* family members, HCV replicates in the cytoplasm, presumably in a membrane-associated compartment (Fig. 106-6). The NS5B recognizes a structure in the 3' UTR and initiates minus-strand RNA synthesis in a primer-independent template-specific process. [123] The synthesis of plus strand is presumably carried out by NS5B in a similar manner. HCV replication in vivo probably occurs in the context of multiple viral nonstructural proteins. The process of viral assembly is poorly understood and probably requires the interactions among viral genome, core, and E1 and E2 proteins.

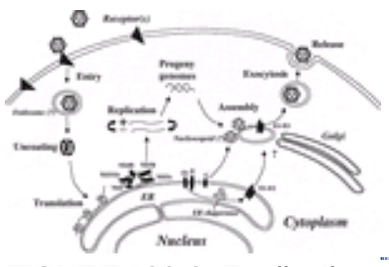

FIGURE 106-6. Replication of hepatitis C virus. The virion attaches and enters the susceptible cell through pathways that are not yet completely defined. The viral genome is then directed to a membranous component in the perinuclear endoplasmic reticulum region and serves as template for HCV protein synthesis. The nonstructural proteins form a replication complex with the genomic RNA and direct RNA replication (to negative and then plus strands). The structural proteins, which are retained in the endoplasmic reticulum, interact with the progeny genomes and assemble into virions. The virions are then secreted through an unknown exocytotic pathway, probably not passing through the Golgi compartment.

Hepatitis D Virus

HDV requires co-infection with HBV for replication. [124] Delta antigen is the inner ribonucleoprotein (RNP) component of a subviral particle that is enveloped by HBsAg. HDV has many features in common with viroids, the subviral agents of plants. [125] The RNP complex consists of small (SHDAg) and large (LHDAg) delta antigens and a single-stranded circular RNA genome 1.7 kb in length that has extensive self-complementation to form a rodlike structure (Fig. 106-7). HDV attachment to the host cell is mediated by HBsAg. [126] The HDV genome uses host RNA polymerase II to carry out RNA-directed RNA synthesis that is dependent on the small delta antigen. [127], [128] Both genomic and antigenomic RNAs possess ribozyme activities that catalyze RNA self-cleavage and self-ligation. Similar to plant viroids, transcription and replication are integrated into a single process using a double rolling-circle mechanism. [125] After entry into cells, HDV genome serves as a template for replication, resulting in the production of multimeric antigenomes. Nascent antigenomes, through their intrinsic ribozyme activities, form circular monomeric RNAs that, in turn, serve as templates for the production of HDV genomes. Alternatively, the elongating product can be cleaved and released as polyadenylated mRNAs, which then direct delta antigen synthesis. [129]

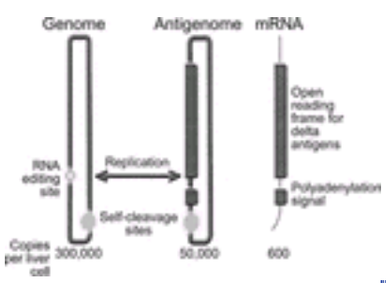

FIGURE 106-7. Genomic organization of hepatitis D virus. The RNA genome has a rodlike structure and contains an RNA editing and a self-cleavage site (*circle*). The antigenome is synthesized from the genomic RNA and is the template for HDV mRNA encoding the delta antigens. The antigenome also serves as the template for genome synthesis. The estimated copy numbers of the RNA species in the infected liver are shown *below*.

Translation of HDV mRNA yields the small and large delta antigens, which differ by the addition of 19 amino acids in the C-terminal end of LHDAg. [130] The small and large delta antigens have distinct functions during HDV replication. The additional C-terminal amino acids of the LHDAg contain an isoprenylation signal that appears to be important for interaction with HBsAg during viral assembly. [131] The RNA editing process results in two mRNA species coding for the two forms of HDAg and

involves the double-stranded RNA-activated adenosine deaminase. [132] This RNA editing activity results in the C-terminal extension of the LHDAg. [133]

HDV assembly begins with the association of the delta antigens with the newly synthesized genome to yield an RNP complex. [134] The RNP complex is transported from nucleus to cytoplasm, presumably mediated by the nucleocytoplasmic shuttling function of delta antigens. The LHDAg of the RNP interacts with HBsAg to facilitate assembly. Large delta antigen is required for particle assembly, whereas small delta antigen is co-packaged but not required for particle formation. [135]

Hepatitis E Virus

HEV is a nonenveloped virus and is currently unclassified but is similar to togavirus and alphavirus. The viral genome is a single-stranded, positive-sense RNA genome of about 7.5 kb. It is polyadenylated and has a capped 5' end. [136] The genome is organized into three overlapping ORFs flanked by noncoding regions (Fig. 106-8). ORF 1 appears to encode the nonstructural gene products, ORF 2 the capsid protein, and ORF 3 a protein with possible nucleocapsid function. [137] Based on sequence analysis and comparison with other viral genomes, ORF 1 contains several functional domains: methyl transferase, papain-like cysteine protease, helicase, and an RNA-dependent RNA polymerase. [138] ORF 2 begins 38 nucleotides downstream from the 3' terminus of ORF 1 and contains arginine-rich regions believed to be involved in genome encapsidation. ORF 3 overlaps one 3' nucleotide of ORF 1 and extends into ORF 2.

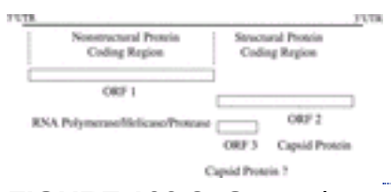

FIGURE 106-8. Genomic organization of hepatitis E virus. The open reading frames (ORF) are flanked by 5' and 3' noncoding regions and a 3' polyadenylation. Within ORF 1: MT (methyl transferase), X and Y (unknown functions), Pro (protease), Hel (helicase), H (proline-rich hinge region), Pol (RNA-dependent RNA polymerase). ORF 2 codes for the capsid, and ORF 3 codes for a protein of unknown function.

Replication of HEV has not been characterized because of a lack of similarity to other viruses and efficient cell culture systems. The mechanisms of viral attachment, entry, and uncoating are unknown. The released genome likely uses the host translation machinery to synthesize viral gene products. Processing of the ORF 1 polyprotein is carried out by either cellular proteases or a viral papain-like proteinase encoded by ORF 1. The viral encoded polymerase mediates synthesis of plus- and minus-strand genomes as well as subgenomic RNA species, which serve as templates for translation of viral antigens. The mechanism of viral assembly is unknown but probably involves the capsid function of ORF 2 and ORF 3.

PATHOGENESIS

Acute infection with hepatitis viruses is associated with a spectrum of liver diseases and systemic manifestations, ranging from asymptomatic infection, to self-limited hepatitis, to fulminant hepatitis. In addition, three of the viruses (B, C, and D) are associated with persistent infection and chronic hepatitis whose clinical manifestations are variable. The outcome, extent, and severity of acute viral hepatitis depend on a variety of viral and host factors. Although host responses play a major role in viral clearance and disease pathogenesis, the outcome of infection is often predicated on a variety of viral adaptive mechanisms. The pathogenesis of acute viral hepatitis involves a complicated set of virus-host interactions and is likely a result of diverse host immunologic responses to the viral infection. In this section, the pathogenesis of acute viral hepatitis is discussed in the general context of viral infection and host responses and with respect to relevant issues specific to each of the viruses. Among the hepatitis viruses, the pathogenetic mechanisms have been much better studied in HBV and HCV than in the others; therefore, we focus more on the former viruses. Furthermore, the pathogenesis of acute hepatitis is often inferred from the various studies during chronic infection (for B, C, and D), and we attempt to highlight these issues during the course of discussion in this section.

Primary Infection

After gaining entry into a susceptible host, the hepatitis viruses are carried by the blood to the liver, which is the major site of viral tropism. For HAV and HEV, the viruses enter through the gastrointestinal epithelium, and the uptake mechanisms remain largely unknown. It is possible that a round of local replication may occur at the site of entry before the virus is further spread to the liver through the portal circulation. Because HBV, HDV, and HCV have been reported to infect nonhepatocytes, the existence of an intermediate compartment of replication before infection of the liver has also been proposed but remains controversial. [139], [140] Many initial events of the viral infection have been characterized in the animal models for each virus. HBV and probably HCV replicate in a noncytopathic manner without causing injury to hepatocytes, whereas the cytopathicity of other viruses is unknown.

Immune Responses

During primary infection, the initial pathway of antiviral immune response is largely unknown. Initial viral infection is associated with activation of innate immunity in the liver. Recognition of infected hepatocytes by resident natural killer or natural killer T cells leads to activation of these cells and induction of antiviral cytokines, including interferons. [141], [142] This phase of innate immunity leads to the initial control of viral replication. Because this antiviral response is likely associated with a noncytopathic mechanism, little or no hepatocellular injury is evident. The innate immunity also plays a critical role in the activation of the adaptive immunity, including humoral and cellular responses. Induction of humoral immune response with production of neutralizing antibodies prevents viral spread and leads to subsequent elimination of circulating viruses. [143] This mechanism is particularly relevant for HAV and HBV infections because of the high level of viral replication and viremia. Neutralizing antibodies against the capsid (for HAV and HEV) or envelope (for HBV) can be induced and lead to viral clearance and protection from subsequent exposure. [144], [145] and [146] This constitutes the basis for the successful formulation of HAV (probably HEV as well) and HBV vaccines based on the capsid and envelope proteins, respectively. In HAV, HBV, HDV, and HEV, immunoglobulin M (IgM) class of antibodies is detected first and serves as a useful marker for acute infection. IgA class of antibodies has been detected in HAV and HEV infections, but its implication in viral clearance and protective immunity remains unknown. [144] On the other hand, neutralizing antibodies probably play little or no role in viral clearance during acute HCV infection. [147] A clearly defined anti-HCV IgM response has not been identified, and the antibody response, [148] especially against the envelope proteins, tends to occur much later than other hepatitis viral infections. [149]

For HBV, the antibody response to the envelope proteins is a T-cell–dependent process. [150] A minority of patients infected with HBV fail to produce antienvelope antibodies, therefore contributing to the establishment of persistent infection. This deficiency resides at the level of T-cell nonresponsiveness, probably as a result of tolerance or anergy induction toward the HBV proteins. [151] The molecular mechanisms underlying this deficiency, however, are largely undefined. For HAV infection, whether the relapsing or prolonged phase is secondary to transient failure of humoral immune response is unknown. On the other hand, antiviral antibodies may play a role in viral pathogenesis. Cell surface forms of viral antigens on infected hepatocytes could be a potential target for antibody-directed cell cytotoxicity. [152], [153] However, this mechanism has not been shown to be operative in hepatocellular injury associated with any of the viral infections. In contrast, immune complex diseases with complement fixation, including glomerulonephritis, vasculitis, and cryoglobulinemia, which are major extrahepatic manifestations of HBV and HCV infections, can result from abnormally activated antibody response to viral antigens.

The other limb of immune response, the cell-mediated immunity (CMI), is critical for the long-term control of viral infections, including the hepatitis viruses. Although this aspect has only been studied in great detail for HBV and HCV, it is not unreasonable to suspect that CMI may play a role in viral clearance and pathogenesis for HAV, HDV, and HEV. Much of the information for hepatitis B has been gleaned from studies in mouse models, chimpanzees, and infected humans. [151], [154] Nonprimate animal models that are susceptible to hepadnaviral infection (woodchucks, ground squirrels, ducks) have also provided utility in this venue of research. In acute HBV infection, individuals can mount a vigorous, multispecific, and polyclonal cellular immune response to HBV. In contrast, chronically infected patients have a weak or barely detectable anti-HBV response. [151] This is true for both CD4 and CD8 responses. During acute hepatitis B, a vigorous HLA class II–restricted, $CD4^+$, helper T-cell response to multiple epitopes of HBc/eAg predominates in virtually all patients. Such a response to HBV envelope antigens, however, is much less evident. The class II–restricted, $CD4^+$ T cells specific for nucleocapsid play an important immunoregulatory role in the control of viral infection. [151], [155] By helping B cells produce neutralizing antienvelope antibodies and activating HBV-specific cytotoxic T lymphocytes (CTL), this $CD4^+$ helper T-cell population may direct the initial antiviral

response. During chronic HBV infection, the once strong nucleocapsid-specific CD4 $^{+}$ T-cell response becomes barely detectable, presumably owing to a switch to T-cell exhaustion or nonresponsiveness. During exacerbation or successful treatment of chronic hepatitis B, these nucleocapsid-specific T-cell responses could reemerge. [156], [157]

In most viral infections, the activation of virus-specific CD8 $^{+}$ CTLs is critical for viral clearance. These cells can detect and eliminate or cure virus-infected cells through recognition of viral peptides in the context of HLA class I molecules. Using short synthetic peptides mimicking processed viral antigens and cells genetically engineered to express viral proteins, CTL responses to HBV in humans have been studied extensively. [151] These studies indicate that patients acutely infected with HBV develop a strong, polyclonal, HLA class I–restricted CTL response that is directed against multiple epitopes in all viral proteins. Similar to the class II–restricted CD4 responses in a minority of infected people, the class I–restricted CTL responses disappear and are barely detectable during the chronic phase of HBV infection. [155], [158]

Studies of immune responses in HCV revealed that both CD4 and CD8 responses can be detected against various viral proteins during acute infection, but the vigor and character of these responses appear to be directly correlated with the outcome of the viral infection. [147] A vigorous and multispecific CD4 and CD8 response is associated with viral clearance in both human and experimental chimpanzee infections. [159], [160] However, in most acute HCV infections, the infected hosts appear to exhibit little or no CMI and progress to chronic infection. This limited immunity suggests an “immune avoidance” model for HCV infection. A recent study has pointed to a defect in dendritic cells in antigen presentation, presumably as a result of infection of these cells by HCV. [161] Other mechanisms, such as the immunomodulatory effects of HCV core protein and the interferon inhibitory property of the NS5a protein, may also contribute to an overall weak immunity to this viral infection. [162], [163]

In chronic HBV and HCV infections, the detection of virus-specific CD4 and CD8 cells, albeit with low frequency and weak activities, in the peripheral blood and liver of chronically infected individuals suggests a pathogenic relationship between the indolent cellular immune response and necroinflammatory liver disease associated with chronic hepatitis. [151] Therefore, the CMI is a double-edged sword: vigorous response leads to viral clearance, whereas ineffective response results in chronic hepatocellular injury.

For HBV infection, the molecular and cellular mechanisms of viral clearance and hepatocellular injury have been elucidated in the animal models, including both transgenic mice and chimpanzees [151], [154] (Fig. 106-9). Adoptive transfer of murine CD8 $^{+}$, class I–restricted HBsAg-specific CTLs into syngeneic transgenic mice expressing HBV envelope protein in the liver leads to acute hepatitis. [164], [165] The CTLs first target the liver through interaction between the HBV-specific T-cell receptors and the antigen-presenting HLA class I molecules on the hepatocytes and cause scattered apoptosis of hepatocytes. By secreting cytokines, including interferons, the CTLs recruit a variety of antigen-nonspecific inflammatory cells into the liver, resulting in more extensive necroinflammatory injury of the liver that resembles acute hepatitis B in humans. The predominant infiltrating effector cells are the macrophages, which probably mediate most of the hepatocellular injury in this model. [166] The CTLs, although not primarily responsible for most of the hepatocellular injury, initiate the cascade of immunologic events leading to hepatitis in this model. A major consequence of these immunologic events is the marked inhibition of hepatocellular *HBV* gene expression and viral replication. [167] Although the CTLs may contribute to a small proportion of inhibition by direct cytolysis of *HBV*-expressing hepatocytes, a noncytolytic mechanism likely plays a substantial role in this effect. [167] Interferon-a and tumor necrosis factor-a produced by activated CTLs and other effector cells are the key cytokines involved in this mechanism. [167] A recent study in chimpanzees [154] also provided support to the noncytopathic mechanism as the major antiviral mechanism responsible for viral clearance during acute hepatitis. The resident natural killer or natural killer T cells, as discussed previously, provide the first line of defense; the CTLs, together with other inflammatory cells and production of antiviral cytokines, likely constitute the final assault on the virus. The CTL response appears to be long-lived because patients recovered from acute HBV infection harbor HBV-specific CTLs many years after viral clearance. [158] The CTLs have been postulated to persist as a result of continuous stimulation by low-level viral replication and in the meantime keep the infection in check. It is not clear how prevalent is this occult HBV infection, but low-level HBV virus can be frequently detected in patients with serologic evidence of recovery. [168], [169] and [170] Furthermore, active HBV infection can be reactivated in these patients upon immunosuppressive therapy, and their serum or organs are capable of transmitting HBV infection. [171], [172] and [173]

FIGURE 106-9. The immunopathogenesis of hepatitis B. See text for details.

In HCV infection, long-term persistence of virus-specific T cells has also been demonstrated despite evidence of recovery. [174] However, low-level viral infection is probably not the reason for this persistence. It is possible that these virus-specific memory T cells have unusual longevity in vivo and can be rapidly activated upon viral antigen stimulation years after infection. Whether these virus-specific T cells can offer protective immunity to subsequent viral infection is unknown. The observation that chimpanzees can be reinfected despite recovery from previous infection [175], [176] suggests that protective immunity may not persist after viral clearance.

The cellular immune responses to HAV, HDV, and HEV are largely unknown. Although HAV-specific CD8 CTLs have been detected in liver biopsies during acute hepatitis A, their role in viral clearance and pathogenesis remains undefined. [177], [178]

CLINICAL MANIFESTATIONS

Symptoms related to acute viral hepatitis are variable and nonspecific. It is impossible to distinguish one form of viral hepatitis from the other based solely on clinical features. The clinical course of hepatitis varies widely from an asymptomatic phase recognized only by elevation in aminotransferase levels to fulminant hepatitis with frank jaundice and hepatic coma. [179], [180] and [181] About 20% of cases of acute hepatitis present with jaundice. There is a variable incubation period for each virus, ranging from 1 week to 6 months. The initial presentation is dependent on age at exposure, integrity of the host immune system, presence or absence of underlying liver disease, and the level of viral inoculum. Overall mortality is low. An overview of the clinical features of each of the five hepatotrophic viruses is given in Table 106-2.

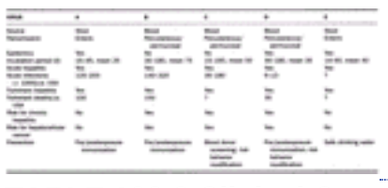

TABLE 106-2 Clinical Overview of the Five Viral Hepatidides

Before the onset of symptoms, there is a prodromal phase that can last from 1 day to 2 weeks and averages 5 to 7 days, during which there are nonspecific constitutional symptoms. By far the most common symptom reported is loss of appetite. Patients report a distinct aversion for food that may worsen as the day

progresses. [182] They may also lose the taste for tobacco and alcohol. Fatigue and weakness are common symptoms reported by 90% of patients and may be severe enough to confine them to bed. Before the onset of jaundice, two thirds to three fourths of patients complain of low-grade fever and flu-like symptoms. Mild headache is reported by 50% to 70% of patients. Vomiting and nausea are experienced by some patients but are not predominant features of acute viral hepatitis, and their continued presence should alert one to consider alternative diagnoses. Diarrhea is not a common feature of acute hepatitis and occurs in less than 25% of cases of HAV infection. Patients often complain of a dull ache under the right rib cage or even frank pain. Closer to the onset of jaundice, the urine may begin to darken.

The prodromal phase is followed by the icteric phase. The onset of jaundice usually coincides with the peak of the serum ALT. The duration of jaundice is variable, ranging from 4 days to several months, but averages 2 to 3 weeks. Patients initially notice a yellow discoloration of the mucous membranes and sclerae, followed later by a sallow discoloration of the skin. The urine becomes intensely dark owing to the release of conjugated bilirubin from necrosed hepatocytes, and stools become pale owing to an inability of the hepatocytes to conjugate bilirubin to its secretory form. During this phase, half of patients may experience itching, which is usually mild and transient. Weight loss of 2 to 10 kg is not uncommon. A minority of patients experience depression.

During the convalescent phase, most symptoms resolve. Jaundice disappears, with a return of normal skin, urine, and stool color. The return of an appetite and weight gain are favorable signs indicating recovery. Fatigue may persist for up to 2 to 6 months.

The physical examination during acute viral hepatitis may be normal, but almost all patients have some degree of hepatic tenderness. Most patients have mild hepatomegaly (12 to 14 cm), and the liver edge should feel soft and smooth. On occasion, it may feel firm to the examining hand, but it should never feel hard or nodular. If these findings are elicited, underlying cirrhosis should be suspected and an acute on chronic hepatitis considered. Splenomegaly and spider angiomas are features not commonly observed with acute hepatitis, but they may occur rarely. Jaundice is present in icteric cases, involving the mucous membranes, sclerae, and skin. The total bilirubin level usually has to be greater than 2.5 mg/dL before jaundice is clinically evident.

Extrahepatic Manifestations

Extrahepatic manifestations may occur in patients with acute viral hepatitis and result from direct infection of another organ or as an immune-mediated phenomenon. A serum sickness–like syndrome may be present in 5% to 15% of patients with acute HBV infection and less so in those with HCV infection. It presents as a low-grade fever, rash, arthralgias, and angioneurotic edema. [183], [184] The rash is usually urticarial but may be maculopapular. The arthralgias tend to involve the large joints, such as the elbows, wrists, knees, and ankles. Symptoms are thought to be immune complex mediated and resolve with onset of hepatitis.

Polyarteritis nodosa (PAN) is well described in association with HBV infection. In one series, PAN occurred in almost one third of newly diagnosed cases of HBV. [185] PAN is thought to result from the deposition of antigen-antibody complexes in the intima of the vessel wall; HBsAg is the suspected antigen. [186], [187] Symptoms include arthralgias, fever, abdominal pain, renal disease, mononeuritis, and skin rash. PAN occurs more often with chronic HBV infection. [188] The mortality rate ranges from 30% to 50%.

Essential mixed cryoglobulinemia (EMC) is a systemic vasculitis characterized by palpable purpura, arthralgias, and weakness. EMC has been linked to hepatitis A, B, and C based on the detection of viral antigens, antibody, and virus in the cryoprecipitate and the vascular lesions. [189], [190] and [191] The association of EMC and viral hepatitis is strongest with HCV infection. [192] Cryoglobulins are proteins that precipitate in the cold and, in the case of HCV infection, may result from HCV infection of B cells [193], [194] with the production of both IgG and IgM antibody; the IgM cross-reacts with rheumatoid factor. [195] The prevalence of cryoglobulins in unselected patients with hepatitis C is unknown. Most cases of HCV-related EMC are associated with chronic infection and do not correlate with viremia or genotype but appear to be related to the duration of infection and to more advanced stages of liver disease.

Renal disease is often seen in patients with acute viral hepatitis, and specific pathology is best characterized for HBV and HCV. Manifestations of renal involvement range from mild proteinuria and abnormal urinary sediment, including red blood cell and hyaline casts, to frank glomerulonephritis with renal failure. The renal lesion is thought to result from the deposition of immune complexes in the glomerular basement membrane. HBsAg, HBeAg, and HCV antigen have been demonstrated in the immune complexes from the glomerular basement membrane. [196], [197] and [198] The most common renal lesions seen in HBV infection were membranous [199] and membranoproliferative glomerulonephritis. [200] Membranous glomerulonephritis occurs mainly in children from endemic regions. The natural history of membranous glomerulonephritis is not well defined. [201] Nephrotic syndrome and proteinuria are the most common presentations. Children are more likely to be asymptomatic and to have spontaneous resolution of the nephrotic syndrome. [199] Progressive renal failure usually develops in adults. Most patients with glomerulonephritis have evidence of active viral replication, but the severity of the renal disease does not correlate with the activity of the liver disease or the viral level in serum. Membranoproliferative glomerulonephritis is the most common renal lesion seen in HCV infection, usually in association with EMC. [202] In the presence of cryoglobulins, 98% to 100% of patients with membranoproliferative glomerulonephritis have detectable anti-HCV. In the absence of cryoglobulinemia, patients with chronic HCV infection may have a variety of renal lesions suggestive of primary glomerular disease including nephrotic syndrome and nonnephrotic proteinuria.

Papular acrodermatitis (Gianotti syndrome) has been described in children with acute hepatitis B. [203], [204] The syndrome is most commonly seen in young children aged 1 to 6 years. It is characterized by erythematous papules on the arms, legs, and face with truncal sparing and lymphadenopathy. The mucous membranes are spared. It is not related to the infecting subtype of HBV. It usually runs a benign course, improving with the onset of hepatitis.

Other organ systems affected during viral hepatitis, although rarely, include the heart and gastrointestinal and nervous systems. Cases of myocarditis, pericarditis and bradycardia, and pericardial and pleural effusions have been described. Pancreatitis is commonly reported, especially in children, [205] and may be due to direct infection of the gland in the case of HAV infection. Neurologic manifestations have included encephalitis, meningoencephalitis, mononeuritis multiplex, transverse myelitis, and Guillain-Barré syndrome. [206], [207] and [208] A variety of hematologic disorders may follow viral hepatitis, including pure red cell aplasia, pancytopenia, aplastic anemia, and hemolytic anemia.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of acute hepatitis is based on the constellation of clinical, biochemical, histological, and serologic findings. The CDC case definition of acute viral hepatitis is an illness with a discrete date of onset, accompanied by jaundice or elevated serum aminotransferase levels greater than 2.5 times the upper limit of normal. The clinical symptoms associated with viral hepatitis were described in the previous section and are nonspecific for etiology. The specific diagnosis depends on the results of serologic testing. The sensitivity of current serologic assays should allow the etiology of acute viral hepatitis to be established in almost all cases by the time patients become symptomatic. In instances in which there may be a late or weak antibody response, sensitive RNA and DNA assays may be helpful in the diagnosis.

Serology

In the setting of a known exposure and appropriate symptoms with elevated serum aminotransferases, acute hepatitis A is diagnosed by the detection of IgM antibody to HAV (anti-HAV IgM) and the absence of other viral markers in serum. [209], [210] Anti-HAV IgM is usually present in serum 5 to 10 days into the incubation period and remains detectable for up to 6 months after infection, when IgG type antibody rises to high titer and persists for life [211] (Fig. 106-10). Commercial assays for total anti-HAV measure both IgG and IgM, and thus a positive test result is not helpful in distinguishing acute from chronic infection. HAV RNA can also be detected in serum and stool during the incubation phase but is primarily a research tool and is not used for diagnostic purposes.

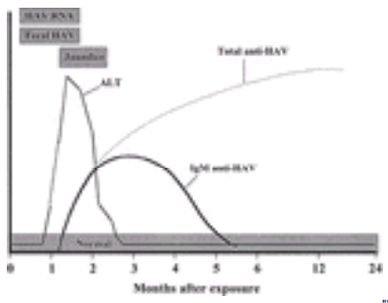

FIGURE 106-10. Typical serologic course of acute hepatitis A virus infection.

A number of viral antigens and their respective antibodies can be detected in serum after infection with HBV, and their interpretation is often the source of great confusion to physicians and patients alike. HBsAg and HBeAg are the first two viral proteins detected in serum [146] (Fig. 106-11). HBsAg may be detected as early as 1 to 2 weeks or as late as 11 to 12 weeks after infection, and its persistence is a marker of chronicity. HBeAg is considered a marker of HBV replication and infectivity. It is more important for assessing risk for transmission in chronic HBV infection. [212] The level of HBcAg in serum is usually too low to detect but can be visualized by immunostaining of liver tissue. A cytoplasmic distribution of HBcAg in hepatocytes was shown to correlate with disease activity.

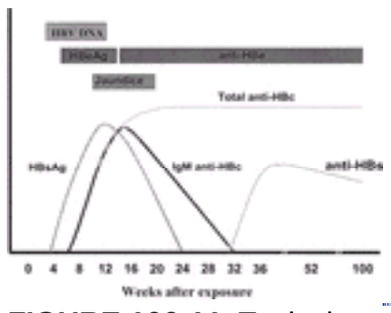

FIGURE 106-11. Typical serologic course of acute hepatitis B virus infection.

Antibodies to three of the viral proteins (HBsAg, HBeAg, and HBcAg) can be detected in convalescent sera. Anti-HBc IgM class is the first to appear, followed by antibody to HBeAg (anti-HBe) and finally antibody to HBsAg (anti-HBs), which is the marker of recovery. Anti-HBc IgG type persists after recovery and is a useful marker for prevalence studies of past exposure to HBV. [213] It should not be used to diagnose acute or chronic infection. HBsAg and anti-HBc IgM are the most frequent markers present during the symptomatic phase of the illness. [146] , [214] Rarely during acute HBV infection, HBsAg is rapidly cleared from serum, and anti-HBV IgM may be the only marker detectable; this scenario is referred to as the “window” period. This situation may also be seen during the convalescent phase of the illness when HBsAg and aminotransferase levels are declining and anti-HBs is not yet detectable. Given the sensitivity of current assays for HBsAg, this window period is rarely observed in clinical practice. Diagnosis of acute hepatitis B rests on the demonstration of anti-HBV IgM and HBsAg and negative tests for anti-HAV and anti-HCV. HBV DNA is present during the incubation and symptomatic phases of infection. Like HBeAg, it correlates with disease activity and infectivity. Current PCR-based assays have a cutoff of 100 virions per milliliter of blood, but routine testing for HBV DNA is not recommended unless the patient is immunocompromised. [215]

Acute hepatitis C infection is difficult to recognize because fewer than 20% of cases present with jaundice. [216] Anti-HCV can be detected as early as 4 weeks after acute infection and in the majority of cases remains detectable lifelong [217] , [218] (Fig. 106-12). The diagnosis of acute hepatitis C infection should be based on a history of exposure, absence of prior liver disease, negative tests for other hepatitis viruses, and a positive test for anti-HCV. [219] A supplemental confirmatory test, such as the radioimmunoassay blot assay, should be performed. HCV RNA is detectable within 2 weeks of established infection and is also used to confirm acute infection. [220] However, routine HCV RNA testing is not currently advocated owing to the lack of standardization of the test. It is recommended in the investigation of immunocompromised patients who may have a low or absent antibody response.

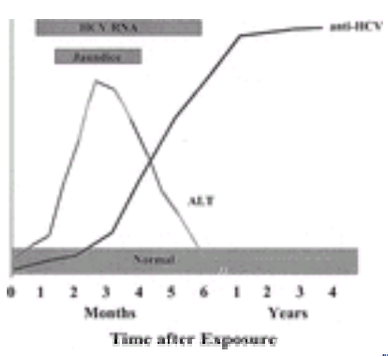

FIGURE 106-12. Typical serologic course of acute hepatitis C virus infection.

Acute delta hepatitis may occur in two settings: simultaneously with HBV (co-infection) or after infection of a chronic hepatitis B carrier (superinfection). The serologic pattern differs in each case. During co-infection, markers of HBV are usually detected first, followed later by markers for HDV. The presence of anti-HBc IgM is an important finding of HDV co-infection and a discriminating marker for HDV superinfection. Early in the course of co-infection, hepatitis D antigen (HDAg) is not detectable unless the hepatitis is severe, but within 1 to 2 weeks, antibody to hepatitis D (anti-HDV) IgM should be detectable (Fig. 106-13). Anti-HDV IgG is usually delayed for several weeks after the onset and in some cases is present only transiently during the convalescent phase. The late and poor antibody response in acute delta co-infection makes the diagnosis difficult. It is advisable to perform repeat testing for anti-HDV IgM to confirm HDV co-infection. HDV RNA can be detected early in the course of co-infection, but commercial assays are not currently available. Thus, the diagnosis of acute delta co-infection depends on the detection of anti-HDV IgM, HBsAg, and anti-HBc IgM.

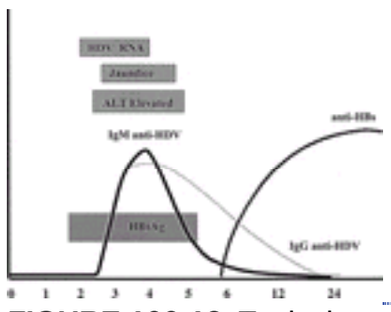

FIGURE 106-13. Typical serologic course of acute hepatitis D virus co-infection.

Acute delta superinfection occurs in the setting of chronic hepatitis B. HDAg and HDV RNA can be detected early in the course of infection by experimental assays. In contrast to HDV co-infection, anti-HDV IgM and IgG are both present early during the symptomatic phase of acute delta superinfection (Fig. 106-14). Anti-HBc IgM is usually absent or present in low titer. Diagnosis of acute delta superinfection thus rests on the detection of anti-HDV and HBsAg and absence of anti-HBc IgM.

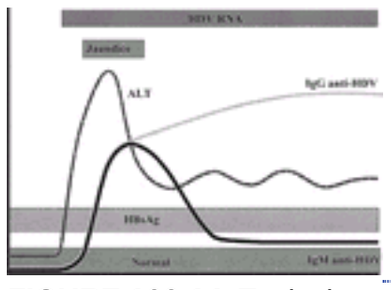

FIGURE 106-14. Typical serologic course of acute hepatitis D virus superinfection.

Diagnostic tests for antibody to HEV (anti-HEV) are now available. In outbreak settings due to HEV, anti-HEV IgM is detectable in greater than 90% of patients' sera during the symptomatic phase and remains detectable for a period of 2 months after the onset of illness (Fig. 106-15). Anti-HEV IgG persists after recovery and appears to be protective against reinfection, at least in the short-term. In the appropriate setting, diagnosis of acute hepatitis E is confirmed by the demonstration of anti-HEV IgM.

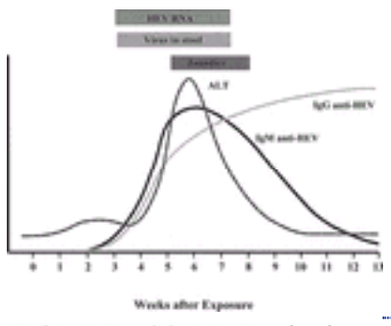

FIGURE 106-15. Typical serologic course of acute hepatitis E virus infection.

Laboratory Features

The laboratory hallmark of acute viral hepatitis is an elevation in the serum aminotransferase level. [221], [222] The serum ALT level is more specific for hepatocyte necrosis and is usually higher than the serum aspartate aminotransferase level. During an acute hepatitis infection, levels range from 10 times the upper limit of normal to greater than 20 times the upper limit of normal and peak with the onset of jaundice. The height of the ALT or aspartate aminotransferase elevation usually correlates with the level of destruction of hepatocytes but not with clinical outcome. The serum alkaline phosphatase level, a marker of biliary epithelial cell damage, may rise to two to three times the upper limit of normal but in most cases remains in the normal range. The conjugated and unconjugated serum bilirubin fractions are elevated. The level is dependent on the extent of hepatocyte damage but typically ranges from 85 to 340 µmol/L (5 to 20 mg/dL). In fulminant cases, laboratory markers of hepatic function become markedly abnormal: the prothrombin time prolongs, serum albumin falls, and higher bilirubin levels are seen. These are ominous signs that indicate impending hepatic failure and should prompt early patient referral to a liver transplantation center. During the acute phase of the illness, leucopenia with neutropenia and lymphopenia may be observed. Rarely, aplastic anemia may complicate acute viral hepatitis.

Histology

A liver biopsy can distinguish acute from chronic hepatitis and viral from nonviral causes but is rarely necessary to establish the diagnosis. Regardless of the etiology, acute viral hepatitis has certain characteristic findings.

There is an acute inflammatory response involving the entire liver. [223], [224] Hepatocyte damage is greatest near the terminal hepatic venules (zone 3). Here, the classic histological features of acute hepatitis are observed. The hepatocytes appear swollen (ballooning change). Ballooned hepatocytes have a granular, pale-staining cytoplasm with enlarged nuclei and are occasionally multinucleated. Numerous perivenular hepatocytes undergo acidophil change as a result of apoptosis. Their cell cytoplasm becomes densely stained and irregular in shape with pyknotic nuclei. These cells are thought to be the precursor of the acidophil body (Councilman body). The acidophil body is not specific for viral hepatitis but is a characteristic feature when present in abundance. The remaining hepatocytes show regenerative hyperplasia. The combination of cell swelling, cell shrinkage, apoptotic body formation, and cell loss gives rise to disruption of the liver cell plate pattern or lobular disarray. [225] When only a few hepatocytes are involved, the damage is designated *focal necrosis*. When groups of adjacent hepatocytes are involved, it is termed *confluent necrosis*.

Inflammatory cells are present within the hepatic lobule, among the damaged cells. Lymphocytes and macrophages are the major cell types. Plasma cells, neutrophils, and eosinophils are present to varying extent. Kupffer cell hyperplasia is recognizable. The mononuclear cell infiltrate also involves the portal tract. The inflammatory infiltrate may spill out of the portal tract, but this should not be confused with piecemeal or interface necrosis, a feature of chronic viral hepatitis. Surprisingly, despite the extensive destruction of liver tissue, the reticulin framework of the liver remains remarkably preserved. Cholestasis may or may not be present. Bile ductular proliferation may be seen but is not a prominent feature. Mild fatty change is seen more frequently with HCV infection. Liver fibrosis is generally absent but may be seen if the biopsy is done late in the course of the illness.

In some cases, the confluent necrosis is severe enough to involve the entire central zone of the acinus. The necrotic cells are replaced by the condensed reticulin framework and inflammatory cells, predominantly macrophages forming central-to-portal bridging necrosis. This entity may be the precursor to fulminant hepatitis, and in one series, its presence was associated with a poorer outcome. [226] In extreme cases, there may be involvement of all zones of the acinus, referred to as *massive necrosis* with total loss of hepatocytes. The parenchyma is replaced by the collapsed reticulin framework and inflammatory cells. This is a manifestation of severe hepatitis seen in the clinical setting of fulminant hepatitis and coma.

The histological changes associated with acute viral hepatitis persist for several weeks after onset. Thus, a nearly normal liver biopsy 2 to 3 weeks after an episode of jaundice effectively rules out acute hepatitis. Late biopsy findings include a decrease in the degenerative changes, macrophages that stain intensely with periodic acid-Schiff stain, and numerous mitotic figures.

Staining the liver tissue with antibodies for hepatitis B surface and core antigens in the case of hepatitis B and delta antigen for delta hepatitis can help with the identification of the etiologic agent of the hepatitis.

Differential Diagnosis

An array of diseases may mimic acute viral hepatitis and should always be considered in the differential diagnosis while awaiting the results of serologic testing. As with other acute medical illnesses, rapid diagnosis permits the prompt institution of specific therapy that may prevent an adverse outcome. The differential diagnosis

of acute viral hepatitis is summarized in Table 106-3.

TABLE 106-3 Acute Viral Hepatitis: Differential Diagnosis, Diagnostic Testing and Specific Therapy

The prevalence of drug-induced liver disease is probably underestimated in clinical practice. Drug-induced liver disease should be considered in every case of acute hepatitis until the cause is firmly established. A wide variety of over-the-counter drugs are associated with hepatic toxicity, which may result in a clinical picture indistinguishable from acute viral hepatitis. Therefore, it is mandatory to obtain a detailed drug history from every patient who presents with acute hepatitis. Clinical clues to the diagnosis are the timing of the rise in serum aminotransferase in relation to the onset of jaundice and presence of a serum eosinophilia. In drug-induced liver disease, the jaundice tends to lag behind the rise in aminotransferases, whereas in viral hepatitis, the serum aminotransferase level tends to peak with the onset of jaundice.

Autoimmune hepatitis may present as an acute hepatitis in up to 30% of cases. [227], [228] The typical presentation is that of a young woman with a high titer of antinuclear antibody and smooth muscle antibody and other clinical evidence of autoimmune disorders such as arthralgias and autoimmune hemolytic anemia. The globulin level may not be elevated during an acute presentation. Testing for the HLA markers A1, B8, and DR3 may be helpful in confirming the diagnosis of autoimmune hepatitis.

Wilson disease is “the great imitator” and has diverse presentations, including that of acute hepatitis. [229] The diagnosis is difficult to confirm during an acute presentation and requires a high index of suspicion. It is important to establish the diagnosis early because of an extremely high mortality rate. In a recent series of fulminant hepatitis, no patients with Wilson disease referred to a transplantation center survived despite undergoing OLT. [230] The usual diagnostic criteria may be normal during an acute presentation. Ceruloplasmin level may be normal because of widespread release from necrosed hepatocytes, and urinary copper excretion may be low owing to altered renal clearance. Diagnostic clues may be the young age of the patient, a low alkaline phosphatase level, and the presence of a hemolytic anemia.

The liver may be an innocent bystander in infections that have multisystem involvement. Yellow fever, malaria, and Q fever may involve the liver and cause a hepatitis-like picture. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpesviruses, and adenoviruses may cause severe infection in immunocompromised patients and those at the extremes of age. These agents should be suspected when routine serologic testing is negative in an immunocompromised patient or when a history of recent travel to an endemic area is obtained from the patient.

Acute cardiovascular failure with hypotension from pump failure or sepsis can result in ischemic injury to the liver, so-called shock liver. In this setting, there can be massive hepatocyte destruction with serum aminotransferase levels greater than 20-fold the upper limit of normal, mimicking acute viral hepatitis. Bilirubin levels usually are only mildly elevated. The history of hypotension and aminotransferase levels that rapidly normalize should establish the diagnosis.

Given the vast number of metabolic functions carried out by the hepatocyte, it is surprising that toxic injury is not seen more commonly. Mushroom poisoning from ingestion of *Amanita phalloides* and exposure to carbon tetrachloride are the best examples of toxic injury leading to markedly elevated aminotransferase levels. The diagnosis depends on a careful medical history indicating ingestion or exposure.

Rarely, biliary tract obstruction (choledocholithiasis or acute cholecystitis) can be confused with acute hepatitis. [231] Usually, other clinical features are present to suggest the diagnosis, such as an elevated serum alkaline phosphatase level and more intense right upper quadrant pain.

Finally, in special populations such as bone marrow transplant recipients, unique diseases should be considered during the investigation of an acute rise in serum aminotransferase levels. These include acute graft versus host disease, which typically occurs within the first 28 days after bone marrow transplantation, and venoocclusive disease, which occurs within the first 2 to 3 weeks. [232], [233] and [234] In pregnancy, acute fatty liver and the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) should be considered. [235], [236]

COURSE AND COMPLICATIONS

Course

Most cases of acute hepatitis are uncomplicated and resolve without sequelae. This is the expected outcome after infection with HAV and HEV in 99% of instances. One to 2% of cases are complicated by a fulminant course with a high mortality rate. Hepatitis B, HCV, and HDV may progress to a chronic hepatitis in 10% to 90% of cases depending on the infecting virus, age at infection, and immune status of the host. This is recognized by persistent elevation in the aminotransferase levels 6 months after the onset of infection and detection of specific serologic or virologic markers. Chronic hepatitis is best assessed by liver biopsy. Occasionally, an acute hepatitis has a prolonged course over 4 months and up to 1 year, typified by the prolonged course of HAV infection. This variant needs to be differentiated from chronic hepatitis, and the best means of doing so is watchful waiting until the aminotransferase levels return to normal.

The prolonged form of HAV infection is characterized by pruritus, fever, diarrhea, and weight loss with serum bilirubin levels greater than 10 mg/dL and a clinical course lasting a minimum of 12 weeks. [237], [238] It is seen more commonly in males and older individuals. Importantly, all patients recover without lasting sequelae. Some patients with this variant of hepatitis A may benefit from corticosteroid therapy. [238]

In addition to the prolonged variant of HAV infection, a relapsing variant is seen in up to 20% of HAV cases, distinguishable from the protracted form by its biphasic presentation. [239] Patients initially present with an acute hepatitis followed by apparent recovery only to have a recrudescence of hepatitis 5 to 10 weeks later. The second phase tends to be associated with higher bilirubin levels and to have a more prolonged course compared with the first phase. [240] Steroid therapy during the early phase of the illness and alcohol consumption have been identified as potential risk factors for relapsing HAV infection. [239]

Despite these complications, complete resolution is the rule. Serologic evidence of HAV IgM in serum during recrudescence of the illness and detection of HAV in stool during relapse are helpful tests for excluding other cause of hepatitis. The pathophysiology of these atypical presentations is currently unknown. A recent study in children reported an association between the protracted form of hepatitis A and HLA-DRB1*1301, a marker for pediatric autoimmune hepatitis. [241] Case reports have noted that acute hepatitis A infection may trigger the onset of autoimmune hepatitis in adults. [242], [243]

Other atypical courses of viral hepatitis have been described, which sometimes lead to diagnostic confusion. A biphasic pattern of hepatitis may also be observed after hepatitis D co-infection, although cholestasis is not a feature. The first peak is related to HBV infection and the second to HDV. On occasion, HBsAg-negative delta hepatitis is encountered during acute infection, owing to suppression of HBV replication by HDV. [244] This presentation can be quite perplexing for the clinician, and repeat testing for anti-HBc IgM and markers of HDV infection are recommended in suspected cases. Flares of chronic hepatitis B or reactivation are well recognized in association with chemotherapy or immunosuppression. It is important to distinguish reactivation from acute infection or nonviral causes of hepatitis because the management is different. The diagnosis of reactivation can be tricky. In most cases, the clinical picture is recognizable by elevated aminotransferase levels with detectable HBsAg and absent anti-HBV IgM in serum. However anti-HBV IgM may be detectable in 25% of cases of reactivation, leading to confusion with acute hepatitis B. The only way to resolve this dilemma is to obtain a history from the patient of previous HBV infection or to perform a liver biopsy, which should

demonstrate changes of both acute and chronic hepatitis in the case of reactivation.

Complications

Fulminant hepatitis is a complication of acute hepatitis characterized by a rapid progression to hepatic failure with associated hepatic encephalopathy. Only 1% to 2% of all cases of acute viral hepatitis result in fulminant hepatitis, but 75% of fulminant cases are caused by viral hepatitis. Fulminant hepatitis has been reported with all of the hepatotrophic viruses. [245], [246], [247] and [248] Fulminant hepatitis has an extremely high mortality rate; survival has improved with the widespread availability of OLT. [249]

Older individuals with hepatitis A may be at increased risk for fulminant hepatitis. [250] A report of a high rate of fulminant hepatitis A in patients with underlying chronic hepatitis C [251] has not been substantiated by other studies. [252], [253]

Epidemics of fulminant hepatitis B have been reported with variant strains of the virus. In several studies, molecular characterization of the virus revealed mutations that led to inactivation of the gene encoding HBeAg. [254], [255], [256] and [257] However, other studies showed a low rate of these mutations in fulminant hepatitis B, and the mutations were also found to arise de novo in patients with chronic HBV infection who did not develop fulminant hepatitis B, suggesting that other factors play a role. [258], [259], [260] and [261] Fulminant hepatitis B has also been reported with emergence of the YMDD variant under lamivudine therapy. [262], [263]

Fulminant hepatitis may occur more frequently with HDV co-infection. [264], [265] In addition, periodic epidemics of a severe fulminant form of delta hepatitis have been described in the Amazon basin, referred to locally as *LaBrea hepatitis* and may be related to the particular genotype of HDV, genotype 3. [266]

Fulminant hepatitis E occurs at surprisingly high rates in pregnant women during the third trimester, ranging from 15% to 25%. [267], [268] The reason for this is currently unknown. Survival is poor.

A hepatitis-associated aplastic anemia and pure red cell aplasia may complicate acute hepatitis and is associated with a high mortality rate. [269], [270] and [271] It appears to be more common in the Far East and in adolescent boys and young men. [272]

Chronic hepatitis is a complication seen only with HBV, HCV, and HDV. Rates of chronic infection depend on immune status of the host and age at time of infection and vary from 10% to 90%. The causes of chronicity are unknown but undoubtedly involve a failure of the cellular immune response.

Other long-term complications of acute viral hepatitis include hepatocellular carcinoma, especially in the case of HBV and HCV infection, and lymphoma associated with HCV infection.

PREVENTION AND IMMUNOPROPHYLAXIS

Hepatitis A Virus

Hepatitis A infection can be prevented by three strategies: active immunization through vaccination, which has the advantage of lifelong immunity; passive immunization through the administration of antibody made from pooled human sera processed by cold ethanol fractionation; and a combination of the two strategies.

Passive Immunization Immunoglobulin provides protection against hepatitis A infection by the passive transfer of antibody. It can be used to provide immunity before and after exposure. The recommended dose is 0.02 mL/kg of immunoglobulin administered intramuscularly for both preexposure and postexposure prophylaxis. If used for preexposure prophylaxis, a dose of 0.02 mL/kg provides protection for less than 3 months. A higher dose of 0.06 mL/kg will provide protection for about 5 months. For postexposure prophylaxis, administering immunoglobulin within 2 weeks of the exposure is greater than 85% effective. [273] Later administration is ineffective in preventing infection but will attenuate the course of disease. [274] Serious adverse events are rare after administration of immunoglobulin, but anaphylaxis has been reported after repeat administration to patients with known IgA deficiency. [275] It is safe to administer during pregnancy or breast-feeding and can be coadministered with inactivated vaccines, oral polio vaccine, and yellow fever vaccine. [3] Immunoglobulin can interfere with the immune response to other live attenuated vaccines, and these vaccines should be postponed for about 2 weeks. [3]

Active Immunization Two commercially inactivated hepatitis A vaccines are available in the United States: HAVRIX and VAQTA. Both vaccines are highly immunogenic in adults, adolescents, and children, with 94% to 100% achieving protective levels of antibody 1 month after a single dose of vaccine. [276] The lower limit of antibody required to prevent HAV infection is unknown, but in vitro studies indicate that levels of less than 20 mIU/mL can be neutralizing. [276], [277] The efficacy of both vaccines was demonstrated in clinical trials. HAVRIX was shown in a large double-blind randomized controlled trial to have an efficacy of 94% after two doses 1 month apart. [278] Similarly, VAQTA was evaluated in a double-blind, placebo-controlled, randomized trial and had an efficacy of 100% after one dose of vaccine. [279] The vaccine has not been evaluated in the postexposure setting. A small randomized trial showed that hepatitis A vaccine was 79% efficacious in preventing HAV IgM positivity after household exposure to hepatitis A compared with no treatment. [280] Hepatitis A vaccine has not been directly compared to immunoglobulin in postexposure prophylaxis. The vaccine appears to confer long-term protection against infection in studies, with follow-up ranging from 6 to 7 years. [281], [282] Hepatitis A vaccination provides preexposure protection against HAV infection, and it is recommended for people who are at increased risk and for anyone wishing to obtain immunity. Individuals who are at increased risk for hepatitis A infection and who should be routinely vaccinated are summarized in Table 106-4. Both vaccines appear to be quite safe. In Europe, Asia, and the United States, about 8 million doses of hepatitis A vaccine have been administered, and serious events, anaphylaxis, Guillain-Barré syndrome, brachial plexus neuropathy, transverse myelitis, multiple sclerosis, encephalopathy, and erythema multiforme, although rare, have been reported. [278]

Group at Risk
People traveling to or working in countries that have high or intermediate endemicity of infection
Men who have sex with men
Illegal drug users
People who have occupational risk factors for infection
People who have clotting factor disorders

TABLE 106-4 People for Whom Hepatitis A Vaccine Is Recommended

The hepatitis A vaccine can be safely coadministered with the hepatitis B vaccine without affecting the immunogenicity of either vaccine or increasing the frequency of side effects. [283] Safety has not been evaluated in pregnancy, but because the vaccine is inactivated, the risk to the fetus is expected to be low. Similarly, no special precautions are required when vaccinating immunocompromised patients. [284] The vaccine is safe and effective when administered to patients with chronic liver disease. [285], [286] Prevaccination serologic testing for susceptibility is not recommended because of the additional costs and because vaccination poses no risk to a person with a history of hepatitis A infection. Postvaccination testing is not recommended because of the high rate of response. A combined hepatitis A and B vaccine is now commercially available.

Hepatitis B Virus

The goals of vaccination against hepatitis B are similar to those for hepatitis A: to prevent infection in susceptible individuals and to prevent spread of infection and chronic liver disease. Additionally, vaccination against hepatitis B can prevent infection with delta virus and prevent hepatocellular carcinoma related to HBV infection. HBV infection can be prevented by passive or active immunization or a combination of the two.

Passive Immunization Hepatitis B immune globulin (HBIG) is prepared from plasma that contains high-titer anti-HBs. In the United States, HBIG has an antibody titer of more than 100,000 IU/mL by radioimmunoassay. HBIG is used in conjunction with hepatitis B vaccination for postexposure prophylaxis to prevent transmission of HBV from a HBsAg-positive mother to her child or alone to prevent reoccurrence of HBV infection after OLT.

Active Immunization Two yeast-derived recombinant hepatitis B vaccines are available in the United States. A plasma-derived vaccine that was licensed for use in the United States in 1982 is no longer available. The vaccine is part of the routine immunization program in many countries and is very effective in reducing the incidence of HBV infection in endemic areas of the world. The recommended schedule is a series of three intramuscular doses of hepatitis B vaccine into the deltoid

muscle of adults and anterolateral thigh of neonates and infants. The recommended dosing schedule induces an antibody response (anti-HBs titer higher than 10 mIU/mL) in more than 90% of adults and more than 95% of children and adolescents. [287], [288] Increasing the interval between the first and second doses of HBV vaccination has little effect on immunogenicity or final antibody titer. The third dose confers optimal protection. Longer intervals between the second and third doses result in higher final titers of anti-HBs. [289] Administration of hepatitis B vaccine does not interfere with the antibody response to other vaccines. [290] The immune response is comparable to a standard course of vaccination if the product of one manufacturer is used with that of another. Hemodialysis patients usually require a higher dose or a greater number of vaccinations to achieve an adequate immune response. [291], [292] This probably also applies to immunocompromised individuals but has not been confirmed. Clinical trials in the United States and other countries have shown that the hepatitis B vaccine is 80% to 95% effective in preventing HBV infection in susceptible people. [288], [293], [294] and [295] If a protective antibody response is elicited, then the vaccine is 100% effective. Studies suggest that even patients who fail to develop an adequate immune response to the vaccine (anti-HBs titer less than 10 mIU/mL) are probably protected against infection. Likewise, individuals who lose detectable antibody are probably protected because of lasting immunologic memory. The vaccine appears to afford long-term protection. Studies in which the plasma-derived vaccine was used indicate that 13% to 60% of patients may lose antibody after 9 years of follow-up. [296], [297] and [298] The efficacy of the hepatitis B vaccine to prevent transmission of HBV was shown in several studies after introduction of vaccine programs in endemic regions. Before vaccination, the carrier rate of HBV infection in Taiwan was estimated to be 15% to 20%. A program of universal vaccination was initiated in 1984. This program was highly effective in reducing the rate of chronic HBV infection. Over the next decade, the rate of chronic HBV infection fell from 10.5% to 1.7% in children aged 6 years, and the annual incidence of hepatocellular carcinoma fell from 0.7 per 100,000 to 0.36 per 100,000. [299], [300] and [301] These findings were confirmed by other studies. [302] Vaccination is not contraindicated in pregnant women or in those who are breast-feeding. Postvaccination testing is not recommended after routine vaccination of children or adolescents. Testing for immunity is advised only for people whose subsequent management depends on their immune status, such as infants born to HBsAg-positive mothers, dialysis patients and staff, and patients with HIV infection. [298] Currently, booster doses are not recommended for vaccinated individuals, nor is routine serologic testing to determine immune status, unless a person was exposed to the virus. Revaccination of nonresponders to a primary course of vaccine should be considered because 15% to 25% develop an adequate antibody response after one dose and 30% to 50% after three doses of vaccine. [296] For hemodialysis patients, vaccine-induced immunity may wane, and patients should probably undergo testing for antibody levels annually and receive a booster dose if anti-HBs levels fall below 10 mIU/mL. [298] Pain and fever are the most common side effects associated with HBV vaccination; however, in placebo-controlled trials, these side effects occurred no more frequently than with placebo. [287], [288], [293], [295] Over 1 billion doses have been administered worldwide, and serious adverse events occur rarely. [22] A possible association between the plasma-derived vaccine and Guillain-Barré syndrome and demyelinating diseases has been reported. [303] Two recent studies failed to confirm an association between hepatitis B vaccine and multiple sclerosis. [304], [305] In addition, there are large differences in the geographic prevalence of HBV and incidence of multiple sclerosis. Furthermore, analysis of postmarketing studies in the United States showed no increase in multiple sclerosis after hepatitis B vaccination, and reanalysis of the French data by the Viral Hepatitis Prevention Board and World Health Organization concluded there was no association between hepatitis B vaccination and multiple sclerosis. [306] Variant viruses, with “escape mutations” in the immunodominant “a” determinant region of the HBsAg gene after vaccination, have been described. These variants have been reported worldwide. Therefore, a theoretical concern of hepatitis B vaccination is the replacement of wild-type virus by the variant strain to which vaccinated individuals in the community will be susceptible. A report from the Taiwan vaccination program described an increased prevalence of vaccine escape variants from 8% to 28% over a 10-year period, lending credence to this concern. [307] However, this finding has not been confirmed in other studies. [308], [309] Furthermore, chimpanzees vaccinated with commercial hepatitis B vaccines were protected from infection after challenge with an infectious strain of the variant virus. [310] Hepatitis B vaccination is recommended for the prevention of perinatal HBV infection, for infants born to HBsAg-positive mothers, and as part of the universal vaccination of all preschool-aged children. [298] Individuals who are at high risk for acquiring HBV infection should receive hepatitis B vaccination and are listed in Table 106-5. The recommendations for use of the hepatitis B vaccine in the postexposure setting are outlined in Table 106-6.

Group at Risk
People with occupational risk
Clients and staff of institutions for the developmentally disabled
Hemodialysis patients
Recipients of clotting factor concentrates
Household contacts and sex partners of HBV carriers
Adoptees from countries where HBV infection is endemic
International travelers
Injection drug users
Sexually active men and women
Inmates of long-term correctional facilities

TABLE 106-5 People for Whom Hepatitis B Vaccine Is Recommended

EXPOSURE	RECOMMENDATION
Perinatal	Vaccination + HBIG
Sexual (acute case)	HBIG +/− vaccination
Sexual (chronic carrier)	Vaccination
Household (acute case)	None
Household (acute case, known exposure)	HBIG +/− vaccination
Household contact (chronic carrier)	Vaccination
Inadvertent percutaneous/permucosal	Vaccination +/− HBIG

HBIG, hepatitis B immunoglobulin.

TABLE 106-6 Recommendations for Postexposure Immunoprophylaxis for Hepatitis B

Hepatitis C Virus

No effective vaccine is available to prevent hepatitis C infection. This is primarily due to a lack of neutralizing antibody, the high mutation rate of the viral genome, existence of viral quasispecies, and a lack of knowledge about protective immunity. Protection against infection after challenge with a homologous strain has been demonstrated in chimpanzees using hyperimmune serum against region 1 of the E2 protein but not against heterologous strains. [311], [312] and [313] Studies in chimpanzees using a DNA vaccine encoding the E2 protein failed to protect against infection with a homologous strain of virus but may have attenuated the course of infection and prevented chronicity. [314]

Studies in the late 1970s showed that use of immunoglobulin failed to prevent transmission of non-A, non-B hepatitis (HCV). [315], [316] Intravenous infusions of immunoglobulin may attenuate the severity of non-A, non-B hepatitis (HCV). [317], [318] Until further studies are carried out, use of immunoglobulin as postexposure prophylaxis for HCV infection cannot be recommended.

Hepatitis D Virus

The dependence of HDV replication on HBV means that the same preventative and postexposure measures use to prevent HBV infection can be employed to prevent hepatitis D co-infection. Risk behavior modification is the only current measure to prevent HDV superinfection.

Hepatitis E Virus

A recombinant vaccine for HEV is being evaluated in Nepal. Immunoglobulin has not been evaluated for postexposure prophylaxis.

Needle-Stick Injury Transmission of blood-borne pathogens through needle-stick injury is an important issue for health care workers. It is a significant contributor to job-related injuries and emotional stress for health care workers. Each year, about 600,000 to 800,000 needle-stick injuries occur in the United States. Infection with HBV, HCV, or HIV constitutes the major risk for the health care worker after needle-stick injury. The risk for HBV infection is primarily related to the degree of contact with blood in the work environment and to the HBeAg status of the source. In studies of nosocomial transmission of HBV through needle-stick injury, the risk for clinical hepatitis if the source was HBsAg and HBeAg positive was 22% to 31%; the risk for serologic evidence of HBV infection was 37% to 62%. In contrast, the risk for developing clinical hepatitis from a contaminated needle from an HBsAg-positive, HBeAg-negative individual was 1% to 6%, and the risk for HBV seroconversion 23% to 37%. [319] Although percutaneous exposure is an efficient mode of transmission of HBV, it presently accounts for a relatively small number of nosocomial infections as a result of increased hepatitis B vaccine use in health care workers. HCV is not transmitted efficiently by needle-stick injury. The rate of seroconversion to anti-HCV after needle-stick injury averages 1.8% per injury and ranges from 0% to 7%. [320], [321] About 2.4% of new cases of HCV infection are due to needle-stick injury. A deep injury, use of a hollow-bore needle, and visible blood on the needle have been identified as risk factors for transmission of HCV. [320] Exposure

prevention is the primary strategy to reduce HBV and HCV transmission by needle-stick injury. Health care workers should be educated concerning the risk for and prevention of blood-borne infections, including vaccination against HBV. Health care workers were required to adopt universal precautions regulations that were introduced in 1987. [322] Despite these recommendations, needle-stick injuries continue to occur. Regulations to prevent needle-stick injury should be enforced in the workplace. General management after a needle-stick injury involves washing the wound with soap and water. The person whose blood was the source of exposure should be evaluated for evidence of HBV, HCV, and HIV infection. No special precautions are necessary to prevent secondary transmission during the follow-up period. However, exposed people should refrain from donating blood, plasma, organs, tissue, and semen. The exposed person does not need to modify sexual practices or to avoid becoming pregnant. Employers should follow all federal and state requirements for recording and reporting occupational injuries and exposures. [323], [324] Specific recommendations for postexposure management are outlined by the U.S. Public Health Service. [325] Any unvaccinated person who sustains a needle-stick injury should receive the hepatitis B vaccine series. The recommendations for management of exposure based on HBsAg status of the source and vaccine status of the exposed individual are shown in Table 106-7. Both HBIG and hepatitis B vaccine can be administered simultaneously.

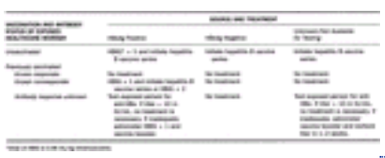

TABLE 106-7 Recommendations for Postexposure Prophylaxis for Health Care Workers Following Exposure to HBV

No specific therapy is available for prevention of HCV infection after needle-stick injury. Recommendations for postexposure management are intended to achieve early identification of chronic cases and, if present, to refer to a specialist for treatment options. The source of exposure should be tested to determine anti-HCV status. Baseline anti-HCV and ALT testing should be performed on the exposed individual and repeated in 4 to 6 months. If desired, HCV RNA testing can be performed after 4 to 6 weeks. All positive tests should be confirmed by supplemental testing using the recombinant immunoblot assay, for example. Immunoglobulin administration is not recommended because of the absence of neutralizing antibody and the failure of immunoglobulin to prevent transmission of HCV. [315], [318] Antiviral agents are not recommended for postexposure management. Counseling should be provided to exposed people.

TREATMENT

Treatment of acute viral hepatitis is largely supportive and directed to ensuring adequate nutrition and hydration and to monitoring patients for the development of fulminant hepatitis. Drug therapy is rarely indicated for acute viral hepatitis A and E because 90% to 95% of patients are expected to recover without sequelae. Hepatitis B and D can progress to chronic infection, but given the current response to antiviral therapy, none is indicated. Based on the high response rate to interferon therapy, it may be reasonable to treat patients with clearly documented acute HCV. [326]

General Recommendations

Most patients with acute hepatitis can be managed outside of the hospital setting as long as they can maintain adequate hydration and intake of calories. The old therapy of bed rest is no longer advocated unless the patient experiences severe fatigue. [327] No specific dietary measure or supplement has been shown to be effective. Protein should be restricted only in patients exhibiting clinical signs of hepatic encephalopathy. During the convalescent phase, a high-protein diet may be necessary to aid in recovery. Alcohol should be avoided, and use of medications should be kept to a minimum. Drugs that are metabolized by the liver, such as benzodiazepines, should be avoided or dose reduced if absolutely essential. Patients should be assessed weekly during the early phase of the illness and followed through recovery. They should be monitored for symptoms and signs of encephalopthy, such as increased somnolence, drowsiness, and asterixis and, if present, assessed with serial trail tests. Monitoring of the serum prothrombin time is a useful marker for assessing hepatic decompensation and for deciding when to refer to a liver transplantation unit. The monitoring of serum aminotransferase levels is not helpful for assessing hepatic function because levels may return to normal in fulminant hepatic failure after massive destruction of hepatocytes. Antiemetics can be used to improve symptoms of nausea. Patients who exhibit clinical features of fulminant hepatitis should be rapidly referred to a liver transplantation unit for management. OLT may be a life-saving procedure for patients who decompensate after acute hepatitis (see Chapter 48 on fulminant hepatitis). It is not necessary to isolate patients with acute hepatitis. People caring for patients with acute HAV and HEV infection should wash their hands with soap and water. Close contacts of people with acute HBV infection should receive hepatitis B vaccine.

Specific Therapy

The rationale for antiviral therapy in acute viral hepatitis is to prevent fulminant hepatitis and progression to chronic hepatitis. The indications for antiviral therapy have not been clearly delineated. Interferon-a was compared with placebo in retrospective fashion for the treatment of acute hepatitis B. A higher rate of clearance of HBsAg and HBeAg and loss of HBV DNA were observed in the group that received interferon-a, 80% versus 54%. Therapy was well tolerated, but the concern remains that interferon therapy may worsen the hepatitis. To date, there have been no randomized, prospective trials evaluating interferon therapy for acute hepatitis, B and use of this agent should be on a case-by-case basis using sound clinical judgment. Lamivudine, a nucleoside analogue, was shown to be effective in treatment of chronic HBV infection and may hold promise as a therapeutic agent for acute infection. This is based on the benefit in a single case of fulminant hepatitis B, and reports of success in treating reactivation of hepatitis B after chemotherapy and acute hepatitis B after OLT. [328], [329] and [330] Studies on therapy of acute delta hepatitis are not available. Until further data are available, specific antiviral therapy is not recommended for acute HBV or HDV infection. Lamivudine should be used to prevent reactivation in patients receiving chemotherapy or high-dose immunosuppressive therapy.

Therapy for acute hepatitis C is controversial. The rate of chronic hepatitis C ranges from 50% to 85%, and therapy during the chronic phase leads to sustained viral clearance in about 50% of cases. [331] This is the rationale for treatment of acute cases of hepatitis C but must be weighed against the risks of therapy. Small published studies indicate that treatment of acute hepatitis C using interferon monotherapy reduces severity of the acute hepatitis and reduces the rate of chronic infection. [332], [333], [334] and [335] The sustained loss of HCV RNA ranged from 39% to 64%, compared with 0% to 20% in untreated controls. A metaanalysis of nine controlled trials assessing the efficacy of a short-course (3 months) of low-dose interferon (3 MU three times per week) for acute hepatitis C showed that therapy was associated with a higher rate of normal ALT levels and clearance of virus at the end of treatment. [336] Long-term follow-up is not available from any of the published series. The argument against treatment of acute hepatitis C is based on the fact that a substantial proportion of acute cases, 25% to 30% resolve spontaneously and that treatment is problematic. It remains to be proved whether antiviral therapy initiated during the acute stage is superior to treatment started shortly after the infection becomes chronic. Based on a recent report showing a high response rate to interferon-a in acute hepatitis C, it may be reasonable to treat bona fide cases of acute HCV. [326]

OTHER VIRUSES

Other nonhepatotrophic viruses can cause hepatitis as part of a generalized systemic infection. Members of the Herpesviridae family are covered here because of their worldwide prevalence and their special role in bone marrow transplant recipients, patients receiving chemotherapy, and post-OLT patients. The identification of other putative hepatotrophic viruses and their role in acute hepatitis are briefly discussed.

Herpes Simplex Virus Types 1 and 2

Infection with herpes simplex virus (HSV) occurs worldwide and affects people of all ages. [337] The clinical manifestations of primary disease depend on the age and immune status of the individual. Primary infection in children tends to be a mild and subclinical illness in almost all cases. Severe infections occur more frequently in infants and immunocompromised patients. HSV 1 classically causes infection above and HSV 2 below the waist. The clinical manifestations of primary disease include vesicular and ulcerative gingivostomatitis and anogenital ulceration. [337] Hepatitis due to HSV 1 and 2 infection tends to occur in the setting of generalized primary infection or reactivation. HSV hepatitis is not a major cause or non-A to non-E hepatitis. [338] Rates of fulminant hepatitis and mortality are high in infants, patients receiving chemotherapy, bone marrow transplant recipients, and women during the third trimester of pregnancy. [339], [340] and [341]

Fever and abdominal pain are the major symptoms of hepatic involvement, and patients are frequently appear ill. The characteristic mucocutaneous lesions usually seen in primary infection are present in less than one third of cases; therefore, a high index of suspicion is required to make the diagnosis. Hepatomegaly may be present on clinical examination. There is often discordance between the aminotransferase levels and serum bilirubin level, with marked elevations in

aminotransferases but minimal jaundice. There may be an associated leucopenia, thrombocytopenia, and coagulopathy. Liver biopsy shows nonspecific hepatocellular necrosis and a mild, scattered inflammatory infiltrate. Multinucleated hepatocytes and nuclear inclusion bodies are specific for the disease.

The diagnosis depends on positive viral cultures from body fluids and PCR detection of viral DNA from serum. Serology is not helpful because the prevalence of antibody is high in the general population. A fourfold rise in IgG titer between acute and convalescent titer is diagnostic but is not practical in acutely ill patients. Immunostaining or PCR analysis of liver tissue is rapid and specific for the diagnosis. When the diagnosis is suspected in acutely ill patients, liver biopsy for culture and immunostaining is recommended for rapid diagnosis. [342]

There have been no clinical trials evaluating therapy for acute HSV hepatitis. Acyclovir, 5 mg/kg, is the treatment of choice based on the success of numerous case reports. [343] Therapy should be initiated promptly while awaiting diagnostic tests because of the high mortality rate. Successful resolution has been reported with vidaribine, and it may be used as an alternative agent to acyclovir. OLT may be a life-saving procedure. [344]

Epstein-Barr Virus

EBV occurs worldwide. Most cases in childhood are asymptomatic, whereas in adults, the typical symptoms of infectious mononucleosis are present: fever, malaise, headache, and cervical and axillary lymphadenopathy. The virus is lymphotrophic, and after initial infection and replication in epithelial cells of the pharynx, infects B lymphocytes. The liver is frequently involved in primary infection, but in contrast to HSV 1 and 2 infection, the hepatitis is usually mild and subclinical. Severe hepatitis has been described in immunosuppressed individuals but is uncommon. Most severe cases are due to reactivation of latent infection.

The clinical features of EBV-related hepatitis in adolescents and adults include fever, malaise, pharyngitis, abdominal pain, and mild adenopathy. The aminotransferase level is mildly elevated and peaks during the second to fourth week of infection. [345] No pattern is specific for EBV. Occasionally, the serum alkaline phosphatase level may be markedly elevated, greater than 15 times the upper limit of normal. A dissociation between the serum alkaline phosphatase and bilirubin, with an elevated alkaline phosphatase and normal serum bilirubin, has been observed. Jaundice is present in about 10% of cases and is usually mild (bilirubin less than 5 mg/dL). The coexistence of a hemolytic anemia may lead to higher than usual bilirubin levels. Most cases resolve in a few weeks, but aminotransferase levels may remain elevated for several months. Splenomegaly is frequently detected in primary infection (50%) and hepatosplenomegaly in 25% of cases. In children, a common presentation is fever, hepatomegaly, and disseminated intravascular coagulation. EBV hepatitis has been described after OLT but is infrequent and not a major cause of graft loss. [346] It may be associated with use of antilymphocyte preparations in the OLT setting. Chronic EBV hepatitis has not been reported. Cases of fulminant hepatitis occur but are rare. [347]

For practical reasons, the virus is not cultured in diagnostic laboratories, and primary infection is diagnosed by demonstration of nonspecific heterophile antibody using Paul-Bunnell or slide agglutination reactions (monospot test). Heterophile antibodies may only be detected after the second week of infection and may be present only for a short period. This test has been replaced by the monospot test, which is quite specific and sensitive for EBV. If more specific and sensitive tests are required, immunofluorescent tests for detection of specific antibodies to EBV proteins are available. Anti–viral capsid antigen IgM and IgG antibodies are usually present at the time of onset of clinical symptoms. EBV DNA can be detected in blood but is primarily a research tool. The liver biopsy shows a mononuclear cell infiltrate involving the portal area and sinusoids with minimal hepatocyte necrosis and Kupffer cell proliferation. The liver biopsy findings may be nonspecific. To aid histological diagnosis, liver tissue can be stained for EBV nuclear antigen 1 or probed for EBV-encoded small nuclear RNA by in situ hybridization. [348], [349]

No controlled trials have been done to assess treatment of EBV hepatitis because of the mild nature of the hepatitis. Successful outcome of severe cases has been reported with acyclovir. Based on these case reports, acyclovir should be tried in severe cases of EBV hepatitis. OLT can be life-saving when medical management fails. In the post-OLT setting, EBV hepatitis should be managed with reduction in immunosuppressive medication and judicious use of intravenous immunoglobulin. [350]

Cytomegalovirus

CMV infection occurs worldwide. In cross-sectional studies, more than 50% of the population exhibited past evidence of infection with CMV. [351] Most infections are asymptomatic, especially in children. Routes of transmission are intrauterine, perinatal, and sexual through contact with blood, genital fluid, or saliva.

In infants, CMV infection can cause a neonatal hepatitis syndrome characterized by jaundice, hepatomegaly, hemolytic anemia, and thrombocytopenic purpura with mild elevations in aminotransferase level. The diagnosis may sometimes be confused with extrahepatic biliary atresia, and indeed CMV infection has been proposed as a causative agent. [352] Most cases resolve without long-term sequelae.

Primary infection in adults presents with symptoms similar to those of infectious mononucleosis. The liver is commonly involved in primary infection, but the hepatitis tends to be mild; jaundice is rarely present. [353] Patients at risk for severe hepatitis include neonates, bone marrow and liver transplant recipients, and those receiving chemotherapy. In severe cases, the level of aminotransferases may mimic acute hepatitis. Distinguishing features are prolonged fever and atypical mononuclear cells on peripheral smear.

The liver biopsy usually shows multinucleated giant cells in neonatal hepatitis. Intranuclear inclusions are observed in hepatocytes, Kupffer cells, and biliary epithelial cells. Hepatic lobular microabscesses are reported in liver transplant recipients. [354]

The presence of atypical mononuclear cells on peripheral blood smear may suggest the diagnosis. More definitive diagnosis rests on recovering the virus from infected body fluids. The shell vial assay, which uses a combination of viral culture and immunologic detection of immediate to early gene expression, is the test of choice. IgM is sensitive for the detection of CMV macroglobulins but does not reliably indicate acute infection. Presence of IgG antibody is not specific for acute infection. A fourfold rise in IgG antibody between acute and convalescent sera is diagnostic but is seen in less than 50% of cases. Liver tissue can be stained with monoclonal antibody against CMV early and late antigen, and PCR techniques can yield a faster diagnosis than routine culture. [355], [356]

There are no controlled trials of therapy for CMV hepatitis. There are several case reports citing the benefits of gancyclovir for severe hepatitis. Patients with normal immunity generally have a mild course and do not require treatment. Treatment should be reserved for immunocompromised patients because of associated toxicity.

Recently Discovered Viruses

Studies indicate that in 10% of cases of transfusion-related hepatitis, 50% of cases of fulminant hepatitis, and 20% of community hepatitis, no cause can be identified. [357] This has led to the search for other hepatotrophic viruses. Using molecular techniques, this search began in earnest, and three candidate viruses have been discovered. Hepatitis G virus (HGV) or GB virus C (GBV-C), basically the same virus, was the first described, TT virus (TTV) (named after the initials of the patient from whom it was discovered) was the second, and SEN virus (SENV) the third.

Hepatitis G Virus HGV is a member of the *Flaviviridae* family and is distantly related to hepatitis C. Based on blood donor studies, the virus appears to have worldwide prevalence, with a rate of viremia of 1% to 2%. It can be transmitted by blood transfusion, and other modes of transmission, such as the percutaneous route, may be possible. It appears to have a high rate of persistence (91%). Initial studies suggested this was a causative agent of non-A to non-E hepatitis, but this has not been substantiated in other studies. [358], [359] Rates of HGV infection appear to be similar in transfusion recipients who developed hepatitis and those in whom hepatitis was not seen. [358] Additionally, most cases were not associated with a rise in aminotransferases. HGV may not even be hepatotrophic because inoculation studies in a chimpanzee failed to demonstrate liver disease. Based on these studies, it has been concluded that HGV is not a cause of acute or chronic hepatitis.
TT Virus TTV was initially discovered in 1997 from the serum of a patient with non-A to non-G hepatitis. [360] TTV is a single-stranded DNA virus belonging to the *Circovirus* family. Studies of multitransfused individuals and blood donors suggest a worldwide prevalence, with rates of viremia ranging from 5% to 90%. [360], [361] and [362] Initial studies from Japan indicated that the virus was related to hepatitis in three of five patients after blood transfusion, suggesting that it was the cause for non-A to non-E hepatitis. [360] However, a study of blood donors and prospectively followed transfusion recipients with and without hepatitis indicated a similar rate of newly acquired TTV infection in patients with (23%) and without (22%) hepatitis. [362] Transmission using serum and stool from two infants with acute TTV infection was observed in chimpanzees, but clinical and histological evidence of hepatitis was not demonstrated. [363] These data support the conclusion that TTV is not a hepatotrophic virus.
SEN Virus SENV is the most recently identified candidate virus as a potential cause for non-A to non-E hepatitis. SENV is a single-stranded DNA virus probably

belonging to the *Circovirus* family and distantly related to TTV. Five strains have been identified (A, B, H, D, and E), but only strains SENV-D and SENV-H had low enough rates in donor populations and high rates in transfusion-related hepatitis to qualify as potential agents of acute hepatitis. Preliminary data supporting SENV as an infectious hepatitis agent included a high prevalence of SENV in injection drug users and multitransfused patients, and the prevalence of SENV was high in cases of non-A to non-E hepatitis but low in control populations. [364] In a prospective study of transfusion-related hepatitis, there was a strong association between SENV with transfusion-associated non-A to non-E hepatitis (92%), compared with transfused controls who did not develop hepatitis (24%). [365] Persistent viremia was demonstrated for up to 12 years, and chronic elevation of aminotransferases was observed, but chronic hepatitis was not documented by liver biopsy. However, most patients with SENV infection did not have hepatitis, and replication within the liver has not been established. [365] These data appear to indicate that SENV-D and SENV-H may have a causative role in non-A to non-E hepatitis. In summary, HGV and TTV are not causative agents of non-A to non-E hepatitis. They can be transmitted by blood transfusion, but it is debatable whether they cause liver disease after infection or are hepatotrophic at all. It is possible they may cause liver disease in certain settings, as in immunocompromised patients infected with CMV and EBV, but this remains to be proved. They do not appear to worsen underlying viral or nonviral liver disease. SENV, another transfusion-transmitted virus, may lead to persistent infection, but more definitive studies are awaited before it can be added to the hepatitis alphabet.

CHAPTER 107

Robert G. Gish and Stephen Locarnini

CHRONIC HEPATITIS B VIRAL INFECTION

There are estimated to be more than 400 million carriers of hepatitis B virus (HBV) worldwide. [1] The prevalence of chronic HBV varies. In the Western world, HBV is usually an adult acquired disease with a prevalence ranging from 0.2% to 1% of the population and is responsible for less than 10% of chronic liver disease. In Asia, Africa, and the Middle East, chronic HBV is acquired at birth or early in life, has a prevalence from 5% to 20%, and is among the leading causes of death in those regions. At least 20% to 30% of those carriers die from complications of chronic liver disease, including cirrhosis and liver cancer. [2], [3] The World Health Organization places HBV in the top 10 causes of death worldwide. [4] The estimated viral burden in the United States is 1.5 million people, with the disease concentrated in ethnic subgroups and populations with high-risk behavior and health care costs to the United States economy that exceed $350 million per year. Although the United States is considered an area of low prevalence for hepatitis B infection, the incidence of new cases, the prevalence of carriers, and the burden of acute and chronic disease maintains hepatitis B among the important communicable diseases. It was estimated that more than 430,000 new cases of hepatitis B infection occurred each year in the United States in the 1980s, compared with a much lower estimate of 185,000 per year in 1997. [5], [6] These acute infections lead to 27,000 to 42,000 chronic carriers, 17,000 hospitalizations, and ultimately 4000 to 5500 deaths per year from cirrhosis and primary liver cancer as well as the morbidity and cost of liver transplantation in about 350 patients per year. [7], [8] and [9] The risk for chronic HBV infection after acute exposure ranges from 1% to 5% for adults and greater than 90% for infants born to infected mothers.

Understanding the prevalence of HBV, patients at risk, clinical presentation, serologic (Table 107-1) and molecular tests, as well the current standards of monitoring and treatment is an essential part of all clinical physicians' practices. Advances in molecular biology and virology, as well as developments in antiviral research, have led to much greater understanding of this virus, allowing implementation of new therapies and more appropriate testing. Sharing of knowledge between investigators and clinicians worldwide will continue to advance our understanding of this extensive health problem.

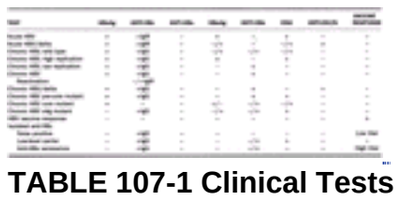

TABLE 107-1 Clinical Tests Used for Hepatitis B Virus

The serious consequences of end-stage liver disease and liver cancer confront patients and physicians throughout the world. Communicating the high rate of severe consequences of this disease is essential to encourage patients to participate in monitoring and follow-up. [10], [11], [12], [13] and [14] Testing patients at risk for HBV, interpreting the serologic tests available, distributing patient education, and implementing regular follow-up are all-important steps in the management of infected patients. Vaccination, the key step in eliminating this global scourge, must be applied to all infants, [15] household contacts of HBV-infected individuals, health care workers, and adolescents and individuals who are sexually active with more than one sexual partner. [16], [17] and [18] Vaccination of all newborns has been calculated to be cost-effective in the developed countries [19], [20] and may become cost-effective in developing countries, depending on the cost of vaccine and methods of administration. Regularly evaluating patients and counseling them about the monitoring process is very important because of the revolution in antiviral therapy taking place today for patients who are infected with HBV.

TERMINOLOGY AND ASSAYS

Terminology and testing for HBV have confounded many students of medicine since the discovery of HBV [19], [20], [21] and [22] because of confusing and misleading nomenclature. Inconsistent and inaccurate terms, such as the oxymoron "healthy carrier," must be removed from our terminology. These outdated terms, often used to reassure patients or physicians, do not represent the true clinical outcome of any patient group and also cannot be applied to any individual with any level of confidence.

The liver biopsy remains a very important step in evaluating patients with chronic HBV infections but is not required for all patients. The outpatient liver biopsy is safe, with a risk for serious complications being less than 1 in 2000 and the risk for death being less than 1 in 10,000. [23], [24] The liver biopsy determines the *stage* of disease (fibrosis) and the extent or level of inflammation (*grade*) (see Chapter 143). This determination then allows the patient and physician to decide on the necessity and urgency of treatment and the need for and frequency of liver cancer screening as well as monitoring of viral replication and liver panels. With the arrival of new antiviral medications aimed at inhibiting HBV replication, increasing rates of resistance to medications have been observed. The clinical significance of these resistant viruses is still being evaluated. Because combination therapy is currently in development, awaiting new information about treatment is reasonable as part of a patient treatment decision for some patients. Conversely, patients with advancing liver disease or impending liver failure usually require immediate treatment with our current best therapy, such as lamivudine.

DEFINITIONS

Chronic Hepatitis B Virus Disease

Chronic HBV disease is defined as hepatic necroinflammation resulting from the presence of HBV. These patients are positive both for hepatitis B surface antigen (HBsAg) and for HBV DNA with serum levels of HBV greater than 100,000 copies per milliliter or the presence of hepatitis B core antigen (HBcAg) staining in the liver. Liver enzyme levels are either persistently elevated or intermittently elevated over time periods of 6 months or longer. The World Health Organization case definition of chronic disease requires the detection in serum of HBsAg on two occasions over a 6-month period. Liver biopsy is an important component in defining the severity of liver disease in these patients. Abnormal liver enzyme levels are defined as an alanine aminotransferase (ALT) of more than 27 IU/mL in women and 30 IU/mL in men when individuals have a normal body mass index. [25] Patients with chronic HBV disease can be divided into two subgroups: hepatitis B e antigen (HBeAg) positive and negative, which will be discussed further in the section on HBV variants. Patients with normal ALT levels but high levels of HBV DNA and necroinflammation on liver biopsy are also included in the group owing to similarity in natural history. [10], [12], [13] and [14] Persistent HBV DNA levels detected over the first 1 to 4 weeks after acute hepatitis B disease indicate a strong likelihood of not clearing HBV infection, and consideration should be given to intervention with antiviral therapy. [26] "Flares" of hepatitis B infection occur in some patients and are defined as intermittent elevations of serum aminotransferase levels to more than 10 times the upper limit of normal. These events occur in 10% to 15% of patients each year and may be asymptomatic and undetected.

Inactive Carrier

Inactive HBsAg carrier state is defined as the presence of HBsAg in serum, no detectable HBeAg, low levels of HBV DNA (less than 100,000 copies per milliliter), and persistently normal ALT levels for periods of longer than 6 months. A liver biopsy can be performed in such patients but is not a usual practice, and the hepatitic activity index is typically less than 3 on a 1 to 22 scale. (See Chapter 143 on liver biopsy and histology scoring systems.) These patients are often described as immunotolerant and remain at risk for HBV DNA integration into hepatocyte nuclear DNA with the attendant risk for liver cancer at a later point in life.

Reactivation

Reactivation of hepatitis B disease occurs when a person is in the inactive HBsAg carrier state and develops an elevation of liver enzyme levels and a rise in HBV viral DNA levels. The HBeAg can become positive in such patients. The liver biopsy typically has an hepatic activity index score of 4 or greater. [27]

Resolved Infection

Resolved hepatitis B infection is defined as serologic tests showing HBsAg negative and HBV DNA negative in a person with a history of acute or chronic HBV infection and currently normal levels of liver enzymes. These patients may remain anti-HBc positive for 5 to 10 years or longer and are at risk for transmitting disease on rare occasions (such as the donation of solid organ tissue) or of reactivating HBV disease if treated with immunosuppressive medications. In addition, those patients who appear to have resolved HBV infection may develop active liver disease if they are treated with immunosuppressive medications such as prednisone, methotrexate, or chemotherapy.

Co-infection

Co-infection with hepatitis delta virus (HDV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) is defined as the presence of active viral replication with one or more of the previously defined viruses by molecular assays. These infectious problems are discussed in detail later.

SEROLOGIC DIAGNOSIS

As a general principle of laboratory-based investigation for the virologic cause of chronic liver disease, testing should include all the major etiologic agents (HBV, HBV plus HDV, HCV) [28] because these are the common infections in high-risk groups such as injecting drug users, multiply transfused patients, and those who are sexually active with different partners. The principal screening assay for acute and chronic hepatitis B, as well as the screening of blood and organ donors, detects HBsAg in serum. [29]

The typical serologic profiles found in current or historical HBV infection are shown in Table 107-1. Hepatitis B core-specific immunoglobulin G (IgG) antibody (anti-HBc IgG) is almost always present in the serum of patients with chronic hepatitis B and may play a role in immunomodulation of fetal serologic responses to HBV after perinatal transmission from HBeAg-positive mother to her neonate. These antibodies cross the placenta in utero and thus the newly infected neonate has high titers of maternal anti-HBc IgG at birth (indicating a strong helper T-cell type 2 (Th 2 response), partly contributing to its "tolerized" state to the HBV. These antibodies are not neutralizing and do not appear to influence viral replication. The detection of anti-HBc IgM is generally diagnostic of acute HBV infection. [30]

Most patients with underlying inflammatory activity in the liver demonstrate one or some markers of virus infection. Typically, HBV DNA is detected and measurable by molecular techniques [31], [32] (Table 107-2). Relative levels of HBV DNA often correlate inversely with the degree of necroinflammatory activity in the liver, reflecting attempts by the host's immune response to control and eliminate the virus.

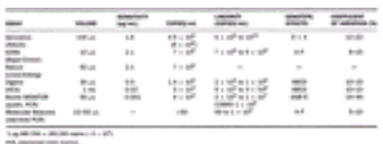

TABLE 107-2 Hepatitis B Virus DNA Viral Load Measurement

HBV has a number of genetic variants, described as genotypes A, B, C, D, E, F, and G. Genotyping is specified by sequencing the HBV genome or by using serologically based antibody testing. Understanding the clinical significance of HBV genotypes is evolving (Table 107-3). Genotype assessment and nucleic acid sequence analysis may allow epidemiologists to track the movement of HBV infections through the world or regions of the world and establish other epidemiologic behavior of HBV infection, including the investigation of common source outbreaks. [33]

CHARACTERISTIC	HEPATITIS B GENOTYPES		
Region	Europe, United States	Asia	Africa
Genotypes	A, D, F, G	B, C	A, D, E
Subject	Adult	Infant	Children
Transmission	Horizontal	Vertical	Vertical
Carrier	20%	30%	80%
Anti-HBe positive and increased ALT	Yes	Yes	Unknown
Response to interferon	30% (G–A)	5%	Unknown
HCC	Low	High	High
Ethnic group	White	Asian	African

ALT, alanine aminotransferase; HCC, hepatocellular carcinoma.

TABLE 107-3 Clinical Characteristics of Hepatitis B Genotypes

Depending on the predominant HBV genotype in the particular geographic setting, patients infected with genotypes other than A often present to the liver clinic seropositive for anti-HBe rather than HBeAg. These patients are infected with the precore G1896 stop codon precore mutation (“precore mutant”). Genotype A HBV infected patients still tend to present to the clinic seropositive for HBeAg.

Prevalence

Regions of high, intermediate, and low endemicity have been identified. High levels of endemicity (positive HBsAg) (at least 8% of population infected) represent more than 45% of global population, intermediate rates of infection (2% to 7%) represent another 43% of global population, and low prevalence (less than 2%) represents the final 12% of global population. Five percent of the U.S. population demonstrates exposure or past infection with HBV. About 1 of 200 people in the United States is currently infected with HBV. Some ethnic subgroups in the United States have up to 7% to 10% prevalence rates that closely approximate their country of origin. HDV infection and its prevalence are discussed later.

Transmission

Modes of transmission vary depending on the country of origin; ethnic background; local, traditional, and Western medicine practices; and most importantly, in developed countries, risk behavior. Understanding each of the major routes of transmission is the key step in preventing HBV transmission and can lead to the eradication of disease through education, prevention, and vaccination. [21], [34] In populations that acquired HBV as adults, heterosexual contact (42%), men having sex with men (15%), and injection drug use (21%) represent the most common modes of acute transmission and may well represent the most common causes of chronic disease.

Vertical transmission is believed to be the leading cause of HBV transmission worldwide. This pathway, as a major cause of HBV transmission, has recently been brought into question with identification of transmission through iatrogenic routes and the application of folk medicine in young populations. Even taking these newly identified risks into account, vertical (predominantly perinatal) transmission probably accounts for more than 50% of all childhood-acquired disease. HBV is believed to infect most commonly neonates at the time of delivery. There has also been a proposal that HBeAg traversing the placenta during pregnancy may induce tolerance to HBV that infects the child during the birthing process, resulting in chronic infection that may persist lifelong in many patients.

Nosocomial and occupational exposure and transmission are also an important issue. Health care workers exposed to patients who carry HBV and patients exposed to medical practitioners who carry HBV infection are both at risk. [35], [36] and [37] Renal dialysis patients are, historically, considered at high risk for acquiring or transmitting HBV because many had extensive blood exposure, and further exposure to other patients took place in the dialysis setting. [35], [36], [37] and [38] Some states require, by law, that practitioners must remove themselves from practice if they perceive that they pose a risk (in this case infectious risk) to their patients. Health care workers that are exposed or potentially exposed to needle-stick injuries or blood-splash exposure are also at risk for acquiring HBV. [39] The most important step is vaccination as a preventative step before risk exposure, immediate testing for immunity to hepatitis B if exposure takes place, and application of hepatitis B immunoglobulin (HBIG) and HBV vaccine if a health care worker who is not immune is exposed to blood or sharps. [35], [36] and [37], [40] Hepatitis B vaccination is strongly advised for all individuals who work in a health care setting that may expose them to blood or body fluids. Elimination of reused needles in developing countries may lead to a marked reduction in childhood, adolescent, and adult-acquired HBV infections. [41]

Household transmission has been clearly identified as a risk for acquiring HBV. [7] The route of exposure is not clear, but HBV is a DNA virus that can exist outside the body on fomites for prolonged periods. Avoiding the sharing of household utensils that may carry blood, such as toothbrushes and razor blades, is also important. The transmission of HBV with common kitchen items and food sharing has not been described. All household members living with an HBV carrier must be tested for HBV and vaccinated if not immune. Recent studies have even suggested bed bugs as a source of HBV transmission. [42], [43]

HBV is a sexually transmitted disease. [7], [44], [45] Individuals attending clinics treating sexually transmitted disease commonly have evidence of exposure to HBV as indicated by the presence of anti-HBs and anti-HBc, and a subset of patients also have HBsAg in their serum. Many of these patients had asymptomatic disease, although some patients present with acute HBV after sexual exposure.

Blood transfusion is a very unlikely source of HBV in Western countries, where effective screening of blood takes place. Screening of all blood units for HBV as well as pre-donation screening for risk behavior should be standard throughout the world. The risk for acquiring HBV through a blood transfusion in the United States is less than 1:400,000 units. The current test used to screen blood for HBV infection is the anti-HBc assay. [21], [46] The reason any risk is present from blood products relates to the fact that some patients donate blood before the onset of an immune response to HBV infection or clinical evidence of hepatitis. Genomic testing is emerging as a method to make the blood supply even safer. [47] A number of developing countries do not screen blood or blood products for HBV, posing a major risk to patients who may undergo blood product transfusion in those countries.

About 20% to 35% of individuals with adult acquired HBV infection in the United States have no known risk factor or easily identifiable risk factor. [7] Possible transmission through sexual contact, medical or dental treatment, sharing household utensils, and blood exposure in an occupational etting must be considered.

Co-infection

In patients who are infected with HBV, co-infection with HCV, [48] HIV, or both exists in certain risk groups, especially those with adult high-risk behavior. All patients with HBV infection must be tested for HCV infection, and if a risk history of sexual exposure, injecting drug use, or intravenous drug abuse is discovered, HIV infection testing is necessary. HIV infection clearly influences the response to HBV vaccine. HDV co-infection is also an important medical issue. HDV infection is specific also to certain world regions, such as Amerindians in South America and high-risk populations in the Mediterranean area.

Prevention

Vaccination is the only medical intervention to date that can markedly change the incidence and prevalence of this disease. The list of HBV vaccine products available worldwide is extensive, and individuals should review local product availability in their own country. All current products appear to be very similar in terms of immune response and level of anti-HBs titer after a series of vaccinations. Worldwide vaccination for HBV has finally come of age, with most countries using or planning a broad-based HBV vaccine program. [8], [49], [50] and [51] Vaccination has already resulted in a marked decline in childhood prevalence of HBV disease in Taiwan and more importantly has already demonstrated a major decrease in hepatocellular carcinoma (HCC), even in this young age group. [52], [53] and [54] This is the ultimate in cancer treatment: prevention through vaccination. All individuals who are exposed to blood or blood products, plan travel to developing countries, live in a household or have intimate contact with an HBV carrier, work in a health care setting with patient contact, are born to HBV-positive mothers, or have chronic liver disease should be vaccinated against HBV infection. Safe sexual practices, needle exchange or nonreusable needles, thorough blood screening, and medical instrument sterilization are all essential components of a prevention program.

For children born to HBV-infected mothers, prevention of vertical transmission with injection of HBIG and vaccine or vaccine alone is recommended or considered the standard of care in most parts of the world. [55] HBIG administration to the infant at the time of birth (in combination with vaccination), because of expense, is reserved for use in countries with higher per-person health care expenditures. Vaccine appears to protect more than 80% to 90% of infants when administered at birth (without HBIG) and followed by two additional doses within the next 6 to 12 months. HBIG intramuscular injection, when used with HBV vaccine, has an even higher efficacy, protecting more than 98% of infants. Some special populations have a low to very low response to conventional vaccines, leading to the development of more

immunologically active vaccines or adjuvants to current vaccines to promote an increased response rate. Examples of such populations include older patients, organ transplant recipients, and other immunosuppressed populations, including patients co-infected with HIV and dialysis patients. Hepatitis A vaccination of carriers with HBV is emerging as the standard of care in many countries owing to the high mortality rate for acute HAV infections in chronic HBV carriers as demonstrated in outbreaks such as the Shanghai epidemic. [56]

Postvaccination testing is only for those individuals who need to know their HBV immune status for their medical management or for potential occupational exposure risks. Revaccination results in an antibody response in more than 30% of all people who do not respond to a primary vaccination series. [57] HBV vaccine levels remain above the level perceived to be protective, (10 IU/mL) in abut 50% of patient for time intervals of up to 15 years. It is also clear that patients who do not have measurable antibodies can mount an amnestic response and be protected from HBV infection. [58], [59] and [60] There is no evidence that HBV vaccine is associate with any form of arthritis or neurological sequelae. [61], [62] and [63]

Based on the previously described epidemiologic behavior, the populations to screen for HBV and subsequently to vaccinate if not infected with HBV are those patients who are born in endemic regions of the world, patients with a history of high-risk sexual activity or more than 50 lifetime sexual partners, men having sex with men, any person with a history of injecting drug use, individuals who have or have had sexually transmitted diseases, household contacts of HBV carriers, sexual contacts of HBV carriers, people who have had medical care or injections in a developing country, any person with acutely or chronically elevated liver enzymes, and carriers of HIV or HCV infection.

Children are a special subgroup of patients who need to be considered as carriers if born to a mother who is an HBV carrier and who did not receive HBV vaccination (with or without HBIG) vaccination at birth. Also, all children who came from orphanages in developing countries should be tested for HBsAg. All immigrants from developing countries where there is a significant prevalence of HBV need to be screened for HBsAg as well. Both pediatric and adult travelers to developing countries are at risk for HBV infection and need to be tested if evidence of liver disease is present.

HEPATITIS B VARIANTS AND MUTANTS

Although HBV is a DNA virus, replication is through an RNA-replicative intermediate requiring an active viral reverse transcriptase polymerase enzyme (Fig. 107-1). The reverse transcriptase of HBV lacks a conventional proofreading function, which is found in other higher-order polymerases. Therefore, HBV exhibits a mutation rate more than 10-fold higher than other DNA viruses and more closely resembles retroviruses such as HIV. The number of nucleotide substitutions varies depending on the stage of disease. The natural evolutionary rate for the HBV genome in chronic hepatitis B is about 1.4 to 3.2 × 10^{-5} substitutions per site per year; however, in the liver transplantation setting, it is almost 100-fold higher. This higher substitution rate may also be a result of the immunosuppression regimen associated with transplantation, especially the use of steroids and the positive enhancing effect on the HBV glucocorticoid response element in the viral genome, resulting in further up-regulation of viral replication.

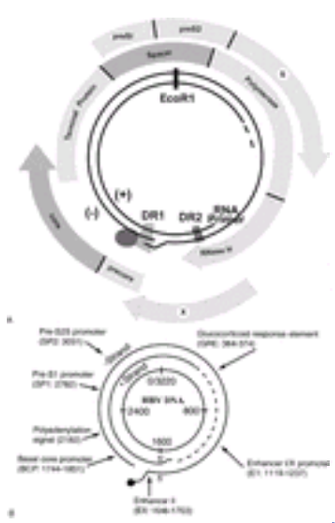

FIGURE 107-1. Molecular structure of HBV virus showing **(A)** the sites of surface, core, and e antigen production, and **(B)** primer sites and areas involved in mutations.

Pre-C and C Gene Mutants

The HBV core gene contains two in-frame start codons that control the synthesis of HBcAg and HBeAg. Both proteins are targets for immune-mediated viral clearance mechanisms. The two major groups of mutations that affect HBeAg synthesis are precore region mutations (G1896A) and mutations in the basal core promoter (BCP) at nucleotides 1762 and 1764, all resulting in diminished production of HBeAg and a resultant increased host immune response. Precore mutations frequently occur temporally related to core gene mutations and deletions. Mutations in the BCP are likely to increase viral replication and enhance disease activity.

X Gene Mutants

The X protein is a nonstructural protein encoded by the *X* gene, which can transactivate a variety of cellular and viral promoters by activating signaling pathways. [64] X has been reported to interact with a number of nuclear proteins involved in cell cycle regulation and DNA repair and transcription. Persistently high levels of the HBx expression have been associated with the development of liver tumors in transgenic mice, and X protein can transform nontumorigenic cell lines in vitro.

Pre-S and S Gene Mutants

The *S* envelope gene contains three in-frame start codons, which divide the gene into the three surface proteins of HBV: The pre-S1 region, the pre-S2 region, and the S region. Three corresponding mRNAs serve for the synthesis of these proteins. The pre-S1 promoter (SPI) is located upstream of the *S* gene, whereas transcription of the pre-S2 and S mRNAs is directed by the S promoter (SPII), which is located within the pre-S1 region. Surface mutations have obvious clinical relevance in the prevention of HBV owing to impact on prophylactic vaccination as well as laboratory-based diagnosis. [19], [20], [65], [66] Several large HBV vaccination programs in endemic regions have revealed a 2% to 3% incidence of vaccine escape mutants resulting from alterations in the HBsAg protein. Generally, the amino acid (aa) substitution of glycine for arginine at aa 145 of the S protein makes this epitope unlikely to bind to antibodies generated to wild-type HBsAg. The “a” determinant of the HBsAg is a peptide sequence located between aa 116 and 160 of the S protein, which represents the major immune target of polyclonal antibody to the HBsAg. This antibody reactivity is directed mainly against the second loop of this determinant, located in aa 139 to 147. In patients infected with HBV exhibiting surface mutations affecting the a determinant, the mutant HBsAg may not be detectable by commonly used HBsAg assays, especially if based on monoclonal antibody “capture” reagents. As a result, these mutants do represent a potential public health problem because patients harboring HBV with these surface mutants remain infectious but do not exhibit readily detectable HBsAg and hence may escape diagnosis, and contacts may not be protected from viral infection. [6], [67], [68], [69] and [70]

Polymerase Gene Mutations

The polymerase open reading frame (ORF) is the longest, covering almost 80% of the whole genome and overlapping the other three ORFs. The HBV polymerase protein mediates encapsidation of the pregenomic RNA into the core particle and synthesizes the HBV DNA genome therein. It has four enzymatic activities: DNA synthesis priming activity, RNA-dependent reverse transcriptase (RT) and DNA-dependent DNA polymerase activity, and RNaseH (RNA degradation) activity.

HBV quasispecies with mutations in the polymerase gene have been detected in patients undergoing antiviral therapy (Table 107-4). These mutations significantly

decrease the in vitro sensitivity of the polymerase to lamivudine-associated chain termination and competition for enzymatic inhibition. Similarly, after famciclovir therapy, polymerase mutations in codon L180M markedly decrease famciclovir efficacy. [71]

Genotypes and Serotypes

HBV has a number of genetic variants described as serotypes (adw, ayw, and adr) and genotypes A, B, C, D, E, F, and G. Genotyping is specified by sequencing the HBV genome or by using serologically based antibody testing. Understanding of the clinical significance of HBV genotypes is evolving (see Table 107-3). Serotyping and genotype assessment may allow epidemiologists to track the movement of HBV infections through the world or regions of the world and establish other epidemiologic behavior of HBV infection and potentially establish specific clinical behaviors to each subgroup.

Depending on the predominant HBV genotype in the particular geographic setting, patients infected with genotypes other than A (B, C, D, and E) often present to the liver clinic seropositive for anti-HBe rather than HBeAg. These patients are infected with the precore G1896 stop codon precore mutation (“precore mutant”). Genotype A HBV-infected patients still tend to present to the clinic seropositive for HBeAg and so have HBeAg-positive chronic hepatitis B (wild-type) infection. The molecular virologic basis for this genotype preference is discussed in more detail below under HBV mutants.

CLINICAL MANIFESTATIONS

Clinical manifestations of chronic HBV infection range from no signs or symptoms of disease (most patients) to the warning signs of end-stage liver disease. [72] The clinical manifestations of end-stage liver disease are the same as those seen in patients with other causes of liver failure. Some patients with HBV develop extrahepatic manifestations of infection, including periarteritis nodosa, leukocytoclastic vasculitis with the increased likelihood of major organ damage through immune complex injury with target organs, including peripheral nerves, kidneys, brain, and gut through immune complex deposition. [73], [74] Examination of the creatinine level in each patient with HBV infection and assessment for proteinuria are important. Peripheral skin rashes can be assessed by punch biopsy to look for signs of vasculitis. Some patients need a visceral and renal angiogram to identify angiographic signs of vasculitis in those organs due to periarteritis nodosa.

Cirrhosis may manifest early and subtly with changes in sensorium, memory loss, and day-night reversal. The signs of sequential liver synthetic test result abnormalities (low albumin, elevated bilirubin, prolonged International Normalized Ratio, low cholesterol, high ammonia) and progression to marked signs of portal hypertension are not peculiar to HBV infection. The presence of portal hypertension is manifested by ascites, varices, thrombocytopenia, leukopenia, and coagulopathy, as seen in patients with cirrhosis of other causes. Acute flares of disease in patients with HBV are more common than conditions such as HCV infection or autoimmune diseases in which the inflammatory process is often “burned out.”

Laboratory tests are an integral part of evaluating patients with chronic HBV infection. It is very important to differentiate liver enzymes from liver function tests, although these two terms are often confused or, unfortunately, combined. Liver enzymes are markers of liver inflammation and do not reflect liver function. The ALT, aspartate aminotransferase (AST), alkaline phosphatase, and gamma-GT are useful markers of liver inflammatory activity only. These tests, if elevated, should lead the clinician to a full laboratory evaluation for HBV infection as well as investigation of other causes of liver disease (fatty liver, herbal medications, alcohol-induced liver disease, [39], [75] over-the-counter and prescription medications, HCV, and hemochromatosis). Elevated liver enzyme levels in a patient who is HBsAg positive provide a compelling indication for liver biopsy and consideration of treatment.

Liver function tests commonly include cholesterol, albumin, International Normalized Ratio, bilirubin, and ammonia. When results of liver function tests become abnormal, there is usually severe liver injury present, which could indicate end-stage liver disease or a flare of hepatitis superimposed on chronic liver disease. A flare, or marked rise in liver enzyme levels, and a decline in liver function occurs as an increased immune response directed at HBV occurs. This flare of disease activity could also represent superimposed infection such as HCV or HDV, worsening HIV disease if HIV infection is present, and potentially progression to end-stage liver disease. When results of liver synthetic tests become abnormal in a patient with chronic HBV, a clinician should strongly consider consulting with a transplantation center if the patient has no contraindications to transplantation. There should also be a strong consideration for immediate initiation of antiviral therapy with a nucleoside or nucleotide analog. In the setting of liver synthetic abnormalities, interferon is relatively contraindicated, unless used by expert hands.

Laboratory surrogates to assess for the severity of liver disease include signs of hypersplenism, such as a low platelet or white blood cell count. Platelet count levels below 100,000 to 150,000 should lead one to a strong suspicion of advanced fibrosis. An elevated alpha-fetoprotein (AFP) level is usually only found in advancing liver disease or much more rarely in the presence of liver cancer. The degree of AFP elevation provides information regarding the likely presence of hepatocellular carcinoma. A high ferritin and iron saturation could make one suspicious for hemochromatosis, although abnormalities in biochemical markers of iron overload are also common in patients with marked fibrosis or cirrhosis. A “reversed” AST-to-ALT ratio, in which the AST is higher than the ALT, also supports advanced fibrosis or cirrhosis.

Patients with chronic HBV infection may have a normal to moderately reduced quality of life compared with those without HBV infection. Patients with end-stage liver disease have a markedly reduced quality of life, although this is true for all patients with advanced liver disease and is not specific to HBV infection. Patients who undergo treatment with interferon often have a reduced quality of life during treatment. If the patient clears HBV infection, the patient’s quality of life may improve after treatment to a normal level, and treatment may be not only cost-effective but also cost-saving. [76], [77]

Hepatocellular carcinoma, hepatoma, and primary liver cancer are serious risks for all HBV carriers (see Chapter 118). The estimated lifetime risk for HCC in patients who are chronically HBsAg positive is estimated to be about 20%. This risk is markedly increased in patients with cirrhosis, active liver disease as demonstrated by biopsy, elevated liver enzyme levels, elevated HBV DNA level, co-infection with HCV, a strong history of alcohol abuse, confirmation as a carrier of HBV for more than 50 years, an exposure to aflatoxins, a family history of HCC, and an elevated AFP level. [78], [79], [80] and [81] Issues such as prevention of HCC by vaccine is covered in other sections, and prevention of HCC by use of interferon and new antiviral therapies is discussed later in the section “Treatment.” Patients who are chronic HBV carriers need to be informed of the risk for HCC and need to be considered for screening, depending on resources and available treatments, for HCC. The initiation and frequency of screening can take place according to relative risk for HCC in special groups of patients with HBV, most importantly, in patients with cirrhosis.

DIFFERENTIAL DIAGNOSIS

All patients with elevated levels of liver enzymes need to be screened for fatty liver, medication toxicity, elevated iron, HBV and HCV infection, and alcohol abuse. The

differential diagnosis of chronic HBV infection includes considering acute HBV infection, which usually can be differentiated by the presence of anti-HBc IgM (see Table 107-1). Patients with elevated liver test results and detectable presence of anti-HCV in serum can be evaluated by the use of molecular testing. If HBV DNA is not measurable and HCV RNA is found to be elevated, HCV is considered the dominant disease, and therapy should focus on the HCV infection. Autoimmune disease rarely occurs concomitantly with HBV disease and is also rarely caused by HBV. One must rule out biliary obstruction if the gamma-glutamyl transpeptidase or alkaline phosphatase is higher than the AST or ALT serum levels. A baseline ultrasound is useful in patients with elevated levels of liver enzymes to rule out other diseases, provide indirect information concerning the presence or absence of portal hypertension, and provide reassurance to the patient about the absence of liver cancer. Examination of the liver biopsy for plasma cells and testing for antinuclear antibodies and anti–smooth muscle antibody is important, especially if serum globulin levels are greater than 4 gm/dL. Patients with elevated levels of liver enzymes who are HBsAg positive with very active liver disease need to be assessed for delta hepatitis infection. [82], [83], [84] and [85]

COURSE AND COMPLICATIONS

Each subgroup of patients with HBV infection has a different clinical course. The chronic carrier with consistently elevated liver enzymes is the patient with the highest risk for progression to cirrhosis and the subsequent complications. The next highest risk patient with risk for progression is the patient who presents with flares of liver enzymes and reactivation of liver disease. Each cycle of liver enzyme elevation purportedly is due to immune activation and attempts, often ill fated, to clear HBV infection (Fig. 107-2). Spontaneous seroconversion from HBeAg to anti-HBe occurs in 1% to 10% of chronic hepatitis B carriers per annum, but seroconversion from HBsAg to anti-HBs, with clearance of HBV from the liver, is very uncommon (at or less than 1% per year). Only about 1% of patients with chronic HBV spontaneously clear infection (convert from HBsAg positive to negative) each year. [86] The rate of HBsAg seroconversion is higher in patients with more active liver disease as measured by liver enzymes than in those with persistently normal liver enzymes but is in general less than 15% over any 3-year interval. [11], [12] During these immune "attacks" or flares, there is ongoing hepatocellular damage and commonly progressive fibrosis. Thus, in general, the degree of liver enzyme elevation, as well as the number of flares, often correlates, over time, with the severity of liver injury. In specific patients, testing and evaluation by sequential liver biopsies may be necessary to determine the urgency of treatment. The liver biopsy also allows a medical practitioner to provide a full level of informed consent to patients before starting therapy. Blood testing for progressive liver disease and screening for HCC should also take place more frequently in those patients with established cirrhosis than in patients with mild or no fibrosis.

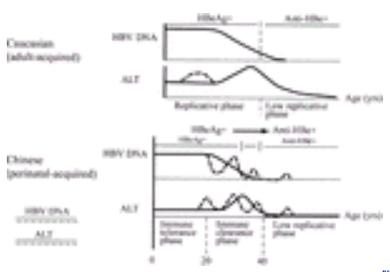

FIGURE 107-2. Natural history of HBV infection. (From ref. [14].)

The chronic carrier with a persistently normal level of liver enzymes (less than 30 IU/mL) is at a much lower risk for progressive liver disease as well as cancer, although the overall risk for HCC is still significant. These patients commonly have minimal liver disease on liver biopsy. The frequency of blood testing of these patients is an important issue because annual testing may be insufficient to document a stable patient or define inactive disease. For such patients, the frequency of screening with blood tests could occur at least biannually, and a more thorough evaluation, testing every 3 months, may be justified.

During regular laboratory testing of liver enzymes, HBV DNA, anti-HBe, and HBeAg testing can determine whether a precore mutant virus has emerged. This viral mutant can be identified by the presence of moderate to high HBV DNA serum levels in the absence of HBeAg. In rare circumstances, patients who appear to clear HBsAg but do not develop anti-HBs may have developed surface mutant viruses. The clinical significance of these mutant viruses is not clear. Long-term studies are in progress to find the specific markers that allow us to identify which patients are at risk for progressive liver disease. As therapy evolves and becomes increasingly complex, the options to treat such patients will expand.

Hepatitis D Virus

The patient with dual HBV and HDV infection has a typical serologic profile of HBsAg and anti-HBe positive (rarely, HBeAg positive) as well as IgG anti–hepatitis delta (anti-HD) seropositivity (see Table 107-1). Specific immunoassays are available for detection of both IgM-(for both acute and active infection) and IgG-specific anti-HD (seen in chronic disease as well as resolved infection). Serum assays for detecting HDAg and HDV RNA are restricted and can typically only be requested from central reference laboratories. HDV infection is easy to miss, and testing should include HDV RNA and anti-HD IgG and IgM as well as markers of HBV infection. These should be repeated in suspected cases.

In the United States, HDV infection occurs predominantly with intravenous drug users in large cities and with high-risk sexual activity. [87] Ethnic populations that may carry HBV from the Mediterranean region or Middle East need to be tested for HDV infection as well. Delta infection leads to more severe liver disease in those patients who acquire HDV and HBV at the same time than in those who acquire acute infection with HBV alone (see Chapter 106 on acute hepatitis). [82], [83], [84] /SUP>and [85] Patients with acute co-infection have a very high rate of viral clearance of both HBV and HDV. When HDV infection is superimposed on chronic HBV infection, the disease commonly accelerates to cirrhosis in a much shorter time. Patients with HDV and HBV co-infection, compared with patients with chronic HBV infection alone, may also be at greater risk for liver cancer, probably because cirrhosis develops as a higher rate. [88]

HDV is a serious disease including both acute infection simultaneously with HBV and superinfection of HDV superimposed on chronic HBV. Acute infection simultaneously with HBV and HDV commonly results in severe disease with a high risk for fulminant liver failure. If the patient survives the acute disease, viral clearance of both HBV and HDV will probably take place. HDV infection can be treated with interferon, although results are discouraging, with patients rarely clearing HDV and HBV long term. Therapy requires at least 1 year of treatment. Nucleoside analog therapy, such as lamivudine, does not suppress HDV infection. Liver transplantation in patients with acute HDV infection is often followed by milder liver disease if HBV and HDV infection persist, compared with HBV graft infection without HDV co-infection. HBIG therapy to prevent graft infection with HBV can also prevent HDV infection of the new graft. [89]

Patients with HDV infection typically have very low levels of HBV DNA owing to the suppressive effect of HDV on HBV viral replication. HBeAg and anti-HBe are variable. HDV co-infection probably results in a higher risk for HCC, although this may be attributable to more active or aggressive liver disease in these patients as opposed to an oncogenic effect of the HDV virus. The key serologic markers include anti-HBc IgM and anti-HD IgM in the acute phase, whereas markers of chronicity (IgG and anti-HBc and anti-HBe) are not detected (see Table 107-1). Thus, the profile is that HBsAg, HBeAg, and HBV DNA become detectable in serum along with HDAg and HDV RNA. Anti-HD IgM becomes detectable soon after onset of illness but is rapidly followed by anti-HD IgG (see Table 107-1). Current assays for anti-HD IgM and IgG tend to detect antibody only transiently, so that the most reliable marker for establishing HDV infection is the detection of HDV RNA by polymerase chain reaction in serum.

Hepatitis D Superinfection in Chronic Hepatitis B

HDV superinfection in chronic hepatitis B is defined as primary virus infection on a preexisting persistent HBV replication. Serologic markers such as titers of HBsAg and HBV DNA can show transient reduction during superinfection. Thus, serial testing is again required. The typical serologic profile is HBsAg positive as well as anti-HD (IgG and IgM) positive, but negative for IgM-specific anti-HBc (see Table 107-1). Again, the diagnosis of persistent infection is established by repeated testing for HDV RNA by polymerase chain reaction. The diagnosis of chronic hepatitis D is readily made when HDAg is detected by immunohistochemistry in the nucleus of hepatocytes of the liver biopsy specimen.

Pathogenesis of Hepatitis D Infection

The manner by which HDV causes liver injury remains controversial. Histological observations of microvesicular steatosis and cytoplasmic eosinophilia in the absence of a mononuclear cell or lymphocytic infiltrate in the liver biopsy specimen of patients with acute HDV infection are consistent with a direct cytotoxic effect of HDV. In vitro molecular studies have supported this view with experimental evidence that the smaller form of HDAg (SHDAg) expression in cells results in the production of pyknotic nuclei and shrunken eosinophilic cytoplasm as well as a reduced cellular nucleic acid synthesis. In contrast, evidence supporting an immune-mediated cytotoxic pathway is sparse, and a direct link between HDV-associated disease expression and the immune response is lacking.

Hepatitis B Interference by Hepatitis D

Suppression of markers of HBV replication during HDV superinfection has been observed in humans as well as in the woodchuck and chimpanzee animal models. In more than 90% of hepatitis B patients superinfected with HDV, seroconversion occurs from an HBeAg-positive to an HBeAg-negative and anti-HBe–positive state. Serum HBV-specific DNA polymerase activity and intrahepatic HBcAg expression can no longer be detected in these patients. On rare occasions, HDV superinfection has been associated with termination of the HBsAg carrier state and seroconversion to anti-HBs. The mechanism for this interference has not been conclusively established.

Hepatitis B Co-infection with Human Immunodeficiency Virus

HIV co-infection with HBV results in more aggressive (progression to cirrhosis and liver failure) liver disease in some patients, although other patients have minimally active liver disease with little or no evidence of progressive liver disease. Why certain patients have progressive liver disease in this setting and others do not is unclear and is not correlated with any specific clinical factor or laboratory test. The discrepancies may be explained by an interaction between the host immune system, helper T-cell subtypes present (Th 1 versus Th 2), host factors that predict fibrosis, and levels of HBV and HIV viral replication. Treatment with lamivudine may slow the progression of liver disease but is problematic from the perspective of increased resistance compared with patients who are not co-infected. [90]

Hepatitis B Co-infection with Hepatitis C

HCV co-infection with HBV results in a higher risk for cirrhosis and a higher risk for liver cancer. Patients often have one dominant viral disease. Treatment focused on the dominant virus, as revealed by blood tests of viral replications, is probably the best management step. [91], [92], [93], [94], [95] and [96]

Acute HAV infection sometimes complicates chronic HBV infection. These patients are at higher risk for severe liver disease. [97] Vaccination for HAV is advocated in all patients with chronic HBV infection. [97]

TREATMENT

Definitions of response to antiviral therapy are very important when evaluating patients who are about to undergo antiviral therapy and for those patients who have been previously treated who appear to need subsequent treatment. Definitions of response are defined as biochemical (liver enzymes), virologic (viral replication), and histological (liver biopsy).

Biochemical response is defined as a fall in liver enzyme levels into the normal range. These events, like the virologic definition given later, can be initial (during therapy), at the end of therapy, or sustained. Sustained response means that the liver enzymes were normal at the end of therapy and at least 6 to 12 months after cessation of therapy. Partial biochemical response means marked fall (greater than 50%) in liver enzyme levels to the near-normal range, reductions typically associated with improvement in histology.

Virologic response means a decrease of HBV DNA to less than 100,000 copies per milliliter when pretreatment levels were greater than 100,000 or by a greater than 2 log reduction from baseline. The reduction in serum HBV DNA viral levels should correlate with HBeAg loss if treatment is given, and finally conversion from anti-HBe negative to positive would complete what is termed *triple seroconversion*. Virologic response can also be termed initial, end of treatment, and sustained if there is loss of viral markers or replication for 6 to 12 months after treatment. HBeAg seroconversion is the terminology used when the HBeAg is lost (negative) long term.

Histological response is defined as an improvement in liver histology on paired liver biopsies. Improvement is usual defined using the histology activity index, the Ishak score or the Metavir score, or one of the modifications. There is no international consensus about which scoring system is best. A significant improvement is based on a decrease in number by one to three points and is usually based on improvement in necroinflammation because the fibrosis score typically lags behind changes in inflammation in the liver.

Complete response means normalization of liver enzymes, virologic response, and loss of HBsAg. HBeAg must be negative, and HBV DNA must be negative by the most sensitive molecular test available, which typically can measure down to 100 copies per milliliter (see Table 107-2). This is thereby synonymous with resolved or cured HBV infection. This term does not require the presence of anti-HBs and does not require a follow-up liver biopsy.

Interferon

The term *interferon* is used to describe a large family of naturally occurring peptides that are included within an even larger group of molecules, termed *cytokines* that modulate immune function. This family of proteins is often involved in the host's control or elimination of acute and chronic viral infections. Interferon directly decreases viral replication by interference with DNA and RNA replication at the genome level. Interferon also indirectly modulates viral replication and viral protein synthesis by activating other immune pathways and modulating the level of other cytokines. The increased synthesis of enzymes, such as 2'5'-oligoadenylate synthetase, further activates the immune system. By enhancing major histocompatibility complex (MHC) antigen expression, interferon increases in the identification of infected cells with HBV and leads to cytolysis and viral clearance.

About 20 natural forms of interferon exist in humans, including interferon-a-2a (produced in lymphocytes), -a-2b, -ß (produced in fibroblasts), -? produced in T cells), and -?. A number of these interferons have been isolated and have been shown to have direct antiviral effects on HBV replication in humans. [98] Interferon is the only medication that has been proved to reduce and eliminate HBV infection in chronically infected patients in randomized controlled trials [99] and is not associated with drug resistance. The patients with HBeAg-positive and HBeAg-negative chronic HBV infection both appear to benefit from treatment, with documented improved outcomes in clinical trials (Fig. 107-3 and Fig. 107-4). Over time, there is an accumulative increase in patients who are HBV DNA and HBeAg negative and a decrease in the number of patients with decompensated liver disease.

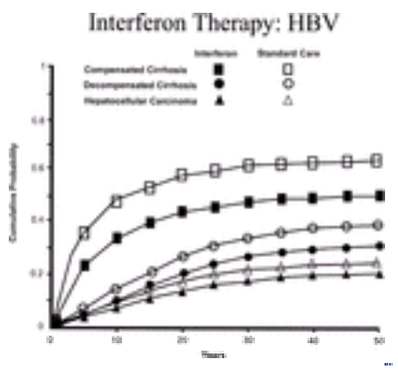

FIGURE 107-3. Short- and intermediate-term outcomes of interferon (IFN) treatment. (From ref. [99].)

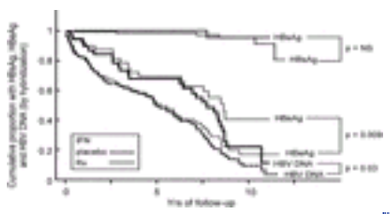

FIGURE 107-4. Long-term outcomes after interferon treatment. (From ref. 57.)

Prednisone has been studied in clinical trials and practice and appears to be beneficial only for certain rare subgroups of patients, such as those with modest viral replication and near-normal levels of liver enzymes. 100 In summary, only an “ideal” subset of patients responds to interferon and clears HBsAg (patients with low levels of liver enzyme elevation). Interferon appears to be efficacious only in patients who have an ongoing native immune response. The presence of elevated levels of liver enzymes and the presence of hepatic inflammation identify these ideal patients who have an inherent immune response to chronic HBV infection. One form of interferon, interferon-a-2b (Intron-A, Schering, Kenilworth, NJ), has been approved for the treatment of chronic HBV infections in many countries throughout the world, including adults and children in the United States. Interferon-a-2b treatment results in HBeAg clearance in 30% to 50% of selected patients and HBsAg clearance in up to 30% of patient with long-term follow-up. 101 Interferon-a-2a (Roferon, Hoffman La Roche Laboratories, Basel, Switzerland) and interferon-a-con-1 (Infergen, Intermune, Brisbane, CA) may also be used to treat HBV infection but have not been approved for this indication by the U.S. Food and Drug Administration. New pegylated forms of interferon-a-2a and -a-2b are undergoing phase III trials to determine whether the longer half-life of this compound imparts any improvement in therapeutic outcome over standard interferon preparations.

The ideal dosing for the different forms of interferon range from 15 to 35 million units (MU) weekly. Interferon is administered by subcutaneous or intramuscular injection three times a week, although some clinical studies have used daily dosing regimens. Prolonged treatment up to 32 weeks may be useful in patients who have an initial reduction in viral levels of HBV DNA without DNA clearance. The side-effect profile of interferon is significant, with a wide variety of side effects that are well described and hopefully will be reduced with newer forms of interferon or with lower doses used in combination with other forms of less toxic therapy. Some examples of interferon side effects (which are often dose related) are bone marrow depression, psychiatric disturbances, alopecia, flu-like syndromes, nausea, weight loss, an increased risk for bacterial infections, and hyperglycemia. The ideal patients who have the best antiviral response to interferon are those with high levels of liver enzymes, moderate levels of serum DNA, and recent or adult-acquired infection ith normal immune response to HBV. Patients who fit this profile may have HBsAg seroconversion that may exceed 30% in long-term follow-up. 101 Other immunomodulators including thymosin-a-1 (Zadaxin, Sciclone Pharmaceuticals, Redwood City, CA) have been shown to be associated with HBeAg seroconversion and triple seroconversion as a single agent and more importantly may be useful in combination with interferon.

Nucleosides and Nucleotides

Modified nucleosides, such as adenosine arabinoside (ara-A) and nucleoside analogs, have been studied during the past few decades. Ara-A was the initial nucleoside analog extensively studied for the treatment of HBV infection. Treatment with ara-A resulted in a decrease in levels of HBV DNA in the serum but had significant untoward side effects, including, in some patients, a permanent peripheral neuropathy.

Toxicity and weak antiviral effects were the major limiting factors behind the failure of ara-A, didanosine (ddI), and similar medications. Fialuridine, a fluorinated nucleoside, has been studied more recently and was found in humans to have major mitochondrial toxicity that resulted in pancreatitis, acidosis, liver failure, and death. Lobucavir was also studied in humans recently, but clinical trials were halted when this agent was associated with gynecologic cancers in animals. These complications support close short- and long-term scrutiny of these powerful medications that can disrupt host cellular homeostasis.

Another important perspective on HBV treatment is the question whether HBV infection is ever cured. HBV exists in a very stable form known as covalently closed circular DNA, or cccDNA, that has a very long intracellular half-life. There are no clearly identified antiviral effects of nucleoside or nucleotide analogs on cccDNA. Clearance of this stable intracellular form of the HBV genome has not been conclusively shown with any antiviral agent.

Currently, adefovir (Hespera®, Gilead, Foster City, CA) lamivudine (3TC, 3-thiacytidine, Epivir, Zeffix, GlaxoSmith-Kline Research Triangle Park, NC) are the only U.S. Food and Drug Administration–approved oral medications that have proven efficacy against HBV, including HBeAg seroconversion and triple seroconversion. Lamivudine is also approved in many foreign countries, including China. Data to date concerning efficacy include a rate of 30% to 35% HBeAg loss at 1 year of therapy. Seventeen percent of patients underwent triple seroconversion, and rare (less than 6%) HBsAg seroconversion to negative has also been reported with most patients remaining HBeAg and HBV DNA negative long term. 18, 102, 103 and 104 (Fig. 107-5). Resistance to lamivudine is very common after 1 year of treatment (greater than 20%) and is associated with mild elevations in levels of liver enzymes compared with the period before emergence of the resistant mutant virus. The presence of the lamivudine-resistant mutant may rise as high as 60% after three years of continuous use of lamivudine. This emergence is associated with more active liver disease as measured by serum levels of liver enzymes. A few patients return to their baseline level of liver disease or viral replication after the emergence of the lamivudine-resistant virus. The lamivudine-resistant mutant virus and other resistant variants are discussed later. This site in the HBV reverse transcriptase or “polymerase” is the most common site of lamivudine resistance, although other sites of mutations associated with resistance have been identified. The rate of viral resistance after 3 years is 50% to 70%. 105 Other nucleosides that confer some level of anti-HBV activity include famciclovir and ganciclovir, but these medications have found little use to date owing to lower levels of efficacy. 106, 107

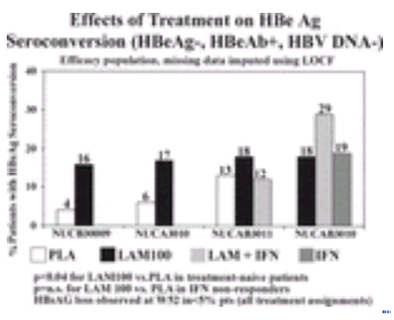

FIGURE 107-5. Outcomes of lamivudine (LAM) treatment for chronic HBV infection. (From refs. 102, 103, 104 and 105, 111.)

Future medications that are in development to treat chronic HBV infection include pegylated interferons, interferons fused to albumin, 5-fluorothiacytidine, tenofovir, entecavir, clevudine L-d4FC, L-ß-thymidine, L-ß-adenine, and L-ß-cytosine, 19, 20, 108 as well as ribozymes and therapeutic vaccines. Other more far-reaching treatments may include dominant negative viral mutants, antisense DNA and RNA, intracellular antibodies, or delivery of current medications through new and advanced deliver methods, such as liposomes or methods that include molecules that bind to specific cellular receptors. Treatment may also take place with DNA vaccines that may provide ongoing internal immune suppression through production of HBV-derived proteins. 42, 109 Liposomes may eventually be used to deliver vaccines such as those originally developed for hepatitis B by oral route or intramuscular injections.

GENOTYPIC RESISTANCE OF HEPATITIS B TO NUCLEOSIDE ANALOGS

To date, the emergence of HBV mutants that show resistance to nucleoside analogs as a result of genetic mutation has been observed only as a consequence of the clinical use of lamivudine or famciclovir. The discussion that follows concerns important amino acid changes in the HBV POL sequence that have been detected in clinical isolates and shown to confer or modify resistance to lamivudine, famciclovir, and other nucleoside analogs.

There has been some confusion over the numbering system used for the HBV POL (see Table 107-4). This inconsistency is the direct result of the heterogeneity between the seven different genotypes of HBV (see Table 107-3). Recently, a standardized numbering system for the HBV POL has been proposed by Stuyver and colleagues, and a consensus is emerging 110 that will be used in this chapter. In this proposal, the HBV reverse transcriptase domain starts with the highly conserved EDWGPCDEHG motif, which includes 344 amino acids and the lamivudine resistance mutations

are designated as HBV POL L180M (previously aa 515, 525, 526, and 528) and HBV POL M204V/I (previously 539, 549, 550, or 552).

Lamivudine Resistance

Initial clinical trials established that treatment of chronic HBV infection with lamivudine was (1) safe and well tolerated, and (2) caused rapid and substantial decreases in viremia. However, decreases in viremia were not stable and rebounded in most cases after treatment stopped. [111], [112], [113] and [114] As long-term trials progressed, it became apparent that during treatment a “rebound” could occur, most of which has been attributed to the development of drug resistance. This resistance was observed at a greater frequency and at an early time point in the transplantation setting [115], [116] and [117] compared with immunocompetent patients. [118], [119], [120] and [121] Lamivudine-resistant populations of HBV were also detected in patients who were co-infected with both HBV and HIV and who were receiving lamivudine as antiretroviral therapy. [122], [123] and [124] Although varying frequencies of resistance and different times preceding the detection of resistance have been reported, the incidence of resistance in immunocompetent patients and immunosuppressed patients clearly correlated with treatment duration. During the first year of lamivudine therapy, resistance developed in 14% to 32% of cases studied, [125], [126] and [127] a frequency that increased to greater than 50% after 2 years. [120]

Sequencing of the HBV POL ORF from drug-resistant isolates revealed mutations in a methionine codon, which caused substitution of isoleucine or valine for methionine 204 (M204V/I) (see Table 107-4). These substitutions affect the catalytic site, changing the conserved YMDD tetrapeptide in motif C from to YIDD or YVDD; these are analogous to substitutions for M184 in the HIV reverse transcriptase, which likewise confers lamivudine resistance. [128] Mutations that alter the YMDD motif appear to have multiple effects on properties of the polymerase, but, in general, they appear to increase fidelity and reduce the ability to process the viral genomic code. Three-dimensional models of the HBV polymerase predict that substitution of ither isoleucine or valine, both of which are smaller than methionine, would increase the size of the dNTP-binding pocket and decrease binding affinity for lamivudine triphosphate. [129], [130]

A number of different mutational patterns appear to be responsible for the lamivudine resistance, but most cases of HBV resistance to lamivudine affect the M204 codon (see Table 107-4). One pattern is associated with two amino acid substitutions (L180M + M204V), whereas a second pattern causes a single substitution (M204I). [115], [117] A variety of other mutations, which cluster mainly in the polymerase B and C motifs, have also been described in association with lamivudine resistance (see Table 107-4).

Nucleotide changes, which produce the M204V/I polymerase mutations also, alter codons in the overlapping surface antigen ORF (see Fig. 107-1). The nucleotide change responsible for the M204V change also results in an isoleucine-to-methionine substitution at residue 195 (I195M) HBsAg. Several nucleotide substitutions can cause the M204I change in the polymerase. Depending on the specific nucleotide substitution, there are three possible alterations to the surface antigen: (1) tryptophan-to-serine change at position 196 (W196S), (2) a tryptophan-to-leucine change at position 196 (W196L), or (3) the introduction of a stop codon, which would truncate the surface antigen. It is unlikely that these surface antigen changes affect drug resistance, but they may perhaps affect antigenicity and subsequent binding of anti-HBs, either natural or through therapeutic administration of HBIG directed at the a determinant. Mutations that generate L180M are silent in the surface antigen ORF.

Other mutations that alter the amino acid sequence of HBV POL have emerged under selection pressure of lamivudine in vivo. Although their functional consequences remain largely unknown, two obvious possibilities exist: changes may enhance (1) drug resistance or (2) replication efficiency. Presumably, increase in fidelity and processivity (respectively) are major contributors to each process.

Resistance to Famciclovir

The antiviral activity of famciclovir against HBV was established in both the liver transplantation setting and chronically infected patients. [107], [131], [132] and [133] In general, treatment with famciclovir is less effective than treatment with lamivudine and results only in single log $_{10}$ decrease in viremia. [107] Furthermore, a significant proportion of patients fail to respond to famciclovir treatment. Nonresponse may be due to natural polymorphisms in the virus that affect antiviral sensitivity, or to variability in host metabolism that affects the production or intracellular stability of penciclovir triphosphate. [134] Resistance to famciclovir appears to develop more rapidly than lamivudine resistance and has been described both in liver transplant recipients and in immunocompetent patients. [134], [135], [136] and [137]

As with lamivudine resistance, efforts to determine the molecular basis of famciclovir resistance focused predominately on sequencing the reverse transcriptase portion of the polymerase. In contrast to lamivudine resistance, which is almost invariably associated with mutation of the codon for M204, famciclovir resistance does not affect the active site (YMDD) motif, nor does it map predominately to a single locus. Furthermore, M204 mutants are not selected by famciclovir. [134], [136]

Antiviral Cross-Resistance of Hepatitis B Variants

Clinically, a variety of drug-resistant HBV mutants have emerged under the selective pressures of lamivudine and famciclovir therapy (Table 107-5). Rational design of effective chemotherapeutic strategies for the future will require the determination of the sensitivities of these mutants to novel nucleoside and nucleotide analogs as they become available. This will be necessary both to provide effective treatment to patients who are already infected with drug-resistant HBV and to prevent, or at least minimize, the possibility of drug resistance arising in treatment-naive individuals.

Lamivudine Resistance	
Group 1: L526M + M550V	(B plus C domain)
Group 2: M550I	(C domain)
Group 3: F512L + L526M +/– M550V	(B and/or C domain)
Group 4: L426V/I + M550I	(A plus C domain)
Group 5: L526M + M550I	(B plus C domain)
Groups 1–3 isolates resistant to famciclovir	
All groups sensitive to adefovir dipivoxil	
Famciclovir Resistance	
A, B, and C domain, typically L526M	
Isolates sensitive to lamivudine, but lamivudine resistance emerges more quickly	
Isolates sensitive to adefovir dipivoxil	
Adefovir Dipivoxil Resistance	
None to date	
Entecavir Resistance	
None to date	

TABLE 107-5 Antiviral Cross-Resistance: Clinical Studies

Recent clinical reports already suggest two ominous conclusions: (1) development of lamivudine resistance is accelerated by preexisting famciclovir resistance, [136], [137] and (2) lamivudine-resistant HBV does not respond to subsequent treatment with either famciclovir or combination chemotherapy with lamivudine and famciclovir. [138], [139] and [140] In vitro assays have confirmed that lamivudine resistance confers resistance to penciclovir.

Fortunately, convincing evidence indicates that adefovir dipivoxil and entecavir inhibit replication of lamivudine- and famciclovir-resistant HBV. Cell-free polymerase assays show that the sensitivities of wild-type and genetically engineered mutant HBV polymerases to adefovir diphosphate are not significantly different. [141], [142] Analyses from several independent laboratories have confirmed that adefovir dipivoxil and entecavir are equally effective as inhibitors of wild-type virus and lamivudine-resistant HBV in cell culture. Furthermore, recent clinical experience shows that treatment with adefovir dipivoxil can suppress the replication of lamivudine-resistant HBV in vivo. [143], [144]

MANAGEMENT OF SPECIAL POPULATIONS

Alcohol use in patients chronically infected with HBV increases the risk for progression to cirrhosis, results in more rapidly progressive liver disease, and also increases the risk for liver cancer. [19], [20], [145] Patients with chronic liver disease should not drink alcohol, and patients with documented chronic HBV infection should be educated about the risks of alcohol use and advised not to drink any alcohol because the threshold for complications of alcohol use are unknown.

Dialysis patients need to be tested for HBV infection, and those without evidence of immunity need to be vaccinated with a double dose of vaccine. Patients who are chronically infected have been historically isolated from other patients in dialysis centers, but at this time, the sterile techniques used, the exchange of equipment in dialysis centers, and other advances in therapy do not mandate

complete separation of such patients.

Treating chronic HBV infection in dialysis patients should focus on the presence or absence of progressive liver disease as demonstrated by biopsy. Interferon probably has less efficacy in dialysis patients owing to the relative state of immunosuppression in these patients. Lamivudine can also be used, but dose adjustments must take place to take into account the dominant renal clearance of these medications.

The management of post–liver transplantation HBV infection is complex. [19] The most important step is to prevent graft infection or reinfection, which can start before liver transplantation by screening donors for anti-HBc and recipients for HBV DNA replication as well as by suppressing HBV replication to low levels using nucleoside or nucleotide analogs before the patient enters the operating room. Perioperative and postoperative HBIG therapy is used to bind circulating virus and prevent graft infection [146] and results in improved survival and a much lower rate of HBV graft infection, thereby preventing aggressive liver disease. Lamivudine maintains viral replication at a very low level and, when used in combination with HBIG, results in a risk of less than 5% for graft infection in compliant patients. [147] Newer nucleoside and nucleotide analogs may also be used in a similar clinical setting. The use of two oral agents may obviate the need for the quite costly use of HBIG. The emergence of mutant viruses that are resistant to lamivudine is a major problem in the treatment of HBV disease after liver transplantation, with more than 30% to 40% of patients developing resistance, and with more aggressive liver disease seen once resistance emerges. [148]

Other solid organ transplant recipients, such as bone marrow, heart, and kidney recipients, are at risk for reactivation of HBV disease after organ transplantation. [149], [150], [151], [152] and [153] An expert in hepatitis B management must evaluate these patients before they undergo transplantation. If active HBV replication is present, avoiding or delaying organ transplantation is advised unless successful suppression of HBV disease can be achieved. Some transplantation centers will not perform organ transplantations in patients who are HBsAg positive. Another clinical setting is the transmission of HBV from the organ donor to recipient, in which the risk for transmission is nearly 100% if the donor is HBsAg positive. Donation is rarely performed in this circumstance. Another risk is the presence of anti-HBc in the donor, which poses a small (less than 3%) risk for HBV transmission in organ transplant recipients other than liver recipients, with a significant risk to liver transplant recipients that ranges up to 70%. [154], [155] Finally, recipients who are anti-HBc positive can reactivate nascent HBV disease once immunosuppression is initiated. [156] Any patient who develops acute liver disease after solid organ transplantation needs to be assessed by HBsAg testing. Conversely, bone marrow transplantations have resulted in HBsAg clearance by adoptive immunity from the donor's immune cells. [157]

In summary, chronic HBV infection continues to pose a very serious health care problem in all countries of the world. There is emerging molecular, clinical, and treatment information that will markedly enhance our ability to manage patients with chronic HBV disease. Hopefully, with the advent of universal infant vaccination, treatment of all forms of chronic HBV disease, and new screening methods and treatment modalities for HBV-induced cirrhosis and liver cancer, we will markedly decrease the incidence and prevalence of this worldwide endemic disease.

Acknowledgment

We would like to acknowledge Dr. Teresa Wright's insightful review of this manuscript and her most helpful comments.

CHAPTER 108

Aijaz Ahmed and Emmet B. Keeffe

HEPATITIS C VIRUS INFECTION

EPIDEMIOLOGY

Chronic hepatitis C virus (HCV) infection has reached pandemic proportions, with an estimated 170 million individuals infected worldwide. [1], [2], [3] and [4] Data from population-based studies demonstrates that chronic HCV infection accounts for 40% of chronic liver disease and results in an estimated 8000 to 10,000 deaths annually in the United States. [5] In addition, there is a marked geographic and temporal variation in the incidence and prevalence of HCV infection. [1]

Incidence

Chronic hepatitis C is the most common chronic blood-borne infectious disease in the United States, even though the number of new infections per year has declined since 1989 by more than 80%, to 36,000 cases in 1996. [5] Current reports on new infections demonstrate that HCV infection is particularly common among young Hispanic men between 20 and 39 years of age. [3] Injection drug use is the most common risk factor currently associated with the transmission of HCV infection and is responsible for as many as 38% of newly diagnosed cases. [5]

Prevalence

The worldwide prevalence rates of chronic HCV infection vary from as low as 0.4% in the Western European countries to as high as 22% in Egypt and other parts of Africa. [6], [7], [8], [9], [10], [11] and [12] About 85% of patients develop chronic liver disease after acute HCV infection. Therefore, the past incidence of acute HCV infection is a key predictor of the current prevalence of chronic hepatitis C. [13] The Third National Health and Nutrition Examination Survey (NHANES-III), conducted from 1988 to 1994, provided data on the past incidence of acute HCV infection using national seroprevalence and age-specific incidence data from the sentinel counties surveillance program. [6], [7] The overall national prevalence of antibody to HCV (anti-HCV) was 1.8 percent, which corresponds to an estimated 3.9 million individuals (95% confidence interval, 3.1 million to 4.8 million) infected with HCV. About 65% of these individuals were 30 to 49 years of age. [6], [7] Serum HCV RNA was detectable in 74% cases, which corresponds to an estimated 2.7 million actively infected individuals nationwide (95% confidence interval, 2.4 million to 3.0 million). Of these chronically infected individuals, 74% were infected with genotype 1 (57% with genotype 1a, and 17% with genotype 1b).

Demographic Characteristics

Infection with HCV has no boundaries and affects individuals from all walks of life, ranging from children to elderly people. The highest incidence of acute hepatitis C is found among individuals between 20 to 39 years of age, with males outnumbering females. [5] African Americans and whites have a similar incidence of acute HCV infection, whereas individuals with Hispanic background have the highest incidence rate. In the general population, the highest prevalence rates of HCV infection are found among individuals between the ages of 30 to 49 years, with males predominantly affected. [4] In contrast to the rate of acute HCV infection, African Americans have a substantially higher prevalence rate of chronic HCV infection when compared with whites. A study conducted to estimate seroprevalence rates of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and HCV among individuals with severe mental illness in the United States showed a 20% prevalence rate of HCV infection, which is 11 times the overall estimated prevalence rate for HCV infection in the general population. [14] Higher rates of HCV infection were also noted in patient groups with HIV and HBV infection. Individuals with asymptomatic HCV infection frequently fail to receive appropriate treatment to eradicate viremia and retard the progression of liver damage and thus may be a source of infection to others. [14]

Infection with HCV may differ in the pediatric age group (as compared with adults) with respect to transmission, natural history, and response to treatment. The prevalence of chronic HCV infection in children ranges from 0.05% to 0.4% [15]. The major mode of acquisition has shifted from parenteral transmission to maternal-infant transmission. However, the actual rate of vertical transmission is low. [15]

Transmission Patterns

Based on age-specific prevalence data, at least three distinct transmission patterns of HCV infection have been established. First, in developed nations such as the United States and Australia, chronic HCV infection mainly affects individuals between the ages of 30 and 49 years, indicating that the risk for HCV infection was at its

peak in the recent past (10 to 30 years ago) and primarily affected young adults. [1] Second, in nations such as Japan and Italy, HCV infection mainly affects older individuals, reflecting that the risk for HCV infection peaked in the distant past. Finally, Egypt is a classic example of an ongoing risk for acquiring HCV: high rates of infection are observed in all age groups. In countries with the first pattern, injection drug use is the most common risk factor associated with chronic HCV infection, whereas in those with the second or third pattern, unsafe injections and contaminated equipment used in health care facilities are primarily responsible for HCV transmission. [1] The contribution of different risk factors predicts the variability in the transmission patterns of HCV infection between various regions and countries.

Modes of Transmission

In the United States, the relative importance of the two most common exposures associated with transmission of HCV, blood transfusion and injection drug use, have undergone a substantial change. [16] Blood transfusion, which accounted for a significant proportion of HCV infections acquired more than 10 years ago, has been almost completely eliminated as a risk factor for HCV infection owing to improved screening of blood and organ or tissue donors. Since 1990, the risk for transfusion-transmitted HCV infection has been almost nonexistent, as demonstrated by the inability of Centers for Disease Control and Prevention (CDC) Sentinel Counties Viral Hepatitis Surveillance System to report any transfusion-associated cases of acute hepatitis C. [6], [7] Therefore, the risk for transfusion-related transmission of HCV is negligible. In contrast, injection drug use has consistently been associated with a significant proportion of chronic HCV infections and currently accounts for 60% of HCV transmission in the United States. Other known exposures (occupational, hemodialysis, household, perinatal) together account for about 10% of HCV transmission. In up to 10% of individuals with chronic HCV infection, no recognized source of infection can be identified, and most individuals in this category come from a low socioeconomic status. Case-control studies have found no association of increased HCV transmission with military service. [16]

The variation in HCV prevalence rates in a certain population is determined by the mode of transmission. [15] The highest prevalence rate of HCV infection is associated with high-dose or recurring direct percutaneous blood exposure, which has occurred in injection drug users, hemophiliacs who received clotting factor concentrates produced before 1987, and transfusion recipients of HCV-positive blood or blood products before 1992. [12], [13], [16], [17] Moderate prevalence rates of HCV infection are associated with smaller direct percutaneous exposures, such as experienced by individuals receiving long-term hemodialysis. Lower prevalence rates are associated with percutaneous or mucosal exposures due to high-risk sexual behavior or with low-dose percutaneous exposures experienced by health care workers. The lowest prevalence rate of HCV infection is found among individuals who lack high-risk characteristics, as exemplified by the screened volunteer blood donor population.

Injection Drug Use In the early 1990s, the decrease in the incidence of HCV infection was associated with a sharp fall in HCV infection among injection drug users. [4], [5] Up to 65% of injection drug users have detectable anti-HCV within 1 year of starting this high-risk behavior. [17], [18] Despite the high proportion of new infections due to injection drug use, for reasons that are unclear, the dramatic decline in incidence of acute hepatitis C since 1989 correlates with a decrease in cases among injection drug users. [4], [5] Several differences in risk factors associated with HCV prevalence rates were observed in two populations of young injection drug users from the same city (New York City), suggesting that indirect transmission of HCV may occur. [17] Among subjects 17 to 59 years of age, the strongest factors independently associated with HCV infection were injection drug use and high-risk sexual behavior. Independent drug-related risk factors included frequent injections, heavy crack smoking, injecting in a shooting gallery, and syringe-mediated sharing. Sharing of drug preparation equipment has been implicated as a possible route of HCV transmission. [5], [19] Intranasal cocaine use can also lead to transmission of HCV infection. [20] Other factors independently associated with HCV infection included poverty, having had 12 or fewer years of education, having been divorced or separated, and residence in an urban area as compared with the suburbs. [21], [22]
Blood Transfusion The current risk for acute infection with any pathogen associated with transfusion has decreased to less than 5%. [4] The exact risk for transfusion-related HCV infection is 0.6% per patient and 0.03% per unit of blood transfused. [23], [24], [25] and [26] Among donors whose blood units passed all screening tests, the risks of donating blood during an infectious window period were estimated as follows: for HIV, 1 in 493,000; for human T-cell lymphotropic virus, 1 in 641,000; for HCV, 1 in 103,000; and for HBV, 1 in 63,000. [25] The incidence of posttransfusion HCV infection has decreased appreciably since the implementation of donor screening using surrogate markers initially and then tests for anti-HCV. [4], [5], [19], [23], [27], [28] and [29] In 1984, the sharp decline in the incidence of transfusion-associated hepatitis was noted when donors were screened with alanine aminotransferase (ALT) and anti-HBc. In 1990, anti-HCV testing was added to the screening protocol and resulted in a further decrease in the incidence of transfusion-related hepatitis. [30] Before 1984, transfusion was the most common route of HCV infection; in particular, patients receiving multiple transfusions had the highest risk. [31], [32], [33], [34], [35], [36], [37], [38], [39], [40], [41], [42], [43], [44], [45] and [46] In hemophiliacs, unheated and dry heat–treated clotting factor concentrates carried a high risk for transmitting HCV infection. [41] In comparison, clotting factor concentrates inactivated by vapor heating had a significantly lower, close to zero, risk for transmitting HCV infection. [41], [47]
Chronic Hemodialysis The transmission of HCV infection is common among hemodialysis patients. Transmission of infection in this setting has been related to the number of blood transfusions, the duration of hemodialysis, and nosocomial transmission of HCV in the dialysis unit. [48], [49], [50], [51] and [52] Studies have failed to determine the most likely mode of transmission in dialysis units; therefore, emphasis is placed on strict adherence to blood collecting and handling using universal safety precautions, careful attention to hygiene in the dialysis units, and sterilization of dialysis machines in order to minimize the risk for HCV transmission. [52], [53] Nosocomial transmission of HCV not related to blood transfusions has been reported between patients dialyzed on the same shift and not sharing the same dialysis machine. [54] In dialysis units in Italy and France, the incidence and prevalence rates of HCV infection are 1% to 2% and 20% to 60%, respectively. [55]
Occupational The reported prevalence of HCV infection in health care workers such as orthopedic and oral surgeons is 1% to 2%, which is comparable to that in the general population. [56], [57], [58], [59], [60] and [61] However, some surveys have demonstrated seroprevalence rates ranging between 0.6% and 4.5% in health care workers, exceeding the seroprevalence rate of HCV infection in blood donors at the same facility by up to 4.5 times. [61], [62] and [63] This observation has been supported by other studies that have demonstrated significantly higher prevalence of HCV in dentists and oral surgeons as compared with controls. [64] There are no reports documenting transmission of HCV through mucus membranes. However, accidental needle-stick exposure and blood splashes to the conjunctiva have been associated with transmission of HCV infection. [60], [65], [66] The incidence of HCV transmission by accidental needle-stick exposure varies from 0% to 10% and has been associated with the viral load in the inoculum, depth of inoculation, and size of needle. [5], [67], [68] and [69] The risk may be higher with needles that have hollow channels as compared with nonhollow sharps. [68] Nosocomial transmission of HCV infection has been suspected, and health care workers have been reported to transmit HCV infection to their patients. [54], [70] HCV was detected in the biopsy suction channel after an endoscopic procedure in 27% of patients with chronic HCV infection, and HCV RNA was detected on the biopsy forceps in 6% of cases. [71] A thorough disinfection procedure appears to be effective in eliminating the risk for HCV transmission. Percutaneous transmission of HCV has been documented due to lack of sterile practices and reuse of contaminated supplies in traditional medicine, folk medicine, tattooing, body piercing, commercial barbering, circumcision, and scarification. [72], [73], [74] and [75] On the other hand, there are case-control studies that show no evidence of increased HCV transmission associated with exposures resulting from medical, surgical, or dental procedures; tattooing; acupuncture; ear piercing; or foreign travel. [16] HCV transmission does not appear to be associated with military service. [16]
Sexual Transmission It is estimated that up to 20% of patients with chronic hepatitis C and no identifiable risk factor may have acquired HCV sexually. [76], [77] HCV RNA has been detected in the semen of as many as one third of HCV viremic men. [76] Although seminal viral loads are low, semen could be infectious and play a role in the spread of HCV infection. The risk for acquiring HCV rises in men who have sex with men and bisexual men, [78], [79] in heterosexuals with multiple sexual partners, [78] with the number of sexual contacts, [80] with other sexually transmitted diseases such as syphilis and HIV, [81] in partners of injection drug users, [11] in prostitutes and their contacts, [82] with failure to use condoms, [78], [79] with sexual activities involving trauma, [78], [79], [82] and with divorce and separation. [2] Patients with HCV and HIV co-infection have a fivefold greater risk for transmitting HCV to their partners. [83] Male-to-female transmission of HCV is higher than female-to-male transmission. [84], [85] The risk for sexual transmission of HCV is significantly lower than that of HBV, HIV, and other sexually transmitted diseases. [79]
Vertical Transmission The rate of mother-to-child transmission of HCV is low. [86], [87] However, based on the prevalence of HCV infection in pregnant women in the Western world (0.09% to 0.25%), a reasonable number of pediatric HCV infections may occur. [87] Prospective trials have shown that the transmission rate of mother-to-infant HCV infection is 7.8% in anti-HCV–positive mothers. [88] It has been demonstrated that high maternal viral load, vaginal delivery, HCV and HIV co-infection, and negative anti-NS4 antibody are significant risk factors for vertical transmission of HCV. [89], [90], [91], [92] and [93] The placenta acts as a barrier and prevents free, direct communication between maternal and fetal blood. [94], [95] and [96] This barrier is broken at birth, resulting in free communication between the maternal and fetal blood. [97] Elective cesarean delivery is associated with lowest amount of microtransfusion from mother to fetus. [97] Therefore, it has been proposed that patients with high HCV viral load and other risk factors for vertical transmission of HCV infection might benefit from elective cesarean section. [97], [98]

MOLECULAR VIROLOGY AND PATHOGENESIS

Molecular Organization and Characteristics

HCV RNA was isolated in 1989 using a random-primed cDNA library established from the plasma of patients with suspected non-A, non-B hepatitis infection. [99], [100]

and [101] Using electron microscopy, HCV has been visualized in chimpanzee hepatocytes and human T and B cells. [102] HCV genome is a 9.6-kb long, single-stranded RNA molecule. The genomic size and molecular organization suggest close association with flaviviruses and pestiviruses. [103] Data from filtration studies indicate that the HCV ranges in size from 30 to 60 nm in diameter. [103] The virus is coated with a bilayer lipid envelope. [104] The crucial structural constituent of the HCV genome is the core protein, which is found at the amino terminal of the polyprotein. The core protein is strictly conserved in HCV genotypes. The coating glycoproteins that form the HCV envelope are referred to as E1 and E2. [105] The E2 glycoprotein has two hypervariable (HVR) segments: HVR-1 and HVR-2. These hypervariable segments provide HCV with the basic mechanisms for evading the host immune defenses and establishing chronic infectivity. [106], [107], [108] and [109] Anti–HVR-1 antibodies provide protection against HCV infection, supporting the fact that this region harbors a crucial signal for a neutralization factor. HVR-1 activates helper T-cell responses during HCV infection. It was noted that the frequency of anti–HVR-1 T-cell responses was more pronounced in patients who recovered after interferon therapy than in patients who did not respond. [110], [111] The HCV must bind to a receptor on the cell membrane to facilitate entry into the cell. It has been shown that E2 envelope proteins have the ability to bind cell membranes. [112] The entry into the cell and exposure to the intracellular acidic environment causes irreversible structural changes in envelope proteins coating the HCV genome. [113] This is followed by release of genomic RNA, triggering protein translation. Furthermore, multiple independent adaptive mutations cluster in the HCV nonstructural protein NS5A and confer increased replicative ability in vitro. [114]

Genotypes and Quasispecies

The open reading frame of HCV RNA demonstrates polymorphism and encodes a polyprotein precursor consisting of about 3000 amino acids, varying among different genotypes. HCV is classified into four hierarchical levels: genotypes, subtypes or subgenotypes, isolates, and quasispecies. [115], [116], [117], [118], [119], [120], [121] and [122] HCV appears to exist simultaneously within an individual as a series of related, but immunologically distinct, variants called *quasispecies*. The existence of these quasispecies may provide a mechanism for the virus to escape the host immune response. The HCV genotype, however, is stable and does not change over the course of infection in an individual. The evolutionary dynamics of the HCV quasispecies during the acute phase of hepatitis C predict whether the infection will resolve or persist. [123] Individuals infected with HCV can develop superinfection with other HCV genotypes, leading to eradication or suppression of the primary genotype. Simultaneous infection with multiple HCV genotypes may result in concomitant infection or eventual dominance by one genotype. [124] The genotype distribution showed no relation to the severity of the liver disease or to the duration of the disease. [125]

Pathophysiology and Immunopathogenesis

The mechanistic pathways involved in the pathogenesis of chronic HCV infection include direct HCV-induced cytopathic insult to hepatocytes or injury resulting from specific or nonspecific immune responses. [126] It has been demonstrated that cytotoxic T cells and cytokines produced by both $CD4^{+}$ (helper T cells) and cytotoxic T cells may trigger the inflammatory response in the hepatocyte. [126] The helper T-cell type 2 (Th 2) immunity, as well as weak HCV-specific T-cell response, is associated with viral persistence. [127] The production of interleukin-12 and nitric oxide is critical for the induction of Th 1 and innate immunity. [127] Patients infected with HCV mount a humoral immune response to epitopes of HVR-1. However, HCV infection may be difficult to eradicate owing to the rapidly evolving nature of HVR-1, which results in the generation of variants that are not recognized by preexisting antibodies. [128] Treatment-induced control of viremia is associated with the development of HCV-specific T-cell responses with enhanced interferon-? and low interleukin-10 production. [129] The greater efficacy of combination therapy using interferon-a plus ribavirin may be related to its ability to suppress HCV-specific interleukin-10 production. [129] The resolution of HCV infection is not followed by protective immunity against reinfection with homologous or heterologous strains. [130]

Histopathology

Histopathologically, chronic hepatitis C does not have characteristic pathognomic features and demonstrates wide variation of pathologic findings. [131] The mechanism underlying hepatocyte and bile duct injury in HCV infection results from host immune response to the virus and direct viral cytopathogenecity. Acute hepatitis C is histologically indistinguishable from other causes of acute viral hepatitis. [131], [132] HCV infection can present histologically as a triad of lymphoid aggregates in portal tracts, epithelial damage of small bile ducts, and microvesicular and macrovesicular steatosis. [131] Antibodies directed against HCV antigens allow identification of viral proteins by immunohistochemistry using monoclonal or polyclonal antibodies, particularly when frozen tissues are employed. [132] Detection of HCV RNA sequences in fixed liver tissues by in situ hybridization appears to be a more sensitive method than immunohistochemical staining. [131], [132] Immunostaining should be performed to rule out other chronic liver diseases.

A number of numeric scoring systems have been used to grade the amount of inflammation and stage and degree of fibrosis in liver biopsy specimens from patients with chronic hepatitis C. The histological activity index was the original scoring system and has been used in many clinical investigations. [133] Biopsies are graded in four categories: periportal necrosis, intralobular necrosis, portal inflammation, and fibrosis. [133] The numeric designations used for the degree of fibrosis in the various scoring systems are generally as follows: (1) stage 1—portal fibrosis; (2) stage 2—periportal fibrosis with few septa; (3) stage 3—bridging fibrosis with many septa; and (4) stage 4—cirrhosis. [133], [134], [135] and [136] These scoring systems provide definitive end points for statistical analysis of serial changes in liver histology and offer an alternative to the use of traditional pathological descriptions in following the natural history and treatment responses of asymptomatic chronic active hepatitis. The terms chronic active hepatitis, chronic persistent hepatitis, and chronic lobular hepatitis are no longer used. [135]

SCREENING AND DIAGNOSIS

Screening

Primary care physicians should routinely screen new patients for a history of risk factors associated with HCV infection. During the history and physical examination, findings suggestive of chronic liver disease include encephalopathy, ascites, edema, spider angiomas, palmar erythema, a firm liver edge, and splenomegaly. Most patients with chronic HCV infection have nonspecific constitutional symptoms, such as fatigue and decreased energy level. Elevated serum ALT levels can predict the prevalence of HCV infection in some populations. [137], [138] and [139] In summary, a test for anti-HCV should be performed if an elevated ALT level is found or a positive history of risk factors for HCV infection or physical findings suggest the presence of chronic liver disease. A qualitative polymerase chain reaction (PCR) test for HCV RNA is warranted in patients who test positive for anti-HCV, particularly those with normal ALT levels or no HCV risk factors, to confirm HCV infection and rule out a false-positive test or recovery from past HCV infection. Serologic tests for anti-HCV are probably the best screening tests for dialysis patients.

Chronic HCV infection may be a multisystem disease, and patients should be screened for cryoglobulinemia by checking serum cryoglobulins, serum creatinine, and a urinalysis. More than 50% of patients with chronic HCV infection have cryoglobulinemia, but only 1% to 5% experience related symptoms. Additional baseline laboratory tests that are commonly obtained after the initial diagnosis of chronic hepatitis C include a standard liver panel, complete blood cell count, prothrombin time, tests for co-infection with HBV or HIV, antinuclear antibody to exclude coexistent autoimmune hepatitis, alpha-fetoprotein level, and abdominal ultrasound. If treatment is being considered, a quantitative rather than qualitative serum HCV RNA test and HCV genotype are also obtained. In acute hepatic injury, prothrombin time and, to a lesser extent, total bilirubin are the best indicators of severity of disease. Although ALT is useful for detecting acute and chronic hepatic injury, it is not related to severity of acute hepatic injury and is only weakly related to severity of chronic hepatic injury. [140]

Diagnosis

The discovery of HCV in 1989 led to the development of diagnostic serologic and virologic tests. [141], [142], [143], [144], [145], [146], [147], [148] and [149] The diagnostic tests used to detect HCV infection can be divided into two main classes: (1) serologic tests or assays that detect anti-HCV; and (2) molecular tests or assays that detect, quantify, and characterize HCV RNA. [142], [143] and [144]

Serologic assays have been subdivided into screening tests for anti-HCV, such as the enzyme immunoassay (EIA), and supplemental tests, such as the recombinant immunoblot assay (RIBA). Three generations of anti-HCV tests have been developed, and each generation has provided higher sensitivity for detecting anti-HCV. Third-generation anti-HCV tests (EIA-3 and RIBA-3) contain antigens from the HCV core, nonstructural 3, nonstructural 4, and nonstructural 5 genes. The EIA-1 contained a single HCV recombinant antigen derived from a nonstructural gene. The specificity of EIA-1 was 30% to 50% in low-risk populations, such as blood donors, and the development of detectable antibodies after acute infection required several months. [142] The use of additional antigens in EIA-2 and EIA-3 tests has increased the sensitivity and shortened the time to detection after acute infection to a median of 7 to 8 weeks, but false-positive anti-HCV by EIA results still occur in low-risk populations. EIA-3 did not detect more HCV-infected individuals in a donor population that previously tested negative in EIA-2, but it did detect HCV

antibodies earlier in some patients with acute HCV infection. EIA-2 and EIA-3 are significantly more sensitive than RIBA-2 and RIBA-3. [145], [146] Supplemental anti-HCV tests are designed to resolve false-positive testing by EIA and are appropriately used in low-prevalence settings in which false-positive anti-HCV tests remain a problem. [144], [145] and [146] In practice, confirmation of HCV infection is performed by detection of HCV RNA by PCR or the branched-chain DNA (bDNA) assay. [145], [146] and [147] The EIA-3 has an estimated sensitivity of 98.9% and specificity of 100% in patients with chronic HCV infection, whereas the sensitivity RIBA-3 is 78.8% in the hemodialysis population. [148] These data provide evidence for the good sensitivity and specificity of EIA-3 assays, particularly in high-risk patient groups, and confirm their use for screening in these populations. [147], [148]

Detection of serum HCV RNA provides evidence of active HCV infection and is useful as a confirmatory test. [142], [143], [144], [145], [146] and [147] Optimal HCV RNA assays using PCR at present have a sensitivity of less than 100 copies/mL. There are several methods for assessing HCV RNA levels, including various PCR assays, the bDNA, and transcription-mediated amplification. Quantitative PCR is the most sensitive test for quantifying hepatitis C viral load, whereas the bDNA test appears to be the most specific method. However, it must be recognized that these molecular tests have their own limitations, which include inadequate dynamic range, high variability of PCR assays, and poor sensitivity of the bDNA test. [142], [149] Commonly used serum HCV RNA qualitative and quantitative second-generation PCR assays are Amplicor HCV v2.0 and Amplicor HCV Monitor v2.0, respectively. Second-generation assays are 1 log more sensitive and genotype independent, compared with their respective first-generation tests (10^{2} copies/mL versus 10^{3} copies/mL for qualitative tests; 10^{3} copies/mL versus 10^{4} copies/mL for quantitative tests). [143], [144]

An anti-HCV–positive result in a low-risk setting, such as blood donation, should be confirmed with an analytical antibody test. Subsequently, a serum HCV RNA test should be performed on donors with a positive or indeterminate confirmatory test result. On the other hand, an anti-HCV–positive test result in high-risk populations is likely to be true positive. A quantitative HCV RNA test and genotyping should be performed if therapy is being considered. [148]

According to data from the CDC, 200,000 to 700,000 new cases of acute viral hepatitis occur in the United States each year. [3], [4], [5] and [6], [149] In 1995, these cases included 180,000 new hepatitis A virus (HAV) infections, 128,000 HBV infections, and 28,000 HCV infections. From these cases, there are about 100 deaths per year from fulminant hepatitis A and 150 deaths from fulminant hepatitis B; hepatitis C has rarely been implicated as a cause of fulminant hepatic failure. Although the death rate from acute viral hepatitis is low, many adult patients with HBV infection (5%) and HCV infection (85%) become chronically infected, and a significant percentage of these patients ultimately develop cirrhosis or hepatocellular carcinoma (HCC) over two or more decades. Because 75% of acute viral hepatitis results from either HAV or HBV infection, initial laboratory investigation should include serologic tests to exclude HAV or HBV infection. In the event these studies are negative, further testing should be performed to rule out acute HCV infection. Serum HCV RNA is detectable 1 to 2 weeks after the onset of infection, whereas antibodies to HCV are not detected until 8 to 10 weeks after infection with HCV. In clinically stable patients, it may be plausible to wait and check antibodies to HCV.

NATURAL HISTORY

Acute Infection

Acute infection with HCV is usually asymptomatic and therefore not diagnosed and underestimated. Acute HCV infection is the third most common cause of acute hepatitis associated with jaundice. The most common cause of acute hepatitis in United States is acute hepatitis A, which accounts for 49% of all cases. [29], [150] This is followed by acute hepatitis B (35% of cases) and acute HCV infection (16% of cases). [29] As many as 43% of cases of acute hepatitis C are associated with intravenous drug use, 17% with sexual exposure to an infected individual or with high-risk sexual behavior, and less than 10% with other risk factors also known to transmit HCV infection. [29], [151] No known risk factors can be identified in 31% of patients with acute HCV infection. [29]

The incubation period from infection to onset of symptoms can range from 2 to 12 weeks, with an average of 6 to 7 weeks. [6], [152], [153] and [154] Serum HCV RNA is detectable within 7 to 21 days after an acute infection. [154] Serum HCV RNA, in titers of 10^{5} to 10^{7} copies/mL, can be detected at the onset of jaundice. [155] Aminotransferase levels are elevated between 14 to 28 days after infection, and anti-HCV becomes detectable about 60 days (varies from 20 to 150 days) after the onset of infection. [154]

Preicteric Period A wide constellation of clinical features, including low-grade fever, decreased energy level, fatigue, nausea, vomiting, right-sided abdominal pain, myalgias, and arthralgia, may develop in 15% to 20% of patients. This clinical syndrome occurs within 2 to 12 weeks of acute HCV infection and also lasts for 2 to 12 weeks. Systemic symptoms may be followed by jaundice. In rare circumstances, patients can develop rash, hives, and arthralgias that are most likely secondary to a serum sickness syndrome precipitated by immune complexes. [152], [153] and [154] Most patients with acute hepatitis C, however, remain asymptomatic.
Icteric Period The nonspecific symptoms, which develop in the preicteric phase, usually persist during the period of jaundice. Infrequently, jaundice can be a presenting symptom of acute HCV infection and typically lasts for 1 to 2 weeks. Serum HCV RNA usually becomes detectable with the onset of jaundice. Fulminant liver failure after HCV infection has been reported but is a rare occurrence. [29], [154]
Resolution Versus Chronicity After the acute onset, HCV infection is self-limiting and resolves 3 to 6 months later in 15% to 30% of cases, with return of ALT levels to normal and disappearance of serum HCV RNA, although anti-HCV remains detectable. During convalescence, patients report resolution of jaundice, improved appetite, weight gain, and feeling of well-being. However, nonspecific clinical features may persist for a few months in a small minority of patients who recover from acute HCV infection. A higher rate of HCV eradication is noted in patients with clinically symptomatic acute HCV infection as compared with those who are asymptomatic. Therefore, the outcome of HCV infection is dependent on the viral host immunologic interactions in the first few weeks of infection. Patients who recover from acute HCV infection usually do so within the first 12 weeks of infection. Nearly 10% of patients who develop anti-HCV response eventually lose the nonneutralizing antibody and evidence of past acute infection. [156] Some patients may not develop anti-HCV response with short-duration, acute hepatitis C; it is difficult to estimate the proportion of patients with this response. Spontaneous clearance and resolution of HCV infection is rare after 6 months of persistent infection. [157] Up to 75% to 85% of adults and 55% of children develop chronic HCV infection. [152], [153] and [154], [158], [159], [160] and [161]

Chronic Infection

Chronic HCV infection develops in as many as 85% of patients after acute infection. [162] Most patients with chronic infection have asymptomatic elevation of aminotransferase levels and lack physical findings suggestive of liver disease. [163], [164] Fatigue is the most common symptom reported by patients with chronic HCV infection. [163] The correlation of symptoms with histological severity of liver disease is poor in patients with chronic hepatitis C; patients may have fatigue associated with either mild or severe disease. [163] Vague and intermittent right upper quadrant pain is the second most frequent symptom noted in patients with chronic HCV infection. Other less common nonspecific symptoms include low-grade fever, nausea, vomiting, myalgia, and arthralgia. Up to 15% to 20% of patients with chronic HCV infection have psychological or psychosocial problems, which complicate initial assessment and later decisions regarding treatment. One third of patients with chronic HCV infection have normal ALT levels, and 25% have ALT levels that are elevated to less than twice the upper limit of normal. [162], [165] ALT elevations are persistent in 26% of cases and intermittent in 40% to 70% cases, with resolution to normal range in 17% of patients on long-term follow-up. [162], [165], [166] Self-limited, intermittent ALT flares have been noted and may be associated with an increase in serum HCV RNA, but not with viral eradication. [167] A 10-fold rise in ALT levels has been associated with severe piecemeal necrosis. [162], [163], [168] The titer of serum HCV RNA is not associated with histological severity.

Hepatitis C–Related Cirrhosis

Several studies have now confirmed that chronic HCV infection demonstrates minimal clinical progression in the initial two decades after infection. [164], [169], [170], [171], [172], [173], [174] and [175] Chronic infection with HCV leads to cirrhosis in at least 20% to 25% of immunocompetent patients within 20 years of the onset of infection.

Risk Factors Associated with Rapid Progression to Hepatitis C–Related Cirrhosis Cirrhosis and end-stage liver disease may develop more rapidly under certain circumstances. [161] Factors influencing the rate of progression of fibrosis include gender (male sex), genetic background (Japanese at higher risk than Americans), age at exposure (higher risk for cirrhosis with age greater than 40 years at time of HCV infection), duration of HCV infection (longer), route of transmission (blood transfusion greater risk than injection drug use), and coexisting conditions, including alcoholic liver disease (daily alcohol consumption of 50 g or more), chronic tobacco use, HIV infection, and HBV infection. [176], [177], [178], [179], [180], [181] and [182] Between 10% and 20% of patients with chronic hepatitis B have detectable anti-HCV. [183], [184] Alternatively, 2% to 10% of patients with anti-HCV demonstrate markers of HBV infection. Co-infection with HBV and HCV results in more severe liver disease than does isolated HBV or HCV infection. The median duration of chronic HCV infection required for the development of cirrhosis can vary from 13 years in men who use alcohol and are older than 40 years of age at the time of infection to as long as 42 years in women who avoid alcohol and are less than 40 years of age at the time of infection. [185] The overall risk for cirrhosis is less than 10% over a 10-year period in patients with mild chronic hepatitis, 44% in those with moderate hepatitis,

and 100% in those with severe hepatitis with bridging fibrosis. [180]

Clinical Presentation The mean age of patients presenting with HCV-related cirrhosis is 55 years, as compared with a mean age of 42 years in patients presenting with chronic HCV infection without cirrhosis and of 66 years in patients with HCC. [186] Other studies have also confirmed a mean difference of at least 10 years between the diagnosis of cirrhosis and detection of HCC in patients with chronic HCV infection. [187], [188] and [189] HCV-related cirrhosis affects men more commonly than women, with a ratio ranging from 1.3:1 to 3.2:1. [165], [190], [191] The diagnosis of HCV-related compensated cirrhosis is often made incidentally during screening of blood donors or at the time of routine laboratory testing. [165] A wide spectrum of nonspecific symptoms can be noted in patients with compensated and decompensated cirrhosis, including fatigue in 75%, abdominal pain in 24%, and anorexia in 13%. [162] Systemic symptoms are more severe in patients with decompensated cirrhosis, and the annual risk for decompensation is 3.9%. [165] The clinical presentation can be dramatic after hepatic decompensation and manifests with ascites in 48%, variceal bleeding in 22%, hepatic encephalopathy in 8%, jaundice in 6%, or combination of complications in 17% of patients. [165] Other clinical features noted with hepatic decompensation include lower extremity edema, easy bruising, pruritus, muscle wasting, muscle cramps, and sexual dysfunction. Patients with HCV-related compensated cirrhosis have a mean survival rate of 80% at 10 years, compared with a mean survival rate of 50% at 5 years once decompensation occurs. [165] Physical findings suggestive of cirrhosis include a palpable firm liver edge in 79%, hepatomegaly in 50% to 78%, splenomegaly in 25% to 37%, and cutaneous stigmata of advance liver disease in 31%. [165] Most patients with HCV-related cirrhosis have mild to moderate elevation of aminotransferase levels, with less than 5% of patients having ALT levels 10-fold higher than the upper limit of normal. [165] The association between ALT levels and histological severity of chronic HCV is poor. [168], [192] Coagulopathy, hypoalbuminemia, hyperbilirubinemia, and thrombocytopenia are associated with a decrease in survival rate at 10 years. [165] The annual risk for HCC in patients with chronic hepatitis C with cirrhosis is 1.4% to 3.3% in the United States and Europe and as high as 6.9% in Japan and Italy. [193] The mean length of time from HCV infection to the development of HCC is 29 years. [162], [165]

CLINICAL MANIFESTATIONS AND COMPLICATIONS

Chronic HCV infection can be associated with extrahepatic organ involvement and can lead to complications primarily involving the hepatic parenchyma. Most of these manifestations are directly associated with HCV infection; however, HCC nearly always develops in the setting of HCV-related cirrhosis. Other complications associated with HCV-related cirrhosis were discussed earlier in the respective section.

Extrahepatic Clinical Manifestations

The prevalence of extrahepatic clinical manifestations is relatively low but can be associated with significant morbidity and even mortality. The precise pathogenesis of these extrahepatic manifestations has not been determined, although most represent the clinical consequences of an immune-mediated response. [194], [195]

Autoantibodies There is a high prevalence of a variety of autoantibodies, usually in low titers, associated with chronic HCV infection. Antinuclear antibody, anti–smooth-muscle antibody, and antithyroid antibody are detectable in 40% to 65% of patients with chronic HCV infection. [196], [197] The clinical significance of most of these autoantibodies is negligible, except for liver-kidney-microsomal type 1 antibodies (anti-LKM1). [197], [198] The patients with anti-LKM1 can be differentiated into two groups, anti-HCV positive and anti-HCV negative. [199], [200] Type 2 autoimmune hepatitis with high anti-LKM1 titers and negative anti-HCV primarily affects young women with moderate to marked elevation of ALT levels. These patients are responsive to immunosuppressive therapy and are HLA-DR3 positive. In contrast, patients with chronic HCV infection and a positive anti-HCV associated with a positive anti-LKM1 have distinctive features, such as an equal distribution between men and women, mildly elevated ALT levels, low anti-LKM1 titers, and responsiveness to interferon therapy. [201] Finally, patients with classic type 1 autoimmune hepatitis can have a false-positive anti-HCV, which can be confirmed with the finding of a negative serum HCV RNA. [202], [203]

Renal Disorders A wide array of renal disorders can occur in association with chronic HCV infection. [204], [205], [206], [207], [208] and [209] The pathogenesis of HCV-related renal disorders remains undefined; however, deposition of circulating immune complexes in the subendothelial space and mesangium in the glomeruli plays a central mechanistic role. These disorders may be manifest as cryoglobulinemic systemic vasculitis, proteinuria, microscopic hematuria, nephrotic syndrome, or acute renal failure. Uremic patients with chronic HCV infection and those undergoing regular dialysis frequently develop immunologic abnormalities. The most common HCV-related renal disorder is type I membranoproliferative cryoglobulinemic glomerulonephritis with a chronic course interspersed by acute recurrent episodes. The membranoproliferative cryoglobulinemic glomerulonephritis is usually associated with type II cryoglobulinemia with immunoglobulin M (IgM) rheumatoid factor, polyclonal IgG anti-HCV antibodies, and HCV RNA IgM as the principal constituents in cryoprecipitate. The treatment of renal disorders associated with chronic HCV infection is discussed in the section on “Treatment.” [210], [211], [212], [213], [214] and [215]

Endocrine Disorders Infection with HCV may contribute to the development of diabetes mellitus. Both disorders are common; therefore, cross-sectional studies were performed to confirm the close association. [216], [217] and [218] Patients with chronic HCV infection have an increased prevalence of type 2 diabetes mellitus. HCV-related cirrhosis can induce insulin resistance and predispose patients to diabetes mellitus. [216], [217] and [218] However, the increased prevalence of diabetes is independent of cirrhosis. [217] Further investigation is needed because the pathogenesis may be multifactorial and unique to HCV. [217] In the United States, type 2 diabetes mellitus occurs more often in individuals with chronic HCV infection who are older than 40 years of age. [218] Autoimmune thyroiditis can be associated with HCV-related liver disease. [219], [220] Antithyroid antibodies are found in 5% to 13% of patients with chronic HCV infection, predominantly affecting older women. [219], [220] Autoimmune thyroiditis is manifested as hypothyroidism in 3% to 6% of patients with chronic HCV infection. Interferon-related thyroid disease is more frequently noted in patients with preexisting thyroid antibodies. However, interferon can induce the formation of antithyroid antibodies. Discontinuation of interferon therapy is usually accompanied by resolution of the thyroid disorder. Salivary and lacrimal gland involvement is common in HCV-infected individuals, but HCV antigens are not detectable in affected glands. [221] Testicular atrophy and sexual dysfunction can be associated with HCV-related cirrhosis.

Rheumatologic Disorders Rheumatologic disorders associated with chronic HCV infection are common and include mixed cryoglobulinemia, vasculitis, sicca symptoms, myalgia, arthritis, and fibromyalgia. [221], [222], [223] and [224] There is a wide spectrum of clinical manifestations that can be noted and are not characteristic of HCV infection. However, a characteristic joint syndrome is associated with the presence of mixed cryoglobulinemia and characterized by intermittent monoarticular or oligoarticular, nondestructive arthritis affecting large and medium-sized joints. Treatment of patients with HCV-associated arthritis is limited and remains controversial.

Cutaneous and Mucosal Lesions The prevalence of anti-HCV varies from 4% to 65% in patients with cutaneous lichen planus or oral lichen planus. [225], [226] These estimates were obtained from populations with a high overall prevalence of HCV infection, such as southern Europe and Japan. [226] Other lesions noted in association with HCV infection include porphyria cutanea tarda, necrotizing cutaneous vasculitis, and Mooren corneal ulcer. [222] The high prevalence of HCV infection in patients with porphyria cutanea tarda is based on epidemiologic data. [222] The precise role of HCV in the pathogenesis of porphyria cutanea tarda is unknown.

Cardiac Dysfunction Recent studies have demonstrated an association between chronic hepatitis C and hypertrophic cardiomyopathy or dilated cardiomyopathy. [227] In a collaborative research project of the Committees for the Study of Idiopathic Cardiomyopathy, the prevalence of anti-HCV was 11% in patients with hypertrophic cardiomyopathy and 6% in those with dilated cardiomyopathy, both of which were significantly higher than the prevalence rate of HCV infection in volunteer blood donors in Japan. [227] Various other cardiac abnormalities were found, of which arrhythmias were the most frequent.

Miscellaneous Extrahepatic Manifestations Many systemic disorders can be associated with chronic HCV infection, including polyarteritis nodosa–type systemic vasculitis, [228] colonic vasculitis, [229] idiopathic thrombocytopenic purpura, [222] celiac sprue, [230] Sjögren syndrome, [222] polymyositis, [231] and multiple myeloma. [232] Systemic sclerosis has been reported in patients with chronic HCV infection, manifested by severe Raynaud phenomenon, progressive skin thickening, painful fingertip ulcers, dysphagia, and Sjögren syndrome. [233] The prevalence of chronic HCV infection in patients with systemic lupus erythematosus is greater than the prevalence of HCV in blood donors from the same population. [234] Patients with coexistent systemic lupus erythematosus and HCV infection tend to manifest a lower frequency of cutaneous systemic lupus erythematosus lesions and anti- double-stranded DNA (dsDNA) antibodies and a higher rate of hepatic involvement, hypocomplementemia, and cryoglobulinemia. [234]

Lymphoproliferative Diseases

The role of HCV infection in the etiology and pathogenesis of lymphoproliferative diseases is supported by several studies reporting high seroprevalence of HCV in patients with B-cell non-Hodgkin lymphoma. [235], [236] and [237] HCV demonstrates high affinity to lymphoid tissue. HCV is associated with type II mixed cryoglobulinemia, a benign monoclonal lymphoproliferative disorder that can transform to overt B-cell non-Hodgkin lymphoma.

Primary Hepatic Lymphoma

The etiologic association of HCV and primary hepatic lymphoma is unclear. [238] Numerous reports of primary hepatic lymphoma of B-cell origin in association with HCV infection have been published. [238] Primary hepatic lymphoma is typically a large cell, high-grade malignant B-cell lymphoma. Only a few cases of T-cell lymphoma

have been described. [238]

Hepatocellular Carcinoma

The current incidence of HCC in United States is 2.4 cases per 100,000 individuals, but the incidence of HCC is as high as 120 cases per 100,000 in China, the Far East, and sub-Saharan Africa. [193], [239], [240], [241] and [242] The occurrence of HCC in association with HCV-related liver disease shows marked geographic variation. [240], [241] and [242] The rate of detectable anti-HCV in patients with HCC varies from 60% to 70% in Spain and Italy, 50% in Japan, and 27% in United States to less than 10% in Hong Kong. [193] Within the United States, the association of HCC with a positive anti-HCV has a much higher prevalence in geographic areas with a large Hispanic population. [242], [243] and [244] About 20% to 25% patients with chronic HCV infection develop cirrhosis within 20 years of the onset of infection. HCC develops at a rate of 1.5% to 9% per year in patients with chronic hepatitis C and cirrhosis. [165], [244] Therefore, there is a 5% risk for developing HCC in patients with HCV infection over a course of 20 years. The risk factors associated with development of HCC in the setting of HCV infection include age greater than 60 years, male gender, alcohol use, co-infection with HBV, porphyria cutanea tarda, increased hepatic iron content, and severity of cirrhosis. [243], [244], [245] and [246] The incidence of HCV-related HCC is steadily rising, and HCV accounts for nearly half of all cases of HCC in the United States. [242], [243]

Ultrasound of the abdomen and serum alpha-fetoprotein are reasonable tests in a screening strategy for early detection of HCC in patients with chronic HCV infection and cirrhosis. [246] There is no consensus on the frequency with which these tests should be performed, but most experts recommend an interval of every 6 to 12 months. Screening is recommended only for patients with known or suspected cirrhosis because the risk for HCC is quite low in patients who do not have cirrhosis.

Cholangiocarcinoma

There is also a somewhat higher incidence of cholangiocarcinoma in patients with HCV-related cirrhosis, and cholangiocarcinoma is also associated with poor prognosis. [247] and [248]

TREATMENT

In general, the treatment of patients with chronic hepatitis C, including patients with compensated cirrhosis, is antiviral therapy with interferon-based therapies. Patients with decompensated cirrhosis should be referred to a liver transplantation center for consideration for liver transplantation, which is the treatment of choice when liver failure complicates chronic HCV infection.

Interferon-Based Antiviral Therapy

The best candidates for antiviral therapy of chronic hepatitis C are patients at the greatest risk for progression to cirrhosis. [181], [249] These patients are characterized by persistently elevated ALT levels for more than 6 months, detectable serum HCV RNA, and either portal or bridging fibrosis with at least moderate degrees of inflammation and necrosis on liver biopsy. Patients treated in clinical trials typically are required to have elevated ALT levels of more than 1.5 times the upper limit of normal, clinically compensated liver disease, and no other significant medical or psychiatric illness that contraindicates therapy (Table 108-1). Clinical guidelines on the management of chronic HCV infection were established at a National Institutes of Health (NIH) consensus conference in 1997 [250] and confirmed at a European consensus conference 2 years later. [251] More recently, these guidelines were confirmed and further modified. [252]

Hematologic
- Hemoglobin <12 g/dL in women and <13 g/dL in men
- White blood cell count $<1500/mm^3$
- Platelet count $<100,000/mm^3$

Hepatic
- Normal aminotransferase levels
- Decompensated cirrhosis

Cardiovascular
- Severe coronary artery disease
- Unstable angina

Endocrine
- Poorly controlled diabetes mellitus

Autoimmune
- Untreated thyroid disease

Neuropsychiatric
- Seizure disorder
- Severe psychiatric illness

Obstetric
- Pregnant or unable to practice contraception

TABLE 108-1 Contraindications: Interferon and Ribavirin Therapy

Virologic and Biochemical Response Responses to antiviral therapy of chronic HCV infection may be defined on the basis of the biochemical, virologic, and histological outcomes. The persistence of a biochemical (normal ALT) or virologic (undetectable HCV RNA) response for 6 months or more after cessation of therapy is the operational definition of a *sustained response* (SR). [253] Several studies, including a mean 4-year follow-up of 80 patients and a 10-year follow-up of 5 patients who all had initial posttreatment 6-month sustained responses showed long-term virologic sustained response rates of 96% and 100%, respectively. [254], [255] In addition, there was improvement of liver histology, including evidence of regression of hepatic fibrosis in noncirrhotic patients. These studies suggest that some cases of chronic HCV may indeed be "cured" and that a benefit on mortality should be expected if cirrhosis, with its risk of HCC, can be prevented. A posttreatment elevated ALT level and detectable HCV RNA that had been normal and undetectable, respectively, during treatment define *relapse* after a course of therapy. *Nonresponse* to antiviral therapy is defined as persistently elevated ALT levels or detectable serum HCV RNA, and a variant of nonresponse called *breakthrough* is characterized by an initial decrease of ALT levels into the normal range or the disappearance of detectable HCV RNA with subsequent elevation of ALT or presence of detectable HCV RNA while still receiving treatment. [256], [257] Failure to clear HCV RNA after 24 weeks of combination therapy predicts the lack of a sustained virologic response and has been used as a stopping rule for antiviral therapy. However, histological improvement may occur with longer therapy, and thus continuation of therapy may be beneficial in selected cases on an experimental basis.

Aims of Antiviral Therapy The primary goal of antiviral therapy in patients with chronic HCV infection is long-term viral eradication as determined by undetectable HCV RNA in serum and liver. [250], [251] and [252] Secondary objectives of treatment include improvement and prevention of liver parenchymal inflammation and fibrosis with normalization of ALT levels and reduced inflammation and fibrosis on liver biopsy.

Selective Role of Liver Biopsy The NIH and European consensus conferences recommended that a liver biopsy be performed when considering treatment for chronic HCV infection to distinguish patients most likely to benefit from therapy, that is, those with moderate histological disease, from those who may be less likely to benefit, that is, those with mild disease and no or minimal fibrosis or those with advanced disease and cirrhosis. A decision to perform a liver biopsy can be influenced by many factors, such as patient preferences, cost-effectiveness, presence of relative contraindications, and suspicion of coexistent liver diseases suggested by laboratory abnormalities like high-titer antinuclear antibody with hypergammaglobulinemia or abnormal iron studies. Liver biopsy is clearly the most reliable method of establishing the severity of liver disease due to chronic HCV infection but provides no superiority to overall clinical assessment in ruling out other unsuspected coexisting liver diseases. [258] Apprehension and anxiety are frequently noted in patients before a liver biopsy is performed. A percutaneous liver biopsy is a blind procedure, which can cause pain in 30%, severe complications in 0.3%, and death in 0.03% of patients. [259], [260] In addition, liver biopsy incurs both direct health care–related and indirect work loss–related costs. Based on a cost-effectiveness analysis, it has been recommended that the most suitable strategy in the management of chronic HCV infection is to initiate therapy in all patients and avoid a liver biopsy. [261] Considering these arguments, there is a trend to initiate therapy without performing a liver biopsy. The role of liver biopsy might be thought of as selective rather than mandatory in identifying candidates for antiviral therapy, such as for the patient who prefers to defer therapy if mild disease with no or minimal fibrosis is present. [250], [251] and [252] A number of studies have been performed in patients with chronic HCV infection to investigate the utility of laboratory tests, such as the aspartate transaminase (AST)-to-ALT ratio or the platelet count, to establish the severity of liver disease, but none of the proposed predictors is as sensitive and specific as liver biopsy. [262], [263], [264] and [265] In one study, a more complex formula correctly classified 46% of patients with or without significant fibrosis into these two respective categories. [265] Unfortunately, this formula required three assays that are not routinely performed in patients with chronic HCV infection (a $_2$-microglobulin, haptoglobin, and apolipoprotein A $_1$), in addition to three routine tests (?-globulin, ?-glutamyltranspeptidase, and total bilirubin). The future treatment of chronic hepatitis C may include antiviral drugs and also antifibrotic agents, which might necessitate the performance of a liver biopsy or the identification of reliable serum markers of fibrosis to establish the end points of therapy. A wide variety of serum fibrosis markers have been studied to predict the stage of fibrosis in HCV-related liver disease. [266], [267], [268] and [269] The serum markers that have been studied include procollagen type III *N*-terminal peptide, 7S fragment of type IV collagen, hyaluronan, matrix metalloproteinase-1 and -2, and tissue inhibitor of

metalloproteinase-1. [266], [267], [268] and [269]

Interferon-Induced Viral and Immune Kinetics The potency of interferon is determined by measuring antiviral activity in biologic assays relative to a number of international reference standards. Further insight into interferon-induced viral kinetics and host immune modulation has been provided by recent studies. [270], [271], [272], [273] and [274] It has been demonstrated that multitarget, potent $CD4^+$ proliferative T-cell responses are maintained long term after eradication of HCV infection, as compared with focused and weak responses in patients with persistent HCV infection. [273] On the other hand, the HCV-specific $CD8^+$ T-cell response is quantitatively weaker in both responders and nonresponders. [273]

Standard Interferon and Ribavirin Combination Treatment of Naive Patients The four types of interferon-a that have been evaluated in a large number of patients with chronic HCV infection include interferon-a-2b, [275] -a-2a, [276] -a-n1 (lymphoblastoid interferon), [277] and a-con-1 (consensus interferon). [278] In the United States, as of late 2001, interferon-a-2b, interferon-a-2a, interferon-a-con-1, combination interferon-a-2b with ribavirin, and peginterferon-a-2b with ribavirin are licensed and marketed for the treatment of chronic HCV infection. The U.S. Food and Drug Administration originally licensed interferon in 1991 for the treatment of chronic hepatitis C, and the initial strategy of treating patients for 6 months yielded 10% to 15% sustained response rates. It was later found that 12 to 18 months of therapy increased the response rates to 20% to 25%. [253] Interferon and ribavirin combination antiviral therapy became the standard treatment for chronic HCV infection from in 1998. [252] Ribavirin, 1000 to 1200 mg/day in two divided doses, combined with interferon-a-2b, 3 million units (MU) three times weekly for 6 months, was found to improve significantly the biochemical and virologic sustained response rates compared with interferon alone in an early pilot experience. [279], [280] Phase III American and European trials comparing standard interferon monotherapy with combination interferon-a-2b plus ribavirin therapy showed a significant improvement in response rates for all measures of efficacy, including virology, ALT levels, and histology in treatment-naive patients with chronic HCV infection. [281], [282] Serum HCV RNA was eradicated in 31% to 35% patients after 6 months of combination therapy and in 38% to 43% patients with 12 months of combination therapy, as compared with 13% to 19% with interferon monotherapy. [281], [282] These studies also showed important differences in the outcome based on genotype: about 30% of patients with genotype 1 versus about 65% with genotype 2 or 3 had sustained virologic responses. In addition, patients with genotype 1 had increased rates of sustained virologic response with 48 versus 24 weeks of therapy, whereas patients with other than genotype 1 achieved no additional benefit after 24 weeks of combination therapy. These studies dictate that combination therapy be administered for 12 months to patients with genotype 1 but only 6 months to those with genotypes 2 and 3 to achieve maximal sustained response rates. Multiple factors, [281], [282] in addition to genotype, are known to predict the likelihood of successful therapy with ribavirin and interferon and may influence the decision of whether to undergo a course of therapy.

Retreatment of Relapsers and Nonresponders Retreatment studies have been performed in patients who received interferon monotherapy and were nonresponders at the end of treatment or relapsed after treatment was discontinued. [278], [283], [284], [285] and [286] Retreatment response rates have been highly variable, depending in large part on the response to the initial course of the treatment. The only treatment strategies that have shown some favorable results with interferon monotherapy are use of a higher dose, treatment for a longer period of time, or use of a different interferon. In general, biochemical end-of-treatment rates are much higher in relapsers (79% to 85%) than nonresponders (14% to 30%). [283] The best predictors of a sustained response to retreatment of relapsers were a negative serum HCV RNA at the end of the first course and an initial treatment course of only 6 months. [283] Retreatment of relapsers with interferon monotherapy, such as interferon-a-con-1, 15 µg three times weekly for 12 months, achieved a 58% sustained virologic response. [278], [285] In contrast to the reasonably good results of retreatment of relapsers, the cumulative data indicate that nonresponders to interferon therapy achieve only modest responses with retreatment, such as 13% sustained virologic response to interferon-a-con-1, 15 µg three times weekly for 12 months. Furthermore, some recent studies suggest that a small proportion of patients who failed to respond to previous interferon monotherapy (i.e., noncirrhotic patients with low levels of virus and genotypes other than 1) may also benefit from retreatment with combination interferon and ribavirin. [287]

Pegylated Interferons Polyethylene glycol (PEG) is a large, inactive water-soluble polymer attached to interferon with a covalent bond. [288], [289] and [290] The process of pegylation results in reduced clearance of pegylated interferon and up to 10-fold increase in drug half-life, allowing once a week administration. [288], [289] and [290] Pegylated interferon has improved efficacy by maintenance of a steady serum level but may suffer a variable loss in interferon activity determined by the size of the PEG molecule and site of pegylation. [271], [288], [289] and [290] The two PEG interferons that have been studied include the long-branched 40-kd peginterferon-a-2a (Pegasys, Roche, Nutley, NJ), which is metabolized by the liver, and the short linear 12-kd peginterferon-a-2b (PEG-Intron, Schering, Kenilworth, NJ), which is excreted by the kidneys. [291], [292] Pilot studies demonstrated that the safety profile of pegylated interferon administered in ascending subcutaneous doses to healthy subjects was comparable to that of standard interferon. [291], [292], [293] and [294] Pegylated interferon monotherapy was more efficacious than standard interferon monotherapy in a dose-dependent fashion. [291], [292], [293] and [294] In one clinical trial, 531 interferon-naive patients with chronic HCV infection were treated for 48 weeks with peginterferon-a-2a, 180 µg once weekly, and showed a sustained virologic response rate of 39% at 6 months after discontinuation of therapy, in comparison to 19% sustained response with standard interferon-a-2a three times weekly. [291] In another study, 1219 interferon-naive patients with chronic HCV infection were treated with peginterferon-a-2b weekly using a weight-based dosing of 1 or 1.5 µ/kg weekly and interferon-a-2b three times weekly in the control group for 48 weeks. [292] The sustained virologic response rates were 25% with pegylated interferon-a-2b, 1 µg/kg once weekly, 23% with pegylated interferon-a-2b, 1.5 µg/kg once weekly, and 12% with interferon- a-2b three times weekly. Therefore, monotherapy with either peginterferon has twice the efficacy of standard interferon monotherapy in terms of sustained virologic response. [291], [292], [293] and [294] The response rates were reduced in patients with genotype 1 and higher viral loads. Both peginterferons were tolerated as well as the standard nterferons, with discontinuation rates ranging from 6% to 11% in all treatment groups. Peginterferon-a-2b was approved and licensed by the U.S. Food and Drug Administration in February 2001, and approval of pegylated interferon-a-2a is expected in 2002. There are no clinical trials comparing the efficacy of the two peginterferons face to face; however, based on available data, it is expected that any differences between the two drugs are not significant. [291], [292], [293] and [294] The combination of peginterferon with ribavirin has yet further improved the efficacy of antiviral therapy of chronic HCV infection. [295], [296] Peginterferon-a-2b at a weekly dose of 1.5 µg/kg, plus ribavirin, 800 mg/day, showed a significantly higher response rate when compared with standard interferon plus ribavirin combination in a large phase III trial. [295] The overall sustained virologic response rate was 54% (genotype 1, SR 42%; genotype 2 or 3, SR 82%). The group treated with the peginterferon plus ribavirin combination reported higher frequency of fever, nausea, and injection-site reaction with erythema as compared with the control group. The rate at which the drugs were discontinued was similar in two arms of the study. The dose of ribavirin may not have been ideal, with higher doses achieving yet better results. A similar large, phase III study of peginterferon-a-2a plus ribavirin reported a sustained viral response rate of 56% (genotype 1, SR 46%; genotype 2 or 3, SR 76%). [296] These results are probably not significantly different than the results using peginterferon-a-2b, making these two drugs interchangeable. Therefore, based on these efficacy data, the use of pegylated interferon monotherapy is only appropriate if there are contraindications to ribavirin use. Based on data from these recent trials, peginterferon and ribavirin combination therapy will become the standard of care in treating patients with chronic HCV infection. [295], [296] Table 108-2 compares the sustained virologic response rates reported with interferon monotherapy, standard interferon plus ribavirin therapy, and treatment with peginterferon plus ribavirin.

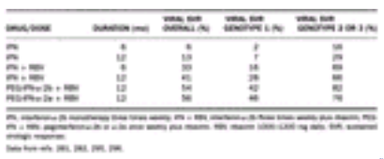

TABLE 108-2 Comparison: Sustained Virologic Response Rates in Treatment-Naive Patients

The use of pegylated interferon has also been investigated in patients with more advanced chronic hepatitis C. Peginterferon-a-2a monotherapy was studied in 271 patients with chronic HCV infection with bridging fibrosis or cirrhosis. [293] These patients were randomized to standard interferon-a-2a three times weekly; peginterferon-a2a, 90 µg once weekly; or peginterferon-a-2a, 180 µg once weekly for 48 weeks with a 6-month posttreatment follow-up period. [293] Intolerance to therapy was not significantly different in the three treatment arms of the study. The sustained virologic response rates with clearance of HCV RNA 24 weeks after treatment were 8%, 15%, and 30% in the three treatment groups, respectively. The biochemical sustained response rate and histological improvement were also better in the peginterferon groups. Thus, the efficacy of 180 µg of peginterferon-a-2a administered once weekly is significantly better than standard interferon-a-2a three times weekly in patients with HCV-related cirrhosis. [293] In summary, the evolution of interferon-based therapy for chronic hepatitis C, particularly combination therapy with ribavirin and pegylation of interferon, has resulted in incremental improvement in the sustained virologic response rate: (1) 10% to 15% with interferon monotherapy for 6 months; (2) 15% to 25% with interferon monotherapy for 12 to 18 months; (3) 40% with combination interferon and ribavirin; and (4) 55% with peginterferon and ribavirin.

Adverse Effects of Interferon and Ribavirin Common side effects associated with ribavirin and interferon treatment, most of which are mild to moderate but may necessitate discontinuation of therapy in 10% to 15% of patients, are listed in Table 108-3. [295], [296], [297] and [298] The major side effect of ribavirin is a dose-dependent hemolytic anemia, which is reversible and usually stabilizes after 5 to 6 weeks of treatment. If severe anemia develops, treatment must be discontinued.

Nonspecific
Flu-like symptoms, including headache, fatigue, rigors, and fever
Cutaneous
Injection-site reaction, pruritus, rash, dry skin, and hair loss
Respiratory
Cough and dyspnea
Gastrointestinal
Anorexia, nausea, vomiting, and dyspepsia
Neuropsychiatric
Depression, insomnia, anxiety, and irritability

TABLE 108-3 Adverse Effects: Interferon and Ribavirin Therapy

There are several contraindications to combination therapy with interferon and ribavirin (see Table 108-1). Patients with preexisting anemia usually cannot tolerate the degree of hemolysis that occurs with ribavirin therapy and it can be dangerous. Patients with significant cardiovascular disease are particularly at risk should severe anemia develop during therapy. Patients with chronic hepatitis C and premorbid conditions preventing the use of ribavirin, particularly anemia, can be treated with peginterferon monotherapy.

Treatment of Variant Clinical Manifestations

Acute Infection A 3-month course of interferon monotherapy at a dose of 3 MU three times weekly for 3 months is associated with higher virologic and biochemical end-of-treatment and sustained response rates compared with no treatment in patients with acute hepatitis C. [249], [253], [299], [300] In a metaanalysis, the virologic sustained response rate was 32% versus 4% in controls ($p < 0.001$). [300] A recent study of 44 patients with acute hepatitis C treated with interferon-a-2b, 5 MU daily for 4 weeks and then three times weekly for another 20 weeks, showed a remarkable 98% sustained virologic response rate 6 months after completion of therapy; that is, prevention of chronic hepatitis C. [301] Further studies are needed to confirm the role of induction with a higher initial dose and daily therapy versus combination interferon and ribavirin therapy or peginterferon therapy.

Children Several trials have examined the role of interferon monotherapy in children with chronic HCV infection and showed an overall sustained response ranging from 0% to 45%. [302] It is reasonable to extrapolate that combination interferon and ribavirin therapy may further improve the rate of HCV clearance. Further studies are needed to study the role of combination therapy in children with chronic HCV infection, particularly to focus on quality-of-life issues, including performance in school.

Normal Alanine Aminotransferase Levels As many as 25% of patients have persistently normal ALT levels in the setting of chronic HCV infection. [303] Fortunately, histologically advanced liver disease is rarely found in these patients. [304], [305] and [306] However, mildly abnormal liver histology may be encountered in these patients, and the reported rate of cirrhosis varies from 0.3% to as high as 10% in patients with normal ALT levels. [304], [307] In these patients, advanced fibrosis was associated with coexistent significant amount of alcohol consumption. [308] Some viremic patients with normal ALT levels develop elevation of ALT levels induced by interferon therapy. [306] The clinical significance of this ALT elevation is unclear. In a recent study, combination therapy with interferon and ribavirin for 6 months was associated with a 33% sustained response rate. [309] The recommendations from the NIH consensus conference in 1997 suggested that patients with normal ALT levels associated with chronic HCV infection should not be treated and followed conservatively. However, these guidelines were made when interferon monotherapy was the standard of care. The improved response rate with combination interferon and ribavirin therapy suggests that these guidelines should be modified, especially in patients with biopsy-proven moderate hepatic inflammation and fibrosis and in patients with genotypes 2 or 3. [309], [310] and [311]

Mixed Cryoglobulinemia and Glomerulonephritis Interferon monotherapy has been shown to be beneficial in the treatment for essential mixed cryoglobulinemia and glomerulonephritis associated with HCV infection. [211], [212], [312] Long-term therapy is usually required to prevent relapse of the underlying disorder. [210], [211] and [212] In the absence of significant renal impairment, combination therapy with interferon-a and ribavirin provide much better efficacy and should be the treatment of choice. [210] Other forms of therapy used in the management of HCV-induced cryoglobulinemic glomerulonephritis include cytotoxic therapy and immunosuppressive therapy. [213], [214] and [215] Cyclophosphamide and corticosteroids, often in combination with plasma exchange, have been used with some success. [213], [214] and [215]

Autoimmune Liver Disease Interferon-based therapy can precipitate a flare-up of coexistent otherwise quiescent autoimmune chronic hepatitis. It is recommended that patients with coexisting chronic autoimmune hepatitis and HCV infection should initially be treated with immunosuppressive therapy to prevent acute exacerbation of autoimmune liver disease. [313], [314]

Immunocompromised Status The efficacy of interferon-based treatment of HCV infection after liver transplantation, end-stage renal disease, or renal transplantation, and HIV co-infection is suboptimal but needs further investigation. [315], [316] There are currently no published guidelines on how to best manage patients who have HCV and HIV co-infection. End-stage liver disease is now the leading cause of death in hospitalized HIV-seropositive patients. [317] Because of similar routes of transmission, an increasing number of patients with either HCV or HIV are being identified as co-infected with both viruses. It has been shown that HCV and HIV co-infected patients have a faster progression rate (up to threefold) of liver fibrosis than HCV-positive patients without HIV. [318] There is a plethora of data now indicating that both HCV RNA levels and survival are directly influenced by HIV infection. These results suggest that HIV infection-induced CD4 depletion is independently associated with severity of liver fibrosis in chronic HCV infection. [318], [319] Because data are limited, a reasonable approach to co-infected patients is to enroll such patients in ongoing clinical trials. At least two of the protease inhibitors used for the treatment of HIV infection, ritonavir and indinavir, can cause serious liver toxicity. [320] Ritonavir leads to late liver toxicity, normally due to triglyceride abnormalities. Indinavir, on the other hand, usually causes only a Gilbert-like syndrome, although in some cases, it may cause a more significant toxicity. The protease inhibitors, saquinavir and nelfinavir, have only minimal liver toxicity. The use of highly active antiretroviral therapy has prolonged the healthy lifespan of patients infected with HIV, and deaths among individuals with acquired immunodeficiency syndrome have declined for the first time in 1996 with the institution of this therapeutic approach. [321]

Novel Investigational Treatment Strategies and Agents

High-dose, initial induction therapy of chronic HCV infection with daily interferon has been suggested as a potentially efficacious regimen. [322], [323] Because of the rapid HCV replication rate, early intervention with an aggressive high-dose interferon regimen may prove the most effective way to prevent HCV persistence.

The role of amantadine in the treatment of HCV as a single agent, [324] in combination with interferon, [325] and as triple therapy with interferon, ribavirin, and amantadine has been evalua- ted. [326] Amantadine monotherapy is not efficacious, [324] but triple therapy has shown some promise. [326] The combination of interferon with other novel agents, such as thymosin-a-1, macrophage colony-stimulating factor, ursodeoxycholic acid, and iron-depleting measures has been studied, but showed minimal or no benefit compared with interferon monotherapy. [327], [328], [329] and [330] Silymarin, extracted from the milk thistle plant, is safe and undergoing study for the treatment of chronic hepatitis C. [331]

Preventive and Safety Measures

Patient should be informed that, although the risk for transmitting HCV infection by sexual contact is low (3% to 5%), HCV is potentially transmissible. Patients should be careful about blood exposure of any type to partners and family contacts. Open wounds must be covered, and razors or toothbrushes should not be shared. Although sexual or intrafamilial HCV transmission is rare, testing sexual partners or other family members if there is a concern regarding infection usually provides reassurance. Patients with chronic HCV infection should be counseled to avoid excessive consumption of alcohol, which can accelerate the progression of hepatitis C when used in moderate or large amounts. It has been recommended that the less alcohol consumed the better and that complete abstinence is ideal. [250], [251] and [252] Finally, it is recommended that hepatitis A and B vaccine be given to patients with chronic HCV infection who are not immune because acute hepatitis A or B superimposed on chronic HCV infection may be more severe. [332] The safety and efficacy of these vaccines have been demonstrated in patients with mild to moderate chronic HCV infection, [333] and a more convenient combined hepatitis A and B vaccine was licensed in 2001. The inability to culture the virus and its genetic heterogeneity are obstacles to developing a vaccine against HCV infection. [334] Investigational vaccination candidates, including recombinant proteins, peptides, virus-like particles, naked DNA, and recombinant viruses, are being explored. [334]

Economic Implications

Current estimates of medical and work loss costs of HCV-related acute and chronic liver disease are in excess of $600 million annually based on unpublished CDC data. In 1995, the outcomes of hospitalizations were analyzed, focusing primarily on inpatient mortality and health care cost. [335] It was estimated that HCV-related liver disease resulted in 26,700 hospitalizations and 2600 deaths in acute, nonfederal hospitals in the United States. The cumulative cost of these hospitalizations was $514 million.

Cirrhosis The sustained response to interferon monotherapy, 3 MU three times weekly for 6 to 12 months, ranged from 5% to 10% in patients with HCV cirrhosis. [336] The sustained virologic response was genotype dependent, that is, 4% in genotype 1 and 10% with genotypes 2 and 3. [337] Results from a metaanalysis of six randomized controlled trials of combination interferon and ribavirin therapy versus interferon monotherapy in 75 patients with compensated cirrhosis showed a 22%

sustained biochemical response with combination therapy in comparison to 4% with interferon monotherapy. [338] Patients with cirrhosis who received combination therapy had a significantly higher sustained virologic response (17% versus 0%). The sustained response was genotype dependent (7% to 10% with genotype 1 versus 24% to 33% with genotypes 2 and 3). The overall data are suggestive of a better outcome of treatment of HCV in cirrhotic patients. [339] Interferon-based therapy reduces the rate of progression of fibrosis and lowers the incidence of HCC by 13% and the mortality rate from HCC by 16%. [339] The persistence of serum HCV RNA after 24 weeks of combination antiviral therapy was predictive of a lack of sustained virologic response in patients with cirrhosis and also in those without cirrhosis. [281], [282] The use of maintenance interferon therapy has been associated with a decline in the incidence of HCC in patients with compensated cirrhosis, even in the absence of end-of-treatment or sustained virologic responses. [188], [340], [341] and [342] Other complications of end-stage liver disease may also be retarded with long-term interferon use in patients with chronic hepatitis C and compensated cirrhosis. [188] The efficacy of 180 µg of peginterferon-a-2a is significantly better than that of standard interferon-a-2a given three times weekly in patients with HCV-related cirrhosis. [293] Patients who eradicate HCV theoretically should have a better prognosis after liver transplantation; however, antiviral therapy for HCV infection is poorly tolerated in decompensated patients. Therefore, interferon therapy alone or interferon plus ribavirin therapy in decompensated liver disease should only be used in the setting of a clinical trial. [343], [344]

Liver Transplantation

In the United States, about 8000 patients die each year from complications of HCV-related cirrhosis. [13], [16] Decompensated chronic hepatitis C with cirrhosis, alone or in combination with alcoholic liver disease, is the most common indication for liver transplantation in the United States and Europe. [345] Based on statistics obtained from the United Network for Organ Sharing (UNOS), 23% of patients who underwent liver transplantation between 1994 and 1998 carried the diagnosis of HCV infection. [346] There has been a dramatic increase in the number of patients with HCV infection undergoing liver transplantation, and HCV currently accounts for up to 50% of liver transplantations both in the United States and Europe. [347]

Candidacy for Liver Transplantation Patients who are being considered for liver transplantation must meet one of the following minimal listing criteria: (1) Child-Pugh class B or C (Child-Pugh score of 7 or greater) in the setting of cirrhosis; (2) history of gastrointestinal bleeding caused by varices, or a single episode of spontaneous bacterial peritonitis irrespective of Child-Pugh score; or (3) small unifocal or multifocal HCC (one lesion less than 5 cm in diameter or three lesions less than 3 cm involving the same lobe of the liver) with no portal vein invasion or metastases. [348] Patients who fulfill the UNOS specified listing criteria for liver transplantation have an estimated 1-year survival rate from chronic liver disease of less than 90%, which is the likely outcome with liver transplantation at major institutions. [349] In patients with compensated HCV-related cirrhosis, the 4- to 5-year survival rate is 91%, and the estimated risk for decompensation is 18% to 20%. [188], [350] Liver transplantation is the best treatment for chronic hepatitis C with decompensated cirrhosis, but HCV reinfection poses challenging management issues that may arise either early or late after transplantation. [351], [352]

POSTTRANSPLANTATION RECURRENT INFECTION

Recurrent HCV infection presenting as acute lobular hepatitis is documented in 75% of patients by liver biopsy by 4 months after transplantation. [347], [353] Most patients (80% to 85%) with recurrent HCV infection develop mild liver disease without life-threatening complications in the short- to medium-term follow-up. The remaining 15% to 20% of patients can have a more severe course with rapidly progressive disease resulting in cirrhosis and decompensation. [347], [353] Recurrent HCV infection can develop anytime during the first year after liver transplantation, but rejection is more common in the first 2 months. A liver biopsy must be performed to differentiate recurrent hepatitis C from rejection based on certain histological characteristics. [354], [355] and [356] Recurrent HCV infection is universal after transplantation, and thus measurement of serum HCV RNA is not helpful.

Risk Factors

The lack of HCV-specific T-cell responses is a crucial underlying defect that results in the pathogenesis of HCV-related graft injury after transplantation. [357] Humoral immunity does not play a role in preventing recurrent HCV after transplantation. [358] A variety of host, viral, and immunosuppressive therapy responses are associated with recurrent HCV infection after transplantation [359], [360], [361], [362], [363], [364], [365], [366], [367], [368], [369], [370], [371], [372], [373], [374], [375], [376], [377], [378] and [379] (Table 108-4). The association of HCV genotype 1b with rapidly progressive liver disease after transplantation has been noted by some investigators, [352], [366], [371], [379] but this observation has not been confirmed by others. [379] High pretransplantation serum HCV RNA levels [360], [363] and early detection of high posttransplantation serum HCV RNA levels were associated with more severe recurrent HCV infection. [364], [377] Fibrosing cholestatic hepatitis is a severe life-threatening variant of recurrent posttransplantation HCV infection associated with very high viral loads. [380] Pretransplantation HCV quasispecies may not be detectable postoperatively but can predict severity of recurrent HCV after transplantation. [381] Increasing age and absence of pretransplantation co-infection with HBV are associated higher allograft reinfection. [366] The posttransplantation course in patients with HCV, HBV, and HDV co-infection has been associated with a slower replication rate of HCV and an innocuous histological necroinflammatory response. [184] Although HGV has been shown to persist after transplantation, it has no influence on the course of recurrent hepatitis C. [382] The role of cytomegalovirus (CMV) and posttransplantation recurrence of HCV is controversial. In the initial 12-month period after transplantation, neither CMV viremia nor CMV disease was noted to have any influence on the histological outcome of HCV recurrence. [383] On the other hand, some observations have associated CMV with the severity of recurrent HCV infection. [359], [369], [375] Reducing the level or dosage of immunosuppression more rapidly than usual after transplantation is crucial to limit HCV replication. [368], [372] High-dose and potent immunosuppressive therapy, including the number of methylprednisone boluses, cumulative steroids dose, or use of OKT3 or mycophenolate, are associated with severe recurrence and rapid progression of recurrent hepatitis C. [361], [377] Extended rewarming time during allograft implantation is associated with higher incidence of recurrent HCV infection and should be minimized. [383]

Host
HLA matching
Age
Nonwhites
Cytomegalovirus co-infection
Absence of pretransplantation co-infection with HBV
Presence of IgM anti-HCV core antibodies after transplantation
Viral
Genotype 1b
Pretransplantation HCV quasispecies
High (> 1 × 10^6 Eq/mL) pretransplant HCV RNA levels
High serum or liver, early posttransplantation HCV RNA viral load
Allograft
Prolonged rewarming time during allograft implantation
Year of transplantation (recent year associated with rapid rate of progression)
Early posttransplantation histological injury
Episodes of rejection
Drugs
High level of immunosuppression
Mycophenolate use
OKT3 use
Methylprednisone boluses
High cumulative steroid dose

TABLE 108-4 Risk Factors: Severe Recurrence of Hepatitis C after Transplantation

Natural History

The observations from short- to medium-term (5 years or less) follow-up studies in patients with recurrent HCV infection after transplantation showed survival rates that were comparable to those in patients who underwent liver transplantation for other indications. [352], [384] It is suspected that longer follow-up after recurrent HCV infection of the allograft will demonstrate a decline in survival rate. [181]

Reinfection with HCV after transplantation is universal in patients with detectable serum HCV RNA before transplantation. [351], [354], [385], [386] Up to 70% of patients with pretransplantation viremia can develop graft hepatitis after transplantation. [351], [352], [386] Data from programs with annual protocol liver biopsies suggest that 20% to

28% patients will develop HCV-related cirrhosis by 5 years after transplantation. [352], [373] Liver biopsy performed at the end of the first year after transplantation is predictive of the future risk for cirrhosis. [352], [373] Less than 10% of patients with mild hepatitis at 1 year showed evidence of cirrhosis at 5 years, whereas two thirds of patients with moderate hepatitis at 1 year progressed to cirrhosis at 5 years. [347], [373], [376] On the other hand, studies with favorable outcomes have been reported with posttransplantation graft and patient survival rates in patients with recurrent HCV infection that are similar to those of uninfected controls. [352], [363], [366], [387], [388] The HCV serologic status after transplantation did not affect 10-year graft or patient survival rates. [387]

The cumulative probabilities of decompensation in patients with recurrent HCV-related allograft cirrhosis were 8%, 17%, and 42% at 1, 6, and 12 months, respectively, after the diagnosis of cirrhosis. Graft and patient survival rates were 100%, 85%, and 71%, and 100%, 92%, and 74% at 1, 6, and 12 months, respectively. Patient survival rates decreased significantly after decompensation (93%, 61%, and 41% at 1, 6, and 12 months, respectively). Variables associated with decompensation, retransplantation, and mortality included a high Child-Pugh score (more than 6), low levels of serum albumin, and a short interval between liver transplantation and posttransplantation cirrhosis.

Treatment

In contrast to the success in preventing HBV reinfection after liver transplantation, there is as yet no effective antiviral strategy to prevent HCV reinfection. [389], [390] Recurrent hepatitis C may be accelerated in immunosuppressed liver transplant recipients, progressing to cirrhosis in 8% to 16% of patients within 5 years in some reports. [352], [391] The rapid rate of progression to liver failure has been observed in a subset of HCV-infected transplant recipients who develop a cholestatic pattern of liver injury. [368], [372], [392] Cholestatic hepatitis is an infrequent cause of jaundice in HCV-infected liver transplant recipients and should be a diagnosis of exclusion. [354], [380] Cholestatic hepatitis C ranges in severity and does not always signal impending graft failure. The natural history of cholestatic hepatitis C differs dramatically from that of cholestatic hepatitis B, which has been shown to lead to death or need for retransplantation within several weeks. [393]

Antiviral Therapy The use antiviral therapy can be preemptive (prophylactic) or after histologically documenting recurrent hepatitis C. The argument in favor of preemptive antiviral therapy is based on the fact that recurrent allograft infection with HCV is histologically noted in more than 50% patients after transplantation. The negative consequence of preemptive interferon-based therapy is the immunomodulatory effect of interferon that may be associated with an increased risk for acute allograft rejection. Interferon has been shown to up-regulate expression of HLA antigens in the allograft, resulting in an increased incidence of rejection in up to 35% of recipients after transplantation. [394] The experience with preemptive antiviral therapy consists of anecdotal case reports and uncontrolled, nonrandomized studies with a limited number of patients. Multicenter, controlled randomized trials are needed to assess the benefit of preemptive antiviral therapy. Treatment of histologically documented recurrent HCV infection with interferon has resulted in a biochemical response with normalization of serum ALT levels in only 10% to 30% of patients. [394], [395] and [396] Patients with low viral loads have higher rates of favorable response. [352] Sustained biochemical and virologic responses are less likely due to the ongoing viral replication facilitated by immunosuppression. Interferon and ribavirin combination therapy has demonstrated improved efficacy as compared with interferon monotherapy in the treatment of patients with recurrent HCV infection after transplantation. [375]

Judicious Immunosuppressive Therapy The intensity of immunosuppression defined by the potency and level of immunosuppressive agents can play a pivotal role in preventing both recurrence of HCV and rejection of allograft. [397] There was no significant difference in graft and recipient survival rates with cyclosporine versus tacrolimus-based induction therapy. [352], [363], [398] Treatment of allograft rejection should be established by performing a liver biopsy. Trial of antirejection therapy must be avoided in patients with inconclusive liver biopsies. It is recommended that the least aggressive antirejection therapy be instituted in patients with documented rejection. The risk for severe, rapidly progressive HCV recurrence in allograft recipients is associated with increasing number of methylprednisolone boluses, mycophenolate use, and OKT3 use. [361], [373], [374], [377], [399]

Retransplantation The number of HCV-related liver transplant recipients who develop allograft failure requiring retransplantation rose from 6.5% in 1990 to 38.4% in 1995. [356] Most patients develop allograft cirrhosis and decompensation due to recurrent HCV infection. Other causes of graft failure may include chronic rejection, biliary complications, and hepatic artery thrombosis. [356] The initial data with liver transplantation in patients with end-stage liver disease secondary to chronic HCV infection demonstrated that less than 10% develop severe allograft damage requiring retransplantation. [366], [388] Unfortunately, for reasons that are not completely clear, current experience and a multicenter trial show a decline allograft survival, with up to 20% of patients developing cirrhosis within 5 years after transplantation. [352], [359], [373], [388] After retransplantation, the 12-month survival rate was less than 50% in patients who developed allograft failure due to recurrent HCV infection. [400] Severe hyperbilirubinemia and renal failure were associated with poor graft survival after retransplantation. [401], [402] Patients who underwent retransplantation before the onset of severe hyperbilirubinemia or renal failure had a 12-month graft survival rate of greater than 75%. [401], [402] and [403] Multicenter, controlled randomized are needed to identify prognostic markers associated with improved graft and host survival after retransplantation.

CHAPTER 109

William M. Lee and Frank V. Schiødt

DRUG-INDUCED LIVER DISEASE

EPIDEMIOLOGY

Drug-induced hepatotoxicity is a frequent cause of acute liver injury of exceptional severity, comprising more than 50% of all cases of acute liver failure (ALF) in the United States [1], [2] (Fig. 109-1). Hepatotoxicity has been described for a large number of drugs, [3] although the number of cases is quite low, given the number of prescriptions written.

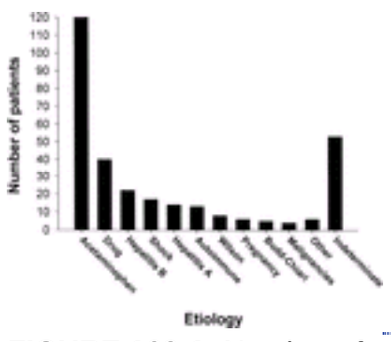

FIGURE 109-1. Number of cases of acute liver failure among 308 patients grouped according to etiology in a multicenter study between 1998 and 2001 at 14 sites around the United States participating in the Acute Liver Failure Study Group. Acetaminophen and idiosyncratic drug reactions were the presumed cause in 160 (52%) cases of acute liver failure in this series.

Different agents cause liver injury in different ways at different rates. The majority of reactions are directed against hepatocytes but biliary injury as well as combined hepatocyte/biliary injury or damage to specific organelles (e.g., mitochondria) produce the different disease patterns observed. While some agents such as isoniazid cause liver injury in as many as 1 in 100 people and fatality in 1:10,000, other agents result in liver damage in only 1:50,000 or may never cause liver injury.

Few data on the epidemiology of drug-induced liver disease are available. A national European registry on adverse drug reactions described an almost doubling of reported cases of drug-induced liver disease from the decade 1968–1978 [4] to the following decade 1978–1987, the last period accounting for 22 cases per million people per year. [5] In developing parts of the world, drug-induced liver disease is much less common and related to very few drugs. [6] However, probably only a small fraction of actual cases are reported, and a true estimate of the incidence of drug-induced liver disease may be impossible to obtain. This is due in part to the difficulty in establishing the diagnosis, as well as inadequate reporting systems.

The exact number of drug-induced liver injuries per year in the United States is unknown, but the severity of many of these cases and the tragedy involved in a presumed preventable injury makes it imperative that all sensible precautions be taken to avoid such incidents.

DRUG METABOLISM AND MECHANISMS OF HEPATOTOXICITY

The liver, situated between the absorptive surface of the gastrointestinal tract and target of drug effects throughout the body, is central to the metabolism of foreign substances. Since hepatocyte metabolism is required for virtually every drug, it is remarkable how seldom injury to liver cells occurs. Most drugs and xenobiotics cross the intestinal brush border because they are lipophilic. *Biotransformation* is the process whereby lipophilic therapeutic agents are rendered more hydrophilic by the hepatocyte, resulting in drug excretion in urine or bile. In most instances, biotransformation changes a nonpolar to a polar compound through several steps. Foremost is an oxidative pathway (e.g., hydroxylation) mediated by the cytochromes P450 (CYPs). [7] This is typically followed by esterification to form sulfates and glucuronides, which results in addition of highly polar groups to the hydroxyl group. These two enzymatic steps are referred to as phase I (P450 oxidation) and phase II (esterification). Other important metabolic pathways involve glutathione S-transferase, acetylating enzymes, and alcohol dehydrogenase, but the principal metabolic pathways for most pharmacological agents involve P450 and subsequent esterification.

The exact details of the pathogenesis of liver injury remain unclear for most drugs. A single drug may cause its toxic effects in several ways. An oversimplified approach suggests that high-energy unstable metabolites of the parent drug, the result of P450 activation, bind to cell proteins or DNA and disrupt cell function. Perhaps the best example is acetaminophen. Although used universally for nonnarcotic pain relief, acetaminophen taken in large quantities causes profound centrilobular necrosis. [8] The metabolic pathway for acetaminophen involves both phase I and phase II reactions, glutathione detoxification, and the formation of reactive intermediates (Fig. 109-2). Glucuronidation and sulfation occur as the initial detoxifying step since the parent compound contains a hydroxyl group. Since glucuronidation and sulfation capacity greatly exceeds daily needs, even patients with far-advanced liver disease continue to have adequate glucuronidation capacity, which explains why no obvious enhancement of toxicity is observed in patients with cirrhosis taking acetaminophen. [9]

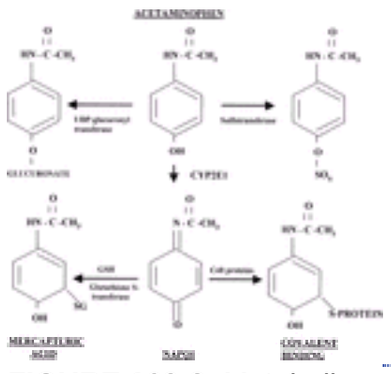

FIGURE 109-2. Metabolic pathway for acetaminophen

Enzyme Polymorphism

The rarity of drug toxicity begs the question of how an infrequent event (1:10,000) occurs. Genetically variant CYP iso-enzymes, such as are observed with metabolism of debrisoquine, partially explain observed individual variation in responses to drugs. Debrisoquine is an antihypertensive drug marketed in Europe which is hydroxylated by CYP2D6, an iso-form that is totally lacking in 5% of healthy individuals, greatly prolonging the half-life of the parent compound in affected individuals. [10] Fast and slow acetylator patterns are observed to affect whole races, and have been implicated in isoniazid metabolism, which includes an acetylation step. [11] Genetic variants, which occur relatively frequently, cannot explain the formation of a toxic intermediate in only a rare individual. While there might be other metabolic variant P450 species that are even rarer, little evidence for these has been found in affected patients. Other explanations are necessary.

Most drugs are small organic compounds that are unlikely to evoke an immune response. While some toxic drug reactions are associated with an obvious allergic response, most are not. Nevertheless, immune mechanisms not associated with systemic allergic immunoglobulin E (IgE) reactions or skin hypersensitivity might be involved. Studies suggest that the very products of CYP metabolism, the highly reactive intermediates formed within the microsomes, covalently bind to the enzyme itself to form a drug-hapten adduct that disables the enzyme and injures the cell. [12] Haptenization then evokes an immune response directed against the newly formed antigen or neo-antigen. P450s have been shown to traffic to the plasma membrane allowing the P450-drug adduct to become the target of a subsequent cytolytic attack (Fig. 109-3). Whether these adducts or smaller peptides processed and presented via the major histocompatibility complex (MHC) class I and class II schemes are the targets remains unclear. Still, the association of neo-antigens, autoantibodies, and hepatotoxic drugs implicates an immunologic mechanism.

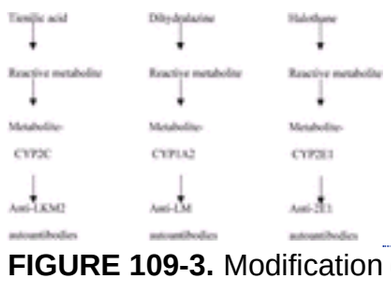

FIGURE 109-3. Modification of host P450 enzymes renders them immunogenic. Autoantibodies can be detected, which recognize the enzyme-metabolite adducts and the enzyme itself. (Adapted from ref. [12].)

Whether the drug causes significant cell necrosis or not, the P450-drug adducts can evoke the immune response. Any subsequent P450-drug adduct present on the hepatocyte surface would evoke a further response. Responses may be antibody-mediated or occur from direct cytolytic attack by primed T cells [12], [13] (Fig. 109-4).

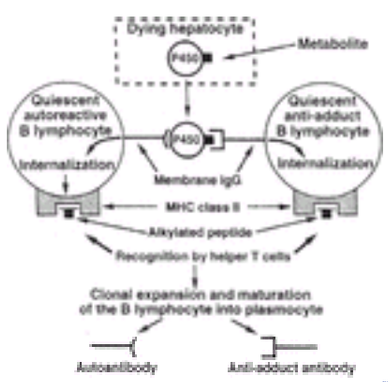

FIGURE 109-4. Possible models of liver injury due to drugs. Direct toxicity may play a role but immune mechanisms are also operative. In this model, re-challenge or continuing to receive the same drug would simply elicit a preformed cytolytic response. (From ref. [12].)

Such a combined toxic/immunologic mechanism is involved in the liver injury caused by halothane. Halothane was a widely used fluorinated hydrocarbon anesthetic which causes severe, often fatal liver injury after multiple exposures. [13] Other fluorinated hydrocarbons also occasionally result in the same response. [14], [15] and [16] While halothane has never been withdrawn, its use has been limited by the advent of safer agents. Both direct cytotoxicity and immune-mediated toxicity are observed in keeping with the clinical observations, that severe halothane toxicity occurs with repeat exposures. Still, evidence of injury can usually be identified within a week of the first exposure. As befits an immune reaction, the interval to toxicity is shortened and the damage more severe with each successive exposure.

Specific genetically determined components of the immune response may be important. For example, the binding of peptides for antigen presentation depends on human leukocyte antigen (HLA) configurations that are genetically determined. This variation among individuals is thought to underlie the diverse responses observed in patients encountering the hepatitis B virus. The highly variable severity of reactions observed depends on the fit of antigen peptides in the HLA groove. A specific HLA haplotype has been associated with amoxicillin-clavulanate–induced hepatitis, being found in 57.1% of patients versus 11.7% of controls. [17] Polymorphisms have also been identified for the interleukin 10 (IL-10) promoter and for tumor necrosis factor-a (TNF-a). These variations in immune responsiveness could modulate the severity of the responses observed. For example, different IL-10 promoter phenotypes are recognized. A C-to-A substitution at position 627 is linked to severe asthma and, by inhibiting IL-10 secretion, an up-regulation of immune reactions of the Th2 type. This same phenotype has been linked to hepatitis C-related liver injury and to the severity of alcoholic liver injury. [18], [19] Variant TNF-a phenotypic expression has been implicated in determining the severity of drug reactions related to acetaminophen. [20] A multistep, immune-based mechanism would best explain both the rarity of idiosyncratic reactions, and their severity, as well as the findings of mild, nonprogressive liver injury in some patients—those with “protective” phenotypes. While an immunologic explanation for many reactions is plausible, the exact mechanism to account for most drug reactions remains obscure. Both cell necrosis and apoptosis have been recognized, and sinusoidal lining cells as well as Kupffer cells are part of the process. [21]

There should be little doubt that the metabolic fate of any compound is a complex process. There are other important environmental and host variables outlined in Table 109-1. Often multiple factors are at play simultaneously, including drug interactions, either induction or competition. Common inducing agents include ethanol, phenobarbital, and phenytoin, but cigarette smoke is also a potent inducer of certain P450 species. Induction or substrate competition for available enzyme may not result in hepatotoxicity but strongly impacts plasma drug levels. For example, the effect of ketoconazole on enhancing cyclosporin levels is the result of induction, [22]

while competitive inhibition by ketoconazole increases serum levels of astemizole (Hismanal) with resulting torsades de pointes. [23]

Age:	Drug reactions appear to impact the elderly more often, P450s vary.[127] Adults more susceptible than children in some scenarios (acetaminophen, halothane, isoniazid) and less susceptible in others (e.g., aspirin, valproic acid).
Gender:	Females are more prone to drug reactions statistically, mechanism unknown.
Size/weight:	Effects on women relate to intrinsic gender differences but also to size.
Pregnancy:	Effects of drugs in pregnancy have been poorly studied.
Preexisting Liver Disease:	Hepatic disease may *protect* against idiosyncratic reactions and may enhance toxicity in dose-dependent hepatotoxins (such as acetaminophen).[126]
Renal Disease:	Slowed disappearance of parent compound yields higher concentrations and affects P450.[128] Tetracycline toxicity is enhanced in renal disease.
Certain Foods:	Grapefruit has an unknown substance that interferes with metabolism.[129,130]
Concomitant Drugs:	Drug-drug interactions are common causes of adverse effects (e.g., valproate and chlorpromazine together lead to enhanced cholestasis).
Genetic Factors:	Enzyme polymorphisms (e.g., enhanced phenytoin liver disease in patients with defective epoxide hydrolase activity), HLA phenotypes (nitrofurantoin susceptibility).

HLA, human leukocyte antigen.

TABLE 109-1 Factors Influencing the Metabolic Fate of Drugs

Other Mechanisms

In drug-induced cholestasis, disruption of specific transport proteins or processes in hepatocytes or cholangiocytes may be the event that results in cholestasis. Bile salt transport from plasma into the hepatocytes is provided for by two basolateral (sinusoidal) transport systems: the sodium-taurocholate cotransporter (NTCP), and the organic-anion transporting polypeptide (OATP), whereas several canalicular export pumps have been identified. [24] Estrogen may cause multiple canalicular membrane transport changes, [25] affecting, among others, the canalicular bile salt pump. [26]

Uncoupling or inhibition of mitochondrial respiration may in some instances lead to microvesicular steatosis. [27] Mitochondrial ß-oxidation of fatty acids is impaired and this may decrease cellular energy supply leading to severe liver dysfunction. The mitochondrial ß-oxidation may be affected either directly or by impairment of mitochondrial respiration. [28]

Drug-induced liver injury may be modulated and enhanced by inflammatory mediators that may trigger hepatocyte apoptosis. [29] Hepatocyte apoptosis is complex and may be controlled by the intracellular energy status [30], [31] and by the redox state of the cell. [32] How the specific drugs involved in hepatotoxicity affect hepatocyte apoptosis remains to be studied.

The new techniques of pharmacogenomics may be helpful in predicting an individual's risk of hepatotoxicity for a given drug. [33], [34]

CLASSIFICATION OF HEPATOTOXIC AGENTS

Two main categories of drugs can produce liver disease. One group consists of intrinsic (predictable) drugs, whereas a second group consists of idiosyncratic (unpredictable) drugs. Unfortunately, the vast majority of drugs involved in liver disease belong to the idiosyncratic, and thus unpredictable, group.

Intrinsic (Dose-Dependent) Agents

Hepatotoxins of this group produce liver disease in most patients in a dose-related fashion if toxic amounts of the drug are ingested. Furthermore, similar lesions can often be found in animal models. [35] Hepatotoxicity may be caused by the drug itself or, most frequently, by toxic effects of its metabolites. Table 109-2 provides a list of known dose-dependent drugs.

DRUG	RESPONSE
Acetaminophen	Total dose, single vs. multiple time points
Amiodarone	Total dose over time
Bromfenac	Toxicity only occurs after extended use
Cocaine	Dose-related vascular collapse
Cyclophosphamide	Dose-related, worse with previous ALT elevations
Cyclosporine	Cholestasis with toxic blood levels, CYP3A phenotype
Methotrexate	Aminotransferase/fibrosis; single dose/total dose
Niacin	Large doses yield vascular collapse
Oral contraceptives	Prolonged usage yields hepatic adenomas
Tetracycline	Total dose, renal dysfunction
Toxins (yellow phosphorus, carbon tetrachloride, amanita toxin, bacterial toxins)	Total dose

ALT, alanine aminotransferase.

TABLE 109-2 Drugs/Toxins in Which a Dose-Response Effect Is Observed

Until recently, occupational hepatotoxic agents, such as carbon tetrachloride [36] and yellow phosphorus, [37] were frequently encountered. In the last two decades, however, these agents were rarely seen. Instead, acetaminophen (paracetamol) has emerged as the most dominant intrinsic hepatotoxic drug. Taken in small doses (4 g or less per day) acetaminophen is an extremely safe drug. However, its therapeutic index is low since only as little as 10 to 12 g may cause extensive hepatic necrosis. [38], [39]

In acetaminophen metabolism, the phase II reactions predominate, with only a small fraction of acetaminophen metabolized by cytochrome P450, until the quantity of acetaminophen exceeds phase II capacity, at which point significant amounts of a toxic intermediate, *N*-acetyl-p-benzoquinoneimine (NAPQI), are formed primarily via CYP2E1 (see Fig. 109-2). [40], [41] NAPQI binds covalently to cell macromolecules disrupting mitochondrial and nuclear function. [35] Antibodies to nitrotyrosine residues can be detected as evidence of oxidative stress in livers of patients (or experimental animals) demonstrating toxicity. [42] These residues are formed by the rapid reaction of superoxide and nitric oxide formed by Kupffer cells reacting to form peroxynitrite, unless covalent bonding of NAPQI is prevented by its conjugation (via glutathione-S-transferase) to form mercapturic acid, a harmless water-soluble product excreted by the kidney. [43] Depletion of glutathione lowers this last defense against the formation of NAPQI-related intracellular adducts. Thus, starvation and chronic alcohol intake by depleting glutathione enhance toxic injury, [44], [45], [46], [47] and [48] while *N*-acetylcysteine, by replenishing glutathione, protects against acetaminophen-induced injury. [49] This direct toxic reaction occurs predictably in all individuals and is not an allergic reaction. The final step leading to cell death remains unclear but may involve an increase in levels of cytosolic calcium altering the cytoskeleton and membrane integrity, leading to "blebbing" of the cell membrane and loss of its integrity. [50] Dose-related necrosis (lysis) of hepatocytes occurs but apoptotic pathways are also implicated. A finding that peroxisomal proliferator activation prevents the liver injury associated with acetaminophen links this liver damage to apoptosis but does not preclude a combined necrosis/apoptosis effect. [51], [52]

Acetaminophen overdose is the most common cause of acute liver failure with hepatic encephalopathy in several Western countries including the United Kingdom and the United States. [39], [53], [54] Although the prognosis for acetaminophen-induced acute liver failure is relatively good, with a spontaneous survival (i.e., survival

without liver transplantation) of approximately 57%. [1] It is still the leading cause of acute liver failure death of in the United States. [2]

Except for acetaminophen-induced liver disease, intrinsic drug cases are rare.

Idiosyncratic Reactions

While acetaminophen is a dose-related toxin, most drug reactions are idiosyncratic, occurring from 1 in 1000 to 1 in 50,000 patients. The etymology of “idiosyncratic” from the Greek loosely translated is “the unique composite of the self”—the particular features of a given individual. This places the emphasis appropriately on the patient’s characteristics rather than on the drug itself. Idiosyncratic reactions are not due to the drug itself, since almost everyone can tolerate them, but to something unique about the patient who ingests them and gets a toxic reaction. Theories abound to explain these reactions. Any theory of pathogenesis must “explain” the features shown in Table 109-3. The proportion of drug-induced liver disease varies greatly among drug classes as evidence of class effect. Nonsteroidal agents, antibiotics, and anticonvulsants are highly associated with drug-induced liver disease, whereas hormones, antihypertensive drugs, digoxin, and antiarrhythmic drugs are very rarely associated. Idiosyncratic reactions occur in small numbers such that some drugs continue to be used when usefulness or uniqueness makes the risk acceptable. Isoniazid is such a drug, virtually the only drug implicated in developing countries, where drug-induced liver injury is otherwise unheard of. [55] Some 15% to 20% of individuals receiving isoniazid as a single agent for tuberculosis prophylaxis may develop increased transaminases, but these usually stabilize or improve, so that less than 1% may develop severe hepatic necrosis. [56] More recently, a lower estimate of severe liver injury of 1:1000 has been given for isoniazid from a large tuberculosis public health clinic, [57] since 11 of 11,141 patients developed isoniazid-induced liver disease. This is still a high rate of injury compared to other idiosyncratic drug reactions, yet the usefulness of the drug has precluded its withdrawal.

1. Occur rarely
2. A pattern consistent for each drug
3. Similar drugs exhibit similar features called “class effects”
4. Individual drugs in a class still vary considerably
5. Reactions occur at varying time intervals after beginning ingested
6. Reactions vary in severity, but typically severe and fatal if drug continued
7. Mild injury can sometimes disappear with continued use
8. Rarity of most reactions suggests possibility of multiple hits
9. Re-challenge is virtually always met with greater severity, shorter latency

TABLE 109-3 Idiosyncratic Drug Reactions

Aside from isoniazid, nonsteroidal analgesics may be the most commonly associated drug class capable of inducing idiosyncratic reactions. [58] The newer cyclooxygenase-2 (COX-2) inhibitors have been implicated. [59], [60] It is important to recognize that certain classes are known to be associated with toxic injury while others are much less likely.

TYPES OF DRUG REACTIONS, CLINICAL PICTURES

While most liver injury involves direct hepatocyte necrosis/apoptosis, some drugs primarily injure bile ducts or canaliculi, causing cholestasis without significant hepatocyte damage. Others affect sinusoidal cells or present a particular pattern of liver injury affecting multiple cell types (mixed type). In a rough way, drug reactions can be grouped as hepatocellular, cholestatic or mixed, but these are only very general terms and do not apply to all circumstances. An additional way to categorize drug reactions emphasizes the histological changes involved as well as the cell type (Table 109-4).

Hepatocellular: isoniazid, trazodone, diclofenac, nefazodone, venlafaxine, lovastatin
Cholestatic: chlorpromazine, estrogen, erythromycin
Mixed: amoxicillin/clavulanate, carbamazepine, herbs, cyclosporin, methimazole
Immunoallergic: halothane, phenytoin, sulfamethoxazole
Granulomatous: allopurinol, diltiazem, nitrofurantoin, quinidine, sulfa drugs
Steatohepatitis: amiodarone, perhexiline maleate, tamoxifen
Autoimmune: nitrofurantoin, methyldopa, lovastatin
Fibrosis: methotrexate, vitamin A excess
Vascular collapse: nicotinic acid, cocaine, ecstasy
Venoocclusive disease: busulfan, herbal medicines

TABLE 109-4 Types of Drug Reactions, With Examples

A distinction between the various types of liver injury can be made based on the liver tests alanine aminotransferase (ALT) and alkaline phosphatase (AP). [61] The liver injury is considered *hepatocellular* when ALT alone is more than two times above upper limit of normal (ULN) range, or when the ratio (ALT/ULN)/(AP/ULN) is greater than or equal to 5. The liver injury is termed *cholestatic* if AP alone is more than two times above ULN, whereas the term *mixed* designates a situation when both ALT and AP are above two times ULN and the ALT/ULN:AP/ULN ratio is between 2 and 5.

Hepatocellular Reactions

Hepatocellular reactions are the most common type of drug-induced liver disease, constituting up to 90% of cases. [62] They are characterized by a hepatocellular pattern of serum liver tests, as defined above. Many drugs have been implicated in hepatocellular type drug-induced liver disease (Table 109-5). Usually, improvement is quick after discontinuation of the drug (1–2 months), and only a few patients develop fulminant, acute liver failure with hepatic encephalopathy. [63]

Acetaminophen
CCl_4
Cloxacillin
Diclofenac
Halothane
Isoniazid
Lovastatin
Nefazodone
Trazodone
Venlafaxine

TABLE 109-5 Agents That May Cause Liver Injury of Hepatocellular Type

Histological findings include necrosis and cellular infiltration. Necrosis may be zonal (e.g., acetaminophen- or CCl_4-induced) or diffuse (e.g., halothane-induced), and the inflammatory response consists of lymphocytes or eosinophils. Massive necrosis formation may cause acute liver failure and death. [8]

Acetaminophen has been the best understood example of direct hepatocyte toxicity. Liver injury occurs predictably after intentional suicidal overdose, [64] and during the “therapeutic misadventure,” in which acetaminophen used in therapeutic or excessive doses for pain relief leads to severe liver injury. [44], [65] Enhanced toxicity occurs due to the enzyme induction and glutathione depletion by alcohol as well as fasting as outlined previously. [45] Acetaminophen toxicity is the most common form of acute liver failure observed in the United States. [2] In a medical record review from an urban county hospital in the United States 71 patients admitted in a 39-month period had actual or *potential* hepatotoxicity due to acetaminophen. [54] Those who ingested acetaminophen accidentally, without suicidal intent fared worse because they presented for treatment late, and did not realize that they had done anything harmful. This group was more likely to develop severe liver injury and to die from the

episode. By contrast, those with suicidal intent took larger doses, presented to a hospital earlier, and received *N*-acetylcysteine, an effective antidote. One fifth of the suicidal cases had severe injury and the potential for a fatal outcome should not be underestimated. Key features in the accidental group were excessive chronic alcohol intake (usually more than 6 drinks/day), and the use of acetaminophen for a specific pain problem, but generally in excess of package recommendations. The extremely elevated aminotransferase values (often greater than 6,000 IU/L and sometimes as high as 30,000 U/L) observed in suicidal and accidental acetaminophen ingestion help distinguish these cases from viral hepatitis or other drug injury. [54] *N*-acetylcysteine should be given by nasogastric tube on admission, and for the ensuing 72 hours, to provide glutathione substrate. In Europe, intravenous *N*-acetylcysteine is the standard treatment. [39] Expected survival is greater than 80%, although transplantation is occasionally indicated. The incidence of acetaminophen poisoning varies widely throughout the world, but is becoming more frequent and widespread as indicated by a report from Taiwan. [66] Acetaminophen poisoning is an increasing cause of ALF in children. [67], [68] and [69] As in adults, two forms are seen: teenagers may overdose with suicidal intent, but more ominous are instances of inappropriate overdosing of acetaminophen in small infants due to parents' ignorance of the high risks involved.

The U.S. Acute Liver Failure Study Group, a national registry established in 1998, reviewed the experience with 108 patients who developed ALF defined as altered mentation and coagulopathy, due to acetaminophen toxicity (Larson AM, et al, unpublished data). The majority (79%) were women, although the gender breakdown for other etiologic categories of ALF is similar, and accidental overdose comprised 58% of patients.

Cholestatic Reactions

Cholestatic reactions have been described for a number of drugs, some of which are listed in Table 109-6. Cholestasis is best defined as failure of bile to reach the duodenum, [70] and common symptoms are jaundice and pruritus. *Pure cholestasis* with no signs of hepatocellular necrosis is almost exclusively seen in patients taking oral contraceptives, anabolic steroids, or sex hormone antagonists such as tamoxifen. [71], [72] Acute *cholestatic hepatitis* is histologically characterized by cholestasis (dilated canaliculi, brown granules in cytoplasm of hepatocytes) and some degree of liver cell necrosis as well as bile duct injury and inflammatory infiltration with polymorphonuclear leukocytes. Drugs related to this type of reaction include carbamazepine, [73], [74] trimethoprim-sulfamethoxazole, [75] captopril, [76] and ticlopidine. [77]

Pure cholestasis	Anabolic steroids
	Tamoxifen
	Estrogens
Cholestatic hepatitis	Allopurinol
	Amoxicillin/clavulanate
	Azathioprine
	Barbiturates
	Captopril
	Carbamazepine
	Chaparral (herbal)
	Chlorpromazine
	Clindamycin
	Erythromycin
	Flucloxacillin
	Gold salts
	Phenytoin
	Ticlopidine
	Trimethoprim-sulfamethoxazole

TABLE 109-6 Drugs Involved in Cholestatic Drug Reactions

Generally, drug-induced cholestasis needs a longer time to resolve than the hepatocellular type of drug reactions. [3] In some instances progressive destruction of segments of the intrahepatic biliary tree may occur, the so-called *vanishing bile duct syndrome* [78] that occurs after a protracted course (more than 6 months) of drug-induced cholestasis. The result is a state of chronic cholestasis, resembling primary biliary cirrhosis. [79] Approximately 30 drugs have so far been implicated in the vanishing bile duct syndrome, including among them chlorpromazine [80] and ajmaline. [81], [82]

A sclerosing cholangitis-like syndrome with jaundice caused by intra- and extrahepatic strictures of the bile ducts is sometimes observed in patients receiving intraarterial floxuridine chemotherapy for hepatic metastases of colorectal cancer. [83]

Immunoallergic Reactions

Drugs may be associated with reactions that are definitely allergic in nature. Hypersensitivity reactions such as fever, eosinophilia, or rash are common. Halothane induces fever, eosinophilia, and antimitochondrial antibodies. [13] Halothane was formerly widely used as an inhalation anesthetic. However, it has been implicated in a high number of very severe cases of liver disease. [4], [5], [84] Halothane causes a hepatocellular injury as evidenced by findings of necrosis—ranging from spotty necrosis to bridging hepatic necrosis and multilobular necrosis—in liver biopsies. [85]

Phenytoin (Dilantin) induces the simultaneous onset of fever, rash, lymphadenopathy, or eosinophilia. [86] The mechanisms responsible for the combined allergic and hepatotoxic reaction are unknown, but the slow resolution of the illness suggests that the allergen remains on the hepatocyte surface for weeks or months. With phenytoin, a mononucleosis-like picture may also be seen and frequently is confused with a viral illness or streptococcal pharyngitis. [87] When the offending agent is not discontinued promptly, despite signs of developing hepatitis, a severe Stevens-Johnson drug eruption and prolonged fever may result. [88] As with any therapeutic agent, rapid recognition of the presence of a toxic drug reaction and immediate discontinuation of the compound are the keys to limiting hepatic damage. It is important to remember that features of an allergic reaction may not be obvious. Even in the absence of systemic signs of allergy, eosinophilia or granulomas may be present on liver biopsy.

Sulindac is a nonsteroidal antiinflammatory drug (NSAID) that causes immunoallergic liver disease with a cholestatic pattern of injury in two thirds of liver injury cases. [89] Sulindac may also cause hepatocellular liver injury and is more frequently implicated in drug-induced liver disease than other NSAIDs, such as ibuprofen. [5]

Steatohepatitis

Steatosis in the liver can be present either in a microvesicular or in a macrovesicular pattern. Macrovesicular steatosis is the most common form and is histologically characterized by hepatocytes containing a single vacuole of fat filling up the hepatocyte and displacing the nucleus to the cell's periphery. [27] Macrovesicular steatosis is typically caused by alcohol, diabetes, or obesity. Sometimes drugs such as corticosteroids or methotrexate may cause these hepatic changes. [90]

In microvesicular steatosis hepatocytes contain numerous small fat vesicles, not displacing the nucleus. [27] These lesions are associated with disruption of mitochondrial DNA with resulting anaerobic metabolism leading to lactic acidosis in the most severe cases. Not uncommonly, macrovesicular and microvesicular lesions are observed concomitantly and in these cases the microvesicular lesions should be given higher attention since they are associated with a more severe prognosis. [28] Hepatocellular necrosis may also be present. Acute fatty liver of pregnancy [91] and Reye syndrome [92] are two examples of severe liver diseases caused by microvesicular steatosis.

Drugs involved in microvesicular steatosis include valproate, [93] tetracycline, [94] fialuridine, [95] and others (Table 109-7). Aspirin use in children has been associated with Reye syndrome, [96] and the incidence of Reye syndrome has decreased since warnings concerning aspirin use in children were issued. [97], [98] The exact causal relationship between aspirin and microvesicular steatosis remains to be studied. [92]

Aspirin
Ethionine
Fialuridine
Nucleoside analogs
Valproic acid
Tetracycline (intravenous administration)
Troglitazone

TABLE 109-7 Agents That May Cause Microvesicular Steatosis of the Liver

Other Drug Reactions

There are several other types of drug reactions involving the liver, which are of lesser importance in terms of number and severity. These include granulomatous reactions, fibrosis, ischemic injury, and chronic autoimmune liver injury (see Table 109-4). The type of reaction observed can be helpful in determining the likely agent, since most drugs have a specific injury profile.

A pattern of venoocclusive disease (VOD) with obliteration of small intrahepatic veins, sinusoidal congestion, and necrosis is observed frequently in patients receiving chemotherapy (e.g., busulfan) following bone marrow transplant. [99], [100] and [101] Symptoms include rapidly accumulating ascites, painful hepatomegaly, and jaundice occurring shortly after the conditioning regimen has been instituted. Rarely, herbal medicines may cause VOD. [102]

TREATMENT

Prompt discontinuation of a suspected drug is mandatory. General supportive therapy may be necessary according to the state of the patient, ranging from none to intravenous fluid replacement to the very intensive monitoring and treatment of patients with acute liver failure with hepatic encephalopathy. [63], [103], [104] Liver transplantation is performed in more than 50% of patients with idiosyncratic drug-induced acute liver failure since spontaneous survival in this setting is less than 20%. [1]

CRITERIA FOR CAUSAL ASSESSMENT OF DRUG-INDUCED LIVER INJURY

How do we decide whether a certain drug is responsible for the liver disease encountered in a certain patient? It is important to understand that we are always trying to assess a possible association from the *past* unlike most other scoring models that try to predict the *future*. [105] A standardized reporting form developed by an international panel working in France provides a worthwhile causality assessment scoring system, [61] called the RUCAM (*R*oussel *U*claf *c*ausality *a*ssessment *m*ethod) (Table 109-8). These guidelines outline the steps an experienced clinician uses to assess likelihood of drug reactions. [106] Causality assessment methods typically include temporal relationship, course after cessation of drug, risk factors, concomitant drugs, a search for nondrug causes (viral hepatitis), previous information concerning the drug, and response to re-challenge, which is usually not available. Validation of the RUCAM scoring system suggests that a RUCAM score could be classified as *highly probable* (RUCAM score >8), *probable* (score 6–8), *possible* (score 3–5), *unlikely* (score 1–2), or *excluded* (score =0). [107]

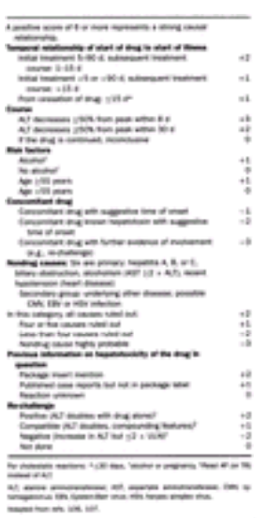

TABLE 109-8 Scoring System for Assessing Causality for Hepatocellular Types of Reactions

A newer model called the clinical diagnostic scale (CDS) was developed in Portugal [108] and tested in the United Kingdom. [109] Features from the CDS include most of the features from the RUCAM plus extrahepatic manifestations such as rash, fever, arthralgia, cytopenia, and eosinophilia. [108] The British study suggests using a CDS score of 9 or more as a very strong indicator of drug-induced liver disease. [109] However, a recent Spanish comparison study in 215 patients suggested that the RUCAM system is more accurate than the CDS model. [110]

LESSONS FROM DRUGS WITHDRAWN FROM THE MARKET

Two drugs withdrawn due to severe and fatal liver injury were bromfenac and troglitazone. There are important lessons from each one, illustrating the difficult issues surrounding drug-induced liver injury. NSAIDs as a class have been associated with considerable hepatotoxicity. [111], [112] Bromfenac was an NSAID marketed as Duract, and introduced in 1997 as a short-term analgesic for orthopedic pain. Aminotransferase elevations had been noted during clinical testing of bromfenac, but no instances of severe toxicity had been reported. However, increased transaminases were associated with longer use, although the total number of patients undergoing long-term treatment was small. No instances of ALF were observed, but less than 1000 patients were studied. Because of concerns that long-term use might be hazardous, approval was given with the limitation that the drug should only be used for intervals of 10 days or less. Once released, bromfenac was associated with more than 50 cases of severe liver injury and the drug was withdrawn in June 1998. All patients in whom toxicity was observed had been taking the drug for more than 8 weeks. [113], [114] With hindsight, a drug that effectively relieved pain would not be prescribed or used reliably only for a 10-day period. Risk/benefit ratio must be an important consideration in the approval process for any new drug—bromfenac offered little that was new and on that basis should have met an even stricter test for safety.

Troglitazone (Rezulin) was approved by the FDA in January 1997, the first of a new class of compounds, the thiazolidinediones. As an agonist of the nuclear regulatory factor peroxisomal proliferator activator receptor-? (PPAR-?), troglitazone reduces insulin resistance and increases insulin-stimulated glucose disposal, resulting in improved glycemic control for patients with type II diabetes. In clinical trials, reversible elevations of aminotransferase levels were observed, occasionally reaching more than eight times ULN, but, again, no examples of ALF. However, once the drug was approved, several reports of severe and fatal liver injury appeared. [115], [116], [117] and [118] Troglitazone has a variable time frame for demonstrating toxicity, from a few days to several months. [119] The pathogenesis is not understood. Unlike bromfenac, troglitazone was not immediately removed. As a new agent, its benefits were initially thought to outweigh the risks. The drug was recalled in the United Kingdom in 1999. The renewed warning in the package insert (in a black box), mandated monthly monitoring during the first 6 months of use. However, the number (>90) and severity of these cases (68 fatal, 10 transplanted) as well as doubts over the efficacy of monitoring led to drug withdrawal in 2000, 3 years after its approval. A factor in the FDA decision was the arrival of two new PPAR-? agonists, rosiglitazone (Avandia) and pioglitazone (Actos), approved, respectively, in May and July 1999. Although of the same class, these agents do not seem to have the same degree of toxicity. Thus far, neither drug has shown the 1:50,000 incidence of severe hepatotoxicity seen with troglitazone. Although there may be intrinsic differences in the drugs, more careful screening of patients by physicians, monitoring of ALT levels, and early discontinuation of moderately severe cases may play a part in limiting the severe toxicity associated with this class of drugs. [119]

THE DRUG APPROVAL PROCESS

How can new drugs get through the drug approval process and still lead to so many deaths that they are ultimately withdrawn? In brief, drug development is divided into three stages: initial research and development, clinical testing for new drug application (NDA), and the post-marketing experience.

Research and Development

The initial stage of drug development includes drug discovery and initial testing for efficacy, or toxicity in animals or in vitro model systems. Most new compounds fail to make it through this stage, either because of toxicity or lack of efficacy. Compounds may be “discovered” in several ways: synthesized to resemble previous compounds, discovered in the field by purification of naturally occurring peptides (e.g., cyclosporin A), or generated by computer modeling. A compound shown to have a desirable effect in vitro or in vivo, then undergoes extensive preclinical testing in a variety of animals using doses up to 50 times that predicted to be useful in humans to ascertain the types of toxicity that might be expected. While metabolic pathways differ in some specific aspects, the similarities between lower mammals and humans are quite notable. Animals are euthanized after short-term experiments and all organs examined; those dying during experiments undergo necropsy to determine cause of death. Long-term exposure studies are performed looking for carcinogenicity or other delayed effects. Preclinical testing, which may take 5 to 6 years to complete, is still a crude technique and no substitute for clinical trials in humans. The use of massive dosing in animals may in part compensate for metabolic differences between species, but human trials are ultimately needed. Toxicogenomics offers some promise of early identification of “toxicity” gene expression profiles (i.e., signatures).

Clinical Trials

In phase I testing, progressively larger doses of the test medication are given to well-paid healthy volunteers. Routine monitoring includes vital signs, electrocardiogram (ECG), assessment of reported side effects, and blood measurements including serum aspartate aminotransferase/alanine aminotransferase (AST/ALT), amylase, and creatine phosphokinase (CPK). In phase II testing, patients are exposed for the first time and the emphasis shifts from safety alone to safety *and* efficacy. Depending on the intended use of the medication and the prevalence of the disease to be treated, from 500 to 5000 study patients may test the medication for periods of up to a year. In early phase II trials, a progressive dosing scheme identifies the maximal dose that is effective and still safe. If a given dose is effective, it is then determined if there are any short- or long-term side effects. In one example, adefovir dipivoxil, a nucleotide analog was being given for human immunodeficiency virus (HIV) infection. Unanticipated renal failure was noted at 60 and 120 mg daily doses, [120] and the dose was then lowered to 30 and finally to 10 mg/day. However, adefovir was not effective at 10 mg and only partially so at 30 mg, so the drug did not gain approval for HIV. Adefovir was recently approved for hepatitis B where its efficacy appears to be better than that observed for HIV infections. Such an example of frequent renal or hepatotoxicity is easy to spot—serum creatinine levels rose in many patients taking adefovir within the first few months on treatment. Several NSAIDs have made it to phase II trials only to be withdrawn due to frequent aminotransferase level increases. However, this is where safety concerns regarding idiosyncratic reactions founder. It is easy to pick up common reactions but hard to pick up the truly rare drug injury during the pre-approval process.

Dr. Hyman Zimmerman stated that if a drug causes enough liver injury to lead to jaundice, even rarely, then 10% of affected patients will develop acute liver failure (“Hy’s rule”). [90] Put another way, any drug that in phase II or III testing demonstrates not only aminotransferase elevations, but increases in bilirubin or jaundice will likely lead to ALF when larger numbers of patients are exposed. This sounds like a very imprecise “rule” but it has served quite well over the years, and there does not seem to be anything better.

How certain can we be that clinical studies identify instances of liver injury? First, all studies are conducted according to previously established guidelines of good clinical practice. In each clinical study, a detailed assessment of liver biochemical parameters are part of every company’s NDA filing. Data supporting the safety of the drug include placebo-controlled trials where the incidence of abnormalities must be shown to be similar to that observed in the placebo group. Aminotransferases exceeding three times the ULN generally require discontinuation of the drug. Increased aminotransferase levels *without* bilirubin elevations may not lead to discontinuation during a phase III trial, but frequent or more severe aminotransferase increases (>8 times ULN) or accompanying increases in bilirubin will likely bring a new drug trial to a halt. If any case of ALF occurs, the trial is discontinued, as was the case with fialuridine.

The FDA approves approximately 50 new drugs each year. The approval process takes between 6 months to a year, once the NDA is filed. Approval brings with it instant widespread, intense marketing efforts and the necessity for all U.S. pharmacies to stock the drug. As noted previously, the number of prescriptions frequently rises rapidly into the millions, within a year or less. This fact explains why some drugs only demonstrate problems once they receive FDA approval. Idiosyncratic events occurring in only 1:50,000 patients are not going to be recognized in a study of 4500 patients. The “rule of threes” applies: to reliably identify a single case of liver injury due to a drug with 95% confidence, there must be three times the number of patients studied as the incidence of the drug reaction. In other words, a 1:1500 reaction requires 4500 patients to reliably detect a single case; a 1:50,000 reaction would require 150,000 patients. No clinical trial will reliably pick up rare drug reactions. Approval by the FDA provides a wider experience than the limited exposure of the carefully controlled clinical trial. Thus, it should not be surprising that drug reactions are observed in the post-marketing period and not before. However, post-approval drug recall still takes time to evolve while the drug continues to be prescribed despite the recognition of adverse events.

Post-Marketing Surveillance

The greatly increased number of patients receiving a new drug ensures that untoward or unusual drug effects will be observed. In addition to increased numbers, a wider range of patients than the defined clinical trial population is exposed. For example, most studies do not include patients with renal failure, heart failure, HIV/AIDS, pregnant women, the elderly, or children. Any of these groups may show enhanced toxicity. Even the best-randomized controlled clinical trial is not a “real-life” experience. The difficulty is in identifying these drug reactions quickly and accurately, once the product is released. During clinical trials and the after market period, pharmaceutical companies must report serious adverse events (SAEs) to the FDA within 24 hours. An SAE is any unexpected medical occurrence that at any dose results in death, is life threatening, requires hospitalization, or results in permanent disability or a birth defect. Pharmaceutical manufacturers maintain a safety monitoring force which gathers reports, assesses likelihood of the reaction being attributed to their product, and issues a report to the FDA and to clinical investigators if there is still an ongoing trial. However, there is bound to be a bias toward any new product, just as there is bias built in to the design of clinical trials. [121]

There are several additional shortcomings to the effectiveness of post-marketing surveillance. First, the reporting system is passive. Physicians and pharmacists are under no obligation to report adverse events. The FDA introduced the Medwatch program to improve surveillance, asking physicians and pharmacists to report on a standardized form all drug reactions they observe. However, it is estimated that less than 10% of severe adverse drug reactions are reported to the company or the FDA. Reasons for under-reporting include: failure to recognize “hepatitis” as being due to a drug, concern about malpractice implications, reluctance to get involved, complacency (“too busy”), and so forth. Reports received from pharmacists or drug representatives (or physicians for that matter) seldom contain full clinical information. Privacy issues may preclude further inquiries and raise concern regarding possible legal implications. For all these reasons, a passive reporting system is inadequate. Nevertheless, the main source of information is the Medwatch system, plus case reports. [122]

HEPATOTOXICITY IN THE PATIENT WITH CHRONIC LIVER DISEASE

Hepatologists are frequently asked “Is the patient with liver disease more susceptible to liver injury?” Intuitively, this makes sense, until we realize that hepatotoxic reactions represent the culmination of hepatic enzyme activity. If liver function is impaired, one might predict diminished activity of certain enzyme systems. Patients with liver disease do not appear to be at increased risk for hepatic injury compared to their counterparts without underlying liver problems. Dr. Zimmerman put it best: “A stubborn [misconception] has been the view that patients with pre-existing hepatic disease are more likely than others to suffer hepatic injury on exposure to drugs that cause liver damage. There is virtually no evidence for this view.” [90] What do we know of the liver function of patients with cirrhosis? Many enzyme systems are well preserved even in advanced disease. For example, patients with terminal alcoholic hepatitis still are able to conjugate most of their bilirubin. Therefore, enzyme activity in many instances exceeds the daily requirement, so that even severe liver injury would not be expected to lead to an adverse drug reaction. In general, phase I reactions may be diminished but this is not uniformly so. In severe liver disease the activity of CYP2C19 is greatly decreased while that of CYP2D6 is intact. [123] In nonalcoholic steatohepatitis (NASH) enzyme cytochrome CYP2E1 is increased, particularly in the centrilobular region, so that acetaminophen toxicity should be enhanced in patients with NASH. [124] Thus far, this has not been appreciated clinically.

Drug metabolism in patients with cirrhosis can be reduced as much as 50%. Whether the cells in a patient with cirrhosis are sick or simply reduced in number but functioning normally is not clear. Neither answer is exactly correct. It appears that the physiological changes seen with fibrosis along the hepatic sinusoids results in a widening of the barrier between the bloodstream and the hepatocyte. In support of this, patients with cirrhosis with comparably diminished metabolism of acetaminophen and theophylline normalize theophylline dis- posal, but not acetaminophen, with oxygen supplementa- tion. [125] The metabolism of theophylline uses CYP1A1 and CYP1A2, which requires oxygen as substrate, unlike acetaminophen conjugation (phase II). The limitation to metabolism is the barrier to oxygen absorption. These studies support the “intact hepatocyte/sick membrane” hypothesis. In summary, dosage adjustments may need to be made in patients with

cirrhosis, but these individuals do not appear to have an abnormally sensitive hepatic metabolic system, just less reserve if an hepatotoxic insult were to occur. [125], [126]

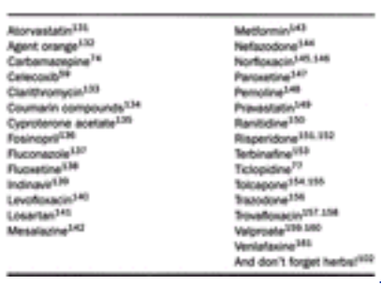
In general, patients with liver disease suffer more renal than hepatic insults. They are particularly prone to nephrotoxicity due to the altered renal circulation of the cirrhotic patient. Nephrotoxicity of aminoglycosides, radiocontrast, and prostaglandin inhibitors such as indomethacin are a frequent problem for patients with cirrhosis, but doses of antibiotics, antipsychotics, and so forth, are seldom adjusted, although any medication with sedating effects may be a problem if metabolism is slowed.

Avoiding further liver injury in the patient with preexisting liver disease is a difficult task. Antituberculous therapy cannot be withheld from patients just because they have alcoholic cirrhosis. In these instances, frequent monitoring appears to be helpful, but the value of this monitoring has not been proven in controlled trials, is seldom adhered to and can prove very expensive. Despite surveillance using liver enzyme levels, acute liver failure has developed in patients treated with isoniazid. In many instances, the presence of preexisting liver disease is subclinical, (e.g., in patients with NASH). Whether the diabetic population is more at risk for troglitazone hepatotoxicity due to their diabetic fatty liver is still debated. Nevertheless, a healthy regard for the possibility of increased hepatotoxic reactions in patients with preexisting liver disease, and the use of periodic surveillance during treatment should allow the maximum chance to avoid prescribing drugs that are harmful.

CLINICIAN'S GUIDE TO HANDLING NEW DRUGS

The best advice in prescribing new pharmaceutical agents is not to prescribe them. It is wise to defer embracing new drugs during their first year of introduction particularly if they demonstrate no unique advantages over accepted formulations. Marketing hype exceeds real-life experience with any new agent. Physicians must strive to instill in their patients a healthy level of alertness with regard to drug-induced liver injury, particularly for agents with known hepatotoxicity. Physicians and pharmaceutical companies should strike a careful balance between alerting patients to the potential for severe reactions without frightening them so that they avoid needed medications. Monitoring aminotransferase levels is suggested for known hepatotoxins such as isoniazid or diclofenac on a monthly basis but is unlikely to be cost-effective when an adverse reaction occurs in only one in 50,000 patients. Since many drug reactions develop within days, monitoring provides no guarantee. Most fatal drug reactions could be prevented if the offending agent were withdrawn immediately, at the first sign of illness. The patient most likely to be harmed is the one who believes in the complete safety of drugs, doesn't realize that drug-induced injury is possible, or is encouraged to be compliant when signs of toxicity are beginning.

New drugs should be prescribed with caution, keeping an eye out for case reports. Some of the newer agents implicated in acute liver necrosis are listed in Table 109-9.



Atorvastatin[131]	Metformin[143]
Agent orange[132]	Nefazodone[144]
Carbamazepine[74]	Norfloxacin[145,146]
Celecoxib[59]	Paroxetine[147]
Clarithromycin[133]	Pemoline[148]
Coumarin compounds[134]	Pravastatin[149]
Cyproterone acetate[135]	Ranitidine[150]
Fosinopril[136]	Risperidone[151,152]
Fluconazole[137]	Terbinafine[153]
Fluoxetine[138]	Ticlopidine[77]
Indinavir[139]	Tolcapone[154,155]
Levofloxacin[140]	Trazodone[156]
Losartan[141]	Trovafloxacin[157,158]
Mesalazine[142]	Valproate[159,160]
	Venlafaxine[161]
	And don't forget herbs![162]

TABLE 109-9 Current List of Newer Drugs Reported to Cause Severe Toxicity

The diagnosis of drug-induced liver injury necessitates determining the precise timing of the drug ingestion, making a careful record of all drugs ingested, and being particularly suspicious of known hepatotoxic agents begun within 3 months of the onset of illness. After withdrawal of the offending agent, improvement should be rapid, within days. Cautious re-challenge may be made *only* if the toxicity observed was highly questionable and if no other drug is available for a serious problem. If jaundice, coagulopathy, or any degree of encephalopathy is present initially, then hospitalization is required since drug reactions worsen quickly, and fatal outcomes are common. [1], [2]

CHAPTER 110

E. Jenny Heathcote

AUTOIMMUNE HEPATITIS

When first described [1], [2] autoimmune hepatitis (AIH) was thought to be a potentially fatal form of chronic hepatitis which predominately affected young women. It is now recognized that this disease may affect all age groups [3], [4] and men are affected in a ratio to women of 1:4. All racial groups are at risk of AIH. Its prevalence in Europe is about 1.9 per 100,000. [5] Spontaneous remission may occur but subsequent relapse is usual; only rarely is the disease curable. Although this disease can be fatal if severe and left untreated, [6], [7] and [8] earlier recognition of the manifestations of AIH has shown that in some instances the disease may be asymptomatic and its course perhaps more benign than was originally thought.

PATHOGENESIS

There are many features of AIH, which suggest the disease is immune-mediated. Certain human leukocyte antigen (HLA) class II alleles are associated with both disease “susceptibility” and treatment responsiveness. [9] In individuals from North America and Europe the class II HLA DRB * 0301 and DRB * 0401 alleles are more common in individuals with type I AIH. In South America and Japan the HLA pattern associated with AIH is different. A common antigenic peptide which recognizes a positively charged amino acid at positions 67-72 on the DRB allele may be the link. [10] The immune response is complex, involving several promoters such as costimulatory signals for T-cell activation, adhesion between immune synapses, cytokine production, and T-cell receptor configuration. Genetic polymorphisms of one or more of these promoters may be relevant to the pathogenesis of AIH. [11]

AIH may be associated with low serum complement levels and a null allotype at the C4A or C4B gene location (a silent C4AQ+0 gene is identified in such patients). [12] This C4A gene deletion is associated with both relapse on therapy and increased mortality. [13]

Immunoglobulin levels are elevated two- to threefold in active AIH, indicating marked B-cell activation, the cause being multifactorial. [14], [15] Several reports imply that the onset of AIH may be precipitated by an acute viral infection [16], [17], [18] and [19] in genetically susceptible individuals. The induction of AIH in a few patients being treated with interferon for chronic hepatitis C has also been described. [20] Certain drugs (e.g., minocycline) may also induce an AIH-like disease. [21], [22] and [23]

The nonorgan-, nonspecies-specific antibodies typically associated with AIH are antinuclear antibodies (ANAs) and smooth muscle (specifically antiactin) antibodies (SMAs). The detection of these antibodies in up to a third of individuals with other liver diseases not thought to have an autoimmune basis [24] makes it unlikely that they have any pathogenic role on their own. Another autoantibody-antisoluble liver antigen (anti-SLA) is described in 11% of patients with type 1 AIH. This antibody is identical to liver/pancreas antibody. [25], [26] Anti-SLA may also be detected in 14% to 30% of patients given a diagnosis of cryptogenic cirrhosis. This latter observation supports the concept that some patients with a diagnosis of cryptogenic cirrhosis may have an autoimmune basis for their liver disease. [27]

There is another distinct form of AIH (type 2) which has been most often described in Europeans but does occur in North America. [28] In these individuals an antibody against liver and kidney microsomes (anti-LKM1) (specifically the cytochrome P450-2D6) can be detected; serum generally tests negative for ANA and SMA. It remains unknown as to whether this antibody has any pathogenic significance. If the immunofluorescence slides are not read carefully this antibody could be misinterpreted as being an antimitochondrial antibody (AMA). [29] Sometimes anti-LKM1 can be detected in the serum of persons with chronic hepatitis C. [30]

There are many other autoantibodies described in association with AIH. Asialoglycoprotein receptor (ASGP-R) antibodies can be detected in 90% of patients with all forms of AIH. This antibody is directed at the receptor for $CD4^{+}$ T cells. [31] Antineutrophil cytoplasmic antibodies (ANCAs) were initially believed to be a hallmark for primary sclerosing cholangitis (PSC) but subsequent case series indicate that these antibodies are not specific and are also common in AIH. [32]

A rare condition known as autoimmune polyglandular syndrome type 1 (APS-1) is associated with AIH in 10% to 20% of patients. APS-1 is associated with a homozygous mutation in an autoimmune regulator (AIRE) gene, which encodes a nuclear transcription factor. A survey of individuals with a variety of autoimmune liver disease did not indicate that this same mutation was present in individuals with AIH. [33]

Some patients thought to have an AIH are found to test positive for only anti-SLA, and have been categorized as having type 3 AIH. However, more than likely as the symptoms are so similar, these rare patients can be categorized as having type 1 AIH.

AIH type 1 is the form most frequently encountered in North America; type 2 appears to be more common in Europe. The latter more commonly affects young persons, generally presents acutely, and is more frequently associated with cirrhosis.

The HLA patterns in type I and type 2 AIH are also distinct but this may be partially explained by the very different geographic distribution of these two forms of AIH. The HLA pattern which appears to confer resistance to AIH type I, confers susceptibility to AIH type 2 (i.e., DRB1 *07 and DRB1 *15 and DQB1 *06) [34] suggesting that the genetic susceptibilities to these two forms of AIH are quite separate. Type 1 and type 2 AIH can often be distinguished clinically by the natural history of the disease, the laboratory parameters for each type, and the different responses to treatment [35] (Table 110-1).

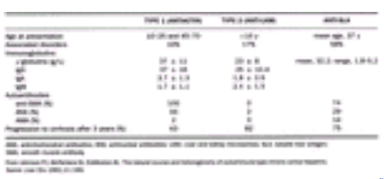

TABLE 110-1 Comparison of the Clinical and Immunologic Features of Types 1 and 2 Autoimmune Chronic Active Hepatitis

CLINICAL MANIFESTATIONS

Presenting Symptoms

At first presentation the diagnosis of AIH may be missed as the symptoms of a mild self-limiting, acute hepatitis are very nonspecific. [36] Most often AIH is diagnosed in individuals who are found to have markedly abnormal biochemical tests of the liver when they present with jaundice. Occasionally presentation may be as an acute [37] and sometimes fulminant hepatitis. [38] Careful history taking may reveal past nonspecific but relevant symptoms such as episodes of malaise, nausea, and arthralgias. There may be a family history of other autoimmune diseases. Sometimes the disease may present de novo with hepatic decompensation (e.g., ascites, variceal hemorrhage). On occasion a complication of AIH (e.g., secondary amenorrhea or delayed menarche) may be the only complaint which leads to a visit to a physician. AIH is sometimes entirely asymptomatic, diagnosed as the result of blood work done as part of a routine physical or as part of the workup of another autoimmune disease.

As with most chronic liver diseases fatigue is the most common symptom; jaundice is a presenting symptom in more than half. Other gastrointestinal complaints include anorexia, diarrhea, sometimes pruritus, and occasionally right upper quadrant discomfort. Associated autoimmune diseases include thyroiditis, inflammatory bowel disease, and rheumatoid arthritis. In children there is a very strong link between AIH and sclerosing cholangitis; [39] up to 50% are found to have both diseases simultaneously at presentation. [40] This dual presentation is much less frequently observed in adults.

Physical Examination

Generally, hepatomegaly is present and jaundice is frequent but there may be no abnormal physical findings noted, particularly if cirrhosis is absent. The spleen may be palpable (50%) and spider nevi may be present but they do not necessarily indicate cirrhosis. Hepatic decompensation is unusual but occasionally patients with “burned out” disease may present with ascites (20%), hepatic encephalopathy (14%), or bleeding varices (8%). The liver is generally small by this time. [36]

Laboratory Investigations

The alteration in liver enzymes in AIH is typically hepatocellular. Elevation in the serum aminotransferase levels may be quite marked, greater than 1000 IU/L in some cases. A conjugated hyperbilirubinemia is common. Further evidence of liver dysfunction may be present, such as a coagulopathy and hypoalbuminemia. The blood film may reveal a pattern typical of hypersplenism (low total white cell count and/or platelet count and/or hemoglobin) even at presentation in those with already established cirrhosis.

Infection with hepatitis A, hepatitis B, and hepatitis C must be ruled out through serological testing. Other viruses may affect the liver as part of a systemic infection, (e.g., Epstein-Barr, adenovirus, parvovirus, and Cytomegalovirus [in the immunocompromised individual]) and these should be sought if an infectious etiology is considered likely.

If viral hepatitis is excluded, testing for serum ANA and SMA should be requested: the immunofluorescence technique is sufficient. Anti-LKM1 and ANA/SMA are nearly always mutually exclusive, thus anti-LKM1 should be requested once serum tests negative for ANA and SMA. If there is concern that anti-LKM1 may have been misread, then an enzyme-linked immunosorbent assay (ELISA) can be used to confirm the identity of AMA. It is probably not clinically helpful to screen for any other autoantibodies. Only when ANA and/or SMA are associated with an at least twofold increase in immunoglobulin G (IgG) should a diagnosis of type 1 AIH be seriously considered. These two antibodies, generally in low titer, are detected in up to a third of individuals with other forms of chronic liver disease but the hypergammaglobulinenemia is much greater in type 1 AIH. In type 2 AIH the hypergammaglobulinemia may not be as profound, even low immunoglobulin A (IgA) levels may be observed. [34]

LIVER HISTOLOGY

To confirm a diagnosis of AIH liver histology is essential even though the pattern of disease is not entirely specific. Both viral hepatitis and drug-induced hepatitis may be histologically indistinguishable from AIH. If there is no evidence of hepatic decompensation, liver biopsy can be performed via the percutaneous route, otherwise the transjugular route is necessary. The liver biopsy should be reviewed by an experienced hepatopathologist. The portal tracts and hepatic lobules need to be examined in minute detail looking for evidence of an interface hepatitis at the junction of the portal region and the liver lobule and a lobular hepatitis caused by infiltration with lymphoplasmacytic chronic inflammatory cells (Fig. 110-1). The intrahepatic bile ducts generally appear normal. If there are cholangitic features then a strong suspicion of an associated cholangitis or a misdiagnosis should be entertained. Copper retention within hepatocytes is one of the hallmarks of Wilson disease but may also be seen to a lesser degree in individuals with AIH with or without cholangitic features. Staining for a-1 antitrypsin globules with the periodic acid-Schiff stain (found then to be diastase-resistant) should be negative and there should be no excess iron noted. In those who present with severe disease, large areas of bridging necrosis may be noted. Even when the clinical presentation is acute, it is common for patients to have evidence of chronic liver disease, possibly even established cirrhosis. The composite histological picture is 81% specific and the positive predictive value is 68% [40] of AIH when compared with tissue from individuals with viral hepatitis and cryptogenic cirrhosis.

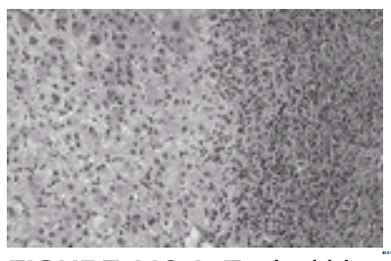

FIGURE 110-1. Typical histological picture of autoimmune hepatitis.

DIFFERENTIAL DIAGNOSIS

There are other liver diseases that may present in a similar fashion to AIH and therefore need to be routinely excluded before a confident diagnosis of AIH can be made. Measurement of serum ceruloplasmin level is essential in those individuals who present when young (<40 years). If the levels are reduced, measurement of 24-hour urine copper and slit-lamp examination of the eyes for Kayser-Fleischer rings are necessary so as to exclude *Wilson disease.* Falsely low values for ceruloplasmin may be seen in patients with severe hepatic decompensation from any cause. Falsely high urine copper may result from severe cholestasis but rarely to the degree (10- to 20-fold elevated) associated with Wilson disease. There are so many genetic mutations associated with this disease that no one mutation can be used as a specific hallmark.

There are several drugs that may cause the clinical, biochemical, serologic, and histological features typical of AIH. The drugs currently most often associated with typical features of type 1 AIH are minocycline [23] and nitrofurantoin. [22] The picture of type 2 AIH may be mimicked by tienilic acid. [2] Withdrawal of the drug may not be instantly associated with biochemical improvement, however, resolution should occur over a matter of months, not years.

Fortunately there are now sensitive and specific tests to identify *viral hepatitis.* Nevertheless hepatitis C may mimic both type 1 and type 2 AIH. [41], [42] In individuals from areas where the prevalence of viral hepatitis is high it is possible for chronic viral hepatitis and AIH to coexist.

Cryptogenic cirrhosis is the diagnosis given to patients in whom no obvious etiology can be identified. Czaja and colleagues [43] compared 12 such cases with 94 cases of clear-cut AIH and showed that there was no statistical difference between the two diseases with respect to gender, age, pattern of histological activity at presentation, or frequency of concurrent autoimmune disorders. However the level of total gammaglobulin and the IgG concentrations were significantly lower in those with a diagnosis of cryptogenic cirrhosis. Patients with cryptogenic cirrhosis had no ANA, SMA, anti-LKM-1, AMA, thyroglobulin, or microsomal thyroid antibodies in

their serum. However HLA class I and II patterns were similar between the groups, suggesting that the etiology in these individuals was likely autoimmune. All patients were treated with corticosteroid therapy and improved. Other authors have described a similar population. [44] However so-called cryptogenic cirrhosis may be caused by other silent diseases (e.g., nonalcoholic steatohepatitis) [45] and it is probably unwise to treat "cryptogenic" cirrhosis with immunosuppressive therapy unless there are some autoimmune features present.

AUTOIMMUNE HEPATITIS/PRIMARY SCLEROSING CHOLANGITIS OVERLAP SYNDROMES

Particularly in children, overlapping features of AIH and primary sclerosing cholangitis (PSC) are common. [39], [40] It is unclear whether the cholangitis visible on radiological delineation of the biliary tree in children with otherwise obvious AIH is the same cholangitis that may be diagnosed in adults. Both are frequently associated with chronic inflammatory bowel disease. There may be no distinguishing features between individuals with AIH and those with AIH plus PSC (i.e., serum alkaline phosphatase/gammaglutamyltranspeptidase and immunoglobulin values may be elevated in both). The therapeutic response cannot distinguish between the two. Thus a high index of suspicion is needed. Recent data suggest that in children it is probably appropriate to examine the biliary tree via endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance imaging (MRI), even if the primary diagnosis is AIH. [39] The cholangitis may affect only the intrahepatic bile ducts, although in most, progression to extrahepatic disease occurs later in life.

When Boberg and associates [46] applied the first AIH scoring system to 114 adults given a primary diagnosis of PSC they found that two individuals scored "definite" and eight "probable" for AIH. Subsequently the application of the modified AIH scoring system [47] has reduced the number of patients with radiological proven PSC who score "probable" for AIH. Two publications indicate that the rate of PSC/AIH overlap ranges from 4% [48] to 8% of patients with PSC. [49] In the latter study the patient population was younger, so it may be reporting the pediatric PSC/AIH overlap described by Gregorio and colleagues. [40]

The *AIH scoring system* can be employed to determine the strength of evidence that an individual has AIH (Table 110-2). Factors considered important (by a panel of experts) when making the diagnosis have been weighted either positively or negatively. They include gender, alkaline phosphatase (ALP):aspartate aminotransferase (ALP:AST) (or alanine aminotransferase [ALT]) ratio, height of IgG, titer ANA, SMA or LKM1, AMA status, viral serology, drug history, average daily alcohol intake, liver histology (interface hepatitis, predominant lymphoplasmacytic infiltrate, rosetting of liver cells, biliary changes), and other autoimmune diseases. Additional measures can include seropositivity of other autoantibodies, HLA DR3 or DR4, and response to immunosuppressive therapy. [47]

TABLE 110-2 Summary of Autoimmune Hepatitis Scoring Revised Sheet

NATURAL HISTORY OF AUTOIMMUNE HEPATITIS

Now that immunosuppressive treatment is the standard of care for symptomatic AIH, the natural history of this disease is rarely observed. Examination of the data from subjects who received placebo in the randomized controlled trials of corti- costeroids ± azathioprine reported in the early 1970s indicate that AIH is a rapidly progressive disease with a 5- and 10-year survival rate of only 50%, and 10%, respectively [4], [5] and [6] (Fig. 110-2). Death is generally due to liver failure often complicated by sepsis. Hepatocellular carcinoma is rare. [50] However it is important to note that 30 years ago, when these trials were conducted most patients presented to their physician with hepatic decompensation and thus the majority had well-established cirrhosis at baseline. With the introduction of routine laboratory checks of liver biochemistry and a heightened awareness of liver disease in general, it is likely that the proportion of individuals diagnosed with less advanced disease is increasing. Sometimes AIH may be diagnosed in the absence of any symptoms. Currently there are no published data on the natural history of asymptomatic AIH.

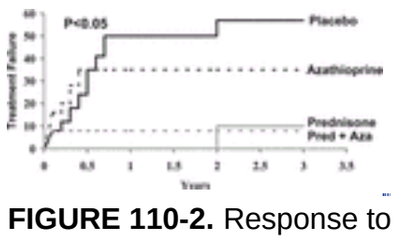

FIGURE 110-2. Response to immunosuppressive therapy. (From ref. [8].)

Treatment, successful in more than 80% of affected individuals, has allowed most patients with AIH to lead a normal life with a life expectancy similar to age- and gender-matched control populations (i.e., 98% at 10 years). [51] This study also indicated that the 10-year survival in AIH is not dependent on baseline liver histology (Fig. 110-3). For the most part young women with this disease, if treated appropriately, may have successful pregnancies (corticosteroids and/or azathioprine should not be stopped during pregnancy). If flare-ups do occur they are nearly always in the postpartum period. [52]

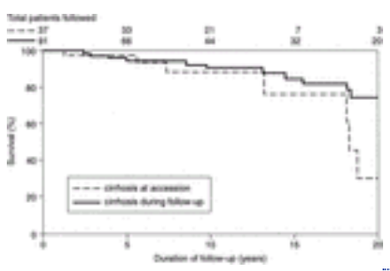

FIGURE 110-3. Survival of patients with type 1 autoimmune hepatitis: comparison of survival, using death and orthotopic liver transplantation as end points, from development of cirrhosis at accession versus follow-up. (From ref. [51].)

Unfortunately most of the complications of AIH are due to side effects from long-term immunosuppressive therapy needed to control liver disease. It is essential to monitor systemic blood pressure, bone mineral density, and blood or urine glucose. Regular eye examinations looking for cataracts should also be performed.

Patients with AIH may develop other autoimmune diseases during follow-up, (e.g., thyroiditis and rheumatoid arthritis). Thus patients given a diagnosis of AIH need to recognize their need for lifelong follow-up. The complications of liver failure are as for all liver diseases, namely, ascites, hepatic encephalopathy, and variceal hemorrhage. It must be determined if liver failure is due to a flare-up of disease in which case medical therapy is appropriate or due to “burned out” end-stage disease in which case liver transplantation is probably the best option.

TREATMENT (Table 110-3)

Initial therapy: Prednisone 30–40 mg/d monotherapy or prednisone 30 mg/d and azathioprine 50–100 mg/d combined therapy
Dose reduction: Slowly reduce prednisone (2.5–5 mg every 1–3 mos) if ALT remains <1.5 uln
Maintenance: Minimum dose prednisone and/or azathioprine to maintain ALT <1.5 uln
Stop therapy: If ALT <1.5 uln for 1–2 y +/−, liver biopsy indicates inactivity
Retreatment of relapse: Reintroduce therapy as for initial treatment
Failure to respond: To above, use either high dose prednisone 40–60 mg daily or another immunosuppressant, or consider liver transplant if appropriate

ALT, alanine aminotransferase; uln, upper limit normal.

TABLE 110-3 Suggested Therapeutic Regimen: for Autoimmune Hepatitis

The first therapeutic trials in patients with AIH conducted in the late 1960s and early 1970s indicated a highly significant improvement in survival following therapy with corticosteroids. [4], [5] and [6] The studies from the Mayo Clinic indicated that treatment with high-dose corticosteroid (60 mg daily initially with 20 mg daily as maintenance) and lower dose corticosteroid combined with azathioprine (30 mg prednisone daily initially and reducing the dose to 10 mg daily as maintenance plus 50 mg/d of azathioprine) were equally effective. Azathioprine 100 mg/d monotherapy was no better than placebo. [7], [8] Several lessons were learned from these trials. First, high-dose corticosteroids are associated with the rapid onset of severe side effects (osteoporosis, diabetes, systemic hypertension, and cataracts) and thus it is wise to treat symptomatic patients from the start with a lower dose of steroids (30–20 mg/d) combined with the steroid-sparing agent azathioprine. As azathioprine takes at least 6 weeks to take effect it makes sense to start this agent when steroid treatment is initiated. The dose of steroid can be tapered once the serum aminotransferase levels have fallen to less than a twofold elevation. Tapering by 2.5 to 5 mg every 1 to 3 months with careful monitoring of the aminotransferase levels is appropriate. Most patients have a rapid symptomatic and somewhat slower biochemical response within the first few weeks of therapy. There are some patients whose serum aminotransferase levels do not return to normal for many months. A fall in the level of IgG is also a good indicator of response. Liver histology does not improve until the biochemical tests have been normal for at least 6 months. About 20% respond poorly with 13% achieving only a partial response and only 7% who do not respond to treatment at all. [53] Poor response to immunosuppressive therapy is more common in patients whose liver biopsy shows areas of submassive necrosis. [54] Patients with cirrhosis, even if decompensated, generally respond well to therapy. Therefore even patients being considered for liver transplantation, if they have active disease, should be given immunosuppressive therapy without delay. No randomized control trials of therapy in patients who have asymptomatic disease have been conducted. An unsuccessful attempt was made, but patients refused to be included, put off by the long list of side effects attributed to corticosteroids (Dr. P. Gregory, personal communication, 1997).

Once the serum aminotransferase levels have returned to near-normal values it may be possible to wean the patient off corticosteroids altogether (this was not done in the early trials) and maintain patients on azathioprine alone in a dose of 1 to 2 mg/kg/d. [55], [56] Such a strategy reduces the deleterious consequences of long-term corticosteroid therapy. The white blood cell count needs to be regularly checked because of the potentially toxic effects of azathioprine on the bone marrow. Some patients cannot tolerate azathioprine, mainly because of its gastrointestinal side effects. Alternate-day immunosuppressive therapy is ineffective in AIH.

It is generally advised that immunosuppressive therapy be continued for up to 2 years after the liver biochemical tests have normalized before cessation of immunosuppressive therapy is contemplated. This timing is arbitrary; however it is likely that at least 1 year of therapy is essential. Some would advocate that prior to stopping treatment another liver biopsy should be performed to confirm that the hepatic inflammation has disappeared. A reduction in fibrosis may be observed [57], [58] but unfortunately half of those patients not cirrhotic at presentation will progress to cirrhosis despite ongoing immunosuppressive therapy and an apparent biochemical response. [59]

In those rare patients with AIH in whom standard therapy with a combination of prednisone and azathioprine fails, other immunosuppressive agents have been tried. Alternatives to classic treatment are also needed for children who may experience devastating growth retardation due to the use of high-dose corticosteroids. However, carefully monitoring corticosteroid therapy is probably still the best treatment in children, although cyclosporin has been used with benefit in children [60] both with type 1 and type 2 AIH. [61], [62] A newer agent used to prevent transplant rejection, mycophenolate mofetil (MMF), may be preferable as it has less nephrotoxicity—but it often causes diarrhea. [63] Methotrexate has been reported to be of benefit, as has cyclophosphamide in refractory type 1 AIH. [64], [65]

Budesonide is a corticosteroid which has a 90% first pass effect in the liver, but nevertheless appears to have a beneficial effect at this site, causing aminotransferase levels to normalize in AIH. [66] Unfortunately these encouraging results were not confirmed in another study; [67] in addition steroid side effects were observed in this latter study likely because intra- or extrahepatic portosystemic shunting was present thus obviating the beneficial properties of budesonide.

Once it is believed that the disease is in long-term remission (sustained normalization of serum aminotransferase levels, with histological evidence on liver biopsy of quiescent disease) immunosuppressive therapy may be stopped. Unfortunately the majority (80%) of individuals with AIH who are weaned off treatment will relapse, [68] generally within the first few months after treatment cessation but sometimes not until several months or even years later. Reinstitution of immunosuppressive therapy is generally successful.

It is now quite unusual for patients who have been treated for AIH to progress to end-stage liver disease. Risk factors for disease progression are a DR4-negative phenotype and the presence of anti-LKM1 antibodies as well as massive necrosis on first biopsy and low albumin and high prothrombin time at present. [69] However when liver transplant is necessary, it is extremely successful (>90% 5-year survival), although a pattern of recurrent liver disease similar to AIH may recur in the transplanted liver in up to 40%. [70], [71] In most cases this responds to increased immunosuppressive therapy. For this reason attempts at withdrawal of anti-rejection therapy in those who received a liver transplant for previous AIH are not recommended.

In addition to specific therapy for liver disease, individuals with AIH may require additional supportive therapy. All should be encouraged to lead an entirely normal life but certain precautions need to be taken, as is the case for anyone on long-term immunosuppressive therapy. In addition the complications of long-term corticosteroid therapy should be anticipated and prevented if possible. Those intending foreign travel should receive appropriate advice from travel medicine specialists, particularly with regard to appropriate vaccinations and how to avoid certain parasitic infections, (e.g., *Strongyloides*). All patients on immunosuppressive treatment should learn to recognize any infection early in its course and rapidly seek medical attention.

In young women who are successful in becoming pregnant it is important to check for the presence of esophageal varices in those who are cirrhotic, as nonselective ß-blocker therapy may well be required during pregnancy. Advice to the obstetrician to avoid a prolonged second stage of labor is also important. It is quite safe to maintain corticosteroid and/or azathioprine therapy during pregnancy; sometimes requirement for immune suppression may lessen during the pregnancy. Flare-ups, if they occur, are most often observed following delivery although they may occur during pregnancy. [52]

Baseline measurement of bone mineral density is wise. Adequate intake of calcium and vitamin D should be recommended to all individuals with AIH given corticosteroids. Preventive biphosphonate therapy has been shown to be of value.

SUMMARY

Although AIH is one of the less common causes of a chronic hepatitis it is essential that the diagnosis not be missed, as therapy is so successful, even curative in up to 20%. Most patients once in remission can be maintained in good health on azathioprine monotherapy with no untoward side effects. Treatment of AIH with immunosuppressive agents does not always prevent progression to cirrhosis, but it does significantly reduce the risk of dying of liver failure.

Key Points

- Two types AIH, distinguished by autoantibody status
- Presentation may be with a silent, or a symptomatic or even fulminant hepatitis
- Differential diagnosis: drug induced hepatitis, Wilson disease, viral hepatitis
- Immunosuppressive therapy markedly improves survival but is curative in only 20% of patients.

CHAPTER 111

Marlyn J. Mayo and Dwain L. Thiele

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis (PBC) is a chronic liver disease that is defined by its clinical presentation, histological features, and serologic findings. The underlying abnormality in PBC is a slowly progressive, nonpurulent inflammatory destruction of the biliary epithelial cells lining the small to medium-sized interlobular ducts. [1] The larger biliary ducts are spared. The pathophysiology of bile duct destruction is poorly understood, but the process is thought to be autoimmune in nature. Autoantibodies are a characteristic feature of the disease; over 90% of patients with PBC have antimitochondrial antibodies (AMAs) and about 30% have antinuclear antibodies (ANAs). [2] Loss of normal biliary drainage eventually leads to a clinical picture of chronic hepatic cholestasis and its complications.

PATHOGENESIS

PBC: An Autoimmune Disease?

PBC is presumed to be an autoimmune disease, although the evidence to support that hypothesis is largely inferential. Clinically, PBC shares features with other autoimmune diseases such as predominance in middle-aged women and frequent concurrence with other autoimmune disorders. [2] Epidemiologic studies have failed to provide evidence for a clear mode of transmission that could be compatible with an infectious etiology, such as parenteral exposure or fecal-oral contamination. [3] Microscopically, bile duct destruction is associated with T-cell infiltrates and expression of biliary epithelial cell surface markers of immune activation such as adhesion molecules and human leukocyte antigen (HLA) class I and II molecules. [4] In many ways, the histological picture resembles that of graft versus host disease, a condition known to be caused by T-lymphocyte–dependent immune responses directed against alloantigens. [5] In addition, virtually 100% of patients with PBC have circulating autoantibodies, often to mitochondrial or nuclear antigens. [2] The response to immunosuppressive therapy has been modest. Liver tests improve with immunosuppression, but the disease does not vanish, as it does in some other autoimmune diseases. Experimental models of PBC are not well established, which has hampered study of the pathogenesis. The best-defined features of the immunopathogenesis of PBC are the T-lymphocyte response in the liver and specific immune response directed at mitochondrial antigens.

Alternative hypotheses regarding the pathogenesis of PBC include a graft versus host disease related to fetal microchimerism or an immune response to endogenous retroviruses. Evidence of persistent fetal cells has been detected in the liver of 70% of mothers with PBC. [6] However, fetal microchimerism has also been detected by sensitive polymerase chain reaction (PCR) in an equal fraction of controls. Mason and colleagues [7] have demonstrated antibody reactivity to the human retroviral intracisternal A type particle in 51% of patients with PBC and have amplified and cloned endogenous retroviral sequences from PBC liver. These retroviruses, however, do not appear to be entirely specific for PBC, since 58% of patients with systemic lupus and 20% of patients with chronic viral hepatitis have the same antibodies.

Pathogenicity of Antimitochondrial Antibodies

In 1987, Gershwin and colleagues [8] identified the primary structure of the major target antigen of the PBC AMAs. This autoantigen was identified as the human mitochondrial enzyme, dihydrolipoamide acetyl transferase, also referred to as the E2 component of the pyruvate dehydrogenase complex (PDC-E2). PDC belongs to a family of multienzyme complexes involved in cellular respiration called the 2-oxo-acid dehydrogenase complexes. Although PDC-E2 is the major autoantigen in AMAs, patients with PBC may have antibodies to any of the 2-oxo-acid dehydrogenase complexes, including branched chain 2-oxo-acid dehydrogenase complex (BCOADC) and 2-oxoglutarate dehydrogenase complex (2-OGDC), or other components of the PDC complex (E1, E3, X) [9] (Table 111-1).

AUTOANTIBODY	PREVALENCE BY IMMUNOFLUORESCENCE (%)	PREVALENCE BY IMMUNODIFFUSION, ELISA, OR IMMUNOBLOTTING (%)
Antimitochondrial	85–95	
Anti-PDC-E2*		95–97
Anti-PDC-E1		41–66
Anti-PDC-E3		38
Anti-PDC-X		95–97
Anti-OGDC-E2		39–88
Anti-BCOADC-E2		53–55
Antinuclear	25–70	50–81
Nuclear rim/peripheral/perinuclear	26	
Anti-gp210 (nuclear pore complex)*		10–30
Anti-lamin B (nuclear membrane)*		1
Homogeneous/diffuse	10	
Antihistone		80
Anti-DS DNA		10
Centromere	10–24	
Speckled	10–20	
Multiple nuclear dot	4–17	
Anti-sp 100/anti-PML*		5–40
Coarse nuclear speckled/nucleolar		
Anti-Smith (Sm) (small RNP)		24
Anti-Scl-70 (DNA-topoisomerase 1)		24
Fine nuclear speckled		
Anti-Ro (SS-A) (small RNP)		25–30
Anti-La (SS-B) (small RNP)		21
Negative by immunofluorescence		
Anti-SS DNA		71
Anti–smooth muscle	20	
Antiactin		13–52
Antiliver membrane	42	
Anti-asialoglycoprotein receptor		15–23
Anti–carbonic anhydrase		8–45
ANCA	16–26	
Antiplatelet		40

*Autoantibodies relatively specific for primary biliary cirrhosis.

TABLE 111-1 Prevelance of Autoantibodies in Primary Biliary Cirrhosis

The role of these autoantibodies in the pathogenesis of bile duct destruction has been the subject of considerable debate. Experimental models have thus far failed to demonstrate that generation of AMAs leads to chronic destruction of bile ducts in PBC. Rats, guinea pigs, rabbits, and rhesus monkeys have all been immunized with

the recombinant form of PDC-E2. Antibodies to PDC-E2 were readily induced, but none of the animals developed abnormal liver tests or abnormal histology after 8 months of follow-up. [10] PDC-E2 is a mitochondrial enzyme that is expressed in the intracellular compartment of all aerobic cells. Tissues with high energy requirements, such as muscle, and even hepatocytes express higher levels of PDC-E2 per cell than cholangiocytes. [11] Thus, it is difficult to reconcile the apparent cholangiocyte specificity of cellular injury in PBC with the ubiquitous presence of mitochondrial antigens.
