Epidermolysis bullosa (EB) is a spectrum of inherited mechanobullous diseases in which blisters occur spontaneously or at sites of friction or trauma. Classification of clinical subtypes of EB has been based on inheritance patterns, the presence or absence of scarring, and, more recently, the electron microscopically determined level of the blistering. Both dominant and recessive forms of dystrophic EB occur. Onset of skin lesions occurs at birth or shortly thereafter, and a dermatologic diagnosis of EB usually has been made before the patient presents to a gastroenterologist. Rarely, pyloric atresia has been found in infants with junctional or recessive dystrophic EB, apparently resulting from mucosal blistering and scarring in utero. The major sites of gastrointestinal involvement, most often occurring in the recessive dystrophic form, are the oral cavity, esophagus, and anal areas [74], [75] (see Chapter 63).

Esophageal lesions may become symptomatic at any time in the first 3 decades of life. Dysphagia is the most common symptom and may reflect the presence of esophageal bullae or weblike scarring, both of which can cause partial or total obstruction. Most such lesions occur in the cervical esophagus near the cricopharyngeal area. Anal involvement, with bullae and subsequent scarring, may lead to constipation. Lesions in this location are also prone to severe secondary infection. Nutritional deficiency is common in severe EB. EB acquisita is an uncommon late-onset disease with skin blistering and scarring at trauma sites and sometimes causing extensive, scarring oral and esophageal lesions. [76] There is no family history of EB in these patients, which occasionally has occurred in association with inflammatory bowel disease.

Pemphigus Vulgaris

Pemphigus vulgaris is an immunologic blistering disease that commonly presents with oral erosions before the onset of cutaneous lesions. Skin or mucosal biopsy findings of an acantholytic blister and direct and indirect immunofluorescence microscopic evidence of IgG in the intraepidermal space confirm the diagnosis. Symptomatic esophageal involvement is rare (see Chapter 63). [77] Pemphigus involving the lower gastrointestinal tract can present with hemorrhage. [78]

Bullous Pemphigoid

Bullous pemphigoid is another immunologic blistering disease in which older patients present with tense bullae. A biopsy specimen of the lesion shows a subepidermal blister, and IgG is found in the basement membrane zone in a linear pattern on direct and indirect immunofluorescence microscopy. Mucosal involvement is less common in bullous pemphigoid than in pemphigus (see Chapter 63), occurring in the mouth in about one third of pemphigoid patients and less often in the esophagus or anus. [79] There have been case reports of bullous pemphigoid occurring coincident with gastrointestinal malignant disease, particularly carcinoma of the colon.

SKIN CONDITIONS ASSOCIATED WITH ABDOMINAL PAIN

Porphyrias

Variegate porphyria is the most common porphyria in which patients present with skin lesions and episodic abdominal pain. The typical skin lesions (the same as are seen in porphyria cutanea tarda; see section "Cutaneous Signs Associated with Liver Disease") are noninflamed blisters and erosions at sun-exposed sites, particularly the backs of the hands. Scarring with milia formation, hyperpigmentation, facial hypertrichosis, and sclerosis may occur. Photoprotection is of minimal benefit because the patients are exquisitely sensitive to light, and avoidance of inducing drugs is important. Hereditary coproporphyria is even more rare but also may have photosensitivity as a component.

Fabry Disease

The skin lesions in *Fabry disease,* a rare lysosomal storage disease, are punctate, 1-mm, red to blue angiokeratomas that do not blanch. They are most densely distributed from the midabdomen to the knees. Lesions have their onset from childhood to adolescence. Decreased or absent sweating also may occur. The gastrointestinal manifestations of this disease are covered in Chapter 127.

Mastocytosis

Mastocytosis is an uncommon disorder of mast cell proliferation. The most common skin lesions are urticaria pigmentosa, with childhood onset. These are usually reddish-brown macules, but solitary nodules may occur. On stroking, these lesions typically itch, and a raised wheal or vesicle occurs (the Darier sign). Much less common is a telangiectatic variant or an erythroderma that occurs in adults. Skin biopsy confirms the increased numbers of mast cells in the dermis. Cutaneous symptoms may be controlled with antihistamines. Topical cromolyn and systemic psoralen in combination with ultraviolet A irradiation (PUVA) have been reported to be helpful in some patients. The gastrointestinal manifestations of mastocytosis are discussed in Chapter 42 and Chapter 128.

Herpes Zoster

T7 through L1 dermatomal involvement of *herpes zoster* may cause abdominal pain before the onset of typical grouped vesicular lesions. Involvement of sacral nerve roots can produce constipation and pain during defecation. [81] Postherpetic neuralgia can cause persistent, recurrent pain in the involved dermatome.

Rosacea

Rosacea is a chronic inflammatory condition characterized by central facial flushing, telangiectasias, acneiform lesions, and possible complication of nasal thickening called *rhinophyma* (Fig. 49-13; see Color Fig. 49-13). Several reports have described a possible relationship between *Helicobacter pylori* infection of the gastric mucosa and rosacea; however, no large case control studies have been performed to date to prove a causal relationship. [82] Rosacea is commonly treated with topical or oral antibiotics, with the highest response rate usually obtained with oral tetracycline.

FIGURE 49-13. (See Color Fig. 49-13.) Characteristic telangiectasias, acneiform papules, and rhinophyma in a patient with rosacea.

CUTANEOUS SIGNS ASSOCIATED WITH LIVER DISEASE

Jaundice

This yellow discoloration of the skin, mucous membranes, and sclerae occurs because of the accumulation of bilirubin and its metabolites in these areas. In liver disease, it usually results from impaired excretion of conjugated (direct) bilirubin and becomes clinically evident at blood levels greater than 2.5 mg/dL. It can occur in almost any type of liver disease. [83] Treatment of the underlying liver condition will cause the jaundice to resolve. Ultraviolet light can resolve neonatal hyperbilirubinemia.

Pruritus

Pruritus, which is often severe and debilitating, can occur in cholestasis, cirrhosis, chronic hepatitis C, primary sclerosing cholangitis, and other forms of liver failure. [84] Patients with liver disease–associated itching often have elevated bile acids, bilirubin, alkaline phosphatase, and cholesterol, but the degree of itching does not generally correlate with the degree of elevation of these values. In fact, as the liver disease progresses, the itch may disappear, and this sign often heralds liver failure.

Pruritus may be the only symptom of cholestasis of pregnancy, which has associated increased fetal morbidity and mortality. A study of 8 women with 13 pregnancies complicated by cholestasis revealed only 1 normal delivery, 8 stillbirths, and 3 cases of fetal distress, 1 of which resulted in fetal death. Three of these women had subsequent pregnancies with cholestasis treated with ursodeoxycholic acid and had healthy deliveries. [85]

Treatment of liver-related itch involves measures to decrease the pruritus as well as measures to target the underlying liver disease (e.g., interferon for hepatitis C or surgery for common duct stones). Topical and systemic corticosteroids, PUVA therapy, and sedating antihistamines can decrease pruritus. Opiate antagonists, such as naloxone, nalmefene, and naltrexone decrease itching, suggesting that a central opioid may be involved in the mechanism of pruritus. Symptoms resembling those of opiate withdrawal may occur with the use of these drugs, and naltrexone can be hepatotoxic. [86]

Other forms of cholestatic itch are treated empirically, because the pathogenesis of this itch is unknown. First-line agents are bile acid sequestering agents such as cholestyramine and colestipol, which are resins that bind bile acids in the bowel and thereby reduce blood levels. They are moderately effective in decreasing itching, but are poorly tolerated because of gastrointestinal discomfort. These agents may work by a means other than just decreasing bile acids, because they also decrease itching associated with uremia and polycythemia vera. It is typical for patients to respond initially, but many become somewhat resistant thereafter. Ursodeoxycholic acid is actually a bile acid that lowers endogenous bile acid secretion into the gut. It is the only specific therapy that causes both a biochemical and survival benefit in

patients with primary biliary cirrhosis. [87] Rifampicin can decrease the pruritus of cholestasis, but it must be used with care, because it can be hepatotoxic. [88] Serotonin antagonists such as ondansetron also work in some cases. [89]

Polyarteritis Nodosa

Polyarteritis nodosa is a reaction pattern characterized by tender palpable purpuric nodules and livedo (Fig. 49-14, see Color Figs. 49-14) most commonly on the anterior legs, often with associated fever, arthralgias, malaise, and fibrinoid necrotizing arteritis histologically. Renal insufficiency and microaneurysms may occur. Hepatic arteritis was seen in 100% of patients with polyarteritis nodosa at autopsy in one study. [90] Intrahepatic hemorrhage is also reported. [91] Polyarteritis nodosa can occur in association with hepatitis B and, less commonly, hepatitis C and infections with parvovirus B19 and human immunodeficiency virus. It is often treated with immunosuppressive medications such as corticosteroids, which could exacerbate the underlying infection.

FIGURE 49-14. (See Color Fig. 49-14.) Polyarteritis nodosa with characteristic livedo reticularis and tender nodules.

Cryoglobulinemia

Cryoglobulins are immune complexes that can form as a reaction to drugs or infections. They can deposit within blood vessels and can create palpable purpuric nodules similar those seen in polyarteritis nodosa, with similar systemic complaints. Signs and symptoms are worsened by cold exposure and may include the Raynaud phenomenon or acral skin infarcts (Fig. 49-15; see Color Fig. 49-15). Hepatitis C is probably the leading cause of essential mixed cryoglobulinemia (type II or III forms). [92] Patients with hepatitis B infections have detectable cryoglobulins, usually of mixed type, in around 15% of cases. [93] Persistent chronic hepatitis A infection with cholestasis may result in cryoglobulinemic vasculitis. [94] Cryoglobulins resolve with treatment of underlying liver disease.

FIGURE 49-15. (See Color Fig. 49-15.) Cryoglobulinemia often results in acral vasculitic infarcts.

Papular Acrodermatitis of Childhood

This condition, also known as *Gianotti-Crosti syndrome,* is associated with hepatitis B, Epstein-Barr infection, and other viral infections in children. [95] It is characterized by asymptomatic erythematous papules that arise on the extremities, may occur on the face, and typically spare the trunk. These lesions tend to last 2 to 4 weeks and resolve on their own.

Lichen Planus

Lichen planus is a mucocutaneous condition characterized by pruritic, purple, polygonal papules with surmounting Wickham striae and lacy reticulate white mucosal plaques. It can occur in conjunction with hepatitis C in significantly higher prevalence than in normal controls. [96] Lichen planus can also be seen in primary biliary cirrhosis and many other liver diseases. Most often, however, there is no underlying disease. Treatments include systemic or topical corticosteroids, dapsone, PUVA therapy, methotrexate, and thalidomide.

Porphyria Cutanea Tarda

Porphyria cutanea tarda is characterized by subepidermal bullae, milia, and scarring most often on the dorsum of the hands, with hypertrichosis and hyperpigmentation of the face, photosensitivity to visible light (Soret band, 410 nm), and iron overload. It is often acquired in chronic liver diseases such as alcoholic or viral hepatitis and cirrhosis. Hepatitis C RNA has been detected in up to 91% of patients with porphyria cutanea tarda. [97] Most often, the predisposition is an inherited, dysfunctional enzyme known as uroporphyrinogen decarboxylase, which is important in porphyrin metabolism, and the liver disease potentiates expression of porphyria cutanea tarda. Treatments include phlebotomy, antimalarials, deferoxamine, and thalidomide.

Hypermelanosis

Several theories exist regarding why patients with chronic liver disease such as cirrhosis may develop hypermelanosis, which usually manifests as a diffuse or patchy grayish mucocutaneous pigmentation. It may occur because of increased levels of adrenocorticotropic hormone or melanocyte-stimulating hormone. As a result, the melanin content of the skin may be increased, and giant melanosomes may be present. Hemosiderin may also be directly deposited in the skin in iron overload conditions such as hemachromatosis.

Vascular Changes

Some of the vascular changes of liver disease are thought to occur because of altered estrogen metabolism. Spider angiomata, which are small arteriovenous malformations characterized by a central feeding vessel and radiating telangiectasias, are often seen in chronic liver disease. They are most common on the face, upper trunk, and distal upper extremities. Palmar erythema may be patchy or diffuse.

Nail Changes

Terry's nails is a term for an opaque whitish discoloration of the nails, with the distal third being pink. This discoloration can be seen in cirrhosis, but it is not specific to liver disease. Azure lunula (blue discoloration of the half-moon distal part of the nail matrix) is seen in hepatolenticular degeneration (Wilson disease), which is the result of abnormal copper metabolism. Clubbing may also occur in liver disease.

Other Cutaneous Manifestations

Urticaria, urticarial vasculitis, other forms of vasculitis, erythema multiforme, erythema nodosum, and pyoderma gangrenosum—all covered elsewhere in this chapter—can occur in liver disease, especially in patients with hepatitis B infection. Acute hepatitis B infection can produce a serum sickness–like reaction with fever, arthralgias, polyarthritis, urticaria, and vasculitis.

PANCREATIC DISEASE

Periumbilical purpura (Cullen sign) and left flank purpura (Grey Turner sign) are caused by dissection of blood along fascial planes from retroperitoneal bleeding of acute hemorrhagic pancreatitis. Presentation of tender, red, subcutaneous nodules, occurring at any site but most commonly on the pretibial region of the extremities, should raise the diagnostic possibility of *panniculitis* (Fig. 49-16; see Color Fig. 49-16). *Pancreatic fat necrosis* may feel fluctuant, but lesions rarely ulcerate or discharge fluid. [98] Pancreatic fat necrosis may be seen as the presenting sign in 22% of patients with pancreatitis or in up to 65% of patients with pancreatic carcinoma. Excisional biopsy (not punch biopsy) is indicated to confirm the diagnosis of panniculitis. The clinical differential diagnosis includes superficial migratory thrombophlebitis, which may be seen in pancreatic, gastric, or other cancers and in Behçet disease.

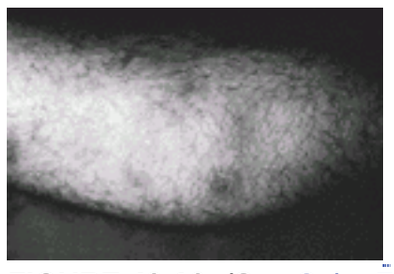

FIGURE 49-16. (See Color Fig. 49-16.) Panniculitis presented as tender erythematous nodules in a patient with pancreatitis.

The eruption of multiple yellow-red papules, predominating over extensor surfaces or buttocks, suggests a diagnosis of eruptive xanthomatosis. These lesions occur in the presence of hypertriglyceridemia and type IV or V hyperlipoproteinemia and may develop in a patient with pancreatitis, particularly in the setting of diabetes mellitus.

DERMATOLOGIC DISORDERS ASSOCIATED WITH MALABSORPTION

Dermatitis herpetiformis is an uncommon blistering disease characterized by intense pruritus and multiple grouped small vesicles distributed symmetrically over the body (Fig. 49-17; see Color Fig. 49-17). The scalp and extensor surfaces are prominently involved, and the itching and excoriation may be so severe that intact blisters are not conspicuous. Diagnosis is made by skin biopsy, which shows a subepidermal blister with a neutrophilic infiltrate of the dermal papillae. Direct immunofluorescence of perilesional skin confirms the diagnosis of dermatitis herpetiformis with the demonstration of IgA at the dermal-epidermal juncture or within the dermal papillae. [99], [100]

FIGURE 49-17. (See Color Fig. 49-17.) Dermatitis herpetiformis. Both elbows are involved. Note the intact vesicles and multiple crusted (i.e., excoriated) lesions.

Gastrointestinal manifestations may not be clinically prominent in patients with dermatitis herpetiformis who initially present to a dermatologist. Nevertheless, almost all patients have gluten sensitivity of the small intestine (see Chapter 76). Steatorrhea is observed in 20% to 30% of patients, and anemia may occur secondary to malabsorption (e.g., of folate or iron). Even in the absence of gastrointestinal symptoms, strict observance of a gluten-free diet leads to improvement of the skin disease (which may take 6 to 24 months of careful diet restriction) and minimizes the need for medication. [101], [102] Gluten challenge may cause a flare of the skin lesions in patients whose condition was previously controlled by diet.

Therapy of dermatitis herpetiformis with one of the sulfones, usually diaminodiphenylsulfone (dapsone) or with sulfapyridine, leads to prompt relief of symptoms and halting of lesion formation (within hours to a few days). Oral dapsone is often started at a dose of 100 to 200 mg daily in adults and is titrated according to the clinical response and with the goal of minimizing side effects.

Malabsorption can occur with other skin diseases. Patients with extensive inflammatory skin disease, such as exfoliative erythroderma or atopic eczema, develop secondary malabsorption, termed *dermatopathic enteropathy.* [103] This is usually manifested as mild steatorrhea and is often asymptomatic; resolution is prompt with treatment of the skin disease. The mechanism is unclear, but it does not appear to result from gluten sensitivity. Malabsorption also can occur as a result of abnormal motility or vascular compromise in systemic sclerosis and systemic vasculitides. Skin manifestations of chronic malabsorption are largely nonspecific and reflect altered nutritional status.

NUTRITIONAL DISORDERS

Although classically, the cutaneous manifestations of nutritional deficiency have been separated with regard to specific nutrients, there is usually considerable overlap, and many of the skin signs are nonspecific. [104] See Chapter 17, Chapter 18, Chapter 19 and Chapter 20 and Chapter 53 for further information.

Protein Malnutrition

Marasmus (total starvation) in the United States is usually limited to severely ill patients. Such patients have dry, loose skin, loss of subcutaneous fat, and thin, slowly growing hair, and, occasionally, prominent facial lanugo hair and hyperkeratosis around hair follicles. Absence of edema separates marasmus from kwashiorkor. In *kwashiorkor* (carbohydrate excess with protein deficiency), there may be hypopigmented and hyperpigmented scaling patches with peeling of the epidermis over edematous sites, joints, and flexural areas (flaky paint appearance). Purpura, which also may occur, results in mixed coloration. The hair may demonstrate alternate bands of dark and light pigmentation that correlate with episodes of inadequate protein intake (flag sign). Zinc and vitamin deficiencies usually accompany these

malnutrition states and undoubtedly contribute to the cutaneous findings. [105]

Essential Fatty Acid Deficiency

Essential fatty acid deficiency can occur in patients with fat malabsorption from any cause. It has been less common in patients who have been receiving fat-free parenteral nutrition because parenteral lipid supplementation is now routine. [106] Cutaneous lesions are typically diffusely distributed, erythematous scaling patches. There may be alopecia and traumatic purpura. Linoleic acid is the major fatty acid involved, and there is direct evidence of its role in the repair of the skin lesions. Older studies suggested that topical application of inoleic acid, as sunflower or safflower oil, could correct the total deficiency, but more recent evidence stresses the importance of systemic replacement.

Vitamin Deficiencies

Vitamin A deficiency may occur with fat malabsorption or liver disease. The classical change is that of multiple keratotic follicular papules over the extremities (phrynoderma), usually with generalized dry skin. Keratinizing metaplasia may occur on mucosal surfaces. Skin improvement occurs slowly with replacement therapy. *Vitamin A excess* may be more common than deficiencies, especially with the use of synthetic retinoids and supplemental vitamin A intake. Alopecia, fine erythematous scaling (sunburn appearance), cheilitis, skin fragility, and brittle nails will slowly resolve after the excess is corrected.

There are many similarities in the cutaneous manifestations of deficiency of the B vitamins riboflavin, pyridoxine, and niacin. Seborrheic dermatitis appearing over the face, prominent involvement of the perioral and groin areas, and a smooth tongue are common features. In *pellagra* (niacin deficiency), there may be painful erosive and pigmented scaling patches, especially in sun-exposed sites. When this occurs on the upper chest, it is termed a *Casal necklace.* Pellagra still occurs in those with inadequate intake (e.g., patients with alcoholism, elderly persons) and in patients with severe malabsorption. It can occur also in patients with carcinoid, or in those receiving therapy with isoniazid, 6-mercaptopurine, or 5-fluorouracil. Skin lesions respond dramatically to niacin replacement therapy.

Cutaneous manifestations of *vitamin B_{12} deficiency* are uncommon. Generalized hyperpigmentation, which may specifically involve palms, soles, nails, and white hair, alopecia areata, or vitiligo may occur in association with pernicious anemia. *Folic acid deficiency* may present with an unusual lemon-yellow skin color.

Vitamin C deficiency still occurs fairly often, especially in elderly persons and in patients with alcoholism who have inadequate dietary intake. Purpura and petechiae, perifollicular hemorrhage with corkscrew-shaped hairs, and gingival erosions around teeth are the prominent features. Mucosal lesions respond first to replacement of vitamin C, followed by slower resolution of purpura.

Zinc Deficiency

Zinc deficiency, or acrodermatitis enteropathica, may be genetic or acquired. [107] The cutaneous manifestations are acrally distributed (hands, face, feet, anogenital region) and are typically erythematous, scaling, vesiculopustular, or eroded plaques. There may be alopecia, impaired wound healing, and stomatitis. Secondary candidal infection is common and should also be treated. Zinc replacement, pancreatic enzyme supplementation, and 8-hydroxyquinoline have been used in the therapy.

PERINEAL SKIN LESIONS

There are several skin lesions that occur in the perianal or perineal areas that may be encountered in the course of examination or endoscopy procedure (Table 49-3) (see Chapter 92). Vesicles or erosions on an erythematous base should suggest herpetic lesions. Herpes simplex is often recurrent in this site, and in immunocompromised patients, lesions may be persistent, crusted erosions or ulcers. Herpes zoster usually presents acutely as dermatomal grouping of vesicles. Perianal ulcers and erosions also may occur in Crohn's disease, in amebiasis, in primary or secondary syphilis, or in nontreponemal venereal disease. Flesh-colored pedunculated papules in the perineal area often are condylomata acuminata (venereal warts). Lesions, if they are few, usually respond well to therapy with cryosurgery, electrofulguration, surgical or laser excision, or application of topical podophyllin. Refractory lesions may respond to intralesional or systemic interferon.

Erythema with Scale or Maceration
Contact dermatitis
Seborrheic dermatitis
Psoriasis
Candidiasis
Dermatophytosis
Secondary syphilis
Extramammary Paget disease
Nutritional deficiencies
Bowen disease
Vesicles, Erosions, and Ulcers
Herpes simplex
Herpes zoster
Impetigo (streptococcal, staphylococcal)
Syphilis (primary or secondary)
Chancroid
Deep fungal, acid-fast bacilli, protozoal infections
Bullous pemphigoid
Pemphigus
Ecthyma
Nodules, Tumors, and Ulceration
Condylomata acuminata (i.e., warts)
Hidradenitis suppurativa
Squamous or basal cell carcinoma
Crohn's disease
Carcinoma: metastatic or direct extension
Kaposi sarcoma
Granulomatous herpes simplex

TABLE 49-3 Perineal Skin Lesions (Practical List of Common Causes)

Erythema with scaling or maceration in the gluteal fold and perianal area raises the major considerations of candidal infection, psoriasis, or seborrheic dermatitis, irritant contact dermatitis (from fecal soiling), or bacterial (streptococcal or staphylococcal) impetigo. Clinical presentation, potassium hydroxide preparation of skin scrapings, and culture are helpful in differentiating these diagnoses. If lesions do not respond to appropriate therapy for one of these diagnoses, biopsy may be indicated to rule out extramammary Paget's disease. Idiopathic pruritus ani is a diagnosis that should be made only after a primary dermatosis, such as those just listed, has been excluded. It is a common complaint, particularly in middle-aged men, and psychological factors have been emphasized in some reviews. [108], [109] The key to effective therapy of pruritus ani is eliminating underlying triggering factors, including infections, irritants, allergies, and anorectal disorders (e.g., rectal fissures, prolapse). Careful cleaning measures, dietary changes, and treatments ranging from topical corticosteroids to intralesional steroids or cryosurgery have been used successfully. Treatment is most successful if the symptoms have been present for less than 2 years.

CHAPTER 50

John Rabine* Timothy T. Nostrant

ORAL MANIFESTATIONS OF GASTROINTESTINAL DISEASE

Many gastrointestinal disease states are associated with oral findings (Table 50-1). This chapter briefly addresses the disorders in which oropharyngeal pathology is most common.

TABLE 50-1 Oral Lesions Associated with Gastrointestinal Diseases

GASTROESOPHAGEAL REFLUX DISEASE

The supraesophageal manifestations of gastroesophageal reflux disease (GERD), including reflux laryngitis and reflux-associated asthma, have gained increasing attention. Dental injuries, predominantly erosions, are also very common. Erosions are defined as circumscribed, punched-out, discolored regions on the surface of a tooth corresponding to enamel loss (Fig. 50-1) and can be differentiated from caries, which are dark defects with jagged edges. [1] Gastric acid exposure has been the proposed mechanism of dental erosions because of its association with salivary loss, [2] bulimia, [3] and hiatal hernias. [4] Reflux has been documented in 83% of patients with erosions referred by their dentists for pH monitoring. [5]

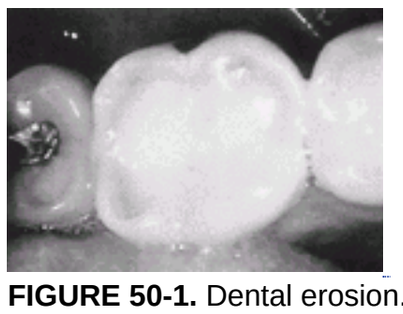

FIGURE 50-1. Dental erosion. Circumscribed yellowish regions correspond to exposed dentin in areas where enamel has been lost during repeated exposure to gastric contents in a female patient with bulimia.

The true incidence of dental erosions in patients with GERD is unclear, but at least 20% of patients with reflux have been found to have erosions, [6], [7] and more than 50% of patients with proven reflux by pH monitoring have been shown to have dental erosions. [5] Extrinsic acid exposure (e.g., citrus fruits, soft drinks, vinegar, chewable vitamin C tablets) is more likely to induce erosions on the labial surfaces of upper anterior teeth, whereas intrinsic acid from GERD is more likely to harm the lingual surfaces of teeth. [1], [8], [9], [10] and [11]

The treatment of GERD-induced dental erosions is obviously aimed at limiting reflux and oral acid exposure. Patients should avoid acidic foods and drinks, allow antacids to dissolve in the mouth during symptomatic reflux events, and avoid brushing their teeth immediately after a reflux event. Chewing gum (sugarless) can be used to stimulate salivary flow between meals, and medications that reduce salivary flow should be avoided. Patients with xerostomia resulting from medications, previous surgery, or previous radiation therapy should drink water frequently or use a saliva substitute. Patients with erosions should be under the care of a dentist, who can provide a polyethylene mouth guard at night to limit dental exposure to acid, topical fluoride pastes, and restorative dental procedures once the underlying reflux disorder has been addressed by the gastroenterologist.

Laryngeal abnormalities are also very common with supra-esophageal acid reflux. Symptoms that suggest reflux laryngitis include hoarseness, throat clearing, globus sensation, halitosis, and prolonged vocal cord warm-up. [12] Barium esophagram, upper gastrointestinal endoscopy, and standard esophageal manometry are diagnostic in fewer than 25% of cases, whereas results of 24-hour pH monitoring are positive for distal reflux in 80% and for proximal reflux in 30%. Reflux laryngitis can be induced with minimal acid exposure. Small amounts of acid applied to the vocal cords only three times per week will induce significant cord edema and inflammation. [13] Therefore, microaspiration of small, undetectable amounts of acid may cause laryngitis, which explains both the need for strong acid suppression for effective treatment and the low number of abnormal pH studies in those patients who do respond to treatment. [14], [15] Proximal acid reflux is cleared more slowly than distal acid reflux, and acid may reflux into the oral cavity when none is present distally. Dual pH monitoring is crucial for a diagnosis in patients with supra-esophageal

symptoms.

The gastroenterologist may be able to identify reflux laryngitis during routine upper gastrointestinal endoscopy because the larynx is well visualized. [16], [17] The posterior glottis, including the posterior edges of the vocal cords and the mucosa overlying the arytenoid cartilage, are seen best during inspiration, when the vocal cords are abducted. The vocal cords are better examined during phonation, when the cords are adducted. Classical posterior laryngitis consists of red arytenoid tissue and "piled-up" interarytenoid mucosa, but these features are seen in the minority of patients with reflux laryngitis (Fig. 50-2). [13] Laryngeal edema is the most common finding but may be easily overlooked. Table 50-2 summarizes the laryngoscopic findings of reflux disease. [16]

Reflux laryngitis
Vocal cord nodules
Polypoid degeneration
Contact ulcers/granulomata
Laryngeal stenosis
Proximal laryngospasm
Laryngeal cancer

TABLE 50-2 Laryngeal Findings of Gastroesophageal Reflux Disease

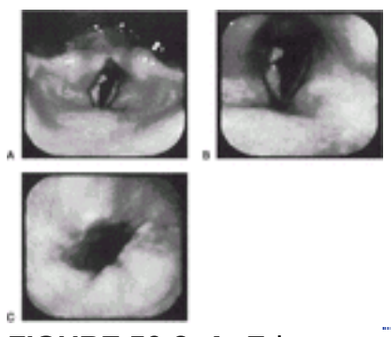

FIGURE 50-2. A: Edema and erythema of the vocal cords and posterior glottis (reflux laryngitis). **B:** Vocal cord granuloma. **C:** Distal reflux esophagitis in the same patient as in **A** and **B**.

Studies have defined the benefits of acid suppression for reflux laryngitis. A 12-week course of omeprazole clearly improved laryngoscopic findings except for granulomata. [18] An initial response rate of 65% was seen in 22 patients treated with 40 mg of omeprazole daily for 8 weeks. Relapse occurred in 38% after omeprazole was stopped. Abnormal pH studies were documented in the majority of nonresponders, and the response was not improved with twice-daily omeprazole. [19]

POLYPOSIS SYNDROMES

Gardner Syndrome

The oral manifestations of diseases associated with intestinal polyposis, such as Gardner syndrome, may be the first clue to the diagnosis.

Multiple mutations of the adenomatous polyposis coli (APC) gene result in multiple forms of Gardner syndrome. Bone tumors, soft tissue tumors, lipomas, desmoids, and sebaceous cysts may be seen (Fig. 50-3). Dental abnormalities, including unerupted teeth, supernumerary teeth, and dentigerous cysts, may predispose these patients to early and profound tooth loss. [20]

FIGURE 50-3. A: Mandibular osteoma of Gardner syndrome. **B:** Radiograph of the mandible in the same patient. (From Bresalier RS. Neoplasia of the colon and rectum. In: Feldman M. Gastroenterology and hepatology: the comprehensive visual reference. Philadelphia: Current Medicine, 1997.)

Peutz-Jeghers Syndrome

Small intestinal hamartomatous polyps are the classical finding in Peutz-Jeghers syndrome, an autosomal dominant disease with variable penetrance. Pigmentation abnormalities with melanin deposition on mucosal surfaces are the visual hallmark. Typically appearing in the first year of life, small black or blue-gray macules form on the lips, perioral region, and buccal mucosa but may develop on any mucocutaneous surface, including the fingers and toes. Perioral lesions often fade with age, while those in the mouth or on the extremities may become more apparent. [21] Overall, the risk for malignancy in multiple organs can be as high as 30%, and patients require periodic surveillance.

Cowden Disease

Multiple hamartoma syndrome, or Cowden disease, is a rare polyposis syndrome in which facial trichilemmomas and oropharyngeal papillomatous growths appear in the second decade. [22], [23] Gastrointestinal tract malignancy is not increased, but a higher incidence of extraintestinal malignancy is noted, particularly breast and thyroid cancers. Patients' overall risk for malignancy and requirement for surveillance are similar to those for patients with Peutz-Jeghers syndrome.

BLEEDING DISORDERS

See Chapter 49 and Chapter 130.

Osler-Weber-Rendu Syndrome

Hereditary hemorrhagic telangiectasia, or Osler-Weber-Rendu syndrome, is an autosomal dominant disorder characterized by widespread mucocutaneous telangiectases of the face, ears, lips, oral cavity, nasopharynx, and hands. Major sources of bleeding are the nose and stomach, although colonic bleeding and oral bleeding are recorded. [20] Similar telangiectases can be seen in scleroderma and CREST (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal motility disorder, *s*clerodactyly, and *t*elangiectasia) syndrome, so the clinical features of these disorders can be used to differentiate them from Osler-Weber-Rendu syndrome. [24]

Blue Rubber Bleb Nevus Syndrome

Blue rubber bleb nevus syndrome is characterized by multiple blue-colored, cavernous hemangiomata of the skin, oropharynx, and gastrointestinal tract that may

rupture and bleed. The skin and gastrointestinal tract are affected more commonly than the mouth. [20], [25] Histologically, these lesions consist of large, thin-walled vascular spaces with vessels lined by hyperplastic endothelium and separated by a scant network of elastin-deficient connective tissue. [26]

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is a rare form of elastic tissue degeneration producing thin vascular abnormalities in the gastrointestinal and genitourinary tracts that bleed.

IMMUNODEFICIENCY STATES

Acquired Immunodeficiency Syndrome

Oral infections are frequently associated with the human immunodeficiency virus and cause significant disability in affected patients from anorexia, decreased oral intake, weight loss, and malnutrition. Common oral findings are listed in Table 50-3.

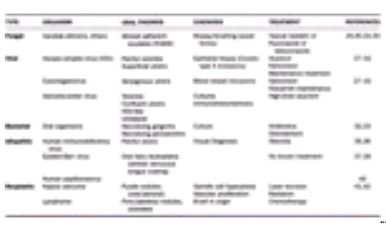

TABLE 50-3 Immunodeficiency States (AIDS)

Graft-versus-Host Disease

Graft-versus-host disease is a significant cause of morbidity in patients who have undergone bone marrow transplantation. It generally occurs within the initial 3 to 4 weeks after transplantation and may present as mucositis, dermatitis, enteritis, and hepatic dysfunction. Chronic graft-versus-host disease often develops in patients with acute graft-versus-host disease and typically presents at 3 months after transplantation. Clinically, patients have symptoms suggestive of sicca complex and scleroderma. Painful oral mucositis and upper gastrointestinal dysmotility may develop, the latter resulting in gastroesophageal reflux and bacterial overgrowth. In addition to more aggressive immunosuppression, patients with graft-versus-host disease require nutritional and fluid support, as well as therapy for any infectious complications.

COLLAGEN VASCULAR DISEASE

Scleroderma is the classic collagen vascular disease associated with oral manifestations. Perioral skin tightening, telangiectases of the lips and tongue, and dysgeusia are common findings. Sclerosis of the esophagus and small intestine may result in the sequelae of reflux disease and malabsorption from bacterial overgrowth, respectively. The sicca complex, characterized by decreased salivary and lacrimal gland secretion, may be seen in numerous connective tissue diseases but is classically associated with rheumatoid arthritis (Sjögren's syndrome). Dental caries, tongue and buccal fissures, and swallowing difficulties may all develop. Based on the presence of serum and salivary antibodies to human T-lymphocyte virus-1 (HTLV-1), this virus has been implicated in the pathogenesis of Sjögren's syndrome. [43] Oral manifestations are not common in dermatomyositis, but oral ulcers, leukoplakia-like lesions, and gingival telangiectases have been reported in association with this disorder. [44]

NUTRITIONAL DEFICIENCIES AND MALABSORPTION

As summarized in Table 50-4, vitamin deficiencies may result in numerous epithelial changes in the oropharynx (Fig. 50-4, Fig. 50-5 and Fig. 50-6). Such deficiencies are usually associated with malabsorption or with inadequate intake in the setting of chronic illness. Rarely, a deficiency stems from competition for normal body stores, such as vitamin B_{12} deficiency in *Diphyllobothrium latum* infestation. The oropharyngeal manifestations of the malabsorptive states depend on the specific nutrient deficiency. A sore mouth (niacin deficiency), cheilitis and glossitis (B vitamin and folate deficiencies), stomatitis and oral ulceration (B vitamin, folate, and niacin deficiencies), and bleeding (vitamin K deficiency) may all develop. White patches on the tongue reflect vitamin A deficiency. The hypermetabolism of tryptophan to serotonin with decreased niacin production can cause pellagra in patients with carcinoid syndrome.

TABLE 50-4 Vitamin/Mineral/Trace Metal Deficiencies

FIGURE 50-4. Angular cheilitis. Inflammation at the angles of the mouth is commonly associated with deficiencies of B vitamins, such as riboflavin (vitamin B_2), niacin (vitamin B_3), and pyridoxine (vitamin B_6). Secondary *Candida* or *Staphylococcus* infection may develop. (From Habif TP. Superficial fungal infections. In: Baxter S, ed. Clinical dermatology: a color guide to diagnosis and therapy, 3rd ed. St. Louis: Mosby, 1996:400.)

FIGURE 50-5. Swollen, inflamed, bleeding gums and poor dentition in a case of scurvy. (From Briggaman R. Clinical nutrition I slide set. Bethesda, MD: American Gastroenterological Association, 2000.)

FIGURE 50-6. Zinc deficiency may present as a scaly, erythematous rash at the angles of the mouth and the nasolabial folds in addition to stomatitis and tongue coating. (From Grossman M. Clinical nutrition I slide set. Bethesda, MD: American Gastroenterological Association, 2000.)

INFLAMMATORY BOWEL STATES

Celiac Disease

Cheilitis, gingivitis, and small vesicular ulcers of the tongue and oral mucosa are seen in celiac sprue. [20] The oral cavity may burn. Numerous small white ulcerations may develop on the dorsum of the tongue, and swelling of the tongue can result in a “strawberry” appearance.

Crohn’s Disease and Ulcerative Colitis

Oral lesions are extremely common in inflammatory bowel disease (IBD), with a prevalence of 4% to 30%, and are more frequently associated with Crohn’s disease than with ulcerative colitis. [45], [46] A prevalence of 0.5% was noted in a tertiary care center specializing in oral dermatology. [47] In addition to extraintestinal inflammation, malabsorption and subsequent malnutrition may develop in IBD secondary to rapid transit, stricture formation, enterocolonic fistulae, severe mucosal loss, and bacterial overgrowth. Deficiencies of folate, iron, vitamin B_{12}, and the fat-soluble vitamins are most common. Trace metal deficiencies may develop in patients with IBD who are on total parenteral nutrition without adequate replacement.

Crohn’s Disease The oral lesions of Crohn’s disease typically reflect active intestinal disease, although they may precede or follow clinically evident intestinal flares. [20] Aphthous linear labial ulcers, pseudopolyps, and labial or buccal swelling have all been reported. [20], [47] The various lesions frequently heal spontaneously but may persist for several years, making it difficult to define a correlation between oral manifestations and intestinal disease activity. [48], [49] Nonetheless, some have proposed that an eruption of aphthous ulcers actually predicts an impending flare of Crohn’s disease. [50] The pathogenesis of aphthous lesions is unclear, but it has been suggested that lymphocytes activated against enterobacterial toxins may release inflammatory mediators; diminished immunoglobulin A secretion may also be involved. [48], [49], [50], [51] and [52] Although not specific for IBD, aphthous ulcers are the most common oral manifestation of Crohn’s disease, seen in up to 20% of patients with this disease. [20] The distinct, shallow white ulcers may occur singly or be widespread throughout the oral cavity (Fig. 50-7). Gingival hyperplasia and nodularity are not uncommon, and a cobblestone pattern may appear on the palate. A cobblestone pattern may also appear on the buccal mucosa when smooth nodules are present. Oral candidiasis has been seen in up to 5% of patients with Crohn’s disease, a feature not found in patients with ulcerative colitis within the same trial. [46] In one trial assessing the treatment of oral lesions in patients with Crohn’s disease, complete remission of the lesions after treatment with systemic steroids or azathioprine was noted in only 50%, whereas topical steroids induced a remission in 58% of cases. [53]

FIGURE 50-7. Aphthous ulcer. Aphthae appear as minute, shallow white ulcers along mucous membranes. Although they may occur in healthy individuals, multiple or persistent lesions suggest an underlying diagnosis such as inflammatory bowel disease or Behçet disease. (From Allison MC. Diagnostic picture tests in gastroenterology. London: Mosby-Wolfe, 1991.)

Ulcerative Colitis Aphthous stomatitis and ulcers may be seen in patients with ulcerative colitis, although ulcers are more typical of Crohn’s disease. Cheilitis may also occur and has been associated with scaling perioral skin and cervical adenopathy. [20], [45] In pyostomatitis, also known as *pyoderma vegetans,* deep pustules may progress to deep ulcers, classically on the lower lip but occasionally also on the buccal mucosa. Like many oral manifestations of IBD, this lesion often develops during a colitis flare and resolves with aggressive IBD management. Although not classically thought of as affecting the oral cavity, pyoderma gangrenosa of the tongue has been reported and is characterized by deep ulceration and necrosis. It has been suggested that all these lesions involve an immunologic reaction, such as circulating antigen-antibody complexes. [20] Unfortunately, many oral manifestations may persist or recur even after total colectomy. Although systemic steroids may relieve these lesions, topical or locally injected steroids sometimes lead to a more rapid and profound resolution.

Behçet Disease

Behçet disease is characterized by orogenital ulceration, ocular manifestations, and arthritis. Common problems include diarrhea, anorexia, bloating, and colorectal ulceration. Oral lesions consist of small or very large aphthous ulcers or herpetiform-like ulcers that tend to involve the palate, pharynx, and esophagus and can cause significant pain and dysphagia. Recurrent oral lesions may be the only manifestation of Behçet disease for several years. [54] Based on the clinical symptoms and appearance of the ulcers, IBD, herpes simplex virus, and Reiter syndrome all must be considered in the differential diagnosis. The oral lesions of Behçet disease are treated with topical steroids, nystatin, and tetracycline. [20] Thalidomide has been suggested as an alternative therapy, with an excellent response rate noted in one early trial. [55]

MISCELLANEOUS DISORDERS

The oral findings and diagnostic considerations in lead poisoning, amyloidosis, and Plummer-Vinson syndrome are listed in Table 50-5.

CHAPTER 51

Edward N. Janoff and Phillip D. Smith

APPROACH TO GASTROINTESTINAL PROBLEMS IN THE IMMUNOCOMPROMISED PATIENT

Gastrointestinal illnesses are an important complication of immunodeficiency diseases and immunosuppressive therapy. Such illnesses may be severe, prolonged, or even fatal, whereas the same illnesses in immunocompetent persons are typically mild and transient. Most, but not all, gastrointestinal illnesses in immunocompromised persons are infections. [1], [2], [3] and [4] During the past 40 years, these infections have received increasing investigative attention, first in adults with hypogammaglobulinemia and children with congenital immunodeficiency syndromes, and then in patients with malignancies or on immunosuppressive drugs. In addition, the spectrum of conditions for which immunosuppressive drugs are used has expanded to include a wide array of autoimmune conditions, rheumatic diseases, malignancies, and organ, bone marrow, and stem cell transplantation. Distinguishing the effects of immunosuppressive drugs from those of infection and graft-versus-host disease has been a major challenge. Most recently, the pandemic caused by human immunodeficiency virus type 1 (HIV-1) has broadened the spectrum of gastrointestinal pathogens associated with immunosuppression and focused attention on effective clinical evaluation and antimicrobial therapy. Thus, although the numbers of immunocompromised hosts and identifiable enteric microorganisms have increased substantially, the efficient recognition and effective treatment of gastrointestinal illnesses and immune dysfunction are now the basis for increased optimism in the evaluation and management of gastrointestinal disease in immunocompromised persons.

The high incidence of gastrointestinal illnesses in immunocompromised patients underscores the fundamental role of systemic and mucosal immunity in host defense. Although these anatomically distinct systems may serve different functions and are composed, in part, of phenotypically and functionally distinct cell populations, systemic immunity and mucosal immunity represent an integrated and dynamic system of host defense. Evidence for the critical role of cellular and humoral defense mechanisms in providing protection against enteric pathogens is the strong association between HIV-1–induced immunosuppression and gastrointestinal infections. An array of other immunocompromising conditions also predispose the gastrointestinal tract to disease. These conditions are classified as primary or secondary (Table 51-1). Primary immunodeficiency disorders, which are uncommon, are caused by congenital defects in the T, B, or phagocytic cells. In contrast, secondary immunodeficiency disorders are more common than primary disorders and are acquired. Identification of the underlying primary or secondary immunodeficiency is important because the relative risk for associated gastrointestinal illness and the spectrum of such illnesses vary with each deficiency (see Table 51-1).

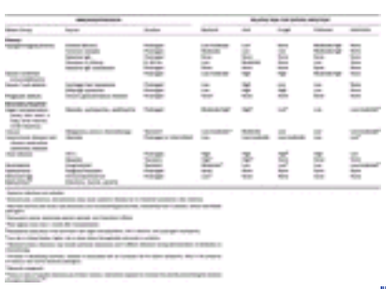

TABLE 51-1 Immunosuppression Disorders and Relative Risk for Enteric Infection

Because the most common gastrointestinal manifestation of immunodeficiency is infection, this chapter focuses on the approach to esophageal and enteric infections in patients with immunocompromising conditions. The first section of the chapter presents the clinical clues that suggest an underlying immunodeficiency in patients with enteric disease. The second section describes the gastrointestinal syndromes associated with immunodeficiency, and the third section reviews the specific pathogens associated with discrete immunologic defects.

EVALUATION OF UNDERLYING IMMUNE DYSFUNCTION ASSOCIATED WITH GASTROINTESTINAL ILLNESS

Clinical and Microbiologic Clues

The clinical history provides some of the most important clues that an underlying immunodeficiency disorder may be the cause of a gastrointestinal illness, particularly an infection. Features of the history that indicate the possibility of an immune disorder are listed in Table 51-2. Foremost among the clinical features is prolonged or severe diarrheal illness. Microbiologic features of the identified pathogen also may indicate a possible underlying immune disorder. Table 51-3 summarizes these features. [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19] and [20] Once a primary or secondary immunodeficiency syndrome is suspected, a simple and sequential diagnostic evaluation of the patient’s immune function and the intestinal syndrome can be initiated.

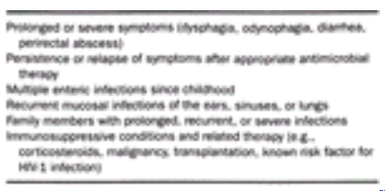

TABLE 51-2 Features of the History that Suggest an Underlying Immunodeficiency Condition

Presence of an opportunistic pathogen
Recurrence of a common enteropathogen (e.g., *Campylobacter jejuni* in children and adults with immunoglobulin deficiencies)
Presence of more than one opportunistic or common enteric pathogen
Persistence of an enteropathogen despite appropriate antimicrobial therapy
Simultaneous systemic and gastrointestinal infection with the same pathogen (e.g., *Streptococcus bovis* in colon cancer patients and *Salmonella* species, *Shigella* species, and *Campylobacter jejuni* in AIDS patients)

TABLE 51-3 Microbiologic Features of Enteric Infections that Suggest an Underlying Immunodeficiency Condition

Initial Evaluation

The physical examination findings, often underappreciated, also may provide information to suggest that an immunologic defect is present. Findings that may be associated with immunocompromising diseases or conditions are listed in Table 51-4. Clinicians should search for these features when an immune deficiency is suspected. After the history has been taken and the physical examination performed, the stool should be examined for enteric pathogens. The protocols for the identification of enteric pathogens in immunocompromised hosts are discussed in the chapters on the specific pathogens and the chapter on the gastrointestinal manifestations of AIDS. The most important tests used to detect pathogens in stool from immunodeficient subjects are listed in Table 51-5. Colonoscopy or esophagogastroduodenoscopy may be helpful for inspecting the mucosa and obtaining tissue for histopathological evaluation.

FINDINGS	IMMUNODEFICIENCY CONDITION
Ataxia, ocular telangiectases	Ataxia-telangiectasia
Facial abnormalities	DiGeorge syndrome
Oral thrush	Neutropenia, cell-mediated immunodeficiency secondary to chronic steroid use, HIV-1 infection, chemotherapy
Oral ulcers	Neutropenia, HIV-1 infection, HIM
Chronic periodontitis	Neutropenia, neutrophil chemotactic defects
Paucity of lymphoid tissues (nodes, tonsils)	X-linked agammaglobulinemia
Edema	Protein-losing enteropathy, nephrotic syndrome
Focal or diffuse adenopathy	HIV-1 infection, lymphoid malignancies, ± CVH, HIM
Splenomegaly	CLL, CML, CGD, ± CVH, early HIV-1 infection, HIM
Seborrheic dermatitis	HIV-1 infection, malnutrition
Petechiae or ecchymoses	Thrombocytopenia with granulocyte leukemias, chronic steroid use
Eczema	Wiskott-Aldrich syndrome, IgA deficiency, hyper-IgE

CGD, chronic granulomatous disease; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CVH, common variable hypogammaglobulinemia; HIM, immunoglobulin deficiency with increased IgM.

TABLE 51-4 Findings on Physical Examination that Suggest the Presence of an Underlying Immunodeficiency Condition

TEST	PATHOGENS
Microscopic evaluation of stool for ova and parasites	*Giardia lamblia*, *Strongyloides stercoralis*, *Entamoeba histolytica*, *Cyclospora*
Culture (stool)	*Campylobacter* species, *Shigella* species, *Salmonella* species, *Aeromonas* species
Culture and/or toxin detection in stool (cytotoxin assay or ELISA for toxin A and B)	*Clostridium difficile*
Acid-fast stain (stool)	*Cryptosporidium*, *Mycobacterium* species, *Isospora belli*, *Cyclospora*
Histology (intestinal tissue)	Cytomegalovirus, herpes simplex virus, fungi, microsporidia
Immunocytochemistry (intestinal tissue)	Cytomegalovirus, herpes simplex virus
Electron microscopy (stool)[223]	Adenovirus, Norwalk virus/calcivirus, astrovirus, microsporidia
Polymerase chain reaction (stool)[223]	Norwalk virus/calicivirus
ELISA (stool)[223]	Rotavirus
Culture (stool)[223]	Adenovirus, rotavirus

*Excluding HIV-1–infected persons.

ELISA, enzyme-linked immunosorbent assay.

TABLE 51-5 Examination of Stool and Intestinal Tissues for Enteric Pathogens in Subjects with Diarrhea and Suspected Immunodeficiency*

Laboratory Analysis

When the history, physical examination, or presence of an unusual enteric pathogen suggests that the patient may be immunocompromised, selected laboratory tests will usually identify the underlying immunologic defect. [21] Although elegant and expensive immunologic tests are available, the laboratory analysis should begin with a complete blood cell count and differential (Table 51-6). The results of this routine test provide important information on the numbers of neutrophils and lymphocytes, particularly the presence of neutropenia and lymphopenia. Certain lymphoid malignancies, such as chronic lymphocytic leukemia, can be efficiently excluded when the number of lymphocytes is not increased. The levels of total serum protein and albumin are helpful in suggesting whether chronic liver disease or hematologic diseases, such as multiple myeloma or hypogammaglobulinemia, may be present. Thereafter, specialized or more complicated immunologic tests are helpful, depending on the suspected underlying immunodeficiency (see Table 51-6).

	ABNORMAL RESULT	IMMUNODEFICIENCY CONDITION
Routine Tests		
Complete blood cell count	Neutropenia	Cyclic neutropenia, chemotherapy, myelodysplasia, drug reaction, HIM
	Neutrophilia	Leukemoid reaction, normal response to infection (especially bacterial), steroids
	Lymphopenia[a]	SCID, HIV-1 infection, malnutrition, lymphoid malignancy, steroids, chemotherapy, ± CVID
	Lymphocytosis	Lymphoid malignancy (e.g., CLL)
	Thrombocytopenia	Wiskott-Aldrich syndrome
Total protein and albumin	Low albumin with high globulins	Chronic liver disease, malnutrition
(Total protein = albumin + γ globulins)	Normal albumin with high globulins	Multiple myeloma, polyclonal gammopathy (including HIV-1, CVID)
	Normal albumin with low globulins	Hypogammaglobulinemia, CLL
Specialized Tests		
Cellular		
Skin testing for delayed-type hypersensitivity (especially to Candida)	No response	Food dysfunction, lack of prior exposure to antigens
Lymphocyte subsets (flow cytometry)		
T cells	Low CD4 with normal-high CD8 percentage and number	HIV-1 infection
	Low CD4 and CD8	Inherited SCID, steroids, DiGeorge syndrome
	Increased with normal CD4/CD8 percentages	Inherited agammaglobulinemia
B cells	Increased number	CLL
	Reduced number	Inherited agammaglobulinemia, inherited SCID, CVID, X-linked immunodeficiency with hyper-IgM (no surface IgD or IgG), selective IgA deficiency
	Normal number	
Humoral		
Serum protein electrophoresis	Normal albumin with increased polyclonal gamma globulins	Polyclonal gammopathy (including HIV-1, CVID, HIV)
	Normal albumin with increased monoclonal gamma globulins	Multiple myeloma, benign monoclonal gammopathy
	Normal albumin with low gamma globulins	Hypogammaglobulinemia
Quantitative immunoglobulins (nephelometry)	Low level of isolated IgA, IgM, or IgG subclass	Selective IgA deficiency, ataxia-telangiectasia (IgA and IgG2)
	All Ig classes low	Hypogammaglobulinemia, CLL
	Increased IgM with low IgG and IgA	HIM
	Low IgM with increase IgG and IgA	Wiskott-Aldrich syndrome
	One Ig class high, others low	Multiple myeloma (IgG or IgA, Waldenström macroglobulinemia (IgM), HIM
	Increased IgA and IgE	Wiskott-Aldrich syndrome, late HIV-1
Specific antibody assays (ELISA)		
Hemagglutinin titers (anti-A, anti-B)	Low	Low IgM from any cause
Response to vaccine antigens and natural (infectious)	Low	Primary immunodeficiency (B and/or T cell)
Response after vaccination (protein and polysaccharide antigens)	Low	Overall B-cell dysfunction
Antipolysaccharide antibodies	Low	Selective unresponsiveness to encapsulated organisms, asplenia (+), IgG2 deficiency
Antibodies to HIV-1 (ELISA, immunoblot)	Positive	HIV-1 infection

*Normal number of total lymphocytes should be age-adjusted in children. Lymphopenia more often detects secure number of T cells.

CMD, chronic granulomatous disease; CLL, chronic lymphocytic leukemia; CVH, common variable hypogammaglobulinemia; ELISA, enzyme-linked immunosorbent assay; HIM, immunoglobulin deficiency with increased IgM; HIV, human immunodeficiency virus; SCID, severe combined immunodeficiency syndrome.

TABLE 51-6 Laboratory Results Suggestive of Potential Immunodeficiency

GASTROINTESTINAL SYNDROMES

Diarrhea

Diarrhea is the prototypical manifestation of intestinal disease in the immunocompromised host. Diarrhea is typically defined as the passage of three or more loose or watery stools per day for more than 2 days. In a healthy population, the vast majority of episodes of infectious diarrhea are acute in onset and self-limited in duration (<2 weeks). Chronic or prolonged diarrhea is defined as lasting 30 days or longer in adults (14 days in children). [22], [23] In the immunocompetent host, prolonged diarrhea is caused predominantly by noninfectious conditions, such as inflammatory bowel disease, celiac sprue, laxative abuse, endocrinopathies, malignancy, short bowel syndrome, eating disorders, functional illness, and surgically induced bacterial overgrowth. [24], [25] and [26] Even when a cause cannot be determined, diarrhea that lasts longer than 30 days in immunocompetent persons resolves spontaneously in most cases. [27] In contrast, in immunocompromised persons, an array of infectious pathogens are the most common cause of diarrheal illness; these are listed in Table 51-7.

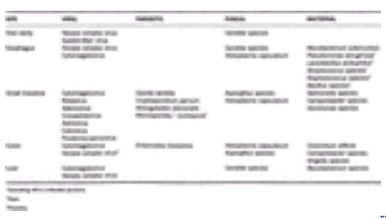

TABLE 51-7 Gastrointestinal Pathogens in Immunocompromised Subjects*

The presence of diarrhea in close contacts, such as family members, household contacts, sexual partners, or community members, suggests that the illness is caused by an environmentally acquired pathogen rather than an underlying immunodeficiency. For example, in 1986, an outbreak of prolonged diarrhea in otherwise healthy persons occurred in Brainerd, Minnesota. [28] No cause of the diarrhea could be determined in this and several similar outbreaks, referred to as *Brainerd diarrhea,* nor was immunodeficiency implicated as a predisposing factor. [23] In other outbreaks, epidemiologic evaluation resulted in the identification of a common pathogen. In this regard, the broad community involvement in outbreaks of diarrheal illness induced by *Cyclospora* [29], [30], [31], [32] and [33] and *Cryptosporidium* [34] did not support immunodeficiency as a factor in the vast majority of symptomatic patients. However, symptoms were more severe and persisted longer in the subset of individuals who were immunosuppressed. Thus, broad community exposure to certain pathogens may uncover underlying immunodeficiency in selected individuals. Similarly, although persistent diarrhea may develop in a small minority of travelers after their return, [35] chronic diarrhea may develop in immunocompromised persons after exposure to microorganisms such as *Cryptosporidium* during their travels.

Clinical clues also help distinguish diarrhea in persons with underlying immunodeficiency from diarrhea in otherwise healthy hosts. In the immunocompromised patient, diarrheal illness is frequently prolonged or recurrent and often quite severe, whereas in the immunocompetent host, it is typically self-limited and mild. In some patients, prolonged diarrhea is the initial clue suggesting the presence of an immunodeficiency disorder, such as HIV-1 infection. Chronic diarrheal illness in immunocompromised patients may be associated with vomiting and abdominal pain. For example, vomiting and abdominal cramps in bone marrow transplant recipients with diarrhea often predicts an infectious enteritis. [36] Other symptoms that may accompany diarrhea in an immunocompromised person include anorexia, nausea, vomiting, gastrointestinal bleeding, fever, weight loss, dehydration, and malnutrition. Bloody diarrhea with fever, although uncommon in the immunocompromised host, should suggest the possibility of cytomegalovirus (CMV) infection when cell-mediated immunodeficiency is present. [37], [38] and [39] Although bloody diarrhea is uncommon in persons with intact immune function, the leading cause of such diarrhea in immunocompetent persons is *Escherichia coli* O157:H7 infection, which appears not to occur with greater frequency in immunocompromised persons. [40] Children are particularly susceptible to the dehydration and malnutrition that accompany prolonged or severe diarrhea. Diarrhea that is associated with recurrent sinopulmonary, skin, oral, or blood infections is strong clinical evidence of an underlying primary immune deficiency. Another important clue that suggests the presence of an underlying immunodeficiency condition is persistence or relapse after appropriate antimicrobial therapy. Whereas the immunocompetent host usually clears an appropriately treated enteric illness, immunocompromised patients frequently experience recurrence of symptomatic infection despite therapy. Thus, recurrent *Giardia lamblia*–associated diarrhea after appropriate antimicrobial therapy suggests the possibility of underlying hypogammaglobulinemia. [41] Recurrent infections with *Salmonella* species, *Shigella* species, and *Campylobacter jejuni,* which are rare in immunocompetent persons, should suggest immunosuppression secondary to HIV-1 infection. [9], [10], [11], [12] and [13], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28] and [29]

Chronic diarrhea greatly diminishes a person's sense of well-being and interferes with the activities of daily living, social interactions, and work. In HIV-1–infected patients, the presence of two loose or watery stools per day for at least 1 month is predictive of a marked reduction in the quality of life. [42] Infectious gastrointestinal disease in immunocompromised patients also may be associated with shortened survival. For example, the mortality rate of bone marrow transplant recipients with infectious gastroenteritis is fourfold higher than that of uninfected patients. [36] Among liver transplant recipients, CMV disease involving any organ is associated with a fourfold increase in the relative risk for death within 1 year after transplantation. [43] However, because gastrointestinal disease in immunocompromised persons is in itself rarely fatal, the associated shortened survival likely reflects the severity and consequences of immune dysfunction, such as associated bacterial and fungal sepsis. [44], [45], [46] and [47] Similarly, HIV-1–infected infants have an 11-fold increased risk for death from diarrhea, which is usually persistent and often preceded by recurrent episodes of acute diarrheal illness. [48] In HIV-1–infected adults, CMV infection of the colon can lead to necrotizing colitis, perforation, and death. [49], [50], [51] and [52] Of note, most infections related to HIV-1 and the acquired immunodeficiency syndrome (AIDS), including CMV and *Cryptosporidium* infections and nonspecific chronic diarrhea, have decreased dramatically in the United States and Europe since the introduction of highly active antiretroviral therapy (HAART). [53], [54] and [55] Drug-related side effects of HAART are now among the most common causes of enteric symptoms in this population (reviewed in ref. [53]).

Oropharyngeal and Esophageal Symptoms

In the immunosuppressed patient, discomfort, pain, and burning sensations in the oral cavity are important symptoms of oropharyngeal opportunistic infections. The most common pathogens causing such symptoms are *Candida albicans,* herpes simplex virus (HSV), and Epstein-Barr virus (EBV). *C albicans* causes (1) pseudomembranous, exudative plaques (thrush) on any oral tissue; (2) erythematous, atrophic lesions on the palate and tongue; (3) adherent hyperplastic lesions (hypertrophic candidiasis); and (4) erythematous fissures at the corners of the mouth (angular cheilitis). [56] These lesions are easily distinguished from HSV vesicular gingivostomatitis [57], [58] and EBV hairy leukoplakia (unilateral or bilateral adherent, white or gray patches on the lateral margins of the tongue and less commonly other regions of the tongue). [59] These oropharyngeal infections are associated with a spectrum of immunosuppressive states and disorders, notably chemotherapy, AIDS, and malignancy.

Dysphagia and odynophagia in the immunocompetent person are usually caused by acid peptic disease, malignancy, or neuromuscular disease. However, in the immunocompromised patient, dysphagia and odynophagia most often indicate the presence of an esophageal infection. Either of these symptoms, frequently both, affects the majority of patients with infectious esophagitis secondary to *Candida* species, HSV, CMV, *Mycobacterium* species, and HIV-1. [60], [61] and [62] Neither dysphagia nor odynophagia, however, is specifically associated with a particular infection [8], [63]; therefore, these symptoms cannot be used to differentiate one esophageal infection from another. In addition, retrosternal chest pain may accompany infectious esophagitis in immunocompromised persons, but this symptom is also nonspecific.

In the immunocompromised patient with dysphagia or odynophagia, the presence of oropharyngeal thrush or HSV gingivostomatis suggests the presence of *Candida* or HSV esophagitis, respectively. In four series of HIV-1–infected patients, between 71% and 100% of those with thrush had *Candida* esophagitis. [64], [65], [66] and [67] In the largest series, which consisted of 110 patients, the presence of thrush had a sensitivity of 53% and a positive predictive value of 77% for *Candida* esophagitis. [67] However, symptomatic infection of the two sites can occur independently. Symptomatic HSV infection of the oropharynx, presenting as either vesicular lesions or ulcerative gingivostomatitis, [68], [69] has been reported in 29% of patients with HSV esophagitis. [60] Heartburn may accompany infectious esophagitis but is less frequent and should suggest gastroesophageal reflux disease. Thus, because symptomatic infectious esophagitis occurs rarely in immunocompetent persons with normal

esophageal structure and function, [70], [71], [72], [73] and [74] the development of infectious esophagitis in a previously healthy subject is strong clinical evidence that an underlying immunodeficiency condition is likely and that the patient should undergo an immunologic evaluation. An exception to the association between infectious esophagitis and an immunodeficiency disorder is the presence of *Candida* esophagitis in persons with severe insulin-dependent diabetes mellitus, which may reflect hyperglycemia-induced phagocyte dysfunction. [75] Infectious esophagitis in the immunocompromised patient also may be accompanied by nonspecific gastrointestinal symptoms, such as nausea and vomiting. [60] These symptoms occur far more commonly in patients with CMV and HSV esophagitis than in those with fungal or bacterial esophagitis. [60], [76] An additional clue that the esophagitis may be caused by CMV is an association of abdominal pain and diarrhea with the esophageal symptoms. [60], [76], [77] When dysphagia or odynophagia occurs in an immunocompromised patient with cough, fever, and weight loss, esophagitis secondary to mycobacterial infection should be considered. [78], [79] and [80] Food aversion and weight loss may accompany prolonged esophageal symptoms, particularly in cases of CMV and mycobacterial esophagitis, which are less responsive to therapy than *Candida* and HSV esophagitis.

Gastrointestinal Bleeding

Gastrointestinal bleeding occurs infrequently in immunocompromised patients. The most common cause of esophageal bleeding in such patients is HSV-induced mucosal ulceration. In a review of 100 HIV-1–infected patients with esophageal disease, 6% of the patients experienced esophageal bleeding, which in the majority of patients was caused by HSV-induced mucosal ulceration. [61] Up to 30% of immunocompromised patients with HSV esophagitis are reported to have esophageal bleeding. [81] Typically, bleeding from HSV esophagitis is slow and limited, but massive bleeding has been reported. [82] Rarely, bleeding secondary to HSV esophagitis may occur in the absence of esophageal symptoms. [83] Esophageal bleeding presenting as hematemesis has been reported in patients with esophagitis caused by CMV, [83], [84] but bleeding secondary to CMV esophagitis is rare, at least in patients with AIDS. [61], [62], [77] Although pathogens other than CMV, HSV, and *Mycobacterium* species seldom cause esophagitis in immunocompromised patients (see Table 51-7), *C albicans* has been reported to cause esophageal bleeding, albeit rarely. [85], [86]

Intestinal bleeding in an immunocompromised patient should alert the physician to the possibility of infectious enteritis or colitis. Similar to esophageal bleeding, intestinal bleeding in immunocompromised persons occurs infrequently. However, in contrast to esophageal bleeding, which is most commonly caused by HSV, intestinal bleeding in immunocompromised persons, such as patients with AIDS, is more commonly caused by CMV. [49], [87], [88] Bleeding from CMV-induced intestinal ulcerations is typically slow and rarely severe. [89] In a prospective study of 44 HIV-1–infected patients with CMV colitis, bleeding occurred in 10% of them. [88] Similarly, among ten heart and heart-lung transplant recipients with CMV gastrointestinal disease, two patients had endoscopically detected gastric bleeding and another had intractable colonic hemorrhage. [90] In solid organ transplant recipients, the highest risk for the development of significant CMV-induced complications occurs between the fourth and twelfth weeks after transplantation, especially in those who receive organs from CMV-seropositive donors. [91], [92] The possibility that intestinal bleeding in an immunocompromised person is caused by CMV is increased when diarrhea, abdominal pain, and fever accompany the bleeding. In the immunocompromised patient who is neutropenic, bloody diarrhea should raise the possibility of typhlitis or necrotizing enterocolitis. [93], [94] and [95]

Abdominal Pain

Abdominal pain frequently accompanies intestinal and colonic infections, particularly when intense mucosal inflammation is present. However, abdominal pain is nonspecific and is not helpful in distinguishing one type of enteric infection from another. Like other clinical manifestations of infection, abdominal pain may be diminished in immunosuppressed patients receiving cytotoxic or corticosteroid agents. Immunosuppressed patients are susceptible to the same common causes of abdominal pain as immunocompetent persons, including peptic ulcer disease, biliary tract disease, appendicitis, pancreatitis, diverticulitis, and inflammatory bowel disease. As summarized in Table 51-8, immunocompromised patients also experience abdominal pain as a result of immunosuppression-associated processes, including CMV disease, perforation secondary to neoplasm or infection, typhlitis, cholecystitis caused by opportunistic pathogens, chemotherapy-induced bleeding, pancreatitis caused by certain drugs, hepatosplenic candidiasis, and tissue infiltration by tumor or lymphoma. In the setting of compromised host defense mechanisms, these processes can progress more rapidly to a medical catastrophe than they can in immunocompetent persons, which underscores the importance of early diagnosis and therapy.

IMMUNOCOMPETENT AND IMMUNOCOMPROMISED	IMMUNOCOMPROMISED ONLY
Peptic ulcer disease	Cytomegalovirus disease
Biliary tract disease	Colonic perforation caused by cytomegalovirus, *Candida* species, *Histoplasma capsulatum*, lymphoma
Appendicitis	Typhlitis
Pancreatitis	Cholecystitis caused by cytomegalovirus, *Cryptosporidium parvum*, *Isospora belli*, *Microsporidium* species, *Pneumocystis carinii*
Diverticulitis	Bleeding secondary to cytotoxic drug-induced thrombocytopenia
Inflammatory bowel disease	Pancreatitis caused by immunosuppressive and antiviral drugs
Colonic perforation	Graft-versus-host disease
	Hepatosplenic candidiasis
	Tissue infiltration by tumor or lymphoma
	Venoocclusive liver disease

TABLE 51-8 Causes of Abdominal Pain in the Immunocompromised Host

Enteric disease caused by CMV is frequently accompanied by abdominal pain in immunocompromised patients, particularly HIV-1–infected patients and transplant recipients. Such pain is often described as constant, intense cramping in the lower quadrants [49], [90] and differs in quality from the pain associated with biliary tract disease and intestinal obstruction, which typically fluctuates in intensity. Severe epigastric pain from CMV pancreatitis has been reported in HIV-1–infected patients. [96] When abdominal pain in a patient with HIV-1 infection suddenly increases, CMV-induced perforation of the colon or distal small intestine should be included in the differential diagnosis. [50], [97], [98] Other causes of perforation in immunocompromised persons include diverticular disease, [99] lymphoma, [100], [101], [102], [103] and [104] and, rarely, *Candida* species [103], [104] and *Histoplasma capsulatum* infections. [105] Typhlitis or necrotizing enterocolitis, as discussed below, should also be included in the differential diagnosis of right lower abdominal pain in neutropenic patients. [106]

Cholecystitis and cholangitis occur in immunocompromised patients secondary to cholelithiasis and the same gram-negative pathogens that cause biliary tract disease in immunocompetent persons. However, in HIV-1–infected patients, these conditions, as well as sclerosing cholangitis and papillary stenosis, are also associated with biliary tract infection by *Cryptosporidium,* CMV, *Enterocytozoon bieneusi, Septata intestinalis, Isospora belli,* and *Pneumocyctis carinii*. [107], [108], [109], [110] and [111] The presence of thrombocytopenia expands the differential diagnosis of abdominal pain in the immunocompromised patient because platelet counts below 20,000/mm ^{3} can cause bleeding into the intestinal wall, retroperitoneum, or abdominal wall. [112], [113] Drug-induced pancreatitis should be considered in immunosuppressed patients on L-asparaginase, the antiretroviral agent didanosine, or corticosteroids. HIV-1 protease inhibitors may be associated with renal stones and secondary abdominal pain. Hepatosplenic candidiasis occurs when the liver is seeded with *Candida* species during disseminated candidiasis in neutropenic patients, usually as a result of therapy for acute leukemia or lymphoma. [114] Typically, patients have right upper quadrant pain and tenderness accompanied by nausea and fever. Venoocclusive disease of the liver is an important consideration when a patient presents within 20 days after bone marrow transplantation with right upper quadrant pain, tenderness, hepatomegaly, hyperbilirubinemia, and sudden weight gain secondary to ascites. [115], [116] and [117] High-dose cytoreductive therapy and underlying liver disease increase the risk for the development of severe veno-occlusive disease, which is reported to occur in 15% of marrow transplant patients. [117]

Anorectal and Perianal Disease

Anorectal disease is one of the most important gastrointestinal complications of immunosuppression, affecting 5% to 7% of neutropenic patients with leukemia or lymphoma. [118], [119] The importance of this complication is underscored by the devastating morbidity and high level of mortality in unrecognized and inappropriately treated cases of anorectal disease in immunocompromised patients. The various manifestations of anorectal disease in neutropenic patients include abscess, fissure,

fistula, and infected hemorrhoids. Typically, lesions present as perianal pain, tenderness, induration, and fever, usually without fluctuation or purulence. Extensive tissue necrosis and breakdown have been reported in many patients. [118] Frequent clinical evaluation is mandatory because lesions can progress rapidly, causing urinary retention and peritonitis, and fascial extension to the genitalia is possible. [118] Culture of material obtained from the lesions by either surgical drainage or needle aspiration usually yields multiple bacteria, with anaerobes the most common organisms. [118], [119] and [120] The high rates of recurrence (12%) and mortality (18%) associated with perianal disease in neutropenic patients managed nonoperatively emphasize the importance of surgical drainage. [119] Unless drainage occurs spontaneously, early operative incision, drainage, and debridement have been associated with prompt clinical improvement and increased survival. [118], [119], [121], [122] and [123] One group, however, has achieved control of anorectal infections in 88% of neutropenic patients with an antibiotic regimen that includes both an aminoglycoside and an agent with anaerobic coverage. [120] Thus, a reasonable approach to the management of anorectal disease in neutropenic patients is to institute immediately a trial of antibiotic treatment with an aminoglycoside and an antibiotic having specific activity against anaerobes during the initial medical and surgical evaluation. When fluctuation, necrosis, local progression of infection, or continued fever is present or when an abscess fails to drain spontaneously, the lesion should be promptly incised, drained, and debrided.

Perianal ulcerative disease can be an incapacitating problem in patients with cell-mediated immunodeficiency. In most patients, this problem is caused by HSV infection, which typically begins as small vesicular eruptions that coalesce and progress to frank ulceration. [124] The lesions are painful and macerated, and they may become secondarily infected. Ulcerative perianal lesions caused by HSV were among the infectious processes that heralded the emergence of AIDS. [125] The infection generally responds to acyclovir, but long-term therapy is often necessary. [126]

SPECIFIC IMMUNODEFICIENCY SYNDROMES AND PATHOGENS

Spectrum of Infections

The risk for acquiring a specific enteric pathogen and the type of pathogen acquired are directly related to the type of immune defect (see Table 51-1). The severity and duration of the immune defect also influence host susceptibility to enteric infections. These infections, which involve predominantly the esophagus, small intestine, and colon and less frequently the liver and oral cavity, are caused by the viral, parasitic, fungal, and bacterial pathogens listed in Table 51-7. Traditionally, infectious agents are regarded as opportunistic pathogens when they consistently cause severe, chronic, or frequent gastrointestinal disease in immunocompromised but not immunocompetent persons, and as nonopportunistic pathogens when they cause treatable infections in immunocompetent and immunocompromised persons. However, because many nonopportunistic pathogens, such as *Salmonella* species, *Shigella* species, and *C jejuni,* cause persistent or recurrent infection in immunocompromised persons, the distinction is not particularly helpful in assessing gastrointestinal infections in this population.

Three pathogens, *G lamblia, Cyclospora cayetanensis,* and *Clostridium difficile,* are noteworthy because they can cause prolonged diarrhea in immunocompetent as well as immunosuppressed persons, and they therefore do not necessarily suggest the presence of an immunodeficiency. Infection with the protozoan *G lamblia* is most often associated with diarrhea, abdominal cramps, bloating, flatulence, and weight loss. A history of exposure to mountain, lake, or stream water, close contact with children in day care centers, or recent travel is common. *G lamblia* also is associated with hypogammaglobulinemia (see below). *Cyclospora,* another protozoan parasite, causes prolonged diarrhea in immunocompetent persons and is endemic in Peru [30], Nepal, and the Caribbean. [29], [127], [128] *Cyclospora* is associated with prolonged diarrhea in AIDS patients. Patients with *C difficile* infection nearly always have a history of recent treatment with antibiotics or chemotherapy, particularly older or hospitalized patients. Although treatment with metronidazole is effective in more than 90% of cases, up to 15% of immunocompetent patients relapse and require repeated treatment, particularly if the inciting antimicrobial agents are continued. [129] In contrast, high rates of relapse with *Salmonella* species and *Shigella* species are indicative of an impaired immunologic response, as in HIV-1–infected persons. [130] Relapse of *C jejuni* infection also occurs in HIV-1–infected patients and patients with hypogammaglobulinemia. [5], [6] and [7], [131] Other bacterial, viral, and parasitic infections rarely cause chronic diarrhea in immunocompetent persons.

In the esophagus, the most commonly identified pathogens in immunocompromised persons are *C albicans,* HSV, and CMV. Two or more pathogens are often present, as has been reported in 20% of HIV-1–infected patients with symptomatic esophagitis. [8] Much less common causes of infectious esophagitis in immunocompromised patients are certain bacteria, [132] including *Mycobacterium tuberculosis,* [133], [134] *Streptococcus* species, [135] and *Lactobacillus acidophilus.* [136] Bacterial esophagitis has been described in bone marrow transplant recipients and in patients with hematologic malignancies, neutropenia, and HIV-1 infection and can be an infrequent source of occult sepsis. Esophagitis caused by *Cryptosporidium* species, [137] *Leishmania* species, [138] and *H capsulatum* [139] has been reported in HIV-1–infected persons but is rare. Fortunately, this persistent pathogen can be treated effectively.

Specific Syndromes

Hypogammaglobulinemia Common variable hypogammaglobulinemia (CVH), also referred to as *common variable immunodeficiency,* represents a group of uncommon (<1 per 100,000 population) disorders usually inherited in an autosomal manner. CVH is characterized by the inability of B cells to differentiate normally into immunoglobulin-secreting cells, which results in a marked reduction in the levels of IgG, IgM, and IgA and immunologic abnormalities that include autoimmune conditions and lymphoproliferative disorders. [140] Recurrent sinopulmonary infections far outnumber intestinal infections in persons with CVH. Atrophic gastritis with achlorhydria may predispose to enteric disease, often with malabsorption. Unlike congenital X-linked agammaglobulinemia, CVH typically manifests during the second or third decade, occurs equally often in men and women, and is infrequently associated with severe enteroviral infections. Among patients with CVH, *G lamblia* infection is the most common cause of symptomatic diarrheal illness. [41], [141] The parasite is identified in up to 90% of hypogammaglobulinemic subjects with chronic diarrhea, but in only 10% of those without diarrhea. [41] Infection with *C jejuni* and *Salmonella* species and bacterial overgrowth are also causes of recurrent diarrheal illness in patients with CVH. Children with hypogammaglobulinemia and chronic diarrhea also have a higher incidence of intestinal infections with *G lamblia, C jejuni, C difficile,* and rotavirus. [5], [142] Importantly, increased rates of *G lamblia* infection are not associated with selective IgA deficiency [41], [141] or cell-mediated immune deficiencies, including AIDS. [143], [144] and [145] The relapse rate for giardiasis after antimicrobial therapy is approximately 15% in both immunocompetent subjects and patients with AIDS, [143] which contrasts with the substantially higher relapse rate in hypogammaglobulinemic subjects. [146] Chronic giardiasis also occurs commonly in patients with nodular lymphoid hyperplasia of the small intestine and immunoglobulin deficiency. [147], [148] and [149] *G lamblia*–associated diarrhea in hypogammaglobulinemic patients is prolonged, with one reported case lasting 10 years, [150] and is often accompanied by malaise, nausea, anorexia, weight loss, and steatorrhea. Thus, prolonged infection with *G lamblia,* the presence of *G lamblia* and other enteric bacterial pathogens or rotavirus, and recurrent giardiasis after antimicrobial therapy should suggest the possibility of underlying hypogammaglobulinemia. Selective IgA deficiency is the most common disorder of immunoglobulin production, affecting between 1 per 500 and 1 per 1000 population, but associated intestinal disease is uncommon. X-linked agammaglobulinemia is the most severe immunoglobulin disorder. Children with this B-cell deficiency experience very high rates of chronic *G lamblia* infection as well as devastating systemic manifestations of chronic enteroviral infections. The latter include enteroviral meningoencephalitis and paralytic poliomyelitis following either natural infection or oral immunization with live vaccine. Among the fewer than 150 cases of immunoglobulin deficiency with hyper-IgM, up to half experience chronic diarrhea, in part related to *Giardia* and *Cryptosporidium* infection. [151] Patients with selective IgG subclass deficiencies, particularly decreased IgG2, often show impaired responses to polysaccharide antigens and an increase in sinopulmonary infections and disease but no appreciable predisposition to intestinal infections.

Transplantation-Associated Gastrointestinal Illness Gastrointestinal disease is an important cause of morbidity and mortality in recipients of bone marrow and solid organ (kidney, liver, heart, lung) transplants. Marrow transplant recipients experience more frequent and more severe gastrointestinal disease than do solid organ recipients. This difference is mainly a consequence of the more profound neutropenia and cell-mediated immune deficiency and the occurrence of graft versus host disease in marrow recipients. In the largest study to date of the incidence, etiology, and outcome of diarrheal illness after marrow transplantation, 43% of 126 transplant recipients experienced an acute diarrheal illness. [152] Graft-versus-host disease accounted for 48% of the diarrheal illnesses, whereas intestinal infections with astrovirus, adenovirus, CMV, rotavirus, *C difficile,* or *Aeromonas* accounted for 13% of the illnesses; no cause could be identified in 39% of the cases. Acute graft-versus-host disease usually begins 3 to 4 weeks after transplantation and presents as anorexia, nausea, vomiting, watery diarrhea and abdominal pain, and gastrointestinal bleeding. [153], [154] The latter may involve the esophagus, stomach, and small intestine and is usually caused by CMV infection and vascular ectasias (stomach). [155] When rash and jaundice are also present, graft-versus-host disease is likely. However, because the gastrointestinal symptoms are nonspecific, the diagnosis of acute graft-versus-host disease is confirmed by histological examination of endoscopically obtained biopsy samples, which typically show single-cell apoptosis of the epithelium, crypt distortion and abscesses, and a periglandular infiltrate. [156], [157] Chronic graft-versus-host disease typically occurs 3 to 12 months after marrow transplantation. The major gastrointestinal manifestations of chronic graft-versus-host disease include mucositis of the oral cavity, dysphagia secondary to esophageal desquamation and stricture, and small bowel dysmotility associated with bacterial overgrowth. [158], [159] and [160] In contrast to marrow recipients, solid organ recipients experience gastrointestinal complications predominantly secondary to infections. Among lung transplant recipients, for example, operative and nonoperative gastrointestinal complications developed in 51%. [161] The nonoperative complications included esophagitis, gastritis, colitis, enteritis, peptic ulcer disease, gastrointestinal bleeding, cholecystitis, diverticulitis, and Ogilvie syndrome; 65% of these processes were caused by infections, excluding cholecystitis and diverticulitis. The frequency and severity of infections diagnosed in transplant recipients vary considerably, depending on the factors listed in Table 51-9. As

previously stated, the enteric infections of bone marrow transplant recipients are more frequent and more severe than those of solid organ transplant recipients. The length of time since the transplant operation is closely related to the development of gastrointestinal complications. [152], [161], [162] During the first month after transplantation, marrow recipients are vulnerable to fungal and bacterial infections as a consequence of cytoreductive therapy, whereas during the same period, organ recipients are more susceptible to the complications of surgery and surgery-related procedures. One month after marrow transplantation, acute graft-versus-host disease should be included in the differential diagnosis of diarrhea, as discussed previously. Between 1 and 6 months after transplantation, both marrow and solid organ recipients are highly susceptible to gastrointestinal infections caused by viruses, including CMV, adenovirus, HSV, varicella-zoster virus, and rotavirus (children); fungi, such as *Candida* species and *H capsulatum* [163], [164]; bacteria, particularly *C difficile*; and less commonly parasites, such as *Cryptosporidium*. [165], [166] and [167] CMV disease is an important complication of transplantation, affecting up to 25% of organ transplant recipients [47], [91], [92]; it causes major gastrointestinal morbidity [90] and is associated with a marked increase in mortality among transplant recipients. [43] The presence of graft-versus-host disease in marrow transplant recipients also significantly increases the risk for CMV disease. [168] After 6 months, gastrointestinal manifestations of chronic graft-versus-host disease may develop in marrow and organ transplant recipients. The susceptibility to an array of enteric pathogens also increases after 6 months (see Table 51-7). In addition, marrow and organ transplant recipients are susceptible to the gastrointestinal complications of chemotherapy and radiation therapy and to typhlitis.

Type of transplantation
Time since transplantation
Prevalence of potential pathogens in the environment
Prevalence of latent infections in the donor and host before transplantation
Level of immunosuppression
Availability of diagnostic tests
Rigor of diagnostic evalution for enteric pathogens

TABLE 51-9 Factors that Influence the Development and Management of Gastrointestinal Infections in Transplant Recipients

Pathogens that are endemic in certain regions may be more common in transplant recipients. For example, *Strongyloides stercoralis,* which is more prevalent in the southeastern part of the United States, has been reported in renal transplant recipients in that region. [169], [170] Similarly, *H capsulatum* infections are more common in transplant recipients in the midwestern and southeastern parts of the United States. Although amebiasis and malaria are common in immunocompetent persons in the tropics, *Entamoeba histolytica* and *Plasmodium falciparum* infections do not appear to be more common in organ (renal) transplant recipients in the same region. [171] In addition, the prevalence of latent infections in the donor and host before transplantation strongly influences the development of infection by the same pathogen after transplantation. For example, among marrow and liver transplant recipients, the rates of symptomatic CMV infection are highest when the donor is seropositive and lowest when both the donor and recipient are seronegative. [172], [173] and [174] The relative risk for death 1 year after transplantation is affected by the presence of latent CMV infection. One year after liver transplantation, the relative risk for death was highest (4.56) when the donor was seropositive for CMV and the recipient seronegative. [43] In addition, the more profound the immunosuppression, as in marrow transplant recipients, the more severe the infections. The rate of infectious complications is also affected by the type of immunosuppressive regimen. Compared with heart transplant recipients who received conventional immunosuppressive therapy, recipients who received cyclosporine had lower rates of complications and morbidity from CMV and HSV infection. [91] Finally, the availability of diagnostic tests and the rigor with which patients are evaluated for the presence of enteric pathogens strongly influence the detection of gastrointestinal pathogens in immunocompromised patients.

Neutropenia A reduction in the absolute number of circulating neutrophils to less than 1000/mm [3] is associated with increased susceptibility to infections. When the level of neutrophils declines to less than 500/mm [3], the normal host defense against endogenous gastrointestinal flora is substantially impaired. Neutropenic patients are far more likely to present with fever and sepsis caused by gram-negative bacteria and with fungemia than with primary gastrointestinal syndromes. Importantly, the intestinal flora is the source of most cases of bacteremia in neutropenic patients. [175], [176] Because the risk for the development of bacteremia in neutropenic patients colonized with potential gram-negative bacterial pathogens is 17- to 174-fold greater than the risk in noncolonized patients, some clinicians advocate surveillance cultures of mucosal and other surfaces. [175] Three gastrointestinal syndromes may complicate neutropenia: oral infections, anorectal infections, and typhlitis. The oral manifestations of neutropenia include gingivitis, periodontitis, and oral ulcers. These complications occur most commonly when the neutrophil count declines below 500/mm [3]. [177], [178], [179], [180] and [181] Anorectal disease is an important and life-threatening complication of neutropenia and has been discussed previously. Typhlitis, an important cause of abdominal pain in neutropenic patients, is discussed next.

Typhlitis Typhlitis, also referred to as *necrotizing enterocolitis, neutropenic enterocolitis,* and the *ileocecal syndrome,* is an infrequent complication of chemotherapy-induced neutropenia in patients with leukemia or lymphoma. [93], [94] and [95], [106], [182], [183] In a minority of cases, the neutropenia is caused by the hematologic disease itself, such as aplastic anemia or multiple myeloma. A clinical condition consistent with typhlitis also has been reported in HIV-1–infected patients, except that neutropenia may be absent. [184], [185] Typically, patients with typhlitis present with right lower quadrant pain, diarrhea, lower gastrointestinal bleeding, and fever. Typhlitis has been associated with *Clostridium septicum* sepsis in several cases, [93], [94], [186] suggesting that local infection with this gas gangrene–producing bacterium may be involved in the pathogenesis of the syndrome in some patients. The syndrome should be recognized early because the characteristic cecal inflammation may progress to life-threatening necrosis and perforation, in which case surgical intervention is imperative. [187], [188], [189] and [190] However, some patients with typhlitis, particularly those with HIV-1 infection, have been managed conservatively with broad-spectrum antibiotics, bowel rest, fluids, and close radiographic and computed tomographic monitoring. [185]

***Candida* Diarrhea** *Candida* species are present in the gastrointestinal tract of most immunocompetent adults, and elderly persons appear to harbor more *Candida* species than younger persons. [191], [192] In the vast majority of such individuals, the fungus is a nonpathogenic commensal. Although pathogenic gastrointestinal candidiasis was previously thought to be associated exclusively with the mycelial phase of the organism, [193] accumulating clinical evidence suggests that the yeast phase may be associated with a diarrheal illness in certain clinical settings. [194], [195], [196], [197], [198], [199] and [200] Patients with *Candida*-associated diarrhea are usually elderly, malnourished, and either critically or chronically ill and do not have other detectable enteric pathogens. The diarrhea is typically prolonged, of the secretory type (volumes often exceed 2 L/d), nonbloody, nonmucoid, and without accompanying symptoms of fever, nausea, or vomiting. [200] Many patients with *Candida*-associated diarrhea have a history of treatment with multiple antibiotics or chemotherapy. Tetracycline therapy in particular is associated with high rates of gastrointestinal colonization with *Candida,* but colonization in this setting is not consistently associated with diarrheal illness. In patients with *Candida*-associated diarrhea and no other detectable pathogens, nystatin or fluconazole therapy may be associated with clearing of the *Candida* and usually, but not invariably, resolution of symptoms. [197], [200], [201]

Small Bowel Bacterial Overgrowth In healthy immunocompetent persons, proximal small intestine fluid usually contains 10 [4] bacteria per milliliter or less; these are predominantly gram-positive aerobes and are similar to the microflora of the stomach and oral cavity. [202], [203] and [204] The presence of small bowel bacterial overgrowth, defined as more than 10 [4] predominantly gram-negative anaerobes of colonic origin per milliliter of small bowel fluid, is a well-recognized complication of small intestinal anatomic abnormalities, motility disorders, reduced acid secretion, and chronic pancreatitis and cirrhosis. [205] Small bowel bacterial overgrowth also has been reported in two populations of immunocompromised or potentially immunocompromised hosts: persons with hypogammaglobulinemia and the elderly. Studies performed before the widespread availability of sophisticated microbiologic techniques showed that some patients with hypogammaglobulinemia were affected with small bowel bacterial overgrowth. [206], [207], [208], [209], [210] and [211] Among such patients, however, the diagnosis of bacterial overgrowth was confounded by several factors: clinical conditions (e.g., achlorhydria and anatomic abnormalities) associated with excessive numbers of bacteria in the proximal small intestine, [209], [210] variations in the rigor with which fluids were anaerobically collected, [206], [207] and [208] and a definition of bacterial overgrowth based on excessive numbers of oral cavity–type bacteria in some cases. [210] Selective IgA deficiency appears not to be associated with bacterial overgrowth by colonic anaerobes. [209], [210] and [211] Among elderly subjects, small bowel bacterial overgrowth with colonic-type bacteria has been detected in 10% of subjects 50 to 74 years of age and in 64% of subjects older than 75 years of age with chronic diarrhea, anorexia, or nausea and no predisposing condition. [212] Malabsorption and undernutrition attributed to small bowel bacterial overgrowth in the elderly [213], [214] and [215] have been effectively corrected with antibiotic therapy. [216] In some elderly subjects, however, small bowel bacterial overgrowth may be a benign condition that does not warrant treatment. [217], [218] Nevertheless, the presence of bacterial overgrowth in some elderly persons without other predisposing conditions may reflect the immune dysfunction that sometimes accompanies advanced age. Regarding the mucosal immune system, such dysfunction includes altered differentiation or homing of antigen-stimulated B cells, impaired initiation or regulation of local antibody production, and a decline in macrophage production of certain effector products (e.g., nitric oxide), collectively referred to as *immunosenescence*. [219], [220] and [221] Thus, larger studies are needed to characterize small bowel bacterial overgrowth fully in subjects who have hypogammaglobulinemia or are at an advanced age and to determine the most sensitive and specific noninvasive tests for clinically diagnosing significant overgrowth. Until such information is available, small bowel bacterial overgrowth should be included in the differential diagnosis of chronic diarrhea in persons who have immunoglobulin deficiency or are at an advanced age without detectable enteric pathogens and treated with appropriate antibiotics when the syndrome is present.

SUMMARY

In summary, gastrointestinal complications are a major problem in patients with primary (genetically determined) and secondary (acquired) immunodeficiency diseases and conditions. The most important of these complications include esophagitis, infectious diarrhea, gastrointestinal bleeding, typhlitis, and anorectal

disease, which can be severe and, in some cases, life-threatening. The dramatic increase in the number of persons with primary and secondary immunodeficiency diseases increases the likelihood that physicians in all specialties will encounter immunocompromised patients with gastrointestinal problems. Consequently, familiarity with the gastrointestinal manifestations of the various immunosuppressive diseases and conditions should facilitate prompt diagnosis and, when possible, effective treatment.

CHAPTER 52

Ellen M. Zimmermann and Gregory M. Christman

APPROACH TO GASTROINTESTINAL AND LIVER DISEASES IN THE FEMALE PATIENT

Gastrointestinal diseases in women, particularly in pregnant female patients, have unique diagnostic and therapeutic implications and warrant specific consideration. Diseases such as hyperemesis gravidarum and intrahepatic cholestasis of pregnancy are unique to pregnancy, whereas other common gastrointestinal diseases, including gastroesophageal reflux disease, may be more severe during pregnancy. Chronic diseases such as inflammatory bowel disease often initially present in women of childbearing age. In addition, it is important to consider the impact of pregnancy on the course and therapy of preexisting chronic gastrointestinal and liver diseases even before conception. This chapter reviews the gastrointestinal diseases associated with pregnancy and the gynecologic diseases relevant to the evaluation of gastrointestinal symptoms.

PHYSIOLOGY OF PREGNANCY

Physiological Changes in Normal Pregnancy

Profound physiological changes occur during pregnancy and affect nearly every bodily system (Table 52-1). The complex hormonal changes that occur during pregnancy are key to understanding the physiological alterations associated with pregnancy. Three hormones are relevant to changes in gastrointestinal physiology (Fig. 52-1). Human chorionic gonadotropin (hCG) is initially derived from the primitive trophoblast and later from the placenta. [1] Levels of serum hCG peak in the first trimester. Measurement of the ß subunit of hCG is widely used as a conventional immunologic pregnancy assay. hCG plays a major role in maintaining the corpus luteum of the menstrual cycle until the placenta is capable of synthesizing adequate progesterone to support pregnancy. [1] hCG may also regulate steroid production in the fetus and in the placenta [2], [3] and appears to have immune-modulating and thyroid-stimulating activities. [4] Because levels of serum hCG peak in the first trimester, when nausea is common, it has been implicated in the pathogenesis of nausea and vomiting of pregnancy and hyperemesis gravidarum, although direct evidence supporting a pathogenic mechanism is lacking. [5]

SYSTEM	CHANGE IN PREGNANCY	COMMENTS
Metabolic System		
Basal body temperature	Increase	
Oxygen consumption	Increase	20%–30% increase
Cardiovascular System		
Cardiac output	Increase	30%–50% increase; peak effect at 20–24 weeks of gestation
Stroke volume	Increase	
Heart rate	Increase	
Peripheral resistance	Decrease	
Blood volume	Increase	40%–50% increase; mostly plasma
Plasma volume	Increase	45%–55% increase; dilutional anemia common
Red cell mass	Increase	20%–30% increase
Urinary System		
Renal pelvic diameter	Increase	Hydronephrosis common
Ureteral diameter	Increase	Hydroureter common
Glomerular filtration rate	Increase	30%–50% increase; peak second trimester
Renal blood flow	Increase	40% increase
Respiratory System		
Respiratory rate	No change	
Total lung capacity	No change	Volumes redistributed second half of pregnancy
Tidal volume	Increase	By 200 mL
Residual volume	Decrease	By 300 mL because of enlarging uterus
Gastrointestinal System		
Lower esophageal sphincter tone	Decrease	Progressive decrease to term
Gastric emptying time	Increase	
Intestinal transit time	Increase	
Colonic transit time	Increase	
Gastric acid secretion	Increase	
Hepatobiliary System		
Gallbladder emptying time	Increase	
Liver size	No change	
Liver histology	Subtle change	Subtle, nonspecific, including cytoplasmic fat vacuoles

TABLE 52-1 Physiological Changes during Pregnancy

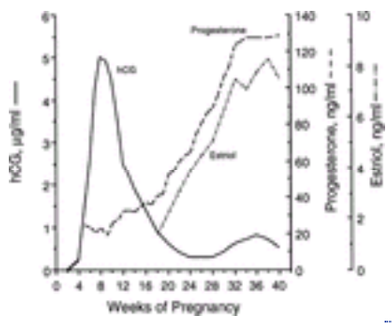

FIGURE 52-1. Changes in the gestational hormones human chorionic gonadotropin (hCG), progesterone, and estriol during pregnancy. (Data from Jaffe RB. Protein

hormones of the placenta, decidua, and fetal membranes. In: Yen SSC, Jaffe RB, eds. Reproductive endocrinology: physiology, pathophysiology and clinical management, 2nd ed. Philadelphia: WB Saunders, 1986:761. Johansson ED. Plasma levels of progesterone in pregnancy measured by a rapid competitive protein binding technique. Acta Endocrinol (Copenh) 1969;61:607. Progesterone and estrogen are the major steroid hormones synthesized during pregnancy. Progesterone is synthesized from cholesterol precursors initially by the ovary and later by the placenta. Several estrogens are synthesized by the placenta, including estradiol, estrone, and the major estrogen specific to pregnancy, estriol. Serum concentrations of progesterone and estriol increase with advancing gestation. Progesterone has a profound effect on uterine smooth muscle, maintaining the myometrium in a relatively relaxed state, and has a similar effect on the smooth muscle of other systems, including the gastrointestinal, renal, and pulmonary systems. Progesterone acts directly on smooth muscle by inhibiting calcium release from intracellular stores without an apparent effect on influx of extracellular calcium. [6], [7] Progesterone may also modulate immune mechanisms responsible for the maintenance rather than the rejection of fetal tissue. Estrogens have a potent ability to increase uteroplacental blood flow, an effect that may be mediated by prostaglandins. [8] Estrogens have also been implicated in changes in smooth muscle physiology, although studies suggest it is a less potent smooth muscle relaxant than progesterone.

Many of the physiological changes occurring during pregnancy result in alterations of the normal values of routine laboratory tests (Table 52-2). Some of the changes in values seen during pregnancy result from the confounding effects of several factors. For example, despite the rise in albumin synthesis during pregnancy, the plasma albumin level decreases during the second trimester because of the increase in plasma volume.

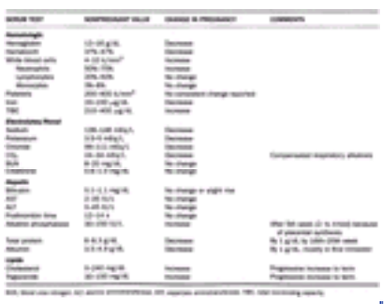

TABLE 52-2 Changes in Common Laboratory Tests during Pregnancy

Drug Metabolism in Pregnancy

Pregnancy induces changes in drug absorption, metabolism, distribution, and elimination. Because of the dynamic nature of these changes, it is often difficult to predict which factors will have a significant impact on drug pharmacokinetics. [9], [10] Knowledge of the changes in drug metabolism can assist physicians and patients in the safe and effective management of medications prescribed during pregnancy. Drug absorption may be affected by the changes in gastrointestinal function that occur during pregnancy. [11], [12] Delayed gastric emptying may delay peak drug levels. [13] Prolonged intestinal transit time may increase the absorption of some relatively water-insoluble drugs or increase the metabolism of drugs by intestinal wall enzymes. [14] Decreased gastric acid secretion may change the gastric pH and alter drug solubility.

Changes in body fluid compartments during pregnancy can profoundly affect drug distribution. [11] Increases in maternal plasma volume and the enlarging fetal compartment increase the volume of distribution of many drugs, altering maternal plasma drug concentrations and elimination half-life. The progressive decrease in maternal albumin concentration causes a corresponding increase in unbound drug fraction. Because pharmacological efficacy and toxicity are related primarily to the concentration of unbound drug, pregnancy-induced changes in protein binding may have important clinical implications, especially for acidic drugs that are highly protein-bound. [11] The 50% increase in the maternal glomerular filtration rate that occurs during pregnancy [15] results in the increased elimination of renally excreted drugs.

The changes in hepatic drug metabolism have not been rigorously studied during pregnancy. 17-Ethynyl estradiol decreases cytochrome P450 activity. [16] On the other hand, drug levels of phenytoin (Dilantin) and carbamazepine (Tegretol) decrease in pregnancy, presumably because of increased P450 activity. [17] Progesterone induces certain cytochrome P450 enzymes and other mixed function oxidase enzymes. [18], [19] These hormone activities can have confounding effects on drug metabolism and make drug levels difficult to predict.

Placental and fetal factors influence the effect of maternal medications on the developing fetus. Although most chemicals enter the fetal circulation by simple diffusion, some cross the placenta by facilitated or active transport processes. [20] The placenta contains enzymes capable of drug oxidation, reduction, hydrolysis, and conjugation. [21] Placental cytochrome P450 enzymes may play a role in fetal protection in the bio-oxidation of xenobiotics, including drugs. [22] Fetal tissues are also capable of metabolizing drugs. Although this contributes little to drug clearance, which is largely effected by maternal systems, it may contribute to fetal toxicity through the accumulation of toxic drug metabolites. This mechanism may be particularly important for polar drugs, which do not readily cross the placenta back to the maternal circulation. [11] Fetal albumin concentrations are below maternal levels early in pregnancy and then rise progressively. Early in pregnancy, fetal unbound drug concentrations may be high, even when maternal drug concentrations are low, resulting in toxicity to the fetus. [23] This potential toxicity during the first trimester, the period of major organogenesis, underlies the recommendations for the conservative use of medications during early pregnancy.

Fetal malformations occur in 3% to 6% of pregnancies. [24], [25] Drugs are probably responsible for only about 1% to 5% of fetal malformations; most malformations result from unknown causes. [25], [26] and [27] Even though the teratogenic effects of drugs account for a minority of fetal malformations, the consequences of a single unrecognized teratogen can be devastating. Unfortunately, few studies have been conducted of medication during pregnancy, and most information on the teratogenic potential of medications is derived from animal studies. [28] The Food and Drug Administration has established five drug categories to assist patients and physicians in the decision about drug use in pregnancy (Table 52-3). [9] The risk categories are based on the degree to which available information has ruled out risk of a drug to the fetus, balanced against the potential benefits of the same drug to the patient. Critics argue that excessive reliance on the results of animal studies can lead to inaccurate and misleading conclusions. The difficulties of extrapolating the results of animal studies to humans are well-known, the most notable example being thalidomide, which was not teratogenic in animal studies. [28] More accurate and reliable methods of determining human teratogenic potential are being studied, [29] and methods of determining patients' genetic predisposition to teratogenicity are being sought. [30] Table 52-3 lists current information and the pregnancy risk category for commonly used gastrointestinal drugs. [9], [10], [31]

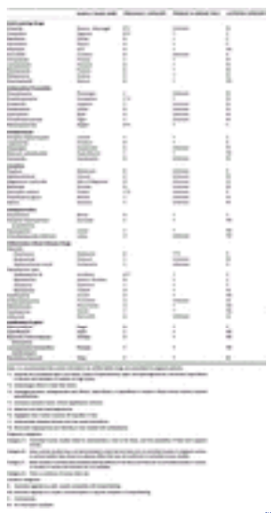

TABLE 52-3 Commonly Used Gastrointestinal Drugs in Pregnancy and Lactation

GASTROINTESTINAL SYMPTOMS IN PREGNANCY

Gastrointestinal symptoms are common during pregnancy. Symptoms such as nausea, constipation, and reflux are common and usually mild, and they rarely require diagnostic tests or drug therapy. Occasionally, however, serious diseases arise during pregnancy, and a reluctance to perform diagnostic tests can significantly delay diagnosis. Studies suggest that endoscopic procedures are safe during pregnancy and should be considered for the evaluation of serious symptoms. [32], [33]

Nausea and Vomiting and Hyperemesis Gravidarum

Nausea and vomiting have been estimated to occur in 50% to 90% of all pregnancies and begin in the first trimester in most patients. [34], [35] It is generally held that nausea and vomiting predict a good pregnancy outcome because the incidence of stillbirths and miscarriages is lower in women experiencing these symptoms. [35], [36] Nausea and vomiting do not affect birth weight and have not been associated with an increased incidence of congenital malformations.

Intractable vomiting that occurs early in gestation, causing dehydration, electrolyte disturbances, or nutritional deficiencies, is called *hyperemesis gravidarum*. [5] The timing, epidemiology, and clinical features are similar to those of the common, milder form of nausea and vomiting in pregnancy, suggesting that nausea during pregnancy may be part of a spectrum, with hyperemesis gravidarum representing the extreme form. The average incidence of hyperemesis gravidarum is 3.5 cases for every 1000 deliveries. [37], [38]

Pathophysiological Considerations Several lines of evidence support a role for the steroid hormones estrogen and progesterone in the pathogenesis of nausea and vomiting of pregnancy. First, a strong correlation has been found between nausea and vomiting and intolerance to oral contraceptives. [35] Second, epidemiologic studies show a higher incidence of nausea and vomiting in nulliparous, nonsmoking, and obese women, all of whom have higher levels of circulating and urinary estrogens. [39] Estrogen and progesterone both have relaxant effects on gastrointestinal smooth muscle. [40] Steroid hormones, particularly progesterone, may prolong gastric emptying and intestinal transit times, which may predispose the patient to nausea and vomiting. Pregnant patients with nausea and vomiting have gastric slow wave dysrhythmias (i.e., tachygastria and bradygastria) [41] and instability of fasting electrical activity and an altered electrical response to food ingestion. [42] The gastric slow wave dysrhythmias can be induced in asymptomatic, nonpregnant patients by administering progesterone alone or in combination with oral estrogen at doses that result in serum hormone levels near the levels of pregnancy. [43] On the other hand, nausea and vomiting are most common in the first trimester, whereas steroid hormone levels peak near term. In addition, estradiol and progesterone levels do not differ between asymptomatic pregnant patients and pregnant patients with nausea and vomiting. [44] These latter observations have led to the hypothesis that it is the rapid changes in gestational hormones early in pregnancy that induce nausea and vomiting in susceptible patients. [45] Levels of hCG peak during the first trimester, at a time when symptoms of nausea and vomiting are commonly recognized. It is controversial whether hCG levels are higher in pregnant patients with nausea and vomiting than in asymptomatic pregnant patients. [46] Women with molar pregnancies have extremely high hCG levels and a higher incidence of nausea and vomiting than women with healthy intrauterine pregnancies. However, hCG levels do not differ between patients who have molar pregnancies with nausea and vomiting and patients who have molar pregnancies without nausea and vomiting. Transient elevations in serum thyroxine levels, especially serum free thyroxine, have been documented in as many as 70% of pregnancies complicated by hyperemesis gravidarum. [38], [47], [48] and [49] Hyperthyroxinemia resolves in the second trimester. Because hCG has inherent thyroid-stimulating activity, it has been suggested that high hCG levels in the first trimester are responsible for the hyperthyroxinemia. [38] It has been postulated that hCG and thyroxine cause maternal nausea and alter the nutrient balance favoring placental growth. [50] *Helicobacter pylori* infection has been found to be more common in patients with hyperemesis gravidarum than in controls, and antibiotics have significantly relieved symptoms of nausea and vomiting in *H pylori*–positive patients. [51], [52] and [53]
Clinical Features, Diagnosis, and Treatment Hyperemesis gravidarum typically begins during the sixth week of gestation and improves in the second trimester. Sixty percent of patients with hyperemesis gravidarum may have symptoms beyond 20 weeks, whereas women with the milder form rarely have symptoms beyond 20 weeks. The sequelae of the intractable vomiting of hyperemesis gravidarum include fluid and electrolyte disturbances, dehydration, weight loss, ketosis, and acetonuria. Laboratory abnormalities, including elevations in aspartate aminotransferase (AST), alanine aminotransferase (ALT), bilirubin, amylase, and lipase, may be seen. [54] Rare complications include neurological abnormalities, retinal hemorrhage, Mallory-Weiss tear, and acid aspiration syndrome. [37], [54] The management of common nausea and vomiting in pregnancy depends on the severity of the condition. Inappropriate weight gain or weight loss may indicate a more serious disease and warrants close monitoring. Patients may be advised to eat frequent small meals and to avoid easily identifiable situations that precipitate nausea and vomiting. Rarely is drug therapy required for nausea and vomiting in early pregnancy, but when needed, antihistamines and phenothiazines are commonly used. [55] Hospitalization is often the key to successful therapy of hyperemesis gravidarum. Fluid and electrolyte therapy is necessary to reverse abnormalities. Enteral or parenteral hyperalimentation may be necessary in extreme cases. [56], [57] The use and therapeutic value of pharmacological therapy in hyperemesis gravidarum is controversial. Phenothiazines and antihistamines have been used with some success, [58] although their safety in pregnancy is not clearly established. The serotonin receptor antagonist ondansetron was no better than promethazine for the treatment of hyperemesis gravidarum. [59] It is reasonable to consider *H pylori* infection in severe cases of hyperemesis gravidarum, although treatment in pregnancy is not straightforward because of medication and safety issues. In general, hyperemesis gravidarum has no adverse effect on pregnancy outcome. [60], [61]

Gastroesophageal Reflux

Heartburn is a common symptom of pregnancy, estimated to affect as many as 60% to 70% of pregnant women. [62] The prevalence of heartburn increases with gestational age. [62], [63] Patients with prepregnancy heartburn and increased parity are at increased risk for experiencing heartburn during pregnancy. Heartburn during pregnancy does not appear to affect maternal health or the well-being of the fetus. [64]

Pathophysiological Considerations Two mechanisms have been proposed to explain the pathophysiology of heartburn in pregnancy: decreased lower esophageal sphincter (LES) pressure and the mechanical effects of the gravid uterus. Other potentially important factors, such as relaxations, mechanisms of esophageal acid clearance, and sensory neuronal mechanisms, have not been established. Women with heartburn during pregnancy appear to have LES pressures lower than those of nonpregnant controls or pregnant women without heartburn. [65] Early in pregnancy, asymptomatic pregnant patients had normal LES pressures compared with nonpregnant patients; however, pregnant patients exhibited blunted responses to pharmacological challenges with edrophonium, methacholine, and pentagastrin, [66] suggesting that LES competence is impaired early in pregnancy, before the development of symptoms. LES pressures progressively fell when studied at 12, 24, and 36 weeks of gestation and returned to normal 1 to 4 weeks after delivery. [65] The perceived importance of mechanical factors in the development of heartburn during pregnancy has diminished in the past decade as more interest has focused on hormonal changes affecting the LES. [67] Theories regarding mechanical factors are based on the positive correlation between the prevalence of heartburn and the size of the gravid uterus. Proposed mechanical factors include loss of the intra-abdominal LES segment, alterations of anatomic structures surrounding the LES, hiatal hernia formation, and delayed gastric emptying. [68]
Clinical Features, Diagnosis, and Treatment A compatible history is usually sufficient to make the diagnosis of reflux in pregnancy. Confirmatory tests are rarely needed; radiographic studies should be avoided. Endoscopy can be performed safely during pregnancy but is indicated only if complications such as stricture or ulceration are suspected. Treatment regimens must consider drug side effects and fetal well-being. A standard antireflux regimen emphasizing frequent small meals

with no food before bedtime, elevating the head of the bed, and avoiding bothersome foods is effective for most patients. Antacids and sucralfate are considered safe when used in the second and third trimesters (see Table 52-3). [69] Little is known regarding the safety of histamine H_2 receptor antagonists during pregnancy. All histamine H_2 receptor antagonists readily cross the placenta. [70] Cimetidine has an antiandrogenic effect in animals [71], [72] but has been safely used to treat peptic ulcer disease and to prevent aspiration at the time of cesarean section. [73] Ranitidine does not have antiandrogen effects. [72] A prospective cohort study showed no increased risk for premature birth or teratogenicity when histamine H_2 blockers were used in the first trimester. [74] Promotility drugs such as metoclopramide, cisapride, domperidone, and proton pump inhibitors have been used to treat reflux associated with pregnancy, although experience is limited and controlled studies are unavailable. [69], [75], [76]

Constipation

Pregnancy is often associated with constipation. In one study, 31% of women were constipated during pregnancy, most commonly during the first trimester and again late in gestation. [77] In another study, 11% of women reported decreased bowel movement frequency during pregnancy, but only 1.5% of this group required laxative treatment. Fifty-five percent did not have any change in their bowel habits, and 54% reported increased frequency. [78]

Pathophysiological Considerations It is postulated that constipation results from bowel hypomotility related to the smooth muscle relaxant effects of estrogen and progesterone. Several studies have shown an increased gastrointestinal transit time during pregnancy, especially during the second and third trimesters. [79], [80] and [81] The increased gastrointestinal transit time was correlated with increased serum progesterone levels and returned to normal as the levels normalized after delivery. [79], [80] The transit time was prolonged during the luteal phase of the normal menstrual cycle when the progesterone level was high compared with the transit time during the follicular phase when the progesterone level was low. In pregnant women, mean plasma motilin concentrations were reduced with fasting and after a glucose load or a mixed meal, with a return to normal within 1 week after delivery. [82] Other factors contributing to the constipation of pregnancy include pressure on the rectosigmoid by the gravid uterus, increased colonic absorption of sodium and water, and prenatal vitamin supplementation with iron.
Clinical Features, Diagnosis, and Treatment Constipation during pregnancy usually does not warrant extensive evaluation. Serious illnesses such as bowel obstruction may present as constipation and can usually be excluded by clinical evaluation. Increased dietary fiber and fluid intake provide symptomatic relief of constipation. If constipation persists, supplemental fiber in the form of psyllium appears to be safe. [69], [76] Other laxatives have not been studied sufficiently, but several are widely used without apparent adverse effects, including bisacodyl, senna, and docusate stool softeners (see Table 52-3).

Acute Abdominal Pain

The differential diagnosis of acute abdominal pain includes all nonobstetrical causes as well as causes specific to pregnant women (Table 52-4). Multiple factors complicate the diagnosis of acute abdominal pain during pregnancy. First, the differential diagnosis of acute abdominal pain changes as pregnancy progresses. For example, ectopic pregnancy must be considered strongly in the first trimester, but other obstetrical causes are more common in the second and third trimesters. Second, anatomic landmarks are shifted by the gravid uterus. Toward the end of gestation, the appendix may be located in the right upper quadrant, often causing confusion between appendicitis and acute cholecystitis (Fig. 52-2). Third, the diagnosis can be delayed by reluctance to perform diagnostic tests during pregnancy, especially tests involving ionizing radiation. The abdominal wall becomes less reactive, probably because of the effects of gestational hormones and the enlarging uterus, and the usual diagnostic signs of rebound tenderness, guarding, and rigidity are less commonly elicited. In the early stages, nonobstetrical pain is often attributed to obstetrical causes, resulting in a delayed diagnosis. The combined effect of these factors is to delay the diagnosis of acute abdomen in pregnancy to the point at which it is often made only after the patient has become extremely ill. Pregnancy outcomes and management recommendations are being reevaluated in light of the increasing use of laparoscopic techniques. [83], [84], [85] and [86]

Nonobstetrical Causes
Acute appendicitis
Acute cholecystitis
Acute pancreatitis
Hepatic rupture
Intestinal obstruction
Adnexal torsion
Sickle cell crisis
Obstetrical Causes
Ectopic pregnancy
Abruptio placentae
Red degeneration of a uterine myoma
Uterine rupture

TABLE 52-4 Causes of Acute Abdomen in Pregnancy

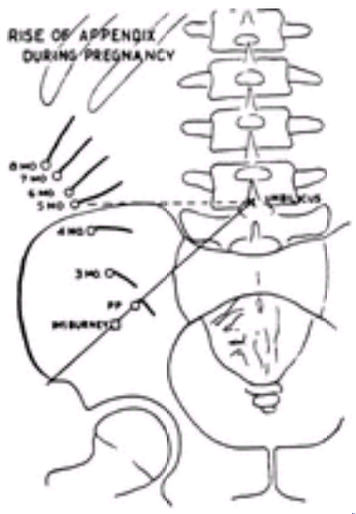

FIGURE 52-2. The position of the appendix changes during pregnancy. (From Baer JL, Reis RA, Arens RA. Appendicitis in pregnancy with changes in position and axis of the normal appendix in pregnancy. JAMA 1932;98:1359.)

Nonobstetrical Causes

Acute appendicitis. Appendicitis develops in approximately 1 in 2,000 pregnant women. [87], [88] Appendicitis is the most common nonobstetrical condition requiring surgery during pregnancy. Symptoms are generally the same as in nonpregnant patients, but the location of abdominal tenderness differs because the enlarging uterus displaces the appendix cephalad (see Fig. 52-2). Guarding, rebound tenderness, and fever all appear to be less common in pregnant patients with acute appendicitis. [89], [90] The differential diagnosis includes ligamentalgia, ovarian torsion, ectopic pregnancy, and pyelonephritis. [91] The physiological leukocytosis of pregnancy reduces the diagnostic utility of this common sign of inflammation. [89] Pyuria and hematuria may be more common, occurring in 10% to 29% of cases, because of the proximity of the appendix to the retroperitoneal ureter. [89] Local perforation and peritonitis may not be immediately evident because the uterus can form a medial wall that contains the abscess. The abscess can stimulate uterine contractions and premature delivery. Transvaginal ultrasonography is a safe and effective means of imaging the pelvis and may be helpful, especially early in pregnancy. [91] Early surgery is indicated because maternal and fetal mortality rates increase with the development of peritonitis. [89] Delayed diagnosis is probably responsible for the higher rates of appendiceal perforation and mortality associated with acute appendicitis in pregnancy. Laparoscopy appears to be as safe as laparotomy. [92]
Acute pancreatitis. The incidence of acute pancreatitis in pregnancy is estimated to be between 1 in 4,000 and 1 in 12,000 pregnancies. [93] It is unclear if this incidence is higher in pregnancy than in a matched nonpregnant population. Most cases occurring in pregnancy are associated with cholelithiasis. [94] Other causes of pregnancy-associated acute pancreatitis include hyperparathyroidism [95] and alcoholism. [96] Acute pancreatitis during pregnancy also occurs in the setting of an underlying lipoprotein disorder. Most women have a modest increase in serum triglycerides during the third trimester [97] because of a direct effect of estrogen on liver lipoprotein synthesis and a decreased clearance of triglycerides secondary to hormonal suppression of lipoprotein lipase activity in the liver and adipose tissues. [98], [99]

This increased triglyceride concentration is usually of little clinical consequence, but significant hyperlipidemia may develop in women with inherited lipoprotein disorders and can result in xanthomatosis and acute pancreatitis. Early recognition is key because patients can be managed successfully with a low-fat diet. [100], [101] Acute pancreatitis in pregnancy carries a high risk for maternal and fetal mortality. The early use of total parenteral nutrition is warranted to maintain maternal and fetal nutrition and to avoid a catabolic state in the pregnant woman. [102] Symptomatic biliopancreatic gallstone disease as a cause of pancreatitis can be managed surgically or endoscopically (see section " Cholelithiasis"). [94], [103], [104] Pseudocysts have been reported to complicate acute pancreatitis in pregnancy, and conservative management is generally recommended until after delivery. [105]

Intestinal obstruction. Intestinal obstruction occurs in between 1 in 2,500 and 1 in 3,000 pregnancies. [106] Most cases occur in patients who have had a prior operative procedure, most commonly appendectomy or gynecologic surgery, and presumably result from pressure on preexisting adhesions by the enlarging uterus. [107], [108] Obstruction is most common in the third trimester and least common in the first. [109] Symptoms of obstruction in pregnant women are similar to those of nonpregnant patients. A single supine and upright abdominal x-ray film may be diagnostic, but the diagnosis is confirmed more commonly by the progression of x-ray findings over several hours. The management principles are similar to those for intestinal obstruction in the nonpregnant patient. Operative therapy is generally required for small bowel obstruction. Cecal or sigmoid volvulus can be successfully treated with endoscopic detorsion. [108] The maternal mortality rate is 10% to 20%. Fetal mortality appears to be even higher secondary to fetal hypoxia and acidosis. [110], [111]

Adnexal torsion. An ovarian cyst in a twisted adnexa can cause an acute abdomen during pregnancy. [112] As with appendicitis, the localization of the pain may not be classical because of the enlarged uterus. A prompt diagnosis and surgical intervention are necessary to avoid tissue necrosis. In the case of a dermoid cyst, prompt surgical therapy decreases the risk for rupture, which can produce a severe generalized peritonitis. [113] Adnexal torsion is often misdiagnosed as acute appendicitis, with the correct diagnosis made at laparotomy. The ultrasonic appearance may differentiate complex and fluid-filled ovarian cyst from an inflamed appendix. [112]

Sickle cell anemia. Patients with sickle cell anemia may present with severe abdominal pain during pregnancy. [114], [115] Severe sickle cell crisis requires treatment, as in the nonpregnant patient, and is associated with a high maternal and fetal mortality rate. [116]

Obstetrical Causes

Ectopic pregnancy. The most common obstetrical cause of an acute abdomen in the first trimester is ectopic pregnancy. History, pelvic examination, measurement of the serum ß-hCG level, culdocentesis, ultrasonography, and laparoscopy can all be valuable in establishing the diagnosis. Medical and surgical therapies are available (see section " Ectopic Pregnancy" for a more detailed discussion).

Abruptio placentae. Abruptio placentae is an important cause of severe abdominal pain during late gestation, occurring in about 8 in 1,000 pregnancies. [117] Abruption occurs when the placenta prematurely separates from its uterine attachment. Classically, patients present with pain, uterine irritability and tenderness, and vaginal bleeding. The diagnosis can be more difficult if blood is retained in the uterus. Ultrasonography may demonstrate a retroplacental blood collection, and amniocentesis may yield bloody amniotic fluid. The diagnosis should be considered if severe, unremitting pain develops during labor. Abruptio placentae may be self-limited or may cause fetal demise and catastrophic maternal complications, including massive hemorrhage, disseminated intravascular coagulopathy, and renal cortical necrosis. Treatment depends on the severity of the abruption but generally consists of blood replacement, correction of disseminated intravascular coagulopathy if present, and expeditious delivery. [118], [119]

Red degeneration of a uterine myoma. Red degeneration of a uterine myoma is caused by a hemorrhagic infarction of a uterine fibroid. Focal acute pain may be associated with low-grade fever and ileus. The diagnosis should be considered in patients with pain and fibroids in whom other diagnoses have been excluded. [118]

Uterine rupture. Uterine rupture generally occurs late in pregnancy in patients with a prior history of cesarean section or myomectomy. Uterine rupture may occur in as many as 1% in patients attempting vaginal delivery after cesarean section with a lower uterine segment incision. The rupture may occur spontaneously or during labor and involves dehiscence of the prior surgical scar with or without expulsion of the fetus into the abdominal cavity. Traumatic uterine rupture usually occurs in the setting of a motor vehicle accident. Expulsion of the fetus usually results in fetal demise and intra-abdominal bleeding. Treatment is surgical. [91]

GASTROINTESTINAL AND LIVER DISEASES IN PREGNANCY

Inflammatory Bowel Disease

The majority of women with inflammatory bowel disease (IBD) are of childbearing age. Recent studies support an optimistic view regarding fertility and the course of pregnancy for patients with IBD. [120], [121] and [122]

Effects on Fertility Little evidence supports fertility problems in patients with ulcerative colitis; two control studies showed no decrease in fertility. [123], [124] and [125] In Crohn's disease, the existing data are not as straightforward. Two case control studies reported decreased fertility in patients with Crohn's disease. [126], [127] Infertility appears to correlate with disease activity and is inversely related to nutritional status. Measures of childlessness, infertility, fecundity, and methods of birth control suggest that in some cases reduced fertility may be the patient's choice rather than a consequence of the disease. [124] Early data were conflicting as to whether infertility was more common with large or small bowel Crohn's disease, [128], [129] although in a recent controlled study, the site of intestinal involvement did not appear to be a factor. [126]

Effects on Pregnancy Outcome Patients with ulcerative colitis deliver healthy offspring, with rates of congenital abnormalities, spontaneous abortion, and stillbirth that approximate those in the general population. [123], [127], [130], [131], [132] and [133] Some studies suggest that spontaneous abortion and stillbirth are increased in patients with severe colitis, especially when the onset of colitis is during pregnancy. [134] Data suggest that patients with severe colitis during pregnancy can be managed successfully with parenteral hyperalimentation. [134], [135] and [136] Patients with Crohn's disease that is mild or in remission at the time of conception appear to have normal pregnancies. [132] However, in patients with active Crohn's disease at the time of conception, the incidence of stillbirth, low birth weight, spontaneous abortion, and premature delivery is increased. [131], [137], [138] and [139]

Effects of Pregnancy Data support the classical concept that IBD that is quiescent at the onset of pregnancy is likely to remain quiescent throughout pregnancy. Patients with an exacerbation of ulcerative colitis brought into remission during pregnancy are also likely to do well for the remainder of pregnancy. However, patients with active disease at the time of conception are likely to experience worsening of their disease. [132], [139] Pregnancy does not appear to change the relapse rate of ulcerative colitis or Crohn's disease. [131], [134], [137], [140], [141] Evidence suggests that the course of ulcerative colitis during a single pregnancy may not necessarily predict its course during subsequent pregnancies. Patients with IBD may experience a marked improvement in their symptoms during pregnancy but then a flare of their disease postpartum.

Effects of Drug Therapy Data suggest that pregnancy occurring during disease remission is more likely to result in a normal full-term baby. A patient who is in a remission that can be sustained without drug therapy should remain off therapy. However, most patients can achieve a satisfactory remission only with medical therapy. It is important to consider the potential side effects of the drugs used and their potential harm to the fetus (see Table 52-3). Sulfasalazine can cross the blood-brain barrier, theoretically causing kernicterus by displacing bilirubin from serum albumin. Fortunately, because sulfasalazine is poorly absorbed and has a low affinity for binding protein, neonatal jaundice is quite uncommon. [142] Sulfasalazine therapy has not been associated with an increase in prematurity, birth weight, or spontaneous abortion. [143], [144] The incidence of developmental defects is only 1%, which is similar to the incidence in the general population. [143] Sulfasalazine is present in small amounts in breast milk. [145], [146] However, no side effects of sulfasalazine have been reported in nursing infants. It is important to recommend that patients on sulfasalazine take a folate supplement because sulfasalazine inhibits the transport and metabolism of folic acid. The 5-aminosalicylates avoid some of the theoretical concerns of sulfasalazine. No known complications of 5-aminosalicylates in pregnancy have been reported. [147] Currently, there is no justification for switching pregnant patients from sulfasalazine to a 5-aminosalicylate. Male patients with IBD who desire fertility should be given 5-aminosalicylates because sulfapyridine, one of the metabolites of sulfasalazine, can decrease sperm count and motility. [148] Steroids have been widely used for many diseases during pregnancy and have not been shown to increase the risk for low birth weight, spontaneous abortion, or fetal abnormalities despite an increased incidence of these findings in animals treated with high doses of steroids. In a series of 287 patients with IBD treated with corticosteroids, the frequency of fetal complications was lower than in the general population. [130] It appears that patients who become pregnant in the setting of severe active Crohn's disease are at risk for complications regardless of the treatment, and it seems prudent to use corticosteroids when needed in moderate or severe disease to induce a remission. Metronidazole in high doses is tumorigenic and teratogenic in animals. It is present in breast milk, and its effect on the human fetus is unknown. Therefore, metronidazole should be avoided during pregnancy. [31] Cyclosporine is embryotoxic and fetotoxic in animals but has been used safely in patients with severe ulcerative colitis. [149] Azathioprine and 6-mercaptopurine are being used increasingly for primary therapy of IBD and for their steroid-sparing effect. These drugs have well-known teratogenic effects in animals. Nevertheless, the drugs have been used safely in more than 1000 renal transplant patients who became pregnant. [150] Even though patients with IBD are on relatively low doses of immunosuppressant therapy, such therapy is not routinely recommended during pregnancy. [151] The risks and benefits of these drugs must be considered with the patient before conception. Infliximab has been used safely in pregnancy, although data are scant. [152]

Peptic Ulcer Disease

Peptic ulcer disease and its complications are rare during pregnancy. [153], [154] It has not been clearly established whether the incidence truly differs between pregnant

and nonpregnant women because peptic ulcer disease is uncommon in all women of childbearing age. [5] Peptic ulcer disease may be underdiagnosed in pregnancy, thus confounding these statistics. Peptic symptoms may more likely be attributed to reflux, and like reflux symptoms, they may improve with antacid therapy. Moreover, diagnostic tests are performed less often in pregnant patients. The symptoms of patients with known peptic ulcer disease usually improve during early gestation, and they appear to be protected from peptic symptoms until late in the third trimester. Other studies report disappearance of ulcer symptoms in 98% of pregnant women, although by the end of the third postpartum month, symptoms may recur in almost 50%.

Complications of peptic ulcer disease during pregnancy, such as perforation, hemorrhage, and obstruction, are extremely rare; however, when they occur, they do so late in the third trimester or early in the postpartum period. [155], [156] During pregnancy, such complications may become life-threatening for both mother and child. All reports of fetal and maternal mortality from complications of peptic ulcer disease precede the widespread use of histamine H_2 receptor antagonists. The treatment of peptic ulcer disease is based on symptoms and a risk-benefit analysis of drug therapy. A cohort study showed no increased risk for premature birth or teratogenicity when histamine H_2 blockers were used in the first trimester. [155] Cimetidine has been used without adverse effects during pregnancy but is not recommended because of antiandrogen effects. [72] Antiandrogen effects have not been demonstrated with ranitidine or other histamine H_2 receptor antagonists. Histamine H_2 receptor antagonists and proton pump inhibitors are listed in Table 52-3 and are discussed in the section “Gastroesophageal Reflux.” [157] Little information is available on the diagnosis or treatment of *H pylori* infection in pregnancy.

Cholelithiasis

Asymptomatic gallstones are found in 4.5% of pregnant women. [158], [159] Cholelithiasis is also more common in women with a history of prior pregnancy. [160], [161]

Pathophysiological Considerations The changes in gallbladder function and bile composition that occur during pregnancy favor gallstone formation. Gallbladder size increases during pregnancy, [162], [163] and [164] with no corresponding change in common bile duct diameter. [165] Gallbladder emptying appears to be impaired and residual volume increased in pregnancy, possibly because of the smooth muscle relaxant effects of progesterone. During the second and third trimesters, a progressive decrease in the rate of chenodeoxycholate synthesis with no change in the rate of cholic acid synthesis results in an altered ratio of bile salts that is characteristic of pregnancy and hormonal therapy. The hepatic secretion rate of cholesterol into bile remains constant during pregnancy. [166] The decreased total bile salt pool in the later half of pregnancy increases the fractional concentration of cholesterol, creating favorable conditions for gallstone formation. [166]
Clinical Features, Diagnosis, and Treatment The signs and symptoms of biliary colic, acute cholecystitis, and cholelithiasis are similar to those in nonpregnant patients. The differential diagnosis includes other causes of acute pain in pregnant women (see Table 52-4). As in nonpregnant patients, the diagnosis is based on typical symptoms, laboratory findings, and the presence of gallstones. Ultrasonography is the preferred method for detecting gallstones, although ultrasonographic examination may be more difficult during late gestation because of gallbladder displacement. Oral cholecystography and isotope scans should be avoided. It is unknown whether the frequency of complications of cholelithiasis is higher in pregnant than in nonpregnant women. Cholecystitis is second only to appendicitis as an indication for surgery in pregnant women. Spontaneous perforation of the gallbladder associated with cholecystitis has been reported. [167] The approach to therapy is similar to that in the nonpregnant patient. The treatment of uncomplicated biliary colic is generally conservative, with analgesics and antiemetics. Surgery is generally indicated for patients with acute cholecystitis. Classically, the second trimester is considered the safest time for surgery because the risk for spontaneous abortion is increased during the first trimester, and the risk for premature labor in the third. [168] Various data suggest that cholecystectomy is safe at any stage of pregnancy. [103], [104], [169] Laparoscopic cholecystectomy is the standard and is associated with fewer complications than open laparotomy. [170], [171] Pancreatitis caused by choledocholithiasis during pregnancy can be serious; high morbidity and mortality rates underlie the recommendations for early intervention. Endoscopic retrograde cholangiopancreatography has been used as a bridge to postpartum cholecystectomy in patients with complications of choledocholithiasis. [172]

Viral Hepatitis

Acute viral hepatitis probably occurs in fewer than 1% of gestations, although the true incidence is unknown. [173], [174] and [175] The clinical manifestations and laboratory findings in acute hepatitis A, B, and C (caused by the hepatitis A, B, and C viruses, respectively) are similar to those in nonpregnant women. The onset is most common in the third trimester. Fulminant viral hepatitis and liver failure can occur but are rare. Recent reports of hepatitis E in India and the Middle East suggest that acute hepatitis E in pregnant women is a more severe disease than in nonpregnant women, and the mortality rate is higher than that associated with other forms of acute viral hepatitis. [176], [177] Acute viral hepatitis of any cause is associated with an increased rate of fetal loss and premature birth. Vertical transmission of hepatitis viruses from acutely infected mothers has been reported but is rare. Infants exposed to hepatitis A are given immune serum globulin and hepatitis A vaccine at delivery. [174], [178] Infants exposed to hepatitis B receive hepatitis B immune globulin and hepatitis B vaccine. [179] No prophylaxis against the vertical transmission of hepatitis C or E is available.

The effect of chronic maternal hepatitis B on pregnancy outcome and maternal well-being depends on the degree of liver dysfunction. Patients with normal liver function have a good prognosis, whereas the disease of women with significant liver dysfunction may worsen, creating a risk for spontaneous abortion, premature delivery, and perinatal death. [180], [181] Hepatitis B virus can be transmitted vertically from chronically infected mothers during pregnancy or at delivery. The risk for vertical transmission increases with the maternal viral load and replication rate and may be as high as 90%. In addition, chronic hepatitis B develops in 90% of infected infants. [182], [183] and [184] Infants exposed to the hepatitis B virus should be treated with hepatitis B immune globulin and hepatitis B vaccine. Immunoprophylaxis is highly effective in preventing both hepatitis B and hepatitis D transmission. [185], [186] and [187] The high incidence of chronic hepatitis B in exposed offspring and the efficacy of hepatitis B immunoprophylaxis underlie the current recommendations for universal screening for hepatitis B surface antigen (HBsAg) in all pregnant women during the third trimester. [179]

Women with chronic hepatitis C generally have mild liver disease with normal or nearly normal liver function; pregnancies in women positive for hepatitis C virus are generally uncomplicated. [188] In many women, the transaminase levels normalize, often concurrently with an increase in the hepatitis C viral load. [189], [190] The cause of these changes is unclear but may be related to immunologic changes occurring during pregnancy. Hepatitis C can worsen after pregnancy. [191] Hepatitis C may be a risk factor for cholestasis of pregnancy. [192]

Hepatitis C virus is transmitted vertically in approximately 5% of deliveries from hepatitis C virus RNA–positive mothers. [189], [193], [194], [195] and [196] Breast-feeding does not appear to be a mode of transmission, even though hepatitis C virus may be detected in breast milk. [189], [193], [194] Although there is no known effective immunoprophylaxis for hepatitis C, it is encouraging that viremia in infected infants may be only transient. [189], [194] Prenatal screening for hepatitis C virus is not yet routine but may be reasonable given that women positive for hepatitis C virus cannot be reliably identified by history or examination. [197], [198] and [199] The safety and efficacy of anti–hepatitis C virus therapy in pregnant women or their infected offspring are unknown. [200], [201]

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy (IHCP) is a benign cholestatic disorder that usually develops in the third trimester and disappears abruptly after delivery. IHCP occurs in fewer than 1% of pregnancies in the United States. The incidence varies geographically and seasonally, and the overall incidence has decreased in the past 20 years. [202], [203]

Pathophysiological Considerations The etiology of IHCP is poorly understood, but hormonal, environmental, and genetic factors likely contribute. The most widely accepted hypothesis is that IHCP is an inherited sensitivity to the cholestatic effects of estrogen. In almost half of women in whom IHCP develops, pruritus or cholestasis also develops when they use oral contraceptives. [204], [205] and [206] Female relatives of index cases are at risk. [207], [208] IHCP is probably related to other genetic defects in bile salt synthesis or transport. [209] IHCP is associated with mutation of MDR3, a gene encoding a biliary canalicular phospholipid translocator and causing some cases of familial intrahepatic cholestasis. [210], [211] Environmental factors such as low dietary levels of selenium have been suggested. [212]
Clinical Features, Diagnosis, and Treatment IHCP typically causes pruritus in the third trimester that generally progresses until delivery or termination of the pregnancy. The pruritus is often severe. IHCP tends to recur during subsequent pregnancies at a rate of 60% to 70%. [213] After delivery, the pruritus quickly resolves within 24 to 48 hours, and biochemical abnormalities and histological changes resolve over weeks to months. Long-term follow-up suggests a higher incidence of cholelithiasis and gallbladder disease but not of chronic liver disease. [214], [215] and [216] The consequences for the fetus can be serious, and close surveillance of the pregnancy is warranted. The rates of premature labor and neonatal death are higher than expected, [215], [217], [218], [219], [220] and [221] although a more favorable outcome has been reported more recently. [222], [223] As expected, the serial markers of cholestasis, including bilirubin and alkaline phosphatase, are usually elevated, as are the

serum levels of bile salts and cholic acid and the Bromsulfophthalein retention time. Also, the markers of hepatocellular function, including AST and ALT, may be elevated several fold, mimicking the patterns seen in viral hepatitis. The timing and clinical course are usually diagnostic, and liver biopsy is generally not necessary for a diagnosis. The histopathological features of IHCP include central lobular cholestasis, canalicular bile plugs, and bile pigment within hepatocytes. Little inflammatory reaction or hepatic necrosis is seen. The portal tracts and intralobular bile ducts are normal. Histological changes and symptoms resolve after delivery. Therapy is directed at relieving the pruritus. Ursodeoxycholic acid relieves symptoms and improves laboratory values [224], [225], [226], [227] and [228]; the fetal outcome may also be improved. [229] Symptoms may respond to oral steroids [230] or cholestyramine. [231], [232] *S*-edenosyl-L-methionine, which antagonizes the cholestatic effects of estrogen, [233], [234] may be effective, particularly when combined with ursodeoxycholic acid. [235]

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is a serious, rare, idiopathic liver disorder of the third trimester. The incidence is likely less than one case per million deliveries, although epidemiologic data are scant. [236], [237], [238], [239] and [240] Milder cases of the disease are now being reported, suggesting that AFLP is a spectrum and may be more common than has been appreciated. [241], [242] AFLP is more common in first pregnancies, twin pregnancies, and pregnancies in which the fetus is male.

Pathophysiological Considerations The cause of AFLP is unknown. It is related to other diseases in the group collectively termed *hepatic microvesicular steatoses*, which also include Reye syndrome, Jamaican vomiting sickness, valproic acid hepatotoxicity, tetracycline hepatotoxicity, and medium-and long-chain acyl-CoA dehydrogenase deficiency. [237], [243] Unlike IHCP, AFLP does not have a strong genetic component, and it does not tend to recur in subsequent pregnancies. The characteristic histological findings are infiltration of hepatocytes with microvesicular fat and pleomorphic and abnormal mitochondria. Based on the histological findings, a metabolic disorder of lipid metabolism or mitochondrial function has been suggested. The microvesicular fat consists principally of triglycerides and free fatty acids and is contained in non–membrane-bound cytoplasmic droplets. Potentially toxic levels of free fatty acids have been found. [244] Several rare defects in fatty acid oxidation have been diagnosed in infants born to mothers with AFLP, [245], [246] the most common being long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency. [247], [248], [249] and [250]

Clinical Features, Diagnosis, and Treatment The disease generally begins near 35 weeks of gestation with nonspecific symptoms such as nausea, fatigue, malaise, vomiting, and abdominal distress. Clinical signs of liver dysfunction and, in severe cases, liver failure, including jaundice, hepatic encephalopathy, and bleeding, develop 1 to 2 weeks later. Physical findings are minimal, with right upper quadrant tenderness the only consistent finding. The liver is generally nonpalpable. Altered mental status and ascites may appear late in the disease. Hypertension, proteinuria, and preeclampsia are seen in 21% of patients. AFLP and HELLP syndrome (see next section) are distinct clinical entities but may coexist. Complications of fulminant hepatic failure, including cerebral edema, hemorrhage, renal failure, and infection, can occur in AFLP and portend a poor prognosis. Maternal and fetal mortality rates are high; outcomes are improved with the prompt initiation of delivery. [173], [251], [252] Delivery is often complicated by severe postpartum hemorrhage. The signs and symptoms gradually resolve over weeks, and liver function returns to normal. Chronic liver disease is not seen. [253], [254] and [255] The AST, ALT, bilirubin, and alkaline phosphatase levels are universally elevated, with a mixed cholestatic and hepatocellular picture. Antithrombin III levels are also elevated, with patients exhibiting other abnormalities consistent with disseminated intravascular coagulation. Leukocytosis is universal. The serum liver chemistries may be only modestly elevated, underestimating the degree of liver dysfunction. As in other forms of hepatic failure, hypoglycemia, impaired synthesis of clotting factors, and hepatic encephalopathy are poor prognostic signs. Renal dysfunction occurs and occasionally requires dialysis. AFLP may be confused with acute viral hepatitis, preeclampsia-related liver disease, and tetracycline-induced fatty liver. Viral hepatitis may occur at any time during pregnancy, whereas AFLP occurs in the third trimester. Serologic testing for hepatitis A, B, or C virus may indicate a viral cause, and AST and ALT values tend to be much higher in acute viral hepatitis than in AFLP. Preeclampsia-related liver disease is always associated with hypertension and proteinuria, which are usually absent in AFLP. Tetracycline-associated liver disease can cause a syndrome that is virtually identical to AFLP. Previously, high doses of tetracycline were used to treat urinary tract infections and pyelonephritis; however, recognition of this potential problem and the use of alternative antibiotics have virtually eliminated this disease. The therapy for AFLP is supportive, and prompt termination of the pregnancy is generally advocated; successful liver transplantation has been performed in patients with fulminant hepatic failure and AFLP.

Preeclampsia-Associated Liver Disease and HELLP Syndrome

Preeclampsia is a common complication of mid to late pregnancy and is characterized by hypertension, proteinuria, and edema. [256] Preeclampsia develops in 5% to 10% of all pregnancies and is more frequent in young primigravidas and women with lupus anticoagulant. [257] Progression to seizures is the hallmark of true eclampsia and is rare. [258] The liver is involved in 10% of women with preeclampsia; liver involvement is more common in eclampsia. [259], [260] and [261] Liver involvement is the primary cause of death in 15% to 20% of fatal cases. [262], [263], [264] and [265]

Pathophysiological Considerations Two pathophysiological conditions have been described. The first, a moderately severe disorder of hepatocyte necrosis associated with thrombocytopenia, is termed *HELLP syndrome* (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets). The second is *acute liver hemorrhage and rupture*. The histopathological findings in preeclampsia-associated liver disease include (1) deposition of fibrin along the sinusoids and portal tract capillaries, hepatic arterials, and portal veins; (2) periportal and portal tract hemorrhage; and (3) ischemic necrosis. In severe cases, diffuse areas of hemorrhage and necrosis are seen. Large hematomas form beneath the capsule and may rupture. Hepatic necrosis is often associated with necrosis in other organs, including the brain and kidney.
Clinical Features, Diagnosis, and Treatment Thrombocytopenia and increased AST and ALT levels are hallmarks of the HELLP syndrome. Renal dysfunction is virtually universal. Hemolysis is due to microangiopathic hemolytic anemia. Ascites is found in 10% of women with HELLP syndrome and is associated with a risk for congestive heart failure and adult respiratory distress syndrome. The abnormalities may begin suddenly and without warning. Close monitoring and rapid delivery are warranted in most cases. [266], [267] Treatment guidelines include close monitoring of the mother's platelet count, coagulation parameters, and disseminated intravascular coagulation screening panel, as well as AST and ALT levels. Hypertension is treated with magnesium sulfate, and fetal lung maturity is monitored. Patients with postpartum HELLP may benefit from corticosteroids. [268], [269] and [270] Preeclampsia and HELLP syndrome are associated with intrauterine growth retardation, sudden fetal death, and perinatal instability. [271], [272] Survival of the fetus is increased with prompt delivery. Maternal mortality is low (2.4%), possibly because of prompt delivery and rapid recovery. Liver necrosis generally heals rapidly after delivery, with little evidence of chronic liver disease. Women are at risk for recurrent preeclampsia and HELLP syndrome in subsequent pregnancies. Hepatic rupture resulting in serious hemorrhage occurs late in pregnancy or up to 48 hours postpartum. Many but not all cases are associated with the HELLP syndrome. [273] The sudden onset of right upper quadrant pain often heralds the onset of hemorrhage and rupture. Rupture often presents with sudden abdominal distention and shock but may rarely evolve over several days. [274], [275] Chest and shoulder pain are sometimes noted. Abdominal computed tomography is the most sensitive and specific method of detecting hepatic hemorrhage or rupture. Paracentesis will confirm intra-abdominal hemorrhage, and results will be negative in patients with contained hematomas. Supportive therapy is recommended for patients with contained hemorrhage, with emergency laparotomy if rupture of the Glisson capsule is suspected. Angiographic embolization has been performed with success. [276] Overall maternal and fetal mortality rates in hepatic rupture are high. Healing of contained hemorrhages occurs slowly, and recurrence in subsequent pregnancies is rare. [277]

Other Conditions

Spontaneous rupture of the spleen has been reported in pregnancy. [278] Sudden left upper quadrant pain associated with signs of intravascular volume depletion suggests the diagnosis. Most ruptures occur in the third trimester. Emergency surgery is indicated.

Rupture of a splenic artery aneurysm is rare, but as in splenic rupture, the risk for maternal and fetal mortality is high. [279] Patients may present with intravascular volume depletion with or without abdominal pain. Angiography confirms the diagnosis, and surgery is indicated.

Acute granulomatous peritonitis has been described as a cause of abdominal pain after cesarean section. [280] The mechanism appears to be premature rupture of fetal membranes or meconium spillage into the peritoneal cavity during cesarean section.

EVALUATION OF WOMEN WITH PELVIC PAIN

This section reviews the gynecologic diagnoses that should be considered in the evaluation of women presenting with acute and chronic abdominal pain (Table 52-5).

Acute Presentation
Pelvic inflammatory disease
Ectopic pregnancy
Mittelschmerz
Ruptured ovarian cyst
Corpus luteum
Ovarian endometrioma
Adnexal torsion[a]
Chronic Presentation
Endometriosis[b]
Ovarian cancer
Dysmenorrhea

[a]May present rarely as chronic pain.
[b]May present rarely as acute pain.

TABLE 52-5 Gynecologic Causes of Abdominal Pelvic Pain in Women of Reproductive Age

Pelvic Inflammatory Disease

Acute pelvic inflammatory disease (PID) is an inflammatory and infectious process of the upper genital tract, including the fallopian tubes, ovaries, and surrounding tissue. The incidence of PID is highest among women in their late teens and early twenties, with an annual rate of 1.5% to 2% in this age group. [281] The risk factors for the development of PID include sexual activity (especially with multiple partners), the presence of a contraceptive intrauterine device (IUD), and prior pelvic surgical instrumentation. [282] PID is less likely to develop in women using oral contraceptives because of the thickening effect of progestins on cervical mucus, which results in a more effective barrier to infectious organisms. [283]

Cervicitis, frequently caused by the sexually transmitted organisms *Chlamydia trachomatis* and *Neisseria gonorrhoeae* often precedes the development of PID. [284] PID commonly develops immediately before or after menstruation because of the physiological loss of the cervical mucus mechanical barrier around the time of menses and because the growth of *N gonorrhoeae*, particularly virulent gonococcal phenotypes, may be stimulated during the secretory phase (second half) of the menstrual cycle. [285] PID results from the ascent of cervicovaginal bacteria along the mucosal surfaces of the uterus and fallopian tubes. Salpingitis (tubal infection) is the most characteristic feature of ascending infection. Infectious organisms may also migrate into the peritoneal cavity, causing peritonitis, intra-abdominal abscess formation; in rare advanced cases, organisms may spread hematogenously.

Patients with PID classically present with the triad of fever, lower abdominal pain, and vaginal discharge. Less acute cases may present with a history of continuous lower abdominal discomfort exacerbated by movement and intercourse; the presence of fever and vaginal discharge varies. In patients with salpingitis, bimanual examination commonly reveals marked tenderness over the region of the cervix, uterus, and both adnexa. Unilateral tenderness occurs in fewer than 10% of women with PID, and when present, it should prompt an investigation for other diagnoses. A Gram stain of cervical secretions may help determine the presence of gonococcal cervicitis by demonstrating leukocytosis and gram-negative intracellular diplococci. Cervical secretions should be assessed for *N gonorrhoeae* and *C trachomatis* by direct culture, fluorescent antibody smear, or enzyme-linked immunoassay. [284] Culdocentesis and pelvic ultrasonography may help exclude other causes. Diagnostic laparoscopy may expedite an accurate diagnosis, especially if appendicitis or ectopic pregnancy is suspected.

Most patients with PID, including patients with tubal-ovarian or pelvic abscesses, can be successfully treated with antibiotic regimens as recommended by the Centers for Disease Control: parenteral cefoxitin plus oral doxycycline or intravenous clindamycin plus gentamicin. [285], [286] and [287] When PID is associated with an IUD, the IUD should be removed.

Ectopic Pregnancy

The incidence of ectopic pregnancy has been steadily rising since 1970. In the United States, approximately 2% of pregnancies are ectopic. [288], [289] Ectopic pregnancy remains the leading cause of maternal mortality despite improved treatments and earlier diagnosis. Risk factors for ectopic pregnancy include a history of PID, previous pelvic surgery, use of progestin-only oral contraceptives, use of an IUD, previous ectopic pregnancy, and use of advanced reproductive technologies, including menopausal gonadotropin-induced ovulation and in vitro fertilization and tubal embryo transfer. Based on the parallel rise in the incidence of ectopic pregnancy and PID during the past two decades, PID is felt to be a major factor in the development of subsequent ectopic pregnancy. [290] One proposed mechanism is that PID causes damage to the ciliated portion of the fallopian tubes, resulting in abnormal transport of the ovum. Ectopic pregnancies may occur in a variety of extrauterine sites, including the fallopian tubes, ovary, cervix, and abdominal cavity. The fallopian tubes are by far the most common extrauterine implantation site.

Patients commonly present with abdominal pain, amenorrhea or abnormal uterine bleeding, and symptoms of early pregnancy, including breast tenderness and nausea. The possibility of intra-abdominal bleeding should always be entertained in patients presenting with syncope, orthostatic hypotension, or pain referred to the shoulder as a result of irritation of the diaphragm from hemoperitoneum. Although virtually all patients have evidence of abdominal or adnexal tenderness, only 50% of patients have an adnexal mass palpable on pelvic examination. Intra-abdominal bleeding may be rapidly determined by culdocentesis, although this may occasionally yield false-negative or false-positive results. Early diagnosis of ectopic pregnancy is facilitated by the hCG assay, measurement of the progesterone level, and high-resolution transvaginal ultrasonography. [289], [291], [292] and [293]

Surgery is the standard therapy for diagnosed or suspected ectopic pregnancy, although newer medical regimens are effective in selected cases. The stability of the patient, size of the ectopic pregnancy, and the patient's desire for future fertility determine the therapeutic approach. In cases of severe hemodynamic compromise, immediate exploratory laparotomy should be performed. In more stable settings, therapeutic laparoscopic options are considered. Selected patients with smaller, unruptured ectopic pregnancies may be treated medically with methotrexate. [294], [295] and [296]

Midcycle Ovulatory Pain

Pain resulting from intraperitoneal bleeding associated with the physiological rupture of an ovarian follicle can range from a mild sensation of discomfort experienced on a monthly basis to severe pain prompting emergency evaluation. Ovulatory pain (i.e., mittelschmerz) is often rather sudden, sharp, and localized to one of the lower quadrants. It usually subsides over a period of several hours. The patient's menstrual history frequently reveals regular menstrual cycles with midcycle pain. Occasionally, normal ovulation may be associated with intraperitoneal bleeding and irritation sufficient to promote symptoms of severe pain, including peritoneal signs, and other diagnoses, such as adnexal torsion, PID, and acute appendicitis, must be excluded. Ovulatory pain in patients receiving anticoagulation, with clotting disorders, or on large doses of nonsteroidal antiinflammatory agents may be more severe because of increased bleeding from the ruptured follicle. When patients have severe symptoms, consideration should be given to ovarian suppression with oral contraceptives.

Ruptured Ovarian Cysts

Acute abdominal pain may be caused by a ruptured corpus luteum cyst with hemorrhage or by rupture and leakage of an ovarian endometrioma. The diameter of a normal corpus luteum commonly varies between 2 and 4 cm. Enlargement and cystic change of the corpus luteum are common and generally painless unless rupture or bleeding into the cystic cavity occurs, with sudden distention of the capsule. With hemorrhage, degeneration of the corpus luteum and subsequent loss of ovarian progesterone and estrogen secretion result in the onset of menstrual bleeding that is often irregular and abnormal. Like ovulatory pain, symptomatic rupture of a corpus luteum is more common in patients on anticoagulant therapy or in patients taking large doses of nonsteroidal antiinflammatory agents.

Hemorrhage into the corpus luteum with subsequent rupture generally occurs late in the menstrual cycle, often immediately before menstruation. Patients may present with concomitant lower quadrant pain, delayed menses, abnormal uterine bleeding, and a slightly enlarged, tender adnexal mass. It is unusual for hemorrhage to result in an acute drop in the hemoglobin level or affect volume status, but significant hemoperitoneum may occur and be evident on culdocentesis.

Ovarian Torsion

Although torsion occasionally occurs in a normal adnexa, ovarian or adnexal torsion is most often associated with ovarian neoplasms, fallopian tube tumors, or paratubal structures, such as paramesonephric cysts. The most common ovarian neoplasms leading to ovarian torsion in women of reproductive age are the benign cystic teratoma and the common fibroma. [257], [258] Teratomas are often recognized by palpable adnexal enlargement on pelvic examination and a semisolid echogenic ultrasonic pattern, reflecting their frequent makeup of sebaceous material, hair, and dedifferentiated tissue. Pain from torsion of an ovarian tumor often presents as

sharp, severe discomfort that is brief, irregular, and repetitive if the torsion is intermittent and self-correcting. It is common for patients presenting with ovarian torsion to describe an acute onset of discomfort after rising or stooping. If rotation around the torsion axis is sufficient, vascular compromise develops, and relief from the discomfort is not obtained. With necrosis of ovarian tissue, the pain may become less precise in location and dull in character, and over a period of 4 to 6 hours, sufficient inflammation of the parietal peritoneum may develop to produce a generalized peritonitis with associated nausea, vomiting, and ileus. Fever often appears late in this process. Although ovarian torsion and necrosis generally present as a rapidly developing acute process, torsion and necrosis of an ovarian neoplasm can occasionally be walled off by omentum or bowel, so that the patient's discomfort becomes low-grade and chronic.

Dysmenorrhea

The term *dysmenorrhea* refers to pelvic pain associated with menstruation. Dysmenorrhea is a spectrum ranging from mild physiological discomfort to severe, debilitating symptoms. Dysmenorrhea is characterized as primary if it has no organic cause and in this case usually begins 2 to 3 years after menarche. Dysmenorrhea is secondary if it is caused by pelvic pathology such as endometriosis, PID, or congenital abnormalities. [297]

Dysmenorrhea appears to be a combined result of hormonal effects, prostaglandins, myometrial activity, and psychological factors. [297] Progesterone stimulation of previously estrogen-primed endometrium and myometrium is necessary for the development of primary dysmenorrhea. Progesterone increases the synthesis of prostaglandins F_{2a} and E_2, which can be found in higher levels in endometrium and in menstrual fluid in patients with dysmenorrhea. [297], [298] Endometrial release of leukotrienes C_4, D_4, and E_4 is also increased. [297] Prostaglandins appear to mediate symptoms of discomfort by enhancing uterine contractility and sensitizing pain fibers to both mechanical and chemical stimuli. [299] Patients with secondary dysmenorrhea have acquired causes of menstrual discomfort, such as abnormalities that inhibit the outflow of blood, including endometrial polyps, pedunculated submucous myomas, and cervical stenosis. Cervical stenosis most commonly results from prior cervical instrumentation, including conization or therapeutic abortion. Secondary dysmenorrhea also may be caused by IUDs and by endometriosis. Adenomyosis, which is an extension of the glandular portion of the endometrium into the underlying myometrium, occurs primarily in multiparous women in their late thirties and early forties. It may cause increased menstrual flow and a symmetrically enlarged uterus. Pelvic endometriosis and its association with secondary dysmenorrhea are discussed in the next section.

Education, including an understanding of normal ovarian physiology, is an important part of the therapy for primary dysmenorrhea. Medical therapy is indicated for patients in whom symptoms of dysmenorrhea interfere with normal activities. Nonsteroidal antiinflammatory medications such as ibuprofen inhibit prostaglandin production and are effective in most patients. Oral contraceptives suppress ovulation and are also effective in the treatment of primary dysmenorrhea. The treatment of secondary dysmenorrhea depends on the cause. Uterine anomalies leading to outflow obstruction should be corrected to prevent retrograde menstruation, which predisposes to the development of endometriosis. Endometrial polyps and pedunculated submucous myomas may be resected surgically.

Endometriosis

Endometriosis is an important cause of lower abdominal pain and gastrointestinal symptoms in women of reproductive age. [300] Endometriosis is not found before menarche and is rare during menopause. The actual prevalence is unknown, but the condition is found in approximately 3% of all fertile women, 20% to 40% of infertile women, and as many as 50% of patients with pelvic symptoms.

Endometriosis is characterized by the ectopic growth of hormonally responsive endometrium outside the uterus. The most common location for endometriosis is the pelvic peritoneum in close proximity to the fallopian tube, cul-de-sac, ovaries, and uterosacral ligament. [301] The most widely accepted mechanism by which endometriosis develops is retrograde menstruation through the fallopian tube into the peritoneum, with subsequent growth of the displaced cells in the pelvis. [302] Retrograde menstruation may be a frequent and perhaps universal occurrence. [303] It is not known why implantation and growth of ectopic endometrium occur in some women. Endometriosis at distant sites such as the pericardium or pleurae is best explained by the vascular dissemination of endometrial cells.

Risk factors for endometriosis include heavy, frequent, or prolonged menstrual periods and increased estrogen exposure. [304] Endometriomas appear to be monoclonal in origin. [305] Data support a genetic basis for endometriosis in a small percentage of overall cases. Genes for factors modulating estrogen exposure have been studied, most significantly aromatase P450. [306] Candidate genes involved in detoxification, including glutathione *S*-transferase (GST) and *N*-acetyltransferase 2 (NAT2), have also been studied. Proinflammatory cytokines, including interleukin-1 (IL-1), IL-6, IL-8, and tumor necrosis factor-a (TNF-a), have been implicated in the pathogenesis. [307]

Endometriotic implants have a variety of phenotypic appearances, including the classical nodular "powder burn" implants, red lesions with a vesicular appearance, and papular implants with a whitish, yellow, or nonpigmented appearance. There is little correlation between the phenotypic appearance of a lesion and the specific symptoms or response to therapy. However, the deeply infiltrating lesions are the ones most often associated with pain. [308]

It has been estimated that endometriotic involvement of the gastrointestinal system occurs in as many as 37% of women with documented pelvic endometriosis. [309] Endometriosis involving the gastrointestinal tract can be localized by frequency of occurrence to the rectosigmoid (72%), rectovaginal septum (13%), small bowel (7%), cecum (4%), appendix (3%), and other intestinal sites (0.5%). [310], [311] and [312] Most gastrointestinal lesions are limited to superficial pinpoint involvement over the rectosigmoid and do not cause significant symptoms. Occasionally, a larger surface area of the bowel wall may be involved with a deeply invasive lesion that is frequently accompanied by extensive fibrosis. The characteristic gross appearance of an endometrioma of the bowel wall is that of an indurated, ill-defined tumor with a glistening gray color on cross section. [313] The tumor and associated fibrosis may be circumferential and narrow the lumen, resulting in symptoms of bowel obstruction. The lesions are usually confined to the serosal and muscular layers, although they may project into the lumen as a polypoid mass covered by intact mucosa. Their appearance on barium study may closely mimic that of carcinoma. Rarely, cancer can arise in endometriosis. [314]

Patients with endometriosis may present with the hallmark symptom of pain and cramps beginning at or slightly before the onset of menses. Pain also may be constant and unrelated to menses. Patients often relate progressively worsening dysmenorrhea and a poor response to prostaglandin synthetase inhibitors. Patients may note that symptoms improve during pregnancy or with oral contraceptive therapy.

Gastrointestinal symptoms are common in patients with endometriosis. The most common gastrointestinal symptoms are rectal pain, constipation, and painful defecation. Symptoms may be referred as a consequence of involvement of the uterosacral ligaments and rectovaginal septum or of compression of the rectum by enlarging endometrial implants in the rectovaginal septum. Lesions within the bowel may result in symptoms of large bowel obstruction. [313] Rarely, endometrial implants may invade the mucosa, resulting in cyclic rectal bleeding at the time of menses. [315], [316] Other rare gastrointestinal complications associated with endometriosis include intussusception, [317] small bowel obstruction, [317], [318] hemorrhagic ascites, [319] protein-losing enteropathy, [320] and bowel perforation. [321] Appendiceal endometriosis is usually asymptomatic and found incidentally, but it may result in perforation or intussusception. [322] Superficial implants on the serosal surface of the bowel rarely cause symptoms.

Patients with endometriosis may have nodular thickening and tenderness along the uterosacral ligaments, on the posterior surface of the uterus, and in the cul-de-sac. Pelvic examination around the time of menstruation can be particularly revealing because nodularity and tenderness tend to be more conspicuous at that time. Because endometriosis tends to involve structures in the posterior cul-de-sac, pelvic findings are best appreciated on rectovaginal examination.

The evaluation of intestinal tract endometriosis if often difficult and inexact. Radiographic studies are useful in demonstrating external compression, angulation, and stricture. However, these findings are nonspecific, and it may be impossible to exclude malignancy based on the radiographic appearance alone. Endoscopic evaluation may be valuable to exclude malignancy and to diagnose the rare occurrence of mucosal endometriosis resulting in hematochezia. Endoscopic ultrasonography may be useful in documenting the depth of invasion. [323] Preoperative evaluation by endoscopy or radiography is advised in all patients with bowel symptoms preoperatively. If intestinal involvement is documented, preoperative bowel preparation can be performed.

The treatment of endometriosis involves the pharmacological suppression of ovarian function or surgical ablation or removal of the lesions. Pharmacological agents used in the medical suppression of endometriosis include combination oral contraceptives, progestational agents, danazol, and gonadotropin-releasing hormone analogs. [324] A variety of laparoscopic and nonlaparoscopic surgical options are available. [325], [326] and [327]

Ovarian Cancer

Ovarian cancer the most common gynecologic malignancy in the United States. [328] It is most prevalent in perimenopausal and postmenopausal women. The survival rate has improved but remains low, possibly because of advanced local spread of the disease at the time of diagnosis in most patients. [329] The risk for the development of ovarian cancer is four times higher for women in the United States than for those in Japan. [330] The risk for Japanese women emigrating to the United States increases, strongly suggesting an environmental factor influencing disease development.

The cause of ovarian cancer is unknown. Epithelial neoplasms constitute 80% to 90% of cases, with the remainder being germ cell and sex cord/stromal cell tumors. [331] Risk factors for the development of ovarian cancer include a history of late childbearing, early menarche and late menopause, and infertility. [332] Three to five percent of cases are familial, with three hereditary syndromes identified: (1) breast and ovarian cancer, (2) HNPCC (Lynch II), and (3) site-specific ovarian cancer. [328], [333] Most cases of familial breast and ovarian cancer are linked to the BRCA1 gene. [334], [335] Repeated ovulatory stimulation is postulated to be a factor in the malignant transformation of ovarian epithelium. Supporting this hypothesis is the observation that ovarian cancer is more common in nulliparous women and less frequent in oral contraceptive users. [336]

Ovarian cancer usually spreads by contiguous invasion and by diffuse intraperitoneal seeding, commonly involving the serosal surfaces of the fallopian tubes, adjacent uterus, bladder, and rectum. Diffuse involvement of the intestinal serosa often results in severe gastrointestinal dysfunction. Intestinal loops may become rigid and inflexible because of encasement by diffuse serosal tumor nodules. Extensive invasion of the myenteric plexus may interrupt normal peristalsis, causing segmental intestinal atony. Encasement of the intestinal wall can lead to lumenal narrowing and obstruction. The incidence of malignant ascites in patients with ovarian cancer ranges from 35% at the time of initial surgical diagnosis to more than 62% in patients dying of ovarian cancer. When a postmenopausal woman presents with ascites, the possibility of ovarian malignancy must always be entertained. Although dissemination beyond the peritoneal cavity occurs infrequently, even in advanced cases, ovarian cancer has the capacity to metastasize to distant lymph nodes and organs. The most common distal sites include the lung and liver.

Patients usually present with nonspecific symptoms, including urinary symptoms, constipation, and abdominal pain. They may present with malignant ascites, abdominal or pelvic masses, or symptoms of gastrointestinal obstruction. Pain is usually a symptom of late-stage ovarian cancer but may be associated with ovarian torsion or rupture early in the course of the disease. When the malignancy involves adjacent pelvic and abdominal sites, traction or compression of the abdominal viscera may result in chronic discomfort.

Ultrasonography is useful in differentiating ovarian neoplasms from enlarged ovarian cysts. [337] Ultrasonography, computed tomography, and nuclear magnetic resonance imaging can also document evidence of tumor spread, such as ascites and metastasis to the liver and aortic lymph nodes. The finding of ureteral dilation may indicate retroperitoneal lymphatic involvement. The level of the tumor marker CA-125 may assist in differentiating malignant epithelial ovarian carcinomas from benign masses in postmenopausal women. In premenopausal women, an elevated CA-125 level may be seen in other conditions, such as endometriosis or liver disease. In addition, advanced ovarian cancer may occur in the absence of CA-125 at any age. [338] Surgical staging and resection/debulking are an important part of the treatment for ovarian cancer. [331] Patients with borderline and highly differentiated localized tumors have a good prognosis and do not require chemotherapy. Platinum-based chemotherapy regimens are recommended in most invasive cases. [339] The prognosis is poor for patients with recurrent disease.

CHAPTER 53

David H. Alpers and Samuel Klein

APPROACH TO THE PATIENT REQUIRING NUTRITIONAL SUPPLEMENTATION

NUTRITIONAL ASSESSMENT

Most methods currently used to evaluate nutritional status are aimed at identifying specific nutrient deficiencies or protein-energy malnutrition. The diagnosis and treatment of specific nutrient deficiencies are usually straightforward. For example, potassium deficiency can be identified by measuring the serum potassium concentration and can be corrected by oral or intravenous potassium supplementation. In contrast, the diagnosis of protein-energy malnutrition is more complicated. Commonly used indicators of nutritional status have been validated by linking nutritional indicators with clinical outcome; patients with abnormal indicators have a worse outcome than patients with normal indicators. However, all indicators are influenced by illness or injury, so it is difficult to separate the contribution of malnutrition from that of the illness itself. Therefore, if nutritional status linked to the severity of disease, patients who are “malnourished” may have a poor outcome simply because they are sicker than patients who are “well nourished.” Moreover, nutritional therapy may not improve outcome unless malnutrition is an independent contributor to adverse medical events.

Nutritional Assessment Techniques

Specific Nutrient Deficiency A careful history and physical examination, routine blood tests, and selected laboratory tests based on the history and physical examination findings can be used to diagnose specific macronutrient, mineral, vitamin, and trace mineral deficiencies (Table 53-1, Table 53-2 and Table 53-3). [1]

TABLE 53-1 Some Physical Signs of Nutritional Deficiency

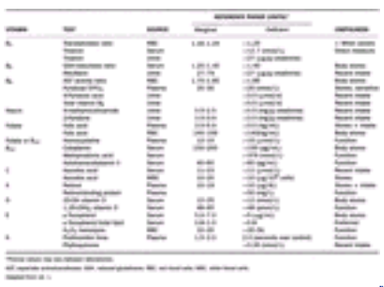

TABLE 53-2 Clinical Laboratory Tests for Detection of Vitamin Deficiency

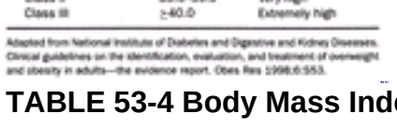

TABLE 53-3 Laboratory Detection of Micronutrient Mineral Deficiency

Protein-Energy Malnutrition Ideally, nutritional assessment is used to identify those patients who will benefit from nutritional support. However, the indicators currently used to assess protein-energy malnutrition have been validated by determining their relationship to clinical outcome rather than to the response of patients to nutritional therapy.

Body mass and composition. In general, unintentional weight loss is associated with an adverse clinical outcome. [2] However, the assessment of changes in body weight can be confounded by errors in recall and changes in body water. Anthropometry, the measurement of triceps and subscapular skinfold thickness, provides an index of body fat and muscle mass, which is compared with the values in standard tables. Although the interpretation of these data may be limited by differences in age and ethnicity between patients and the standard population, interrater variability, and hydration, markedly abnormal values (below the 5th percentile) usually predict a poor clinical outcome. Body muscle mass can also be assessed in the clinical setting by measuring the urinary creatinine excretion. [3] Patient values can be compared with those in tables indicating an expected amount of creatinine excretion in relationship to height in subjects consuming a meat-free diet. [1] The body mass index (BMI), which is obtained by dividing weight (kilograms) by the square of the height (square meters), can help identify patients at increased risk for medical complications (Table 53-4).

WEIGHT CATEGORY	BMI (kg/m^2)	RISK
Extremely underweight	<14.0	Extremely high
Underweight	14.1–18.4	Increased in smokers, chronic illness
Normal	18.5–24.9	Normal
Overweight	25–29.9	Increased
Obesity		
Class I	30.0–34.9	High
Class II	35.0–39.9	Very high
Class III	≥40.0	Extremely high

Adapted from National Institute of Diabetes and Digestive and Kidney Diseases. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults—the evidence report. Obes Res 1998;6:553.

TABLE 53-4 Body Mass Index As a Measure of Associated Disease Risk

Serum protein concentrations. The concentration of several plasma proteins, particularly albumin, correlate with clinical outcome; a low plasma albumin concentration is associated with an increased incidence of medical complications. [4], [5] Illness or injury, however, rather than malnutrition per se, is responsible for hypoalbuminemia in sick patients. [6] Inflammation and injury decrease albumin synthesis, increase albumin degradation, and increase albumin transcapillary losses. Specific gastrointestinal, renal, and cardiac diseases can increase albumin losses through the gut or kidney. Wounds, burns, and peritonitis cause losses from surface tissues. Nutritional support itself does not usually alter serum albumin levels. [7] Serum concentrations of transferrin, retinol-binding protein, and thyroxine-binding prealbumin are also affected by inflammation, so that they are unreliable as a measure of protein-energy malnutrition.

Immune system function. The total circulating lymphocyte count and delayed cutaneous hypersensitivity to skin test antigens have been used as clinical indicators of malnutrition. Although depression of circulating lymphocytes (<200/mm [3]) and anergy assessed by delayed cutaneous hypersensitivity are associated with a poor clinical outcome, they are not specific for nutritional deficiency and are affected by specific diseases, injury, and certain drugs.

Multivariate analysis. Multiple regression analyses of selected indicators of nutritional status have been used to provide a score for individual patients and thereby identify those at increased risk for medical complications. [8], [9]

Subjective global assessment. The subjective global assessment involves a focused history and physical examination to determine the adequacy of nutrient intake and the possible effect of malnutrition on body composition and organ function (Table 53-5). [10], [11] In addition, it includes an analysis of the patient's future ability to ingest adequate nutrients. The findings of the history and physical examination are subjectively weighted to rank patients as well nourished, moderately malnourished, or severely malnourished. Patients who are judged to be severely malnourished are at high risk for medical complications and adverse outcome. [10], [12]

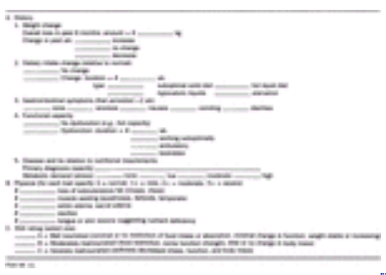

TABLE 53-5 Subjective Global Assessment (SGA) of Nutritional Status

There is no "gold standard" for determining nutritional status. All current approaches are influenced by the severity of illness and have been validated by assessing clinical outcome rather than by nutrition-specific parameters. Therefore, current nutritional assessment techniques identify sick patients. Although it is often assumed that "malnourished" patients will benefit from nutritional support, this assumption has not been documented in prospective randomized clinical trials. [13]

CHOOSING THE ROUTE FOR NUTRITIONAL SUPPORT

The decision to initiate nonvolitional nutrition support is complex and involves a clinical assessment of the patient's nutrient intake, body fat and protein mass, protein and energy requirements, severity of illness, and anticipated duration of inadequate volitional intake. Once it has been decided that nonvolitional nutrition support is indicated, the route of nutritional support must be considered. The usual course is to choose the oral or enteral route when this approach can be used effectively and safely. There are several reasons for this choice. First, enteral nutrition may provide nutrients that are not available from parenteral nutrition. The best example of this principle is the provision of short-chain fatty to the colonic mucosa via the bacterial degradation of fiber or unabsorbed carbohydrate. The provision of this important colonic energy source may maintain colonic function. [14] Second, it is felt that lumenal nutrients may prevent atrophy in the small intestinal mucosa. Atrophy occurs in rats fed by parenteral nutrition, but the importance of this phenomenon in humans is still uncertain. [15] Finally, enteral feeding may be safer than parenteral nutrition. [16], [17] and [18]

If oral or enteral feeding is chosen, intestinal motility and absorptive surface must be adequate. Other disorders that interfere with enteral feeding include severe diarrheal illnesses, extensive inflammatory bowel disease, acute gastrointestinal bleeding, conditions that will require abdominal surgery in the near future, obstructing small bowel or colon lesions, and acute inflammation of the pancreas or biliary tract. A number of guidelines have been developed that provide useful and practical information for the clinician. [19], [20] The guidelines for use in specific disorders, such as acquired immunodeficiency syndrome (AIDS), are practical modifications of the generalized guidelines, with special emphasis on the problems of feeding patients with that disorder. [21] However, the clinician should not rely on a

set pattern of guidelines for decisions regarding nutritional support. The published guidelines should be used as resource material to aid in the clinical judgment required for each patient.

ENTERAL NUTRITION

The availability of so many different types of whole-food diets and defined formulas makes it possible for many hospitalized patients to receive adequate nutrient intake by oral or enteral tube feedings.

Whole-food diets include a regular hospital diet and diets modified in either consistency (e.g., clear liquid, full liquid, pureed, and soft diets) or nutrient content (e.g., low-residue, low-fat, low-sodium, low-protein, and high-fiber diets). In many cases, nutrient intake can be increased by encouraging the ingestion of ordinary food and by avoiding missed meals and unpalatable diets. Many patients eat more if they are given assistance at mealtime and provided with desired foods and if some food supplied by relatives and friends is allowed.

Defined formulas are commercially made products with a known “defined” nutrient composition (Table 53-6). These formulas can be divided into five categories: feeding modules, monomeric formulas, oligomeric formulas, polymeric formulas, and disease-specific formulas. Feeding modules consist of single nutrients, such as protein (intact protein, hydrolyzed protein, or crystalline amino acids), carbohydrate (glucose polymers), or fat (long-chain or medium-chain triglyceride), that can be used to supplement a specific diet or be part of a modular enteral system composed of several nutrient modules.

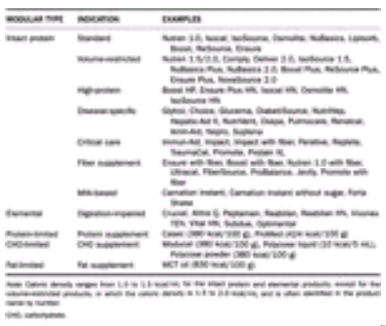

TABLE 53-6 Classification of Commercially Available Enteral Nutrition Products

Monomeric (elemental) formulas contain nitrogen in the form of free amino acids and usually only small amounts of fat (<5% of total calories). Therefore, these formulas can be useful in patients who require an extremely low-fat diet. However, monomeric formulas are hyperosmolar, unpalatable, and more expensive than polymeric formulas, and in the absence of pancreatic insufficiency, they are not absorbed better than oligomeric or polymeric formulas. [22]

Oligomeric (semi-elemental) formulas contain hydrolyzed protein in the form of small peptides and sometimes free amino acids. Fat represents 5% to 40% of energy content as either long-chain triglycerides or a combination of long-chain and medium-chain triglycerides. Data from several studies suggest that oligomeric diets can reduce diarrhea and other gastrointestinal side effects in critically ill patients [23] and in patients receiving abdominal irradiation and chemotherapy. [24], [25] However, the purported clinical benefits of oligomeric formulas require confirmation in large prospective clinical trials before precise recommendations regarding their use can be made.

Polymeric formulas contain nitrogen in the form of whole proteins. These formulas can be categorized into three groups: blenderized food formulas, milk-based formulas, and lactose-free formulas. Milk-based formulas usually contain milk as a source of protein and fat and tend to be more palatable than other defined diets. Although milk-based formulas can be problematic for lactose-intolerant patients, they are often tolerated when infused continuously to decrease the load of lactose delivered to the intestine at any one time. Lactose-free formulas are the most commonly used polymeric formulas in hospitalized patients, and many modifications in protein and fat content are available. Disease-specific formulas have been designed for patients who have specific illnesses, including hepatic insufficiency, renal insufficiency, pulmonary insufficiency, diabetes, and severe metabolic stress. In general, the clinical superiority of these formulas over less expensive, standard polymeric enteral formulas remains controversial. However, branched-chain amino acid–enriched formulas may permit greater nitrogen intake in selected patients with chronic protein-intolerant hepatic encephalopathy (see section “ Nutritional Support in the Hospitalized Patient with Gastrointestinal Disease ”), and renal failure formulas contain much smaller amounts of sodium, potassium, phosphorus, and magnesium than standard formulas.

A positive caloric balance is necessary to optimize and sometimes to achieve positive nitrogen balance and to incorporate amino acids into new protein. To achieve this goal, the ingestion of about 25 to 35 kcal/g of protein (~150–200 kcal/g of nitrogen) is required. This ratio is based on the derivation of 10% to 15% of caloric needs during catabolism from protein degradation.

Oral Rehydration Therapy

Patients with protracted vomiting or diarrhea can lose excessive amounts of fluid and electrolytes. Oral rehydration therapy enhances sodium and water absorption by stimulating sodium/glucose cotransport in the small intestine. Oral rehydration therapy has been demonstrated to have considerable clinical benefits in patients with severe gastrointestinal fluid and mineral losses, such as those with cholera-induced diarrhea, high-output ostomies, and short bowel syndrome. [26], [27], [28], [29], [30], [31] and [32]

A variety of oral rehydration solutions are currently available (Table 53-7). The World Health Organization developed a solution based on the results of studies in patients with cholera. [31] The glucose component of an oral rehydration solution should be provided at concentrations between 70 and 150 mmol/L. Higher concentrations of glucose can be deleterious because the increase in osmolality may reduce water absorption. Making the solution hypotonic by replacing glucose with rice solids or other polymeric forms can decrease stool output compared with isotonic solutions. [24], [25], [26] and [27] In patients with short bowel syndrome ending in a jejunostomy, net sodium and fluid balance is related to jejunal length. Patients with less than 100 cm of jejunum are usually net secretors, whereas those with more than 100 cm of jejunum are usually net absorbers. [32] The use of oral rehydration therapy can markedly decrease ostomy output and convert some patients from net secretors to net absorbers. In these patients, the consumption of electrolyte replacement drinks containing 60 mmol or less of sodium per liter causes a negative sodium and fluid balance, whereas the balance becomes positive after the ingestion of solutions containing 90 mEq/L and is maximal at a concentrations of 120 to 160 mEq/L. [33] Sport drinks and commercially made defined liquid formula diets do not contain an adequate amount of sodium for maximal fluid absorption in patients with severe short bowel syndrome and a jejunostomy.

TABLE 53-7 Characteristics of Selected Oral Rehydration Solutions

Tube Feeding

General Principles Enteral tube feeding is useful in patients who have a functional gastrointestinal tract but who cannot or will not ingest adequate nutrients. Many

approaches to tube feeding are possible (e.g., nasogastric, nasoduodenal, nasojejunal, gastrostomy, jejunostomy, pharyngostomy, esophagostomy tubes) and depend on physician experience, clinical prognosis, anticipated duration of feeding, patency and motility of the gut, risk for aspiration of gastric contents, and patient preference. Short-term feeding (<6 weeks) can be achieved by the placement of a soft, small-bore nasogastric or nasoenteric feeding tube. These tubes are made of silicone or polyurethane and can be left in place without the tissue irritation or pressure necrosis caused by larger polyvinyl chloride tubes. Many patients are able to eat with the tube in place, which permits the use of tube feeding to supplement oral intake. Nasogastric feeding is usually the most appropriate route, but orogastric feeding can be used in cases of nasal injury or gross nasal deformity. Nasoduodenal or nasojejunal feeding is useful in patients with gastroparesis. In addition, by taking advantage of the barrier function of the pyloric and gastroesophageal sphincters, nasoenteric feeding may decrease the incidence of aspiration in high-risk patients. However, the prevention of aspiration by feeding beyond the pylorus has not been proved in clinical trials. Most patients who require long-term tube feeding (>6 weeks) should have a gastrostomy or jejunostomy tube placed. These tubes can be placed endoscopically, radiologically, or surgically, depending on the clinical situation and local expertise (see Chapter 146). Percutaneous endoscopic gastrostomy can be performed within 30 minutes and is successfully completed in more than 90% of attempts. [34] Gastrostomy tubes can be placed percutaneously without endoscopy by inserting the catheter directly into the stomach via a peel-away sheath introduced over a previously placed J-wire guide. [35] This approach is particularly useful in patients with an obstructing lesion of the esophagus or hypopharynx that prevents passage of an endoscope or a gastrostomy tube bumper. A summation of data from several large series suggests that percutaneous endoscopic gastrostomy tube placement is associated with mortality in 0.5%, major complications (peristomal leakage with peritonitis, necrotizing fasciitis of the anterior abdominal wall, gastric hemorrhage) in 1%, and minor complications (minor wound infections, stomal leaks, tube extrusion or migration, aspiration, gastrocolic fistula, ileus, fever) in 8% of patients. [36] Jejunal tube placement can be achieved by threading a tube through an existing gastrostomy or by percutaneous endoscopic jejunostomy in patients with previous partial or total gastrectomy. [37], [38], [39], [40] and [41] Surgical gastrostomy is more expensive than percutaneous endoscopic gastrostomy unless the tube is placed during an operation performed for another reason. A jejunostomy tube may also be placed at the time of abdominal surgery and consists of a subserosal tunnel or needle catheter jejunostomy. Gastrostomy and jejunostomy tubes can also be placed by using laparoscopic techniques.

Administration of Tube Feeding Patients with feeding tubes in their stomach can often tolerate intermittent gravity feedings, in which the total amount of daily formula is divided into four to six equal portions that are infused by gravity over 30 to 60 minutes. The patient's upper body should be elevated by more than 30° during and for at least 1 hour after feeding. Intermittent feedings are useful for patients who cannot be positioned with the head of the bed continuously elevated or who require greater freedom from feeding. However, patients who experience nausea and early satiety with bolus gravity feedings may require continuous infusion at a slower rate. Patients who have gastroparesis often tolerate gastric tube feedings when they are started at a slow rate (e.g., 10 mL/h) and advanced by small increments (e.g., 10 mL/h every 8–12 hours). However, patients with severe gastroparesis require passage of the feeding tube tip past the ligament of Treitz. Continuous infusion should always be used when feeding directly into the duodenum or jejunum to avoid distention, abdominal pain, and dumping syndrome.

Complications Mechanical, metabolic, and gastrointestinal complications can occur in patients receiving tube feedings. Although the placement of nasogastric tubes is usually safe, tubes can be misplaced, particularly in unconscious patients. Intubation of the tracheobronchial tree has been reported in up to 15% of patients, and intracranial placement can occur in patients with skull fractures. Feeding tubes can cause nasopharyngeal erosions, pharyngitis, sinusitis, otitis media, pneumothorax, and gastrointestinal tract perforation. Small-diameter nasogastric tubes (e.g., 8F or 9F) are usually used to lessen nasopharyngeal irritation. These small tubes often become occluded by inspissated feedings or pulverized medications given through the tube. Frequent flushing of the tube with 30 to 60 mL of water and avoiding the administration of pill fragments whenever possible help maintain patency. Many techniques for unclogging tubes have been published and include the gentle infusion of small quantities of carbonated beverage, pancreatic enzymes, and 95% ethyl alcohol into the tube. In addition, commercially made products can be obtained that either dissolve or mechanically remove the obstruction. Metabolic complications, such as hypokalemia, hyponatremia, hypophosphatemia, and hyperglycemia can occur. [40] Patients should be monitored for metabolic abnormalities, particularly severely malnourished patients during the initial refeeding period. Gastrointestinal side effects of tube feedings include nausea and vomiting, pulmonary aspiration, abdominal pain, and diarrhea. Diarrhea is the most common complication and occurs in 30% to 50% of critically ill patients receiving tube feedings. Diarrhea is often caused by antibiotic use [41] and the use of liquid medications and elixirs that contain nonabsorbable carbohydrates, such as sorbitol. [42] Patients with normal gastrointestinal tract function can tolerate larger volumes of tube feedings. In one study, tube feeding did not cause diarrhea in healthy subjects until it was given at rates exceeding 200 mL/h. [43] Several case reports have also documented an association between small bowel necrosis and jejunal feedings in critically ill patients. [44] Most of these patients were receiving pressors to maintain an adequate blood pressure, suggesting that the increased oxygen requirements associated with feeding can cause ischemia in patients whose intestinal blood flow is unable to increase.

PARENTERAL NUTRITION

In some patients, enteral feedings are either contraindicated or cannot be provided in sufficient quantities to meet nutritional requirements. In these cases, parenteral nutritional support can be a valuable adjunctive and sometimes life-saving therapy. Certainly, patients unable to ingest "adequate" nutrients for a "prolonged" period of time require nutritional therapy to prevent the adverse effects of malnutrition. However, the precise definitions of "adequate" and "prolonged" are not clear and are likely to differ from patient to patient depending on the amount of body energy stores and lean body mass, the presence of preexisting medical illnesses, and the level of metabolic stress. The use of parenteral nutrition is often recommended if enteral intake has been, or is anticipated to be, inadequate for 5 to 10 days. [45] However, carefully performed, well-designed prospective randomized clinical trials to support the efficacy of this approach for many clinical situations are few in number. [46] Therefore, the use of parenteral nutrition requires a careful integration of data from pertinent clinical trials, clinical expertise in the illness or injury being treated, a reasonable estimate of the anticipated duration of inadequate food intake, clinical expertise in nutritional therapy, and input from patients and their families.

Central Parenteral Nutrition

General Principles The ability to use a central vein to supply nutrient requirements for growth and maintenance was realized more than 30 years ago when catheters were inserted into the superior vena cava of beagle dogs to provide the sole source of nutrients for 72 to 256 days. [47] Today, the use of central parenteral nutrition (CPN), also known as *total parenteral nutrition (TPN),* is commonplace. Although percutaneous infraclavicular subclavian vein catheterization with advancement of the catheter tip to the junction of the superior vena cava and right atrium is the most commonly used technique for catheter placement, many other approaches have been successfully performed when the subclavian vein is not accessible, including internal jugular, basilic, saphenous, and femoral veins and even thoracotomy with direct insertion into the right azygos vein [48] or the right atrial appendage. [49] In addition, peripherally inserted central venous catheters can be used to provide CPN. In this approach, insertion by a physician is not required, and the technique cannot cause pneumothorax or traumatic injury to arteries or nerves, but it is associated with an increased risk for thrombosis if the catheter tip is placed proximal to the superior vena cava. [50] Parenteral nutrient solutions provide all the basic nutrient requirements, including fluids, proteins, carbohydrates, fats, minerals, trace elements, and vitamins (Table 53-8). The lipid component can be piggybacked to the primary nutrient mixture, or a total nutrient admixture can be prepared, which reduces handling costs and potential breaks in sterility. However, total nutrient admixtures prevent visible inspection for particulate matter. Invisible calcium and phosphorus precipitates have caused fatal pulmonary emboli in patients receiving parenteral nutrition. [51] Therefore, pharmacy standards regarding physical-chemical compatibility should be closely followed in all patients receiving CPN, and in-line filters should be used with all parenteral nutrient solutions. Even a careful inspection of clear nutrient solutions cannot detect small microprecipitates, which can obstruct very small pulmonary capillaries. [52]

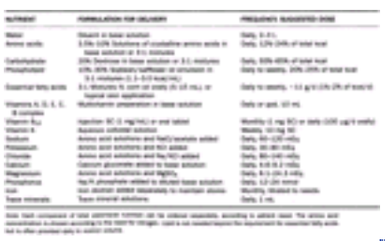

TABLE 53-8 Delivery of Nutrients During Total (Central) Parenteral Nutrition

The specific formulation prescribed for a patient depends on the patient's estimated nutrient requirements and ability to tolerate specific nutrients without adverse effects. The patient's protein, energy, and fluid requirements are the most important initial considerations in designing the appropriate parenteral formulation. Protein requirements are met by infusing standard solutions composed of crystalline amino acids containing 40% to 50% essential and 50% to 60% nonessential amino acids, usually with little or no glutamine, glutamate, aspartate, asparagine, tyrosine, and cysteine. Most hospitalized patients require between 1.0 and 1.5 g of protein per kilogram of body weight per day. Some amino acid solutions have been modified for specific disease states, such as those enriched in branched-chain amino acids, advocated for patients with hepatic encephalopathy, and those containing 67% to 100% essential amino acids, advocated for patients with renal insufficiency. However, the clinical superiority of these formulations over standard amino acid solutions has not been well documented in clinical trials. [53], [54] The major sources of energy are glucose and lipid. However, infused amino acids are also oxidized and should be included in the estimate of energy provided as part of the parenteral formulation. Glucose (dextrose) is usually the predominant energy source in CPN formulations and is the required fuel for erythrocytes, white blood cells, bone marrow, and renal medulla (~40 g/d) and the preferred fuel for the brain (~120 g/d). Each gram of hydrated dextrose provides 3.4 kcal and is readily oxidized unless

excessive amounts are infused. In stable postoperative patients, increasing the rate of glucose infusion up to, but not more than, 7 mg/kg per minute increases the rate of glucose oxidation. [55], [56] Lipid emulsions contain soybean oil or a combination of soybean and safflower oil triglycerides, egg yolk phospholipids as an emulsifying agent, and glycerin to maintain isosmolarity. These emulsions provide energy and are a source of essential fatty acids, linoleic and linolenic acids. Lipid calories are as effective as additional glucose calories in conserving body nitrogen economy and supporting protein metabolism once absolute tissue requirements for glucose have been met. [57], [58] The optimal percentage of calories that should be infused as fat is not known. At least 5% of total calories should be given as lipids to prevent essential fatty acid deficiency. The rate of lipid emulsion infusion should probably not exceed 0.7 kcal/kg per hour because most complications associated with lipid emulsion infusions have been reported when more than 1.0 kcal/kg per hour (0.11 g/kg per hour) was provided. [59] Lipid emulsion infusion can cause pulmonary dysfunction, [60] hepatic phospholipidosis, [61] impaired immune system function, [62] pancreatitis, [63] decreased platelet aggregation, [64] fat overload syndrome, [65] and hypersensitivity reactions. [66] Together, carbohydrate and lipid should provide 25 to 35 kcal/g of protein to optimize incorporation of amino acids into new protein.
Complications Mechanical, infectious, metabolic, and gastrointestinal complications are associated with the use of CPN. Administering CPN under the guidance of experienced teams decreases the incidence of most complications. [67] Percutaneous insertion of a central venous catheter can damage local structures and cause pneumothorax, brachial plexus injury, subclavian and carotid artery puncture, hemothorax, thoracic duct injury, and chylothorax. In addition, the catheter can be sheared off, become occluded, or cause subclavian vein or superior vena cava thrombosis. [68], [69] and [70] Catheter-related sepsis is the most common serious complication in patients receiving CPN; even when meticulous care is provided, catheter-related sepsis occurs in up to 4% of hospitalized patients. [71] Multiple-lumen central catheters that are used for CPN are associated with an increased incidence of infections compared with single-lumen catheters. [71] Catheter-related sepsis should be considered in all patients in whom a fever or leukocytosis develops while they are receiving CPN. The catheter tunnel and exit site should be carefully inspected, and any exit site drainage should be cultured. Blood cultures should be obtained from the central line and a peripheral vein. The presence of subcutaneous infection along the catheter tunnel or clinical toxicity (e.g., hypotension) without another known source of infection is an indication for immediate catheter removal. If no evidence of tunnel infection or clinical toxicity is found, the catheter can remain in place, and empiric antibiotic therapy should be started through the central venous catheter. Blood cultures should be obtained again in 48 to 72 hours to ensure clearance of bacteremia. The catheter should be removed from patients who have blood cultures that are positive for fungus or *Staphylococcus aureus,* polymicrobial infection, persistent or recurrent catheter-related bacteremia, or persistent fever without another suspected source of infection. The metabolic complications observed in patients receiving parenteral nutrition are usually caused by inappropriate nutrient administration resulting in nutrient excesses or deficiencies or both. A blood glucose level above 200 mg/dL should be avoided because it is associated with leukocyte and complement dysfunction and may increase the risk for infection. [72] Blood glucose goals for most patients are 100 to 200 mg/dL initially and 100 to 150 mg/dL when stable. Blood glucose should be kept below 120 mg/dL in pregnant patients to avoid the complications of gestational diabetes and large-for-gestational-age births. Metabolic bone disease, including osteopenia and osteomalacia, has been observed in patients receiving long-term (>3 months) CPN. [73] Several hepatobiliary abnormalities have been observed in patients receiving CPN and are usually more severe and more frequent in infants than in adults. [74] Hepatic abnormalities include alterations in liver biochemistries, steatosis, steatohepatitis, lipidosis and phospholipidosis, cholestasis, fibrosis, and cirrhosis. Most hepatic abnormalities occur early and are transient, but in a small subset of patients receiving long-term (>16 weeks) CPN, progressive and more serious liver disease develops. [75] Biliary abnormalities include acalculous cholecystitis, gallbladder sludge, and cholelithiasis and usually occur in patients receiving relatively prolonged (>4 weeks) courses of CPN. Acalculous cholecystitis has been reported in about 5%, [76] cholelithiasis in about 30%, and gallbladder sludge in up to 100% [77] of patients receiving prolonged CPN. The pathogenesis of acalculous cholecystitis is unclear. Gallbladder stasis is an important contributing factor in the pathogenesis of gallbladder sludge and stones. Maintaining regular gallbladder contractions by either enteral feedings or cholecystokinin injections prevents gallbladder sludge and gallstone formation. [78], [79]

Peripheral Parenteral Nutrition

Peripheral parenteral nutrition (PPN) consists of a mixture of nutrients containing a final concentration of 5% to 10% dextrose, 2% to 5% amino acids, electrolytes, and vitamins and minerals. This crystalloid solution is mixed with a 10% or 20% lipid emulsion as an all-in-one admixture, or the lipid emulsion can be piggybacked to the distal port of the intravenous infusion line. So that adequate calories can be given in a reasonable volume, the lipid component usually provides approximately half of the total calories.

The use of a peripheral vein to provide nutritional support avoids many of the mechanical and infectious complications of CPN but is associated with a high risk for thrombophlebitis, which occurs in up to 94% of patients. [80] However, the use of PPN has become possible in many patients since safe isotonic lipid emulsions have been developed and a better understanding of the causes of PPN-induced thrombophlebitis has been acquired. Several factors are important in the pathogenesis of thrombophlebitis in patients receiving PPN: (1) the osmolality, pH, and lipid content of the PPN solution, and the presence of particulate matter; (2) the diameter, length, and composition of the catheter; (3) the duration, rate, and volume of the infusion; (4) the diameter and anatomic position of the vein; and (5) the insertion technique. [81], [82] Adherence to the following principles can increase the life of a single infusion site to more than 10 days in many patients: (1) Provide at least 50% of total energy as a lipid emulsion, add 500 to 1000 U of heparin and 5 mg of hydrocortisone per liter of solution, and add sodium hydroxide if needed to achieve a pH of 7.4; (2) insert a fine-bore 22- or 23-gauge polyvinyl pyrrolidine-coated polyurethane catheter in as large a vein as possible in the proximal forearm with use of a sterile technique; (3) place a 5-mg glyceryl trinitrate ointment patch over the infusion site; (4) infuse the PPN solution with a volumetric pump and keep the total infused volume below 3500 mL; and (5) filter the solution with an in-line 1.2-µm filter.

Home Parenteral Nutrition

The ability to provide parenteral nutrition at home was first demonstrated in 1970. [83] In 1992, approximately 40,000 patients (120 per 1 million residents) received home parenteral nutrition (HPN) in the United States, [84] a rate tenfold higher than the prevalence rate in Europe (1 per million to 12 per million residents). [84], [85] and [86] Patients with benign diseases have a much better outcome than those with terminal illnesses. Most HPN patients with benign gastrointestinal diseases achieved complete rehabilitation; only 5% of the total HPN days were spent in the hospital. [84] Approximately 5% of patients died each year of HPN-associated complications. [87] In contrast, more than half of the patients receiving HPN who had cancer or AIDS died within 6 months, and more than 80% had died at 1 year.

HPN is usually given through an implantable subcutaneous port or a catheter inserted in the subclavian vein and tunneled subcutaneously to exit on the anterior chest. Nutrient formulations are infused for 8 to 12 hours overnight to allow patients to be active during the day. Intravenous lipids may not be necessary for patients who eat and are able to absorb adequate amounts of fat, whereas others may receive 20% to 30% of their calories as a lipid emulsion. The protein, energy, electrolyte, vitamin, and trace mineral requirements are normal unless the disease process increases requirements or losses.

The most serious common complication is catheter-related sepsis, most often caused by *S aureus* or *Staphylococcus epidermidis*. In addition, venous thrombosis, chronic liver disease, cholelithiasis, and metabolic bone disease are associated with the prolonged use of HPN.

MICRONUTRIENT DEFICIENCY AND TREATMENT

Tissues that proliferate rapidly (skin, oral and gastrointestinal mucosa, hair, bone marrow) or in which metabolic rates are high (muscle, gastrointestinal mucosa) are at greatest risk for signs of deficiency at an early stage. Clues regarding deficiency come from a history of reduced intake or increased losses (or of conditions that make those situations more likely), physical examination findings, and results of laboratory tests that ideally determine body stores of the nutrient. The signs and symptoms of nutritional deficiency in adult patients are listed in Table 51-1. The laboratory values for the major vitamins and minerals are listed in Table 51-2 and Table 51-3. A more detailed discussion of these nutrients and the assessment of their status can be found in general references. [1], [88], [89]

Sodium

Deficiency Sodium depletion usually presents with symptoms of dehydration because of concomitant water loss. Severe depletion presents with nausea, vomiting, exhaustion, cramps, seizures, and ultimately cardiovascular collapse. On the physical examination, mucosal xerosis, sunken eyeballs, and mental confusion can be present, but none of these are specific findings. In older patients, other explanations are often present for all these signs. [90] Orthostatic hypotension is often used to estimate the intravascular volume and is defined as a systolic blood pressure below 20 mm Hg or a diastolic blood pressure below 10 mm Hg within 3 minutes after standing, with or without a rise in the heart rate of 5 to 10 beats/min. [91] The signs of total body sodium excess are weight gain and edema. The presence of either of these would not reflect sodium deficiency. If sodium deficiency is the result of increased gastrointestinal or cutaneous losses, the urine osmolality is increased and the urine sodium concentration is less than 10 mEq/L. If sodium deficiency is the result of diuretic therapy, the urine osmolality is decreased and the urine sodium concentration is more than 10 mEq/L.
Assessment The serum sodium concentration primarily reflects water, not sodium, balance. Thus, any serum concentration is possible when deficiency is present, depending on the relative deficits of water and sodium. If hyponatremia is present but the cause is not apparent, the serum osmolality should be measured. In

hospitalized patients, hyponatremia is most often the result of dilution by excess free water, not depletion of sodium. The free water excess is usually caused by cardiac, hepatic, or renal insufficiency or by overly enthusiastic fluid administration and is accompanied by edema and weight gain. When normovolemia is present, the hyponatremia may be caused either by inappropriate secretion of antidiuretic hormone or by displacement of sodium osmoles with elevated glucose or urea as osmoles.

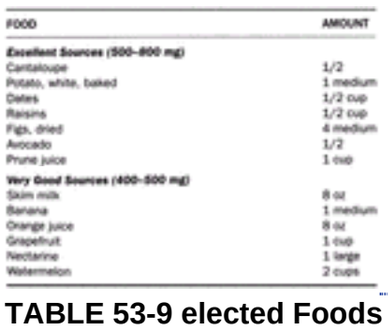
Treatment When signs of volume depletion are present, at least a 10% reduction in extracellular fluid volume has occurred. [92] The sodium deficit can be estimated as follows: Na deficit (mEq) = ([Na desired] - [Na observed]) × 0.6 × weight (kg). Sodium is usually replaced with NaCl (1 g = 17 mEq of Na), either orally, enterally, or parenterally. Symptomatic hyponatremia (e.g., seizures, lethargy) is treated with intravenous 0.9% NaCl or occasionally with hypertonic (3% or 5%) NaCl. Sodium infusion should be designed to increase the serum concentration by 1 mEq/h until it reaches 120 mEq/L. Too rapid restoration has been associated with permanent neurological deficits resulting from central pontine myelinolysis. When sodium depletion is accompanied by hypernatremia or normonatremia, the appropriate amount of water should be supplied along with the sodium to achieve or maintain a normal serum sodium concentration. Chronic losses from diarrhea, vomiting, or ileostomy should be treated in adults with an oral rehydration solution that provides a carbohydrate source along with adequate sodium, so that Na/solute–coupled cotransport can occur and maximize the rate of sodium repletion. These solutions are discussed in the section “Enteral Nutrition.” Sodium toxicity can result from excessive administration of NaCl. Symptoms of toxicity include vomiting, diarrhea, peripheral vascular collapse, respiratory depression, and death.

Potassium

Deficiency Hypokalemia (<3.5 mEq/L) rarely is caused by decreased intake but can result from shifts between the extra- and intracellular compartments of the body occurring while the total body potassium remains normal. This shift can be caused by alkalosis and the administration of glucose or insulin. Alternatively, decreased body stores result from increased renal excretion or intestinal losses, with subsequent shift of potassium from extra- to intracellular compartments. Other causes of renal losses include mineralocorticoid excess, some antibiotics, and rarely renal tubular acidosis. In pure deficiency states, each decrease of 1 mEq/L corresponds to a loss of 200 to 300 mEq of body potassium. The loss of 5% to 10% of body stores is usually tolerated without symptoms, but when serum levels fall below 3.0 mEq/L, weakness, paresthesias, confusion, cramps, myalgias, and cardiovascular abnormalities can occur. [93]

Assessment The normal serum level of potassium is 3.5 to 4.5 mEq/L and reflects both body stores and the availability of glucose as an energy source. Red blood cell hemolysis or extreme leukocytosis without hemolysis can result in spurious hyperkalemia. Total body potassium deficit cannot be estimated accurately. Treatment should be provided if symptoms are attributed to the hypokalemia, or if other conditions, such as chronic liver disease, are present that would exacerbate the hypokalemia. Alkalosis tends to lower the serum potassium concentration, whereas acidosis raises it. Thus, alkalosis can be treated first before the addition of potassium salts, but the same should not be done when acidosis is present.

Treatment Oral replacement should be used if possible because this allows the serum potassium concentration to rise slowly in equilibrium with the intracellular compartment. Either food (Table 53-9) or supplement (Table 53-10) sources should be used. The administration of 20 to 40 mEq at a time up to four times a day is safe. The chloride salt is preferred when renal or gastric losses account for the hypokalemia. When hypokalemia is secondary to diarrhea, one of the alkalinizing salts (e.g., citrate, acetate, bicarbonate) is preferred. The slow-release, matrix, and microencapsulated forms are better tolerated than liquid preparations. The slow-release forms have reduced the chance for small bowel ulcers and strictures but may not be useful for patients with short bowel syndrome. For intravenous therapy, the infusion rate should not exceed 20 mEq/h unless cardiac monitoring is included. The chloride salt is usually best for intravenous therapy, except when phosphate is used for treating the associated hypophosphatemia of diabetic ketoacidosis. In the presence of acidosis, potassium acetate is the best choice. Hyperkalemia should be avoided during therapy because levels above 8.0 mEq/L carry a severe risk for cardiac dysfunction, including bradycardia, asystole, and ventricular fibrillation. Skeletal muscle weakness, areflexia or hyperreflexia, paralysis, and fatigue may also occur at these high levels.



FOOD	AMOUNT
Excellent Sources (500–800 mg)	
Cantaloupe	1/2
Potato, white, baked	1 medium
Dates	1/2 cup
Raisins	1/2 cup
Figs, dried	4 medium
Avocado	1/2
Prune juice	1 cup
Very Good Sources (400–500 mg)	
Skim milk	8 oz
Banana	1 medium
Orange juice	8 oz
Grapefruit	1 cup
Nectarine	1 large
Watermelon	2 cups

TABLE 53-9 elected Foods Rich In Potassium

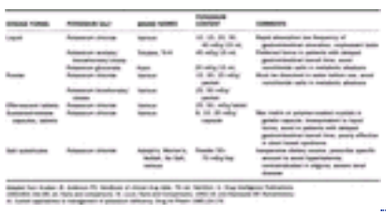


TABLE 53-10 Oral Potassium Products Comparison Chart

Calcium

Deficiency The conditions that cause hypocalcemia requiring calcium supplementation include vitamin D deficiency, failure of vitamin D synthesis or action, hypoparathyroidism, hypomagnesemia, severe acute pancreatitis, malabsorption syndromes, neoplasms with osteoblastic metastases, and medications, including aminoglycosides, cisplatin, calcitonin, furosemide, mithramycin, phosphates, and anticonvulsants. [94] Acute manifestations include tetany, altered myocardial function and arrhythmias, hyperreflexia, paresthesias, seizures, mental status changes, and choreoathetotic movements. The electrocardiogram shows prolonged QT intervals with normal QRS complexes. Chronic deficiency may not be associated with hypocalcemia. With a total body content of 100 g and a net daily loss of 100 mg/d, a 20% decrease in body stores that could be easily detected would develop in 2000 days, or about 6 years. Osteopenia usually presents with fractures or bone pain. However, patients identified as being at high risk for the development of osteopenia should begin treatment well before this occurs. Risk factors include cigarette smoking, family history of osteoporosis, sedentary lifestyle, long-term glucocorticoid therapy, long-term anticonvulsant therapy, early surgical or natural menopause (<50 years), and testicular failure (secondary to drug therapy or disease).

Assessment Recent intake or absorption is assessed by 24-hour urinary calcium. [88] At levels of absorption above 2 mg/kg (corresponding to an intake of 6 mg/kg), urinary calcium equals absorbed calcium. When absorption is low, urinary calcium levels do not decline proportionally, unlike the levels of sodium, potassium, magnesium, and phosphorus, all of which are better absorbed with better-regulated urinary excretion. Urinary calcium is used primarily to determine that absorption is low and to follow the patient after oral replacement is begun, to ensure that absorption becomes normal and that hypercalciuria does not ensue. Urinary calcium excretion of more than 300 mg/d is an indication to reduce the dose of calcium (or vitamin D). Body stores of calcium are assessed by bone densitometry, with many centers now using dual-energy x-ray absorptiometry. The accuracy of this method is equal to that of quantitative computed tomography and is sensitive to changes of 9% to 12% in bone mass. [95] Results must be compared with those of age- and gender-matched controls and are useful for diagnosis and following the response to therapy. Bone densitometry should be used to screen all patients at high risk for the development of osteopenia and to guide treatment decisions for selected postmenopausal women, but it is not recommended for routine screening. Serum calcium and alkaline phosphatase levels do not become abnormal until total body calcium depletion is quite severe.

Treatment The treatment of acute symptomatic hypocalcemia is required immediately to prevent laryngospasm, seizures, and cardiac arrhythmias. A total of 200 to 300 mg of elemental calcium should be given intravenously over 5 minutes as 1 g of calcium chloride or 2 to 3 g of calcium gluconate. This should be followed by an infusion of calcium of 0.5 to 2.0 mg/kg per hour. [94], [96] The serum calcium should normalize in 6 to 12 hours while the vital signs and electrocardiographic activity are monitored. Patients with chronic hypocalcemia or osteopenia on the basis of poor intake or absorption should be treated with oral supplements of up to 2.5 to 3.0 g/d given in divided doses. The best dietary source of calcium is milk, and this can be used if clinically tolerated. Otherwise, a number of oral calcium salts are available that vary in elemental calcium content (Table 53-11). [97] Calcium carbonate is used most often because of the high percentage of elemental calcium, but it is rather insoluble. If the urinary calcium does not increase with calcium carbonate, another, more soluble salt (e.g., calcium gluconate) may be tried, with or without the addition of vitamin D. People who take calcium supplements may be at risk for ingesting lead, even though the amount of lead in bone meal has dropped as a consequence of a decrease in the levels of environmental lead from gasoline and paint. When tested by the Natural Resources Defense Council, many of the 20

major brands of calcium supplements marketed in California contained enough lead to increase the average intake of 5 to 10 µg by 50%. [98] The supplements tested that were lowest in lead content (<0.5 µg per dose) were Children's Mylanta, Posture-D High Potency Calcium with Vitamin D, and Tums 500 Calcium Supplement.

SALT	PERCENTAGE OF ELEMENTAL CALCIUM (%)	TABLET SIZE (mg)	AMOUNT OF CALCIUM PER TABLET (mg)
Calcium carbonate	40		
Caltrate		1500	600
Os-Cal 500		1250	500
Tums		500	200
Calcium phosphate	38		
Posture		800	300
Calcium acetate	25	1000	250
Calcium citrate	21		
Citracal		950	200
Calcium lactate	13	650	85
Calcium gluconate	9	500	45
Calcium glubionate	6.5	1800/5 mL	115/5 mL

TABLE 53-11 Selected Oral Calcium Supplements

When malabsorption is present, the doses of vitamin D used are large (25,000–50,000 IU given from once a week to daily). Alternatively, the more soluble forms of vitamin D, especially 1,25-dihydroxyvitamin D, may be effective. Treatment programs must be individualized and monitored closely. Thiazides can decrease the urinary loss of calcium (thereby rendering the urinary determination less meaningful) buy also increase the urinary loss of magnesium. Thus, their use in patients with osteopenia must be carefully considered. Supplemental calcium may predispose some individuals to kidney stones but decreases the risk for oxalate stones in patients with short bowel syndrome. The development of calcium toxicity in patients with malabsorption is rare but can occur in patients with osteopenia and normal absorption, especially if they are also receiving supplemental vitamin D. Hypercalcemia can cause anorexia, nausea, constipation, polyuria, fatigue, weakness, confusion, lethargy, decreased deep tendon reflexes, shortened QT and prolonged PR interval and QRS complex duration, and cardiac arrest. [96]

Magnesium

Deficiency Symptomatic magnesium deficiency is usually the result of decreased absorption or increased losses in the urine or from the gastrointestinal tract, especially in patients with extensive small bowel resection. [99] Excessive urinary loss, usually caused by decreased tubular reabsorption, occurs in a variety of circumstances. Medications promote renal loss, including diuretics, aminoglycosides, cyclosporine, amphotericin B, cisplatin, and digitalis. [100], [101] Increased renal losses also occur in hypercalcemia, volume expansion, tubular dysfunction, acute and chronic alcoholism, diabetes mellitus, hyperparathyroidism, and hypophosphatemia. Hypomagnesemia caused by a shift of magnesium from the extracellular to the intracellular compartment may result from feeding, treatment of diabetic ketoacidosis, parathyroidectomy, acute pancreatitis, and correction of acidosis in renal failure. Hypomagnesemia is often associated with and can be a cause of hypocalcemia, hypokalemia, and hypophosphatemia. [101] Hypomagnesemia can present as tremor, myoclonic jerks, ataxia, tetany, ventricular dysrhythmias, tachycardia, hypotension, cardiac arrest, apathy, depression, delirium, hallucinations, and psychosis. [102] The signs and symptoms of hypomagnesemia are often a consequence of the hypocalcemia resulting from the same condition (e.g., malabsorption) or of the decreased parathyroid hormone secretion that occurs when hypomagnesemia is severe.

Assessment In the absence of excess fecal or renal losses, urinary excretion reflects intake and absorption of magnesium. [89] When the serum magnesium is very low in patients with short bowel syndrome, the urinary magnesium excretion may also be low and perhaps more sensitive than the serum magnesium. [103] Serum magnesium concentrations do not correlate well with total body stores, but it is reasonable to assume that depletion is present when the serum concentration is less than 1.0 mg/dL. [101] Because magnesium is primarily an intracellular ion, the best indicator of depletion may be a measurement of the content in white cells, although only a few studies have compared this value with those in other tissue pools. [89] A load test for magnesium depletion has been described, but its usefulness has not been satisfactorily documented.

Treatment Moderate to severe deficiency should be treated parenterally, especially if tetany or ventricular arrhythmias are present. An intravenous loading dose of 4 to 8 mmol should be given first, followed by 25 mmol/d thereafter until the plasma magnesium is above 0.4 mmol/L. [104] If hypocalcemia or hypokalemia is present, magnesium should be replaced first. Repletion is best achieved with slow, continuous infusions to avoid rapid increases in urinary excretion. Replacement should be monitored closely with serial serum concentrations and evaluation of deep tendon reflexes. Hypermagnesemia (>3.0 mg/dL) should be avoided because vasodilation, nausea, vomiting, drowsiness, lethargy, hypotension, bradycardia, depressed deep tendon reflexes, and a prolonged PR interval can develop. Patients with mild deficiency or ongoing magnesium losses should receive foods rich in magnesium or an oral supplement. A variety of magnesium salts are available, but many of them, especially the oxide and hydroxide, are very insoluble (Table 53-12). Because magnesium is poorly absorbed, it is best to give it in frequent small doses. Potassium-sparing diuretics such as spironolactone decrease urinary magnesium losses and may be useful, especially in patients who are also hypokalemic. However, some patients will require parenteral supplements. Outpatients unresponsive to oral therapy can be treated with intramuscular injections of 2.0 mL of 50% magnesium sulfate solution (8.1 mEq) in each buttock at intervals as needed.

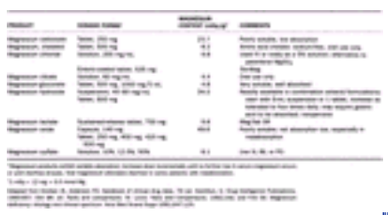

TABLE 53-12 Magnesium Products Comparison Chart

Phosphorus

Deficiency Most patients in whom clinical evidence of hypophosphatemia develops have an underlying wasting condition, [105] such as malabsorption, malnutrition of any cause, cancer, or chronic alcoholism. Causes of hypophosphatemia include increased urinary losses, shifts of serum phosphorus into the intracellular compartment, and reduced absorption. Absorption is decreased with the use of phosphate-binding antacids, vitamin D deficiency, and parathyroid hormone deficiency. Renal loss is increased in metabolic alkalosis, diuretic therapy, renal tubular dysfunction, osmotic diuresis, hyperparathyroidism, and long-term corticosteroid therapy. [104] When carbohydrate is administered or when phosphate-rich lean tissue is restored and insufficient phosphorus is available, serum levels can fall. [104] Signs and symptoms of hypophosphatemia include hemolytic anemia (serum phosphorus concentration <0.5 mg/dL), rhabdomyolysis (<1.0 mg/dL), and other complications that occur with lesser degrees of depletion, including platelet dysfunction, metabolic acidosis, peripheral neuropathy, central nervous system dysfunction, metabolic encephalopathy, and cardiac failure. Most cases of hypophosphatemia appear to be associated with intercompartmental shifts of phosphorus rather than with decreases in the total body pool, although this distinction is not easy to make.

Assessment The normal serum phosphorus concentration is 2.5 to 4.5 mg/dL. Levels lower than 1.0 mg/dL usually cause symptoms. [104], [105]

Treatment If hypophosphatemia is the result of therapy with phosphate-binding medications (antacids, sucralfate), stopping the medication is sufficient. If oral or enteral intake is possible, supplementation for other causes of a serum phosphate level below 2.5 mg/dL can be provided with milk (1000 mg or 32 mmol/quart of skim milk) or with other oral preparations in doses of 2 to 3 g/d (e.g., Neutra-Phos K or Uro-KP Neutral with 250 mg or 8.0 mmol per capsule or dose of powder). Most of the oral preparations, however, cause diarrhea (secondary to lactose intolerance in the case of milk and the phosphate content in the others), which may limit their use in patients with malabsorption. Intravenous supplementation should be limited to those who cannot take oral preparations or who have severe hypophosphatemia (<1.0 mg/dL). Initially, the dose used should be 2.5 to 5.0 mg of elemental phosphorus per kilogram administered over 6 to 8 hours in normal saline solution, not to exceed 7.5 mg/kg every 6 to 8 hours over an extended period to avoid hypocalcemia or sodium or potassium overload. The exact amount needed to restore serum phosphorus cannot be predicted because severe hypophosphatemia may occur with normal body stores of phosphorus. When hypocalcemia or renal failure is present, great caution should be used in administering phosphate by any route, but especially intravenously. Too rapid administration can cause calcium phosphate precipitation in renal tubules and other tissues.

Iron

Deficiency For clinicians, the sequelae of the last stage of iron deficiency, when stores are depleted and anemia occurs, are equated with iron deficiency. However, the role of delivering oxygen to the tissues is dependent not only on hemoglobin concentration but also on the ability of iron-containing proteins in mitochondria to

process the oxygen. Some evidence demonstrates alterations in the activity of iron-containing respiratory chain enzymes in iron-deficient animals. [106] Such changes may account for the symptoms more prevalent in children (i.e., anorexia, decreased resistance to infection, and reversible protein-losing enteropathy) and for other features not easily explained by anemia, such as angular stomatitis, atrophic lingual papillae, koilonychia, and behavioral or cognitive changes. [107] Cognitive changes have been correlated with low hemoglobin levels in dieting adults, although it is not clear whether the iron was causative. [108] When anemia develops, weakness and pallor predominate.

Assessment The hemoglobin and hematocrit are the initial and best screening tests, [109] but the results should be interpreted with caution. The patient's age and gender have to be considered in an assessment of the iron status of any individual. Moreover, hemoglobin concentrations can be altered by dehydration or overhydration, chronic inflammation or infection, protein-calorie malnutrition, cobalamin or folate deficiency, hemoglobinopathies, and pregnancy. Thus, hemoglobin is at best an indirect index of the iron status. The ferritin levels in serum are directly proportional to marrow iron stores and inversely proportional to transferrin levels, with each milligram per liter representing 10 mg of storage iron. Low levels of serum ferritin (<15 ng/mL) in the presence of anemia nearly always reflect decreased iron stores, and values up to 35 ng/mL are very suggestive. [1] However, ferritin levels can be elevated in cases of acute and chronic inflammation, cobalamin or folate deficiency, leukemia or lymphoma or other tumors, alcohol intake, and hyperthyroidism. Thus, values between 15 and 100 ng/mL can be seen in patients with iron deficiency. Serum iron levels alone are not a good measure of the iron status because they do not reflect a stable body pool. About 35 mg is turned over in the plasma each day, and levels can change rapidly in response to acute inflammation. In iron deficiency, serum transferrin levels rise while iron levels fall, so that the percentage of saturation falls below 15%. When chronic inflammation, infection, or liver disease is present, serum transferrin levels fall. Transferrin synthesis is down-regulated at the level of translation by iron, so that transferrin levels are elevated in iron deficiency. Thus, a low percentage of saturation in the presence of low transferrin levels does not reflect iron deficiency but rather the anemia of chronic inflammation. Table 53-13 outlines the predictive value of the usual tests relative to the stage of iron deficiency.

TEST	STAGE OF IRON DEFICIENCY (Predictive Value, %) I	II	III	IV
Bone marrow iron stain	100	100	100	100
Serum ferritin (μg/L)	100	100	100	100
Zinc protoporphyrin (μmol/mol of heme)	0	100	100	100
Transferrin saturation (%)	0	71	78	96
Hemoglobin (g/L)	0	0	100	100
MCV (μm^3)	0	0	22	100
MCH (pg)	0	0	33	100

Note: The prevalence rates of patients presenting in each stage of deficiency are about 24%, 23%, 15%, and 38%, respectively, for stages I through IV.

MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin.

Modified from Hastka J, Lasserre J-J, Schwarzbeck A, et al. Laboratory tests of iron status: correlation or common sense? Clin Chem 1996;42:5.

TABLE 53-13 Predictive Values of Laboratory Tests in Different Stages of Iron Deficiency

How to proceed when ferritin values are above 35 ng/mL is not clear, and transferrin receptors have been suggested as a possible aid. [110] The amount of uptake of transferrin into cells is regulated by alterations in the number of transferrin receptors on the surface of cells and is dependent on the intracellular concentration of iron, cell proliferation status, and metabolic need. The highest concentration of transferrin receptors on cells is on those with the greatest need for iron, such as reticulocytes. A truncated form of the receptor is found in human plasma bound to transferrin, and its content is elevated in iron deficiency, even if mild and of recent onset. The levels of transferrin receptor are not affected by inflammation or liver disease, and theoretically, the levels can be used to distinguish iron deficiency from the anemia of chronic disease. However, receptor levels are also increased in ß-thalassemia, hemolytic anemia, sickle cell anemia, polycythemia, myelofibrosis, and chronic lymphocytic leukemia. [111], [112] The value of the transferrin receptor in iron deficiency has yet to be corroborated by a widespread experience, although a radioimmunoassay detecting human soluble receptor is now commercially available.

Treatment Oral iron is available in a wide variety of preparations as a single nutrient or in combination with other vitamins and minerals. The amount used is not important so long as it is adequate to replenish body stores, with an assumption of 20% absorption at the start of treatment for iron deficiency. The approximate percentages of the preparations as elemental iron are as follows: sulfate anhydrous, 30%; sulfate $7{\cdot}H_2O$ hydrated, 20%; fumarate, 33%; and gluconate, 11.6%. The dose should be calculated based on the elemental iron content. A standard dosing schedule is ferrous sulfate (65 mg of elemental iron) two to three times a day between meals. Side effects include nausea, indigestion, diarrhea, and abdominal cramping and can limit the amount that can be ingested. Side effects may be less common when slow-release forms are used, but the iron may be made less available by delaying release to beyond the duodenum, the site of maximal absorption. The total iron deficit can be determined roughly by calculating the amount needed to replenish hemoglobin, with an additional gram for repleting tissue stores. Iron deficit (mg) in males = body weight (lb) × [15 - hemoglobin (g/dL)] + 1000. A hemoglobin value of 12 or 13 g/dL can be used for females. If 10% absorption throughout therapy is assumed, the total dose required can be calculated. Once the daily tolerable supplement is determined for a patient, the length of treatment necessary to replete the stores can be calculated. Oral preparations should be continued for 1 to 3 months after the hemoglobin level is restored to allow for restoration of other tissue stores. Parenteral iron is used only when oral iron is not tolerated or effective. Iron dextran (50 mg/mL) is available for intramuscular or intravenous use. The total dose required to replete stores is based on the patient's weight and hemoglobin level:

$$\text{Total Iron (mg)} = 0.3 \times \text{Body Weight (lb)} \times 100 - \frac{\text{Hemoglobin(g/dL)} \times 100}{14.8}$$

The intravenous route is safe when the iron is diluted in normal saline solution and administered over 2 to 3 hours. [113] A test dose of 25 mg should be given initially, and the daily dose should not exceed 100 mg if one wishes to minimize the risk for side effects. However, medium-dose (100–400 mg) or high-dose (500–1000 mg up to full replacement) regimens can be used safely and more conveniently, provided adequate precautions are taken and the patient is observed during the infusion. [113] Anaphylaxis is extremely rare when iron dextran is given in this way. However, the patient should be closely supervised and parenteral iron given with caution anyone with asthma or allergy. Epinephrine should be available for acute hypersensitivity reactions, and antihistaminics can be given for symptoms of urticaria, rashes, sweating, dizziness, headache, nausea, and fever. Most patients with Crohn's disease who require parenteral iron will respond, but erythropoietin can enhance the response. [114]

Zinc

Deficiency Zinc deficiency is difficult to identify and thus is probably underdiagnosed. Overt deficiency in otherwise healthy individuals is not reported in the United States, but the growth of children can be limited by inadequate dietary zinc. [115] Patients with gastrointestinal disease (Crohn's disease, short bowel syndrome), cystic fibrosis, pancreatic insufficiency, or chronic diarrhea from any cause are at increased risk for zinc deficiency because of increased losses in the stool and decreased intake. [116] Diarrheal stool contains about 17 mEq of zinc per liter, in excess of the Recommended Dietary Allowance (RDA). Other conditions predisposing to zinc deficiency include cirrhosis, sickle cell anemia, pregnancy, pica, and penicillamine treatment. [115] Clinical manifestations include growth retardation (in children), skin lesions on the face and limbs (which can vary from moist and pustular to seborrheic and acneiform), alopecia, diarrhea, apathy, night blindness, and possibly poor wound healing and loss of taste. However, the single double-blinded study of the effect of zinc supplements on taste and smell dysfunction did not support a role for zinc. [117]

Assessment None of the available methods reliably reflect either recent intake and absorption or body stores. The fasting plasma concentration is most often used, but it correlates poorly with total body zinc except when the patient is severely deficient. Most zinc in blood is in red cells, so that even small amounts of hemolysis can alter plasma zinc. Most plasma zinc is bound tightly to a $_2$-macroglobulins or loosely to albumin. Thus, hypoproteinemia can lower zinc levels. The plasma level may be falsely low because it can be decreased by many other factors, such as stress, infection, polypharmacy (displacing zinc from albumin), and corticosteroids. [1], [89] Levels below 50 μg/mL are often associated with some symptoms, and patients with levels below 30 μg/mL nearly always have some manifestation of deficiency. Metallothionein is a zinc/copper–binding protein that is reduced in zinc deficiency, and its red cell content has been low when zinc plasma levels were normal, perhaps reflecting a functional zinc pool. [118] If these results are reproducible, this test might prove useful in the early detection of zinc deficiency. At present, however, if zinc deficiency is suspected, it is best diagnosed by the symptomatic response to zinc therapy.

Treatment Zinc is available as a single nutrient and as a component of many multivitamin/mineral preparations. Zinc supplementation should be provided to persons at risk for the development of deficiency, as well as to those with symptomatic deficiency. [119] Zinc sulfate (67 or 220 mg) contains 15 or 50 mg of elemental zinc. Thus, unlike a single dose of other minerals, a single dose of zinc exceeds the RDA, and oral therapy is usually sufficient, even though absorption is only about 20%. Parenteral zinc therapy is also available as the sulfate or chloride. Zinc is safe to use; the minimum oral toxic dose is 500 mg/d. [1] Long-term ingestion of high doses (450 g/d) can induce copper deficiency. [120] Zinc supplements have reduced the incidence, prevalence, duration, and severity of diarrhea and pneumonia in children from developing nations, presumably because the availability of dietary zinc in such regions is limited. [121]

Copper

Deficiency Copper deficiency in adults is rare. It can occur in patients receiving TPN without copper supplementation and in patients treated with chelating agents, such as D-penicillamine, with or without large doses of zinc. [122] Premature infants, malnourished or malabsorbing patients, and persons with Menkes syndrome, an inherited defect in copper absorption, are at higher risk for the development of deficiency. [123] Neutropenia, anemia, diarrhea, and scurvylike bone changes can occur. [124] Copper supplementation should also be considered for patients with increased gastrointestinal fluid losses, especially from chronic biliary tract fistulae, because biliary secretion is the major excretory route for copper. [122]
Assessment The laboratory assessment of the copper status is difficult because serum concentrations do not correlate well with tissue levels. Because 80% of copper is bound to ceruloplasmin (each milligram binds 3.3 µg of copper) and the rest to other proteins, the level does not correlate with intake. [125] However, tissue copper levels are quite stable and change slowly. Thus, when deficiency occurs, the plasma level often falls earlier than the tissue levels. Normal levels are increased by estrogens or oral contraceptives, pregnancy, and acute and chronic infections. Levels are decreased in nephrosis, Wilson disease, and any cause of protein malnutrition. Free copper levels are more instructive than total levels and can be estimated by calculating bound copper [bound copper = ceruloplasmin (µg/dL) × 3] and subtracting it from the total. Values below 25 µg/dL are normal. [126] This calculation is more sensitive in detecting elevated copper levels (as in Wilson disease) than in detecting copper deficiency.
Treatment Oral supplementation can be provided by the copper sulfate in multivitamin/mineral preparations, which contain 0.4 mg of elemental copper per milligram of copper sulfate. The daily dose of 2 to 3 mg is adequate to treat deficiency in adults. The suggested maintenance intravenous dose is 0.3 to 1.5 mg/d, but the dose should be reduced to 0.15 mg/d for patients with cholestasis. [127] To treat deficiency, 2 to 7 mg/d has been given intravenously. There is a large margin of safety in using copper supplements, but acute oral ingestion of more than 15 mg of elemental copper produces nausea, vomiting, diarrhea, abdominal cramps, and mucosal ulceration. At larger doses, hemolysis, gastrointestinal bleeding, azotemia, and jaundice can occur. The treatment of toxicity includes gastric lavage and 1 g of D-penicillamine per day. [128]

Thiamin (B_1)

Deficiency Deficiency may be caused by decreased intake or increased tissue utilization, or by a combination of the factors. Thus, the usual clinical settings include pregnancy, chronic alcoholism, malabsorption syndromes, chronic nausea and vomiting, prolonged febrile illnesses, and chronic renal dialysis. The total daily requirement is usually more than 1 mg/d in adults, and the total stores are only about 30 mg, so deficiency can develop fairly rapidly. In parts of the world where polished rice is the staple cereal in the diet, beriberi (weakness, paresthesias, high-output cardiac failure) is seen. In the United States, where food thiamin is abundant, the deficiency syndrome is often seen in conjunction with deficiency of other B vitamins. Symptoms and signs include peripheral neuropathy, limb weakness, cerebellar dysfunction, subacute necrotizing encephalomyelopathy, and Wernicke encephalopathy (apathy, confusion, ataxia, photophobia, nystagmus, paralysis of upward gaze). Signs of deficiency may worsen if glucose is given without thiamin. If lactic acidosis is also present, signs of heart failure may develop. [129] Thiamin deficiency should be considered in the differential diagnosis of lactic acidosis.
Assessment Recent intake or absorption, but not body stores, is correlated with urinary excretion. The amount excreted is higher during childhood, when growth is rapid, so the result (micrograms of thiamin per gram of creatinine) must be compared with the values in age-matched controls. Body stores are measured either directly in blood or serum by high-performance liquid chromatography or by the erythrocyte transketolase assay, which measures a thiamin-dependent enzyme activity. The activity coefficient of the enzyme is determined by the activity in the presence and absence of added thiamin. In deficiency states, more stimulation occurs, and the activity coefficient is above 1.25. [89]
Treatment Thiamin HCl is available as a single nutrient in oral and parenteral forms and as a constituent of almost all multivitamin preparations. Adults with mild deficiency should receive 10 to 20 mg intramuscularly or 25 to 50 mg orally twice daily for 1 week, followed by an oral maintenance dose of 2 to 5 mg/d. Critically ill patients, especially those with central nervous system manifestations of deficiency, should receive doses of 50 to 100 mg twice daily intravenously for 3 days, followed by oral supplementation of 5 to 30 mg/d until a normal diet is resumed. The thiamin should be given before any carbohydrate is administered to avoid enhancing the deficiency. Because thiamin deficiency is often associated with deficiencies of other B vitamins, multiple vitamins should be given. Rare responses to parenteral thiamin include feelings of warmth, tingling, pruritus, nausea, sweating, and anaphylactic reaction. [130] It has been suggested that thiamin improves energy levels during exercise and in the elderly, and cognition in Alzheimer disease, but the few studies performed do not support these conclusions. [131]

Riboflavin (B_2)

Deficiency Riboflavin deficiency usually occurs along with deficiencies of other B vitamins, especially in patients with malabsorption and chronic alcoholism. Early symptoms relate to oral or eye lesions. Angular stomatitis (maceration and fissuring of the mucocutaneous junction at the angles of the mouth), cheilosis (inflammation of the lips), glossitis, geographic tongue, seborrhea-like dermatitis, pruritus, photophobia, corneal vascularization, and visual impairment may occur. The differential diagnosis of the lip lesions includes poorly fitting dentures with malocclusion, allergy (e.g., lipstick, tooth paste), and iron deficiency anemia. Other vitamin B deficiencies can cause the tongue lesions. Some of these symptoms occur in vitamin B_6 deficiency because the oxidase necessary to produce functional vitamin B_6 is riboflavin-dependent. [132]
Assessment Urinary excretion correlates well with intake because the vitamin is excreted unmetabolized. With fasting or prolonged bed rest, urinary excretion can be falsely elevated. Levels below 40 µ/g of creatinine signify very low intake in an adult. Body stores of riboflavin are assessed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase in the blood. An activity coefficient above 1.2 (stimulated/control activity) signifies deficiency. [89]
Treatment Deficiency can be treated with 5 to 10 mg/d orally, along with other vitamins. [133] When malabsorption is present, a prophylactic dose of 3 mg/d is recommended, usually as part of a multivitamin preparation. Riboflavin may cause a yellow-orange appearance to the urine but is remarkably nontoxic.

Niacin (B_3)

Deficiency Because of the current niacin supplementation of grains and breads, the classical deficiency syndrome of pellagra (dermatitis, dementia, diarrhea) is rare in the United States. Deficiency is seen most often in patients with chronic alcoholism, malabsorption syndromes, or carcinoid syndrome, in which a large amount of tryptophan (niacin precursor) is converted instead to serotonin. Pellagra rarely occurs in the carcinoid syndrome, and when it does, it can be overcome with oral niacin. Hartnup disease is associated with a defect in tryptophan absorption and can also predispose to deficiency. [134] Isoniazid therapy can lead to deficiency because hydrazines form adducts with pyridoxal phosphate. The last enzyme in the conversion of tryptophan to nicotinic acid, kynureninase, requires pyridoxal, thereby linking the deficiency of these two vitamins. Moreover, isoniazid resembles nicotinic acid and acts as an inhibitor. In niacin deficiency, the dermatitis occurs over exposed areas and is scaly. Painful tongue and angular stomatitis are seen but may be caused in part by accompanying riboflavin deficiency. Diarrhea is probably caused by the direct effect of niacin deficiency on epithelial cell function. Central nervous system dysfunction includes irritability, headache, insomnia, psychosis, hallucinations, and seizures.
Assessment The urine content of a niacin metabolite, *N*-methylnicotinamide, reflects intake and absorption and is less than 0.5 mg/g of creatinine in adults with deficient intake. No test is available for body stores of niacin, although the results of one study in young men suggested that an erythrocyte ratio of nicotinamide adenine dinucleotide (NAD) to nicotinamide adenine dinucleotide phosphate (NADP) below 1.0 might reflect deficiency. [89]
Treatment Isolated niacin deficiency is unusual in the United States, so treatment with other B vitamins often accompanies niacin replacement. [134] Depending on their severity, the symptoms of pellagra respond to oral doses of 100 to 500 mg of niacin per day. [134] Mental, gastrointestinal, and oral symptoms clear rapidly, but the resolution of skin lesions may require weeks to months. Large doses of nicotinic acid (1–3 g/d) used to treat hypercholesterolemia can cause flushing, pruritus, burning sensations, nausea, vomiting, heartburn, diarrhea, dizziness, and tachycardia. Hyperglycemia and increased serum transaminase and bilirubin levels can occur at doses as low as 750 mg of nicotinic acid per day. [135]

Pyridoxine (B_6)

Deficiency Because the vitamin is abundant in foods and is produced by colonic bacteria, dietary deficiency is rare. It is most often reported as a result of treatment with pyridoxine antagonists, especially isoniazid, hydralazine, oral contraceptives, dopamine, and D-penicillamine. Rarely, deficiency occurs in chronic alcoholism or malabsorption, usually in association with deficiencies of other B vitamins. The clinical manifestations include peripheral neuropathy, seborrheic dermatitis around the eyes and nasolabial folds, and oral lesions (angular stomatitis, cheilosis, glossitis), similar to those seen in riboflavin and niacin deficiencies. Seizures and sideroblastic anemia may also occur. [136] Hyperhomocystinuria has been identified as an independent risk factor for vascular disease and may be caused in part by a deficiency of cystathionine synthase, the vitamin B_6–dependent enzyme that catalyzes the conversion of homocysteine to cystathionine. When serum homocysteine levels were elevated (>16.3 µmol/L), lower levels of plasma pyridoxal 5-phosphate, cobalamin, and folic acid were found, and supplementation with all three vitamins

normalized the homocysteine levels. [137] However, it is premature to recommend the use of these supplements to alter atherogenesis in this subset of patients with hyperhomocystinemia. [138]

Assessment Recent intake is reflected by the urinary excretion of metabolites. A low intake correlates with excretion of less than 500 µg of 4-pyridoxic acid per day. Body stores are measured by the erythrocyte aminotransferase index, with a determination of enzyme activity in the presence and absence of pyridoxal phosphate. Deficiency is correlated with an erythrocyte aspartate aminotransferase (E-AST) index above 2.2. Alternatively, pyridoxal phosphate can be measured in whole blood (50–120 nmol/L) or plasma (>30 nmol/L), although the levels associated with deficiency have not been precisely determined. [89]

Treatment Pyridoxal phosphate is available in both oral and parenteral forms. Suspected deficiency should be treated with 50 to 150 mg/d orally, especially when neuropathy is present. A multiple vitamin preparation containing 2 to 5 mg of pyridoxine should be added to provide the other B vitamins. Some experts suggest such a supplement for all patients on isoniazid and similar inhibitors, whereas others suggest supplements only for those patients at high risk for the development of neuropathy. When pyridoxal phosphate is ingested in large amounts (2–6 g/d), a peripheral neuropathy may develop. [139] Pyridoxine antagonizes levodopa by stimulating the decarboxylation of dopa to dopamine. Therefore, patients taking levodopa should limit their pyridoxine intake to less than 5 mg/d. [140]

Folate

Deficiency Folate deficiency is associated with poor socioeconomic and dietary conditions, especially with chronic alcoholism (usually >80 g/d) and malabsorption syndromes. Alcohol can increase urinary folate excretion. [141] Deficiency also results from competition for absorption (sulfasalazine), long-term anticonvulsant therapy (usually years), increased utilization (pregnancy, hemolytic anemia, leukemia, chronic myelofibrosis), and inhibition of dihydrofolate reductase (the enzyme that converts folate to the active coenzyme) by methotrexate, trimethoprim, and pyrimethamine. [142] If folate stores are normal initially, symptoms will appear in about 4 months. The primary manifestation of classical folate deficiency is macrocytic anemia, often accompanied by thrombocytopenia and leukopenia. Other symptoms may include glossitis, diarrhea, fatigue, and possibly (but uncommonly) neurological signs. Two other significant forms of folate deficiency occur in the absence of classical evidence of deficiency. Women consuming too little folic acid during early pregnancy are at increased risk for delivering children with neural tube defects. The Dietary Reference Intake Committee has confirmed the recommendation of the U.S. Department of Health and Human Services that all women capable of becoming pregnant ingest 400 µg of synthetic folic acid daily. [142] Hyperhomocystinemia can be caused by folate deficiency if it is not accompanied by elevated methylmalonic acid levels. High levels of homocysteine are correlated with an increased risk for myocardial infarction in about 10% of patients. [138] Although the folate levels are normal, the hyperhomocytinemia can be corrected by supplemental folate, but it is not clear that the risk for heart disease is altered. The epidemiologic data implicating homocysteine as a factor in cardiovascular risk are strong, but data from some prospective studies have been less consistent. [138], [143] Although a low folate status is a strong determinant of elevated total homocysteine levels, the folate status was not associated with an increased risk for coronary atherosclerosis. [144]

Assessment Because folate deficiency develops during decreased intake or absorption, the first laboratory abnormality to develop is a decrease in the serum folate (2–6 ng/mL), which is sensitive to changes in intake. [89] Values below 2 ng/mL are usually associated with megaloblastic anemia and decreased tissue reserves. Because about 50% of serum folate is bound to albumin, hypoalbuminemia can produce falsely low serum folate levels. Body stores of folate can be measured by red cell folate more accurately than by serum folate. Because both red and white cells contain much more folate than serum does, hemolysis or leukemoid reaction can falsely elevate the serum folate. When both serum (<2 ng/mL) and red cell folate (<140 ng/mL) are low, folate deficiency is the cause. When cobalamin deficiency is present, folate may not be well utilized in 15% to 25% of cases, so serum folate rises and red cell folate falls. Multilobed polymorphonuclear cells and macrocytic anemia develop after tissue folate levels fall. [89] Serum homocysteine levels above 30 µmol/L are consistent with folate deficiency if the methylmalonic acid levels are normal.

Treatment Oral folate supplements are available in tablets up to 1 mg, but the unreduced pteroylglutamic acid is the form used. Most of this form is excreted unchanged or after degradation, so the dose of this supplement cannot be compared with the real requirements. The parenteral route is used only if oral therapy is not possible or malabsorption is severe. A reticulocyte response is seen in 3 to 5 days, and a peak response occurs in 5 to 10 days. The 400-µg dose found in multivitamin preparations is usually adequate as maintenance therapy for patients with malabsorption or alcoholism. For patients on sulfasalazine or with hemolytic anemia, a dose of 1 mg/d is suggested. Folate is remarkably nontoxic. Very large doses (>100 times the RDA) can precipitate convulsions in patients treated with phenytoin. [145] Giving folate to a patient with cobalamin deficiency corrects the anemia but does not prevent irreversible neurological damage. The Tolerable Upper Intake Level (UL) for folate of 1000 µg/d has been challenged because all but eight cases of masking neurological progression in vitamin B_{12} deficiency occurred in patients taking more than 5 mg of folate per day. [146]

Cobalamin (B_{12})

Deficiency A dietary deficiency of cobalamin occurs only in lacto-ovo-vegetarians who do not consume any food of animal origin. The most common causes in adults are gastric lesions (especially the atrophic gastritis associated with pernicious anemia or gastrectomy), lesions or resection of the terminal ileum (especially in Crohn's disease), and bacterial overgrowth. Gastric pathology accounts for well over half the cases. An increasingly common cause of low serum cobalamin levels is AIDS. The significance of the low levels is not always clear, but some patients manifest subtle alterations in mental and cognitive abilities. [147] Deficiency also occurs rarely in patients with severe chronic pancreatitis, congenital deficiency of the carrier protein transcobalamin II (TCII), or an inability to utilize food-bound cobalamin in the absence of other gastric pathology. [148] Symptoms are insidious and develop over 2 to 3 years, sooner if malabsorption is the cause. A sore tongue, paresthesias, anorexia, loss of taste, diarrhea, dyspepsia, hair loss, impotence, irritability, and psychiatric illness (e.g., depression) can be present. Numbness and tingling, especially in the lower extremities, can progress to loss of vibratory sensation, loss of coordination, muscle weakness, and atrophy, and memory disturbances can develop. [149] Macrocytic anemia with megaloblastic bone marrow and multilobed nuclei in the polymorphonuclear leukocytes are frequently, but not always, present. The macrocytic anemia must be differentiated from chronic liver disease and from hypothyroidism. Many patients, especially those who are elderly, now present with neurological symptoms and signs in the absence of anemia assessment The diagnosis of cobalamin deficiency is usually suspected on the basis of hematologic findings. [150] The serum concentration of cobalamin usually correlates with body stores. Unlike the folate concentration, the cobalamin concentration in red cells is not higher than that in serum, so hemolysis is not a cause of falsely high values. In humans, only a small proportion of cobalamin is carried on TCII, the protein that delivers the vitamin to the tissues. Thus, there can be a stage at which the serum level is normal (cobalamin is bound to haptocorrin) but tissue levels are low. Falsely high levels can be seen in leukocytosis (release of haptocorrin, increasing the total serum binding capacity) and in acute liver disease (release of body stores). Conversely, serum levels can be low when body stores are normal. Protein deficiency can lower serum levels without affecting tissue delivery if the TCII levels are normal. Levels are low in pregnant women because of dilution and redistribution of binding proteins. Serum cobalamin levels below 150 pg/mL (110 pmol/mL) are always associated with deficiency if causes of falsely low levels are not present (folate or protein deficiency, pregnancy). Levels between 150 to 200 pg/mL should be considered suspect and should lead to further testing with methylmalonic acid and homocysteine levels, correlation with abnormal hematologic or neurological findings, or both. A subtle presentation of cobalamin deficiency is especially likely in elderly patients. [151] In doubtful cases, a therapeutic trial with cobalamin is safe, and reversal of the abnormal findings is diagnostic. Biochemical tests for cobalamin deficiency can clarify cases in which the serum cobalamin levels combined with the clinical picture are not definitive. The workup should also include a careful neurological examination. The serum can be assayed for metabolites that increase when the function of the two cobalamin-dependent enzymes is impaired: methylmalonyl-CoA mutase (methylmalonic acid increased) and methionine synthase (homocysteine increased). Folate deficiency leads to an increase in homocysteine levels (>20 µmol/L) but not in methylmalonic acid levels, whereas cobalamin deficiency increases methylmalonic acid (>390 nmol/L) as well. [152] Methylmalonic acid levels can be elevated in the absence of cobalamin deficiency when renal insufficiency is present. Because TCII is the protein that delivers cobalamin to tissues but accounts for less than 10% of serum cobalamin binding, low holo-TCII concentrations have been reported as the earliest sign of negative cobalamin balance. [89] This test is not used routinely. The selection of the various tests for cobalamin deficiency depends on the stage of deficiency suspected (Table 53-14).

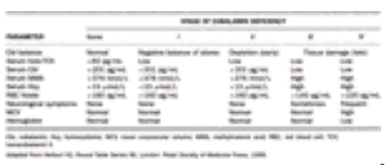

TABLE 53-14 Laboratory Tests in Sequential Stages of Cobalamin Deficiency

Because abnormal serum measurements of cobalamin metabolism precede the late manifestations of tissue damage, it is recommended that populations at risk be screened. These include strict vegetarians, persons older than 65 years of age with decreased food intake, and patients with any of the following: unexplained neurological/psychiatric symptoms or anemia, long-term use of proton pump inhibitors, autoimmune diseases, AIDS, previous gastric surgery, Crohn's disease of the ileum, and malabsorption from any cause. Screening should be done with serum holo-TCII measurements if available, either alone or in conjunction with serum cobalamin. If serum cobalamin alone is used and values below 350 pg/mL are obtained, metabolite assays should be performed if cobalamin deficiency is suspected clinically. The combination of a serum cobalamin value below 350 pmol/mL and an elevated methylmalonic acid concentration has a specificity of 98% for cobalamin

deficiency. [153] Intake or absorption should be assessed only when clinically indicated. If gastric atrophy is demonstrated by biopsy, or if gastrectomy is known from the history or the roentgenographic findings, it is not usually necessary to confirm the absence of intrinsic factor by a Schilling test. Urinary excretion of less than 5% labeled cobalamin is diagnostic of malabsorption and of more than 10% labeled cobalamin is normal, but many results are indeterminate (5%–10%). [1], [89] This lack of sensitivity is also a factor in deciding whether to proceed with the test. The two major causes of a falsely normal Schilling test result are an erroneous value (intertest variability can be as high as 30%–50%) and malabsorption of food cobalamin, presumably because of an inability of gastric proteases to liberate the vitamin. The Schilling test must be performed with labeled food cobalamin (usually in liver or scrambled eggs) to make the diagnosis because the standard Schilling test uses free cobalamin. However, the commercially available versions of the test have not been uniformly standardized.
Treatment If cobalamin deficiency is caused simply by decreased intake without malabsorption, 3 to 6 µg of oral cobalamin per day will suffice. However, if malabsorption is present, either because of lack of intrinsic factor or of intestinal disease, then losses of up to 10 µg/d must be allowed for. Deficiency is treated with 100 to 1000 µg/d for 5 to 10 days, followed by at least 300 µg/mo given by subcutaneous injection indefinitely. Alternatively, oral cobalamin can be given (1000 µg/d) to take advantage of the inefficient (~1%) absorption of the vitamin in the absence of intrinsic factor. [154] Increased well-being is noted within 24 hours after the initiation of treatment, painful glossitis improves in 48 hours, and reticulocytosis begins in 5 to 7 days. Serum folate falls rapidly. The reversal of neurological findings may take 6 months or more. No significant toxicity has been reported with therapeutic doses of oral or parenteral cobalamin.

Ascorbic Acid (C)

Deficiency Scurvy develops in 2 to 3 months if the diet is deficient in ascorbic acid. It occurs in the United States only rarely, usually in cases of chronic alcoholism, malabsorption, or food faddism. Early symptoms are weakness, lassitude, irritability, aching joints and muscles, and weight loss. Later, perifollicular hyperkeratotic papules appear on the buttocks, thighs, and legs, followed by petechiae on the lower legs. [155] In advanced deficiency, the gums become swollen, red, and spongy and hemorrhaging occurs, especially from the gums and in the skin and muscles. Anemia is common. No deficiency syndrome other than scurvy has been reported.
Assessment Plasma ascorbate levels reflect recent intake. Thus, a low serum concentration precedes clinical scurvy. [89] Low levels do not necessarily denote scurvy, however. Levels can be falsely low in patients with chronic inflammatory diseases, in cigarette smokers, after severe emotional stress, and in women taking oral contraceptives. [89] Levels below 0.2 mg/dL (11 µmol/L) denote deficient intake or absorption; that level is reached in 3 to 5 months. Leukocyte ascorbate concentration is better correlated with body stores (<150 µmol/L represents a high risk for deficiency), but the assay is technically difficult and requires large blood samples. Because the diagnosis of scurvy should be made quickly, plasma ascorbate is the initial test of choice.
Treatment Scurvy may respond to as little as 10 mg of vitamin C per day, but doses between 60 to 100 mg/d and 250 mg four times daily are recommended to replenish body stores. Large doses of ascorbic acid (2–6 g/d) have been reported to cause diarrhea, promote the formation of renal oxalate stones, increase the excretion of basic drugs by acidifying the urine (e.g., tricyclic antidepressants), decrease the excretion of acidic drugs (e.g., aspirin), and interfere with many laboratory tests, including the fecal tests for occult blood that depend on oxidation of the substrate for a positive reaction. However, the reports of clinical adverse effects with supplemental vitamin C have largely not been substantiated in normal healthy populations. [156] On the other hand, a metaanalysis of the six largest supplementation trials for rhinovirus infection found no evidence of benefit. [157] Epidemiologic studies have noted an inverse relationship between serum levels and coronary artery disease, hypertension, cataracts, and carcinomas, but no prospective studies have been performed. [1] It is premature to recommend supplemental vitamin C for these conditions.

Biotin

A dietary deficiency of biotin is very rare, [142], [158] but it can be caused by excessive consumption of raw egg white, which contains avidin, a biotin-binding glycoprotein. The effects of deficiency include anorexia, nausea, dermatitis, alopecia, mental depression, and organic aciduria. Symptoms disappear with doses of 0.15 to 0.3 mg parenterally, or with 0.2 to 10 mg/d orally for a few days. No adverse effects of such treatment have been reported.

Pantothenic Acid

Definite clinical deficiency has not been reported in humans, probably because the vitamin is so abundant in foods. [142] The “burning feet” syndrome seen in malnourished patients may respond to pantothenic acid, but it is unclear whether this represents a specific deficiency. If deficiency is suspected, 10 mg of calcium pantothenate can be used.

Vitamin A

Deficiency Vitamin A deficiency is usually the result of decreased intake or of fat malabsorption. Contributing factors include impaired conversion of carotenoids to vitamin A (in mucosal disease), decreased storage capacity (in liver disease), decreased levels of serum transport proteins (in liver disease or protein malnutrition), and increased urinary losses (in cancer, tuberculosis, or urinary tract infections). [159] Inadequate intake is rare in the United States, but the number of new cases of corneal disease caused by vitamin A deficiency worldwide approaches 1 million each year. [160] It takes about 2 years to deplete hepatic stores. Symptoms of deficiency are night blindness, xerophthalmia, follicular hyperkeratosis, altered taste and smell, increased cerebrospinal fluid pressure, and increased infections. [161] When zinc deficiency is also present, the effect on visual adaptation may be magnified.
Assessment The intake of both carotene and vitamin A is reflected in the serum levels. Decreased intake is reflected in serum vitamin A levels between 10 and 20 µg/dL. [89] A level below 10 µg/dL indicates deficiency. Low carotene levels are meaningful only if carotene is being ingested in the diet because there are no body stores of carotene. In severe liver disease and chronic infection, serum vitamin A levels may fall because retinol-binding protein is not produced in normal amounts. However, carotene levels tend to rise because less carotene is converted to vitamin A in these conditions. Vitamin A can be elevated with normal carotene levels in patients ingesting excess amounts of vitamin A or in patients on chronic hemodialysis because of a decreased conversion of retinol to retinoic acid. Elevated carotene levels with normal retinol are seen in persons ingesting excess amounts of carotene and also in patients with anorexia nervosa, hypothyroidism, hyperlipidemia, or the hypercholesterolemia of diabetes. [89]
Treatment Vitamin A is provided in the form of free retinol. Deficiency states respond to oral doses of the daily vitamin between 5000 and 50,000 IU. Intramuscular delivery can also be used. [1] Because of their antioxidant properties, carotenoids have been implicated in many chronic diseases often linked with vitamins E and C, the other vitamin antioxidants. [155] However, no convincing evidence is yet available to support supplementation of any antioxidant vitamins, carotenoids, or preformed vitamin A to prevent malignancies or cataracts. Doses of vitamin A above the RDA are contraindicated in pregnant women because of the potential for teratogenicity. The minimum daily dose that is toxic to patients without malabsorption is 25,000 to 50,000 IU. Toxicity is correlated with serum levels of vitamin A above 1000 µg/dL. Symptoms of chronic toxicity include dry mouth and mucous membranes, skeletal pain, increased cerebrospinal fluid pressure, alopecia, anorexia, irritability, hepatic dysfunction, exophthalmos, and hypercalcemia. Carotene cannot be converted to retinol fast enough for even large doses to produce retinol toxicity.

Vitamin D

Deficiency Vitamin D deficiency secondary to inadequate intake is rare in the United States, in part because milk products are fortified with the vitamin. Even persons who do not consume dairy products usually obtain adequate sunlight exposure to prevent vitamin D deficiency. However, in elderly persons with little exposure to sunlight, decreased vitamin D intake or synthesis along with inadequate calcium intake may contribute to a high incidence of bone fractures. [162] Deficiency should be considered in any patient with steatorrhea (malabsorption of dietary vitamin and polar metabolites via the enterohepatic circulation) or severe liver (decreased 25-hydroxylase activity) or kidney (lack of 1a-hydroxylase) disease, as well as in patients with Crohn’s disease or previous ileal resection. [163] Vitamin D deficiency causes hypocalcemia and hypophosphatemia, which result in increased parathyroid hormone secretion and bone demineralization. In time, this sequence leads to osteomalacia in adults and rickets in children and can be an unrecognized factor in acute hip fracture. [164] Tetany results from severe hypocalcemia, and muscle weakness is correlated with hypophosphatemia and depletion of muscle phosphate. Patients with risk factors for the development of osteopenia (cigarette smoking, family history, sedentary lifestyle, long-term glucocorticoid therapy, long-term anticonvulsant therapy, early menopause, testicular failure) should be followed even more carefully if they are at risk for vitamin D deficiency. Long-term alcohol abuse is also an overlooked cause of osteoporosis in men. [165]
Assessment The 25-hydroxyvitamin D level is low when body stores, intake, or endogenous production of the vitamin is low. [166] Thus, the level is satisfactory for assessing vitamin D status with respect to deficiency and toxicity. The production of 25-hydroxyvitamin D is not closely regulated and rises or falls as its substrate is made available. The concentration in serum is 5 to 10 times that in other tissues except for adipose tissue. It is bound in serum to a binding protein that is normally only 5% saturated, and the half-life is long (24 hours). Thus, recent exposure to sunlight or increased oral intake is reflected in the serum level. Levels are low in dietary deficiency, decreased absorption, lack of sunlight, prematurity, and severe liver disease; low levels are also associated with drugs that alter the metabolism (e.g., anticonvulsants). High levels are seen in growing children, conditions in which parathyroid hormone levels are elevated, sarcoidosis, and some forms of idiopathic hypercalciuria. Patients at risk for deficiency should be followed with periodic measurements of the serum 25-hydroxyvitamin D level, as well as bone density and 24-hour urinary calcium measurements, to assess the status of calcium stores and intake (see section “ Calcium”). 1,25-Dihydroxyvitamin D can also be

measured in the serum. The production of this isoform is closely regulated, but by extracellular ionized calcium, not by vitamin D stores, unless they are very low. The level of this vitamin correlates with vitamin D function more than with stores. Serum 1,25-dihydroxyvitamin D levels are low in profound vitamin D deficiency, chronic renal disease, hypoparathyroidism, vitamin D–resistant rickets type I, and osteolytic conditions not caused by increased parathyroid hormone levels (cancer, hyperthyroidism). Primary hyperparathyroidism, vitamin D–resistant rickets type II, and pregnancy are conditions in which levels are elevated. Hypervitaminosis D elevates 25-hydroxyvitamin D levels markedly, but 1,25-dihydroxyvitamin D levels are little affected. Table 53-15 provides suggested guidelines for evaluating the vitamin D status.

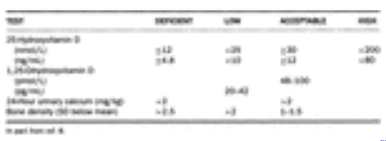

TABLE 53-15 Suggested Guidelines for Evaluating Vitamin D Status

Treatment Oral vitamin D does not maintain the vitamin D status as well as endogenous vitamin D; the latter is released more constantly from the skin and is not converted so rapidly to other isomers by the liver, to which virtually all orally administered vitamin D is exposed following absorption. Nonetheless, oral supplements are needed sometimes, especially in patients with fat malabsorption, uremia, long-term corticosteroid use, and possibly postmenopausal osteoporosis, although its proper place in the management of osteoporosis is still uncertain. Adults with vitamin D deficiency should receive 0.1 to 0.2 mg (4000– 8000 IU) of cholecalciferol daily by mouth. Much larger doses should be used if malabsorption is present, although the exact dose needed may vary widely. Theoretically, the more polar forms, 25-hydroxyvitamin D (calciferol) and 1,25-dihydroxyvitamin D (calcitriol), should be useful in patients with malabsorption, [167], [168] but the absorptive advantage is probably not sufficient to justify the great increase in cost. The efficacy of treatment should be assessed by periodic measurement of the 25-hydroxyvitamin D level, with the dose adjusted to keep the serum level within normal range. In patients with malabsorption, one should determine that the function of vitamin D has also been restored—that is, that calcium absorption has been normalized—by bringing the 24-hour urinary calcium into the normal range. The risk for toxicity in patients with malabsorption is extremely slight. In other patients, hypercalcemia and hypercalciuria may develop. The estimated minimal toxic daily oral dose for healthy adults is 0.125 mg (5000 IU). [1], [162] Nausea, anorexia, itching, polyuria, abdominal pain, constipation, bone pain, metallic taste, and dehydration may be present early, followed by other manifestations of hypercalcemia. Vitamin D toxicity is reversible if renal damage is not severe.

Vitamin E

Deficiency Deficiency of vitamin E is uncommon in humans. Persons at risk include newborns and premature infants, patients with fat malabsorption or biliary obstruction, and food faddists. Vitamin E does not cross the placenta well and is poorly absorbed in newborns. Severe fat malabsorption in cystic fibrosis, abetalipoproteinemia, short bowel syndrome, biliary obstruction, and excessive mineral oil ingestion can lead to deficiency. [169] Unsteady gait, tremor, weakness, ophthalmoplegia, pigmentary retinopathy, and proprioceptive impairment have been noted in adult malabsorptive syndromes, along with red cell hemolysis. A similar progressive neurological syndrome has been reported in children with cholestatic liver disease. [170]
Assessment Deficiency can be documented by a low serum a-tocopherol concentration (<11.6 µmol/L or 5.0 µg/mL). [89] Because the vitamin is carried in serum by lipoproteins, the plasma concentration of vitamin E is low in any hypolipidemic state. Therefore, the ratio of a-tocopherol to total lipid (triglyceride + cholesterol) is a more accurate indicator of vitamin E status than is the vitamin level alone. [171] Ratios of more than 0.8 mg of a-tocopherol per gram of total lipid or more than 0.22 mg of a-tocopherol per gram of cholesterol are normal. Ethane and pentane are generated through the peroxidation of n-3 and n-6 fatty acids, respectively. Breath ethane has been used to evaluate the vitamin E status and follow therapy in children because the level rises with deficiency. [172]
Treatment Large oral doses of D-a-tocopherol acetate, up to 600 mg (800–900 IU) per day, are needed, especially in patients with malabsorption. A water-soluble form of the vitamin (D-a-tocopherol-PEG-1000 succinate) is available over the counter as Liqui-E. [173] This compound forms micelles when given in doses above 25 mg/kg per day and may assist in the absorption of other fat-soluble vitamins. The results of the use of vitamin E to treat chronic diseases have been mixed, promising for preventing heart disease, but not for cancer. [1], [155] The American Heart Association consensus statement does not recommend the routine use of vitamin E at this time. [174] No consistent ill effects are seen with up to 3200 IU (2112 mg) per day in healthy persons. However, at doses from 100 to 1100 mg/d, oxidation of vitamin K to its active form can be inhibited, and high-dose vitamin E may be problematic in patients with bleeding disorders. However, the use of 800 to 1200 IU/d had no effect on the prothrombin time of patients on warfarin therapy. [131]

Vitamin K

Deficiency Nutritional deficiency is uncommon in adults because of the large amount in foods and because bacteria synthesize the vitamin in the intestinal lumen. Deficiency is most commonly the result of fat malabsorption, often compounded by poor intake and diminished liver function or decreased bile excretion. [175] Inhibition of bacterial biosynthesis by broad-spectrum antibiotics can be important. Deficiency is manifested by easy bruising and clotting abnormalities.
Assessment The most commonly used clinically applicable test for vitamin K deficiency is the one-stage prothrombin time. The clotting factors tested (II, V, VII, and IX) are all responsive to vitamin K except for factor V. Factor VII has the shortest half-life and is the usual rate-limiting factor. The prothrombin time does not test vitamin K stores and is abnormal when deficiency is present, when the synthesis of clotting factors is impaired by liver disease, or when factors are consumed in intravascular coagulation. Thus, the test is nonspecific. Response of the prothrombin time to 5 to 10 mg of parenteral vitamin K for 2 to 3 days confirms the presence of a deficiency state. Determination of the urinary a-carboxyglutamic acid (Gla) level may be even more sensitive because it tests a function of vitamin K, and the level can be low when blood coagulation is normal. [176] Plasma levels of Gla proteins may be useful in detecting deficiency of vitamin K but have not been widely used. These proteins include undercarboxylated prothrombin (PIVKA-II) and carboxylated/undercarboxylated osteocalcin. [8]
Treatment Long-term therapy with doses titrated to the prothrombin time (~2 mg daily or every other day) should be restricted to patients with malabsorption. The vitamin is available for subcutaneous or intramuscular injection at 2 or 10 mg/mL. Vitamin K is not a component of any multivitamin preparation and must be prescribed individually.

NUTRITIONAL SUPPORT IN THE HOSPITALIZED PATIENT WITH GASTROINTESTINAL DISEASE

The major purpose of nutritional therapy is to prevent or correct specific nutrient deficiencies and to prevent the adverse effects of protein-energy malnutrition. Nutritional support has also been proposed as a primary therapy for patients with certain gastrointestinal diseases, such as inflammatory bowel disease and hepatic encephalopathy. In this section, we review the available data evaluating the clinical efficacy of nutritional support in patients with gastrointestinal diseases. Whenever possible, only the data from prospective randomized clinical trials are considered because this approach is the most reliable technique for evaluating the usefulness of therapy.

Short Bowel Syndrome

Patients who have undergone massive intestinal resection often require nutritional support for optimal function and survival. The length of the remaining jejunum, the presence of the ileocecal valve, and whether the colon is intact are critical determinants of the need for nutritional support. [177] In general, patients with a jejunostomy and less than 90 cm of jejunum, or those with a colon in continuity but less than 50 cm of jejunum, are likely to require parenteral nutrition. Providing nutrients with continuous nighttime tube feedings [178] or fluid and electrolytes with oral rehydration therapy [33] (see section “ Oral Rehydration Therapy”) can sometimes decrease or eliminate the need for parenteral therapy.

Inflammatory Bowel Disease

Enteral Nutrition Three metaanalyses of published prospective randomized clinical trials concluded that enteral nutrition is not as effective as corticosteroids. In addition, no benefit of elemental over non-elemental formulas was noted. [179], [180] and [181] The true clinical efficacy of enteral nutritional therapy has not been evaluated because no study has compared patients receiving dietary therapy with an untreated control group. However, the overall remission rate reported with enteral nutrition therapy is about 60%, [179], [180] which is higher than the range of 20% to 40% reported for placebo treated patients with moderate disease. [182], [183]
Parenteral Nutrition Data from several prospective randomized clinical trials found that “bowel rest” is not necessary to achieve clinical remission in patients with active Crohn’s disease; patients who received TPN plus bowel rest fared no better than those receiving TPN plus oral/enteral feeding. [184], [185] A beneficial effect of TPN in patients with Crohn’s disease or ulcerative colitis has not been demonstrated in prospective randomized clinical trials. No significant differences in clinical response rates were found in hospitalized patients with severe disease exacerbations who were randomized to receive TPN and steroid therapy or an oral/enteral diet

and steroid therapy. [186], [187] and [188] Nonetheless, TPN may be useful in patients with severe inflammatory bowel disease who cannot eat because of prolonged ileus or who might benefit from bowel rest because of severe diarrhea or anticipated surgery.

Specific Nutrient Therapy Fish oil supplementation may produce a modest decrease in the activity of ulcerative colitis, [189], [190] may help to lower the steroid dose, and may prevent early but not late relapse, [191] but it is not effective by itself. Two prospective randomized clinical trials of maintaining clinical remission in patients with Crohn's disease have shown both success [192] and failure. [193] Short-chain fatty acids have not been shown to be effective for rectal disease in ulcerative colitis. [194]

Gastrointestinal Fistulae No prospective randomized clinical trials have evaluated the efficacy of TPN, but "bowel rest" may improve the clinical outcome of selected patients with fistulae. Before the use of TPN, mortality in patients with gastrointestinal fistulae was caused by malnutrition, fluid losses, and peritonitis. A retrospective analysis of patients with small bowel fistulae showed an improved outcome for those who received nutritional support. [195] Anastomotic fistulae at sites of recent resection in Crohn's disease may close permanently with TPN and bowel rest, although octreotide therapy may also be necessary for success in some patients. [196] However, fistula closure is not well maintained after an oral diet is reinstituted in patients with active disease at the origin of the fistula, or with post-fistula obstruction.

Growth Failure in Children TPN or oral/enteral supplemental feedings can initiate catch-up growth, resulting in marked increases in height and weight, in children with inflammatory bowel disease and growth failure. [197], [198], [199] and [200] In fact, even intermittent enteral feeding can improve growth. [201], [202]

Acute Pancreatitis

Most patients with acute pancreatitis are unable to eat because oral feeding can cause abdominal pain and increase serum amylase and lipase concentrations. Nonetheless, nutritional support is not useful in patients with mild or moderate pancreatitis because of the rapid resolution of symptoms and ability to begin oral feeding within several days. In addition, no benefit of parenteral nutrition compared with enteral nutrition has been demonstrated in patients with mild or moderate pancreatitis, [203] and in one study, the use of TPN was associated with a higher prevalence of catheter-related sepsis and insulin requirements. [204] However, nutritional support may be necessary in about 10% to 20% of patients with pancreatitis who have severe and complicated disease when a prolonged period of starvation is anticipated.

It has been shown that it is possible to provide enteral feeding to patients who have mild to moderate [203] or severe [205], [206] pancreatitis, without causing an exacerbation of symptoms, when feeding is delivered distal to the ligament of Treitz into the upper jejunum. Moreover, in prospective randomized clinical trials that compared enteral with parenteral nutritional therapy in patients with severe pancreatitis, those who were randomized to receive enteral nutrition showed a greater reduction in acute phase response proteins, a greater improvement in disease severity scores, and fewer medical complications than those given parenteral nutrition. [205], [206] However, it is not known whether enteral feeding was beneficial or whether parenteral feeding was harmful because no study included an unfed control group.

Providing a portion of total calories as lipid can help prevent hyperglycemia in glucose-intolerant patients with pancreatitis. However, it is important to ensure adequate triglyceride clearance because hypertriglyceridemia induced by infusion of fat emulsions can cause a relapse of pancreatitis. [63]

Liver Disease

Alcoholic Hepatitis One prospective randomized clinical trial compared PPN with an anabolic steroid, oxandrolone, or the combination for 21 days and found no change in mortality but improved Child-Pugh scores in those receiving PPN plus oxandrolone. [207], [208] In another study, nutritional therapy improved liver function and reduced early mortality (1 and 6 months) in a subgroup with moderate "malnutrition" or liver disease. [209] No improvement was noted in the group with severe disease. It is clear that these markers correlate with the severity of liver disease and with clinical outcome. [210]

Alcoholic Cirrhosis Several prospective randomized clinical trials showed that enteral nutrition in patients hospitalized for complications of cirrhosis led to an improved clinical status. [211], [212] and [213] A single study showed that enteral feeding of a branched-chain amino acid formula reduced mortality. [214] However, the ad lib diet group ingested only about half the calories of the enterally fed group, and the control group had an unusually high mortality rate (47%).

Hepatic Encephalopathy In a metaanalysis of nine prospective randomized clinical trials evaluating the use of TPN enriched with branched-chain amino acids in patients with acute encephalopathy, [53] recovery from encephalopathy was improved during short-term (7–14 days) treatment. However, the variability in mortality rates was so great that no conclusion could be reached regarding that outcome measure. No benefit of branched-chain amino acid therapy was detected in the one study that compared a group that received branched-chain amino acid–enriched TPN with a control group that received standard amino acids. Studies of the use of enteral solutions containing branched-chain amino acids in patients with chronic encephalopathy have yielded conflicting results. However, the studies with the largest number of patients showed clinical benefits in protein-intolerant patients. [215]

GENETIC COUNSELING FOR GASTROINTESTINAL PATIENTS

P>Medical science, like medical economics, is in the midst of a major revolution. A large part of that revolution derives from the science of genetics. In past years, clinical genetics belonged to the practice of pediatrics and concerned primarily rare inherited diseases. Genetics was of minor practical importance to physicians in adult medicine. That era can now be considered historical, and gastroenterology, as much or more than any clinical specialty, is evidence of this.

The etiology of many gastrointestinal (GI) diseases, both inherited and acquired, both malignant and benign, is now understood at the DNA level. Additionally, many diseases that were once considered single entities are now known to be of heterogeneous etiology. Causes often include inherited abnormalities, environmental factors, and complex interactions between the two. Relevant examples of GI disease include colon cancer, inflammatory bowel disease, many liver conditions, and even peptic ulcer disease.

This new science of genetics has quickly translated into medical applications, including new methods of disease screening, susceptibility testing, diagnostics, and therapeutics. The clinical application of genetic knowledge is expected to expand dramatically with the recent sequencing of the entire human genome. All this change requires that the physician have a thorough understanding of modern genetics. Only in this way can the application of the many genetic advances be realized in the clinic.

An important part of the clinical application of genetics is patient education by the health care team. Many disease discussions now must involve genetics. Patient education is particularly important when genetic testing is being considered. Both patient and physician must understand the impact of genetic testing on medical management, future health, insurance, employment, and psychosocial issues. Each of these issues must be addressed in making the decision to proceed with genetic testing. For many diseases, the incorporation of formal genetic counseling into the evaluation and treatment process is becoming a practical necessity.

This chapter reviews the basic and clinical genetics needed by the practicing gastroenterologist, both to understand emerging relevant genetic discoveries and to apply them in the clinical setting. The principles of genetic counseling are then presented, followed by issues specific to genetic testing. Such knowledge is also imperative to enable the practitioner to educate the patient toward informed clinical decisions and to decide when formal genetic counseling is needed. Many of the examples used relate to genetic counseling and testing for inherited colorectal polyp and cancer conditions because much knowledge and experience have been accumulated in this area. However, with an increased understanding of other pediatric and adult conditions, such as celiac disease, irritable bowel disease, and pancreatitis, genetic counseling and testing for these conditions may soon become mainstream.

GENETIC KNOWLEDGE FOR CLINICAL PRACTICE

Basic Concepts of Molecular Genetics

Structure of DNA and RNA The most basic components of genetic material are the nucleotides that make up deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), which in turn are the building blocks of the genome. Each nucleotide has a backbone composed of a 5-carbon sugar (deoxyribose for DNA and ribose for RNA), a phosphate, and one of several different nitrogen-containing rings known as *bases*. The bases are either pyrimidine or purine compounds. Pyrimidines include cytosine (C), thymidine (T), and uracil (U), and purines include adenine (A) and guanine (G). Nucleotides are joined together by a phosphodiester link between the 5' and 3' carbon atoms of the sugars to make a strand of DNA or RNA. Strands are described and schematically viewed in the 5' to 3' orientation because enzymes almost always work in that direction. DNA exists as a double-stranded helix in the nucleus of cells. Each DNA strand is oriented in complementary, but opposing, 5' to 3' directions. The strands are held together by noncovalent and very specific interactions; adenine pairs only with thymidine of the opposing strand and cytosine with guanine. The opposing or complementary pair of DNA nucleotide bases is referred to as a *base pair*. RNA, on the other hand, is single-stranded and is found in the nucleus and cytosol of the cell.
Replication, Transcription, and Translation DNA is replicated for cell division, called *mitosis,* or for gamete (egg and sperm) formation, called *meiosis*. Replication proceeds by way of a protein complex referred to as *DNA polymerase*. Errors in DNA replication are monitored and repaired by mismatch repair (MMR) protein complexes, a function that maintains the integrity of the DNA. RNA synthesis is the first step in protein production. RNA is synthesized from a single strand of DNA, which serves as the template. Synthesis is accomplished by a complex of proteins called *RNA polymerase*. The process of making RNA from DNA takes place in the nucleus and is called *transcription*. In RNA, the pairing of bases is slightly different in that uracil pairs with adenine and cytosine with guanine. Although the primary function of RNA is to encode proteins, RNA itself is also a part of ribosomes, transfer RNAs, and small ribonucleoprotein particles. The primary RNA transcript contains three domains: (1) regulatory elements, which are involved in controlling the protein synthetic process; (2) exons, which contain coding sequences, or those parts of the RNA that are actually translated into amino acids and eventually protein; and (3) introns, which are interspersed between the coding sequences but are themselves noncoding and thus not translated into amino acids (Fig. 54-1).

FIGURE 54-1. Organization of genetic material. DNA is the double-stranded molecule that contains the genetic code and includes coding (exons) and noncoding (introns) segments. In a multiple-step process, DNA is transcribed into RNA and spliced into messenger RNA (mRNA), which contains regulatory elements and exons but no introns. The mRNA is translated into a series of amino acids that combine to form a specific protein. Proteins are the molecules that function within cells.

Before the RNA leaves the nucleus, enzymes remove all the introns, and the resulting messenger RNA (mRNA) molecule contains only the regulatory elements and a

continuous stretch of coding sequence to be translated into protein. In the cytosol, the mRNA strand is read in sets of three nucleotides, called *codons*, each of which is translated into a specific amino acid. As reading proceeds, these amino acids are linked together as a polypeptide chain by the ribosome complex. In a manner analogous to the 5' to 3' directionality of nucleic acids, amino acids are added to the carboxyl-terminal end of a growing polypeptide chain, resulting in an “amino” to “carboxyl” orientation. Each of the codons is translated into one of 20 amino acids or a stop codon. The stop codon tells the ribosome that it is at the end of the protein. The genetic code is very precise but is also “degenerate,” meaning that multiple codons can encode a single amino acid. For example, the genetic code for the amino acid valine can be GUU, GUC, GUA, or GUG.

Types of Mutations Many types of genetic mutations can result in a defective protein and thereby cause a genetic or inherited disorder. Many genetic changes, however, do not result in genetic disorders but rather are part of normal genetic variation. Such changes are called *polymorphisms* and are typically seen in at least 1% of the population. Polymorphisms can be completely inconsequential or can have a phenotype with subtle consequences (e.g., differences in drug metabolism or minor variations in disease susceptibility). When new genetic changes are identified in symptomatic or presymptomatic individuals, it is important to clarify whether the variant is a deleterious (disease-causing) mutation or a polymorphism. Understanding the basis of the genetic changes is important because it significantly influences the type of molecular diagnostic testing that should be considered.

Amino acid changes. The first major class of mutations consists of amino acid changes in the coding sequencing. Nucleotide errors can result in three categories of amino acid changes: silent, missense, and nonsense mutations. Mutations are said to be *silent* when the altered codon encodes the same amino acid as the normal nucleotide sequence. For example, if a GUU is changed or mutated to a GUC, it still encodes the amino acid valine. Mutations are called *missense* when the substitution results in a changed codon that encodes a different amino acid. As an example, if a GUA is changed to a CUA, the resulting amino acid is changed from a valine to a leucine. Finally, nucleotide changes are called *nonsense mutations* when the alteration results in a “stop” signal codon instead of an amino acid codon. Stop codons include the base triplets UAA, UAG, and UGA. In the wrong place, these codons result in a truncated or shortened protein.

Deletions and insertions. The second class of mutations includes deletions and insertions, whereby nucleotide(s) are deleted from or added to the DNA sequence. If the changes are within the exons or coding portions of the DNA, they often result in a shift of the triplet reading frame and are thus called *frameshift mutations*. The triplet code “downstream” from the insertion or deletion (also said to be “3-prime” or “after” the insertion or deletion) is shifted out of phase, and the result is a nonsense code that may code for erroneous amino acids or a stop codon. Frameshift mutations are therefore also categorized as nonsense mutations (Fig. 54-2). In most frameshift situations, an accidental “stop” codon is encountered in the mRNA downstream of the mutation within the frameshift. Thus, insertions and deletions causing frameshifts almost always result in truncated or shortened proteins. The exception to this result occurs when the deletion or insertion of nucleotides is in a multiple of 3, whereby the triplet reading sequence stays in-frame, with only the insertion or deletion of amino acids. This error can still be deleterious, however, because the loss or gain of amino acids can alter protein product and function.

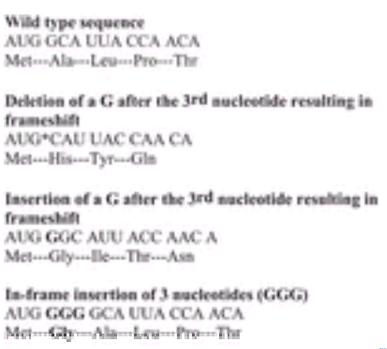

FIGURE 54-2. Nucleotide insertion and deletion mutations. Nucleotide insertions and deletions may cause in-frame or frameshift mutations. The deletion or insertion of nucleotides in multiples of other than 3 base pairs causes frameshift mutations that result in major alterations to the amino acid sequence. The insertion of nucleotides in multiples of 3 does not cause frameshift mutations but does cause alterations in amino acid sequence.

Splice site and regulatory mutations. Mutations also occur outside the coding sequence, or in the intron area. Introns contain specific nucleotide sequences immediately next to the exons that dictate exactly where the introns are to be excised. The sequence is a GT on the 5' end of the intron and an AG on the 3' end before the next exon. These sequences are conserved (i.e., not altered). Changes that do occur are called *splice site mutations*. The sequence of four to ten nucleotides into the intron on both the 5' and 3' ends is important as well, but not as rigorously conserved. Some mutations in these extended regions of introns can also result in improper splicing. When splice site mutations occur, an exon is often skipped, and a protein with a deleted segment is the result. A protein normally is encoded from a number of exons, so the result is a partial protein. Additionally, frameshifts can occur when the exons combine improperly, as previously described. Mutations can also occur in the regulatory segments of the DNA, although these are often difficult to identify. These types of changes can result in a failure of proteins to be expressed at the correct levels, in the correct tissues, or at the correct time.

Large deletions, duplications, translocations, and inversions. The last class of mutations consists of large deletions, duplications, translocations, and inversions of DNA. These typically arise during gamete formation as the consequence of an uneven exchange of DNA between chromosomes and can be passed down through generations. A *deletion* involves loss of genetic material, and *duplication* occurs when one section of genetic information is repeated more than once. *Translocations* occur when a section of DNA moves to another location on the same chromosome or onto a different chromosome. In an *inversion,* a section of DNA inverts itself into the opposite orientation. In each of these situations, the genetic changes can result in loss of expression of the gene, expression of a mutated or truncated protein, misregulation of the gene, or generation of a novel hybrid protein. Some of these mutations can be detected by cytogenetic methods that look at chromosomes. Large alterations in DNA, for example, can be detected by examining the Giemsa banding patterns of metaphase chromosomes for correct number and size (karyotyping) or by probing chromosomes with fluorescent DNA markers (fluorescent in situ hybridization, or FISH). The more subtle changes can be detected by Southern blotting methods.

Human Genome Project

The Human Genome Project was conceived in the 1980s, and an international multicenter program was organized in 1990. The program was designed to construct detailed genetic and physical maps of the human genome, to determine the complete nucleotide sequence of human DNA, to localize all genes within the human genome, and to sequence genomes of other model organisms. In 2001, a draft of the entire human genome was completed. [1], [2] Based on this initial sequence framework, it is estimated that the human genome contains 3 billion base pairs and 30,000 to 40,000 protein-coding genes. The number of protein-coding genes is significantly lower than the previously predicted 100,000 genes, but alternative splicing of RNA accounts for much of the protein complexity.

Data and research tools from the Human Genome Project are available to the public and can be assessed through the National Center for Biotechnology Information (NCBI) Web site. The NCBI Web site is a user-friendly resource that integrates multiple sources of public genome information (http://www.ncbi.nlm.nih.gov/genome/guide/human/). At this Web site, you can search for specific genetic markers or genes and also browse through a genomic region while using the information resources that you select. Most of the genetic loci that are displayed link to detailed descriptions of the gene or marker. Within the NCBI site is a useful search and retrieval program with which proteins and nucleotide sequences can be accessed (http://www.ncbi.nlm.nih.gov/Entrez/). The actual assembly of the draft genome sequence is located at http://genome.ucsc.edu/.

The Human Genome Project also recognizes the ethical, legal and social implications of the acquisition and use of the genetic knowledge by individuals and society, and it is driving policy discussions in both the public and professional arenas.

Genetic Tools and Technologies

The cooperative effort of the Human Genome Project, together with extensive genetic work in numerous laboratories, has given rise to powerful new tools and technologies for genetic research and clinical application. Familiarity with these tools is important for the practice of medicine as clinical genetic offerings continue to emerge.

Genetic Markers

Short tandem repeats. One tool developed throughout the 1990s is a set of genetic markers placed in order along chromosomes and spanning the entire human genome. Many of these markers are unique regions of the genome that contain variable numbers of nucleotide repeats resulting in variable length of the DNA segments in the human population. These are referred to as *short tandem repeats (STRs)* or *variable nucleotide tandem repeats (VNTRs)*. STRs can be repeats of any length, but the most utilized are the dinucleotide repeats (CACACA…) and the tetranucleotide repeats (AGATAGATAGAT…). Genotyping of individuals at these markers is used extensively in genetic linkage studies to search for new familial disease genes. This tool has thereby dramatically changed the pace of gene discovery because the entire genome is now systematically scanned by using these markers. Linkage by means of these markers is used in the clinical setting to identify mutant gene carriers when a specific mutation cannot be found.

Single-nucleotide polymorphisms. More recently, 1.4 million *single-nucleotide polymorphisms (SNPs)* have been identified within the human genome. [3] A SNP is a site on the DNA where a single base pair varies from person to person. SNPs can also be used as genetic markers for linkage and association studies, described later. Researchers estimate that 60,000 of these SNPs are within exons. In addition, a small portion of SNP variants encode amino acid changes (0.12%–0.17%) and may have functional consequences. Thus, a small fraction of SNPs are not only markers but may contribute to certain diseases.

Genetic Technologies

The DNA microchip. The DNA microchip is a new research tool with anticipated use in clinical genetic diagnosis in the near future. A DNA microchip contains sub-nanoliter amounts of DNA spotted on a solid surface, such as a silicon wafer or a glass microscope slide. Thousands of different DNA fragments can be spotted onto a single microchip, and each fragment is analyzed as an independent data point. Under appropriate thermodynamic conditions, DNA or RNA will bind to its specific complementary strand. Typically, the DNA or RNA to be tested is tagged with a fluorescent or radioactive label. Because RNA is readily degraded, it is copied into DNA, thereby called *complementary DNA (cDNA),* with the use of an enzyme discovered in viruses called *reverse transcriptase*. Many thousands of DNA sequences with known mutations are spotted onto a test microchip. DNA or cDNA from a test sample, possibly DNA from a cancer specimen, is then applied to the microchip. If binding to a specific sequence occurs, fluorescence is observed and the cancer in question contains the specific mutation on the chip. DNA microchips can be used to determine if genomic DNA has a mutation or if there are multiple copies of DNA in a sample (gene amplification), and to investigate differences in gene expression levels (microarray).

Microarray technology. Microarray technology is a method to examine simultaneously all the messenger RNA that is expressed or suppressed in a certain tissue, such as a polyp. A window is thereby obtained on the cellular pathways that are playing an active role in the tissue. The technique of microarrays involves the quantitative hybridization of a large panel of known cloned genes or synthetic oligonucleotides with the total cDNA derived from a particular cell or tissue type, such as the polyp. The overall hybridization to the microarray provides a comprehensive profile of the relative RNA message levels for all genes represented in the microarray chip. Although this technology is still in its infancy, it offers great potential for the molecular characterization of both normal and pathological tissues and of clinical diagnoses.

Gene Discovery Methods

A number of methodologies are used to identify the particular genes involved in inherited conditions. This work, called *gene discovery,* has been a major focus of molecular genetics for the past 15 years. The results have been rather remarkable, in that genes for most of the major inherited diseases have now been identified. Much work in gene discovery is now focused on less penetrant genes that appear to play a role in inherited susceptibility to many common diseases.

Some basic vocabulary of the human genome is important in understanding gene discovery work. The human genome is composed of 22 pairs of chromosomes, called *autosomes,* plus two sex chromosomes, XX for females and XY for males. Chromosomes segregate independently during gamete formation. The location of a gene or genetic marker on a chromosome is called a *locus*. Each person has two copies of each chromosome and consequently two copies of each gene (or set of genetic material), a maternal copy and a paternal copy. The two copies can vary, and each alone is called an *allele*. Multiple alleles of each genetic element may exist in the population, but an individual is limited to two alleles at each locus, a paternal allele and a maternal allele.

Linkage Studies Linkage analysis investigates whether specific genetic markers segregate with a certain disease or characteristic in a family. In a dominant genetic condition, one set of genetic markers near the gene responsible for the syndrome is passed from an affected parent to his/her offspring with a 50% probability. By following the unique pattern of genetic markers from affected parent to affected child, but not from affected parent to unaffected child, linkage to the genetic disorder can be established. In a recessive genetic condition, the set of genetic markers is followed from both parents, and the combination of two sets of genetic markers in offspring segregates with the genetic condition. In this case, both parents are usually clinically unaffected. The multiple applications of the basic concept underlying linkage analysis are described in later sections. Linkage analysis is used to find new genes causative of a genetic disorder. This requires obtaining blood specimens for DNA analyses from a large family or multiple unrelated families with the disorder in question. It is then clinically determined which family members have the disorder, a process called *phenotyping*. Next, the DNA of family members is analyzed, a process called *genotyping,* with multiple genetic markers across chromosomal regions. This may include all chromosomes when a candidate genomic region is not already identified. When certain genetic markers of known chromosomal location segregate with the disease in question, the disease gene is thereby known to be in that chromosomal location or at that locus. The statistical analysis used in this method is called *logarithm of the odds,* or *lod score*. The lod score compares the likelihood of a real association with the likelihood of chance association. Lod scores of 3.0 or higher are considered significant. A genetic marker within 5 centimorgans (cM, about 5 million base pairs of DNA) of a disease gene is considered useful for genetic counseling. Identification of the disease gene typically requires a better resolution of the locus because more than 50 genes can be contained within a 5-cM span.

Sibling Pair Studies Sibling pair studies are being increasingly used to identify common disease genes, such as those for inflammatory bowel disease, coronary heart disease, diabetes, and colon cancer. Hundreds of siblings, both of whom have the disease in question, are identified and undergo genetic analysis. As in the family linkage studies, DNA from the sibling pairs is analyzed with multiple genetic markers in the human genome. The linkage analysis involves the identification of genetic loci where the population of affected siblings co-inherit a significantly higher average number of alleles than would be expected by normal mendelian inheritance.

Association Studies In contrast to family or sibling pair studies, association studies are population based. Association studies investigate differences in allele frequencies between persons with a specific disorder (cases) and individuals without the disorder (controls). If an allele frequency is statistically different in the case population, it is considered to have a causative role in the disorder. This role may be direct, in which the allele is a causative change, or indirect, as the consequence of proximity of the allele to another disease gene. The relative risk imposed by an allele associated with a disorder can be calculated from the magnitude of the difference in allele frequency between the case and control populations.

Mutation Detection

Use of Mutation Detection Once genes and their locations have been identified, mutation detection is often possible for both research and the diagnosis of clinical disease. Mutation detection is the identification of the specific disease-causing mutation in a person or family. Most inherited conditions arise from multiple different mutations in the same gene (allelic heterogeneity). However, a separate and distinct mutation segregates in each family with a particular disease. The success of identifying this causative mutation in an index case (i.e., a case clinically known to have the disease) varies depending on the disease. Once a mutation has been found in an index case, other family members can be tested for the presence or absence of that specific mutation with nearly 100% accuracy. If a mutation cannot be found in the index case, however, then all family members must be treated as potentially having the disease gene. Alternatively, linkage analysis can be used to indicate the likelihood that individual family members carry the mutant gene.

Specific Techniques Used in Mutation Detection

Sequencing. Sequencing is a standard method used to detect mutations. Sequencing is the process of determining the order of nucleotide bases (A, C, G, and T) for all the coding regions and certain intron regions of the gene of interest. Although sequencing is the gold standard for clinical genetic testing, it has limitations, including high cost and failure to detect some genetic rearrangements, deletions, and mutations in regulatory regions. Currently, sequences can be resolved on stretches of DNA 500 to 800 base pairs in length. Sequencing is often more effective when complemented with an initial DNA screening method that detects the presence of a mutation and narrows the DNA area to be sequenced. The next three methods described represent such screening methods. Once one of these methods indicates a DNA variant, sequencing is required to confirm the change and determine if it is a normal variant in the human population or a disease-causing mutation.

Conformation-specific gel electrophoresis (CSGE). CSGE, also called *heteroduplex analysis (HA),* is one method used to complement sequencing. Numerous copies of the specific region of genomic DNA, from 150 to 300 base pairs in length, are synthesized by the polymerase chain reaction (PCR), then denatured and renatured. If a sequence variation in the two alleles of genomic DNA is present, some strands will renature as a hybrid of the wild type and the variant DNA strands, called a *heteroduplex*. When analyzed by gel electrophoresis, the hybrid DNA will migrate through the gel matrix at a different rate and can be visualized as a distinct band on the gel. CSGE is thought to detect more than 90% of mutations.

Single-strand conformation polymorphism (SSCP). Like CSGE, SSCP initially requires PCR amplification of a specific region of DNA. The resulting double-stranded DNA is then denatured and quickly renatured so that some strands are not able to find their complementary strand before renaturation. This results in a population of single-stranded DNA folded on itself, forming a secondary structure. The renatured DNA is next run on a gel, and DNA variants that vary from the normal sequence form unique secondary structures that migrate at a different rate within the gel matrix. This method has been successfully used to detect mutations; however, it is only 60% to 95% effective and is dependent on the DNA sequence being examined and the laboratory conditions used.

Denaturing-gradient gel electrophoresis (DGGE). DGGE is similar to CSGE, but it differs in that the double-stranded DNA is run through a gel matrix that has an increasing gradient of urea and formaldehyde, chemicals that denature DNA. Variations in DNA sequence will denature under different stringencies and consequently migrate differently in the gel matrix. The DNA can be visualized, and differences (mutations) are detected. DGGE can detect as many as 95% of sequence changes.

Protein truncation test (PTT). PTT uses in vitro methods to synthesize protein from the DNA in question. Viable cells from the subject are required to generate a full-length cDNA of the gene. If a nonsense mutation is present (i.e., one that results in a shortened protein), two bands are observed on the electrophoresis gel, one for the normal protein and one for the shortened protein. PTT fails to detect changes in cases of a large deletion, or if the truncation is at the very start or the very end of the gene or gene segment. In the clinical setting, PTT is used to indicate the presence of a truncating mutation, and it may be followed by sequencing to determine

the exact mutation.
Linkage analysis. Linkage analysis is used not only in gene discovery but also clinically to determine the likelihood that a person at risk carries the mutant gene. Linkage analysis can be used if the gene location is known but a specific mutation has not been identified in the family. The method is identical to that described in the section “Gene Discovery Methods” and is informative in 90% to 95% of families that are able to submit the appropriate samples from multiple members for testing.
Site-specific mutation analyses. Once a specific mutation has been identified in an index case of a family, “site-specific mutation analyses” are used to examine the presence or absence of that particular mutation in other family members. A number of PCR-based methods are used, often specific to the mutation found in the family. The various techniques are not described here, but of note, these techniques are all highly accurate and much less expensive than the original mutation identification in the index case of a family. Familiarity with the types of mutations that occur in specific diseases is important and determines the specific test ordered. Site-specific mutation analysis for specific mutations, for example, is performed for hemochromatosis and cystic fibrosis, whereas complete gene sequencing are performed for the diagnosis of familial adenomatous polyposis (FAP).

Types of Genetic Disorders

Genetic disorders can be categorized into four major groups. Knowledge of the types of genetic disorders is important to understanding the etiology, occurrence, and recurrence risks of inherited diseases.

Chromosomal Disorders Chromosomal disorders occur when the chromosomal number or structure differs from that normally expected. A person with a chromosomal disorder may have an extra chromosome (e.g., Down syndrome, in which an individual has three copies of chromosome 21) or lack a chromosome (e.g., Turner syndrome, in which a female subject has one instead of two X chromosomes). Chromosomal disorders also include duplication, absence, or structural rearrangement of large segments of chromosomes (e.g., DiGeorge sequence). Examples of chromosomal disorders and their GI manifestations can be found in Table 54-1. If a chromosomal disorder is suspected, karyotype or other analysis can be performed on blood lymphocytes.

CHROMOSOMAL DISORDERS	GASTROINTESTINAL MANIFESTATIONS
Duplication of 3q	Umbilical hernia, omphalocele
Deletion of 9p	Inguinal and/or umbilical hernia, diaphragmatic hernia
Deletion of 11q	Pyloric stenosis, inguinal hernia
Microdeletion of 22q 11.2 (DiGeorge sequence)	Esophageal atresia, velopharyngeal insufficiency, imperforate anus, diaphragmatic hernia
Trisomy 13 (Patau syndrome)	Omphalocele, heterotropic pancreatic or splenic tissue, incomplete rotation of colon, Meckel diverticulum, enlarged gallbladder, diaphragmatic defect
Trisomy 18 (Edwards syndrome)	Inguinal or umbilical hernia, malposed or funnel-shaped anus, hypoplastic diaphragm, Meckel diverticulum, heterotopic pancreatic and/or splenic tissue, omphalocele, incomplete rotation of colon, pyloric stenosis, extrahepatic biliary atresia, hypoplastic gallbladder, gallstones, imperforate anus
Trisomy 21 (Down syndrome)	Tracheal stenosis with hourglass trachea and midtracheal absence of tracheal pars membranacea, tracheoesophageal fistula, duodenal atresia, omphalocele, pyloric stenosis, annular pancreas, Hirschsprung disease, imperforate anus

TABLE 54-1 Examples of Chromosomal Disorders with Associated Congenital Gastrointestinal Manifestations

Additionally, chromosomal mosaicism is possible, in which an individual’s genetic makeup comprises two or more populations of cells that vary in chromosomal content. Mosaicism occurs when one cell sometime later in embryonic development acquires a mutation during mitosis. Any future cells (clonal population) derived from this one stem cell will contain the same genetic error. Consequently, the individual will have both normal and abnormal cells and is mosaic for the chromosomal disorder. Mosaicism may or may not affect the phenotype of the individual or pose a risk to his/her offspring.
Mendelian Disorders Mendelian disorders are named after Gregor Mendel, an Austrian monk who lived in the mid-19th century and is considered to be the father of genetics. Mendelian disorders are caused by mutations in single genes and can be passed to offspring in an autosomal dominant, autosomal recessive, or sex-linked fashion. Although a mutant gene may cause the condition, the severity of the disease may be influenced by environmental factors. Examples of single-gene disorders affecting the GI tract are listed in Table 54-2 and Table 54-3, and the rules of inheritance are discussed in a later section.

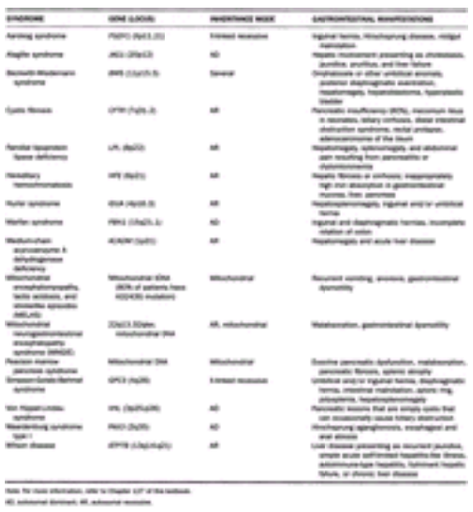

TABLE 54-2 Examples of Monogenetic (Mendelian) Disease with Congenital Gastrointestinal Manifestations

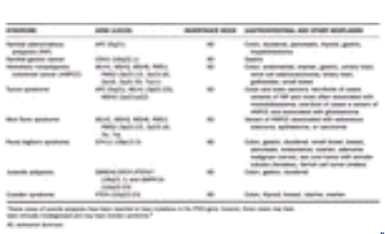

TABLE 54-3 Hereditary Cancer Syndromes Predisposing to Increased Risk for Gastrointestinal Neoplasms

Mitochondrial Disorders Mitochondria, organelles found in the cytoplasm of a cell, produce adenosine triphosphate (ATP), an energy-rich molecule, through the oxidative phosphorylation process. Mitochondria have their own DNA molecules, distinct from nuclear DNA, and these code for genes important in oxidative phosphorylation. Mutations in the mitochondrial genes cause several genetic conditions, including Pearson marrow pancreas syndrome (see Table 54-2). Mitochondria are maternally inherited through the mitochondria in the cytoplasm of the egg. Sperm have few mitochondria; none of them enter the egg during fertilization and thus are not passed on to offspring. A female affected with a mitochondrial disorder will pass the disease to all her offspring (100% transmission), whereas no offspring will inherit the disorder from an affected male (Fig. 54-3).

FIGURE 54-3. Typical pedigree showing mitochondrial inheritance. Males are represented by *squares* and females by *circles.* All offspring of an affected female will inherit the condition, whereas none of the children of an affected male will.

Multifactorial/Complex Disorders Although much is understood about chromosomal, mendelian, and mitochondrial disorders, these conditions reflect only a small proportion of inherited diseases. Multifactorial/complex disorders are more common and currently less well understood. As their name implies, these conditions are caused by a combination of factors through gene-gene interactions or gene-environment interactions. Twin studies can be used to assess the quantitative impact of gene and environmental influences on diseases. One twin study, for example, found that approximately 35% of colon cancers arise from an inherited predisposition. [52] The known inherited colorectal cancer predisposition syndromes constitute 5% to 10% of the familial aggregation, implying that additional colon cancer susceptibilities are yet to be defined.

Modes of Inheritance

Mendelian (monogenetic) disorders include those passed to offspring through autosomal dominant, autosomal recessive, and sex-linked forms of inheritance. As previously discussed, humans have two copies (alleles) of each gene located on the autosomes. If both alleles at the locus are the same, the individual is homozygous for that gene. If two different alleles are present at a given locus, the individual is a heterozygote.

Autosomal Dominant The basis of autosomal dominant inheritance is that an alteration in *one* of the two copies of the gene leads to disease. One allele has a mutation, and the corresponding allele on the homologous chromosome is normal. Autosomal dominant conditions express themselves in the heterozygous state. Figure 54-4 shows a typical autosomal dominant pedigree. The rules of autosomal dominant inheritance are as follows: An affected individual has a 50% chance of passing on the mutant gene and a 50% chance of passing on the normal gene to each offspring.
The condition appears to be transmitted vertically (i.e., multiple generations are affected).
Both male and female parents can pass on the mutant gene to both male and female offspring (i.e., male-to-male transmission occurs).
An affected individual has an affected parent and generations are not skipped (exceptions are new mutation and incomplete penetrance).

FIGURE 54-4. Typical pedigree showing autosomal dominant inheritance. Males and females are equally affected. Vertical transmission of the condition is apparent.

Autosomal Recessive Autosomal recessive conditions require that an individual inherit *two* copies of a mutant gene at a given locus, one disease-causing allele from each parent (Fig. 54-5). Autosomal recessive conditions express themselves in the homozygous state. Individuals who are heterozygous for a recessive condition (i.e., have only one mutant allele) typically do not manifest symptoms of the condition and are referred to as *carriers*. In some conditions, carrier status affords a selective advantage (e.g., carriers of sickle cell anemia are resistant to malaria). The rules of autosomal recessive inheritance are as follows: A mating between two carrier parents results in a 25% chance that they will have an affected (homozygous) child, and a 75% chance that they will have a normal child. Of the phenotypically normal children, two thirds will be carriers and one third will be homozygous normal.
The condition appears to be transmitted horizontally (i.e., multiple individuals in one generation can be affected).
Males and females are affected equally.

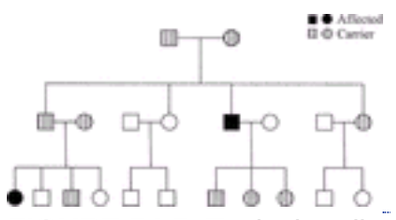

FIGURE 54-5. Typical pedigree showing autosomal recessive inheritance. Males and females are equally affected. An individual must inherit two copies of a mutant gene at a given locus to be affected.

Sex-Linked Sex-linked disorders involve the sex-determining X and Y chromosomes. The difference in sex chromosome composition between males and females is the basis for understanding X-linked conditions. Men who inherit an abnormal gene on the X chromosome (the X chromosome in males is always inherited from the mother) will be affected with the associated condition. Because women have two X chromosomes, the inheritance is similar to that of autosomal dominant and recessive conditions. In X-linked dominant conditions, one mutant allele is sufficient to cause the condition in females, whereas two mutant alleles are required to cause the condition in X-linked recessive disease in females. A typical pedigree showing X-linked recessive inheritance appears in Figure 54-6. X-linked recessive disorders are more common than X-linked dominant conditions. The rules of X-linked recessive inheritance are as follows: Affected men are common, whereas affected women are not (unless an affected man and a carrier woman produce offspring).
All the daughters of an affected male will be carriers. None of his sons will be affected because fathers pass on a Y chromosome to their sons, not an X chromosome (no male-to-male transmission).
Male offspring of carrier women have a 50% chance of being affected and a 50% chance of being unaffected.
Female offspring of carrier women have a 50% chance of being a carrier and a 50% chance of having two normal alleles.
Because affected men have carrier daughters, who in turn have affected sons, the condition appears to “skip” generations.
Rarely with certain X-linked recessive conditions, female carriers display mild symptoms of the disease (e.g., fragile X syndrome).

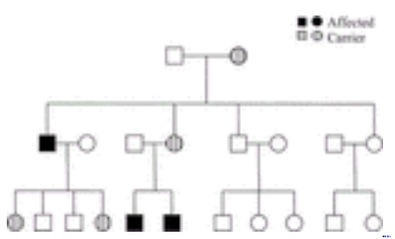

FIGURE 54-6. Typical pedigree showing X-linked recessive inheritance. Males are more likely to be affected, whereas females are more likely to be carriers.

Other Rules of Genetics Knowledge of the basic modes of inheritance is important in assessing occurrence and recurrence risks for patients. Other genetic concepts must also be applied to provide accurate education and risk assessment to individuals and their families.
Delayed age at onset. FAP demonstrates the feature of delayed age at onset. Children born with the FAP genotype have one mutant copy of the *APC* gene on chromosome 5 and typically do not exhibit any of the phenotypic characteristics of the condition in childhood (see Table 54-3). In FAP, the average age at polyp development is 16 years. The presence of a deleterious genotype does not necessarily lead to a phenotypic expression from birth.
Penetrance. *Penetrance* refers to the likelihood of disease expression if the disease-causing gene is present. For example, individuals with FAP are thought to have nearly a 100% chance of developing colon polyps and subsequent colon cancer if prophylactic colectomy is not performed, and therefore the penetrance of FAP is

100%. The likelihood of an individual with hereditary nonpolyposis colorectal cancer (HNPCC) developing colon cancer in his/her lifetime is close to 80%; therefore, the penetrance of colon cancer in HNPCC is 80%. Every clinical feature of a genetic condition has a penetrance level.

Nonpenetrance. Fundamental to the interpretation of the family history is an awareness of nonpenetrance. Nonpenetrance is illustrated by the individual with a mutant genotype in whom the disease or condition never develops. Nonpenetrance may complicate the interpretation of the family history, especially in the case of conditions inherited in an autosomal dominant pattern, which one would expect to observe in all successive generations. Nonpenetrance is also illustrated by the individual who dies of other causes before the disease develops or who undergoes prophylactic surgery.

New mutation. The clinician must also consider the possibility of a new mutation. Mutations in human genes may occur randomly during gamete maturation or very early in embryogenesis. A mutation will be replicated and become a part of every cell in the body of the affected individual. Every genetic condition has an associated new mutation rate. For example, although reports of new mutations in the genes associated with HNPCC are rare, 30% of individuals in whom FAP is newly diagnosed and do not have a previously known family history of FAP represent new mutations (i.e., neither parent has an *APC* mutation).

Pleiotropy. Many genes, including mutated *APC* genes that cause FAP, exhibit pleiotropy. Pleiotropy occurs when a mutated gene has more than one phenotypic effect on the body. For example, in an individual with FAP, colonic polyps, desmoid tumors, osteomas, or thyroid cancer can develop. Although colon cancer is the greatest risk, it is not the only phenotypic effect. The other findings are said to be pleiotropic manifestations of the mutant gene.

Variable expressivity. Variable expressivity is the concept that the same genetic condition is expressed to a different extent in different individuals. In some individuals with HNPCC, for example, multiple cancers, including colon cancer, uterine cancer, and urinary tract cancer, develop, whereas only colon cancer may develop in other individuals. Gene expression can be modified by genes, environmental factors, and other unknown factors.

Genetic heterogeneity and locus heterogeneity. Critical to identifying the possible etiology of a clinical presentation is the awareness that similar phenotypes may have different genetic causes. For example, although pancreatitis is strongly associated with environmental factors such as alcohol use or gallstones, mutations in three genes have been shown to be associated with pancreatitis. These include the genes for cystic fibrosis (*CFTR*), cationic trypsinogen (*PRSS1*), and a trypsin inhibitor (*PST1* or *SPINK1*). Table 54-4 outlines several GI diseases and their genetically heterogeneous causes. The term *locus heterogeneity* indicates that mutations in any one of several related genes may result in the same genetic disorder. Although FAP is not considered to have locus heterogeneity (all cases of FAP are thought to be caused by mutations in the *APC* gene), HNPCC is a condition caused by mutations in any one of several DNA mismatch repair genes (*MLH1, MSH2, MSH6, PMS1, PMS2*). Knowledge of the genetic conditions that have locus heterogeneity is essential in ordering the proper genetic test.

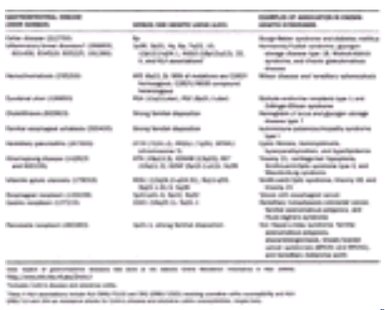

TABLE 54-4 Gastrointestinal Disease Displaying Genetic Heterogeneity

Allelic heterogeneity. One contribution to variable expressivity is allelic heterogeneity. The term *allelic heterogeneity* simply means different mutations in alleles of the same gene. These different mutations may result in different and distinct phenotypes. A good example is FAP, in which some features are related to the location of the mutation in the *APC* gene. Mutations in the 5' or 3' (beginning or end) region of the *APC* gene are generally associated with an attenuated version of FAP (also called *attenuated adenomatous polyposis coli*). In this condition, fewer polyps form at later ages than in typical FAP. [4] In contrast, mutations located between codons 1250 and 1464 are associated with a diffuse (>5000 polyps) phenotype. [5] An ongoing area of study involves the correlation of genotype to phenotype and understanding genes well enough to know the molecular and health impact of mutations in certain areas of the gene.

Compound heterozygosity. Compound heterozygosity occurs when an individual has two different disease-causing alleles at a specific locus. Individuals with compound heterozygosity can be affected with an autosomal recessive condition such as cystic fibrosis. The *CFTR* gene is responsible for cystic fibrosis when both alleles contain mutations. Seventy percent of all *CFTR* mutations are caused by deletion of 3 base pairs at position 508 of the gene, commonly called the *?508 mutation*. Many individuals with cystic fibrosis have two ?508 mutations and are homozygotes. Individuals who have a ?508 mutation on one allele and a different mutation, such as the R117H mutation, on the second allele are compound heterozygotes. Different disease-causing mutations can affect the phenotype of an individual, as explained in the section “Allelic Heterogeneity,” and this holds true for autosomal recessive conditions. For example, individuals with cystic fibrosis who have two ?508 mutations almost always have pancreatic insufficiency, whereas compound heterozygotes with one ?508 mutation and one R117 mutation are less likely to have pancreatic insufficiency.

Somatic versus germ-line mutations. In the field of cancer genetics, it is important to understand the concept of somatic versus germ-line mutations. Somatic mutations are acquired mutations. Only the daughter cells of the somatically mutated cell carry the mutation. Somatic mutations are not found in cells in other parts of the body and cannot be passed on to offspring. Germ-line mutations are inherited mutations or those that occur at the beginning of embryogenesis, so that they are present in every cell of the body. An individual with a germ-line mutation can pass the mutation on to his/her offspring. Mutations of the *APC* gene, for example, may be germ-line or somatic. Germ-line *APC* mutations are present in every cell of the colon (and body), so that colonic polyposis and FAP develops and the disease is passed on to offspring. Somatic *APC* mutations in a colonic epithelial cell appear to be the first step in the development of a sporadic polyp. Only the daughter cells carry the somatic mutation. A single polyp eventually forms from this clone of cells. The mutation is not found in other cells of the colon or body, however, and therefore cannot be passed on to offspring.

PRINCIPLES OF GENETIC COUNSELING

Definition

The first official definition of genetic counseling was proposed and adopted by the American Society of Human Genetics (ASHG) in 1975. The practice was defined as follows:

> Genetic counseling is a communication process that deals with the human problems associated with the occurrence or risk of occurrence of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or family to: (1) comprehend the medical facts including the diagnosis, probable course of the disorder, and the available management, (2) appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives, (3) understand the alternatives for dealing with the risk of recurrence, (4) choose a course of action which seems to them appropriate in view of their risk, their family goals, and their ethical and religious standards and act in accordance with that decision, and (5) make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder. [6]

Modern genetic counseling practice continues to encompass these core components. Additionally, as the repertoire of clinically available molecular tests continues to grow, patients and their families should be educated about available genetic tests together with the risks and benefits of genetic testing.

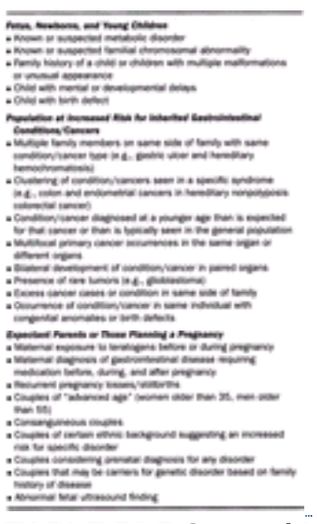
Genetic Providers

Medical geneticists (PhD or MD), advanced practice nurses with genetic certification (MSN), and genetic counselors (MS) are specialty-trained clinical genetic practitioners who provide education, a diagnosis based on the clinical findings or results of genetic testing, therapeutic management and options, and psychosocial support throughout the duration of care for the patient at risk for or affected with a genetic disorder. Genetic providers also stay abreast of the social-ethical, legal, ethnic-cultural, and financial issues that surround genetic testing.

Although the majority of genetic services are in obstetrical care (>60%), other subspecialties have quickly developed because of the expanding knowledge of the genetic etiology of human disease. Subspecialty areas include cancer, neurogenetics, psychiatric, and pediatric counseling. In genetics clinics, a consultation may require a multidisciplinary team comprising PhD/MD geneticists, surgeons, genetic counselors, nurses, nutritionists, and other practitioners of health care disciplines to address the patient’s complex needs and manage the pleiotropic effects of a genetic condition. Some gastroenterologists may have specialty training or knowledge to provide genetic counseling, whereas others may find it valuable to consult with or refer to genetic practitioners. A directory of national and international genetic counselors and geneticists can be found at the Web sites http://www.nsgc.org/resourcelink.asp and http://www.faseb.org/genetics/memb-dir/ashg.htm, respectively. The following is an overview of clinical genetic counseling for the gastrointestinal patient.

Components of Clinical Genetic Counseling

Indications for Counseling Any patient with a GI condition for which a genetic etiology is suspected or known is an appropriate candidate for genetic counseling. The genetic counseling session is collaborative in nature because of the tremendous amount of education and personal decision making involved for the patient. [7], [8] Family members are often seen conjointly with the patient because of the hereditary nature of the disease. The patients who undergo genetic counseling for most GI diseases with a known genetic etiology can generally be grouped by age or special populations, and although the list is not exhaustive, the common considerations for a genetic consultation are summarized in Table 54-5.



Fetus, Newborns, and Young Children
- Known or suspected metabolic disorder
- Known or suspected familial chromosomal abnormality
- Family history of a child or children with multiple malformations or unusual appearance
- Child with mental or developmental delays
- Child with birth defect

Population at Increased Risk for Inherited Gastrointestinal Conditions/Cancers
- Multiple family members on same side of family with same condition/cancer type (e.g., gastric ulcer and hereditary hemochromatosis)
- Clustering of condition/cancers seen in a specific syndrome (e.g., colon and endometrial cancers in hereditary nonpolyposis colorectal cancer)
- Condition/cancer diagnosed at a younger age than is expected for that cancer or than is typically seen in the general population
- Multifocal primary cancer occurrences in the same organ or different organs
- Bilateral development of condition/cancer in paired organs
- Presence of rare tumors (e.g., glioblastoma)
- Excess cancer cases or condition in same side of family
- Occurrence of condition/cancer in same individual with congenital anomalies or birth defects

Expectant Parents or Those Planning a Pregnancy
- Maternal exposure to teratogens before or during pregnancy
- Maternal diagnosis of gastrointestinal disease requiring medication before, during, and after pregnancy
- Recurrent pregnancy losses/stillbirths
- Couples of "advanced age" (women older than 35, men older than 55)
- Consanguineous couples
- Couples of certain ethnic background suggesting an increased risk for specific disorder
- Couples considering prenatal diagnosis for any disorder
- Couples that may be carriers for genetic disorder based on family history of disease
- Abnormal fetal ultrasound finding

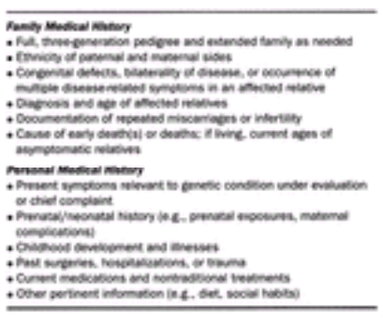
TABLE 54-5 General Indications for Genetic Consultation Based on Needs of Special Populations

Counseling for conditions involving fetuses, newborns, or young children. Fetuses, newborns, or young children who present with congenital GI malformations may have chromosomal abnormalities or single-gene mutations. For example, 25% of fetuses with cystic fibrosis and 12% of fetuses with chromosomal disorders present with an echogenic bowel seen on ultrasonography during the second trimester. It is currently estimated that more than half of all birth defects have a genetic origin. Some types of GI dysfunction may be seen as part of a syndrome or display genetic heterogeneity (see Table 54-2, Table 54-3, and Table 54-4). Pyloric stenosis is such a condition. It is an associated feature in some genetic syndromes but is also seen as an isolated condition. Single-gene mutations for isolated pyloric stenosis have been mapped to several chromosomal regions.

Counseling for adults and for cancer predisposition. Although some predominantly GI diseases of young adolescent/adult population have been linked to genes or genetic loci, most GI diseases for which genetic testing is commercially available relate to cancer predisposition. A small but significant number of colon cancers (5%–10%) belong to a distinct class of inherited colorectal cancer predisposition syndromes (see Table 54-3). [9] Lastly, expectant mothers or women considering pregnancy who may be exposed to teratogens (external agents such as GI medications) that may affect fetal GI or other organ development will benefit from a genetic consultation.

Personal and Family Medical History

Pedigree. At the core of genetic counseling is a family "pedigree." A pedigree is a schematic diagram of familial generations, including personal and family medical history, in which standardized symbols are used. [10] Pedigrees aid geneticists in evaluating for the inheritance pattern of disease and therefore should include both the family history and the personal medical history of the patient (Table 54-6). [11] The information gathered is pertinent to propose the differential diagnoses of genetically related GI disorders, to provide risk assessment, to determine which diagnostic test to order, to interpret genetic test results accurately, and to guide individualized medical intervention. When genetic tests are unavailable or declined by the patient, the family history remains valuable in providing targeted surveillance and aiding in management decisions. [12]



Family Medical History
- Full, three-generation pedigree and extended family as needed
- Ethnicity of paternal and maternal sides
- Congenital defects, bilaterality of disease, or occurrence of multiple disease-related symptoms in an affected relative
- Diagnosis and age of affected relatives
- Documentation of repeated miscarriages or infertility
- Cause of early death(s) or deaths; if living, current ages of asymptomatic relatives

Personal Medical History
- Present symptoms relevant to genetic condition under evaluation or chief complaint
- Prenatal/neonatal history (e.g., prenatal exposures, maternal complications)
- Childhood development and illnesses
- Past surgeries, hospitalizations, or trauma
- Current medications and nontraditional treatments
- Other pertinent information (e.g., diet, social habits)

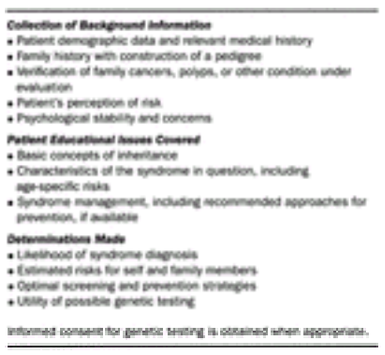
TABLE 54-6 Suggested Components of Personal and Family History

Accuracy and perceptions. Generally, individuals report accurate medical diagnoses for first-degree relatives (parents, children, siblings) and second-degree relatives (grandparents, aunts, uncles, grandchildren), but reports for distant relatives may be less accurate. [13], [14] Confirmation of the information provided by the patient through medical records collection and review can be insightful and necessary. Subtle differences detected from pathology records or a repeated consultation of a previous histopathological report can change the diagnosis, affect appropriate medical recommendations, and necessitate different genetic testing or screening. For example, it is common for family members to know if a close relative has colonic polyps, but it is unusual for the patient to know whether the polyps are adenomatous, hyperplastic, or hamartomatous. Knowledge of the histology of polyps is highly pertinent when a family is evaluated for an inherited colon cancer condition (see Table 54-3). A review of the family history information during clinic visits can also provide an opportunity to learn about the patient's health beliefs. An example of beliefs would be, "Aunt Mary got cancer because she has a stressful job," and an example of family dynamics would be, "My brother and I haven't spoken since I was diagnosed with cancer."

Risk Assessment and Physical Evaluation High, moderate, and general population (average) risks are defined as part of the counseling evaluation. Risk assessment involves a discussion of the likelihood of a possible genetic component and its implications. An individual or family that fulfills one or more of the criteria listed in Table 54-5 is generally considered at increased risk and appropriate for genetic counseling to identify the role of contributing hereditary factor(s) and provide risk assessment. Genetic testing ultimately defines the genetic risk with precision. The results of genetic testing can direct those with the inherited condition in question to proper management, and at the same time allow those without the condition to avoid unnecessary medical screening and management procedures. Depending on the condition suspected, a physical examination can be extremely important in determining the likelihood it is present. FAP is a good example. The presence of associated extracolonic manifestations, such as osteomas, fibromas, and congenital hypertrophic retinal pigment epithelium, in a patient at risk makes the diagnosis much more likely. The family and personal history, environmental risk factors, and complete physical examination are collectively meaningful in an assessment of the probability that a genetic disease is present. Mathematical predictive models that utilize this information are emerging to assist with risk assessment and to predict the likelihood of finding a mutation with genetic testing for some conditions. Interestingly, some insurance companies already rely on these probability models to determine eligibility for the coverage of molecular testing costs. The general rule often followed by genetic providers is that it is appropriate to offer available diagnostic genetic testing to individuals whose chance of having a genetic mutation is 10% or more.

Education and Genetic Discrimination

Content of patient genetic education. Patient education consists of information about the nature and etiology of the disorder, its natural history and prognosis, the mode of inheritance, the occurrence or recurrence risks, the recommended prevention, screening and treatment options, the availability of research studies, and the possibilities for prenatal diagnosis (Table 54-7). Helping patients understand the basic principles of genetics and disease can dispel myths. It is not uncommon for individuals with a strong family history of a condition to develop their own beliefs about the inheritance, such as "The disease only affects males in my family" when the disease is actually autosomal dominant. Very common is an association with physical features, such as "Everyone in my family with red hair gets cancer."



Collection of Background Information
- Patient demographic data and relevant medical history
- Family history with construction of a pedigree
- Verification of family cancers, polyps, or other condition under evaluation
- Patient's perception of risk
- Psychological stability and concerns

Patient Educational Issues Covered
- Basic concepts of inheritance
- Characteristics of the syndrome in question, including age-specific risks
- Syndrome management, including recommended approaches for prevention, if available

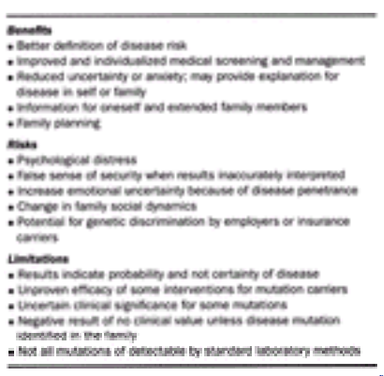
Determinations Made
- Likelihood of syndrome diagnosis
- Estimated risks for self and family members
- Optimal screening and prevention strategies
- Utility of possible genetic testing

Informed consent for genetic testing is obtained when appropriate.

TABLE 54-7 Areas to Be Covered by Genetic Counseling

Informed consent for genetic testing is obtained when appropriate. In a discussion of the quantitative risks of health problems associated with an inherited condition, it is important to recognize that many patients do not understand statistical terminology. It may often be better, for example, to state that eight of ten individuals with HNPCC will acquire colon cancer in their lifetime, rather than that the lifetime risk of associated colon cancer is 80%. It may also be useful to compare risks with the risks in the general population. For example, although 6% of Americans will acquire colon cancer in their lifetime, the risk of individuals with HNPCC for the development of colon cancer is increased approximately 13-fold. Risk communication geared towards the patient's educational background and personal experience will improve understanding and facilitate compliance with the recommended surveillance.

Issues, benefits, and risks of genetic testing. In a discussion of the option of genetic testing, education should include applicability, cost, turnaround time, and the personalized meaning of results. It should also include the benefits, risks, and limitations of testing (Table 54-8). Particular concerns of the patient are inevitably the insurance issues and the employment and social discrimination that may follow a genetic diagnosis. Consumer education by the genetic provider is an approach that may involve many practitioners and can often facilitate the decision regarding genetic testing for the patient. [15], [16] and [17] Additionally, individuals who are considering genetic testing need to be informed about current federal and state legislation regarding genetic privacy and the potential for genetic discrimination. [18] Presently, 42 states have enacted some level of protection for genetic privacy, but fewer states have legislative protection in place for employment, disability insurance, and life insurance (www.nhgri.nih.gov/Policy_and_public_affairs/Legislation/insure.htm). There are some federal safeguards for genetic information. One example is the Health Insurance Portability and Accountability Act of 1997 (Kennedy-Kassebaum Bill), which precludes the use of genetic information as the basis for a preexisting condition when a person is asymptomatic. This law also prohibits insurers from using genetic information to exclude a person from group coverage or individually charging higher premiums within a group. In the context of employment, the Americans with Disabilities Act of 1990 now includes "genetic or medically identified potential of or predisposition toward a physical or mental impairment that substantially limits a major life activity" as a definition of a disability. To date, no cases have been prosecuted with this act as legal grounds. Loopholes exist in these federal and states laws, and the potential remaining risk for the misuse of genetic information by third parties is unclear.



Benefits
- Better definition of disease risk
- Improved and individualized medical screening and management
- Reduced uncertainty or anxiety; may provide explanation for disease in self or family
- Information for oneself and extended family members
- Family planning

Risks
- Psychological distress
- False sense of security when results inaccurately interpreted
- Increase emotional uncertainty because of disease penetrance
- Change in family social dynamics
- Potential for genetic discrimination by employers or insurance carriers

Limitations
- Results indicate probability and not certainty of disease
- Unproven efficacy of some interventions for mutation carriers
- Uncertain clinical significance for some mutations
- Negative result of no clinical value unless disease mutation identified in the family
- Not all mutations of detectable by standard laboratory methods

TABLE 54-8 Benefits, Risks, and Limitations of Genetic Testing

At the time of this writing, it appears that despite the cited laws, some risk for genetic discrimination remains, even though it appears to be very low and often not different from that of an individual with a clinical diagnosis or known familial risk. Nonetheless, it is the obligation of the provider to outline appropriately the risks and benefits of a genetic diagnosis. In many cases, the medical benefit of a genetic diagnosis far outweighs the risks, but in some instances, the reverse may be true. Thus, an informed and supportive discussion of the issues is extremely important and will allow patients to reach decisions on genetic testing that are appropriate for them and their families. Lack of such a discussion may well lead to inappropriate decisions based on lack of knowledge, fear, and misconception. Education about familial risks and genetic results not only provides the setting for appropriate testing decisions but can also promote long-term patient satisfaction and adherence to medical management. [19]

Psychosocial Issues and Support

Burden of a genetic diagnosis. Genetic information may sometimes be psychologically overwhelming, akin to a cancer diagnosis. The patient may display emotional responses through a variety of protective psychological mechanisms: denial, anger, guilt and shame for passing on a disease to children, despair, grief, and depression. The most important initial step for the provider is acceptance of the patient's responses and vulnerabilities. [20], [21] An environment of trust and openness can then be provided so that short- and long-term psychological support can be given. The genetic diagnosis frequently delineates risks that differ widely from the patient's beliefs or perceived risks. Challenges for the provider thus also include the reconciliation of unexpected news with long-held beliefs and ideas.

Decision to pursue genetic testing. The decision of whether or not to pursue genetic testing is often connected to the psychological issues. Several studies carried out before the implementation of clinical genetic testing noted high acceptance rates and an intention to pursue testing when it became available. [22], [23], [24], [25], [26] and [27] However, the acceptance of genetic testing since it became available has been lower than originally expected. [28], [29] Reasons for the low acceptance rate include costs, perceived lack of medical benefits, perceived risks, personal goals, ethnicity, gender, and fear of genetic discrimination. Each of these issues is inextricably intertwined with patient psychology in addition to the disease and risks at hand. [26], [30], [31], [32], [33], [34], [35] and [36]

Psychological assessment associated with genetic counseling. In view of the many psychological issues surrounding genetic diagnosis and testing, a thoughtful psychological assessment, usually informal but sometimes formal, should be included in pretest or posttest counseling. Pretest counseling prepares both patient and clinician for receiving the test results. Counseling should assess the patient's perception of genetic testing results, in addition to the psychological and social effects of testing on the patient and extended family members. The decision to test should complement the patient's personal and family goals, ethical and religious standards, and medical goals. In some cases, psychological intervention may require additional referrals to psychiatrists, clinical psychologists, support groups, or counseling groups.

Return of results. Because testing has implications not only for the testing candidate but also for extended family members, a discussion during pretest or posttest counseling regarding how to share test results with other family members or children at risk is appropriate. Results disclosure is usually presented in person to ensure a precise understanding of the test results, to provide appropriate support for the psychological consequences surrounding the results, and to outline individual surveillance or medical options that derive from the results. Disclosure of results by telephone or through a primary health care provider as an intermediary is generally not considered sufficient—again, akin to disclosing a cancer diagnosis in this way.

Reproductive Counseling Gastroenterologists caring for women who are either pregnant or of childbearing age and being treated for chronic GI disease must be familiar with the topic of reproductive counseling. A major topic in reproductive counseling is teratogens. A teratogen is defined as an environmental agent, such as a GI medication, that is capable of causing either structural or functional abnormalities in the developing fetus. In an assessment of potential risk to a pregnancy, an environmentally induced malformation depends on several measures. These may include the time of exposure during pregnancy, the dosage of the drug, the duration of exposure to the drug, individual susceptibility, the potential interaction with other environmental agents, placental transport, species differences, and pharmacokinetics and metabolism of the agent. [37] In counseling a pregnancy at risk for teratogenicity, it is important to compare the risk of 2% to 5% in the general population that any pregnancy will result in a major birth defect, regardless of family history and exposures, with the potential for increased risk based on currently known teratogenic exposure(s). If discontinued before pregnancy, most drugs generally pose no increased risk to the developing fetus. Moreover, the developmental period at which exposure occurs can be a predictor of the type of embryonic damage. Typically, medications taken during the preimplantation phase, or the first 2 weeks after conception, exhibit the all-or-none phenomenon. This should not be misinterpreted to mean that malformations cannot be induced at this stage. Rather, embryonic lethality resulting in an unrecognized pregnancy is more likely than a surviving fetus with anomalies. [37] The period of organogenesis (gestational day 18 through about day 60) is when most major and gross anatomic and functional development occurs, and therefore this is the time when fetal exposure to teratogens is most likely to result in severe malformations. During the second and third trimesters of pregnancy, damage to the genitourinary system and the brain is more likely. The Food and Drug Administration (FDA) has developed a rating system that combines what is known regarding the teratogenicity of a given drug and the potential benefit of that drug to a pregnant woman. *Physicians' Desk Reference* provides a similar rating scale. Table 54-9 lists some commonly prescribed GI medications and their FDA ratings for use in pregnancy. Additionally, several comprehensive and up-to-date resources provide detailed information on teratogenicity and pregnancy risk to clinicians (Table 54-10).

TABLE 54-9 Commonly Prescribed Gastrointestinal Medications and the Food and Drug Administration Use-in-Pregnancy Rating System and Lactation Studies

TABLE 54-10 Database Resources for Teratology Information

Developing Technology From our experience, a frequently asked question during genetic counseling pertains to gene therapy. Gene therapy involves introducing genetic material into human cells with the goal of achieving a preventative or therapeutic effect. [38] To date, gene therapy has had limited success. Gene therapy was initially considered useful, but has not been accomplished, for monogenic conditions such as cystic fibrosis and familial hypercholesterolemia. Gene therapy is now under investigation for use in treatment of more complex genetic and infectious diseases. The main challenges are finding safe, reliable and efficient vehicles through which genetic material can be transferred to the target cells in the body. An additional challenge involves having the replaced gene express itself in the target cells at the right time and quantity to be beneficial to the patient. Lists of clinical trials currently underway can be found at www4.od.nih.gov/oba/rac/clinicaltrial.htm and at www.wiley.co.uk/genetherapy.

GENETIC TESTING

Definition and Clinical Value

Genetic testing has recently become a part of the standard care for a number of GI conditions and is currently the most common topic of genetic counseling in the GI patient. *Present genetic testing* usually refers to testing for the presence of inherited conditions and involves analyzing DNA, RNA, chromosomes, proteins, or certain metabolites to detect changes related to a genetic disorder. GeneClinics is a federally funded and continually updated database of clinical and research laboratories that perform molecular analyses for inherited genetic diseases (http://www.genetests.org/). The discoveries of the Human Genome Project will inevitably lead to an increasing array of genetic tests for the diagnosis of both unusual and common GI disorders. Less commonly, genetic testing involves an analysis of specific tissue to assess for acquired or somatic mutations, such as the genetic testing performed as an adjunct in staging certain cancers. The information can be used to acquire a better understanding of the molecular and biologic nature of a particular disease so that treatment can be targeted. This type of genetic testing is not discussed here.

Classification of Approaches to Genetic Testing

Genetic testing falls into several classifications, discussed in the next sections. Although genetic testing is a powerful tool in guiding the clinical care of the at-risk or affected individual, attention should be given to its current limitations. Currently, the main limitation of genetic testing is that the sensitivity and specificity of testing methodologies for most conditions are not 100%. A negative or indeterminate result in an individual without a prior known family-specific mutation does not indicate the absence of a deleterious mutation for a suspected syndrome or the lack of a genetic etiology. Such misinterpretations are potentially fatal when medical management ceases for an at-risk individual. [39]

Diagnostic or Initial Genetic Testing Diagnostic testing is genetic testing performed in a person suspected of having an inherited disease, the mutation for which has not been sought or identified previously in relatives. An example would be a 40-year-old with ten adenomatous polyps but no known family history of FAP or attenuated FAP. Finding an *APC* mutation would confirm the diagnosis of FAP or attenuated FAP and would allow the clinician to proceed with appropriate screening and therapy. Failure to identify a mutation, however, is not helpful because mutations are not invariably found initially. Thus, the diagnosis remains unclear and may or may not be caused by an *APC* mutation. Clinicians are thus left to use their best clinical judgment.

Presymptomatic Testing or Testing When the Disease Mutation Is Known Knowledge of a specific disease mutation in a family allows family members at risk for the disease to undergo presymptomatic testing, the second classification of genetic testing. Presymptomatic testing involves testing healthy family members for the presence or absence of a specific mutation previously identified in an affected family member. A positive test result in a presymptomatic family member indicates that the person being tested carries the mutation and therefore has a genetic diagnosis of the disease in question. Appropriate screening and surveillance can then be planned. A negative test result (i.e., failure to find the mutation known to be segregating in the family) means that the person tested does not have the disease that is present in the family. Further screening or management of the disease in question is unnecessary for the person with a negative test result in this situation. A note of caution here is that a positive genetic diagnosis is not equivalent to a clinical diagnosis. Many features of the disease in question may or may not appear, depending on the observed penetrance of each of the features. This concept is frequently misunderstood by patients and requires careful attention. Retrospective study, for example, has shown that many patients thought a positive result of a test for FAP meant that they had colon cancer. Precise genetic counseling is thus extremely important at this stage. The patient must be educated about the likelihood of the development of certain disease features and must understand that appropriate management can prevent many of the consequences of the condition. A genetic diagnosis of FAP, for example, implies a 100% risk for eventual polyposis, but colon cancer can virtually always be prevented with appropriate therapy. A genetic diagnosis of HNPCC confers an 80% lifetime risk for colon cancer (not 100%), which likewise can almost always be prevented through appropriate screening.

Carrier Testing Carrier testing is performed for autosomal recessive and sex-linked conditions to learn if an individual is a heterozygous carrier of a gene mutation. Carrier testing may be appropriate for unaffected individuals with a relative who has an autosomal recessive or sex-linked condition. Additionally, members of different ethnic groups may be more likely to be gene carriers because of increased carrier frequencies in specific populations, and carrier testing is routinely offered to these groups (see section “ Genetic Screening for the General Population ”).

Prenatal Testing In prenatal testing, the health status of a fetus is evaluated during pregnancy. This may be desired because of an abnormal result of a screening test, such as ultrasonography, or because of an increased risk associated with the family history or maternal age. Fetal cells are obtained through procedures such as amniocentesis and chorionic villus sampling. Karyotyping to look for chromosomal disorders, or mutation analysis to look for a specific gene mutation known to be present in the family, may be applied to these cells. Many health, ethical, and social issues surround prenatal testing and require careful attention of the genetic counselor and the health team.

Newborn Screening In newborn screening, genetic testing is performed shortly after birth to learn if an infant is at an increased risk for having a specific genetic condition, the consequences of which could be prevented or ameliorated by immediate treatment. All states in the United States now require screening for several genetic conditions, most of which are metabolic (Table 54-11).

SCREENING TESTS	GASTROINTESTINALLY RELATED SYMPTOMS
Phenylketonuria	Neonatal vomiting
Galactosemia	Diarrhea, hepatomegaly, vomiting, progressive liver dysfunction leading to cirrhosis if untreated
Maple syrup urine disease	Pancreatitis, vomiting
Homocystinuria	Inguinal hernia, fatty changes in liver, pancreatitis
Sickle cell disease	Cholelithiasis, splenomegaly, splenic syndrome
Cystic fibrosis	Pancreatic insufficiency, meconium ileus in neonates, biliary cirrhosis, distal intestinal obstruction syndrome, rectal prolapse, adenocarcinoma of the ileum
Tyrosinemia (type I)	Hepatosplenomegaly, hepatic cirrhosis, hepatocellular carcinoma, pancreatic islet hypertrophy, ascites, jaundice, vomiting, paralytic ileus, diarrhea, melena

TABLE 54-11 Newborn and Prenatal Screening

Social Issues Surrounding Genetic Testing

The recent availability of genetic testing for many diseases adds a new dimension to clinical care and genetic counseling. Position statements on genetic testing have emerged and serve as valuable references to guide clinicians in routine and special situations. Additionally, issues surrounding genetic testing are being extensively debated by medical scientists, by legislative bodies, and in the courts.

Informed Consent The informed consent process is uniformly accepted by professional genetic societies as an integral part of genetic testing and should be an essential part of pretest counseling before any molecular testing is undertaken. [40], [41] This is a consensus opinion of the Task Force Committee on Informed Consent. Key elements of the informed consent include a description of the potential risks and benefits of genetic testing, current limitations of testing, and an elicitation of the patient's and family's expectations, concerns, and risk perceptions (Table 54-12). Guidelines are also available for genetic testing in special circumstances, such as presymptomatic testing in minors and potential adoptees. [42], [43] and [44]

The patient should have a working understanding of the following issues:
Medical Issues
• The syndrome in question, including inheritance, risks, screening guidelines, and disease management
• Medical care possibly better directed with genetic diagnosis
• Compliance with surveillance guidelines necessary for benefit
• Prevention possibly improved with knowledge and compliance
Genetic Issues
• Interpretation and implications of a positive, a negative (dependent on whether familial mutation is known), and an indeterminate genetic test result
• Risk to self and family members better defined if genetic testing successful
• Methods of testing and the accuracy associated with each testing option
• Alternatives to genetic testing
Psychological Issues
• Failure to detect a mutation in the first person tested in family: frustration, anxiety, disappointment, possible relief
• Positive test: coping with possible anger, anxiety, responsibility guilt, illness, self-image issues
• Negative test in a member of a family with a known mutation: possible relief, decreased worry for self and offspring, survivor guilt
Social/Economic Issues
• Failure to detect a mutation in the first person tested in family: no information for self, children, and other at-risk relatives
• Positive test: possible insurance, employment, and social discrimination
• Negative test in a member of a family with a known mutation: possible resolution of insurance problems, family relationships possibly positively or negatively affected
Special Issues for Testing in Children
• Protection of children's rights
• Self-image problems
• Possible problems with parent-child relationships, sibling-sibling relationships
• Social stigmatization
Other Issues
• Cost of test, insurance coverage, and genetic discrimination
• Confidentiality of results

TABLE 54-12 Informed Consent for Genetic Testing

Genetic Testing for Children Because of the potential for adverse psychological effects resulting from stigmatization and other harms, [20], [45] genetic testing in children should be considered only if medical benefit is clearly possible. [42], [46] FAP testing by the age of 10 to 12 years is one such example; screening and preventive measures are indicated by that age in carriers, whereas screening is unnecessary in noncarriers. [47] A parent's intense desire to be certain that a child does not have FAP at a younger age, however, may not justify the potential social stigmatization and self-image issues a child may have to faced if FAP is actually diagnosed. When the testing of minors is being considered, both the parents and health care professionals need to weigh the potential medical benefits against the psychosocial well-being of the child very carefully. The decision-making capacity of a child should also be considered, and whether advocacy for testing is truly on the behalf of the child's interests. Age-appropriate education for the child undergoing testing is also a necessity. Continuing education and follow-up as the child matures can focus on information relevant for life decision making.

Testing of Adopted Persons The American Society of Human Genetics (ASHG) recommends that the guidelines for the testing of adoptees (newborns and children) be consistent with those for genetic testing performed in all children of similar age (as discussed previously). Thus, the timing of genetic testing should be primarily justified for reasons such as the initiation of preventive or therapeutic medical management through early diagnosis. [44] Additionally, the ASHG recommends that a relevant family history and medical history for the adoptee be accessible and updated so that this information can be shared by all parties involved, including the adoptee, the biologic parents, and the adoptive parents when medically appropriate. Currently, however, only Wisconsin, mandates the collection of medical and genetic information on adoptees. [43]

Duty to Warn Relatives Recently, the duty to warn at-risk relatives about the ramifications of inherited disease has been heavily debated. [48] Two legal cases have concluded that at minimum, there appears to be at least a duty to warn the patient about the familial implications of genetic disease. In one of the cases, it was further declared that "reasonable steps be taken by the provider to assure that the information reaches those likely to be affected or is made available for their benefit" (*Pate v Threlkel,* 661 So 2d 278 [Fla 1995] and *Safer v Estate of Pack,* 677 A2d 1188 [NJ Super Ct App Div 1996]). The disclosure of information regarding oftentimes treatable and curable inherited disease to offspring and other relatives is still debated and unrefined. [49]

Who Should Be Tested First?

In a family believed to have an inherited syndrome, initial genetic testing to find the causative mutation should be offered to the person most likely to carry the mutant gene. In an FAP family, for example, genetic testing would start with a person clinically known to have the disease. This individual is considered the ideal "testing candidate." A negative test result in this case would be interpreted as a failure to find a disease-causing mutation in that person, and would simply mean that genetic testing cannot be used in the family and that other family members must be managed on the basis of the clinical findings. Another example would be a kindred meeting the Amsterdam criteria for HNPCC. The youngest person with colon cancer would be the testing candidate because that person would be most likely to carry the mutant gene. Further genetic testing in the family would be irrelevant if a mutation could not be found in that person, whereas finding a mutation would allow testing in other family members with nearly 100% accuracy. Thus, if a familial mutation is detected by genetic testing, a negative result in a member of this family is interpreted as a true negative—that is, this individual has not inherited the condition.

An important issue to keep in mind is that finding a mutation in the child of a living parent often indicates that a parent also has the mutation. This situation can be challenging when the parent has not consented to know his/her genetic status, has not learned about genetic testing, and possibly does not want such information at all. Assessing the family dynamics as well as encouraging family decision making regarding genetic testing should therefore be part of the pretest counseling, although ultimately genetic testing is the individual's choice.

Because most testing methodologies require a fresh blood sample, the first person tested must also be living. DNA banking is frequently considered when the death of an individual key to the genetic diagnosis in a family is imminent. DNA banking is the process of obtaining a biologic specimen, usually blood, from which DNA can be extracted. A laboratory will store the DNA for a certain length of time for a specified cost so that it will be available for genetic testing or testing that becomes available in the future. However, before the sample is drawn, informed consent for DNA banking is necessary outlining what it is permissible to do with the sample and who has authority over it after the death of the donor. After the death of the affected individual, individuals who have permission to access the sample may request genetic testing so that the information can be used by at-risk family members.

Regulatory Issues

Clinical genetic testing is presently controlled by specific regulations and oversights implemented to ensure that tests are performed properly. In the United States, the Clinical Laboratory Improvement Amendments of 1988 oversee all testing on human samples for health assessment or for the diagnosis, prevention, or treatment of

disease. [50] Genetic test results to be returned to the patient should be performed in a Clinical Laboratory Improvement Amendments–approved laboratory.

Impact of Genetic Testing on Clinical Management

Genetic testing results are frequently used to direct screening in a family to those who are gene carriers. Precise screening recommendations are emerging for many of the genetic conditions, in part because of the ability to determine accurately who has the inherited disease in question (see Chapter 90 for present examples).

Chemoprevention is an emerging approach that may eventually be of great benefit to those at increased risk for colon cancer. The use of celecoxib (Celebrex), a cyclooxygenase-2 inhibitor, to induce the regression of adenomatous polyps in FAP patients who still have a rectum after colectomy has been approved by the FDA. Aspirin, other nonsteroidal antiinflammatory drugs, folate, calcium, and estrogens have shown promise in decreasing the incidence of adenomatous polyps and colon cancer. Genetic testing may well direct how such therapies are applied by precisely defining the precancerous conditions.

The choice of surgery for colon cancer may be affected by genetic testing. A right hemicolectomy, for example, is appropriate for most cases of cecal cancer, whereas a subtotal colectomy is indicated if a person is known to have a mutation of HNPCC. Prophylactic colectomy is also being discussed in that condition, as prophylactic gastrectomy is for inherited gastric cancer that arises from mutations of the *CDH1* gene. [51]

Pharmacogenetics is the study of variations in drug uptake, binding, distribution, metabolism, and excretion based on inherited determinants. As information emerges, genetic testing may be a major factor in medication choice and dosing.

Genetic Screening for the General Population

General population screening is commonly encountered in prenatal diagnosis or newborn screening because early medical intervention prevents disease or reduces its severity. A number of state-supported screening programs for genetic diseases with GI involvement are outlined in Table 52-11; the panel of screening tests varies by state.

Presently, population-wide screening for most genetic diseases is not available or even indicated. Screening of the general population for a particular disease could be justified only in the case of a highly penetrant condition for which effective medical treatments were available. Founder mutations or a high prevalence of disease carriers supports population genetic screening for certain diseases, such as sickle cell anemia, in certain countries and ethnic groups. On the other hand, population screening for FAP is impractical in view of the cost of screening and the rarity of the condition. Population screening may become more applicable and attractive in the future, however, as high-prevalence genes that affect common disease susceptibility are elucidated.

SUMMARY AND CONCLUSIONS

The genetic revolution and its emerging implications to clinical medicine make it necessary for the gastroenterologist to have a basic understanding of genetics and to know when genetic testing is a part of disease management. Furthermore, the far-reaching effects of genetic diagnoses on patients require the physician not only to have a medical understanding of inherited disease but also a familiarity with the psychosocial issues surrounding genetic testing. Only then can proper education and advice be given to patients as inherited conditions and genetic testing are considered in the clinical setting.

CHAPTER 55

David W. Crabb

APPROACH TO THE PATIENT WITH DRUG OR ALCOHOL DEPENDENCY

Americans commonly abuse drugs or alcohol; approximately 14 million Americans abuse alcohol, [1] tens of millions have tried cocaine and marijuana, a million may have tried anabolic steroids, and 700,000 are addicted to heroin. The results of urine tests to detect drug use are positive in 3% to 16% of preemployment screens. [2] Because patients deny drug use, its occurrence is nearly always underestimated, leading to significant clinical problems. Drugs have effects that simulate pathological conditions, and hospitalized users may undergo withdrawal syndromes. Patients with chronic abdominal pain are also at risk for becoming addicted to narcotics. [3] Therefore, it is important for physicians to be alert for occult alcohol and drug abuse, to understand the biology of drug dependence, to recognize personality disorders in patients susceptible to drug addiction, and to know how drug abuse can mimic and complicate other illnesses. It is also important to recognize that some prevention programs have been shown to be effective [4] and that drug and alcohol abuse is treatable, albeit with less success than could be hoped for. We have entered an era of pharmacotherapy for drug and alcohol abuse. [5] This chapter is concerned with the neurobiology and clinical presentations of traditional drugs of abuse, such as alcohol, sedative-hypnotics, narcotics, stimulants and hallucinogens, and cannabis, as well as tobacco, laxatives, diuretics, and anabolic steroids.

The three general responses to drugs of abuse are tolerance, dependence, and withdrawal. Most drugs produce tolerance with continued use, so that the abuser must increase the dose to obtain the desired effects. Three forms of tolerance are recognized. Pharmacokinetic tolerance results from the induction of drug-metabolizing enzymes, usually in the liver, and increased rates of drug metabolism. Pharmacodynamic tolerance denotes decreased activity of the drug in the central nervous system (CNS) and may result from decreased receptor number or action, as well as the plasticity of the nervous system. Tolerance may even develop in the setting of the first exposure of the nervous system to a drug, and this may contribute to addiction. Conditioned tolerance is the ability of individuals to perform better only in an environment in which they have previously used the drug. Conditioning also plays an important role in drug craving because environmental cues, which are stimuli that the abuser associates with the psychic effects of the drug, can trigger the emotional memory of drug use and craving for the drug. Responses to conditioned cues appear to persist much longer than the physical abstinence syndrome. Tolerance is often but not invariably accompanied by dependence. Physical dependence is an adaptive state manifested by intense physical disturbances that develop when the administration of the drug is suspended. Psychic dependence is a condition in which a drug produces a feeling of satisfaction and a psychic drive that requires periodic or continuous administration of the drug to produce pleasure or to avoid discomfort. [6] However, this dichotomy may not have a valid neurobiologic basis. If dependence involves neural systems such as the sympathetic outflow tracts, the withdrawal syndrome will be physiologically violent, with sympathetic overactivity. Dependence involving inhibitory systems may be followed by withdrawal seizures. However, if the dependent systems are those mediating pleasure and reward, withdrawal symptoms may be limited to depression, dysphoria, and drug craving. The current *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (DSM-IV) criteria for psychoactive substance dependence and abuse are presented in Table 55-1 and Table 55-2. [7] These definitions apply to any substance. They emphasize the behaviors leading to increased consumption of drugs or alcohol, as well as withdrawal and tolerance.

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:
1. Tolerance, as defined by either of the following:
   a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect.
   b. Markedly diminished effect with continued use of the same amount of the substance.
2. Withdrawal, as manifested by either of the following:
   a. The characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances given in DSM-IV).
   b. The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms.
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

From American Psychiatric Association. Diagnostic and statistical manual of mental disorders, 4th ed. Washington, DC: American Psychiatric Association, 1994:181.

TABLE 55-1 Criteria for Psychoactive Substance Dependence

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following occurring within a 12-month period:
   1. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household).
   2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine while impaired by substance use).
   3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct).
   4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights).
B. The symptoms have never met the criteria for substance dependence for this class of substance.

From American Psychiatric Association. Diagnostic and statistical manual of mental disorders, 4th ed. Washington, DC: American Psychiatric Association, 1994:182.

TABLE 55-2 Criteria for Substance Abuse

DRUGS OF ABUSE AND BRAIN REWARD SYSTEMS

The initial studies of the action of drugs of abuse focused on identifying the cellular receptors through which they, like most drugs, act. It is now the goal of drug abuse research to identify the neural systems and intracellular signaling pathways that are activated or inhibited by individual drugs. Drugs of abuse alter activity within the brain reward system, [8], [9] which consists of the mesoaccumbens system, which in turn is comprised of dopaminergic neurons of the ventral tegmental area (VTA) projecting to the nucleus accumbens (NAc) and the limbic system (Fig. 55-1). Simplistically, brain reward/pleasure is associated with increased activity of dopaminergic neurons in the VTA, which release dopamine in the NAc. Many actions of drugs of abuse are mediated by drug-induced increases in dopamine levels in the NAc. Cocaine and amphetamines increase dopamine levels by inhibiting dopamine uptake or by acting as dopamine agonists in the NAc. Indeed, dopamine transporter–deficient mice are insensitive to the motor-activating effects of cocaine. [10] Opiates, [11] barbiturates and benzodiazepines, [8] and cannabis [12] interact with inhibitory receptors (μ-opioid receptors, ?-aminobutyric acid [$GABA_A$] receptors, and tetrahydrocannabinol [THC] CB_1 receptors, respectively) and are presumed to inhibit pathways that tonically inhibit dopamine neurons in the VTA. This disinhibition results in increased dopamine release in the NAc. Similarly, phencyclidine (PCP) is an *N*-methyl-D-aspartate (NMDA) receptor antagonist and is presumed to stimulate dopamine release by blocking an NMDA-stimulated system that normally inhibits dopamine neurons in the VTA. Nicotine probably stimulates nicotinic acetylcholine receptors present on VTA neurons, leading to increased dopamine release in the NAc. [13] The action of ethanol is perhaps the most complex. It can stimulate inhibitory $GABA_A$ receptors (similar to sedative-hypnotics), inhibit excitatory NMDA receptors (similar to PCP), and stimulate inhibitory opioid pathways. [14] Thus, ethanol probably inhibits pathways that inhibit dopamine neurons in the VTA, leading to increased dopamine release in the NAc. It is important to note that the chronic abuse of these drugs also has long-term effects on these neurons, [11] and that these changes are important in the development of tolerance, withdrawal, and craving. Although the abuse potential of these drugs may depend on their shared ability to activate dopaminergic reward systems, their other pharmacological effects seen following acute and chronic use may differ, as is described in the following sections.

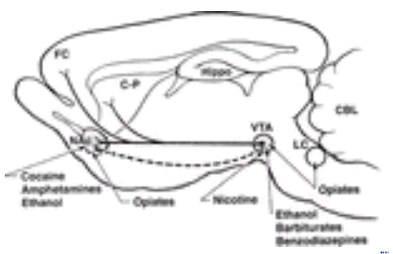

FIGURE 55-1. Anatomy of the mesoaccumbens reward system in the rat and probable sites of action of drugs of abuse. Dopaminergic pathways from the ventral tegmental area (*VTA*) are shown as *solid lines*; the pathway from the nucleus accumbens (*NAc*) is shown as a *dashed line*. The sites of drug action are inferred from neurochemical and intracranial self-administration studies. *CBL*, cerebellum; *C-P*, caudate-putamen; *FC*, frontal cortex; *Hippo*, hippocampus; *LC*, locus ceruleus. (Modified from ref. [8].)

PRINCIPLES OF TREATMENT

The treatment of drug and alcohol abuse revolves around several principles. [15], [16] First, abuse of multiple substances must be suspected so that the proper detoxification program is used. Detoxification is the separation of the patient from the drug(s) with the prevention of severe withdrawal syndromes (particularly those associated with alcohol, sedative, and opiate abuse). Detoxification is followed by counseling that attempts to generate insight and to teach the patient how to avoid high-risk situations predisposing to relapse. The goal of complete abstinence is central and is generally monitored by urine testing. A better monitoring test is a significant need in alcohol treatment. Pharmacological therapy includes naltrexone for alcoholism, opiate antagonists for opiate abuse, experimental treatments for cocaine abuse, and nicotine substitution for tobacco. [5] It is obvious, however, that the use of these drugs requires a motivated patient. These therapies are discussed in the following sections.

INDIVIDUAL DRUGS OF ABUSE

The actions of drugs of abuse are summarized in Table 55-3. Discussions of diagnosis and treatment are found in several books, [15], [16] and methods of detecting the drugs are described in the section “Diagnosis of Patients with Suspected Substance Abuse.”

Depressants	
Ethanol	Fluidize membranes (ethanol), induce cytochrome P450 (ethanol and barbiturates)
Barbiturates	Facilitate Cl^- conductance by effects on $GABA_A$-barbiturate-benzodiazepine-receptor-Cl^- channel
Benzodiazepines	Inhibit NMDA and voltage-sensitive calcium channels (ethanol)
Opiates	Interact with μ-opioid receptors, increasing K^+ conductance, reducing cAMP and Ca^{2+} influx
Cannabis	Interacts with cannabinoid receptor, reducing cAMP levels
Stimulants	
Cocaine	Blocks uptake of dopamine and norepinephrine
Amphetamines	Release norepinephrine, inhibit monoamine uptake, activate serotoninergic and dopaminergic receptors
Phencyclidine	Blocks dopamine uptake, increases dopamine release, anticholinergic, interacts with σ-opioid and NMDA receptors
Hallucinogens	Sympathomimetic, inhibit serotoninergic neurons
Nicotine	Activates ganglionic nicotinic receptors
Anabolic Steroids	Activate muscle and central nervous system (?) androgen receptors, increase growth hormone (?)
Laxatives	Stimulate intestinal motility and ion secretion, mechanisms not clearly established
Diuretics	Inhibit electrolyte reabsorption in renal tubules

GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

TABLE 55-3 Pharmacological Actions of Drugs of Abuse

Ethanol

Pharmacology The biologic actions of ethanol are remarkably diverse. Ethanol interacts with microdomains of neuronal proteins, especially ion channels. [14], [17] In particular, $GABA_A$ and NMDA receptor–associated ion channels are thought to mediate many psychomotor effects of ethanol. Ethanol at low concentrations (20–100 mmol/L) stimulates chloride uptake by isolated brain vesicles [17], [18] and augments the action of GABA at the benzodiazepine-barbiturate-$GABA_A$ receptor chloride channel. [14] Only a subset of $GABA_A$ receptors are so affected, possibly as a result of different receptor complex subunit compositions. [14], [17] This effect is blocked by Ro15-4513, a benzodiazepine receptor inverse agonist. Ro15-4513 also appears to antagonize certain behavioral effects of low-dose, but not high-dose, ethanol. [18] Flumazenil, a benzodiazepine antagonist, does not influence ethanol intoxication. Thus, ethanol may selectively enhance GABAergic transmission. This is consistent with the antianxiety effects of ethanol and the cross-tolerance between ethanol, barbiturates, and benzodiazepines. Tolerance at this receptor may result from membrane changes because the receptor number does not change. [19] Calcium channels are also important mediators of ethanol effects. The NMDA receptor is a glutamate-operated calcium channel. Low doses of ethanol inhibit NMDA-induced increases in neuronal intracellular calcium and resulting depolarization. [14], [20], [21] and [22] Ethanol also inhibits neuronal voltage-sensitive calcium channels. [23], [24] Tolerance to the effects of ethanol on both types of calcium channels develops in some brain regions with chronic use, possibly as a result of increased numbers of the channels. [24] Additional actions of ethanol include alterations of protein kinase activity (e.g., protein kinases A and C). Prolonged ethanol use leads to pharmacokinetic tolerance, in part by induction of the ethanol-metabolizing cytochrome P450 isoenzyme CYP2E1 and other cytochromes, [25], [26], [27] and [28] resulting in up to 30% faster ethanol metabolism. These cytochromes also metabolize a number of drugs

more rapidly in the chronic alcohol user [29]; those of greatest clinical relevance include warfarin, sulfonylureas, phenytoin, rifampin, diazepam and other hypnotics, and propranolol.

Clinical Features and Diagnosis The lifetime risk for alcohol-related problems is 20% to 25% for men and 5% for women; skid row, homeless alcoholics are in the minority. [1] The risk for alcoholism involves a genetic component, as has been demonstrated by adoption studies [30], [31], [32] and [33] and twin studies, [34], [35] whereas the inherited predisposition of some alcoholics to drinking problems is highly sensitive to environmental factors. Alcohol dehydrogenase and aldehyde dehydrogenase variants are the only genes that have been associated to date with an altered risk for alcoholism. [36], [37] and [38] Features of the alcohol dependence syndrome are listed in Table 55-4. [39] The most important diagnostic tool is a careful history elicited from the patient and family members regarding alcohol use and any related difficulties. This can be supplemented with the CAGE test, [40] a simple, nonthreatening list of questions; patients are asked if they have felt the need to *c*ut down on drinking, are *a*nnoyed by questions about their drinking behavior, feel *g*uilty about their drinking and its effects, and need an *e*ye opener (i.e., an early morning drink) to feel better. Two or more positive responses are highly suggestive of alcohol abuse, with a 93% sensitivity and 76% specificity. Increased values of the mean corpuscular volume, uric acid, triglycerides, or ?-glutamyl transpeptidase should suggest occult alcohol abuse, [41] but none of these tests is especially sensitive or specific for alcoholism. Two promising markers are acetaldehyde-protein adducts and carbohydrate-deficient transferrin. The adducts form in liver [42], [43] and blood [44], [45] by the condensation of acetaldehyde with proteins. Carbohydrate-deficient transferrin is formed in the liver during heavy drinking and can be detected immunologically or electrophoretically. [46] The test seems to be highly specific for alcohol consumption in excess of 60 g/d and has a sensitivity of about 90%. [46]

1. Narrowing of the drinking repertoire
   With increased severity of dependence, there is little variability of drinking pattern between drinking days and occasions.
2. Salience of drinking behavior
   Negative social, family, and/or health consequences will not deter drinking behavior. Highest priority is given to securing alcohol.
3. Subjective awareness of a compulsion to drink
   Severely dependent alcoholics are aware of an impaired capacity for moderate drinking. In the past, this characteristic was called "loss of control" drinking; in some cultures, it is characterized by an inability to abstain.
4. Tolerance
   With increased severity of dependence, and prior to the development of severe liver damage, alcoholics are less sensitive to the effects of alcohol.
5. Physical dependence
6. Relief avoidance drinking
   With increased severity of dependence, drinking occurs earlier in the day (e.g., upon awakening) in order to avoid the discomfort of "morning-after" symptoms.
7. Rapid reinstatement of the syndrome with recurrent drinking

From ref. 39.

TABLE 55-4 Alcohol Dependence Syndrome

Treatment The treatment of alcoholism requires detoxification on an inpatient basis [47] or on an outpatient basis in the absence of major medical illnesses or severe withdrawal symptoms. [48] The alcohol withdrawal syndrome is the consequence of adaptation of the neuronal membranes and ion channels to ethanol. During withdrawal, inhibitory GABAergic transmission may be reduced, and the excitatory effects of glutamate- and voltage-dependent calcium influx may be increased, [49] resulting in neural overactivity. In the first day or two of abstinence, tremor and tachycardia occur. Hallucinations are experienced by 10% to 20% of patients. Seizures occur somewhat later, and subsequently delirium tremens occurs in a minority of patients. This delirium is characterized by hallucinations and severe sympathetic overactivity, manifested by tachycardia, fever, dilated pupils, hypertension, and diaphoresis. The efficacy of barbiturates or benzodiazepines in preventing alcohol withdrawal symptoms is based on the augmentation of GABAergic transmission and neural inhibition. [50] Subsequent to detoxification, intensive counseling, behavior modification, and involvement with Alcoholics Anonymous and other support groups are helpful. The outcome of therapy may be better predicted by the characteristics of the patient than by the specific type of therapy. [1], [51] Individuals with intact support (i.e., those who are married, have a stable job, have no antecedent psychopathology, and are middle or upper class) have abstinence rates of up to 60% at 12 to 18 months after treatment, whereas unemployed individuals in the lower economic class have an abstinence rate of only 30%. Monitoring alcohol consumption with carbohydrate-deficient transferrin during treatment appears to be useful. [52] Pharmacological agents help maintain sobriety. [5], [53] Serotonin reuptake inhibitors (e.g., fluoxetine, zimeldine) are ineffective. [53] Alcohol-sensitizing drugs (e.g., disulfiram, cyanamide) are relatively ineffective. They act by inhibiting aldehyde dehydrogenase, so that acetaldehyde accumulates if ethanol is consumed, causing nausea, tachycardia, facial flushing, and hypotension. However, in the largest controlled trial, [54] disulfiram-treated, placebo disulfiram–treated (1-mg tablets), and control groups had nearly identical 1-year abstinence rates (approximately 20%). The oral opiate antagonist naltrexone reduces alcohol craving and relapse, [53], [55], [56] although it does not increase the rate of complete abstinence. [53] It is approved for this indication. The drug can cause hepatotoxicity and is contraindicated in patients with acute hepatitis. A number of studies in Europe have shown that acamprosate (calcium acetylhomotaurinate, a homologue of GABA) improves abstinence rates and duration of abstinence. [57], [58] Drugs on the horizon include nalmefene, [59] an opioid antagonist without the liver toxicity of naltrexone, and the 5-HT $_3$ receptor antagonist ondansetron, which may be particularly valuable in early-onset alcoholism, [60] as this subgroup has been suggested to have abnormalities of serotoninergic systems. Ondansetron may also have additive effects with naltrexone. [61] In alcoholics with coexistent psychiatric diagnoses, specific psychiatric and pyschopharmacological therapy is indicated.

Sedative-Hypnotics

Pharmacology Barbiturates and benzodiazepines interact with the GABA $_A$ receptor and augment the inhibitory action of GABA. [62], [63], [64] and [65] This explains the dangerous interaction between alcohol and these sedatives. Users of benzodiazepines develop tolerance to the sedative effects of the drugs but not to the anxiolytic effects. Barbiturates, but not benzodiazepines, induce hepatic microsomal enzymes and pharmacokinetic tolerance. [66]

Clinical Features and Treatment Barbiturates and benzodiazepines are used for sedation and muscle relaxation and to treat seizures, anxiety, and panic disorders. High doses of these drugs cause emotional lability, slurred speech, and ataxia. Rarely, the drugs induce delirium with incoherence, disorientation, and disturbances of perception. Benzodiazepines are ineffective in reducing pain, and some suggest that they may in fact lower the pain threshold. [67] They are therefore best avoided in patients with chronic pain. Dependence on barbiturates can develop after about a month of use at high doses; benzodiazepine dependence requires substantially longer use, probably about 20 weeks. Abrupt withdrawal from these drugs causes tremor, dysphoria, insomnia, hyperreflexia, anxiety, and, in severe cases, seizures. [66], [68] Barbiturate withdrawal in particular can be as dangerous as delirium tremens. Safe withdrawal can be achieved by reducing the dose of the barbiturate or benzodiazepine by about 10% per day. [15], [16] Persons who are tolerant of or dependent on benzodiazepines may experience seizures if they are given flumazenil. This drug does not, however, reverse sedation from or overdoses of barbiturates, ethanol, or opiates.

Opiates

Pharmacology Opiate abuse is probably as old as alcohol abuse. The Greek word *opion* means “juice of the poppy,” as does the Dutch word *doop,* the roots of the English words *opium* and *dope,* respectively. The effects of intravenous opiates include an initial intense euphoria that is followed by a dreamlike, tranquil state. Opiates act through μ receptors, which have a high affinity for morphine, other alkaloid opiates, and ß-endorphin. [8], [11], [69] Activation of μ receptors inhibits neural activity by increasing K^+ conductance and inhibiting adenylyl cyclase and Ca^{2+} channels through G-protein interactions (see Table 55-3). [8], [11], [70], [71] Chronic use of opiates does not reduce the number of neural μ receptors; rather, tolerance involves the increased expression of adenylyl cyclase and cAMP-dependent protein kinase A and the activation of slowly depolarizing Na^+ channels. [11] This has been best studied in the locus ceruleus, a sympathetic control center. [70] As a result, within 10 hours after discontinuation of a short-acting drug like heroin, the noradrenergic neurons of the locus ceruleus become hyperactive, leading to the autonomic features of opiate withdrawal. It appears that the cAMP-responsive element binding protein (CREB), a nuclear transcription factor, is a central participant in opiate dependence, as CREB knock-out mice have a greatly attenuated withdrawal syndrome. [72] Most opiates are metabolized in the liver. Morphine is glucuronidated; heroin is deacetylated to morphine and then glucuronidated. Meperidine has a significant first-pass metabolism of an oral dose and undergoes oxidation to meperidinic acid or *N*-demethylation to normeperidine. The latter is proconvulsant [73] and can accumulate in chronic renal failure. The half-life of meperidine is prolonged from 3 to 6 hours in cirrhosis. Codeine (3-methoxymorphine) undergoes less first-pass metabolism than other opiates, which accounts for its usefulness for oral administration. It is metabolized to morphine (10%) or norcodeine (10%) or is glucuronidated before renal excretion. Of the opiates used for the treatment of diarrhea, loperamide has the advantage of a very low incidence of CNS effects (including euphoria), in part because of its concentration in the gastrointestinal tract. A large fraction is excreted in the stool. Very high doses of loperamide have been used for severe diarrhea, possibly acting through mechanisms not involving opiate receptors. [74] Diphenoxylate can induce dependence at doses only five times the usual dose. For this reason, atropine was added to diphenoxylate (Lomotil) to reduce

the likelihood of abuse. The constipating effects of 45 mg of codeine, 5 mg of diphenoxylate, and 2 mg of loperamide are equal. Conversely, the opiate antagonist naloxone has been reported to increase fecal output in a patient with idiopathic constipation and intestinal pseudo-obstruction [75]; this has not been shown to help the majority of such patients. Oral naloxone may also be of use in treating the constipation caused by opiates; because it has a high rate of first-pass metabolism, it does not antagonize the central analgesic effects. [76]

Clinical Features and Diagnosis Heroin is the drug of choice of most narcotic addicts; however, prescription drugs like codeine, methadone, and oxycodone are also widely abused. Fentanyl is abused by medical personnel, and it and its illicit derivatives, such as 3-methylfentanyl, have such a high degree of potency that overdose is a serious risk. [77] Methylphenyltetrahydropyridine (MPTP) is a synthetic derivative of meperidine that destroys dopaminergic neurons in the substantia nigra. Its use caused an outbreak of toxic parkinsonism in the 1970s. [78] Tolerance to miosis or constipation does not develop, so these remain clues to opioid abuse. Requests for escalating doses of codeine for the control of diarrhea therefore indicate worsening of the underlying disease or abuse of the drug. Fully developed withdrawal symptoms result from overactivity of the sympathetic nervous system and include lacrimation, rhinorrhea, dilated pupils, piloerection (hence the term *cold turkey*), sweating, yawning, hypertension, tachycardia, and fever. Hallucinations, tremor, and delirium are not typical and suggest that the patient is also withdrawing from another drug.

Treatment The patient is first withdrawn from opiates. [15], [16] Withdrawal symptoms can be blocked by clonidine, which is given in 0.1- to 0.3-mg doses four times a day. [15], [16] This drug acts on presynaptic a_2-adrenergic receptors; like μ receptors, these are coupled by G proteins to K^+ channels and thereby inhibit neural activity in the locus ceruleus. [79], [80] Methadone can also be used to wean the patient from shorter-acting opiates. Relapse can be blocked by the chronic use of methadone or the antagonist naltrexone. Naltrexone can cause dose-dependent liver injury. [81] Unfortunately, patients maintained on these drugs often abuse other drugs, especially alcohol and cocaine. [82] Newer medications reported to reduce relapse include levomethadyl acetate (L-a-acetylmethadol, LAAM) and buprenorphine (a μ-opioid partial agonist). [83], [84] These drugs are longer-acting and may be given three times a week rather than daily, as is the case for methadone. Buprenorphine may be associated with a lower risk for physical dependence and have weaker opiate effects, and overdose is less likely.

Cocaine and Other Stimulants

Pharmacology Cocaine hydrochloride is used nasally (i.e., snorting) or intravenously. The base (“free base,” “crack”) is stable to heat. It is vaporized by heating it in a pipe and is absorbed from the pulmonary circulation, and it reaches the brain very rapidly. The neuronal effects of cocaine are biphasic. [85] It initially blocks the reuptake of dopamine, increasing its concentrations in the NAc [10], [86], [87] and activating both D_1 and D_2 receptors. [69], [71] Presynaptic feedback, probably involving dynorphins and opioid receptors, [10] subsequently reduces the release of dopamine. The late decrease in dopamine release may induce postcocaine dysphoria and facilitate craving. Cocaine is metabolized by hydrolytic and *N*-oxidative pathways. Hydrolysis inactivates the psychomotor effects of the drug and generates nonhepatotoxic intermediates, benzoylegconine and methoxyegconine. *N*-oxidative metabolism generates a series of *N*-hydroxyl and nitroxide intermediates. These intermediates are hepatotoxic. [88] However, cocaine hepatotoxicity [89], [90] is probably underrecognized owing to the high prevalence of viral hepatitis and alcohol abuse among these patients. Alcohol enhances cocaine hepatotoxicity by inducing cytochrome P450s of the *N*-oxidative pathway. [88] Amphetamines are active orally or intravenously. Derivatives used on the street include methamphetamine (“crystal”), methylenedioxyamphetamine (MDA), methylenedioxymethamphetamine (MDMA, “ecstasy”), para-methoxyamphetamine (PMA), methylenedioxyethylamphetamine (MDEA), and methyldimethoxyamphetamine (DOM). MDMA is a neurotoxin that may have delayed consequences. [91] Amphetamines release norepinephrine in the CNS and may activate dopamine receptors, and the hallucinogenic derivatives also activate serotonin receptors (see Table 55-3). [92] However, their major effect, like that of cocaine, is at the dopamine transporter, where they cause reverse transport of dopamine back into the synaptic cleft. Metabolism of amphetamines involves *p*-hydroxylation, *N*-demethylation, deamination, and conjugation. Because all the amphetamines are weak bases, their renal excretion is greatly increased by acidification of the urine.

Clinical Features and Diagnosis The effects of cocaine, amphetamines, and other stimulants are similar and result from sympathetic activation (pupillary dilation, tachycardia, and hypertension), [85] so that users are predisposed to cardiac arrhythmia or infarction, acute hypertensive crises, aortic dissection, myocarditis, and seizures. Necrotizing angiitis is associated with intravenous methamphetamine use. [93] Additional complications are intestinal ischemia, disseminated intravascular coagulation, rhabdomyolysis, and possibly perforating ulcers. [94], [95] Use during pregnancy can cause microcephaly, growth retardation, intrauterine cerebral infarction, and hemorrhage. [96], [97] and [98] Amphetamines can produce persistent hallucinations and delirium. The most common medical complication of intravenous cocaine abuse is the acquisition of hepatitis B or C.

Treatment Withdrawal from stimulants produces a mild physical abstinence syndrome characterized by depression, fatigue, disturbed sleep, and intense craving. Stimulant abusers are often detoxified as outpatients, and abstinence is documented by mandatory urine testing. The craving for cocaine is treated by intensive counseling and may be helped by pharmacological therapy. The tricyclics imipramine and desipramine, by blocking the reuptake of amine transmitters, may reduce dysphoria and improve sobriety, [99], [100] and [101] but controlled trials have yielded mixed results. Mazindol, [102] fluoxetine, [103] carbamazepine, [104] methylphenidate, lithium, [99] and bupropion [105] lack efficacy. Phenytoin [106] and amantadine [107] may help to maintain abstinence. The fact that cocaine abuse remains pervasive indicates that current therapy is inadequate. Auricular acupuncture has been reported to reduce cocaine use. [108] Another form of treatment is extinction therapy, in which the patient is allowed to watch videotapes depicting the use of cocaine or to handle drug paraphernalia without the reward of cocaine. It is hoped that this treatment will extinguish conditioned cues. Those with more severe problems, such as criminal involvement, may be treated for 6 to 12 months in therapeutic communities. Stimulant users commonly abuse other drugs with relaxing properties, such as heroin, alcohol, marijuana, barbiturates, and benzodiazepines, which complicates their treatment. Disulfiram has also been reported to reduce the use of cocaine by individuals treated with buprenorphine [109] or methadone [110] for combined heroin and cocaine addiction. It has been suggested that disulfiram inhibits dopamine ß-hydroxylase and reduces the conversion of dopamine to norepinephrine, thus maintaining neuronal dopamine.

Phencyclidine

Phencyclidine, or phenylcyclohexylpiperidine (“angel,” “angel dust,” “peace,” “zombie,” “supergrass rocket fuel,” “hog,” other names), can be taken by any route, including smoking. The pharmacological actions of PCP include potent activation of NMDA receptors, inhibition of dopamine reuptake (similar to the action of cocaine), stimulation of dopamine release, blockade of cholinergic receptors, and possibly interaction with opioid receptors (see Table 55-3). [111] It induces euphoria at low doses, and stimulates the sympathetic nervous system, hyperactivity, and hallucinations at higher doses. The hallucinations are frequently auditory, and the behavior of the abuser can closely resemble paranoid schizophrenia. [111] Intoxicated subjects have vertical and horizontal nystagmus, evidence of sympathetic overactivity, numbness and an increased pain threshold, ataxia, and dysarthria. The drug is hydroxylated and conjugated before excretion; its elimination is accelerated by acidifying the urine and by nasogastric suction. PCP is commonly misrepresented and sold on the street as lysergic acid diethylamide (LSD), mescaline, psilocybin, or THC. Other abused drugs that stimulate NMDA receptors include ketamine (used in pediatric and veterinary anesthesia and known on the street as “cat Valium,” “K,” “special K,” “super acid,” “vitamin K,” and other names) and dextromethorphan (DXM, “robo”). The latter is present in over-the-counter cough medications, so that the effects of high doses of these medications include the effects of the antihistamines and sympathomimetics as well.

Hallucinogens

Hallucinogens, including LSD, PCP, and amphetamine derivatives, are sympathomimetics, producing hypertension, pupillary dilation, tachycardia, and hyperreflexia as well as disturbances of perception. LSD acts presynaptically as a 5-HT_{1A} receptor agonist in the dorsal raphe nuclei to inhibit neural firing (see Table 55-3). LSD and hallucinogenic amphetamines are 5-HT_2 receptor agonists as well. [92] Users risk loss of control and experience recurrent drug-induced perceptions (flashbacks) and terrifying hallucinations (bad trips). Hallucinogens offer an interesting example of the dissociation of tolerance and dependence; tolerance appears to develop rapidly (after three to four doses) by unknown mechanisms, but there appears to be little physical or psychic dependence or craving.

Inhalants

Inhalants include a number of chemically distinct compounds that produce vapors that can be inhaled, resulting in CNS effects. Examples include solvents in paint and gasoline (toluene, benzene, methylene chloride, hexane), nitrous oxide (used as a propellant for canned whipped cream), and trichloroethylene (found in spot removers). Inhalants are often the first drugs abused by children, with as many as 6% of fourth graders trying these substances. The acute effects are similar to the CNS depressant effects of alcohol, including disorientation, slurred speech, incoordination, and irritability. A “sudden sniffing death syndrome” is recognized that may be the result of asphyxia. Longer-term toxicity includes demyelination, brain atrophy, toxic hepatitis, and renal dysfunction (including renal tubular acidosis). In addition, volatile nitrites, which cause vasodilation, are abused in the hope of enhancing sexual performance.

Club and Date Rape Drugs

These drugs are discussed together because of the circumstances of their use rather than their chemical similarity. Club drugs include MDMA, flunitrazepam (Rohypnol), ?-hydroxybutyrate (GHB), and ketamine. They are commonly used by teens and young adults at raves and trances (all-night dances). MDMA has been discussed in the section “Cocaine and Other Stimulants.” Rohypnol, GHB, and ketamine have largely CNS depressant effects. Rohypnol (“rophies,” “roofies,” “roach,” “rope”) is a benzodiazepine. Clonazepam, another benzodiazepine, is sometimes sold as Rohypnol. GHB (“liquid ecstasy,” “somatomax,” “scoop”) is abused for euphoric, sedative, and anabolic effects. It cannot be sold over the counter, but a related compound, ?-butyrolactone, can still be purchased. This substance is converted to GHB in the body. Each of these drugs is odorless, colorless, and tasteless. They can be added to beverages to sedate unsuspecting victims before sexual assault.

Cannabis

The active constituent of marijuana is ? ^{9}-THC. [112] THC binds to a membrane receptor [113] that is linked to G_{i} and G_{0} proteins; hence, stimulation of the receptor inhibits the formation of cAMP and has indirect effects on ion channels. [114] Regions of receptor density are found in the basal ganglia, hippocampus, cortex, and cerebellum. [115] The fatty acid derivative arachidonylethanolamide (anandamide) is an endogenous ligand for the THC receptor. [116], [117] THC causes euphoria, relaxation, subjective intensification of perception, alteration of the sense of time, and impaired psychomotor function. THC also causes vasodilation, which is responsible for tachycardia and conjunctival injection, and stimulation of appetite. Paradoxically, a rare cannabis arteritis has been reported in young men, manifested as distal arterial lesions and venous thrombosis, similar to Buerger disease. [118] The drug is metabolized by hydroxylation to the active compound 11-hydroxy-? ^{9}-THC and then to the inactive compound 8,11-dihydroxy-? ^{9}-THC. Cannabis dependence is recognized in the DSM-IV, [7] and withdrawal symptoms of restlessness, insomnia, and nausea have been observed. Users with a prior history of schizophrenia may be at increased risk for the precipitation of psychosis. Attacks of anxiety or paranoia occur in about 5% of episodes of cannabis use. Prolonged use of cannabis is reported to result in an amotivational syndrome characterized by preoccupation with drug use, passivity, and decreased drive and memory. [16] Treatment is based on counseling and must include suspicion of abuse of multiple drugs.

Tobacco

Pharmacology The major pharmacologically active compound in tobacco is, of course, nicotine, [119] which is thought to act on nicotinic cholinergic receptors in the mesoaccumbens system. This alkaloid is absorbed through the oral mucosa and the lungs. Smokers unconsciously regulate the amount of nicotine they absorb by altering how they smoke; therefore, nicotine intake is little changed by use of low-nicotine cigarettes or by a reduction in the number of cigarettes smoked. [119] Nicotine has a short half-life (1–2 hours) and is extensively metabolized in the liver by CYP2A6 to cotinine, which can be measured to monitor tobacco use. Nicotine increases sympathetic outflow, resulting in tachycardia, vasoconstriction (which can reduce the rate of absorption of subcutaneous insulin), hypertension, and mental arousal. Stimulation of Renshaw cells may inhibit anterior horn cells and cause muscle relaxation. Smoking also induces hepatic drug-metabolizing enzymes, resulting in increased rates of metabolism of imipramine, desmethyldiazepam, lidocaine, oxazepam, pentazocine, propranolol, and theophylline. The altered metabolic rate declines toward normal within 2 weeks of abstinence.

Clinical Features and Treatment Tobacco is surprisingly addictive. [120] It has been suggested that variants of the dopamine D_{2} receptor, the dopamine transporter, and CYP2A6 may contribute to the risk for addiction. Smoking during pregnancy is a common cause of premature delivery and low-birth-weight infants. Nicotine is concentrated in the tissues of the fetus, and the elevated levels of carbon monoxide in the blood of these women may reduce oxygen delivery to the fetus. Tolerance to nicotine, although partial, occurs very rapidly (within several hours), and a withdrawal syndrome consists of restlessness, irritability, anxiety, impatience, and inability to concentrate. These symptoms can be mitigated by clonidine. [121] Withdrawal from cigarettes is facilitated by alternative nicotine delivery systems. Controlled trials of nicotine replacement, used in combination with counseling, have shown an improvement in the rate of abstinence at 6 months (20%–30%) compared with placebo (10%–20%). [122], [123] Nicotine gum and patches are available over the counter. The transdermal systems cost about twice as much as the chewing gum, with similar response rates. Additional formulations of nicotine, including nasal spray and inhalers, are now available by prescription. The nicotine delivered by these systems should be given cautiously to patients sensitive to increased sympathetic tone (e.g., those with a recent myocardial infarction, cardiac arrhythmias, or angina pectoris), and use of these agents must be coupled with counseling. Cigarette smokers have perhaps a twofold increased risk for peptic ulcer, discussed in detail in Chapter 66. Aside from the use of nicotine replacement, other medications have been assessed for activity in helping patients to stop smoking. Systematic reviews indicate that nortriptyline and bupropion increased cessation rates. [124], [125] Anxiolytics have not been shown to be effective. Some data suggest that bupropion reduces the weight gain that often accompanies smoking cessation. [126] Women appear to have unique risks associated with smoking. More men have quit smoking during the past decades than women, so that the prevalence of smoking is now roughly equal between men and women. Furthermore, nicotine replacement does not seem to be as effective for women, and women are more likely to gain weight when they stop smoking.

Anabolic Steroids

Pharmacology The names of commonly used anabolic steroids are listed in Table 55-5. Although it is difficult to obtain controlled data, their use in combination with intensive weight training probably increases lean muscle mass and strength. They may induce an anabolic state by interacting with muscle androgen receptors, by antagonizing glucocorticoid receptors, or by inducing central effects of increased aggressiveness that makes training more effective. [127] Growth hormone secretion may be increased in some persons using the drugs.

Bolasterone	Methyltestosterone[†]
Boldenone*[‡]	Nandrolone[‡]
Clostebol	Norethandrolone
Dehydrochlormethyltestosterone	Oxandrolone[†]
Fluoxymesterone	Oxymesterone
Mesterolone	Oxymetholone[†]
Methandienone[†]	Stanozolol[†‡]
Methenolone[†]	Testosterone[‡]
Methandrostenolone[†‡]	Trenbolone*[‡]

*Veterinary preparation.
[†]Oral agent.
[‡]Used parenterally.

TABLE 55-5 Anabolic Steroids Used by Athletes

Clinical Features and Diagnosis Anabolic steroids are widely used among athletes to augment training, particularly in power sports such as weight lifting and football, [128] as well as among individuals who simply wish to improve their appearance. [129] Six percent of male high school students and 1% of female students acknowledge use of anabolic steroids. These individuals often share needles and may abuse other drugs. [129], [130] Typically, oral (C-17 alkylated steroids) and injected drugs are used together in cycles of 4 to 12 weeks during heavy training, at doses that are orders of magnitude higher than those used for medical indications. [131] The side effects of androgenic steroids have largely been reported for patients receiving long-term, low-dose therapy. Other side effects may be caused by intermittent high-dose administration. Among competitive power lifters assumed to have used anabolic steroids, increased premature mortality has been observed. [132] The liver may be affected by any of the C-17 alkyl androgens, [133] with minor, reversible elevations of alkaline phosphatase and transaminases and, rarely, jaundice. More serious problems include liver cell hyperplasia, liver cell adenoma, hepatoma, and angiosarcoma. [133] Interestingly, liver malignancies have regressed in some instances after the steroid was discontinued. Peliosis hepatis (blood-filled cysts communicating with the sinusoids) may complicate steroid use and can cause death from bleeding. Metabolic effects of androgens include increases in low-density-lipoprotein (LDL) cholesterol and decreases in high-density-lipoprotein (HDL) cholesterol, occasionally associated with myocardial infarction and stroke in steroid users. [134] Prostatic hypertrophy and, very rarely, prostatic carcinoma have been reported. Testicular atrophy and decreased spermatogenesis, although reversible, result from the suppression of gonadotropin secretion. Some athletes inject human chorionic gonadotropin (hCG) to prevent testicular atrophy. [135] Estradiol is increased by aromatization of the androgens, and gynecomastia occasionally occurs. Premature closure of the epiphyses may develop in adolescents, [136] and irreversible masculinization may develop in women. [137], [138] Lastly, the use of androgenic steroids may induce neuropsychiatric disturbances. Surveys have uncovered significant mood changes, psychotic episodes, and aggressive behavior during steroid use; the occurrence of dysphoria and depression after steroid use suggests addictive potential. However, under controlled conditions, the manic effects of testosterone affect only a small proportion of men. [139] Steroid abuse should be suspected because of the muscular development of the patient and should be considered in athletes with hypercholesterolemia, abnormal liver serum liver chemistries or hepatomegaly, and psychiatric disturbances. Needle marks are often visible on the thighs or buttocks of these patients and obviously are markers of a risk for hepatitis and human immunodeficiency virus (HIV) infection. Abusers of anabolic steroids commonly abuse other substances, such as stimulants (e.g., pseudoephedrine, phenylpropanolamine, ephedrine, clenbuterol [140]), diuretics (to help them lose weight), beta-blockers (to reduce hand tremor in accuracy competitions such as archery), and peptide hormones (e.g., growth hormone or erythropoietin), [135], [140] as well as other illicit drugs.

BULIMIA AND SUBSTANCE ABUSE

Eating disorders, such as anorexia nervosa and variants of binge eating (i.e., bulimia), are recognized to be quite prevalent. [141] These disorders are discussed in detail in Chapter 35 (for the diagnostic criteria, see Table 35-7 and Table 35-9). Bulimia patients commonly abuse other substances. About 61% abuse laxatives, 50% use over-the-counter diet pills, typically sympathomimetics, and 33% use diuretics for weight loss. [142] More than one third admit to alcohol or drug abuse. An eating disorder (and associated drug abuse) may be suspected in young women with the signs and symptoms listed in Table 35-8. [143] Both anorexic and bulimic patients are at increased risk for suicide. The therapy for these conditions centers on counseling. Placebo-controlled, double-blinded studies have demonstrated the effectiveness of tricyclic antidepressants [144], [145] and fluoxetine [146] for bulimia, whereas these drugs are of no proven benefit for anorexia. [147] Long-term follow-up of bulimic patients suggests that although many recover, a substantial fraction continue to have problems at 10 years. [148]

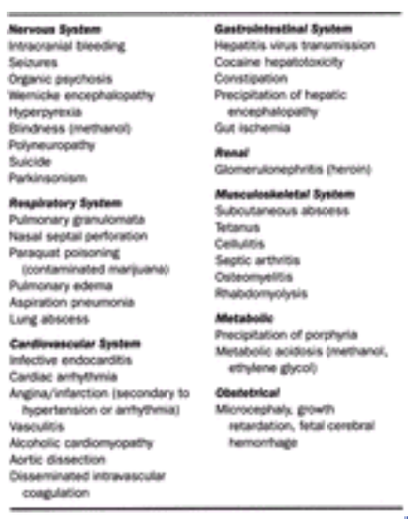
Laxative abusers are predominantly female, and the detection of laxative abuse should strongly suggest bulimia. [142] The laxatives may be taken to reduce distention after a binge or because of the perception that their use speeds weight loss. However, cathartics result in at most a 10% reduction in energy absorption. [149] The typical patient has multiple complaints, including weakness, nausea or vomiting, diarrhea or constipation, and abdominal pain. Cutaneous signs such as clubbing, skin eruptions from phenolphthalein use, and hyperpigmentation have also been observed. [150] Laxative abuse is one of the more common causes of chronic unexplained diarrhea referred to a university medical center study. [151] The diagnosis rests on detection of the laxative in the stool (alkalinization to detect phenolphthalein) or urine (bisacodyl, danthron, rhein, and phenolphthalein); methods are available to determine the latter by thin-layer chromatography. [152], [153] In some cases, a room search may be necessary. Although it is important to make this diagnosis to prevent unnecessary testing, long-term improvement in these patients is not often seen. Factitious diarrhea is also discussed in Chapter 42.

Other substances abused by bulimic patients include diuretics (confirmed by blood or urine testing for furosemide and thiazides), thyroid hormone preparations, and syrup of ipecac (emetine) to induce vomiting. The latter has been linked to the development of skeletal and cardiac myopathy. [154]

DIAGNOSIS OF PATIENTS WITH SUSPECTED SUBSTANCE ABUSE

The clinical features of drug use are summarized in Table 55-6. Medical complications can be seen with any injected drug and may be the first clue to substance abuse (Table 55-7). They include skin infections, tetanus, septicemia, infectious endocarditis (most commonly staphylococcal tricuspid endocarditis), venous thrombosis and pulmonary embolism, pulmonary granulomata, focal sclerosing glomerulonephritis, and acquisition of hepatitis B, C, or D or HIV infection. The threat of transmission of malaria may be the original reason why heroin is commonly mixed with quinine. [155] Illicit drugs may be adulterated with other compounds, resulting in additional toxicity, [155] or may not be the substance anticipated. Even the history of use of a particular drug must therefore be viewed skeptically and polydrug abuse assumed.

TABLE 55-6 Recognition of Drug Intoxication and Overdose



Nervous System
Intracranial bleeding
Seizures
Organic psychosis
Wernicke encephalopathy
Hyperpyrexia
Blindness (methanol)
Polyneuropathy
Suicide
Parkinsonism

Respiratory System
Pulmonary granulomata
Nasal septal perforation
Paraquat poisoning (contaminated marijuana)
Pulmonary edema
Aspiration pneumonia
Lung abscess

Cardiovascular System
Infective endocarditis
Cardiac arrhythmia
Angina/infarction (secondary to hypertension or arrhythmia)
Vasculitis
Alcoholic cardiomyopathy
Aortic dissection
Disseminated intravascular coagulation

Gastrointestinal System
Hepatitis virus transmission
Cocaine hepatotoxicity
Constipation
Precipitation of hepatic encephalopathy
Gut ischemia

Renal
Glomerulonephritis (heroin)

Musculoskeletal System
Subcutaneous abscess
Tetanus
Cellulitis
Septic arthritis
Osteomyelitis
Rhabdomyolysis

Metabolic
Precipitation of porphyria
Metabolic acidosis (methanol, ethylene glycol)

Obstetrical
Microcephaly, growth retardation, fetal cerebral hemorrhage

TABLE 55-7 Medical Complications of Drug Abuse

Alcohol use within 6 to 12 hours can be detected by analysis of breath, blood, or urine. Alcohol is eliminated at a rate of about 100 mg/kg per hour, but this rate varies substantially among individuals. There is a great need for a test for chronic alcohol abuse. Detection of the other drugs of abuse is complicated by variable amounts of drugs used and attempts by the user to avoid detection (e.g., by adulterating urine samples) (Table 55-8). Detection strategies can be divided into two phases, screening and confirmation. [156], [157] Routine toxicologic screening tests, usually based on thin-layer chromatography and used for patients suspected of taking a drug overdose, are the least sensitive. More sensitive screening tests are generally immunologic tests: radioimmunoassay, enzyme-multiplied immunoassay technique (EMIT), or fluorescence polarization immunoassays (see Table 55-8). These are widely available and are inexpensive. Positive screening tests are then confirmed, generally by gas chromatography–mass spectrometry (GC-MS), which is almost absolutely specific and extremely sensitive. [77], [158], [159] Establishing drug abuse also entails careful collection of the urine sample to prevent substitution or adulteration and attention to the chain of custody required to prove that a given patient has in fact been using the drug detected. Urine drug testing requires informed consent of persons older than 18 years of age except in medical emergencies.

1. Document quality of specimen: check temperature, color, pH, and specific gravity of urine to detect adulteration; check for presence of blood.
2. Document chain of custody.
3. Be aware of approximate duration of positive urine screening test results after drug use:
Alcohol: 6–12 hours.
Barbiturates and benzodiazepines: several days.
Opiates: 2–5 days.
Cocaine: 2–4 days.
Amphetamines: 2–4 days.
Marijuana: up to 30 days.
PCP: up to 8 days.
4. Be alert to false-positives:
Barbiturates and benzodiazepines: ibuprofen.
Opiates: poppy seeds (morphine), dextromethorphan.
Amphetamines: ephedrine, phenylpropanolamine, pseudoephedrine, other sympathomimetics.
Marijuana: ibuprofen, naproxen, fenoprofen (older screening tests), passive smoke.
5. Be alert to false-negatives:
Adulteration of sample: addition of acids, bases, benzalkonium chloride (Visine), soap.
Dilution of urine (includes use of diuretics for this purpose).
Short time elapsed after ingestion.
Intentional acidification of urine to speed elimination of amphetamine or PCP before test; alkalinization of urine to slow excretion during the testing period.
Ibuprofen may interfere with the derivatization step in GC-MS confirmation for marijuana.
Screening tests generally not available for LSD, mescaline, psilocybine, designer drugs.

GC-MS, gas chromatography-mass spectrometry; LSD, lysergic acid diethylamide; PCP, phencyclidine.

Compiled from refs. 2,77, and 158.

TABLE 55-8 Guidelines for Using Urinary Screening Tests for Drug Abuse

Benzodiazepines and barbiturates present few difficulties in identification. Tests for opiates may yield positive results for morphine if the patient has consumed poppy seeds; however, there can be no doubt of the origin of 6-monoacetylmorphine, a metabolite of heroin identifiable by GC-MS. Dextromethorphan, found in certain cough and cold medications, usually does not give a false-positive result at ordinary doses [158] and can be positively identified by GC-MS. [77] Fentanyl, methylfentanyl, and LSD may present problems of detection because they are so potent and are used at low doses. [77] Cocaine metabolites can be detected for up to 48 hours after use. The detection of amphetamines and PCP in screening tests is complicated by cross-reactions with over-the-counter medications. Several sympathomimetics can give positive results on amphetamine screening: ephedrine, pseudoephedrine, phenylpropanolamine, phentermine hydrochloride, fenfluramine hydrochloride, and others. [158] Both ? [9] -THC and PCP are lipophilic and can be detected in the urine for many days after use because they redistribute from fat stores. Phenylcyclohexyl pyridine (PHP), a compound related to PCP, can be synthesized from pyrrolidine instead of pyridine and cannot be detected by currently available urine screening assays. Occasional false-positive results have been observed for PCP screening tests when the patient was using the decongestant combinations Rondec or Dimetapp.

Anabolic steroid use can be documented by GC-MS and measurement of serum gonadotropins. Testosterone use is detected by finding increased ratios of testosterone to epitestosterone in urine. Epitestosterone is an endogenous steroid produced independently of testosterone. Surreptitious use of diuretics can be detected by measuring blood furosemide or urinary thiazide concentrations. [160]

MANAGEMENT OF ACUTE DRUG OVERDOSE OR TOXICITY

Table 55-6 summarizes the pharmacological effects of several classes of drugs of abuse. It is important to ensure that the apparently intoxicated individual does not have an additional medical problem, such as alcoholic hypoglycemia, head injury, meningitis, Wernicke or hepatic encephalopathy, seizures, or intracranial bleeding. [161] The overdose may have been accidental, as in the case of body packers who smuggle drugs by swallowing packages of the substances; if the packages do not pass spontaneously, surgical removal may be required. [162] Abused drugs are commonly adulterated with other compounds, such as quinine or lidocaine, but these are rarely the cause of acute toxicity. [155] Patients in coma need circulatory and respiratory support and care to avoid pressure complications. [161] A specific diagnosis should be made if possible, recalling that multiple drug abuse is the rule. Any suspicion of opiate overdose warrants a trial of 0.4 to 2 mg of naloxone intravenously, and benzodiazepine overdose responds to flumazenil; however, the latter drug may precipitate seizures. Specific antagonists are not otherwise available. Excretion of amphetamines and PCP is increased by acidifying the urine, achieved by infusion of ammonium chloride. Attempted suicide or homicide should be kept in mind. Seizures, agitation, or delirium caused by cocaine, stimulants, and PCP can be managed with diazepam or haloperidol and by reducing sensory stimulation.

CHAPTER 56

Samuel L. Stanley, Jr.

ADVICE TO TRAVELERS

The advent of the jet age has revolutionized international travel. Persons now can be transported from one corner of the world to another in hours rather than days or weeks. Greater accessibility and lower prices for international travel have created a booming business, and it has been estimated that foreign travel and tourism now account for more than 25% of all world trade. [1] As more people travel, the importance of preventing disease has become increasingly recognized. The population at risk is significant. Annually, more than 25 to 30 million persons travel from nontropical regions into regions with malaria. [2] About 24 million persons from the United States alone travel into regions where hepatitis A is highly endemic each year. [3] In addition to infectious diseases, travelers may be at increased risk for a number of other problems, including jet lag, high-altitude sickness, excessive sun exposure, venous thrombophlebitis, and accidental death.

The goal of the physician is to minimize the traveler's risk for illness. To accomplish this goal, physicians must rely on educating travelers about specific risks and methods to reduce them, appropriate vaccinations and prophylactic medications, and the provision of medicines to treat certain illnesses that may arise during travel. The key to providing these services is the pretravel office visit, a visit that optimally should take place at least 6 weeks before the trip. At this visit, travel risks can be assessed, appropriate counseling offered, prophylactic medications dispensed, and vaccinations initiated. This chapter reviews the important components of the pretravel history, discusses noninfectious risks to travelers, provides a detailed description of the vaccination options available to travelers, discusses the problem of malaria prevention, describes current approaches to preventing travelers' diarrhea, and concludes with a brief synopsis of how to approach the problem of diarrhea in the returning traveler. Issues that may be of special interest to the gastroenterologist include the problem of prevention of travelers' diarrhea in persons with altered gastric acidity, the diagnostic approach to diarrhea in the returned traveler, and the use of vaccines and prophylactic medications in the immunocompromised patient (such as patients who have undergone liver transplantation).

PRETRAVEL HISTORY

The important components of the pretravel history are outlined in Table 56-1. A detailed itinerary represents a critical first step. The exact dates of travel, all countries to be traversed, and the length of stay in each country are the first components needed. Knowing the exact route of travel is important because even a layover at the airport in a country where yellow fever is endemic can entail a requirement for vaccination at subsequent destinations. The duration of the stay in a country is especially critical because the risk for contracting many of the infectious diseases (typhoid fever, hepatitis A) increases with longer periods of exposure. The planned itinerary of the traveler within each country is also important. In some regions of the world (e.g., much of Southeast Asia), malaria has been eliminated from major urban areas, but it remains a significant risk in rural areas. High-altitude destinations in otherwise malarious countries may be associated with no risk for malaria but present the potential problem of altitude sickness. Where ground travel is involved, even the timing of travel may be important; in countries where mosquito-borne illnesses are endemic, travel from dusk to dawn presents a higher risk for disease than do daytime excursions.

Detailed itinerary
Destination and route of travel
Duration of stay
Urban versus rural
Type of travel (e.g., business, tourist, Peace Corps, missionary)
Planned diet
Accommodations
Activities/work
Health profile
Immunization status
Underlying chronic diseases—immunocompromised?
Pregnancy status
Current medications

TABLE 56-1 Important Elements of the Pretravel History

Many important items fall under the rubric of the type of travel planned. The 1-week business trip involving accommodations at a four-star hotel in a major city in Southeast Asia presents significantly fewer health risks for a given traveler than the 1-year stay for the volunteer at a village hospital in sub-Saharan Africa. The traveler's planned activities should be established. Whether travel will involve primarily day trips to frequently visited tourist sites or will be a safari into the heart of the bush country directly affects the relative risks for disease. An expedition or job in which frequent contact with animals is expected is an indication for the rabies vaccine. The nature of the planned accommodations and how and where water and food will be obtained during the trip bear directly on the risk for insect-borne diseases and fecally-orally transmitted diseases, respectively.

Once the details of the trip have been established, a health profile of the traveler should be obtained. Important details include any underlying medical conditions that may create special problems during travel. Persons who are taking medications should ensure that they have an adequate supply for the duration of the trip, with an extra amount in case of loss or travel delays. Patients with chronic lung disease may have problems with hypoxemia in the reduced cabin pressure (similar to an altitude of 5000–8000 feet) of airplanes at maximum cruising altitude (30–40,000 feet above sea level). [4] In the case of persons whose arterial oxygen pressure is likely to be less than 50 mm Hg during the flight, supplemental oxygen can be obtained, but special arrangements with airlines must be made (usually at least 48 hours in advance). Although the leading cause of death in travelers from the United States to other countries is a cardiovascular event (49% of reported fatalities in one study), [5] travel for patients with stable heart disease is generally not medically contraindicated. However, persons with uncontrolled heart failure, unstable angina, or a recent (within 4 weeks) myocardial infarction should avoid travel if possible.

Travelers who have a pacemaker should have it evaluated before travel, and like all persons with cardiac disease, they should travel with a copy of their electrocardiogram. Because pacemakers may trigger metal detection devices at airports, travelers should carry a letter from their physician stating that they have a cardiac pacemaker, along with the model number and type of pacemaker.

Diabetic persons need to recognize that travel may disrupt routines in exercise, meals, and sleep, and hence change insulin requirements. Diabetic travelers should

carry a full supply of insulin and syringes adequate for longer than the expected duration of the trip as well as at least one bottle of regular insulin. Because customs officers of some countries may be suspicious of travelers carrying syringes and needles, they should carry a signed note from a physician stating that they require needles and syringes for the treatment of diabetes. Snacks should be carried at all times, and sugar cubes or candy for the management of hypoglycemia should be readily available. A travel companion who is educated about the symptoms and signs of hypoglycemia can be invaluable.

Women of reproductive age must be questioned about whether they are currently pregnant or are considering conception during the period of travel. Certain vaccines are contraindicated in pregnant women, as are some of the antibiotics used to treat or prevent travelers' diarrhea and some of the medications used to prevent chloroquine-resistant malaria. In addition, certain vacation activities, such as scuba diving and immersion in hot tubs, pose direct risks to the fetus and should be avoided. Plane travel is generally considered safe until week 36 of gestation, but pregnant women should be cautioned to move around the cabin whenever it is safe to do so to reduce the risk for thromboembolic disease associated with venous stasis. Finally, activities and destinations that take the pregnant traveler far from adequate emergency medical care should be avoided. Special recommendations for infants and children are beyond the scope of this chapter; the reader is referred to the article by Barnett and Chen for a review. [6]

Other persons also may require specialized recommendations. Immunocompromised individuals generally should not receive vaccines containing live viruses, and certain countries may restrict the entry of persons infected with the human immunodeficiency virus (HIV). Patients with gastrointestinal disease whose gastric acidity is reduced as a result of either gastric surgery or treatment with histamine H_2 blockers or antacids are more susceptible to enteric pathogens and may be candidates for prophylactic antibiotics to prevent infection. The physician needs to be aware that persons with malabsorptive states may require dosage adjustments or medication alternatives for commonly used drugs.

GENERAL PRECAUTIONS

Water

With few exceptions, water in developing countries should be considered contaminated and should not be used for drinking or brushing teeth or consumed in the form of ice. Locally bottled water also should be considered suspect, as should iced tea, and unpasteurized dairy products should be strictly avoided. Alcohol should not be relied on to sterilize the water in ice cubes or nonalcohol components in mixed drinks. Safe beverages generally include brand name carbonated drinks, wine, and hot coffee or hot tea that has been prepared with boiling water. It has been said that there is no such thing as a bad bottle of beer, and this appears to be true worldwide. Wet cans and bottles should be wiped clean and dried before use. When water is the only available beverage, boiling represents the best method for sterilization. Because most organisms are killed at 100°C, simply bringing water to a boil is adequate for sterilization. [7], [8] Chemical sterilization of water with halogens (chlorine or iodine) is less effective but can be used when boiling is impossible. A standard protocol would be 0.1 mL (about 2 drops) of 5% chlorine bleach in a liter of water, or 0.2 mL (about 4 drops) of 2% tincture of iodine in a liter of water. The water should set for at least 30 minutes at room temperature before it is used. Halogenation is less effective in cold or turbid water, and iodine should be avoided in persons with known iodine allergy, patients with unstable thyroid disease, and pregnant women. Commercially produced kits that use iodine resins and filters to purify water are available.

Food

Food can be the source of enteric pathogens, tissue parasites, and microbial toxins. The old adage "Boil it, peel it, cook it, or forget it" should be the traveler's mantra when confronted with dietary choices in developing countries. Food should be well cooked and served hot to avoid the possibility of bacterial growth from contamination after food preparation. Raw foods should be avoided, and the many diseases associated with shellfish (e.g., cholera, hepatitis A) and the fact that shellfish often are consumed uncooked or poorly cooked make them particularly risky for the traveler. [9], [10] Fruits, such as bananas and oranges, that can be peeled are safe, but uncooked fresh vegetables should not be consumed. Vegetables with a high water content, such as lettuce, are particularly risky, and salads probably are a common source of enteric pathogens. Ciguatera fish poisoning is a threat from fish caught in Caribbean and Indo-Pacific waters in tropical latitudes. Whereas the source of the food (expensive restaurants, private homes) does not guarantee safety, consuming food from street vendors is most kindly described as adventurous and more accurately described as foolhardy. In one study of students in Mexico, persons who purchased food from street vendors were three times more likely to acquire diarrhea than those who had never frequented street vendors. [11]

Accidents

Although much of the emphasis in ensuring safe travel focuses on infectious diseases, accidents represent the most common cause of travel deaths in persons under 40 years of age and the second most common cause of death overall. [5] In a study of U.S. travelers to Mexico, half of 396 deaths were injury related. [12] It should be emphasized that in both studies, the proportion of death resulting from injury was significantly higher in the group of travelers than in all age groups within the United States. Travelers need to be counseled about this increased risk for accidental injury and death and reminded that travel is not an excuse to forget the need to drive all motor vehicles carefully, adhere to the rules for water safety, and the danger of mixing activities with alcohol consumption.

Jet Travel

Travelers should be reminded to keep well hydrated and to move about the airplane cabin when it is safe to do so to reduce the risk for venous stasis and thromboembolic disease. Although not life-threatening, the disruption of sleep and waking cycles that occurs with traversing multiple time zones can be a significant problem for the business traveler and the tourist. When possible, some adjustment of the sleep cycle and timing of meals to the time zone of the travel destination before departure may be useful in mitigating jet lag. Short-acting benzodiazepines (e.g., triazolam) can be used to facilitate sleep during long (>6 hours) plane flights and to induce sleep at the appropriate bedtime hours after arrival. These agents have potential side effects that may be worse in elderly patients. Retrograde amnesia has been reported and may be associated with concurrent alcohol consumption. [13]

High Altitude

Travelers who find themselves at an altitude of 3000 m above sea level or higher are at risk for high-altitude illness (mountain sickness). If the ascent is gradual, the body can acclimatize, and symptoms may be minimal or absent. When the ascent is rapid or immediate (as in the case of the traveler who flies into a high-altitude city), symptoms of headache, fatigue, mild dyspnea, and insomnia are more likely to develop. With further ascent, life-threatening conditions, such as high-altitude pulmonary edema and high-altitude cerebral edema, can develop. The key to prevention is gradual ascent (300–500 m/d), acclimatization at each new altitude, and descent to lower elevations when symptoms arise. Acetazolamide, an inhibitor of carbonic anhydrase with some diuretic action, appears to be somewhat effective in preventing mild to moderate cases of high-altitude illness. The drug should be taken at a dose of 125 to 250 mg three times a day beginning 24 hours before the ascent and continued for 48 to 72 hours after the high elevation has been reached. Persons who are allergic to sulfa should not take acetazolamide.

Sunstroke/Sunburn

Sun and specifically ultraviolet radiation exposure may be particularly intense at high altitudes and at tropical latitudes, and the typical "sun and surf" or "sun and ski" vacation puts travelers at risk for sunburn. Hats and sunglasses are desirable, and sunscreens should be mandatory for travelers. The sunscreen should be formulated to prevent damage from ultraviolet B radiation (mainly responsible for sunburn) and ultraviolet A radiation (mainly responsible for photoallergic reactions), and it should have a sun protection factor (SPF) of at least 15. Overexertion by travelers unaccustomed to the intense heat and humidity of tropical climates can also put them at risk for sunstroke. A reminder about these dangers during the pretravel visit is important.

Insects

Some of the most dangerous infectious diseases worldwide are transmitted by insect vectors, including malaria, yellow fever, sleeping sickness, and rickettsial infections. In addition, insect contact can result in reactions ranging from local skin lesions to anaphylaxis and death. The risk for insect contact can be greatly reduced by wearing appropriate clothing, using bed netting, reducing nighttime exposures, and judiciously applying insecticides and insect repellents. Clothing that is light-colored and that covers as much of the body as possible is desirable (long-sleeved shirts, pants tucked into socks and boots); for maximum resistance, clothing should be treated with a permethrin-containing insect spray. Permethrin repels and kills ticks, mosquitoes, and chiggers, and permethrin-impregnated bed netting represents a significant barrier to mosquitoes. To protect exposed areas of skin, an insect repellant containing *N,N*-dimethyl- *m*-toluamide (DEET) should be used. Because of the risk for systemic toxicity from skin absorption, formulations containing high concentrations of DEET should not be used by infants, children, pregnant

women, and persons with desquamating skin conditions. [14]

Sexually Transmitted Diseases

A number of studies indicate that travel increases a person's risk for sexually transmitted diseases (STDs). [15], [16] and [17] People away from home may feel free from everyday restraints and engage in activities that they would not consider under normal circumstances. Long-term residents or business travelers in foreign countries appear to have a high rate of sexual involvement with native peoples. [18] Because STD rates are higher in many developing countries, travelers can put themselves at risk for a variety of diseases, including HIV infection, hepatitis B, syphilis, gonorrhea, chancroid, herpes simplex, and granuloma inguinale. The widespread heterosexual transmission of HIV in sub-Saharan Africa, areas of South America, and many countries in Asia has led to a high prevalence of HIV infection in the general population and an extraordinarily high HIV prevalence among commercial sex workers. [19] Travelers need to be counseled that abstinence is the only absolutely sure way to avoid STD. If abstinence is not considered an option, travelers should be informed that the proper use of condoms can decrease the risk for acquiring STD. Because the failure rates of latex condoms made in the United States appear to be lower than those of condoms manufactured abroad, [18] travelers should be advised to take along an adequate supply of condoms for their trip.

VACCINATIONS

Vaccines for the traveler can be divided into three major categories. The first includes vaccines required for entry into certain countries. The only vaccine that can be required by countries as a prerequisite for entry under the International Health Regulations adopted by the World Health Organization is the yellow fever vaccine. In response to disease outbreaks or special circumstances, individual countries occasionally adopt different rules, and the traveler always is cautioned to contact an authority such as the Centers for Disease Control and Prevention (CDC) on their hotline (404-332-4555) or the embassy or consulate of the destination country before travel. The second category comprises vaccines that are not required for entry into a country but are recommended because of specific health risks within that area. Examples in this category would be the typhoid fever vaccine and the vaccine to prevent Japanese encephalitis. The final category is made up of vaccines that are not specific for travelers but should be administered if the traveler's vaccination status is not up to date before the trip. An example of this latter category would be vaccination against tetanus. The detailed immunization history obtained in the pretravel visit may reveal gaps in vaccine coverage, and the physician should take advantage of this opportunity to provide all necessary vaccines for the traveler. Vaccine dosing regimens are outlined in Table 56-2.

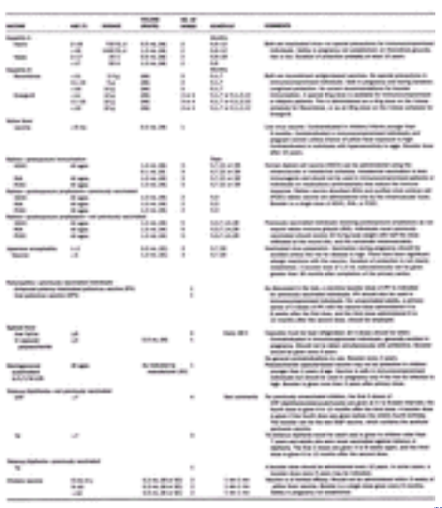

TABLE 56-2 Immunization Schedules for Vaccines That May Be Administered to International Travelers

Required Vaccines

Yellow Fever Yellow fever is caused by a small RNA virus of the flavivirus family and is transmitted by the bite of *Aedes* and *Haemagogus* mosquitoes. It is confined to countries in tropical South America and Africa and is not found in Asia (Table 56-3). Epidemics within South America and Africa continue to occur, and it is estimated that hundreds of thousands of persons in these areas may be infected yearly. [20] Clinical manifestations range from a mild febrile illness to a fulminant, sometimes fatal disease with hepatic, renal, and myocardial damage. Fortunately, the number of cases of yellow fever reported in travelers has been extraordinarily low, but this may, in part, reflect widespread use of the yellow fever vaccine in this population. Prevention of the disease is based on avoiding mosquito bites and provision of the yellow fever vaccine. Yellow fever vaccine is composed of attenuated live yellow fever virus (strain 17D) and is estimated to provide protection in more than 95% of vaccinated persons. Protective immunity lasts for at least 10 years after the single-dose vaccination. The vaccine is extremely safe, and side effects of vaccination are unusual. The most serious complication reported has been encephalitis (fewer than 20 cases), which was seen almost exclusively in infants younger than 4 months of age. [21] For this reason, the vaccine is not administered to children younger than 6 months of age, and vaccination usually is deferred until they are at least 9 months old. Persons with egg allergies should not receive the vaccine, and its use should be avoided in pregnant women unless they are felt to be at high risk for disease. In this case, the known benefit of vaccination would outweigh a potential (but undocumented) risk to the fetus. It is preferable that immunocompromised patients not receive the yellow fever vaccine because of the theoretical risk for vaccine-induced encephalitis. In the case of persons who wish to travel to a country where yellow fever is endemic, but whose travel plans put them at low risk for yellow fever, a medical waiver of vaccination form can be provided to satisfy entry requirements. When the immunocompromised person must travel to an area of endemicity where the risk for yellow fever transmission is high, it is probably prudent to administer the vaccine, but the potential risks and benefits should be discussed in detail with the traveler.

COUNTRIES IN AFRICA	COUNTRIES IN SOUTH AMERICA
Angola	Bolivia
Burkina Faso	Brazil
Cameroon	Colombia
Democratic Republic of Congo	Ecuador
Gabon	French Guiana
Gambia	Peru
Ghana	Venezuela
Guinea

TABLE 56-3 Countries Where Yellow Fever Is Endemic

Recommended Vaccines

Hepatitis A Hepatitis A is an enterically transmitted viral disease that is highly endemic in most of the developing world (Fig. 56-1). Travelers from developed countries to these regions of endemicity are at significant risk for the development of hepatitis A. Symptomatic hepatitis A is the most common serious illness in travelers and is probably the most frequent medical reason for a premature return to the United States by persons who had planned a long stay in a developing country. [22], [23] Published attack rates of 0.1% to 1% for unprotected travelers contracting hepatitis A during a 2- to 3-week stay in an area of endemicity, [24] and the development of symptomatic disease in 1 in 300 travelers during a 1-month stay, illustrate the risk. [25] Hepatitis A virus is transmitted by the fecal-oral route and can be spread through person-to-person contact or by the consumption of fecally contaminated water and food. The prevention of hepatitis A virus infection is based on the avoidance of potentially contaminated food and water and the administration of the hepatitis A vaccine. Both currently available preparations are purified, formalin-inactivated, whole-virus vaccines that appear to be highly effective in preventing symptomatic hepatitis A. In a prospective study undertaken in Thailand, 40,000 primary school children were randomized to receive either the hepatitis A vaccine or the recombinant hepatitis B vaccine. The protective efficacy of the hepatitis A vaccine in preventing symptomatic hepatitis A was 95%. [26] A second inactivated hepatitis A vaccine showed 100% efficacy in preventing symptomatic

hepatitis A in a randomized, placebo-controlled trial involving 1000 children in an upstate New York community with frequent outbreaks of hepatitis A. [27] A protective antibody response probably is obtained within 2 or 3 weeks after the initial dose of either vaccine. [3] Firm evidence regarding the total duration of protection after completion of the two- or three-dose vaccine regimen is not available, but based on the observed rate of decrease in antibody levels, protective immunity may persist for 10 years or longer. [28] The vaccines are well tolerated; mild tenderness at the injection site is the most frequently reported side effect.

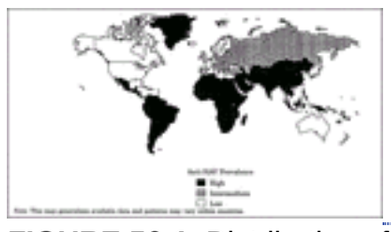

FIGURE 56-1. Distribution of hepatitis A virus prevalence. The prevalence of antibodies to hepatitis A virus (*anti-HAV*) in populations within countries is shown. (From Centers for Disease Control and Prevention. Health Information for International Travel 1999–2000. Atlanta, GA: Department of Health and Human Services, 2000.)

Because of its efficacy and excellent safety profile, inactivated hepatitis A vaccine probably should be administered to all travelers to areas where hepatitis A is endemic, including the Caribbean and Mexico. The role of passive immunization with immune serum globulin (administered as a single dose of 0.02 mL/kg) in preventing hepatitis A infection is now limited to providing protection for persons who have not received the vaccine and will be entering areas of endemicity before protective levels of antibody can develop after vaccination (2 to 3 weeks after the initial dose of vaccine). In this instance, both the hepatitis A vaccine and immune serum globulin can be administered into separate sites in the deltoids, and although the ultimate titer of anti–hepatitis A virus antibodies obtained may be lower than that obtained with vaccination alone, it still appears to be adequate for protection. [29]

Hepatitis B The prevalence of hepatitis B infection in the population of many developing countries is in excess of 8%. The virus is transmitted by contact with infected blood or through sexual activity. Risk factors for blood transmission are working in the health care field, any exposure to needles (intravenous drug use, tattooing), and receiving a transfusion of blood not screened for hepatitis B virus. For most travelers, the risk for hepatitis B is relatively low, but the following persons should be vaccinated: anyone working in a health care–related area who has not been vaccinated previously, anyone contemplating a stay of longer than 6 months in an area where the disease is highly endemic, anyone who may be sexually active with members of the local population in an area of endemicity, and anyone who has a health condition and may require hospitalization in an area of endemicity. The preparations available in the United States are recombinant vaccines consisting of highly purified viral surface antigens expressed in yeast. Vaccination requires three or four doses, with the final dose scheduled for 6 months or 1 year after the primary dose. Optimal protection is not achieved until after the final (third or fourth) dose; for travelers who cannot complete the full schedule before departing, however, it is worthwhile to initiate the vaccine series because some protection is conferred after the first and second doses. The vaccine appears to be highly effective, with more than 90% of vaccinated persons acquiring high anti–hepatitis B surface antigen antibody titers after the third vaccine dose, and 80% to 95% of persons protected against symptomatic hepatitis B based on the findings of multiple double-blinded, placebo-controlled clinical trials of the vaccine. [30], [31], [32] and [33] For persons who obtained initial antibody titers above 10 MIU/mL, complete protection against symptomatic infection was provided during a 10-year follow-up period. The overall duration of protective immunity is not yet known, but it is believed to be long, [34] and there are no current solid recommendations for boosters after completion of the primary three- or four-dose vaccine series. Side effects of vaccination are rare, and the vaccine is safe for use in immunocompromised persons, who may have defects in antibody responses after immunization; therefore, it may be worthwhile to check anti–hepatitis B surface antigen antibody titers after completion of the vaccine series to determine whether protective levels have been achieved.

Rabies Rabies remains a significant health problem in many areas of the world, and it is conservatively estimated that 35,000 rabies deaths occur annually. [35] The greatest risk for travelers is in areas where canine rabies remains highly endemic, which includes the Indian subcontinent, Nepal, the Philippines, Thailand, Sri Lanka, Vietnam, Guatemala, Peru, Colombia, Ecuador, El Salvador, and parts of Mexico. Canine rabies also can be found in many other countries in South America and Asia and in much of Africa. Travelers who will be staying for more than 30 days in an area where rabies is a significant threat should receive preexposure vaccination with the human diploid cell rabies vaccine (HDCV), purified chick embryo cell vaccine (PCEC), or rabies vaccine adsorbed (RVA). [36] Preexposure vaccination may provide protection in cases of unrecognized exposure to rabies virus or delayed postexposure prophylaxis. It must be emphasized to the traveler that preexposure vaccination does not eliminate the need for additional therapy after a rabies exposure, but it does reduce the number of postexposure vaccine doses and obviates the need for rabies immune globulin (RIG). The HDCV, PCEC, and RVA vaccines are inactivated vaccines; hence, they are not contraindicated for immunocompromised individuals or pregnant women at risk. In immunocompromised persons, neutralizing antibody titers should be determined 2 weeks after the final dose; if they are inadequate (complete neutralization in the rapid fluorescent focus inhibition test at a minimum of a 1:25 dilution), another booster dose should be given. [36] Chloroquine, and possibly other antimalarials being taken for antimalarial prophylaxis, may reduce the antibody response to the rabies vaccine, and the more immunogenic intramuscular administration schedule of the vaccine should be used when the patient is taking drugs that can interfere with the immune response. Side effects noted with the rabies vaccine include pain and erythema at the injection site and mild systemic reactions such as fever, nausea, abdominal pain, muscle aches, and dizziness. An immune complex–mediated reaction, with urticaria, pruritus, fatigue, and sometimes angioedema, has developed in a few persons receiving booster vaccinations with rabies vaccine. [37]

Japanese Encephalitis Japanese encephalitis is a mosquito-borne flavivirus infection that occurs in Japan, China, Korea, India, and much of Southeast Asia. The disease is transmitted by *Culex* mosquitoes, and the highest prevalence is highest in rural areas, although transmission in cities has been reported. In countries in temperate regions, a marked seasonal variation is noted, with most cases seen in the summer. In tropical latitudes, cases occur throughout the year. Most infections probably do not result in symptoms, but in the estimated 1 in 300 infected persons in whom encephalitis develops, the case fatality rate approaches 25%. [38] From 1978 to 1992, 24 cases of Japanese encephalitis in travelers (including 11 Americans) visiting or residing in Asia were reported. [38] The prevention of Japanese encephalitis is based on taking measures to prevent mosquito bites and, for some persons, administering the inactivated Japanese encephalitis virus vaccine in a three-dose regimen. The vaccine licensed in the United States appears to be about 90% effective in preventing disease, but it has been associated with a significant number of allergic reactions. Urticaria, angioedema, and anaphylaxis appear to occur at a rate of between 15 and 62 per 10,000 vaccine doses, and persons who have a history of severe allergic reactions to other allergens appear to be at higher risk for severe allergic reactions to the vaccine. [38] These allergic responses have occurred as late as 2 weeks after the administration of a dose of vaccine, so that that it may be prudent to complete the course of vaccination at least 2 weeks before travel is begun. Because of the significant number of allergic reactions and the relatively low risk for Japanese encephalitis in most travelers to Asia, the vaccine should be limited to travelers to areas where the Japanese encephalitis virus is endemic and who will be staying at least 1 month, who are likely to have significant exposure in rural areas, and who will be in an area of endemicity in temperate zones during the appropriate (summer) season.

Typhoid Fever Infection with *Salmonella typhi* remains a significant problem in much of the developing world. Of the approximately 500 cases of typhoid fever reported in the United States yearly, about 60% are acquired during foreign travel. [39] The risk for typhoid fever in travelers to areas where the disease is highly endemic, such as India and Peru, is estimated to be as high as 100 cases per 1 million travelers. [39] Typhoid fever can be prevented with strenuous efforts to avoid ingesting potentially contaminated food and water and with vaccination against typhoid fever. Vaccination is generally indicated for anyone traveling to a developing country where typhoid fever is endemic and exposure to contaminated food or water may be unavoidable. Three vaccines are available to prevent typhoid fever: the older, parenterally administered inactivated vaccine; a live attenuated oral vaccine; and a newly licensed acellular parenteral vaccine. There are probably no indications for using the older inactivated vaccine, which, although effective, is associated with significant injection site and systemic reactions. The oral vaccine consists of an attenuated (Ty21a) strain of *S typhi* and has been demonstrated to be effective (67% protection) in large-scale clinical trials, [40] probably providing protection for 5 years. [41] The oral vaccine should not be administered to immunocompromised persons or to pregnant women. Because dosing at home is required, careful instructions must be given to the traveler to ensure compliance. The vaccine should not be given to persons who are taking antibiotics, and it should be administered before travelers begin malaria prophylaxis with mefloquine. The new acellular vaccine, which contains polysaccharide components, is administered in a single parenteral injection and provides 2 years of protection against disease. [42] It is especially useful for persons who have medical contraindications to the oral vaccine, for travelers who do not have time to complete the oral vaccine dosage schedule before travel, and for those who cannot easily swallow capsules or may have other compliance problems.

Meningococcal Disease Travelers to destinations where epidemics of meningococcal disease are frequent (much of sub-Saharan Africa during the months of December to June) or countries with current epidemics of meningococcal disease should receive the meningococcal vaccine. Because of outbreaks in Saudi Arabia associated with the yearly arrival of pilgrims to Mecca (the hajj), Saudi Arabia now requires proof of meningococcal vaccination for all pilgrims. The quadrivalent polysaccharide vaccine available in the United States provides protection against serotypes A, C, Y, and W135. No vaccine that prevents serotype B disease is available. Protective immunity appears to last at least 3 years; the vaccine is less effective in children younger than 4 years of age. Significant side effects of vaccination are rare, and although the safety of the vaccine in pregnancy has not been established, available clinical data do not suggest any adverse effects of vaccination on the mother or fetus.

Cholera Cholera, caused by *Vibrio cholerae* O group 1 or O group 139, is associated with significant morbidity and mortality in many developing countries. The risk that travelers who follow basic precautions about avoiding contaminated food (especially uncooked or inadequately cooked fish and shellfish) and water will contract cholera is extremely low, however. The currently available cholera vaccines (prepared from killed bacteria) are only 50% effective in preventing disease, and the duration of protective immunity is no more than 6 months. For these reasons, the CDC does not recommend cholera vaccination for most travelers. [43] Persons with

impaired gastric acidity [44] or impaired immune systems who will be spending a significant amount of time in areas where the disease is highly endemic are at higher risk, however, and are candidates for the complete cholera vaccine series. Although cholera vaccination cannot be required for entry under the International Health Regulations, local authorities in certain countries may request documentation of cholera vaccination. In this case, a single dose of cholera vaccine will satisfy the requirement. Reactions to the vaccine include pain and erythema at the injection site and occasionally systemic symptoms such as fever, malaise, and headache.

Vaccines That May Be Updated

Poliomyelitis Significant progress is being made in the worldwide eradication of poliomyelitis, but foci of infection in developing countries in Africa, Asia, and the Indian subcontinent still present a risk (albeit extremely low) to the traveler. For persons who have completed the primary immunization schedule, a one-time booster dose before travel should be administered. It is best given in the form of the enhanced potency inactivated vaccine (IPV) rather than the oral polio vaccine (OPV) to minimize the risk for transmission of vaccine-associated disease. [45] If possible, the vaccination of pregnant women should be deferred; if immediate protection against poliomyelitis is needed, the current recommendation is for OPV. For adults who are uncertain about their vaccination status or who know they were never vaccinated, a complete series with IPV should be administered. If time does not permit a complete series, alternative schedules are available. [45]
Tetanus/Diphtheria Outbreaks of diphtheria in former states of the Soviet Union have served as a potent reminder of the ability of diphtheria to reemerge when breakdowns in public health result in inadequate immunization levels in the population. Diphtheria also remains a significant health problem in many developing countries worldwide. Tetanus is a global health problem that is completely preventable by adequate immunization. Adults and children older than 7 years of age who never were vaccinated against diphtheria and tetanus should receive primary immunization with the tetanus/diphtheria toxoid formulation for adult use (Td). The standard recommendation is that previously vaccinated persons should receive a booster immunization if more than 10 years has elapsed since completion of the primary immunization series or the last booster dose. More frequent Td booster schedules (every 5 years) appear to increase the number of adverse reactions to the vaccine. Because a booster immunization within the past 5 years obviates the need for a booster immunization in the event of a tetanus-prone wound, it may be prudent to vaccinate on the 5-year schedule patients who will not have access to good health care and will be in areas where the sterility and safety of injections are questionable.
Measles The risk for exposure to measles overseas is probably relatively high, and it is recommended that persons traveling abroad be immune to measles. Adults born before 1957 are presumed to be naturally immune to measles and generally are not considered for vaccination. For adults born in or after 1957 who have not received two doses of measles vaccine, a single dose of live attenuated measles vaccine should be administered before travel unless vaccination is specifically contraindicated (e.g., pregnancy, immune compromise in some cases, severe egg allergies). The measles, mumps, rubella (MMR) vaccine has been administered safely to HIV-infected individuals, and it is recommended that measles-susceptible HIV-infected travelers be vaccinated regardless of their current disease status. [46]
Other Vaccines Influenza occurs in the winter in temperate zones and year-round in tropical regions. The same groups that receive influenza vaccine during the influenza season in the United States (the elderly, patients with chronic diseases, health care workers) should be considered for vaccination before travel to an area at risk. Pneumococcal vaccine should be administered to travelers older than 65 years of age and persons with chronic illnesses.

PROTECTION AGAINST MALARIA

Malaria is caused by protozoan parasites of the *Plasmodium* genus, which are transmitted to humans by the bite of female *Anopheles* mosquitoes. It is estimated that more than 100 million people are infected with malaria worldwide, with 1 to 2 million deaths yearly, primarily in infants and children, attributable to malarial infection. Malaria in humans is caused by *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale,* and *Plasmodium malariae*. *P vivax* is probably the most prevalent cause of malaria worldwide, but *P vivax*–associated disease is rarely fatal. *P falciparum* is associated with the highest levels of parasitemia (the percentage of erythrocytes invaded), and it can cause fatal disease. The mortality rate in nonimmune adults for untreated *P falciparum* malaria is about 25%. [47] The risk of unprotected travelers to malarious areas is significant. From 1980 to 1992, more than 2500 cases of *P falciparum* malaria were reported to the CDC. Travel to sub-Saharan Africa was associated with the highest risk for disease (82% of reported cases); 8% of cases were acquired in Asia, 5% in the Caribbean and South America, and 5% in other regions. In 1992, 910 cases of malaria were reported in the United States and U.S. territories. Most were caused by *P vivax* (51%) and *P falciparum* (33%); few cases of *P malariae* (4%) or *P ovale* (3%) infection were reported. [48]

The prevention of malaria in travelers is based on two critical components. First, it is vitally important that persons in malarious areas take precautions to avoid the bite of mosquitoes (see section " Insects"). The second critical component is chemoprophylaxis, the use of antimalarial agents to prevent the establishment of infection. Chemoprophylaxis for malaria has become increasingly complicated as a result of the development of drug resistance in *P falciparum* and *P vivax* parasites. For years, chloroquine taken on a weekly schedule served as safe and effective prophylaxis against all forms of malaria; however, the past three decades have seen a spread of chloroquine-resistant *P falciparum* malaria from foci in Southeast Asia and South America to most of the rest of the malarious regions of the world. As shown in Figure 56-2, chloroquine-sensitive malaria is now confined to just a few areas of the world. The ineffectiveness of chloroquine has greatly complicated chemoprophylactic regimens. It is important for the physician to recognize that recommendations for malaria chemoprophylaxis for travelers to a given region of the world can change rapidly based on the emergence of drug-resistant strains, and physicians must keep up to date (through the CDC or other agencies) on the latest recommendations. The drug currently used for most travelers from the United States to malarious areas is mefloquine, which is taken on a weekly dosing schedule and, in large-scale studies, appears to be effective and safe (Table 56-4). [49] The most significant side effects associated with mefloquine are neuropsychiatric, but these effects are seen most frequently at the doses used for the treatment of malaria, not for prophylaxis. Mefloquine is not recommended for persons with a history of epilepsy or severe psychiatric conditions and is not recommended for patients with cardiac conduction abnormalities. The available data suggest that mefloquine is probably safe in pregnancy and should be the drug used for prophylaxis in pregnant women or in women who may become pregnant in areas where exposure to chloroquine-resistant malaria cannot be avoided. For persons who cannot take mefloquine or who are traveling to the few regions of the world where mefloquine-resistant *P falciparum* has been reported, doxycycline, taken daily, is an effective alternative regimen (see Table 56-4). A new agent, a combination of atovaquone and proguanil (Malarone), has appeared safe and effective in early trials and represents an alternative for those who cannot take mefloquine or doxycycline. [50]

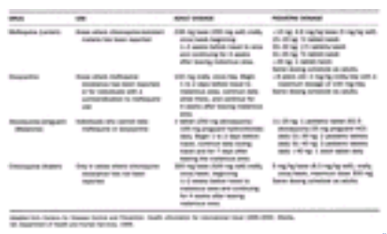

TABLE 56-4 Drugs Used for Malaria Prophylaxis

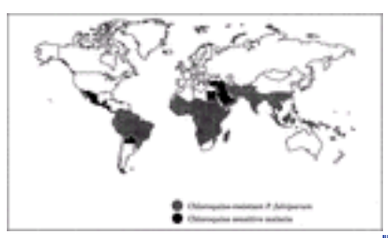

FIGURE 56-2. Distribution of malaria and chloroquine-resistant *Plasmodium falciparum.* (From Centers for Disease Control and Prevention. Health Information for International Travel 1999–2000. Atlanta, GA: Department of Health and Human Services, 2000.)

When travelers take precautions to prevent mosquito bites and are compliant with an appropriate chemoprophylactic regimen, the risk for acquiring malaria is probably low, but not nonexistent. For this reason, travelers should be counseled about the symptoms of malaria (fever, headache, malaise, fatigue, muscle aches, gastrointestinal upset) and told to seek medical care if they develop. Some physicians provide curative treatment regimens, with instructions for the traveler to take

the drug if symptoms of malaria develop. The traveler's ability to make the correct diagnosis is probably low, [51] however, and the side effects of drugs used in curative doses should make this a rarely used option.

OTHER INFECTIOUS DISEASES THAT POSE A RISK

Dengue fever is a viral disease transmitted by *Aedes* mosquitos. Symptoms of dengue fever include high fever, frontal headache, joint and muscle aches, nausea, and vomiting. A rash may be seen 3 to 5 days after the onset of illness. Dengue fever has now become the most common arbovirus disease of humans, and it is estimated that millions of cases occur each year. Epidemics have occurred throughout most of the tropics, including many countries in South America, Africa, and Asia. The disease is present in Mexico and the Caribbean, two major destinations for American tourists. The prevention of dengue fever is currently based solely on the avoidance of mosquito bites by means of the strategies outlined above.

Hepatitis E virus infection has been identified in a few American travelers. Epidemic and endemic hepatitis E transmission occurs in much of Asia, North Africa, and rural areas of central Mexico. The prevention of hepatitis E in travelers is based on the avoidance of potentially contaminated food and water.

TRAVELERS' DIARRHEA

Travelers' diarrhea affects 30% to 50% of travelers to developing countries. [52] Although the disease is generally mild and self-limited, it can severely disrupt travel plans. A recent survey of almost 800 American travelers found that 46% had an episode of diarrhea during their trip, and diarrhea was one of the major reasons individuals sought medical care on their return to the United States. [53] Long-term travelers also are afflicted. A study of 36 Peace Corps volunteers in Guatemala revealed that each individual had on average seven episodes of diarrhea during a 2-year stay. [54] Diarrheal episodes accounted for 10% of the 23,689 person-days of illness in the study.

Enterotoxigenic *Escherichia coli* (ETEC) is the most common cause of travelers' diarrhea worldwide, but *Shigella* species also account for a significant proportion of cases, and *Campylobacter* species are being increasingly recognized as a problem among travelers to Asia. Among bacterial pathogens, *Aeromonas, Plesiomonas,* and *Vibrio* species also are occasionally isolated. [55] Rotaviruses and the Norwalk virus may account for 5% to 15% of cases of travelers' diarrhea. [56] Whereas parasitic causes are relatively uncommon, *Giardia* species are seen in 5% of cases, [57] and a newly recognized protozoan pathogen, *Cyclospora cayetanensis,* is an occasional cause of travelers' diarrhea. [58], [59] *Cryptosporidium parvum* is seen relatively infrequently as a cause of travelers' diarrhea, but it can be a particular problem for immunocompromised individuals. Microsporidia have been identified in the stool of some travelers with diarrhea, but whether these are clinically important is unclear. [60] *Entamoeba histolytica* is an unusual cause of travelers' diarrhea but must be considered in anyone with bloody stools. The etiologic agents of travelers' diarrhea vary by geographic region. In an analysis of 432 military personnel in whom diarrhea developed during Operation Desert Shield, an enteropathogen was isolated in about half, with 29% of these having ETEC, 25% *Shigella* species (mostly *S sonnei*), 7% *Salmonella* species (not *S typhi*), and only 2% *Campylobacter* species. [61] In contrast, among American military personnel deployed in Thailand, more than half of those in whom diarrhea developed were infected with *Campylobacter* species, whereas only a few cases of diarrhea caused by *Shigella* species or ETEC were detected. [62]

Most cases of travelers' diarrhea occur between 5 and 15 days after arrival. [63] The illness is heralded by malaise, anorexia, and abdominal cramps, followed by watery, usually nonbloody, diarrhea. In some cases, nausea and vomiting may be a prominent component, whereas a low-grade fever is present in about 33% of cases. Most bouts of travelers' diarrhea are self-limited, with resolution after 4 to 6 days, but in a significant number of travelers, disease is longer-lasting (6–10 days). Persons with gastric hypoacidity and immunosuppressed patients are probably at greater risk for the development of travelers' diarrhea. [63] These epidemiologic findings are supported by studies that show that gastric hypoacidity leads to a reduction in the infectious dose of *V cholerae* and *Salmonella* species. [44], [64] Travelers with ulcerative colitis, Crohn's disease, or celiac sprue appear to be at greater risk for severe cases of travelers' diarrhea, which may exacerbate their underlying disease. [65], [66] Many infections, such as those caused by *Shigella, Salmonella,* and *Cryptosporidium* species, may be much more severe in immunocompromised patients.

Travelers' diarrhea is contracted by the ingestion of fecally contaminated food or water; hence, the first line of defense for the traveler is care in selecting food and beverages, as previously outlined. Whereas stringent precautions can reduce significantly the chances of contracting travelers' diarrhea, they do not completely eliminate the risk. For this reason, two other measures can be used. The first approach is chemoprophylaxis with antibiotics to prevent diarrhea from developing. An alternative approach is to provide the traveler with antibiotics to be taken when diarrhea develops. Benefits and risks are associated with each of these approaches. Prophylactic antibiotics represent the most effective approach to preventing diarrhea in travelers. Agents tested for their ability to prevent the onset of diarrhea in travelers include doxycycline, trimethoprim-sulfamethoxazole (TMP-SMX), and quinolones. Doxycycline was studied in Kenya, Morocco, and Mexico and showed efficacy of 81% to 86% in preventing diarrhea. [67] The development of widespread resistance to doxycyline in *Shigella,* ETEC, and other enteropathogens, however, has effectively ended the use of doxycyline for this indication. TMP-SMX has been tested in Mexico, where a single-dose regimen conferred 95% protection during a 2-week period. [68] The use of TMP-SMX has been curtailed by the development of resistant organisms in areas of endemicity, and the possibility of severe side effects (allergies and rarely Stevens-Johnson syndrome) should limit the use of TMP-SMZ for this indication. The most commonly used agents currently are quinolones. Norfloxacin in a daily dose of 400 mg had a protective efficacy of 93% in Egypt, and of 88% in a study in Mexico. [65], [69] A single daily dose of ciprofloxacin (500 mg) had a protective efficacy of 94% in a study in Tunisia. [70] In areas where ETEC and *Shigella* and *Salmonella* species predominate as causes of travelers' diarrhea (most of the developing world), a quinolone represents the drug of choice for travelers if antibiotic prophylaxis is used or for the treatment of travelers' diarrhea. This is not the case for travelers to Thailand and neighboring regions in Asia, where *Campylobacter* species are an important cause of travelers' diarrhea. [62], [71] Many isolates of *Campylobacter* species in these areas are resistant to quinolones, and azithromycin, a new, broad-spectrum macrolide that is effective against *Campylobacter* species and other enteric pathogens, can be used at a dose of 500 mg/d as prophylaxis or as treatment by travelers to these regions. [72] As a cautionary note, it should be stated that a few isolates of azithromycin-resistant *Campylobacter* species have been recognized in Thailand. [62]

The advantage of prophylactic antibiotics is their high level of efficacy in preventing disease, which in most cases ensures that travel will not be interrupted by the development of diarrhea. The disadvantages relate to the possibility of side effects of the antibiotics and concerns about the selection of antibiotic-resistant organisms. For these reasons, the routine use of antibiotic prophylaxis to prevent travelers' diarrhea is generally not recommended. Because travelers' diarrhea is usually a relatively benign and self-limited illness, the potential risks of any prophylactic therapy must be low to justify its use. There are two settings in which prophylactic antibiotics may be useful. First, for the short-term traveler (2 weeks or less in an area of endemicity) whose vacation or business schedule would be severely disrupted by a bout of diarrhea, the potential benefits of prophylactic antibiotics may outweigh the risks. This should be discussed in detail with the traveler before prophylactic antibiotics are prescribed. Second, persons who cannot tolerate a bout of travelers' diarrhea because of a medical condition or who are at increased risk for acquiring the disease (e.g., immunocompromised persons, those with gastric hypoacidity, and those with underlying gastrointestinal diseases) are reasonable candidates for longer-term prophylaxis.

Some authorities recommend chemoprophylaxis with bismuth subsalicylate. [73], [74] However, this is only moderately effective (approximately 65%) in preventing diarrhea and can be associated with side effects related to both the salicylate and bismuth components. For this reason, we do not routinely advocate the use of bismuth subsalicylate for the prevention of travelers' diarrhea.

The most widely used approach to travelers' diarrhea is probably the provision of antibiotics to be used by the traveler if and when diarrhea strikes. It needs to be emphasized before travel that self-treatment regimens are not appropriate for the traveler with bloody diarrhea, severe abdominal pain, or high fever. In these cases, medical care should be sought immediately. A reasonable current recommendation is to provide a 3-day course of a quinolone for travelers to most developing countries. Travelers to Thailand and surrounding countries in Southeast Asia are provided with a 3- to 5-day course of azithromycin instead. The patient is told to begin the antibiotic when diarrhea starts and to continue the treatment for 3 days. Studies have demonstrated that a single dose of ciprofloxacin (500 mg taken orally) can reduce the duration of travelers' diarrhea from 50 hours to 24 hours and reduce the number of liquid stools from 11.4 to 5.0. [75] Forty-eight hours after a single dose of fleroxacin (400 mg orally), 67% of travelers had stools of normal consistency, compared with 37% of travelers receiving a placebo. [76] These studies suggest that single-dose antibiotic therapy with one of the quinolone regimens is effective treatment for travelers' diarrhea and also can be recommended for self-treatment by travelers. Whether the addition of the antimotility agent loperamide to antibiotic treatment is beneficial is unclear. The combination of the antimotility agent loperamide and TMP-SMX was superior in reducing the duration of diarrhea to either agent alone in a study undertaken in Mexico. [77] In a placebo-controlled, randomized trial comparing the combination of loperamide and ciprofloxacin with ciprofloxacin alone, a slight but statistically insignificant benefit of the combination was noted during the first 24 hours after the initiation of therapy, but only in individuals infected with ETEC. [78] This may reflect a greater efficacy of the quinolone regimen in controlling diarrhea in comparison with the TMP-SMX regimen. [78] Because the addition of loperamide was not associated with any adverse effects in either study, it probably is

reasonable to continue to offer loperamide as an adjunctive treatment for the symptomatic relief of travelers' diarrhea, pending the results of further studies of its efficacy. For the traveler who cannot be given one of the suggested antibiotics, bismuth subsalicylate also has been used to treat diarrhea and has been shown to shorten the course of illness in placebo-controlled studies. [79] The same cautions about the potential side effects of ingesting large quantities of salicylate in prophylactic bismuth subsalicylate are even more applicable to the higher doses recommended for treatment.

Finally, the most important component of self-treatment is the replacement of the fluid and electrolytes lost during diarrhea. The best approach is the use of an oral rehydration solution, such as the World Health Organization oral rehydration salts solution. Packets are available at stores or pharmacies in most developing countries, and when dissolved in boiled or chemically treated water, a safe solution is created containing sodium chloride (3.5 g/L), potassium chloride (1.5 g/L), glucose (20.0 g/L), and trisodium citrate (2.9 g/L).

Returning Traveler

Watery diarrhea occurring in travelers within the first few days after return usually represents travelers' diarrhea that was contracted before the return trip. [24, 80, 81] The initial approach should be that used for the self-treatment of travelers' diarrhea (provision of a 3- to 5-day course of a quinolone or azithromycin and possibly loperamide with appropriate fluid replacement). The diarrhea should resolve in 24 to 48 hours with therapy. It is critical to remember that diarrhea can be a prominent symptom of malaria, and the traveler returning from malarious areas who has fever and diarrhea must have blood smears examined to exclude *Plasmodium* infection. Watery diarrhea that occurs later after return or that persists longer than 10 days despite antibiotic therapy is most commonly caused by *Giardia lamblia* infection. [81] Stools (preferably three) should be examined for parasites, including *Giardia, Cryptosporidium* (especially in immunocompromised individuals), *Cyclospora,* and *Isospora* species (see Chapter 125). *E histolytica* has been reported as cause of nondysenteric chronic diarrhea, but even if not frankly bloody, stools are almost always guaiac positive in amebiasis. Stool cultures should be obtained, and testing for *Clostridium difficile* should be performed. If no pathogen is detected and a trial of antibiotics (quinolone or azithromycin) was not previously administered, it should be initiated at this time. If antibiotics were used previously or are now unsuccessful, presumptive treatment for *Giardia* infection with metronidazole (250 mg taken orally three times a day for 5 to 7 days) is indicated. [82] If the diarrhea fails to respond to metronidazole, a gastrointestinal evaluation should be performed, including upper gastrointestinal endoscopy, small bowel biopsy, examination of smears for parasites, cultures for enteropathogens, quantitative culture for small bowel overgrowth, and examination of biopsy specimens for evidence of tropical sprue. [82] Flexible sigmoidoscopy and biopsy of the rectal mucosa also may be useful in this setting. Studies of absorptive function may help to localize disease to the small bowel. [82] If the clinical symptoms and biopsy specimen findings are consistent with tropical sprue, treatment with tetracycline (250 mg four times daily for 6 weeks) given with folate (5 mg daily) is indicated. If no cause is found for the diarrhea after this extensive workup, the traveler should be advised to try symptomatic treatment and should be reassured that most cases of chronic diarrhea eventually resolve.

The diagnostic and therapeutic considerations differ somewhat for the returning traveler with bloody diarrhea, and the pace of the workup should be accelerated. *Shigella, Campylobacter,* and *Salmonella* species are the most likely initial possibilities, and amebiasis is a consideration in this setting. Stool culture, with a search for the aforementioned three agents in addition to enterohemorrhagic *E coli* and *C difficile* (if there is a history of prior antibiotic ingestion), and examination of three stools for ova and parasites or a specific enzyme-linked immunosorbent assay (ELISA) for amebiasis also should be performed. After the stools have been collected, empiric therapy with a quinolone or azithromycin can be initiated pending the results of culture and microscopy. If the stool is negative for enteropathogens, including *E histolytica,* flexible sigmoidoscopy to examine the rectal and colonic mucosa is indicated. Samples for culture and microscopy for *E histolytica* should be obtained, and serologic testing for amebiasis should be performed. Biopsy specimens of abnormal tissue should be examined for amebiasis and for noninfectious causes of bloody diarrhea, including inflammatory bowel disease. It must be remembered that travel can unmask previously unrecognized or dormant intestinal diseases, such as inflammatory bowel disease, irritable bowel syndrome, celiac sprue, and lactose intolerance.

CHAPTER 57

Craig J. McClain, Gerald Dryden, and Kristine Krueger

COMPLEMENTARY AND ALTERNATIVE MEDICINE IN GASTROENTEROLOGY

One of the major trends in health care during the past decade has been the marked growth in the use of complementary and alternative medicine (CAM). Two widely used definitions of CAM are “those health care and medical practices that are not currently an integral part of conventional (Western) medicine,” and “those interventions neither taught widely at U.S. medical schools nor generally available in U.S. hospitals.” During the 1990s, the federal government created the National Center for Complementary and Alternative Medicine (NCCAM), as well as the Office of Dietary Supplements. Moreover, versions of *Physicians’ Desk Reference* have been created for both herbal therapies and dietary supplements. [1], [2] CAM has been grouped within five major areas by the NCCAM. The greatest proportion of human as well as experimental animal and in vitro research relating CAM to gastrointestinal (GI) diseases has evaluated biologically based therapies (the focus of this chapter). Other forms of CAM include manipulative and body-based methods, energy therapies, mind-body interventions, and alternative medical systems (Table 57-1).

TYPE OF CAM	EXAMPLES
Biologically based therapies	Herbal therapies
	Special diets to promote health
	Orthomolecular therapies (e.g., megavitamins)
	Biologic therapies (e.g., shark cartilage)
Alternative medical systems	Oriental medicine
	Maintaining proper balance of Qi
	Traditional Indian medicine, Ayurveda
	Homeopathy (dilute treatments more potent)
Mind-body interventions	Meditation
	Prayer
	Mental healing
	Art, dance, and music therapy
Manipulative and body-based methods	Osteopathy
	Massage therapy
	Chiropractic
Energy therapies	Qigong
	Touch therapy to maintain body's energies and balance
	Bioelectromagnetically based therapies

TABLE 57-1 Types and Examples of Complementary and Alternative Medicine

The increasing interest in CAM was highlighted in a study by Eisenberg and colleagues [3] that demonstrated a high prevalence of CAM use and a large sum of out-of-pocket dollars spent on CAM in the United States in 1990. A follow-up survey documented trends in CAM use in the United States between 1990 and 1997. [4] CAM use increased from 36% to 46% during that 7-year period. Of great importance, almost 40% of patients did not disclose their CAM use to their traditional physicians. In 1997, approximately 15 million adults took prescription medicines in conjunction with herbal remedies or high-dose vitamins, and total out-of-pocket costs for CAM were estimated to be at least $27 billion. Patients reported equal confidence in their CAM providers and their traditional medical doctors. [5] A 2001 survey found that approximately half of American adults were taking nonprescription dietary or mineral supplements. [6] Moreover, approximately one in six Americans reported regular use of a supplement such as ginseng, amino acids, or over-the-counter hormones. CAM users tend to be highly educated, are often white (non-Hispanic), and frequently use CAM therapy for chronic diseases. CAM use in chronic illness may result from frustration with the lack of efficacy of conventional therapy and the fact that CAM allows patients some control over their therapy. Thus, it should not be surprising that CAM is frequently used by patients with chronic GI diseases. Moreover, many users of CAM (especially dietary supplements) emphatically believe in the usefulness of this therapy. Indeed, when asked what they would do if a government agency said that the supplement they used most often was ineffective, 71% of regular users reported they would still continue to take the supplement. [6] Because of all these factors, it is important that health care providers be knowledgeable about CAM, including both potential benefits and side effects. This chapter reviews CAM use as it applies to major GI disease processes.

CAM USE IN LIVER DISEASE

Use of CAM in liver disease appears to parallel overall widespread CAM use in the United States, as indicated by data presented at the 1999 Complementary and Alternative Medicine Symposium on Chronic Liver Disease at the National Institutes of Health. [7] We will review milk thistle (silymarin), glutathione prodrugs, SAMe,

vitamin E, lecithin, herbals, and glycyrrhizin in liver disease.

Silymarin (Milk Thistle)

Silymarin is the active ingredient extracted from *Silybum marianum* (“milk thistle”). The plant is a member of the daisy family, and the leaves have prominent white “milky” veins. [8] This agent protects animals from multiple types of experimental liver injury induced with carbon tetrachloride, acetaminophen, iron overload, bile duct obstruction, and, very importantly, mushroom poisoning. [8], [9] and [10] Its hepatoprotective effects are highlighted by its use in the treatment of *Amanita* mushroom poisoning. Studies in several animal species have documented the efficacy of this agent in mushroom poisoning, both in pretreatment phases and following ingestion. [8], [9] and [10] Moreover, several cases have been reported in which dramatic results were achieved in patients up to 3 days after accidental ingestion.

In the United States, silymarin is probably the most widely used form of CAM in the treatment of liver disease. Clinically, it may have hepatoprotective effects in various forms of toxic hepatitis, fatty liver, cirrhosis, ischemic injury, and virus-induced liver disease. [8], [9] It has antioxidant activities, protects against lipid peroxidation, and has antiinflammatory and antifibrotic effects. Large controlled trials of silymarin have been performed in Europe, with variable results. Ferenci and colleagues [11] evaluated 170 patients with cirrhosis in a treatment program (140 mg three times daily) that had a mean duration of 41 months. They observed a positive beneficial effect, especially in patients with alcoholic cirrhosis and in those with milder disease (Child class A). On the other hand, a study by Pares and colleagues [12] found no beneficial effects (150 mg of silymarin three times daily) in a study of 200 patients with alcoholic cirrhosis, some of whom also had hepatitis C. Both of these trials had major shortcomings, including high dropout rates and compliance issues. Despite these limitations, silymarin is likely to remain one of the most popular forms of CAM therapy for liver disease because it has a good safety profile and has been extensively investigated in multiple forms of experimental liver injury in animals, and some positive results have been reported in humans.

Glutathione Prodrugs

Glutathione is a tripeptide that is synthesized from glutamate, cysteine, and glycine. Glutathione, in its reduced form, is the main nonprotein thiol in the cells and has an important role in the detoxification of electrophils and protection against reactive oxygen toxicity. [13] Glutathione cannot be taken up by hepatocytes, but a number of pharmacological agents have been devised to enhance intracellular pools. The most widely used include *N*-acetylcysteine (NAC) and 2-oxothiazolidine-4-carboxylic acid (OTZ), with NAC available as a supplement. [14]

Glutathione prodrugs have been used extensively in virtually every known experimental model of hepatotoxicity with beneficial results. [13], [14] The glutathione prodrug NAC (given as Mucomyst) is the standard therapy for acetaminophen toxicity in humans. [15] Maintaining adequate hepatocyte glutathione levels has been documented to prevent acetaminophen liver injury. However, the information on glutathione prodrugs in prospective randomized studies in other forms of liver disease is very limited. Unfortunately, the initial promise of increased efficacy of using reduced glutathione (GSH) prodrug/antioxidant therapy in combination with interferon for hepatitis C appears not to have held up under scrutiny. [16] Glutathione prodrugs can directly affect the hepatocyte, and they can also positively modulate proinflammatory cytokine production with inhibition of cytokines such as tumor necrosis factor (TNF) and interleukin-8 (IL-8). [17] This presumably occurs through inhibition of the oxidative stress–sensitive transcription factor nuclear factor-?B (NF-?B), which plays a central role in lipopolysaccharide (LPS)-stimulated TNF production. Pena and colleagues [18] demonstrated that the GSH prodrug procysteine can increase whole-blood GSH and inhibit monocyte TNF and IL-8 production when given intravenously to patients with stable cirrhosis. Similarly, procysteine was shown to protect against alcohol-induced liver injury in the intragastric ethanol feeding model. [19] Thus, GSH prodrugs can, in theory, decrease oxidative stress in hepatocytes and attenuate proinflammatory cytokine production in Kupffer cells to inhibit hepatotoxicity in processes such as alcoholic liver disease (Fig. 57-1).

FIGURE 57-1. Most forms of complementary alternative medicine therapy in liver disease have antioxidant effects. These theoretically decrease proinflammatory cytokine production, decrease stellate cell activation and subsequent collagen production, attenuate oxidant injury in hepatocytes, and decrease endothelial cell adhesion molecule expression. *IL-8,* interleukin-8; *NF-?B,* nuclear factor-?B; *TNF,* tumor necrosis factor.

***S*-Adenosylmethionine**

S-Adenosylmethionine (SAMe, adomet) is an obligatory intermediate in the conversion of methionine to cysteine in the hepatic trans-sulfuration pathway. The conversion of methionine to SAMe involves transfer of the adenosyl moiety of ATP to the sulfur atom of methionine and is catalyzed by methionine adenosyltransferase (MAT). SAMe is a precursor for the synthesis of polyamines, choline, and GSH. SAMe is also the major methylating agent for a vast number of molecules via specific methyltransferases. [20]

Patients with many types of both acute and chronic liver disease have elevated plasma methionine levels, markedly delayed clearance of an oral methionine load, and decreased hepatic MAT activity. Because SAMe is a precursor of GSH synthesis, its deficiency may result in the GSH deficiency reported in the liver and serum of patients and experimental animals with liver disease. Because GSH is required for the optimal expression of MAT activity in liver, hepatic deficiency of MAT may in part be a consequence of GSH deficiency. Hepatic-specific MAT is sensitive to oxidative stress, and it is likely that the subnormal hepatic MAT activity reported in alcoholic liver disease is a result of oxidation of the active site through increased oxidative stress. [21]

Subnormal hepatic SAMe levels have been reported in various experimental models of liver injury, and SAMe therapy in rats attenuates liver injury secondary to cholestasis, ethanol, carbon tetrachloride, fatty liver, acetaminophen, or galactosamine. [20] MAT A1 (liver-specific MAT) knock-out mice have been generated. [22] Initially, they are highly susceptible to another “stress,” such as a choline-deficient diet. Later, fatty liver and periportal inflammation develop, which may have a great relevance not only to alcoholic liver disease but also to nonalcoholic steatohepatitis (NASH). Lastly, very late in life, hepatic cancer develops in some mice. MAT deficiency modulates the expression of many genes, especially those involved in proliferation/growth, and normal MAT A1 activity appears to be important for maintaining the hepatocyte in a “differentiated” state. [22], [23] Studies from our laboratories have shown that SAMe down-regulates production of the cytotoxic proinflammatory cytokine TNF in animal models of liver injury and in peripheral blood monocytes or macrophage cell lines in vitro. [24] Mato and colleagues [25] reported that patients with alcoholic liver cirrhosis who were randomized to receive SAMe (1200 mg/d orally) for 2 years had decreased rates of liver mortality/liver transplantation (16% versus 30%) compared to a placebo-treated group. SAMe has also been used successfully in various types of cholestatic liver disease. Thus, substantial animal studies and emerging clinical data indicate that SAMe may be useful in several forms of liver disease. Some potential beneficial effects of SAMe include increased GSH production, improved mitochondrial function, decreased proinflammatory cytokine production, and enhanced methylation reactions.

Vitamin E

Vitamin E is a potent chain-breaking antioxidant that is widely used as a nutritional supplement. In several types of liver disease, depressed serum and hepatic levels of vitamin E have been documented. [26]

Vitamin E has been used extensively with hepatoprotective effects in experimental models of liver injury, such as that induced by carbon tetrachloride or ischemia. [27], [28] and [29] Vitamin E has been used in human liver disease with some success, with probably the most compelling data generated in children with NASH. [30] Obese children were given vitamin E (400–1200 IU) in an open-label pilot study, and all children with NASH demonstrated an improvement in liver enzymes without losing weight. Vitamin E has multiple potential beneficial effects, probably the best recognized being membrane stabilization. [28] Vitamin E–treated peripheral blood monocytes and Kupffer cells demonstrated reduced NF-?B activation and TNF production. [17] Vitamin E also inhibits hepatic stellate cell activation and collagen

production, thus inhibiting fibrosis (see Fig. 57-1). [31]

Polyenylphosphatidylcholine (Lecithin)

Polyenylphosphatidylcholine (PPC) is a lipid extract from soybeans that has been shown to have hepatoprotective effects, especially in alcoholic liver disease. [32, 33] PPC (specifically, dilinoleoylphosphatidylcholine, or DLPC) was shown to prevent the development of septal fibrosis and cirrhosis in alcohol-fed baboons, and to stimulate the release of collagenase activity by cultured hepatic stellate cells. DLPC was also shown to decrease stellate cell activation in rats. [32, 33] The effect of this agent was subsequently extended to two different models of experimental liver fibrosis (CCl_4 and heterologous albumin) in which DLPC was shown not only to attenuate liver fibrosis, but also to accelerate its regression. DLPC was also shown to decrease the hepatic levels of lipid peroxidation metabolites (4-hydroxylnoneneal and F2 isoprostanes) in ethanol-fed animals (rats and baboons), [34] suggesting that DLPC possesses antioxidant properties that may contribute to its antifibrotic and cytoprotective effects. These animal studies of DLPC have led to a Veterans Administration cooperative study evaluating its effects in patients with early alcoholic liver disease, the results of which should influence our use of this CAM agent.

Oriental Herbals

Herbals are widely used for a variety of chronic inflammatory processes, such as rheumatoid arthritis, as well as chemoprevention of cancer. Green tea and green tea polyphenols down-regulate proinflammatory cytokine production (e.g., TNF) and block endotoxin lethality and endotoxin-induced hepatotoxicity in galactosamine-sensitized rats. [35] Other major polyphenols are made from grape seeds; they also have antioxidant/antiinflammatory properties and have been used to protect experimental animals from liver injury.

TJ9 is commonly used in China and Japan and comes from an aqueous extract from the roots of a variety of plants. This agent has been shown to be hepatoprotective/antibiotic in certain animal models of liver injury and to down-regulate proinflammatory cytokine production. [7, 36] It is frequently used to treat both hepatitis B and hepatitis C in the Orient. Compound 861 is an aqueous extract of ten defined herbs that is reported to have very potent antifibrotic activity. It has been used extensively in China as an antifibrotic agent and has been reported actually to decrease fibrosis in sequential liver biopsy specimens from patients with hepatitis B. [7, 37] It has also been shown to be effective in CCl_4-induced liver injury and to have antiproliferative effects on stellate cells in vitro. One of the major problems with herbals is that they are actually a combination of agents that are poorly characterized and not highly reproducible from one lot to the next. The potential uses and risks of herbals have recently been reviewed, and summaries are available in the Cochrane Reviews. [7, 8, 38]

Glycyrrhizin

Glycyrrhizin is an extract made from licorice roots that has been used in a variety of GI disease processes ranging from peptic ulcer disease to liver disease. Glycyrrhizin has been reported to improve liver enzymes in a variety of patients with chronic hepatitis, including hepatitis C. [39] A retrospective study of intravenous glycyrrhizin therapy in patients with chronic hepatitis C showed approximately a 2.5-fold reduction in the risk for hepatocellular carcinoma. [40] Although glycyrrhizin has potential beneficial effects, it also has aldosterone-like properties that predispose to electrolyte imbalance and fluid retention, and therefore we do not recommend that our patients use this drug. [41]

CAM USE IN PANCREATIC DISEASE

Currently, effective therapies for pancreatic disease, especially chronic pancreatitis, are limited. Relief of abdominal pain, malabsorption, and diabetes are the main areas of focus, with abdominal pain being the most difficult symptom to treat. Because pancreatic enzyme replacement therapy is ineffective in controlling pain [42] and large randomized studies evaluating endoscopy or surgery are lacking, [43] patients and providers are actively seeking alternative therapies for chronic pancreatitis, including acupuncture, herbal therapies, and antioxidant therapy.

Acupuncture

Acupuncture has been used for decades in traditional Chinese medicine. The Chinese believe that the interaction of yin and yang creates the vital life force known as Qi (Chee) and that diseases occur when the flow of Qi is disrupted (excessive or deficient). Qi flows through the body in meridians or channels and can be accessed via acupoints. Modern functional magnetic resonance imaging studies have shown reproducible, regionally specific, and quantifiable effects on relevant structures in the brain when acupoints are stimulated. [44] However, in the only randomized prospective study of 23 patients with nonalcoholic chronic pancreatitis, neither electroacupuncture nor transcutaneous electrical nerve stimulation was as effective as medical therapy. [45]

Antioxidants

The increased use of antioxidants as an alternative therapy for chronic pancreatitis is based on the compelling evidence of persistent oxidant stress in patients with chronic pancreatitis, [46] in addition to increased lipid peroxidation and altered glutathione metabolism. [47] Furthermore, regardless of the cause of injury, oxidative stress is felt to be pivotal in the progression to parenchymal pancreatic tissue destruction. [48] Serum antioxidant profiles of patients with acute and chronic pancreatitis, and of those with hereditary pancreatitis, reveal lower plasma concentrations of selenium, vitamin A, vitamin E, xanthine, ß-carotene, ß-cryptoxanthine, and lycopene in comparisons with control subjects. [49, 50] Additionally, selenium deficiency in chronic pancreatitis has been well documented, with some patients experiencing relief of chronic pain after selenium supplementation. [51]

The histological hallmarks of chronic pancreatitis include loss of parenchyma, fibrosis, blockage of pancreatic ducts with protein plugs that calcify, and variable degrees of inflammatory cell infiltration with a predominance of lymphocytes. Cytokines and chemokines released from these cells promote ongoing inflammation. Elevated proinflammatory cytokines have been found in the serum, [52] peripheral blood monocytes, [53] and more recently in the pancreatic tissue [54] and pure pancreatic juice [55] of patients with acute and chronic pancreatitis. Cytokine response predicts disease severity and outcome, supporting the rationale for the antioxidant/cytokine blocking therapies now under development. In a prospective trial of ten patients with chronic and acute recurrent pancreatitis of various causes, supplementation with a complex containing vitamin E, vitamin C, and organic selenium resulted in significant pain relief and a decreased need for hospital admission during the year of treatment in comparison with the year before treatment. [56] In a 20-week, double-blinded, placebo-controlled, switch-over trial of supplementation with selenium, ß-carotene, vitamin C, vitamin E, and methionine, most patients reported fewer attacks with significantly less background pain while on treatment. [57] A retrospective cross-sectional audit of 94 consecutive patients with chronic pancreatitis on antioxidant therapy followed for an average of 30 months showed a decrease in the requirements for surgical intervention, in the number and intensity of painful attacks, and in absences from work. [58] Large prospective placebo-controlled trials are needed to confirm these preliminary observations.

CAM USE IN PEPTIC ULCER AND NONULCER DYSPEPSIA

Peptic ulcer disease remains prevalent despite the recognition of its association with *Helicobacter pylori* infection and the availability of potent antisecretory medications. For thousands of years, alternative therapies were used to provide symptom relief and promote ulcer healing, especially in Indian and Chinese traditional medicine.

Acupuncture

Acupuncture has been used extensively in China and the former Soviet Union for the treatment of peptic ulcer. The physiological basis of acupuncture effects on acid secretion has been well studied in animals and humans. [59] In a prospective randomized study of human volunteers, electroacupuncture, but not sham acupuncture or simple acupuncture, significantly reduced vagally stimulated acid secretion. [60] Clinical trials reporting efficacy for acupuncture in humans with gastric or duodenal ulcer have been criticized for poor study design and lack of randomization.

Acupuncture may be useful for persons with nonulcer or functional dyspepsia. These patients have been shown to be hypersensitive to gastric distention, and somatic stimulation with transcutaneous electric stimulation can reduce the discomfort associated with gut distention. [61] Electroacupuncture modulates gastrointestinal motility

by significantly increasing the percentage of regular gastric slow waves as measured by electrogastrography (EGG) [62] and by influencing duodenal peristalsis. Several small uncontrolled trials claim efficacy for acupuncture in subjects with nonulcer dyspepsia. [63], [64] Future controlled randomized trials are needed to clarify whether patients with nonulcer dyspepsia or documented gastroduodenal dysmotility can benefit from acupuncture.

Herbal Therapies

Sangre de grado is derived from the sap of several Amazonian trees of the *Croton* genus (*C dracanoides, C planostigma, C lechleri*). It is commonly used in tropical South America to treat a variety of GI illnesses, including infectious diarrhea, gastritis, and peptic ulcer, and it is also used topically for wounds, bites, and insect stings. [65] It is inexpensive and widely available, unlike many of the Western pharmaceuticals. Its mechanism of action is unknown, but its efficacy has been attributed to potent antibacterial properties. Despite the high prevalence of *H pylori* infection in South America, no current studies have focused on sangre de grado and *H pylori* eradication per se.

In a randomized clinical trial of 508 patients with endoscopically proven gastric or duodenal ulcers and documented *H pylori* infection, the Chinese herb Chuanjia Weidan was compared with cimetidine. Ulcer healing rates and symptom reduction were comparable, but the *H pylori* clearance rate was 75% with Chuanjia Weidan therapy, versus 6% for the cimetidine-treated group. Ulcer recurrence rates were also higher for the cimetidine treated group. [66] A preliminary screening of more than 200 different Chinese herbal medicines revealed that 38 of the preparations had growth-inhibiting effects on *H pylori* organisms cultured from 136 subjects with antral infection. [67]

Other botanicals and herbals with reported efficacy and extensive use in the treatment of humans with peptic ulcer include flavonoids (quercetin, silymarin, naringin, anthocyanosides, sophoradin derivatives), saponins, tannins, gum guar and mucilages (myrrh), licorice, aloe gel, goldenseal, and capsicum (chili). [68] Proposed mechanisms of action include inhibition of prostaglandins, cytoprotection, antiinflammatory or immune modulatory effects, altered nociception, and suppression of *H pylori*. However, well-designed randomized controlled trials supporting these claims are lacking.

CAM USE IN IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is one of the functional bowel disorders characterized by chronic or recurrent abdominal pain and disturbed defecation without structural or biochemical abnormalities. Although the pathogenesis of IBS remains unknown, the documented altered bowel motility patterns and exaggerated pain perception to visceral distention (“visceral hyperalgesia”) suggest neurohormonal or autonomic dysfunction as a likely cause. [69], [70]

Treatments for IBS generally focus on symptom reduction; however, no single treatment is reliably effective. Rather, multiple regimens combining dietary and lifestyle modification, normalization of bowel habits, antispasmodics when indicated, and anxiolytics or antidepressants are used. Often, an initial approach is to increase dietary fiber; however, clinical controlled studies of fiber therapy have revealed conflicting results. [71] Because of the limited efficacy of conventional treatments for IBS, many patients seek alternative therapies. A questionnaire completed in a physician’s waiting room in Britain revealed that one in five patients with IBS had used some form of alternative therapy. Also, 41% were agreeable to consultation with alternative medicine practitioners, compared with only 6% of patients with “organic” upper GI diseases. Of alternative medicines used at home, herbal remedies were most common. [72] However, most people with IBS symptoms do not seek formal medical care, and the use of alternative therapies in these individuals will remain difficult to quantify unless surveys of large cross sections of the population are developed and administered.

Acupuncture

Acupuncture therapy may benefit patients with IBS through a variety of mechanisms, including its effects on GI motility and autonomic function. Coffin and colleagues [61] examined the effects of transcutaneous electrical nerve stimulation of the hand during balloon distention of the stomach and duodenum and found that it induced somatosensory stimulation and raised the discomfort threshold. Kunze and colleagues [73] found a greater relief of symptoms with real (31%) than with sham (17%) acupuncture in patients with IBS. Among ten patients with IBS, Diehl and colleagues [74] reported a good response to acupuncture in four and a partial response in five, with one nonresponder. In another small study of seven patients given acupuncture for IBS, all reported an improved sense of general well-being and less abdominal bloating, but no change in abdominal discomfort or bowel patterns. [75]

Commonly Used Herbal Therapies

Essential oils are known for their carminative and antispasmodic properties and thus have been used for various GI ailments. Peppermint oil is derived from steam distillation of the arial parts of flowering *Mentha X piperita L*. Its active component is menthol, which has pharmacological properties similar to those of calcium channel antagonists. [76] Peppermint oil has been shown to relax smooth muscle from isolated human colonic cells. In a review of eight randomized controlled trials, peppermint oil use was associated with relief of IBS symptoms. However, only one trial selected patients based on the Manning diagnostic criteria for IBS, and many studies had methodological flaws, such that the authors of this metaanalysis recommended additional well-designed studies before definitive judgment about the use of peppermint oil in IBS could be made. [77]

Ginger root (*Zingiber rhizoma, Zingiber officinale*) has been used for thousands of years in Asia to treat multiple GI ailments, including nausea, dyspepsia, cholera, and diarrhea, as well as motion sickness, postoperative vomiting, and hyperemesis gravidarum. The pharmacological properties of ginger include antioxidant effects and inhibition of prostaglandins. It also increases intestinal tone and peristalsis. Ginger supplementation enhanced charcoal meal transport in mice, with effects felt to be similar to or slightly weaker than those of metoclopramide and domperidone. [78]

Licorice (*Glycyrrhiza glabra, Glycyrrhiza uralensis*) is used to treat functional dyspepsia, bronchitis, and peptic ulcer. It has expectorant properties and antiinflammatory and antiplatelet effects, and it increases prostaglandin levels. Overuse can result in salt and water retention, hyperkalemia, hypertension, and edema. Many drug-drug interactions are also possible.

Derived from the plant *Hypericum perforatum,* St. John’s wort is the most commonly used herb worldwide to treat depression and anxiety. In clinical studies comparing St. John’s wort with various serotonin reuptake inhibitors, it was equally effective for the treatment of depression and had fewer side effects. [79] The active ingredient of St. John’s wort, hypericin, acts by inhibiting the reuptake of norepinephrine, serotonin, and dopamine. Controlled trials of St. John’s wort use in IBS have not been reported.

Perhaps because of their agreeable flavor and aroma, or the ceremony of making and sharing a beverage with others, the commercial use of herbal teas is increasing. The following have reported benefits for the GI tract and their use is felt to be safe, but controlled clinical trials of efficacy have not been published. Chamomile (*Matricaria camomilla, Chamaemelum nobile*) is felt to have GI antispasmodic, antiinflammatory, and antimicrobial activities, in addition to anxiolytic and slight sedative effects. The licorice-tasting herbs fennel (*Foeniculum vulgare*) and anise (*Pimpinella anisum*) are touted to help expel gas and aid digestion. Lemon balm (*Melissa officinalis*) has mild sedative, carminative, and antispasmodic effects, and fragrant raspberry leaf (*Rubus idaeus,* the “pregnancy tea”) is reported to relieve morning sickness, nausea, and dyspepsia. [80]

Chinese Herbal Agents

In traditional Chinese medicine, rather than single agents being used, multiple herbs are combined for their synergistic properties. In a randomized placebo-controlled trial of 176 patients with IBS according to the Rome criteria, those receiving treatment with individualized herbs (n = 58) or a standard formulation of Chinese herbs (n = 63) reported significant relief of bowel symptoms and quality of life in comparison with those receiving placebo (n = 55). No greater benefit for those receiving individualized herbs rather than standard herbs during the 4-month study was found. However, only the subjects who had received individualized herbs showed a sustained relief of symptoms at 14 weeks after completion of the study. The authors concluded that further investigation of Chinese herbal medicine as a treatment for IBS should be undertaken. [81]

Indian Herbal Agents

The bilva (*Aegle marmelos correa*) plant from the Indian Ayurvedic system of medicine has been used to treat chronic constipation, flatulence, diarrhea, and colic. Yadav and colleagues [82] randomized patients with IBS to one of three groups: standard treatment (clidinium bromide, chlordiazepoxide, and ispaghula), herbal therapy (bilva plus the sedative herb *Bacopa monniere Linn*), or placebo. Both active treatment groups significantly improved compared with the placebo group. A subanalysis revealed the standard therapy was most beneficial for patients with pain as a predominant symptom, whereas the Ayurvedic herbs were most beneficial for those with diarrhea. At 6-month follow-up, relapse rates did not differ between the active treatment and placebo groups.

CAM USE IN INFLAMMATORY BOWEL DISEASE

Inflammatory bowel diseases (IBD) exhibit a large degree of heterogeneity, both in disease expression and in response to established therapies. The toxicity and relatively low efficacy of many standard medical therapies impel some patients with IBD to seek alternative therapies, including probiotics, nutritional supplements, and botanical products. Clinical evaluations of alternative therapies suggest therapeutic benefits, and studies of probiotic organisms and helminthic parasites provide new insights into the effects of host and environmental factor interactions on GI inflammation.

Probiotics

Probiotics are defined as “preparations or products containing viable, defined microorganisms in sufficient numbers, which alter the microflora (by implantation or colonization) in a compartment of the host and exert beneficial health effects.” [83] Probiotic bacteria stimulate nonspecific host resistance to microbial pathogens and enhance humoral immune responses to those pathogens. [84] They also alter the composition of the lumenal flora by producing lactic acid, bacteriocins, and other antimicrobial peptides that are efficacious against pathogens.

Lactobacterium species, in general, perform well against pathogenic bacteria without inhibiting other probiotic organisms. Most species adherent to the small bowel belong to the *Lactobacillus* genus and perform well as potential probiotics. *Lactobacillus salivarius* was noted to compete exceptionally well against pathogenic bacteria without inhibiting other beneficial strains of lactobacilli or bifidobacteria isolated from the human ileum. [85]

Often, GI inflammation leads to imbalances of the intestinal microflora. [86] Some patients with ulcerative colitis have high numbers of pathogenically adhesive and enterohemorrhagic *Escherichia coli* organisms. [87] The presence of pathogenic *E coli* strains is reciprocally related to the number of nonpathogenic *E coli* bacteria, [88] suggesting that augmentation of the normal flora with nonpathogenic strains may be helpful. A randomized blinded study of a nonpathogenic strain of *E coli* (Nissle 1917) [89] demonstrated efficacy equal to that of 5-acetylsalicylic acid (5-ASA) in maintaining remission of symptoms and preventing an active flare of ulcerative colitis. A larger study designed to compare rates of efficacy between therapeutic arms compared the remission rates for treatment with *E coli* (Nissle 1917), mesalazine (1.2 g/d), and a combination of both. [90] This study reported equivalent remission rates; however, large numbers of patients relapsed in all arms, perhaps because of low doses of 5-ASA in the control and combination arms. In an open-label pilot trial, patients with Crohn’s disease treated with 5-ASA were offered a novel probiotic, *L salivarius,* when they needed a change in therapy. Colonization of the GI tract by this organism promoted a systemic antibody response and, if they were elevated before treatment, a decline in TNF levels. [91] These trials suggest efficacy equivalent to that of 5-ASA; however, further clinical trials designed to test the therapeutic benefits of probiotics rigorously are needed to confirm these preliminary observations.

Studies in mice reveal that probiotic administration leads to the competitive displacement of intestinal pathogens and the engagement of cell membrane receptors that modulate signaling events for cytokine synthesis. [83] Mice bred to be deficient in IL-10 have no colonic inflammation while maintained in isolation, but they acquire colitis on exposure to environmental bacteria. On exposure to the environment, IL-10-/- mice showed an increase in the number of bacteria adhering to and translocating across the colonic mucosa in comparison with age-matched controls. After environmental exposure, colonic *Lactobacillus* levels steadily increased over 16 weeks to match control levels, but colonization in the IL-10-/- mice did occur with a different species of *Lactobacillus*. These investigators then repopulated the colons of the IL-10-/- mice by using a rectal enema containing *Lactobacillus reuteri,* followed by daily rectal swabs with the same organism. At 4 weeks, colonic levels of *L reuteri* were similar in the IL-10-/- and control mice. Repopulation with *L reuteri* was associated with a decrease in levels of anaerobic bacteria adhering to and translocating across the colonic mucosa, in addition to attenuation of the colonic inflammation. [92] In another study, intragastric instillation of a genetically altered IL-10–secreting *Lactococcus lactis* probiotic organism caused a 50% reduction in dextran sulfate–induced colitis, preventing the onset of colitis in IL-10-/- mice following exposure to environmental bacteria. [93]

Helminthic Parasites

A theory recently advanced suggests that tolerance to lumenal bacterial antigens (helper T cell type 2 [Th2] mucosal conditioning) may be conferred via exposure to helminthic parasites. [94] The decline in helminthic infestations in the United States during the past 60 years has been offered as an explanation for the rise in the incidence of Crohn’s disease during the same period. [94] A naive Th0 cell begins to secrete IL-2 and proliferate when presented with a specific antigen. With prolonged antigen exposure, the cytokine profile can polarize to either a Th1 (interferon-?, TNF-a) or Th2 profile (IL-4, IL-5, IL-10, IL-13). [95], [96] Immune response to helminthic infection generally elicits a strong Th2-type reaction, whereas patients with Crohn’s disease mount a Th1 response to lumenal antigens. Persons harboring helminths are more apt to mount a diminished Th1 response when challenged with other antigens. [94] Mice exposed to *Schistosoma mansoni* before trinitrobenzene sulfonic acid and ethanol were protected from the development of experimental colitis. [97] In IL-10-/- mice inoculated with the helminths *Heligmosomoides polygyrus* and *Trichuris muris,* far less inflammation developed than in those given a sham inoculation. [94] These data suggest a possible link between decreasing rates of helminthic infections in developed nations and the rising incidences in Crohn’s disease, and may offer another method by which immune modulation can be used to treat patients with this chronic disease.

Prebiotics

Prebiotics, described as “nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of beneficial bacteria in the colon, thereby improving the host’s health,” [98] provide an additional mechanism for influencing the population dynamics of the intestinal microflora. The most beneficial prebiotics reach the cecum, where they can promote the growth of lactic acid–producing microorganisms. Recovery of a high proportion of the chicory *Fructans inulin* and its hydrolysate, oligofructose, from ileostomy outputs supports their ability to reach the cecum. [99] Prebiotics are present in significant amounts in a wide variety of fruits and vegetables and are fermented by colonic bacteria to lactic and short-chain carboxylic acids. [100] Other oligomers with prebiotic potential are lactulose and such sugar alcohols as mannitol and xylitol. Additionally, prebiotics such as oligofructose may function in a primary antibacterial role by augmenting the growth of beneficial probiotic strains, as seen in competition experiments between strains of *E coli, Clostridium perfringens,* and *Bifidobacterium infantis*. [99]

Transforming Growth Factor-ß

Therapy with enteral nutrition has been shown to be efficacious in Crohn’s disease. A specific dietary component, transforming growth factor-ß (TGF-ß), has been studied individually for its applicability as an IBD treatment. TGFs are multifunctional polypeptides found in milk. An oral polymeric diet rich in TGF-ß was studied in 29 children with Crohn’s disease. Seventy-nine percent achieved remission within 8 weeks of therapy, with two treatment failures that required surgical intervention or steroid therapy. Laboratory indicators of inflammation decreased with therapy, and a follow-up colonoscopy revealed endoscopic improvement in about 50% of cases, with some demonstrating complete mucosal healing.

Green Tea

Green tea extracts contain high levels of antioxidants. The polyphenol fraction accounts for most of the antioxidant potential and includes the compounds (-)-epicatechin (EC), (-)-epigallocatechin (EGC), (-)-epicatechin-3-gallate (ECG), and (-)-epigallocatechin-3-gallate (EGCG). [35] Green tea polyphenols are more potent antioxidants that either vitamins E or C and have potent antiinflammatory properties. [101] Green tea polyphenols have been shown to inhibit intestinal inflammation in the IL-2 knock-out mouse model of IBD. [35] An important potential mechanism for treating IBD, independent of antioxidant properties, relates to the effects of the green tea polyphenol fraction on NF-?B, a nuclear activating protein. [102] In a dose-dependent fashion, EGCG inhibits the effects of inflammatory mediators on NF-?B by inhibiting the phosphorylation of I?B by I?B kinase (IKK). When bound to I?B, NF-?B cannot migrate to the nucleus and bind with cytokine promoter sequences,

interrupting the proinflammatory cascade. [102]

Fish Oil

Arachidonic acid metabolites, particularly leukotriene B_4 (LTB_4), are important components in the inflammatory processes associated with IBD. Arachidonic acid metabolites cause increased vascular permeability, vascular dilation, and neutrophil recruitment. Serum LTB_4 levels are increased in patients with ulcerative colitis. [103] Eicosapentaenoic acid (EPA), a component of fish oil, can reduce the formation of LTB_4 by serving as a competitive substrate for 5-lipoxygenase, thereby producing a less potent metabolite, LTB_5. Controlled trials of fish oil in patients with ulcerative colitis have demonstrated trends toward efficacy. The data of Hawthorne and colleagues [104] suggested a steroid-sparing effect from 4.5 g of EPA per day in patients with ulcerative colitis. Belluzi and colleagues [105] found that an enteric-coated preparation of 1.8 g of EPA per day maintained remission in patients with Crohn's disease. Fish oil therapy is limited by the induction of an unpleasant body odor and the need for large doses.

Nicotine

Tobacco use has a well-described dichotomous effect in IBD. Although smoking may aggravate Crohn's disease, patients with ulcerative colitis may experience disease onset or a flare of their existing disease with smoking cessation. [106] This prompted investigators to evaluate the use of nicotine supplementation in the treatment of ulcerative colitis. In a randomized double-blinded placebo-controlled study of nicotine patches (average, 17 g/d) for active ulcerative colitis, a statistically significant response was observed in comparison with placebo. [107] Two subsequent studies with the nicotine patch as monotherapy showed no statistical improvement in remission rates, [108] but a study by Sandborn and colleagues [109] did demonstrate a significant improvement in clinical parameters. Because of poor tolerance of the side effects of nicotine, nicotine patches might be considered as an alternative therapy for former smokers with ulcerative colitis who find their disease exacerbations difficult to control with standard medications.

Soybean Derivatives

Two soybean derivatives have shown promise as antiinflammatory agents in laboratory animals. Genistein, a principal soy isoflavone, induced a mild improvement in endoscopic findings in guinea pigs with a chemically induced colitis. [110] A soybean extract with a high concentration of a potent protease inhibitor (Bowman-Birk inhibitor) attenuated the colitis caused by dextran sodium sulfate in mice. [111] Researchers at the University of Pennsylvania are exploring the efficacy of Bowman-Birk inhibitor in humans with ulcerative colitis. [101]

Short-Chain Fatty Acids

Colonic aerobic bacteria act to salvage energy for the host by fermenting undigested food materials to short-chain fatty acids, which in turn are absorbed by colonocytes. [92] Butyrate has been shown to inhibit the production of cytokines as well as the activation of NF-?B. [112] Initial trials of short-chain fatty acids demonstrated efficacy, but subsequent trials showed mixed results, possibly because of poor compliance. An open-label study investigated the effects of *Plantago ovata* (an alternative source of butyrate) on 12-month remission rates, either alone or in combination with standard 5-ASA therapy. Remission rates were similar for the groups. [112] A subsequent abstract evaluated butyrate yields from a variety of fibers, comparing *P ovata* seeds, husks, and other forms of fiber. All produced significant amounts of butyrate, but butyrate production from the seeds trended toward a higher output. [113]

CAM USE IN DIARRHEAL STATES

Antibiotic-associated diarrhea occurs in approximately 20% of hospitalized patients receiving antibiotics, with up to 33% of cases related to *Clostridium difficile*. [114], [115] The other 66% experience symptoms related to alterations in the bacterial production of short-chain fatty acids. [116] Antibiotic-associated diarrhea was reduced from 27% in a placebo group to 9% in a group taking the probiotic *Enterococcus faecium*. [117] Other organisms shown to be efficacious in antibiotic-associated diarrhea include *Lactobacillus* GG, *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* administered in combination, and *Saccharomyces boulardii*. [116] Worldwide, infectious diarrhea remains a leading cause of morbidity and mortality in infants and children. Numerous studies have investigated the potential of many probiotic and prebiotic agents for the treatment of these conditions. Trials with *Lactobacillus* GG and *S boulardii* used as prophylactic therapy for diarrheal infections demonstrated small overall reductions in diarrhea in comparison with placebo, although some subgroups experienced particularly substantial benefit. The evaluation of probiotics as abortive agents for diarrheal illnesses has been carried out mainly in children, who are at the greatest risk for serious illness and death. *E faecium* and *S boulardii* relieve symptoms in acute diarrheal illnesses, and *Lactobaccillus* GG decreases the rate of rotaviral diarrhea and viral shedding. [118]

Traditional remedies for diarrhea and various intestinal disorders include the ingestion of pectin and green bananas, which serve as a supply of amylase-resistant starch. [119] These starches pass through the small intestine undigested, so that they can undergo fermentation in the colon into short-chain fatty acids. [120] The presence of short-chain fatty acids in the colon stimulates salt and water absorption and also has a trophic effect on colonic and small bowel mucosa. [121] When dietary pectin and green bananas were blended into a rice-based diet and used to treat children with persistent diarrhea resulting from a variety of infectious and noninfectious causes, a statistically significant reduction in stool weight and relief of symptoms were noted in the treated children in comparison with the children on control diets. [119]

SAFETY ISSUES

The safety of CAM agents is not well defined, in large part because of a lack of regulatory guidelines. In 1994, Congress passed the Dietary Supplement Healthy and Education Act (DSHEA), which exempted dietary supplement producers from many Food and Drug Administration (FDA) regulations. Consequently, dietary supplements are under less government scrutiny than over-the-counter nonprescription drugs. Thus, it is critical that both consumers and health care workers understand that the labeling of CAM products is not necessarily correct, that products may not be pure, and that the advertised dose may not be correct.

Concerns about safety relate to both product content and potential harm. Multiple studies have documented great variability in the composition of herbal products/supplements, with some products containing only a small fraction of the advertised dose. [122], [123] and [124] This product variability is probably an unavoidable aspect of many Chinese herbal compounds, and traditional prospective clinical trials difficult are difficult to design because of the inherent variability in the therapeutic agent. Toxicity induced by CAM products has been reported. [123], [125] Hepatotoxicity is one of the most frequently reported side effects of CAM products (e.g., germander and pyrrolizidine alkaloid–containing compounds), sometimes leading to liver transplantation or death. [125], [126] and [127] Unfortunately, few prospective studies have evaluated the incidence/prevalence of toxicity. In a retrospective study evaluating liver enzymes in all patients receiving Chinese drug therapy in a German hospital, clinically important liver enzyme elevations occurred in about 1% of patients. [128] In all patients, liver enzyme levels improved or normalized after discharge, even though almost half of these patients continued to take their Chinese medications. Because this was a hospital-based study, the herbal medications may have been more carefully scrutinized than they are in general practice.

Some CAM products are contaminated with drugs/toxins. [122] A classical example is the report of a young woman who presented with nausea, vomiting, and an irregular heart beat after she initiated an oral regimen of dietary supplements for "internal cleaning." The patient was found to have an elevated digoxin level, and her herbal medications were contaminated with plant extracts containing a cardiac glycoside (*Digitalis lanata*). [129] Importantly, some Chinese patent medicines purposely contain small amounts of prescription drugs (e.g., antibiotics, ephedrine, methyltestosterone). [122], [130] These drugs may also be contaminated with heavy metals (e.g., lead, arsenic, mercury). [131] CAM agents can interact adversely with traditional medications. An example is the potential interactions of St. John's wort with cyclosporine and indinavir. [132] This interaction was highlighted when cardiac transplant patients underwent rejection shortly after starting St. John's wort, presumably because of the induction of cytochrome P450 3A4 by the St. John's wort. [133] It is important to instruct all transplant patients (and other patients on immunosuppressive therapy) to inform their physician before starting any CAM agent. Other more common side effects can also be seen with relatively safe agents such as St. John's wort, including photosensitivity, especially in virally infected patients. A variety of herb-anesthesia interactions are possible (e.g., garlic, gingko, St. John's wort), such as bleeding, and the American Society of Anesthesiologists recommends that patients discontinue all herbal medicines 2 to 3 weeks before elective surgery and inform their physicians about their CAM use. [134] Lastly, the public can be easily misinformed about CAM agents and inadvertently take an unintended product with a

subsequent adverse outcome.

CONCLUSION

In conclusion, CAM is already being widely used by our patients. Some forms of CAM therapy are based on substantial scientific rationale (e.g., SAMe for liver disease, certain green tea polyphenols as antiinflammatory therapy). Some forms of CAM have yielded very positive clinical trial data (e.g., acupuncture for nausea and vomiting). However, because a great potential for toxicity/drug interactions also exists, both the patient and health care provider need to be optimally educated about CAM. In addition to the previously mentioned versions of *Physicians' Desk Reference,* the Web sites of the Cochrane Database System Reviews (http://www.cochrane.org/) and the NCCAM (http://nccam.nih.gov/) are valuable sources for updated information.

CHAPTER 58

H. Worth Boyce, Jr. and Gregory A. Boyce

ESOPHAGUS: ANATOMY AND STRUCTURAL ANOMALIES

Clinicians who assume responsibility for the diagnosis and treatment of esophageal disorders must have a knowledge base of esophageal anatomy. Recognition of pathological alterations in their earliest stages and optimal interpretation of every test of esophageal function and morphology can be accomplished only through awareness of normal anatomy and its variants. As understanding of the manifestations of esophageal disease advances, a knowledge of esophageal anatomy will be increasingly recognized as essential to clinical success.

EMBRYOLOGY

During the fourth week of embryologic development, a small diverticulum forms on the ventral surface of the foregut adjacent to the pharyngeal gut. This tracheobronchial diverticulum separates gradually from the dorsal foregut through the esophagotracheal septum, with eventual separation into the trachea and esophagus. [1] With cranial growth of the embryonic body, the esophagus elongates rapidly. During the sixth week of gestation, the circular muscle coat and ganglion cells of the myenteric plexus form. During the seventh week, blood vessels enter the submucosa.

The esophageal epithelium rapidly proliferates and almost completely fills the lumen in the seventh and eighth weeks, leaving residual channels within the nearly occluded lumen. [2] A single esophageal lumen returns in the tenth week, leaving a superficial layer of ciliated epithelial cells.

In the fourth month, ciliated epithelial cells are replaced by stratified squamous epithelium, a process that continues until birth. Residual islands of ciliated epithelium at the proximal and distal ends of the esophagus remain and give rise to esophageal glands. [3]

ADULT ANATOMY

Gross Anatomy

The adult esophagus is a flattened muscular tube that arises proximally at the pharyngoesophageal junction (i.e., C5-6 vertebral interspace) and courses through the posterior mediastinum to end at the gastroesophageal junction (i.e., T10 vertebral level). The esophageal lumen can distend to approximately 2 cm in anteroposterior diameter and up to 3 cm in lateral diameter. The length of the adult esophagus is variable but ranges from 18 to 26 cm. [4] The cervical esophagus extends from the pharyngoesophageal junction to the suprasternal notch and is about 4 to 5 cm long. At this level, the esophagus is surrounded by the trachea anteriorly, the vertebral column posteriorly, and the carotid sheaths and thyroid laterally.

The thoracic esophagus passes just posterior to the tracheal wall and courses right posterior to the aortic arch (i.e., T4 vertebral level) and posterior to the tracheal bifurcation and left main stem bronchus. At the T8 vertebral level, the esophagus turns left and crosses anterior to the aorta at the level of the diaphragmatic hiatus. At the T10 vertebral level, the esophagus passes through an elliptical opening (hiatus) in the muscular diaphragm and enters into the cardiac portion of the stomach at an oblique angle.

The abdominal portion of the esophagus, or the submerged segment, is short, varying in length from 0.5 to 2.5 cm. [5] At this level, the left lobe of the liver lies anteriorly, the caudate lobe of the liver lies to the right, the fundus of the stomach is to the left, and the right crus of the diaphragm and aorta lie posteriorly. The borders of the esophageal hiatus are formed by the diaphragmatic crura and median arcuate ligament, if present. The crura arise from the first four lumbar vertebrae, intervertebral discs, and anterior longitudinal ligament. The fibers of the left and right crura pass upward and anteriorly to form the muscle borders of the hiatal ring and then insert into the transverse ligament of the central tendon of the diaphragm. [6] The crural origin of the muscle margins of the esophageal hiatus is variable. [7], [8] and [9]

At the level of the diaphragm, the esophagus is surrounded by collagen and elastic fibers of the phrenoesophageal membrane. This membrane extends from the hiatal margin to insert into the circumference of the esophagus both above and below the diaphragm. [10], [11] It is most pronounced in infants. With age, the esophagus is less firmly fixed to the hiatus, and fat appears between the fibers. [12] This membrane is lacking in patients with long-standing hiatal hernia. [13]

The esophageal mucosal surface is rather homogeneous in color and topography. The color is a pinkish gray from the cricopharyngeus to the squamocolumnar junction (Fig. 58-1). Small, linearly oriented mucosal vessels may be seen on close inspection with good illumination. These and many other vessels are apparent when the esophagus is distended, as in achalasia. In achalasia, the vascular pattern of the esophagus is difficult to differentiate from that of the rectum. The squamocolumnar mucosal junction is detected easily in normal subjects by the abrupt disappearance of this vascular pattern and the dramatic color change to the reddish orange, slightly granular mucosa of the gastric cardia. [14] This mucosal junction normally is located at or below the level of the diaphragmatic hiatus.

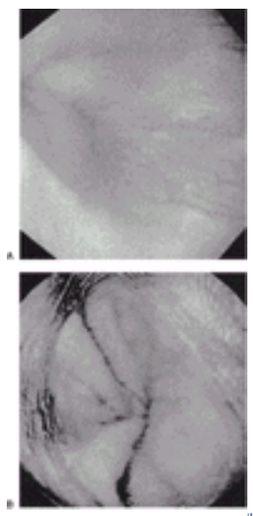

FIGURE 58-1. (See Color Fig. 58-1.) **A:** This view of the normal squamocolumnar junction reveals a slightly serrated contour, a distinct color difference between the two types of mucosa, and linear esophageal vessels that disappear at the mucosal junction. The slightly elevated gastric mucosal folds contact the squamous margin. **B:** The squamocolumnar junction has been better defined by dark Lugol iodine staining of the glycogen-containing squamous cells. This normal junction is located just below the diaphragmatic hiatus.

The esophagogastric muscular junction is represented intralumenally by the cephalic margin of the longitudinal mucosal folds in the gastric cardia. [14], [15] These folds are best seen when a hiatal hernia is present. [14]

Blood Supply

The arterial blood supply to the esophagus is largely segmental, with little vascular overlap (Fig. 58-2). The cervical esophagus is supplied mainly by branches of the inferior thyroid artery. Branches of other arteries, such as the common carotid, subclavian, vertebral, and ascending pharyngeal, may provide additional blood supply. The thoracic esophagus is supplied by branches of the aorta and the right intercostal and bronchial arteries. The abdominal esophagus is supplied by branches of the left gastric, short gastric, and left inferior phrenic arteries. Devascularization and ischemia of the esophagus are of concern during resection operations because of the segmental nature of the blood supply.

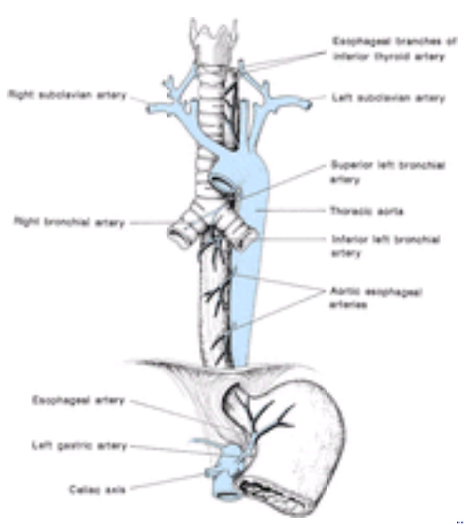

FIGURE 58-2. Arterial system of the esophagus.

The venous anatomy of the esophagus has been well defined (Fig. 58-3). Fine intraepithelial channels drain into a subepithelial superficial venous plexus. This plexus drains into deep intrinsic veins in the submucosa. At the level of the gastroesophageal junction, the superficial venous plexus and deep intrinsic veins communicate with their gastric counterparts. [16]

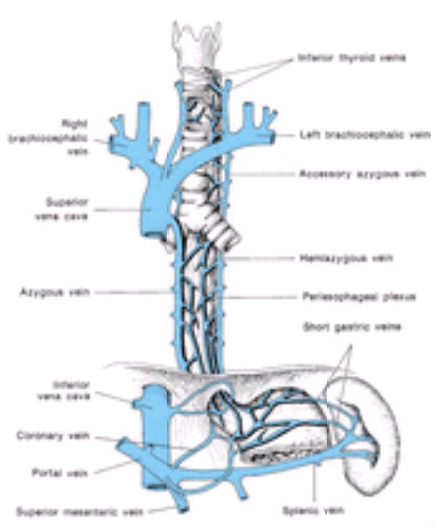

FIGURE 58-3. Venous drainage of the esophagus.

Perforating veins connect the deep intrinsic veins to adventitial veins. At the level of the cervical esophagus, the adventitial veins drain into the inferior thyroid vein, deep cervical vein, vertebral vein, and peritracheal venous plexus.

At the thoracic level, adventitial veins drain into the azygous vein on the right, the hemizygous vein on the left, and the intercostal veins when the hemizygous vein is absent. At the gastroesophageal junction, the portal systemic circulation involves venous drainage of the esophagus, stomach, pancreas, spleen, diaphragm, and retroperitoneum. Anatomic studies have suggested a high-pressure watershed region between the portal and azygous systems at the region of the gastroesophageal junction that is prone to venous dilation in portal hypertension. [17] In portal hypertension, the deep intrinsic veins in the submucosa and subepithelial superficial venous plexus dilate, protrude into the lumen, and may markedly stretch and thin the epithelial surface, forming esophageal varices. [16] In patients with portal hypertension, these vessels serve as collateral channels to provide a route of return for portal blood to the systemic circulation. If pressure and flow increase sufficiently, these dilated veins, or varices, may spontaneously rupture and lead to severe bleeding. The precise pathophysiology of variceal bleeding is not known, but the explosion theory (i.e., rupture from high pressure) seems to be favored over the erosion theory (i.e., mucosal destruction by refluxed gastric contents). Variceal bleeding is from the distal 6 to 8 cm of the esophagus in nearly all cases. Varices may extend up to about the aortic arch level, the upper limit of the venous drainage of the lower esophagus by way of the azygous vein system into the superior vena cava. Varices in a location cephalic to this level have been termed *“downhill” varices*. The

“downhill” description refers to the anatomic site of venous obstruction above the level of the varices, in either the cervical venous system or the superior vena cava. The varices then develop below the site of venous obstruction, whereas typical distal esophageal varices develop in a location cephalic to or above the portal venous flow.

Innervation

The vagus nerve supplies only parasympathetic innervation to the esophagus, although below the neck, the vagus nerve carries a mixture of parasympathetic and sympathetic nerve fibers (Fig. 58-4). The cervical esophagus is innervated by the recurrent laryngeal nerves, which arise from the vagus. Branches of the vagus nerves and the left recurrent laryngeal nerve innervate the upper thoracic esophagus. The left and right vagus nerves intertwine with sympathetic fibers to form the esophageal plexus. [18] , [19] Out of the esophageal plexus, the anterior and posterior vagus trunks form at a variable distance above the diaphragm. [18] Below the diaphragm, the anterior (i.e., left) vagus trunk splits into anterior gastric branches and hepatic branch. The posterior (i.e., right) vagus trunk splits into posterior gastric branches and a branch to the celiac plexus. Sympathetic innervation is supplied by the superior cervical ganglion, sympathetic chain, major splanchnic nerve, thoracic aortic plexus, and celiac ganglion.

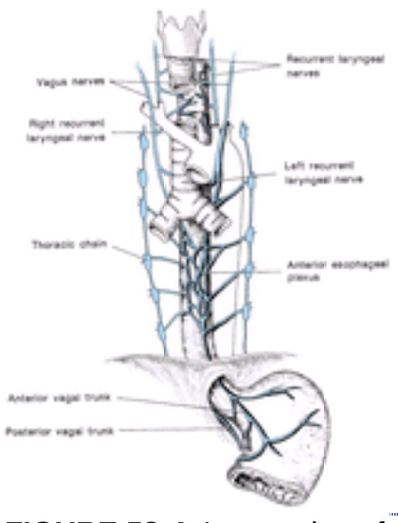

FIGURE 58-4. Innervation of the esophagus.

Lymphatics

A dense network of lymph vessels is found in the mucosa and submucosa of the esophageal wall (Fig. 58-5). These vessels travel a variable distance longitudinally before penetrating the muscular wall and draining into adventitial lymph nodes. The deep cervical lymph nodes drain the proximal esophagus. At more distal levels, the lymph vessels drain into the adjacent lymph node chain. Internal jugular, tracheal, tracheobronchial, posterior mediastinal, and pericardial nodes drain adjacent esophageal segments. Unlike the arterial supply, the lymphatic drainage of the esophagus is not segmental. Multiple interconnections exist between nodal chains. This arrangement accounts for the frequent wide intramural and mediastinal lymphatic spread of esophageal carcinoma.

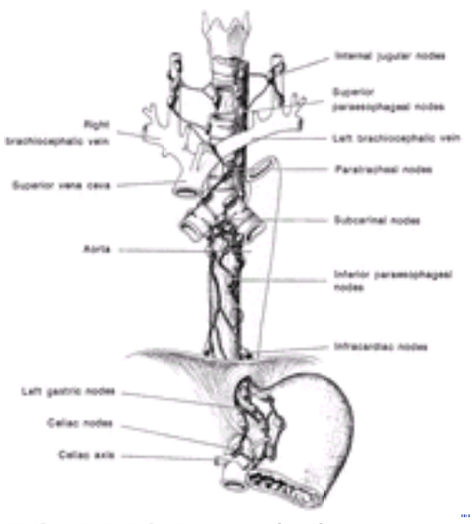

FIGURE 58-5. Lymphatic system of the esophagus.

HISTOLOGY

Light Microscopy

The esophageal wall is composed of four layers: mucous membrane, or tunica mucosa; submucosa, or tunica submucosa; muscularis externa, tunica muscularis, or muscular propria; and adventitia, or tunica adventitia (Fig. 58-6). [20] , [21] The absence of a serosal layer allows esophageal malignancies to spread readily and makes esophageal anastomosis and surgical repair more difficult.

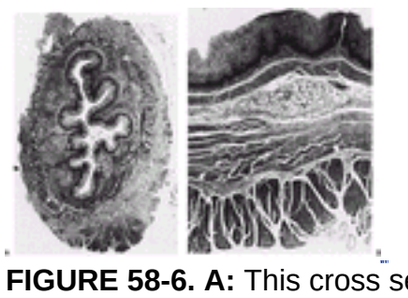

FIGURE 58-6. A: This cross section (×2.5) from the middle third of the esophagus has a mixture of skeletal and predominantly smooth muscle in the muscularis propria. The submucosal glands are clearly shown. At one point, there is an esophageal cardiac gland in which a small focus of glandular epithelium interrupts the squamous mucosa. This is a normal finding, seen in at least 1% of all esophagi. **B:** Longitudinal section of esophageal wall (×10). (Courtesy of Rodger C. Haggitt, M.D., Seattle, WA.)

The innermost layer, the mucous membrane, is composed of nonkeratinized squamous epithelium supporting connective tissue called the *lamina propria* and a thin

layer of smooth muscle called the *muscularis mucosae*. The squamous epithelium is composed of a basal cell layer known as the *stratum basale,* a prickle cell layer known as the *stratum intermedium,* and a superficial layer known as the *stratum superficiale*. The inner border of the epithelium is irregular because of protrusions of the lamina propria called *dermal papillae* or *rete pegs*. The basal cell layer is composed of basophilic, cylindrical cells that have the capacity to divide and replenish the superficial layers. [20]

The esophagus contains cells that are a part of the gut-associated lymphoid tissue. Cytotoxic T cells (i.e., intraepithelial lymphocytes) and Langerhans cells (i.e., macrophages) are found in the squamous epithelium. [22] Helper T cells and B lymphocytes are seen primarily in the lamina propria. [20] Intraepithelial melanocytes and argyrophil cells can be found in the basal cell layer. [23]

The muscularis mucosae is composed of smooth muscle cells that separate the lamina propria from the submucosa (see Fig. 58-6). The submucosa consists primarily of loose connective tissue. The vascular network known as the *Heller plexus,* a nerve plexus, mucin-secreting glands, lymph follicles, and lymphocytes are located at the level of the submucosa.

Striated muscle fibers of the inferior pharyngeal constrictor and cricopharyngeus muscles overlap with striated circular muscle fibers of the cervical esophagus at the level of the C5-6 vertebral interspace. This corresponds to the level of the physiological upper esophageal sphincter segment, of which the cricopharyngeus appears to be the major component. [24], [25], [26] and [27]

The muscular wall of the esophagus is composed of an inner circular and an outer longitudinal layer, the inner circular layer being the thicker of the two (see Fig. 58-6). The first centimeter of the proximal esophagus is striated muscle alone, the muscle of the next 6 to 8 cm is mixed (i.e., both striated and smooth), and the remaining length is all smooth muscle. In situ, longitudinal muscle fibers run in an elongated spiral. Circular muscle fibers run in an elliptical course, with some fibers leaving their bundle to join higher or lower bundles. [27]

Below the diaphragm and proximal to the angle of His (i.e., the abdominal or submerged segment), an area has been described in fixed gastroesophageal specimens in which the inner circular muscle layer thickens and the fibers become semicircular and interlaced. Oblique fibers of gastric type from the greater curve are also found. [28], [29] It has been suggested that this area corresponds to the physiological lower esophageal sphincter, but by most observations the sphincter lies proximal to this level just cephalic to the diaphragmatic hiatus. [14], [15]

The myenteric plexus, or Auerbach plexus, is found between the inner circular and outer longitudinal muscle coats. The adventitial layer consists of connective tissue with networks of nerve plexus, vascular structures, and elastic fibers. Other specialized elements can be seen in the esophageal wall. Islands of gastric mucosa, sebaceous glands, taste buds, and foci of hyperplastic epithelial cells with intranuclear glycogen (i.e., glycogenic acanthosis) have been described. [30], [31], [32] and [33] The latter condition is commonly seen during video-esophagoscopy as focal white elevations, several millimeters in diameter, scattered randomly at any level of the esophagus, and it has no clinical significance. Glycogenic acanthosis stains more intensely with Lugol iodine chromo-endoscopy than the surrounding typical mucosa.

Electron Microscopy

With electron microscopy, basal cells appear as oblong or cuboidal structures with central nuclei. The cytoplasm contains mitochondria, small Golgi complexes, free ribosomes, lysosomes, and little endoplasmic reticulum. No glycogen is seen in these cells. As these cells mature and leave the basal layer, they become larger and more flattened, with cellular constituents similar to those of basal cells. They constitute the prickle cell layer, or stratum intermedium. Glycogen is present in these cells, and membrane-coating granules believed to play a role in cell cohesion are seen in the superficial prickle cell layer. [34], [35] The presence of glycogen in the superficial mucosal cells accounts for their brownish black staining by Lugol iodine solution as applied for chromo-endoscopy. In the superficial layer, the squamous epithelial cells are more flattened and oriented parallel to the surface. The cell membrane becomes more prominent, and the cell edges may overlap. Membrane-coating granules are present. Acid and neutral mucosubstances are found on all layers of epithelial cells. Acid mucosubstances are present in larger amounts on superficial cells and may play a protective role. [36], [37] Microplicae seen on surface cells by scanning electron microscopy may function in holding the mucus in place. [38]

With electron microscopy, the submucosal nerve plexus is seen as an irregular network near the inner coat of the muscularis externa. [39] In the lower esophageal sphincter region, nerve endings are seen as multiple varicosities with close contact to differentiated smooth muscle cells (i.e., Cajal cells) that play a role in the initiation and coordination of contraction. [40]

DEVELOPMENTAL ANOMALIES

Tracheoesophageal Fistula and Atresia

During embryogenesis, the process of elongation and separation of the trachea and esophagus can be disrupted. If fusion of the tracheoesophageal septum is incomplete, a tracheoesophageal fistula (TEF) results. If elongation outstrips foregut cell proliferation, ventral or dorsal cells may form tracheal tissue and esophageal atresia may develop, [1] either with or without associated TEF. Five basic types of TEF and atresia have been described (Fig. 58-7). Esophageal atresia with lower-pouch fistula is by far the most common. [41], [42], [43], [44], [45] and [46] Hydramnios and prematurity are common in infants with atresia or TEF. [47], [48] and [49] Up to 50% of infants may have other associated congenital anomalies. [49]

FIGURE 58-7. The spectrum of esophageal atresia, tracheoesophageal fistula, and congenital stenosis. Atresia with lower pouch fistula (third from left) is by far the most common anomaly.

Symptoms vary with the type of tracheoesophageal anomaly. In infants with atresia alone, the diagnosis is often made after birth. Unswallowed saliva fills the mouth and nostrils, and formula is regurgitated. Infants with proximal fistula exhibit respiratory distress and cyanosis during feedings. In infants with atresia and distal fistula, excessive salivation and regurgitation occur along with cyanosis and pneumonia secondary to reflux of gastric contents. If both proximal and distal fistulae are present, the proximal fistula usually is the cause of most symptoms. The fifth type, isolated TEF or H-type fistula, leads to cough and choking with feedings, recurrent pneumonia, and intermittent abdominal distention. In rare cases, this anomaly is initially diagnosed in adulthood. Adult patients present with a history of recurrent pneumonia and bronchiectasis. [50], [51], [52] and [53]

TEF suspected by the clinical signs and symptoms and can be diagnosed by cautiously introducing radiographic contrast through a catheter. This will delineate the atretic segment and the location of the fistula. In patients with H-type TEF, repeated contrast examinations may be necessary before the fistulous tract is demonstrated. [54]

The surgical trend has been toward early primary fistula repair, with staged repair reserved for infants with respiratory distress or severe associated congenital anomalies. Repeated bougienage may be used to lengthen the atretic segments, allowing subsequent primary anastomosis. [55], [56] Delayed colon interposition is used if primary anastomosis is impossible. The primary determinants of survival are the coexistence of other congenital anomalies and the severity of associated pulmonary disease. [57], [58]

Significant complications may occur after a successful repair of esophageal atresia. [59]

Congenital Esophageal Stenosis

Congenital esophageal stenosis is rare, estimated to occur once in 25,000 live births (see Fig. 58-7), and is thought to result from failure of the normal embryonic separation of trachea and esophagus. [60]

Little information is available about possible pathophysiological mechanisms that contribute to congenital esophageal stenosis. One study of the histological and immunohistochemical features found in esophagi from two young adults has provided several unique observations. [61] Quantitative experiments compared the numbers of myenteric neurons and amount of fibers in the circular muscle. Congenital esophageal stenotic esophagi showed infiltration of neutrophils in the myenteric plane, without any increase in collagen. NADPH-diaphorase histochemistry showed a significant reduction of myenteric nitrinergic neurons (7 ± 2.3 versus 2.7 ± 1.8 neurons per high-power field) and fibers at the circular muscle. Other peptidergic neurons studied were not significantly reduced in congenital esophageal stenosis. The specific total lack of oxide inhibitory innervation may be an important mechanism in the pathogenesis of stenosis and aperistalsis of the esophagus in the disorder. [62]

Stenoses caused by cartilage, residual respiratory epithelium, and muscular wall maldevelopment have been described (Fig. 58-8). [62], [63], [64] and [65] Unlike atresia and TEF, congenital stenosis often is not diagnosed until later in childhood, and several cases have been reported in adults. [66], [67] and [68] Symptoms include regurgitation, prolonged eating time, and dysphagia with recurrent solid bolus impaction. An esophagram usually demonstrates segmental stenosis in the middle third of the esophagus. With adequate insufflation during endoscopy or by barium during contrast esophagrams, the appearance of multiple rings with normal overlying mucosa can be seen in most cases (see Color Fig. 15-11 in *Atlas of Gastroenterology,* 3rd ed.). Segmental resection has been advocated for these patients; however, properly performed bougienage has been reported to be safe in children and adults. [60], [68] Esophageal stenosis may result when tracheobronchial remnants remain within the esophageal wall after repair soon after birth. [69]

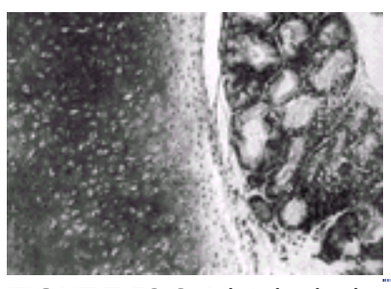

FIGURE 58-8. Histological section from the esophageal wall of a resected segment of congenital stenosis. Note the cartilage (**left**) and tracheal glands (**right**). (From Ishida M, Tsuchida Y, Saito S, et al. Congenital esophageal stenosis caused by tracheobronchial remnants. J Pediatr Surg 1969;4:340.)

Congenital Esophageal Duplication

Congenital esophageal duplications, tubular or cystic, represent about 15% of digestive duplications. They develop in the third week of embryonic development because of failure of vacuoles to coalesce properly, preventing recanalization of the esophageal lumen. As a result, a cyst or parallel tubular channel forms within the esophageal wall. [70] Duplications of the gastrointestinal tract have three common characteristics: (1) They are contiguous with some segment of the gastrointestinal tract; (2) they are lined by alimentary epithelium; and (3) smooth muscle is present in their walls. Tubular duplications are rare and may be associated with other congenital abnormalities, mainly of the spine. [71] They may be asymptomatic or present with dysphagia. Tubular duplications may communicate at both ends with the esophageal lumen or be closed at one end, [72], [73], [74] and [75] but more than 80% are cystic and do not communicate with the lumen. Most patients present before 1 year of age, but as many as 25% to 30% of cases are first diagnosed in adults. The most common presenting symptom is dysphagia, but the diagnosis is most often made as an incidental finding in patients studied for other reasons. [71] The presence of a posterior mediastinal, soft tissue mass on the chest x-ray film is the usual finding.

Congenital Duplication Cyst

Cystic duplications are less rare; they constitute 0.5% to 2.5% of esophageal tumors. They are the second most common benign esophageal tumor, with leiomyoma being the most common. [76], [77] They occur within the wall of the esophagus and are surrounded by two layers of smooth muscle. They are lined by squamous columnar, cuboid, pseudostratified, or ciliated epithelium. [78], [79] Sixty percent arise in the distal third of the esophagus, 17% in the middle third, and 23% in the upper third. [80], [81]

Cysts in the distal two thirds of the esophagus may result in symptoms of dysphagia, epigastric discomfort, retrosternal pain, cough, dyspnea, or regurgitation, although many are diagnosed without being symptomatic. [82] Cysts located posterior to the heart have been associated with cardiac arrhythmias. [83] Intraspinal cystic extensions can cause neurological deficits that may be the initial sign of these disorders. [84] In one report, intraspinal anomalies coexisted with mediastinal masses in almost 25% of patients, and these anomalies were often asymptomatic initially. [85]

Gastric cysts, inclusion cysts without a smooth muscle wall, bronchogenic cysts, and neuroenteric cysts also rarely are found in the esophageal wall. [80]

Congenital duplication cysts can be seen on chest radiographs as posterior or middle mediastinal masses. On barium esophagram, a smooth, curved displacement of the esophagus is seen without the sharp, steplike proximal and distal margin seen with a leiomyoma.

Computed tomography can be helpful in determining the location, size, and anatomic relation to other organs. [86], [87] At endoscopy, a soft, compressible bulge into the esophageal lumen without overlying mucosal abnormality can be seen. [88] Endoscopic ultrasonography can define the structure of a duplication cyst. [89]

Surgical resection is usually recommended for definitive treatment and pathological diagnosis. [90], [91] Marsupialization has been used for the treatment of large cysts, and needle aspiration has been used to relieve tracheal compression from a duplication cyst. [92], [93] Although rare, the development of malignancy within a tubular or cystic duplication has been reported. [94], [95] and [96]

Bronchopulmonary Foregut Malformation

Bronchopulmonary foregut malformations are pulmonary sequestrations with a patent congenital communication to the upper gastrointestinal tract. [97], [98], [99], [100] and [101] Bronchopulmonary foregut malformations develop when cell rests with respiratory potential arise from the esophagus caudal to the lung bud or when a portion of the lung bud arises from the dorsal esophagus rather than the ventral trachea. [98] The tract within the sequestered pulmonary lobe typically involutes because of outgrowth of its blood supply; incomplete involution of the tract leads to a gastrointestinal tract communication. [99] Bronchopulmonary foregut malformations are most commonly seen in the lower lobes. The arterial supply and venous drainage are variable. [100], [101] Up to 40% of children with communicating bronchopulmonary foregut malformations have associated congenital anomalies. [102] The clinical presentation in infants is respiratory distress that is exacerbated with feedings. Congestive heart failure also may occur. In adults and older children, recurrent pneumonia, bronchiectasis, hemoptysis, gastrointestinal bleeding, and dysphagia may develop. [100] Contrast esophagram, bronchography, and angiography are used for diagnosis and surgical planning.

Aortic Arch Vessel Abnormalities

It has been estimated that 3% of the population have a congenital abnormality of the aortic arch vessels, but only rarely does this result in symptomatic compression of the esophagus. [103] In the embryo, the foregut is surrounded by vascular structures of the branchial arches. Normally, portions of the branchial arches obliterate to form the great vessels and aortic arch. Abnormalities in developmental obliteration of the branchial arches may lead to vascular compression of the trachea and esophagus. [104]

The term *dysphagia lusoria,* literally translated from the Latin *lusus naturae* ("trick of nature"), [105] is used to describe symptomatic esophageal compression resulting from any vascular anomaly of the aortic arch, but it usually results from an aberrant right subclavian artery. Symptoms of this anomaly may occur at the onset of semisolid feedings, later in childhood, or in adult life. With this anomaly, the right subclavian artery arises from the left side of the aortic arch and courses obliquely upward and posteriorly, compressing the esophagus (Fig. 58-9 *A*). It is estimated that aberrant right subclavian artery occurs in 0.5% to 1% of the population, with only 10% of these affected individuals having symptoms related to compression. [106] During esophageal endosonography performed in 3334 patients, an aberrant right subclavian artery was identified in 12 (0.36%). None of the patients had symptoms of this entity. [107] This is the vascular anomaly that most typically causes symptoms later in life, [108] although most patients with this condition do not have symptoms.

FIGURE 58-9. A: Angiography reveals an aberrant right subclavian artery (*arrow*) arising from the aortic arch. **B:** Barium esophagram in the same patient reveals oblique esophageal compression (*arrow*) by the aberrant right subclavian artery posterior to the esophagus.

Barium esophagram demonstrates an oblique filling defect just above the level of the aortic arch (see Fig. 58-9B). Aortic arch angiography has been the standard for diagnosis, although computed tomography and magnetic resonance imaging may be used for more precise delineation of this anomaly. Magnetic resonance imaging is particularly sensitive for this disorder and permits examination in both coronal and sagittal planes. Endoscopy may demonstrate a posterolateral pulsatile compression of the lumen. The right radial pulse may be weakened or obliterated by endoscopic compression of the vessel or during bougienage. [109], [110] Correction is performed in children by division and ligation of the aberrant artery. In adults, reanastomosis to the ascending aorta is performed to avoid the development of a subclavian steal syndrome. [111], [112] For patients with intractable dysphagia, a cervical approach has been reported to be successful, with ligation of the aberrant artery near its root and then connected to the right carotid artery. [113] Surgery is not always needed because many adult patients can easily tolerate minor degrees of dysphagia by simply modifying their diet. Asymptomatic persons not recognized to have this vascular anomaly pose a potential problem to the surgeon who operates on the neck, especially during a thyroidectomy. [105] In these patients, the inferior laryngeal nerve is displaced from its usual position and can easily be injured if not carefully identified.

Esophageal compression by an anomalous vertebral artery and right aortic arch with constricting left ligamentum arteriosum has been reported in adults and can be successfully repaired surgically. [114], [115] Other vascular anomalies are causes of tracheoesophageal compression in infants, and these require early surgical intervention. [116], [117]

Heterotopic Gastric Mucosa

Heterotopic gastric mucosa (inlet patch) can be seen occasionally in the esophagus during careful endoscopic inspection. Autopsy studies of infants and children indicate the prevalence of ectopic gastric mucosa as 7.8%. The majority of these are in the proximal one third of the esophagus. [118] Endoscopic studies reveal a prevalence of 2.8% to 10% of consecutive endoscopies. [119], [120] and [121] Inlet patches have been reported to occur in 5.6% of patients with Barrett esophagus but in none with achalasia. [122] It is provocative and interesting to speculate that this relationship has a pathogenetic significance.

At endoscopy, these areas of gastric mucosa typically are small, distinct patches of reddish orange or salmon-colored mucosa in the proximal 3 cm of esophagus (see Color Fig. 15-5 in *Atlas of Gastroenterology,* 3rd ed.). One report describes a patient with heterotopic mucosa in the left piriform sinus and cervical esophagus associated with a fistula. [123] This heterotopic mucosa, referred to as an *inlet patch* if it is found in the cervical esophagus, [119] can occur throughout the esophagus and can have a linear appearance. [124] Inlet patches can be dramatically demonstrated by injecting topical dilute iodine solution (i.e., Lugol) through an endoscopic cannula to stain the squamous mucosa around their margin. On biopsy, corpus-fundic or antral-type mucosa is seen, sometimes containing parietal cells capable of acid secretion. [125] Complications of TEF and adenocarcinoma arising from heterotopic gastric mucosa have been reported. [126], [127] and [128] An apparently increased risk for peptic esophagitis has been noted in biopsy specimens taken from squamous mucosa adjacent to these patches of columnar epithelium, some of which contain parietal cells. The degree of histological change typical of esophagitis appears to be inversely related to the distance from the margin of columnar epithelium at which the specimen is taken. [129] Other reported complications include cervical webs or rings. [130] Transendoscopic thermal ablation of an inlet patch combined with high-dose omeprazole therapy has been shown to allow replacement of the inlet patch by normal squamous mucosa, with resolution of related symptoms. [131]

Esophageal Rings and Webs

Mucosal Rings The lower esophageal mucosal ring, or "B" ring, was initially described by Templeton in 1944. [132] In 1953, Ingelfinger and Kramer [133] and Schatzki and Gary [134] independently described the association of lower esophageal mucosal rings with dysphagia. Lower esophageal mucosal rings are located at the level of the squamocolumnar mucosal junction. These rings consist of mucosa and submucosa and are covered by squamous mucosa on the proximal side and either columnar mucosa or several millimeters of squamous mucosa on the distal or gastric side. [135], [136] The true ring is circumferential, symmetric from all radiographic angles of view, and 3 mm or less in thickness (Fig. 58-10). Most lower esophageal mucosal rings are asymptomatic; however, they may be a cause of intermittent dysphagia and typically present in patients older than 40 years of age. [137], [138]

FIGURE 58-10. A: Barium esophagram demonstrates a lower esophageal ring at the upper end of a hiatal hernia pouch. **B:** Lower esophageal "B" or Schatzki ring. The ever-present hiatal hernia is shown below the ring. The ring margin is smooth, less than 3 mm thick, and without inflammation or evidence of fibrosis. **C:** Retroview into a small hiatal hernia, with the gastric folds effaced by inflation, reveals the appearance of a "B" or Schatzki ring with squamous mucosa over the caudal margin of the ring. The proximal, intrinsic muscular, segment of the lower esophageal sphincter is snugly closed around the endoscope (**top center**). This 12-mm

segment of squamous mucosa between the endoscope and the squamocolumnar junction that normally lies within the diaphragmatic hiatus represents the crural segment of the lower esophageal sphincter, displaced cephalad by the hiatal hernia.

The severity of symptoms depends on the diameter of the ring. Rings larger than 20 mm in diameter usually are asymptomatic, rings 13 to 20 mm in diameter cause variable degrees of dysphagia depending on type and size of bolus, and rings less than 13 mm in diameter regularly cause solid food dysphagia. [139], [140] True rings usually are not associated with inflammation, although serial esophagrams have confirmed unexplained development and progressive narrowing of true lower esophageal mucosal rings. [141], [142] and [143] A good deal of misunderstanding in the literature and in practice has resulted from confusing true rings with ringlike strictures caused by acid reflux. On esophagram, a lower esophageal mucosal ring appears as a thin (<3.0 mm) transverse circumferential ridge above the hiatus of the diaphragm. To visualize the ring, the region of the esophagogastric junction must be adequately distended (see Fig. 58-10 *A*). By definition, a hiatal hernia is always present. Mucosal or Schatzki rings are not present in patients with columnar cell–lined (Barrett) esophagus. Performing a Valsalva maneuver during the esophagram is helpful in demonstrating a ring. [144] Symptomatic mucosal rings are reproducible and do not disappear during radiographic examination. Barium esophagram with a prone full-column technique is more sensitive than double-contrast radiography or endoscopy in detecting many lower esophageal mucosal rings. [145] The use of a barium tablet or marshmallow bolus may further improve the sensitivity of the barium esophagram to correlate dysphagia with the ring. The endoscopic characteristics of lower esophageal rings and the associated findings should be understood by all endoscopists (see Fig. 58-10B,C). [146] These rings are different from ringlike strictures and are usually treated differently by dilation. Symptomatic lower esophageal rings should be treated (see Chapter 145). Most patients can be effectively treated with passage of a 16.5- to 20-mm (50F–60 F) Maloney dilator. [147] For very tight rings, some clinicians use the standard gradual peroral sequential dilation technique rather than passage of a single large-diameter bougie.

Muscular Rings The lower esophageal muscular ring, or "A" ring, occurs about 1.5 cm proximal to the squamocolumnar junction at a level that corresponds to the most cephalic segment of the lower esophageal sphincter. [14], [148] Muscular rings are seen most often in patients with esophageal motor disorders, gastroesophageal reflux, and hiatal hernia. The most common symptom associated with muscular rings is intermittent dysphagia. On barium esophagram, muscular rings are smooth, symmetric narrowings that are broader (4–5 mm) in longitudinal extent than mucosal rings. They may vary in caliber during radiographic examination and may disappear with full distention. [144] The treatment of symptomatic muscular rings by passing a 16.5- to 20-mm (50F–60F) Maloney dilator is helpful, but only for a limited time. Injecting botulinum toxin A into a hypertensive muscular ring also often provides symptomatic relief for a limited time. [149], [150] and [151]

Webs Esophageal webs are thin (1–2 mm) transverse membranes of squamous epithelium (see Color Fig. 15-7 in *Atlas of Gastroenterology,* 3rd ed.). They usually occur in the cervical esophagus, may originate from either wall, and are rarely circumferential. They may be multiple. Cine radiography performed for symptoms of dysphagia detected esophageal webs in 7% of patients in a large series. [152] Cervical esophageal webs have been reported to occur in association with heterotopic gastric mucosa, perhaps as the result of chronic injury caused by local acid production by oxyntic cells in the heterotopic gastric tissue. [130] The association of postcricoid webs with iron deficiency anemia (i.e., Plummer-Vinson or Patterson-Kelly syndrome) is rare. [152], [153], [154] and [155] However, this group of patients may be at increased risk for the development of pharyngeal and cervical esophageal carcinoma. [156], [157] Most webs are asymptomatic. Intermittent solid food dysphagia is the usual complaint in symptomatic patients. Midesophageal webs are rare and typically present with dysphagia. They may be single or multiple and are believed to be of congenital origin. [158], [159], [160], [161] and [162] They may be confused with congenital esophageal stenosis or the so-called ringed esophagus. [66], [68] If symptomatic, they are best treated with bougienage. Treatment with transendoscopic incision or surgical resection has been reported but is rarely necessary. [159], [160], [161], [162], [163] and [164]

PHARYNGOESOPHAGEAL DIVERTICULA

Pharyngoesophageal diverticulum was first described by Ludlow in 1769. [165] Zenker and Ziemssen subsequently reviewed the world literature in 1877–hence the association of Zenker's name with this condition. [166] Pharyngoesophageal or Zenker diverticula form from a protrusion of the posterior hypopharyngeal mucosa between the oblique fibers of the inferior pharyngeal constrictor and the transverse fibers of the cricopharyngeus (i.e., triangle of Killian) proximal to the esophagus. Debate has long continued regarding the mechanisms for the formation of pharyngoesophageal diverticula. [167] Evidence suggests that during swallowing, high hypopharyngeal pressures occur in some people because of poor compliance of the upper esophageal sphincter, and this may be important in the development of Zenker diverticula. [168] Associated neurological disorders, usually substantiated by cranial computed tomography or magnetic resonance imaging, have been found in up to 83% of cases. Basilar brain and brainstem lesions are most common. Peripheral neuropathies are found in some cases. [169]

Patients typically present after 50 years of age with a duration of symptoms ranging from weeks to years. Symptoms include dysphagia for both solids and liquids, regurgitation of undigested food, cough, and halitosis. If a large diverticulum is present, gurgling in the neck or a bulge in the left side of the neck can be seen during eating. Aspiration pneumonia or significant weight loss can occur. The diagnosis is obtained by barium swallow with lateral views of the pharyngoesophageal junction (Fig. 58-11). Caution must be used during the passage of nasogastric tubes or endoscopes because of the risk for inadvertent perforation of the diverticulum. Endoscopy is important for adequately evaluating the diverticulum. Passage of the endoscope over an endoscopically or fluoroscopically placed intraesophageal guidewire may be necessary in some instances to intubate the esophagus safely.

FIGURE 58-11. A: Anterior view of barium-filled Zenker diverticulum (*arrow*). The narrowed segment just distal to the diverticulum is the lumen of the cricopharyngeus. **B:** Lateral view of Zenker diverticulum (*arrow*) in the same patient. The prominent closure of the cricopharyngeus muscle (upper esophageal sphincter) is shown just distal to this diverticulum.

The usual approach to symptomatic pharyngoesophageal diverticulum is surgery. [170], [171] A dynamic videofluoroscopic examination or a manometric study of pharyngeal motility should be performed before cricopharyngeal myotomy to ensure adequate pharyngeal function. Cricopharyngeal myotomy is the primary surgical method in all cases, with either resection of the diverticulum or diverticulopexy. Diverticulectomy is preferred for diverticula larger than 3 cm, but in patients of advanced age or with significant comorbidity, diverticulopexy may be preferable therapy. Surgical morbidity and recurrence rates vary widely in reported surgical series.

Endoscopic therapy of Zenker diverticula has been tried with different techniques since 1917, but because of technical difficulties and complications, none has been considered ideal. [172] Techniques have included use of a diathermy knife, surgical stapling gun, and carbon dioxide laser diverticulotomy. [173], [174] and [175] The newest endoscopic method is performed with prior antibiotic prophylaxis, intravenous sedation, and topical anesthesia. The septum between the posterior wall of the proximal esophagus (cricopharyngeus muscle) and anterior wall of the Zenker diverticulum is incised with a needle-knife papillotome and electrical monopolar cautery. [176], [177] The patient may resume oral intake 18 hours after the procedure. In about two thirds of cases, a second procedure is needed to complete the myotomy for good dysphagia relief. Patients with chronic cough are not good candidates because they are at higher risk for cervical emphysema. Other complications, such as bleeding, stenosis, and fistula, are unusual. [176]

Postoperatively, radiographic recurrence appears to be more common than symptomatic recurrence. [177] Squamous cell carcinoma can complicate a long-standing pharyngoesophageal diverticulum. In a series of 1249 patients seen during a 53-year period, squamous cell carcinoma was found in 0.4%. [178] With barium swallow, carcinoma may appear as a persistent filling defect in an otherwise smooth-walled diverticulum. [179] Spindle cell carcinoma and benign tumors also have been reported to arise in pharyngoesophageal diverticula. [179], [180] Simple diverticulectomy has been recommended for localized tumor, with pharyngolaryngectomy reserved for more extensive disease. The 5-year survival for reported cases is 14%. [181]

ESOPHAGEAL DIVERTICULA

Midesophageal and Epiphrenic Diverticula

Diverticula also may occur in the middle or distal esophagus. It used to be thought that midesophageal diverticula developed secondary to traction from contiguous mediastinal inflammation and adenopathy (e.g., fungal, tuberculous). Evidence now indicates that these diverticula probably develop secondary to motility disorders.[182] In children, retained esophageal foreign bodies may be a cause.[183] Midesophageal diverticula can be large and wide-mouthed, small, or ultiple. The diagnosis is typically made by barium swallow (Fig. 58-12).

FIGURE 58-12. Barium radiograph demonstrates three diverticula: Zenker diverticulum (*upper arrow*), midesophageal diverticulum (*middle arrow*), and barium-filled epiphrenic diverticulum (*lower arrow*). This occurrence of three types of diverticula in the same patient is distinctly rare.

Distal esophageal or epiphrenic diverticula usually develop secondary to motility disorders, including achalasia. Dysphagia and chest pain are probably caused by the underlying motility disorder.[184] An epiphrenic diverticulum is seen on barium swallow as a smooth lateral pouch, usually protruding from the right wall just proximal to the lower esophageal sphincter (see Figure 58-12).

Endoscopically, a diverticulum appears as a smooth pouch off the axis of the esophageal lumen. As it enlarges, the mouth of the diverticulum may open in direct line with the axis of the proximal esophagus. If this occurs, food and fluid first enter the diverticulum and then enter the distal esophagus by spillover. Food impaction leads to enlargement of the diverticulum, regurgitation, dysphagia, and retrosternal discomfort. Dilation over a guidewire under fluoroscopy provides partial and temporary symptom relief in some patients with diverticula. Small diverticula are often asymptomatic, but transthoracic diverticulectomy may be needed for regurgitation and pulmonary sequelae. Botulinum toxin A injection of the lower esophageal sphincter has been effective in providing excellent relief of dysphagia, although of limited duration, in patients with epiphrenic diverticula associated with achalasia and other motility disorders.[150] The evolution of laparoscopic surgery now includes therapy for epiphrenic diverticula. A thorough presurgical evaluation, including barium esophagram, esophagoscopy, and esophageal manometry, should be carried out in all cases. Divertulectomy, accompanied by lower esophageal sphincter myotomy plus some degree of fundoplication, has been successfully accomplished via the laparoscopic transhiatal approach without complications in several cases.[185]

Esophageal Intramural Pseudodiverticulosis

Esophageal intramural pseudodiverticulosis is a rare condition, first described by Mendl and colleagues in 1960,[186] in which multiple small pseudodiverticula form in the wall of the esophagus by dilation of the excretory ducts of the submucosal esophageal glands.[187], [188]

Most patients present with chronic dysphagia.[186], [187] Esophageal strictures are seen in 70% to 90% of patients, and esophageal manometric abnormalities have been found in two thirds of those studied. Esophageal candidiasis has been described in up to 50% of reported cases; however, its role in the development of esophageal intramural pseudodiverticulosis is unknown.

The relation of corrosive injury of the esophagus to intramural pseudodiverticulosis has been emphasized.[189] A report of 14 cases of this entity in 59 patients with corrosive esophageal injury noted that an esophageal stricture was a constant association. No correlation was found between the length of the stricture and the number of diverticula, and the diverticula regressed in number or disappeared altogether after the stricture was dilated.

The treatment of esophageal intramural pseudodiverticulosis is directed toward underlying conditions. Dilation of strictures, antireflux therapy, and calcium channel blockers have been reported to relieve symptoms.[189], [190]

ESOPHAGEAL HIATAL HERNIAS

Hiatal hernia, one of the most common maladies of humans, is covered in detail in Chapter 60 and Chapter 71.

CHAPTER 59

Peter J. Kahrilas and John E. Pandolfino

MOTILITY DISORDERS OF THE ESOPHAGUS

One of the many complexities of the esophagus is that it encompasses the anatomic and physiological transition between two distinct regions, the oropharynx and the gut. The oropharynx is composed of striated muscle, controlled by the cerebral cortex and medulla, and is capable of precise tactile sensation; the distal esophagus is composed of smooth muscle, controlled by the vagus nerve and enteric nervous system, and is capable only of notoriously imprecise sensation. Between these end points, a gradual transition occurs within the esophagus. It follows from this arrangement that proximal esophageal motor dysfunction closely mimics that of the pharynx, whereas distal dysfunction is more akin to that observed in the remainder of the alimentary tract. Recognizing this natural grouping, this chapter on motility disorders of the esophagus first considers oropharyngeal dysphagia, which includes most physiological aberrations of the upper esophageal sphincter (UES) and proximal esophagus, and then focuses on purely esophageal motor disorders, which include considerations mainly relevant to the distal smooth muscle esophagus.

OROPHARYNGEAL SWALLOWING DISORDERS

Oropharyngeal dysphagia is associated with high morbidity, mortality, and cost. Estimates of the prevalence of dysphagia among persons older than 50 years of age range from 16% to 22%. [1], [2] Within health care institutions, it is estimated that up to 13% of hospitalized patients [3] and 60% of nursing home residents [4] have feeding problems, most of which are attributed to oropharyngeal dysfunction, as opposed to esophageal dysfunction. The consequences of oropharyngeal dysphagia are severe: dehydration, malnutrition, aspiration, choking, pneumonia, and death. In fact, mortality of nursing residents with dysphagia and aspiration can be as high as 45% over 1 year. [5] As our population continues to age, oropharyngeal dysphagia will become an increasing problem associated with complex medical and ethical issues.

Mechanics of Swallow

Oropharyngeal swallowing begins with an oral phase that is then followed by a pharyngeal phase. The oral phase of swallowing is largely voluntary and is highly variable depending on, for example, taste, environment, hunger, and motivation. Disorders of the oral phase of swallowing occur with many conditions characterized by global neurological dysfunction such as head trauma, cerebral tumors, or chorea. Detailed discussion of these conditions can be found in texts on swallow evaluation and therapy. [6], [7] The pharyngeal phase of swallowing is the complex oropharyngeal contractile event referred to as the *swallow response.* Afferent sensory fibers capable of triggering the pharyngeal swallow travel centrally through the internal branch of the superior laryngeal nerve (from the larynx) and through the glossopharyngeal nerve (from the pharynx). [8] These sensory fibers converge before terminating in the medullary swallow center. The location and architecture of the medullary swallowing center have been extensively investigated. [9] The evolving model is summarized in Figure 59-1. [10] The clinical significance of this neuronal architecture is that swallowing is relatively resistant to disturbance by diseases affecting brain centers higher than the medulla. However, medullary motor neuron diseases such as bulbar poliomyelitis or amyotrophic lateral sclerosis can lead to severe dysfunction.

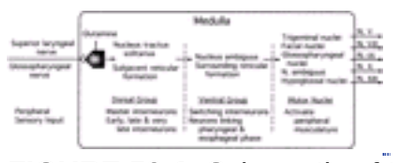

FIGURE 59-1. Schematic of the neural organization of the pharyngeal swallow response. Sensory input enters the medulla at and below the nucleus of the solitary tract, and motor output exits through five cranial nerves. The presumed function of each group of neurons is itemized beneath each anatomical grouping. The “master neurons” that establish the timing of sequential excitation of specific cranial motor nuclei are believed to be among the dorsal group, located in and around nucleus tractus solitarius. Once activated, the master neurons can establish the entire motor sequence of the swallow without further sensory input. Also among the dorsal group are interneurons activated at specific times within the swallow pattern, corresponding to the activity of specific groups of pharyngeal and esophageal muscles. Depending on the temporal relationship of neuronal activity with the onset of deglutition, these medullary neurons are classified as “early,” “late,” or “very late” neurons. The second group of interneurons located in and around the nucleus ambiguus probably function as switching neurons to relay the swallowing orders from the dorsal pattern generators to the various motor neuron pools involved in enacting the muscular response. (From Kahrilas PJ. Functional anatomy and physiology of the esophagus. In: Castell DO, ed. The esophagus, 2nd ed. Boston: Little, Brown, 1995:1.)

Although understood physiologically as the patterned activation of motor neurons and their corresponding motor units, swallowing is clinically evaluated in mechanical terms, specifically, the effect of this motor activity on the configuration of the oropharyngeal cavity. The anatomic complexity of the oropharynx is best evaluated by videofluoroscopic or cineradiographic analysis. The major events within the pharyngeal swallow are illustrated by representative x-ray images and three-dimensional reconstructions in Figure 59-2. Evident in this figure, swallowing results in the transient geometric rearrangement of pharyngeal structures from a respiratory to an alimentary pathway that is normally accomplished and reversed within 1 second. The overall swallow response can be subdivided into several closely coordinated actions:

- Nasopharyngeal closure by elevation and retraction of the soft palate
- UES opening
- Laryngeal closure
- Tongue loading (ramping)
- Tongue pulsion
- Pharyngeal clearance.

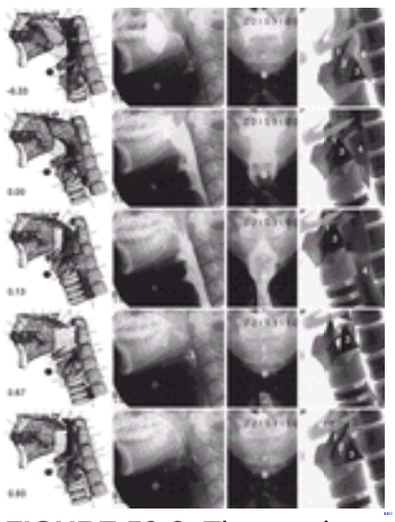

FIGURE 59-2. The oropharyngeal swallow as imaged by videofluoroscopy and is reconstructed in three dimensions with computer graphics. From **left** to **right,** each horizontally arranged group of images contains the three-dimensional reconstruction of the pharyngeal cavity and surrounding structures, the lateral radiographic appearance of the pharynx during a 10-mL barium swallow, the corresponding posteroanterior radiographic appearance, and a magnified view of the hypopharynx at the instant in time indicated at the **left.** Time 0.00 is the instant of upper esophageal sphincter (UES) opening; the entire sequence of events transpires within 1 second. The metal sphere under the chin is used to correlate among images. In the magnified hypopharyngeal reconstructions, *1* is the epiglottis, *2* is the laryngeal vestibule, *3* is the arytenoid cartilage, *4* is the esophagus, and *4'* is the pyriform sinus after closure of the UES. Note the importance of laryngeal elevation during the pharyngeal reconfiguration and synchrony of UES opening with laryngeal vestibule closure.

Precise coordination of these actions is an obvious imperative, and early attempts at defining that coordination focused on timing these individual elements of the swallow response relative to each other. However, that timing is affected both by volition and by the volume of the swallowed bolus, making it difficult to establish a universal temporal reference among elements. A detailed analysis of the coordination among swallow events concluded that there is, in fact, constant coordination at the beginning and end of the swallow but variability in how long the alimentary pharyngeal configuration persists before reverting to the respiratory configuration. [11] Thus, to construct a time line of the biomechanical events within the swallow and still preserve the constancy of the most stereotyped aspects of the swallow, onset events must be timed from the beginning and offset events from the end, as illustrated in Figure 59-3.

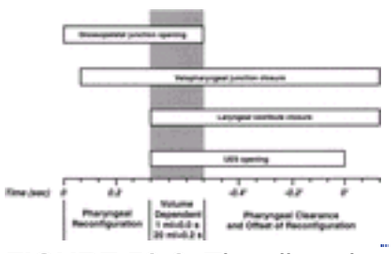

FIGURE 59-3. Time line showing the coordination and volume-induced modifications in the timing of events within the pharyngeal swallow. Each *horizontal bar* depicts the period during which one of the oropharyngeal valves is in its swallow configuration, as opposed to its configuration during respiration. Events at the onset and offset of pharyngeal reconfiguration bear a fixed time relation to each other regardless of swallow bolus volume. The stereotypy of these phases is demonstrated by referencing onset events from *time 0,* counting forward, and offset events from *time 0',* counting forward or backward, respectively. This timing scheme defines the volume-dependent, middle portion of the time line (*shaded*) that has a value of 0 for 1-mL swallows and 0.2 seconds for 20-mL swallows. Thus, the alteration in the timing of the swallow response with larger-volume swallows occurs by prolonging the persistence of pharyngeal reconfiguration without changing the synchrony of events at onset or offset. (From Kahrilas PJ, Lin S, Chen J, Logemann JA. Oropharyngeal accommodation to swallow volume. Gastroenterology 1996;111:297.)

The most fundamental anatomic reconfiguration required to transform the oropharynx from a respiratory to a swallow pathway is to open the inlet to the esophagus and to seal the inlet to the larynx. As suggested in Figure 59-2 and Figure 59-3, these events occur in close synchrony. On examining Figure 59-2, it is apparent that the larynx exhibits substantial axial mobility, and the UES is obligated to move with the larynx because the cricopharyngeus attaches to the lateral aspects of the cricoid cartilage and the lamina of the cricoid underlies the anterior wall of the sphincter. The mechanical determinants of UES opening are laryngeal elevation and anterior traction on the hyoid. [12], [13] The mechanical determinants of laryngeal vestibule closure, which is almost exactly synchronized with UES opening, are laryngeal elevation and anterior tilting of the arytenoid cartilages against the base of the epiglottis. [7] Thus, analyzing the efficacy of either of these events inevitably focuses on laryngeal elevation, which is greater and persists longer for larger volume swallows. [14] UES relaxation occurs at roughly the same degree of elevation regardless of swallow volume, and it precedes sphincter opening by about 0.1 second. What changes with swallow volume is the persistence of laryngeal elevation above this critical value, consistent with the scheme of Figure 59-3. It is important to recognize the distinction between UES relaxation and UES opening. UES relaxation results from cessation of excitatory neural input while the larynx is elevating. Once the larynx is elevated, UES opening results from traction on the anterior sphincter wall caused by contraction of the suprahyoid and infrahyoid musculature that also results in a characteristic pattern of hyoid displacement. [12], [13] Both the diameter and the duration of sphincter opening increase with increased bolus volumes.

The two main determinants of bolus transport out of the oropharynx are the actions of the tongue and of the pharyngeal constrictors. In the case of the pharyngeal constrictors, the propagated pharyngeal contraction has similar propagation and vigor regardless of bolus volume. [15] However, the propagated pharyngeal contraction is more involved with the process of clearance than of bolus propulsion; it strips the last residue from the pharyngeal walls. Tongue motion, conversely, varies substantially with bolus volume, suggesting that it has a cardinal role in determining differences in bolus propulsion among swallow volumes. [16]

UES closure coincides with the arrival of the propagated pharyngeal contraction, as evident by the fixed time relationship between these events. [13] However, the contractile activity of the sphincter has an added dimension as well, exhibiting increased electromyographic activity during laryngeal descent. [17] The magnitude of this deglutitive UES contractile activity is further augmented by either sphincteric or proximal esophageal distention. The net result is a grabbing effect in which reflexive contraction of the sphincter and laryngeal (UES) descent complement each other to clear residue from the hypopharynx. [18] This clearing function probably acts to minimize the risk of post-swallow aspiration by preventing residual material from adhering to the laryngeal inlet when respiration resumes.

Evaluation and Classification of Oropharyngeal Dysphagia

The evaluation of patients with presumed oropharyngeal dysphagia should focus on five fundamental questions:

1. Does the patient describe dysphagia, as opposed to globus sensation or xerostomia?
2. Is the dysphagia oropharyngeal or esophageal in origin?
3. Is the dysphagia secondary to a structural or functional disorder?
4. Is there an underlying related or causative disorder?
5. Should therapy be directed toward the underlying cause or the dysphagia itself?

These questions can usually be answered with a careful history and physical examination. However, further diagnostic tests may be needed to determine both the cause of oropharyngeal dysphagia and the proper treatment.

The patient history is crucial in the evaluation of oropharyngeal dysphagia. Major objectives of the history are to differentiate oropharyngeal dysphagia from esophageal dysphagia, xerostomia, or globus sensation. Whereas patients almost invariably accurately recognize the locus and consequence of oropharyngeal dysphagia, they mistakenly identify the neck as the locus of bolus hang-up with esophageal dysphagia about 30% of the time. Therefore, elicitation of symptoms such

as aspiration, coughing, nasopharyngeal regurgitation, or drooling are of great value in distinguishing oropharyngeal dysphagia from proximally referred esophageal dysphagia.

Distinguishing oropharyngeal dysphagia from globus sensation can be particularly vexing. Unlike dysphagia, which occurs only during swallowing, globus sensation is prominent between swallows. Patients relate the nearly constant sensation of having a lump in their throat or feeling a foreign object caught in their throat. In some instances, globus sensation is associated with reflux symptoms and in others with substantial anxiety; that anxiety is sometimes thought to be etiologic (globus hystericus). Unfortunately, studies have failed to define an objective anatomic or physiological cause for globus sensation, and we are left with the crucial data being in the history; globus sensation persists regardless of the act of swallowing.

Physical examination may help to identify features of the underlying systemic or metabolic disorder or to localize the neuroanatomic level and severity of a causative neurological lesion when present. The patient's general condition should be assessed to determine the degree that dysphagia is affecting fluid and nutritional status. Patients may require hydration and correction of electrolyte abnormalities before a thorough examination is undertaken. Examination of the oral cavity, head, and neck for masses, lymph nodes, goiter, and evidence of previous surgery or radiation therapy will help to define structural abnormalities associated with dysphagia. Neurological examinations may indicate cranial nerve dysfunction, neuromuscular disease, cerebellar dysfunction, or an underlying movement disorder. Of note, contrary to popular belief, the gag reflex is not predictive of pharyngeal swallowing efficiency or aspiration risk. The gag reflex is absent in 20% to 40% of physiologically normal adults. [19]

If the cause of oropharyngeal dysphagia is not readily apparent after initial evaluation, further diagnostic studies are indicated. Because the management implications are so different, *the first task in the evaluation of suspected oropharyngeal dysphagia is to distinguish between structural and functional etiologies.* Structural abnormalities that may result from trauma, surgery, tumors, caustic injury, congenital anomalies, or acquired deformities are identified by endoscopic or radiographic examination. Functional abnormalities can be attributable to dysfunction of intrinsic musculature, peripheral nerves, or central nervous system control mechanisms. Endoscopy may be performed either transorally or transanally to identify tumors, webs, or hypopharyngeal diverticula. Barium studies may define areas of obstruction and hypopharyngeal diverticula; however, they add little structural information to endoscopic studies.

After structural defects have been excluded, videofluoroscopic evaluation of swallowing is used for a functional evaluation. This approach is frequently referred to as a modified barium swallow, which Logemann [7] described as a protocol composed of a series of swallow tasks. Images are obtained in a lateral projection, framed to include the oropharynx, palate, proximal esophagus, and proximal airway. These images are then evaluated with respect to four major categories of oropharyngeal dysfunction:

1. Inability or excessive delay in initiation of pharyngeal swallowing
2. Aspiration
3. Nasopharyngeal regurgitation
4. Residue of the ingestate within the pharyngeal cavity after swallowing.

Furthermore, the procedure allows for evaluation of the efficacy of various compensatory dietary modifications, postures, and swallowing maneuvers in compensating for observed swallowing dysfunction.

Intralumenal manometry can quantify the strength of pharyngeal contraction, the completeness of UES relaxation, and the relative timing of these events. When coupled with concurrent videofluoroscopy, it may provide useful complementary information regarding UES dysfunction. High intrabolus pressures may distinguish impaired UES opening from impaired UES relaxation and weak pharyngeal contractions as a cause of oropharyngeal dysphagia.

Structural Causes of Oropharyngeal Dysphagia

Implicit in the mechanical description of swallowing summarized earlier is that normal swallowing is associated with minimal outflow resistance from the oropharynx. Identification of obstructing lesions that cause dysphagia will lead to specific management in most cases. For example, cervical webs and pharyngeal or cricopharyngeal strictures or tumors are indications for surgery, dilation, antineoplastic therapy, or some combination of these treatments. In the setting of benign lesions such as strictures or postcricoid webs, simple dilation is safe and effective. Cervical osteophytes, if prominent, can also cause obstructive dysphagia. Because the posterior wall of the pharynx is so closely opposed to the anterior aspect of the cervical vertebrae, cervical osteophytes result in an anterior bulging into the hypopharynx that can make passage of a normal-sized bolus difficult. [20] The most common structural abnormalities of the hypopharynx associated with dysphagia are hypopharyngeal diverticula and cricopharyngeal bars. Given the interplay between both structural and functional defects involved in these two disorders, further consideration is merited.

Hypopharyngeal Diverticula and Cricopharyngeal Bars Acquired hypopharyngeal diverticula are most common in men after the age of 60 years. The most frequent site of herniation is Killian's dehiscence between the oblique fibers of the inferior pharyngeal constrictor and the cricopharyngeus muscle in the midline posteriorly, this being the location of a Zenker diverticulum (Fig. 59-4). [21] Other locations of acquired pharyngeal diverticula include the lateral slit separating the cricopharyngeus muscle from the fibers of the proximal end of the esophagus through which the recurrent laryngeal nerve and its accompanying vessels run to supply the larynx, the location of penetration of the inferior thyroid artery into the hypopharynx, and the junction of the middle and inferior constrictor muscles. The unifying theme of these locations is that they are sites of potential weakness of the muscular lining of the hypopharynx. Hypopharyngeal diverticula are often asymptomatic until they enlarge sufficiently to store a significant amount of food or liquid. In most instances, symptoms are dysphagia, halitosis, post-swallow regurgitation, or even aspiration of material from the pharyngeal pouch.

FIGURE 59-4. Radiograph of a large Zenker diverticulum partially filled with barium. Although the point of herniation is midline posterior, the diverticulum necessarily migrates laterally in the neck because there is no potential space between the posterior pharyngeal wall and the vertebral column.

Hypopharyngeal diverticula have been hypothesized to result from delayed UES relaxation, failure of relaxation, or premature contraction. [22] However, few data and considerable contradiction accompany each of these hypotheses. A more plausible explanation for the development of diverticula is that they form as a result of a restrictive myopathy associated with diminished compliance of the cricopharyngeus muscle. Surgical specimens of cricopharyngeus muscle strips from 14 patients with hypopharyngeal diverticula demonstrated structural changes that would decrease UES compliance and opening. [23] The cricopharyngeus samples from these patients had "fibro-adipose tissue replacement and (muscle) fiber degeneration." Thus, although the muscle relaxes normally during a swallow, it cannot distend normally, resulting in the appearance of a cricopharyngeal indentation, or bar, during a barium swallow (Fig. 59-5). Diminished sphincter compliance necessitates increased hypopharyngeal intrabolus pressure to maintain transsphincteric flow through the smaller UES opening. The increased stress on the hypopharynx from the increased intrabolus pressure may lead to the formation of hypopharyngeal diverticula.

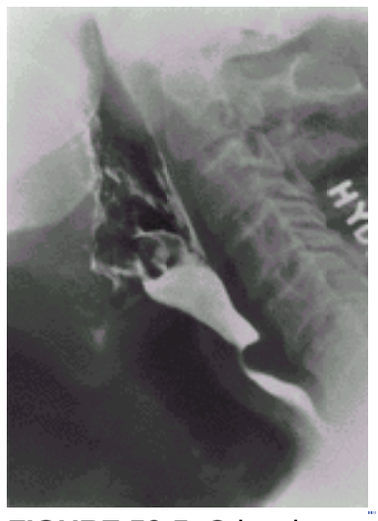

FIGURE 59-5. Cricopharyngeal bar in a patient with oropharyngeal dysphagia. The posterior indentation of the barium column is caused by a noncompliant cricopharyngeus muscle. (Courtesy of Dr. Richard Gore.)

Management of Structural Oropharyngeal Dysphagia The treatment of hypopharyngeal diverticula is cricopharyngeal myotomy with or without diverticulectomy. Cricopharyngeal myotomy reduces both the resting sphincter tone and resistance to flow across the UES. Resting UES tone is reduced to approximately 50% of baseline, suggesting that the derived benefit is from increased compliance at the UES. One study found that the compliance of the sphincter after diverticulectomy with myotomy was restored to normal in five patients after surgery, as indicated by normal hypopharyngeal intrabolus pressure during swallowing. [24] Good or excellent results can be expected in 80% to 100% of patients with Zenker diverticula treated by transcervical myotomy combined with diverticulectomy or diverticulopexy. [25] There are instances in which a limited procedure would be adequate, but a definitive approach to the problem of pulsion diverticula should involve both diverticulectomy and myotomy. Diverticulectomy alone risks recurrence because the underlying stenosis at the level of the cricopharyngeus is not remedied. Similarly, myotomy alone risks not solving the problem of food accumulation within the diverticula, with attendant regurgitation and aspiration. Small diverticula may, however, disappear spontaneously after myotomy. Whether a cricopharyngeal bar in the absence of a diverticula requires treatment is less clear. Certainly, if dysphagia exists and combined fluoroscopic and manometric analysis demonstrates reduced sphincter opening in conjunction with elevated upstream intrabolus pressure, there is good rationale for treatment. Anecdotal evidence suggests that, in this situation, simple dilation with a large-caliber bougie may be efficacious, and this is certainly a reasonable treatment option before myotomy.

Functional Causes of Oropharyngeal Dysphagia

Primary neurological or muscular diseases involving the oropharynx can be associated with dysphagia. Thus, whereas esophageal dysphagia usually results from esophageal diseases, oropharyngeal dysphagia is frequently the result of neurological or muscular diseases, with oropharyngeal dysfunction being just one pathological manifestation. Although the specifics of the diseases vary, the net effect on swallowing can be analyzed according to the mechanical description of the swallow outlined earlier. Table 59-1 summarizes the mechanical elements of the swallow along with the manifestation and consequence of dysfunction and representative pathological conditions in which they are likely encountered. Some of the more distinct pathological entities are discussed in the following sections.

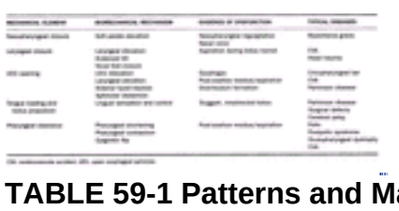

TABLE 59-1 Patterns and Manifestations of Oropharyngeal Dysphagia

Neurological Causes Neurological diseases can damage the neural structures requisite for either the afferent or efferent limbs of the oropharyngeal swallow. Because there is nothing unique to neurons that control swallowing, their involvement in disease processes is usually random. Furthermore, in most instances, functions mediated by adjacent neuronal structures are concurrently involved. Virtually any disease of the central nervous system can potentially cause dysphagia. The following discussion focuses on neuropathological processes with the best-characterized patterns of dysphagia.

Cerebrovascular accidents. Aspiration pneumonia has been estimated to have a 20% death rate in the first year after a *stroke* and 10% to 15% each year thereafter. [26] It is usually not the first episode of aspiration pneumonia but the subsequent recurrences over several years that will eventually cause death. [27] The ultimate cause of aspiration pneumonia is dysphagia leading to aspiration, which can occur by numerous mechanisms: absence or severe delay in triggering the swallowing reflex (swallow apraxia), reduced lingual control, and unilateral or bilateral weakened laryngopharyngeal musculature. [7] Conceptually, these causes can be divided into motor or sensory impairments. Although sensory and motor impairment frequently coexist, each is addressed separately. Consistent with the neuronal architecture outlined in Figure 59-1, cortical strokes are less likely to result in dysphagia than are brainstem strokes. [28] In a report of 100 consecutive patients, 37 of 86 (43%) who sustained an acute cerebral infarct experienced dysphagia when they were evaluated within 4 days of the event. [28] However, 86% of these patients were able to swallow normally 2 weeks later. Two-dimensional scalp topographic maps of the pharyngeal muscles obtained by transcranial magnetic stimulation suggests that recovery occurs as a result of contralateral areas' taking over the lost function. [29] Thus, dysphagia is more prevalent among patients incurring larger strokes or in patients who have had prior infarcts. The sensory cues required for eliciting the pharyngeal swallow are unclear. In pathological circumstances in which one or the other neural substrate of the afferent signal has been damaged, patients may experience a relative inability to initiate a swallow. A study of sensory acuity in the supraglottic and pharyngeal regions in patients who had suffered strokes revealed either unilateral ($n = 9$) or bilateral ($n = 6$) sensory impairment of moderate to severe degree in all 15 patients studied. [30] Impaired sensation in these critical areas likely results in swallow apraxia. An interesting compensatory strategy for this sensory defect is to accentuate oropharyngeal stimulation during eating to facilitate achieving the threshold for triggering the medullary swallowing center. [7] Preliminary data suggest that the sour bolus is particularly effective in some patients with swallow apraxia, and this provides some hope for the treatment of this disabling condition. [7]

Poliomyelitis. Most cases of *poliomyelitis* involve only the spinal cord; however, the fatality rate from bulbar disease far exceeds that of spinal disease, with the most common fatal complication being respiratory depression. In addition to its dreaded effect of respiratory depression, bulbar poliomyelitis is also associated with dysphagia. In one analysis of the persistent sequelae of bulbar poliomyelitis, 28 of 47 patients (60%) had recurrent or continued involvement of the pharynx 17 or more months after their acute illness. [31] Speech and swallowing dysfunctions are the result of weakness of the levator veli palatini muscle, pharyngeal constrictors, and hyolaryngeal elevators. [32] Neurologists have observed an increasing number of patients with new paretic symptoms traceable to their remote poliomyelitis infection 30 to 40 years earlier. The slowly progressive postpolio muscular atrophy may occur in muscles that were clinically unaffected by the acute illness. [33] One investigation studied 13 patients with postpolio dysphagia and demonstrated palatal, pharyngeal, and laryngeal weakness. [34] Over half of the patients evaluated demonstrated silent aspiration, suggesting that the clinician should maintain a low threshold for evaluating such patients with videofluoroscopy. Accumulating evidence suggests that at least some of these patients with postpolio syndrome respond to pyridostigmine (Mestinon), a cholinomimetic agent.

Amyotrophic lateral sclerosis. *Amyotrophic lateral sclerosis* is a progressive neurological disease characterized by degeneration of motor neurons in the brain, brainstem, and spinal cord. Specific symptoms are dependent on the locations of affected motor neurons and the relative severity of involvement. When the degenerative process involves the cranial nerve nuclei, swallowing difficulties ensue. Oropharyngeal dysfunction characteristically begins with the tongue and progresses to involve the pharyngeal and laryngeal musculature. Patients experience choking attacks, become dehydrated or malnourished, and incur aspiration pneumonia. The decline in swallowing function is progressive and predictable, invariably leading to gastrostomy feeding. Some patients die as a consequence of their swallowing dysfunction in conjunction with respiratory depression. [35]

Parkinson disease. Although only 15% to 20% of patients with *Parkinson disease* complain of swallowing problems, more than 95% have demonstrable defects videofluoroscopically. [7], [36] The disparity between these numbers suggests that patients compensate effectively during the early stages of the disease and complain of dysphagia only when it becomes severe. Abnormalities of the oral phase of swallowing include repetitive lingual pumping before initiation of a pharyngeal swallow, piecemeal swallowing, and oral residue after the swallow. [7], [36] Patients may also exhibit a delayed swallow response and a weak pharyngeal contraction, resulting in vallecular and pyriform sinus residue after each swallow. [36] Combined manometric and fluoroscopic data suggest this to be related to the combination of incomplete UES relaxation and a weakened pharyngeal contraction. [36] Although no controlled trials are available, dysphagic symptoms have improved after therapy with levodopa

and carbidopa. [37], [38]

Tumors. Medullary or vagal *tumors* are potentially debilitating with respect to swallowing. Astrocytomas are the most common histological subtype affecting adults, whereas medulloblastomas are the most common type encountered in children. [39] The relative inaccessibility of the medulla to surgery usually means that substantial morbidity is incurred during attempted resection or palliation. Unilateral lesions of the vagus nerve can result in hemiparesis of the soft palate and pharyngeal constrictors, as well as of the laryngeal musculature. Surgical manipulation of this region can even result in complete loss of the pharyngeal swallow response. [40] The recurrent laryngeal nerves can be injured as a result of thyroid surgery, poliomyelitis, aortic aneurysms, pneumonectomy, primary malignant tumors of the mediastinum, or metastatic lesions to the mediastinum. Owing to its more extensive loop into the chest, the left recurrent laryngeal erve is more vulnerable to involvement with mediastinal node malignancy. Unilateral recurrent laryngeal nerve injury results in unilateral adductor paralysis of the vocal cords. This defect can result in aspiration during swallowing because of impaired laryngeal closure. Although some reports state the contrary, [41] it is probably rare to have any primary pharyngeal dysfunction associated with recurrent laryngeal nerve injury.

Muscular Diseases Primary muscular diseases involving the oropharynx are associated with dysphagia reflective of the pattern of involvement. Nasal voice and nasopharyngeal regurgitation indicate either weakness or paresis of the soft palate elevators, and tongue weakness can cause poor control of the bolus within the mouth. Post-swallow residue in the valleculae or hypopharynx reflects an ineffective, presumably weakened pharyngeal contraction. Aspiration suggests either weakened laryngeal elevators or post-swallow residue that is then aspirated after the swallow sequence is completed. As with neurological disorders, virtually any disorder affecting skeletal muscle can result in dysphagia. The following discussion focuses on a few of the better characterized entities.

Oculopharyngeal dystrophy. *Oculopharyngeal muscular dystrophy* is a syndrome characterized by progressive dysphagia and palpebral ptosis first described by Taylor in 1915. [42] He noted that all of his afflicted patients reaching age 50 years died of starvation resulting from pharyngeal paralysis. [42] The disease is now known to be a form of muscular dystrophy inherited as an autosomal dominant disease with occurrences clustered in families of French-Canadian descent. Genetic studies of an afflicted family indicate linkage to chromosome 14, perhaps involving the region coding for cardiac a or ß myosin heavy chains. [43] Oculopharyngeal dystrophy affects the striated pharyngeal muscles and the levator palpebrae. Other forms of muscular dystrophy occasionally affect the pharyngeal constrictors but rarely, if ever, is this a dominant manifestation. The first symptom of oculopharyngeal dystrophy is usually ptosis, which develops slowly and eventually dominates the patient's appearance. Dysphagia may begin before the ptosis but is more often manifest simultaneously with it or a few years later. The dominant functional abnormalities are weak or absent pharyngeal contraction with hypopharyngeal stasis. [44] Dysphagia progresses slowly but may ultimately lead to starvation, aspiration pneumonia, or asphyxia.

Myotonic dystrophy. *Myotonic dystrophy* is a rare disorder characterized by prolonged contraction and difficulty in relaxation of involved skeletal musculature. Dysphagia is a common complaint among affected patients. Early investigations suggested that the dysphagia was the result of myotonia of the cricopharyngeus with resultant overflow into the airway during attempted swallowing, [45] but subsequent manometric and radiographic investigations have not confirmed this. [46] The experience in more recent investigations was that even though only half of the patients studied complained of dysphagia, motor abnormalities could be demonstrated in every patient studied. The pattern of abnormality was of a weakened pharyngeal contraction, absent peristalsis in the striated muscle esophagus, and diminished or absent peristalsis in the smooth muscle portion of the esophagus. No study has demonstrated myotonia in any part of the esophagus. Thus, the consequences of the disease are identical to other forms of muscular dystrophy; poor pharyngeal clearance with risk of aspiration during the swallow if there is concurrent weakness of the laryngeal elevators or after the swallow, when the substantial pharyngeal residue may fall into the reopened airway.

Myasthenia gravis. *Myasthenia gravis* is a progressive autoimmune disease characterized by high circulating levels of acetylcholine receptor antibody and destruction of acetylcholine receptors at neuromuscular junctions. Musculature controlled by the cranial nerves is almost always involved, particularly the ocular muscles. Dysphagia is prominent in more than one third of patients with myasthenia gravis, and, in unusual instances, it can be the initial manifestation of the disease. [7] In mild cases, dysphagia may not be evident until after 15 to 20 minutes of eating. Classically, manometric studies reveal a progressive deterioration in the amplitude of pharyngeal contractions with repeated swallows. Peristaltic amplitude recovers with rest or after the administration of 10 mg edrophonium chloride. [47] In more advanced cases, the dysphagia can be profound and associated with nasopharyngeal regurgitation and nasality of the voice, even to the extent of being confused with bulbar amyotrophic lateral sclerosis or brainstem stroke. [48]

Management of Functional Oropharyngeal Dysphagia Management of functional causes of oropharyngeal dysphagia begins with definition of the aberrant physiology along the lines summarized in Table 59-1. This is most easily accomplished with a videofluoroscopic swallowing study. After definition of the patient's swallowing dysfunction, four specific issues pertaining to management of oropharyngeal dysphagia can be addressed:

1. Identification of an underlying systemic disease
2. Characterization of a disorder amenable to surgery or dilation
3. Identification of a specific pattern of dysphagia amenable to swallowing therapy
4. Assessment of aspiration risk.

Identifying underlying disease. A potential outcome of the swallowing evaluation is the identification of an underlying neuromuscular, neoplastic, or metabolic disorder that will dictate specific management. For example, dysphagia can be the presenting symptom in patients with myopathy, myasthenia, thyrotoxicosis, motor neuron disease, or Parkinson disease. In each instance, identification of the underlying disease will result in specific treatment. Whether identification and treatment of the underlying disorder improve swallowing function depends on both the natural history of the disease and the existence of effective treatment.

Disorders amenable to surgery. In marked contrast to the high efficacy observed with structural cricopharyngeal disorders, the efficacy of myotomy in neurogenic dysphagia is variable. Furthermore, most series evaluating the efficacy of myotomy in neurogenic dysphagia are uncontrolled, without specific outcome measures. Thus, although an overall favorable response rate in excess of 60% is reported, there are currently no validated criteria for preoperative selection. Theoretically, the functional limitation in these circumstances is of pharyngeal propulsion, and the potential benefit of myotomy is less obvious. [49]

Specific patterns of dysphagia amenable to swallowing therapy. After characterization of a patient's swallow dysfunction, the radiographic study should proceed to test selected compensatory or therapeutic treatment strategies. Compensatory treatments include postural changes, modifying food delivery or consistency, or the use of prosthetics. For instance, head turning can eliminate aspiration or pharyngeal residue by favoring more functional structures in patients with hemiparesis. [7] Similarly, diet modifications can reduce the "difficulty" of the swallow. [7] Therapeutic strategies are designed to alter the physiology of the swallow, usually by improving the range of motion of oral or pharyngeal structures using voluntary control of oropharyngeal movement during swallow. Depending on the severity of the impairment, level of motivation, and global neurological intactness, defective elements of the swallow can be selectively rehabilitated. For a detailed description of the techniques and limitations of swallow therapy, the reader is referred to treatises on the topic. [7], [25]

Detection of severe aspiration. Oropharyngeal dysphagia associated with aspiration is responsible for an estimated 40,000 deaths a year from aspiration pneumonia. [30] Videofluoroscopy is believed to be the most sensitive test for detecting aspiration that is not evident by bedside evaluation in 42% to 60% of patients. However, despite the logical association between deglutitive aspiration and the subsequent development of pneumonia, this sequence is not inevitable. In fact, available data suggest that radiographic aspiration has a positive predictive value of only 19% to 68% and a negative predictive value of 55% to 97% for pneumonia. [25] Nonetheless, the balance of evidence suggests that detection of aspiration is a predictor of pneumonia risk, and its detection dictates that compensatory swallowing strategies, nonoral feeding, or corrective surgery be instituted. Whether nonoral feeding eliminates the risk of aspiration is controversial. A provocative finding by Croghan and associates [5] was that, in 22 patients with radiographic aspiration, pneumonia and death were more frequent among patients who received feeding tubes. This finding suggests that aspiration of oral secretions may be important in determining pneumonia risk and has led some clinicians to consider procedures such as tracheostomy to protect the airway.

Xerostomia Although not an esophageal motility disorder, *xerostomia* (the subjective feeling of oral dryness) is covered briefly, given its association with dysphagia. Xerostomia is usually associated with reduced salivary secretion. The normal, unstimulated salivary flow rate should be 0.3 to 0.5 mL/min, whereas flow rates of less than 0.1 mL/min are consistent with xerostomia. The most common causes of xerostomia are drugs, autoimmune diseases including Sjögren syndrome and rheumatoid arthritis, and radiation therapy. Symptoms associated with xerostomia are as follows: pain, burning, and soreness of the oral mucosa, especially the tongue; difficulty in mastication, swallowing, and speech; impairment of taste; painful oral ulcers; difficulty in wearing dentures; increased dental caries; and increased frequency or volume of fluid intake. [50] The dysphagia associated with xerostomia is primarily attributable to the absence of lubricating properties of saliva. Therapy ranges from attempts to increase secretion with sugarless gum, sour lozenges, or pharmacological agents such as pilocarpine and cholinergic agents. Patients without stimulated salivary response can try commercially available saliva substitutes. [51]

ESOPHAGEAL MOTILITY DISORDERS

Neuromuscular function of the esophagus (motility) has the consistent objective of emptying the esophagus despite intrusions from above or below: primary esophageal peristalsis empties swallowed material from the esophagus; secondary peristalsis eliminates air or fluid refluxed from the stomach; the UES contracts during inspiration to exclude inspired air from the digestive tract; and elements of the gastroesophageal junction contract during transient increases of intra-abdominal pressure, preventing gastroesophageal reflux. A basic characteristic of *esophageal motility disorders,* conversely, is failure in preserving esophageal emptiness. Retained material within the esophagus, or the excessive entry of material into the esophagus, is abnormal. Such dysfunction can be categorized as disorders of peristalsis or of sphincter competence. The main dysfunction of sphincter competence occurs with gastroesophageal reflux disease (GERD; see Chapter 60). This discussion focuses on less common causes of sphincter dysfunction and on disorders of peristalsis. However, before considering these functional aberrations,

consider our present understanding of the mechanics of esophageal peristalsis.

Mechanics of Peristalsis

Esophageal Body Both the inner circular and outer longitudinal muscle layers of the proximal esophagus are composed of striated muscle and are controlled by somatic motor fibers from lower motor neurons in the nucleus retrofacialis and the nucleus ambiguus. Axons of these lower motor neurons course through the vagus nerve through the recurrent laryngeal nerve. The thoracic esophagus is mostly composed of smooth muscle receiving innervation from preganglionic neurons in the dorsal motor nucleus of the vagus. Vagal fibers synapse on myenteric plexus neurons situated between the circular and longitudinal muscle layers, rather than directly at neuromuscular junctions. Although the relationship between morphology and function of the neurons remains undetermined, vagal stimulation can either excite or inhibit esophageal musculature, depending on the intensity of the stimulus used. [52] Excitatory neurons mediate contraction of the circular and longitudinal muscle through cholinergic receptors. Inhibitory neurons affect predominantly the circular smooth muscle through nitric oxide and exert a progressively prolonged inhibition at more distal esophageal loci. Esophageal peristalsis commences as the pharyngeal contraction traverses the UES and progresses along the esophagus at 2 to 4 cm/s. Whereas primary peristalsis is that initiated by a swallow, secondary peristalsis can be elicited in response to esophageal distention at any level with air, fluid, or a balloon. [53] Primary peristalsis is dependent on activation of the swallowing center and vagal pathways. Peristalsis in the striated muscle esophagus is a function of sequential firing of efferent vagal neurons, and, thus, in this segment both primary peristalsis and secondary peristalsis are blocked by bilateral cervical vagotomy. Although primary peristalsis in the smooth muscle segment of the esophagus is also blocked by bilateral cervical vagotomy, secondary peristalsis is preserved and can be initiated by esophageal distention or vagal nerve stimulation. The progression of primary peristalsis in the smooth muscle segment is governed by the gradient of excitatory and inhibitory influence. Mechanical inhibition or latency results from membrane hyperpolarization through nitric oxide release, [54] whereas cholinergic nerves cause depolarization and decreased latency. Cholinergic influence is most prominent proximally and progressively decreases distally, whereas the inhibitory influence increases distally. [55] The mechanical correlate of peristalsis is of a stripping wave that milks the esophagus clean from its proximal to distal end (Fig. 59-6). The velocity of movement of the stripping wave corresponds closely with that of the manometrically recorded contraction such that the point of the inverted “V” seen fluoroscopically at each esophageal locus occurs with the upstroke of the pressure wave. [56] Detailed analyses of the vigor and propagation of esophageal peristalsis have concluded that progression through the tubular esophagus is not seamless. Rather, there is a distinct transition zone between the striated and smooth muscle esophagus characterized by low peristaltic amplitude, slight delay in progression, and an increased likelihood of failed transmission. [57] This transition zone becomes quite evident when peristaltic amplitude and progression are plotted topographically. The topographic analysis reveals not only the proximal transition zone, but also a segmental characteristic of peristaltic progression through the smooth muscle esophagus with two distinct contractile segments followed by the lower esophageal sphincter (LES), which contracts with vigor and persistence quite dissimilar to the adjacent smooth muscle esophagus. [58]

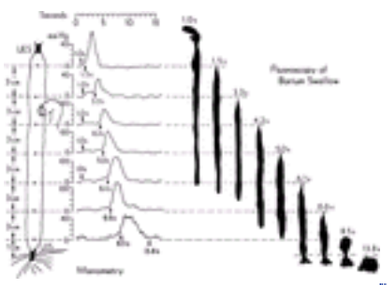

FIGURE 59-6. The relationship between manometric and fluoroscopic recordings of esophageal peristalsis during concurrent manometric and video recording of a 5-mL liquid barium swallow. The tracings from the video images of the fluoroscopic sequence on the **right** show the distribution of the barium column at the times indicated above the individual tracings and by *arrows* on the manometric record. In this example, a single peristaltic sequence completely cleared the barium bolus from the esophagus. Pharyngeal injection of barium into the esophagus occurs at the 1.0-second mark. The entry of barium causes distention and a slightly increased intralumenal pressure, indicated by the *downward pointing arrows* marked *1.0 s*. Shortly thereafter, esophageal peristalsis is initiated. During esophageal peristalsis, lumenal closure and hence the tail of the barium bolus passed each recording site concurrent with the onset of the manometric pressure wave. Hence, at 1.5 seconds, the peristaltic contraction had just reached the proximal recording site, and barium had been stripped from the esophagus proximal to that point. Similarly, at 4.2 seconds, the peristaltic contraction was beginning at the third recording site, and, correspondingly, the tail of the barium bolus was located at the third recording site. Finally, after completion of the peristaltic contraction (time 13.8 seconds), all the barium has been cleared into the stomach. (From ref. [56] .)

The longitudinal muscle of the esophagus also contracts during peristalsis, with the net effect of transiently shortening the structure by 2 to 2.5 cm. [59] Similar to the pattern of circular muscle contraction, longitudinal muscle contraction is propagated distally as an active segment at a rate of 2 to 4 cm/s. [60] The segment of contracting longitudinal muscle precedes but overlaps with the contracting segment of circular muscle. Thus, within a given esophageal segment, the contractions of the longitudinal and circular muscle are slightly out of phase with each other. Another crucial feature of the peristaltic mechanism is deglutitive inhibition. A second swallow, initiated while an earlier peristaltic contraction is still progressing in the striated muscle esophagus, causes rapid and complete inhibition of the contraction induced by the first swallow. [61] Deglutitive inhibition is secondary to hyperpolarization of the circular smooth muscle and is mediated by noncholinergic neurons in the myenteric plexus. An experimental model illustrating deglutitive inhibition in the tubular esophagus by the creation of an artificial high-pressure zone was described by Sifrim and colleagues [62] (Fig. 59-7). The artificial high-pressure zone is created by distending the esophageal lumen with a balloon and recording intralumenal pressure between the balloon and the esophageal wall. Once the high-pressure zone is established in the normally flaccid tubular esophagus, deglutitive inhibition can be demonstrated throughout the length of the esophagus, commencing concurrently with the pharyngeal swallow. [62]

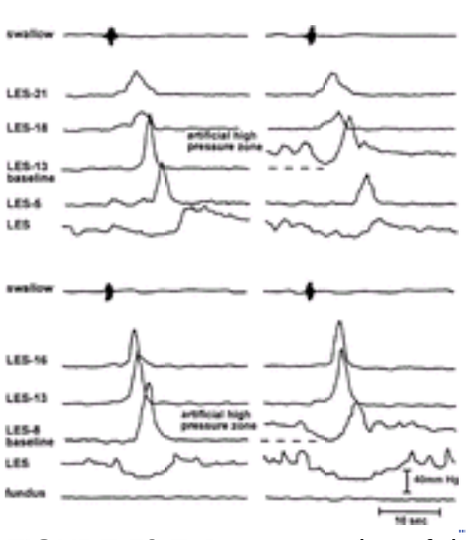

FIGURE 59-7. Demonstration of deglutitive inhibition in the tubular esophagus by the creation of an artificial high-pressure zone. The **top tracing** is a swallow marker, and the position from which each of the other tracings was obtained is referenced to the lower esophageal sphincter (LES). The artificial high-pressure zone was created 13 cm above the LES in the **upper panel** and 8 cm above the LES in the **lower panel** by inflating a balloon within the esophagus and interposing the manometric sensor between the wall of the esophagus and the balloon. The **tracings on the left** are before balloon inflation, whereas the **tracings on the right** are with the balloon inflated and the high-pressure zone developed. The contraction within the artificial high-pressure zone is inhibited concurrently with the pharyngeal swallow, much the same as with the LES illustrated in Figure 59-8. (From ref. [62] .)

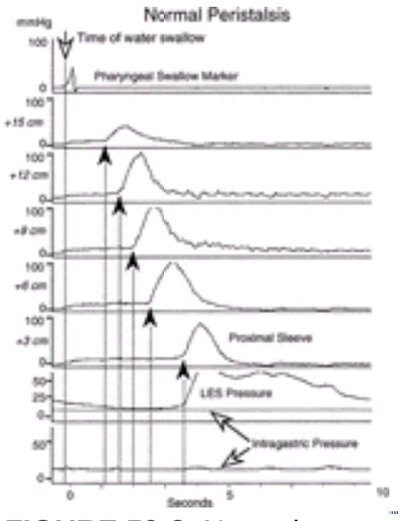

FIGURE 59-8. Normal manometric recording of an esophageal peristaltic contraction. The timing of the swallow is indicated by the first *vertical dotted line.* The *italicized numbers* to the **left** of the pressure calibrations indicate the position of each recording site relative to the midpoint of the sleeve sensor that is centered within the lower esophageal sphincter (LES). The onset of the peristaltic contraction at each esophageal recording site is indicated by a *solid arrowhead* and a *vertical dotted line*. Propagation of the peristaltic contraction is judged by the timing of the onset of the pressure complex at each recording site because this is the event indicative of lumenal closure. The propagation velocity of the peristaltic contraction is not uniform along the length of the esophagus, varying from 3 to 6 cm/s. LES pressure is recorded by a sleeve transducer that eliminates artifactual relaxation caused by esophageal shortening during swallow. LES relaxation is measured relative to intragastric pressure, indicated on the LES tracing by a *horizontal dotted line*. LES relaxation commences at the time of the pharyngeal swallow.

Lower Esophageal Sphincter Physiologically, the LES is a 2- to 4-cm-long segment of tonically contracted smooth muscle. Manometric studies reveal both axial and radial asymmetry. [63] Endoscopic ultrasound suggests that axial asymmetry may be explained by variable muscle thickness, [64] whereas radial asymmetry is likely the result of the surrounding diaphragmatic crus. [63] The LES is innervated by vagal and sympathetic efferents, which synapse on the myenteric plexus neurons. Basal LES pressure results from myogenic tone, and modification of that tone occurs through excitatory and inhibitory neurohormonal influences. The tonic behavior of the LES has been attributed to a depolarized state with the presence of continuous spike-burst activity. [65], [66] Relaxation of the LES occurs with swallowing, esophageal distention related to refluxed material or incomplete emptying, and transient LES relaxation (tLESR). Swallow-induced LESR occurs less than 2 seconds after initiation of swallowing and concurrently with deglutitive inhibition that traverses the smooth muscle esophagus. As evidenced by the manometric recording of normal peristalsis illustrated in Figure 59-8, LESR commences before the onset of the peristaltic contraction in the proximal esophagus. The LESR induced by primary peristalsis and pharyngeal stimulation is mediated by vagal efferents and is abolished by bilateral cervical vagotomy. [67] Esophageal distention of either the striated or smooth muscle esophagus induces LESR along with secondary peristalsis. It is presumed that distention-induced LESR in the striated muscle portion is centrally mediated, whereas that in the smooth muscle is mediated by the myenteric plexus. Relaxation may occur transiently without swallowing or esophageal contraction. These tLESRs are thought to be an important mechanism in the pathogenesis of GERD. Proximal gastric distention is the major stimulus for generating tLESRs. Distention stimulates gastric mechanoreceptors in the proximal stomach activating afferent fibers projecting to the nucleus of the solitary tract. Interactions with as yet undefined interneurons then result in activating vagal efferents in the dorsal motor nucleus of the vagus that stimulate prolonged LES and crural diaphragm inhibition. This reflex is also vagally mediated and can be abolished by vagotomy. [68]

Evaluation and Classification of Esophageal Dysphagia

Dysphagia is a fundamental symptom of esophageal disorders. Esophageal as opposed to oropharyngeal dysphagia is suggested by the absence of associated aspiration, cough, nasopharyngeal regurgitation, dry mouth, pharyngeal residue after swallow, or concurrent neuromuscular dysfunction. Conversely, the associated conditions of heartburn, esophagopharyngeal regurgitation, chest pain, odynophagia, or intermittent esophageal obstruction suggest esophageal dysphagia. However, an important limitation of the patient history with esophageal dysphagia is that patient identification of the location of obstruction is of limited accuracy. Specifically, a distal esophageal obstruction caused by an esophageal ring or achalasia will often be sensed as cervical dysphagia such that patients correctly locate distal dysfunction only 60% of the time. [69] Because of this subjective difficulty in distinguishing proximal from distal lesions within the esophagus, an evaluation for cervical dysphagia should encompass the entire esophagus.

Another important consideration in patient management is that esophageal motility disorders are much less common than mechanical or inflammatory causes of dysphagia: tumors, strictures, rings, and peptic, pill, or infectious esophagitis. Historical points suggestive of a motor disorder are difficulty with both solids and liquids as opposed to only solids, which is more suggestive of mechanical obstruction. However, as will become evident in the ensuing discussion, the functional consequences of mechanical or inflammatory disorders can exactly mimic those of primary motility disorders. Thus, as with oropharyngeal dysphagia, an esophageal motility disorder should be considered *only after exclusion of these more common diagnoses* by endoscopic or radiographic examination.

As outlined earlier, the physiological elements of esophageal peristalsis are the coordinated inhibition and excitation of the circular and longitudinal muscle layers of the esophagus. It follows that pathophysiological processes can involve dysfunction of deglutitive inhibition (including sphincter relaxation) or of the propagated contraction. Furthermore, because esophageal motor disorders are not usually diagnosed on histopathological grounds, their diagnosis depends on defining these functional aberrations. Table 59-2 illustrates an attempt at categorizing esophageal motility disorders on the basis of regional function of deglutitive inhibition and sequenced excitation. On examining Table 59-2, there are few well-defined esophageal motility disorders, and, as one could predict, in some circumstances it can be very difficult to choose definitively among the diagnostic possibilities. However, such is the state of the art. Furthermore, in the instance of spastic disorders, there is considerable debate over the clinical significance of some manometric findings. [70] With these considerations in mind, the following discussion emphasizes disease entities with clear diagnostic or therapeutic implications, rather than manometric phenomena of unproved significance. The exception is GERD which, although highly significant, is discussed in Chapter 60.

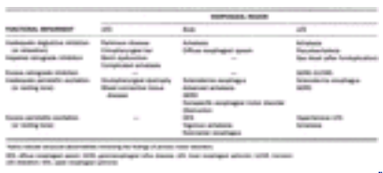

TABLE 59-2 Patterns of Esophageal Dysmotility*

Esophageal Manometry The clinical use of manometry is in defining the contractile characteristics of the esophagus in an attempt to identify pathological conditions. Manometric evaluation of the tubular esophagus assesses the success rate, rate of progression of the contractile complex, and characteristics of the contractile complex (amplitude, duration, repetitive contractions). *Failed peristalsis* is defined as the absence of contraction after a swallow or a contraction that proceeds only part way down the esophagus and either disappears or ends with a simultaneous contractions. Each of these outcomes results in incomplete esophageal emptying. [56] The progression rate of peristaltic contraction is measured by identifying the timing of the initial upstroke of the peristaltic contraction at adjacent recording sites and knowing the distance between these sites. Progression rates greater than 6.25 cm/s are associated with poor esophageal emptying and are considered a simultaneous contraction. [71] Contractile amplitude is considered hypotensive if it has an amplitude of less than 35 mm Hg because this, too, is associated with impaired esophageal emptying. [56] A typical convention for scoring hypertensive peristalsis is that the mean amplitude of contractile complexes is greater than 180 mm Hg, but this upper limit has varied among investigators. Repetitive contractions are multipeaked complexes. By convention, a contraction is scored as multipeaked if the valley between the peaks is at least 10 mm Hg less than and at least 1 second after the preceding peak. Both the magnitude of LES pressure and LES sphincter relaxation characteristics are determined from manometry. The three most widely used techniques are a stationary sleeve sensor, a rapid pull-through of side-hole sensors across the sphincter during suspended respiration, and a station pull-through of a side-hole sensor recording pressure activity for 30 to 60 seconds at 1 cm increments as the catheter is withdrawn. LES pressure varies by up to 25 mm Hg with the method of measurement used and with whether midrespiratory or end-expiratory LES pressure is reported. In addition to the varied methodology, the minute-to-minute variations of LES secondary to normal physiological events, such as the migrating motor complex, make it extremely difficult to establish normal ranges. Therefore, the most meaningful statement that can be made regarding an isolated measurement of LES pressure is that it is abnormal to have an extremely low value (<10 mm Hg). Relaxation characteristics can be evaluated using a sleeve

sensor, during a station pull-through, or after repositioning a side hole at the optimal position. A sleeve sensor is most suited to evaluate LESR, given that esophageal shortening occurs with swallowing. Deglutitive LESR has been characterized using a sleeve sensor in normal control subjects, in patients with GERD, in patients with achalasia, and in patients with diffuse esophageal spasm (DES). This system reliably records LESR characteristics and has a high diagnostic value in suspected achalasia. [72] Clinically, manometry can potentially aid in the diagnosis and management of esophageal syndromes involving dysphagia, chest pain, or GERD and in defining multisystem diseases that have esophageal dysmotility as one component. Unfortunately, along with pathophysiologically important abnormalities, manometry also detects insignificant aberrations of esophageal motility that have no proven relevance to the symptoms or management of patients with esophageal syndromes. This limited specificity and low prevalence rates of significant disorders in symptomatic patients make it a poor screening test, and, thus, it should never be the initial diagnostic test performed.

Achalasia

Achalasia is the most easily recognized and best-defined motor disorder of the esophagus. First recognized more than 300 years ago, the disorder was initially labeled cardiospasm, reflecting the observation that it was caused by a functional obstruction of the esophagus at the cardiac sphincter with no obstructing lesion evident in autopsy specimens. The first reported case was treated by passing a piece of carved whalebone with a sponge affixed to the distal end through the esophagus to facilitate esophageal emptying after meals. [73] That patient apparently sustained himself in this fashion for 15 years. During the next 2 centuries, there were sporadic reports of cases similarly treated with crude ramrods or dilators. In 1937, Lendrum [74] proposed that the functional esophageal obstruction in this syndrome resulted from incomplete relaxation of the LES and renamed the disease achalasia ("failure to relax"), ushering in our current concept of the disease.

Epidemiology Achalasia is a rare disease with an estimated incidence of 1 per 100,000 population per year in the United States and Europe. [75], [76] The incidence in Zimbabwean blacks may be much lower, raising the issue of racial or environmental predisposition. [77] The disease affects both sexes equally and usually presents in adult life, most commonly between the ages of 25 and 60 years. [78] Because achalasia is a chronic condition, its prevalence greatly exceeds its incidence. Estimates of the prevalence of achalasia in Europe range from 7.1 per 100,000 in Wales to 13.4 per 100,000 in Ireland. [79] Reports of familial clustering of achalasia raise the possibility of genetic predisposition; however, the data on this are inconclusive. Achalasia has been reported in monozygotic twins, [80] in siblings, [81] and in children of affected parents. [82] However, other reports of the occurrence of achalasia in only one of a pair of monozygotic twins speak against strong genetic determinant. [83] Emphasizing this point, a survey of 1012 first-degree relatives of 159 patients with achalasia identified no affected relatives. [84]

Neuropathology Achalasia is characterized by failure of the LES to relax completely with swallowing and aperistalsis in the smooth muscle esophagus. The resting LES pressure is elevated in about 60% of cases. If there are nonperistaltic, spasmlike contractions in the esophageal body, the disease is referred to as *vigorous achalasia.* These physiological alterations are thought to result from damage to the innervation of the smooth muscle esophagus (including the LES). Proposed neuroanatomic changes responsible for achalasia include loss of ganglion cells within the myenteric (Auerbach) plexus, degeneration of the vagus nerve, and degeneration of the dorsal motor nucleus of the vagus. Of these possibilities, the loss of ganglion cells is best substantiated. Several observers reported fewer ganglion cells and ganglion cells surrounded by mononuclear inflammatory cells in the smooth muscle esophagus of patients with achalasia. [85], [86] One report additionally noted ganglion cell degeneration extending into the proximal stomach in half of 34 specimens analyzed. [87] The degree of ganglion cell loss parallels the duration of disease such that ganglion cells are almost absent in patients afflicted for 10 years or longer. [88] A morphologic study of 42 esophagi resected from patients with advanced achalasia revealed diminished myenteric ganglion cells and inflammation within the myenteric plexus in all cases. [89] The ultimate cause of ganglion cell degeneration in achalasia is unknown; however, there is increasing evidence consistent with an immune-mediated process. Immunohistochemical analysis of the myenteric infiltrate in patients with achalasia revealed that most inflammatory cells are CD3/CD8-positive lymphocytes that express T-cell internal antigen-1 (TIA-1), indicating that these cells are either resting or activated cytotoxic T cells. [90] In addition to this histological support, there is also an association with the class II human leukocyte antigen antigens DQW1 [91] and DQB1. [92] Achalasia may also be associated with degenerative neurological disorders such as Parkinson disease. Patients with both achalasia and Parkinson disease were noted to have Lewy bodies (intracytoplasmic hyaline or spherical eosinophilic inclusions) in the degenerating ganglion cells of the myenteric plexus. [86] Physiological studies also provide evidence of at least partial postganglionic denervation of esophageal smooth muscle in achalasia. Such damage can potentially affect excitatory (cholinergic) ganglionic neurons, inhibitory (nitric oxide ± vasoactive intestinal polypeptide) ganglionic neurons, or both. Consider first the excitatory ganglionic neurons. Muscle strips from the circular layer of the esophageal body of patients with achalasia contract when they are directly stimulated by acetylcholine but fail to respond to ganglionic stimulation by nicotine, indicating a postganglionic excitatory defect. [93] An in vivo demonstration of smooth muscle sensitivity to acetylcholine is the Mecholyl test, in which the injection of this acetylcholine analog evokes profound contraction of the otherwise flaccid achalasic esophagus. [94] This exaggerated response has been interpreted as a demonstration of Cannon's law of denervation supersensitivity. However, it is likely that loss of excitatory innervation is variable among patients with achalasia. Partial preservation of the postganglionic cholinergic pathway is suggested by the observations that the LES pressure in patients with achalasia increases after administration of the acetylcholinesterase inhibitor edrophonium and decreases after administration of the muscarinic antagonist atropine. [95] These observations are crucial to understanding why botulinum toxin may have therapeutic benefit in achalasia (see later). Regardless of excitatory ganglionic neuron impairment, it is clear that the inhibitory ganglionic neurons are necessarily impaired as an early manifestation of achalasia. Functionally, these neurons are responsible for deglutitive inhibition (including LESR) and for the timing of propagation of esophageal peristalsis; their absence offers a unifying hypothesis for the key physiological abnormalities of achalasia: impaired LESR and aperistalsis. It is increasingly evident that the inhibitory ganglionic neurons use nitric oxide as a neurotransmitter. [96] In support of this conclusion, patients with achalasia have been shown to lack nitric oxide synthase in the gastroesophageal junction. [96] Furthermore, vasoactive intestinal polypeptide may be a cotransmitter in these neurons, and immunohistochemical studies have demonstrated a marked reduction of vasoactive intestinal polypeptide–staining neurons in patients with achalasia. [97] A multitude of evidence supports impaired physiological function of postganglionic inhibitory innervation in the smooth muscle esophagus of patients with achalasia. Animal models of achalasia have been established using nitric oxide inhibitors such as N^{G}-nitro-L-arginine. [98] Muscle strips from the LES of patients with achalasia do not relax in response to ganglionic stimulation as they do in normal controls. [93] Cholecystokinin octapeptide, which normally stimulates the inhibitory ganglionic neurons, thereby reducing LES pressure, paradoxically increases the LES pressure in patients with achalasia. [99] Impaired inhibitory innervation of the tubular esophagus above the LES is more difficult to demonstrate than within the sphincter itself because of the absence of resting tone in this region. However, in a clever experiment, Sifrim and colleagues [100] used an intraesophageal balloon to create a high-pressure zone in the tubular esophagus that then relaxed with the onset of deglutitive inhibition. This deglutitive relaxation in the esophageal body was absent in early, nondilated cases of achalasia.

Clinical Presentation Clinical manifestations of achalasia may include dysphagia, regurgitation, chest pain, weight loss, and aspiration pneumonia. All patients have solid food dysphagia; most patients also have variable degrees of liquid dysphagia. The onset of dysphagia is usually gradual, with the duration of symptoms averaging 2 years at presentation. [78] Dysphagia severity fluctuates, but eventually it plateaus. Predictably, regurgitation occurs when large amounts of food are retained in the dilated esophagus. The regurgitant is often recognized as food that has been eaten hours, or even days, previously. It tends to be nonbilious, nonacidic, and mixed with copious amounts of saliva. Chest pain is a frequent complaint early in the course of achalasia, occurring in approximately two thirds of patients. [101] Its cause is unknown, but it is speculated to be related to the occurrence of esophageal spasms or to the process of esophageal dilation associated with disease progression. Treatment of achalasia is less effective in relieving chest pain than it is in relieving dysphagia or regurgitation. However, unlike dysphagia or regurgitation, chest pain may improve or disappear over time. [101] An estimated 10% of patients with achalasia have bronchopulmonary complications as the result of regurgitation; in some instances, it is these complications rather than dysphagia that prompts them to seek medical care. [102] Other interesting, but fortunately rare, symptoms of achalasia are airway compromise and stridor as a result of the dilated esophagus compressing the trachea. [103] This occurs secondary to dysfunction of the belch reflex either because of neural degeneration or because esophageal dilation prevents activation of stretch receptors within the esophageal wall. [104] It is paradoxical that many patients with achalasia complain of heartburn, even after the onset of dysphagia. [105] Although reflux may be a common sequela of the treatments for achalasia, it seems physiologically inconsistent to have dysphagia from impaired LESR and reflux from excessive LESR simultaneously. In support of this skepticism, ambulatory 24-hour esophageal pH studies of patients with achalasia have shown only periods of esophageal acidification caused by the bacterial fermentation of retained food in the esophagus rather than discrete gastroesophageal reflux events. [106] Furthermore, prolonged LES recordings have shown a complete absence of tLESRs in patients with achalasia. [107] However, there are occasional exceptions to this, evident from a well-documented case of a patient with achalasia with intact tLESR despite the absence of deglutitive LESR. [108]

Radiographic and manometric findings. Barium swallow radiography (Fig. 59-9) or esophageal manometry (Fig. 59-10) can demonstrate the physiological abnormalities of achalasia. The characteristic x-ray finding is of a dilated intrathoracic esophagus with impaired emptying, an air-fluid level, absence of a gastric air bubble, and an LES that tapers to a point giving the distal esophagus a beaklike appearance. Occasionally, an epiphrenic diverticulum, immediately above the LES, is observed with achalasia. [109] With long-standing achalasia, the esophagus may assume a sigmoid configuration, and in some instances an air-fluid level, mediastinal widening, and outline of the dilated esophageal wall are even evident on a plain chest film. The characteristic radiographic findings depend on esophageal dilation. Because dilation is not always present in achalasia, sensitivity of the radiographic examination is limited. [76]

FIGURE 59-9. Characteristic barium swallow in idiopathic achalasia. Note esophageal dilation with an air-fluid level and the smooth tapering at the gastroesophageal junction. Radiographic findings can be much more subtle in the early phases of the disease.

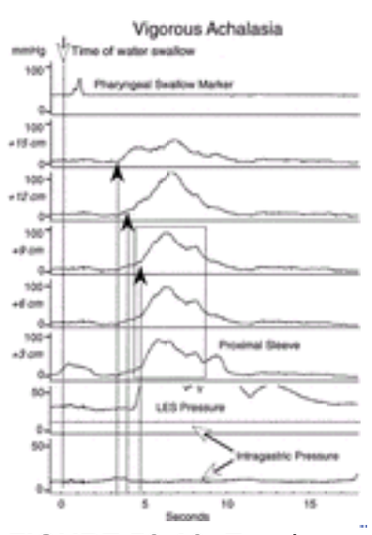

FIGURE 59-10. Esophageal manometric recording in a patient with idiopathic achalasia, in this case vigorous achalasia and a nondilated esophagus. The timing of the swallow is indicated by the *first vertical dotted line*. The *italicized numbers* to the **left** of the pressure calibrations indicate the position of each recording site relative to the midpoint of the sleeve sensor that is centered within the lower esophageal sphinter (LES). Although there is a propagated contraction in the proximal (striated muscle) esophagus, there is no propagated contraction in the smooth muscle esophagus, as indicated by the simultaneous onsets of the contraction waves. The *rectangle* surrounds a section of the tracing demonstrating isobaric waves across three esophageal recording sites. During this period of the recording, those three recording sites are contained within a “common cavity” sealed from above and below by higher-amplitude, lumen-obliterating contractions. The resting LES pressure is 20 mm Hg relative to intragastric pressure (indicated by the *horizontal dotted line*) and demonstrates minimal deglutitive relaxation.

The defining manometric features of achalasia are aperistalsis and incomplete LESR. In cases of achalasia established by all available clinical criteria, the defining manometric features are present in more than 90% of patients. An analysis of manometric LES parameters in patients with achalasia found that impaired LESR by itself (to a nadir value greater than 12 mm Hg) had a 92% sensitivity and 94% specificity for the detection of achalasia. [72] However, even though manometry is the current standard, there is manometric heterogeneity in achalasia such that manometric findings must sometimes be combined with additional clinical data to detect atypical cases, such as patients with only short segments of aperistalsis or quantifiable normal LESR. [108] Some patients exhibit higher-amplitude (>60 mm Hg) simultaneous repetitive contractions in response to swallows, thereby defining the variant known as vigorous achalasia. These patients in particular tend not to have esophageal dilation, making them difficult to diagnose radiographically. [110] In a comparison among diagnostic modalities, one prospective study showed that achalasia was suggested by the radiologist in only 21 of 33 patients who were given this diagnosis at manometry. [76] Other manometric features (increased resting LES pressure, increased intraesophageal baseline pressure, or isobaric waveforms) provide supportive evidence to improve the suspicion rate of achalasia.

Endoscopic findings. Endoscopy is relatively insensitive in the detection of achalasia; endoscopists prospectively suggest the correct diagnosis in fewer than one third of patients. [76] Typical endoscopic findings include retained food or saliva and dilation and atony of the esophageal body. With progressive dilation and stasis, erythema, friability, and superficial ulcerations may be seen. Whitish plaque covering the epithelial surface may be seen as the result of *Candida* overgrowth; this is usually asymptomatic. The achalasic LES has a pinpoint appearance and does not open with air insufflation. Nonetheless, the instrument should easily pass through the sphincter into the stomach with minimal pressure. Resistance, or a feeling of stiffness as the endoscope crosses the gastroesophageal junction, should immediately raise the suspicion of malignant disease (see section “ Pseudoachalasia”). Equivocal mucosal abnormalities of the gastroesophageal junction, evident on forward viewing or retroflexed inspection, should always undergo biopsy because of the possibility of pseudoachalasia.

Differential Diagnosis The differential diagnosis of achalasia includes both other esophageal motility disorders with functional attributes overlapping those of achalasia and diseases of distinct pathophysiology that duplicate the functional consequences of achalasia. With respect to other motility disorders, inspection of Table 59-2 suggests many similarities between esophageal spasm and achalasia, especially vigorous achalasia. In fact, the only distinction between these entities is the demonstration of incomplete LESR in vigorous achalasia. Thus, it has been speculated that in some instances esophageal spasm (and vigorous achalasia) may represent an early stage of achalasia and may evolve into full-fledged achalasia. Vantrappen and colleagues [111] first speculated on this relationship and reported several cases demonstrating just such an evolution. However, as discussed later in this chapter, spastic disorders of the esophagus are a heterogeneous lot, and a few, at best, are part of this continuum. With respect to diseases of distinct pathophysiology that duplicate the functional consequences of achalasia, the main considerations are Chagas disease and pseudoachalasia. These disorders are considered in some detail because they may resemble achalasia so closely that conventional diagnostic tests are misleading. A rare genetic achalasia syndrome has also been described; *familial adrenal insufficiency with alacrima* is inherited as an autosomal recessive trait that manifests itself with the childhood onset of autonomic nervous system dysfunction including achalasia, alacrima, sinoatrial dysfunction, abnormal pupillary responses to light, and delayed gastric emptying. [112]

Chagas disease. Although achalasia is almost universally idiopathic in North America, the disease can be closely mimicked by esophageal involvement in *Chagas disease,* which is endemic in areas of central Brazil, Venezuela, and northern Argentina. Cases have also been reported in southern Texas. Chagas disease is spread by the bite of reduvid (kissing) bug, which transmits the culprit protozoan, *Trypanosoma cruzi.* After infection, an acute septicemic phase of the illness develops that varies in severity from being so mild as to go unnoticed to being so severe as to be fatal. [113] The chronic phase of the disease develops many years after infection and results from destruction of autonomic ganglion cells throughout the body, including the heart, gut, urinary tract, and respiratory tract. Chronic cardiomyopathy with conduction system disturbances and arrhythmias is the most common cause of death. The digestive tract organs most often affected are the esophagus, duodenum, and colon. The severity of esophageal dysfunction is directly proportional to the degree of intramural ganglion cell loss; abnormal peristalsis is first detectable after 50% of ganglion cells are destroyed and esophageal dilation only after 90% are destroyed. [113] Paralleling this, the initial dysfunction is confined to the esophageal body, with LES dysfunction occurring late in the course of the disease. [113] The most useful clinical distinction between idiopathic achalasia and esophageal involvement in Chagas disease is evidence of other tubular organ involvement (megaureter, cardiomyopathy, megaduodenum, megacolon, megarectum) in the latter. Otherwise, patients with Chagas disease have the same clinical, radiographic, and manometric characteristics as those with idiopathic achalasia. The diagnosis of Chagas disease is confirmed by a serologic test using complement fixation or polymerase chain reaction. The treatment of the achalasia syndrome in Chagas disease is similar to that for idiopathic achalasia. Treatment of the infection itself is of limited efficacy in the acute phase of the disease and is of no proven efficacy in chronic disease.

Pseudoachalasia. Neither the radiographic nor the manometric features of achalasia are specific for idiopathic achalasia or achalasia associated with Chagas disease; tumor-related *pseudoachalasia* accounts for up to 5% of cases with manometrically defined achalasia. Pseudoachalasia is more likely with progressive age (>50 years), abrupt onset of symptoms (<1 year), and early weight loss in excess of 7 kg. [78] However, even though these criteria make pseudoachalasia more likely, they still have poor predictive value in the individual patient. [114] Tumor infiltration (especially carcinoma in the gastric fundus) can completely mimic the functional impairment seen with idiopathic achalasia [115] (see Table 59-2). It is because of this potential pitfall that a thorough anatomic examination including endoscopy should be done as part of the diagnostic evaluation of every new case of achalasia. A clue to the presence of pseudoachalasia on the endoscopic examination is more than the slightest resistance of passage of the endoscope across the gastroesophageal junction. In idiopathic achalasia, the endoscope should pop through with only

gentle pressure required. If suspicion of pseudoachalasia persists, endoscopic biopsy, computed tomography, magnetic resonance imaging, or endoscopic ultrasound should be considered for further evaluation, depending on the special circumstances. Adenocarcinoma of the gastroesophageal junction accounts for more than one half of pseudoachalasia cases, with a myriad of tumors and miscellaneous conditions accounting for the remainder. Within the spectrum of malignant diseases, pancreatic cancer, oat cell tumors, hepatoma, bronchogenic tumors, esophageal squamous cell carcinoma, prostate tumors, and lymphoma have been reported. [78] These tumors produce an achalasia syndrome by infiltrating the wall of the esophagus at the gastroesophageal junction, in essence causing a malignant obstruction at the LES with proximal esophageal dilation. [115] Similarly, pseudoachalasia has also been reported to result from esophageal infiltration by amyloid, [116] eosinophilic gastroenteritis, [117] and sarcoidosis. [118] Although often speculated in the literature, it is less certain, and certainly much less common, that an achalasic syndrome occurs as a paraneoplastic syndrome without direct tumor stenosis of the gastroesophageal junction. [78]

Management Because the underlying neuropathological condition cannot be corrected, treatment of achalasia is directed at compensating for the functional abnormalities and preventing complications. The main functional abnormality in achalasia is poor esophageal emptying, and this is treated by reducing the LES pressure. With reduced LES pressure, gravity promotes esophageal emptying. Peristalsis rarely returns with therapy. LES pressure can be reduced by pharmacological therapy, forceful dilation, or surgical myotomy. Pharmacological treatments, on the whole, are not very effective, perhaps indicated more as temporizing maneuvers than as definitive therapies. The definitive treatment of achalasia is still disruption of the LES either surgically (Heller myotomy) or with a pneumatic dilator. The optimal approach is an issue of debate, given the lack of randomized controlled trials with accepted criteria for assessing efficacy. Thus, there is no alternative but to compare therapies based on the numerous uncontrolled series that have been published using a variety of qualitative end points as indications of efficacy. Table 59-3 summarizes the pooled estimate of response rate of medical and surgical treatment data in achalasia. Data in the table are uncontrolled and were consecutive series collected both prospectively and retrospectively. Because there was no uniformity in assessment of efficacy among trials, the proportion with a good-to-excellent response was extracted from each study, regardless of criteria. Only studies including more than ten patients and with a follow up of 1 year were tabulated.

TABLE 59-3 Pooled Estimate of Response Rate of Achalasia Treatments across Referenced Studies*

Pharmacological therapy. Smooth muscle relaxants such as nitrates or calcium channel blockers, administered sublingually immediately before eating, may offer partial relief of the dysphagia accompanying achalasia by reducing the resting sphincter pressure. Anticholinergics, [119] amyl nitrite, [120] sublingual nitroglycerin, [121] theophylline, [121] and ß $_2$-agonists [121] have also been tried, with variable results. The greatest reported experience has been with isosorbide dinitrate and nifedipine. [122] Isosorbide dinitrate (Isordil), 5 to 10 mg sublingually before meals, reduces the resting LES pressure by 66% for 90 minutes, with clinical efficacy paralleling the magnitude of LES response. [123] A 19-month trial of this therapy has been reported to provide marked or complete relief of dysphagia. [123] Side effects, particularly headache, are common. Placebo-controlled trials have not been reported. Calcium channel blockers (diltiazem, nifedipine, verapamil) reduce the LES pressure by 30% to 40% for more than an hour with potential benefit in achalasia. [124], [125] The greatest clinical experience has been with nifedipine (Procardia), which can be administered at 10 to 30 mg sublingually (capsules are crushed in the mouth) 30 to 45 minutes before meals. The benefit of nifedipine, 30 to 40 mg sublingually per day, was assessed in a group of 29 patients with early achalasia (before esophageal dilation) in a placebo-controlled trial. Nifedipine was significantly better that placebo (which had no significant benefit), yielding good to excellent results in 70% of patients with achalasia who were followed-up for 6 to 18 months. [122] However, subsequent placebo-controlled crossover trials found only minimal clinical improvement with nifedipine. [126], [127] Limiting side effects of nifedipine use are flushing, dizziness, headache, peripheral edema, and orthostasis. Sildenafil is another smooth muscle relaxant that has been shown to decrease the LES pressure and deglutitive relaxation pressure in patients with achalasia by blocking phosphodiesterase type 5, the enzyme that destroys cyclic guanosine monophosphate induced by nitric oxide. A double-blind placebo-controlled trial revealed that 50 mg of sildenafil caused a significant decrease in LES pressure and relaxation pressure when compared with placebo. [128] The effect peaked at 15 to 20 minutes after administration and persisted for less than 1 hour.

Botulinum toxin injection. Pasricha and associates [129] first reported the effects of botulinum toxin on the LES in patients with achalasia in 1994. These investigators found that intrasphincteric injection of botulinum toxin decreased LES pressure by 33% and improved dysphagia in 66% of patients for a 6-month period. Botulinum toxin works by irreversibly inhibiting the release of acetylcholine from presynaptic terminals, effectively eliminating the neurogenic component of LES pressure. However, because this effect is eventually reversed by the growth of new axons, it is not surprising that the effect of botulinum toxin is not long lasting. Although most patients initially experience a good response, there is minimal continued efficacy at 1 year (see Table 59-3). [130], [131], [132] and [133] The technique for administering botulinum toxin involves injecting a total of 80 U into four quadrants of the LES with a sclerotherapy catheter. Doses higher than 100 U have not been shown to be more effective. [134] Studies comparing botulinum toxin with pneumatic dilation suggests that the added expense for repeated injection outweighs the potential economic benefits of the added safety, unless life expectancy is 2 years or less. [135] Thus, this therapeutic option should be mainly reserved for elderly or frail patients who are poor risks for more definitive treatments.

Pneumatic dilation. Therapeutic dilation for achalasia requires the forceful distention of the LES to a diameter of approximately 3 cm to disrupt the circular muscle of the sphincter partially and to effect lasting reduction of LES pressure. Dilation with an endoscope or with standard bougies (=60 F) provides only very temporary benefit. Only balloon dilators specifically designed to treat achalasia achieve adequate diameter for lasting effectiveness. The basic element of an achalasia dilator is a long, noncompliant, cylindrical balloon that can be positioned fluoroscopically (Rigiflex dilator [Microvasive, Millford, MA]) or endoscopically (Witzel dilator [Medi-Globe, Tempe, AZ]) across the LES and then inflated to a characteristic diameter in a controlled fashion using a handheld manometer. The technique of pneumatic dilation is variable among practitioners in terms of patient preparation, parameters of balloon inflation, and postdilation monitoring. There is general agreement that pneumatic dilation can be done on an outpatient basis with the patient under conscious sedation. In patients with substantial esophageal retention, it is useful to have them on a liquid diet for one or more days before the procedure. Reported balloon inflation pressures range from 360 mm Hg (7 psi) to 775 mm Hg (15 psi), with periods of inflation ranging from several seconds to 5 minutes. [136], [137] Although there is minimal methodological consistency among authors, a cautious approach of beginning with relatively low inflation pressures or a smaller-diameter dilator (3.0 to 3.5 cm) is fairly universal. The major complication of pneumatic dilation is esophageal perforation; mortality is very rare. [138] Most series report an incidence of esophageal perforation during pneumatic dilation of between 1% and 5%. [102], [136] Because most perforations are readily evident within a few hours of the procedure, patients should be observed closely for signs of an esophageal leak for 3 to 6 hours after pneumatic dilation. Alternatively, some practitioners routinely obtain a fluoroscopic examination of the esophagus after pneumatic dilation to make sure that perforation has not occurred. Usually, a water-soluble contrast agent is given first, followed by barium. If the perforation appears small and confined, or intramural, conservative management consisting of close observation while allowing the patient nothing by mouth and administering intravenous antibiotics is appropriate. [102] If any substantial perforation has occurred, or if worsening pain and fever occur during observation of what was thought to be a small perforation, surgical repair should be pursued quickly. Patients with perforation from pneumatic dilation that is recognized and promptly treated surgically (within 6 to 8 hours) have outcomes that are comparable to those of patients undergoing elective Heller myotomy. [139] The best predictor of efficacy after a pneumatic dilation is the postdilation LES pressure; neither sphincter relaxation nor peristaltic function is significantly changed. LES pressure values of less than 10 mm Hg are associated with prolonged remission, whereas patients with values greater than 20 mm Hg derive little benefit from the procedure. [140] It is neither unusual nor dangerous to repeat a pneumatic dilation two to three times in instances of an unsatisfactory result. The clinical efficacy of dilation has been reported to range between 32% to 98% (see Table 59-3). [130] Patients having a poor initial result or rapid recurrence of symptoms have diminished likelihood of responding to additional dilations. [141] /SUP>Subsequent response to surgical myotomy is not influenced by the history of previous dilations. [142]

Heller myotomy. The surgical objectives in the treatment of achalasia are to reduce the LES pressure enough to eliminate dysphagia but not enough to allow gastroesophageal reflux. Current procedures are variations on the esophageal myotomy described by Heller in 1913. [143] In Heller's operation, anterior and posterior myotomies were performed through either a laparotomy or a thoracotomy. Although clearly efficacious, open Heller myotomy is associated with considerable morbidity related to thoracotomy, which led most patients to pursue pneumatic dilation as the initial intervention. However, adoption of the laparoscopic approach for achalasia surgery has led many practitioners to use surgery as an initial intervention because this technique offers similar efficacy to the open procedure and substantially reduced morbidity. Surgical series of patients with achalasia who were treated with myotomy reported good to excellent results in 62% to 100% of patients, with persistent dysphagia troubling fewer than 10% of patients overall (see Table 59-3). [130] The appeal of myotomy is that it offers a more predictable method of reducing LES pressure than does pneumatic dilation. [144] Studies suggest that laparoscopic and thoracoscopic approaches are associated with similar efficacy and reduced morbidity when compared with myotomy through thoracotomy or laparotomy. [130], [145], [146], [147], [148], [149] and [150] Patti and associates [147] reported the clinical outcomes of 168 achalasic patients who underwent thoracoscopic myotomy (35 patients) or laparoscopic Heller myotomy accompanied by a partial fundoplication (133 patients). There were no deaths in this series, and only eight patients required reoperation. Relief of dysphagia was obtained in 93% of the patients who underwent the laparoscopic Heller myotomy and in 85% of those treated with thoracoscopic myotomy. Not only did the laparoscopic approach improve dysphagia more effectively, but also it was associated with shorter hospital stay and less postoperative gastroesophageal reflux. Historically, postmyotomy reflux in patients with achalasia was particularly severe. [151] However, with the availability of proton pump inhibitors, reflux is usually easily controlled, making these complications very unlikely. Thus, laparoscopic Heller myotomy combined with a partial fundoplication has

become the preferred surgical procedure for achalasia. Occasionally, patients fail to respond to dilation and myotomy and require more extensive surgical procedures. In extremely advanced or refractory cases of achalasia, esophageal resection with gastric pull-up or interposition of a segment of transverse colon or small bowel may be the only surgical option. [152], [153] Indications for this intervention include unresolvable obstructive symptoms, cancer, and perforation during dilation. Although excellent long-term functional results can be achieved, the reported mortality of this surgery is about 4%, consistent with the mortality rate of esophagectomy performed for other indications.

Medical versus surgical treatment. Although pharmacological therapy is simple and safe, it has become increasingly clear that this should be reserved for use as a temporizing measure while more definitive therapy is being considered. Thus, practically speaking, the choice is between pneumatic dilation and laparoscopic Heller myotomy as the primary therapy for achalasia. However, there are no prospective controlled trials comparing these treatments. One controlled trial exists comparing pneumatic dilation with myotomy through thoracotomy. That study reported 95% symptom resolution with myotomy and 51% symptom resolution in the dilation group, but the study was criticized for the methodology of pneumatic dilation used. [154] Most studies report symptom resolution in approximately 70% of patients with pneumatic dilation, substantially higher than the 51% reported in the controlled trial but still substantially lower than that reported in uncontrolled series of laparoscopic Heller myotomy (see Table 59-3). Furthermore, although laparoscopic Heller myotomy is invasive, its morbidity is low. Conversely, pneumatic dilation has a perforation rate that averages 3%. Even though these patients do well if the perforation is recognized and is operated on promptly, they require a thoracotomy. Thus, it appears that, in expert hands, laparoscopic Heller myotomy is likely the optimal initial therapy when one considers both the safety and the efficacy of the procedure.

Risk of squamous cell cancer. Numerous series report cases of squamous cell carcinoma developing in the achalasic esophagus, [155], [156] and the relative risk of developing squamous cell cancer has been estimated to be 33-fold relative to the nonachalasic population. [157] The pathogenesis of the carcinoma is obscure, but stasis and mucosal irritation may be precipitating factors. The tumors develop many years after the diagnosis of achalasia. Because the tumors often arise in a greatly dilated esophagus, symptoms can be delayed, and the neoplasms are large and advanced at the time of detection. These considerations raise the issue of surveillance endoscopy in patients with achalasia to detect early squamous cell cancer. However, an elegant analysis by Sandler and colleagues [158] of a database encompassing the entire Swedish population of 1062 patients with achalasia suggests that, after discounting incident carcinomas, the overall squamous cell cancer risk for patients with achalasia compared with age-matched controls is 17-fold, making for a 0.15% incidence of cancer among the patients with achalasia. The authors calculated that, if surveillance endoscopy were to be done annually, 406 examinations would need to be done in men and 2220 in women before a single potentially treatable tumor was found.

Spastic Disorders

The concept of *esophageal spasm* is credited to Hamilton Osgood, [159] based on his 1889 description of six patients with episodic chest pain and dysphagia: “sudden and often intense constriction in the epigastrium… with an arrest of food at the cardiac orifice.” From the time of that report until the present day, further insight into the entity of esophageal spasm has paralleled the development of imaging or measurement technology that could detect it. “Diffuse spasm of the lower part of the esophagus” was first described radiographically in 1934, [160] and the first manometric descriptions of spasm came in the late 1950s. [161] Introduction of the term *diffuse esophageal spasm* and our present concept of this entity followed the description in 1967 by Fleshler [162] of a “clinical syndrome characterized by symptoms of substernal distress or dysphagia or both, the roentgenographic appearance of localized, nonprogressive waves (tertiary contractions), and an increased incidence of nonperistaltic contractions recorded by intralumenal manometry.”

In broad terms, DES as described by Fleshler represents a disorder of peristalsis. However, the esophagus of the patient with DES usually retains its ability to propagate normal primary peristaltic waves most of the time, suggesting that the responsible neuromuscular disorder must be more subtle than with achalasia. Partly because of this fact, the criteria for diagnosing DES (which is the best accepted of proposed disorders of peristalsis) remain variable and confusing. [163] Furthermore, along with the evolution of manometric techniques capable of accurately recording intralumenal esophageal contractile activity came the description of other minor aberrations of peristalsis (nutcracker esophagus, hypertensive LES, and nonspecific esophageal motor disorder) to which symptoms, especially chest pain, may be attributed. [164] Despite this proliferation of literature, whether these entities have any clinical significance remains controversial. The heterogeneity among patients, the absence of specific pathological features, and the absence of well-defined clinical implications caution against considering them akin to achalasia. Strict criteria for defining a disease would stipulate that the peristaltic abnormality cause a major alteration of esophageal physiology demonstrable by both manometric and nonmanometric measures, that it be temporally associated with symptoms, and that its correction result in symptomatic improvement. [165] If these criteria are applied to these aberrations of peristalsis, only severe DES would be judged significant. [70], [165] With this caution in mind, consider what has been learned of spastic disorders of peristalsis.

Neuromuscular Pathology The esophageal muscularis propria and myenteric plexus are not readily accessible for biopsy; the result is that little material is available for histopathological examination. Furthermore, because patients with spastic disorders of the esophagus rarely undergo esophageal surgery and the diseases are not fatal, making for a paucity of pathological specimens; the limited information that does exist pertains only to DES, as opposed to the minor aberrations of peristalsis. The most striking reported pathological change is diffuse muscular hypertrophy or hyperplasia, mainly of the distal two thirds of the esophagus. Muscular thickening of up to 2 cm has been reported in patients with clinical and manometric evidence of DES. [166] However, there are other well-documented cases of spasm in which esophageal muscular thickening was not found at thoracotomy, [167] and still other instances of patients with muscular thickening not associated with DES symptoms. [168] Similarly, little evidence of neuropathology has been reported; diffuse fragmentation of vagal filaments, increased endoneural collagen, and mitochondrial fragmentation have been described, but the significance of these findings is unclear. [166]

Pathophysiology of Spastic Disorders of Peristalsis Despite the absence of defined histopathology, physiological evidence implicates myenteric plexus neuronal dysfunction in spastic disorders of the esophagus. During peristalsis, vagal impulses reach the entire smooth muscle segment of the esophagus simultaneously and activate myenteric plexus neurons between the longitudinal and circular muscle layers. [169] Ganglionic neurons then intervene between the efferent vagal fibers and the smooth muscle, belonging to either an inhibitory population (using nitric oxide as a neurotransmitter) that hyperpolarize the muscle cell membrane and inhibit contraction or to an excitatory (cholinergic) population that depolarizes the membrane thereby prompting contraction. Thus, the instantaneous activity of the musculature at each esophageal locus is determined by the balance between these controlling influences from the myenteric plexus. Experimental evidence suggests heterogeneity among patients with spastic disorders such that some primarily exhibit a defect of inhibitory interneuron function, whereas in others the defect is of excess excitation. Two in vivo experiments implicated a defect of myenteric plexus inhibitory interneuron function in the genesis of simultaneous contractions in the distal esophagus. Behar and Biancani [170] timed the propagation of a swallow-induced contraction in physiologically normal persons and in a group of patients whose dominant manometric abnormality was of a simultaneous contraction in the distal 10 cm of esophagus. Figure 59-11 illustrates the key finding of that work. Within the proximal (striated muscle) esophagus, the two groups exhibited similar contraction propagation, consistent with this timing’s being the result of the sequenced activation of motor units by vagal efferents programmed within the medullary swallowing center. However, once entering the smooth muscle segment, the patients’ contractions diverged from those of the normal subjects and resulted in a simultaneous contraction in the distal esophagus. The duration and amplitude of contraction at each esophageal locus were normal, but the progressive delay of initiation of that contraction, a function attributable to increasing influence of inhibitory interneurons in the distal esophagus, was absent. Furthermore, when these persons swallowed twice within a 5-second interval, there was no deglutitive inhibition of the first peristaltic contraction within the smooth muscle esophagus, as is observed in normal subjects. Another experiment demonstrating impaired deglutitive inhibition in DES comes from work using an artificial high-pressure zone within the distal esophagus, as illustrated in Figure 59-7. Patients with motor disorders characterized by rapidly propagating or simultaneous contractions exhibited only partial relaxation of the artificial igh-pressure zone, proportional to the impairment of propagation velocity. [100] Taken together, these findings strongly suggest that one potential neuropathological process in DES is a selective, intermittent dysfunction of myenteric plexus inhibitory interneurons.

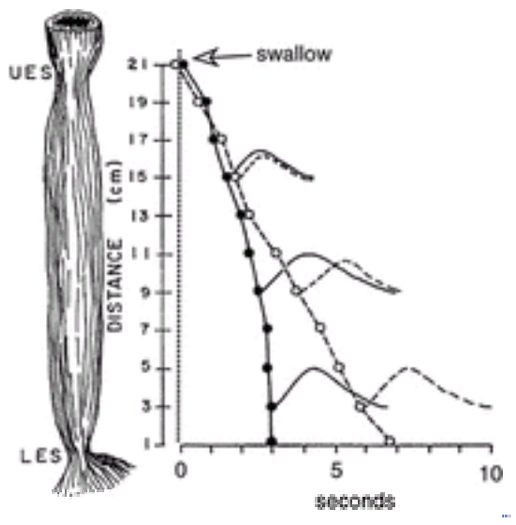

FIGURE 59-11. Rate of propagation of an esophageal contraction in persons with normal peristalsis (*open circles*) and in a group of patients with a motor disorder characterized by dysphagia and simultaneous contractions in the distal esophagus (*filled circles*). The propagation is similar between the two groups in the proximal (striated muscle) esophagus but diverges in the distal (smooth

muscle) esophagus. Because the prolonged latency in the distal esophagus is believed to be a function of postganglionic inhibitory interneurons with the myenteric plexus, this finding suggests selective dysfunction of these cells. (From ref. [170].)

As outlined earlier, dysfunction of the excitatory population of interneurons within the myenteric plexus, or abnormal excitability of the muscle itself, can also cause an aberration of peristalsis. Several lines of evidence suggest instances of excess excitation in response to hormonal or cholinergic stimulation. Representative of such an abnormality is a second group of patients in the analysis of Behar and Biancani [170] whose main manometric abnormality was of frequent spontaneous distal esophageal contractions. These patients had normal propagation latency, as defined by the parameters of Figure 59-11, but a significantly longer and higher amplitude contraction at each locus within the smooth muscle. [170] On examining the categorization of disorders of peristalsis outlined in Table 59-4, these individuals would be labeled as having nutcracker esophagus. Patients with peristaltic disorders characterized by excess excitation demonstrate heightened sensitivity to stimulation with cholinergic agents, [171], [172] the cholinesterase inhibitor edrophonium, [173] pentagastrin, [174] and ergonovine. [175] An electromyographic correlate of this excitability is found from bipolar ring electrode recordings from the distal esophagus. [176] Whereas physiologically normal persons uniformly exhibited spiking activity before each esophageal contraction, patients with DES exhibited spike-independent spontaneous esophageal contractions.

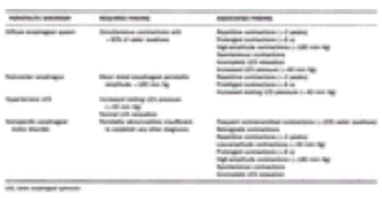

TABLE 59-4 Manometric Criteria for Disorders of Peristalsis

The foregoing discussion suggests that the physiological abnormalities of patients with spastic disorders are heterogeneous, but all are characterized by an imbalance between the excitatory and inhibitory influences on the esophageal smooth muscle. The suggestion of an impairment of the pathway of deglutitive inhibition is particularly interesting in that it places DES in a pathophysiological continuum with achalasia, consistent with documented case reports of patients undergoing this evolution. [111] Furthermore, there are marked similarities between vigorous achalasia and DES; both are characterized by simultaneous contractions of the esophageal body; the only differences being involvement of the LES and constancy of the disorder in vigorous achalasia. As in achalasia, the simultaneous contractions typifying DES impair bolus transit through the esophagus, potentially explaining the associated dysphagia. [177] Considerable attention has been focused on the clinical significance of the disorders of peristalsis other than DES described in Table 59-4, particularly *nutcracker esophagus.* Esophageal bolus transit is normal in this condition, [178] and no associated neuromuscular pathology is recognized. A few instances in which patients with nutcracker esophagus were subsequently diagnosed with achalasia have been reported, [179], [180] but considering the rarity of this observation and the high prevalence of nutcracker esophagus, the association is most likely explained by chance. No correlation has been shown between the severity of nonspecific peristaltic abnormalities and the severity of symptoms. [181] Long-term observation has shown neither a parallel in clinical course with manometric findings nor consistency in manometric diagnosis over time. [182] A therapeutic trial with nifedipine showed that significant reduction of wave amplitude in patients with nutcracker esophagus was not accompanied by a significant reduction in chest pain. [183] Conversely, a controlled trial of trazodone produced significant symptomatic improvement but no change in manometric findings. [184] One controlled trial demonstrated an association of symptomatic and manometric improvement with diltiazem, but the correlation for individual patients was not reported. [185] Finally, provocation of nonspecific motility abnormalities with cholinergic stimulation has not proven useful in detecting patients who are subsequently responsive to pharmacological treatment. [186], [187] In summary, it has been difficult to determine a direct relevance of nonspecific motility disturbances to either symptoms or function, making their detection of no generalizable clinical value.

Epidemiology No population-based studies exist on the incidence or prevalence of esophageal motility disorders other than achalasia. Thus, the only way to estimate the incidence or prevalence of spastic disorders is to examine the data on populations at risk and to reference the observed frequency of spastic disorders to the incidence of achalasia which, as detailed earlier, is about 1 per 100,000 population. Populations at risk for motility disorders are patients with chest pain or dysphagia, so it is among these patients that extensive manometric data have been collected. As detailed in Table 59-5, summarizing representative studies of at least 30 subjects, manometric abnormalities are prevalent among these groups. [155], [164], [188], [189], [190], [191], [192], [193], [194], [195], [196] and [197] Asymptomatic volunteers (usually younger than the patients) were evaluated to define normal values in five of these studies. [155], [189], [196], [197] and [198] The manometric pattern of achalasia was not detected in any volunteer. Similarly, although DES is more variably defined than is achalasia, [163] simultaneous contractions after at least 30% of swallows were not found in any volunteer. [196]

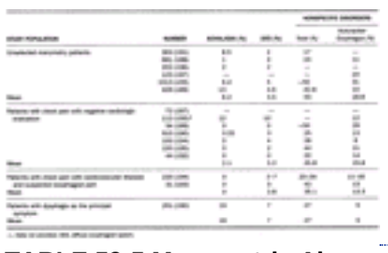

TABLE 59-5 Manometric Abnormalities in Patients with Chest Pain or Dysphagia

Most manometric findings among the patients in Table 59-5 fall under the categories other than DES in Table 59-4. Of the group, increased wave amplitude (nutcracker esophagus) is the most commonly detected pattern, accounting for a large portion of patients in the nonspecific disorders category. Variability in the prevalence values of the nonspecific disorders in Table 59-5 is partly attributable to a lack of uniform definitions of the motility disorders listed as well as to the inhomogeneity of patient populations studied. [70]

Clinical Presentation The major symptoms of spastic disorders are dysphagia and chest pain; regurgitation is infrequent compared with achalasia. The prevalence of chest pain is constant among the spastic disorders listed in Table 59-4, but the prevalence and severity of dysphagia are greater with DES. [181] Among the patients with chest pain as a dominant symptom, there is a high prevalence of psychiatric diagnosis, particularly anxiety and depression. [199] Evidence also exists suggesting a lower visceral pain threshold in this group; balloon distention and esophageal compliance studies reproduce esophageal pain at low distending volumes without corresponding motor changes. [200], [201] Finally, symptoms compatible with the irritable bowel syndrome may be seen in more than 50% of these patients. [202] Dysphagia for both liquids and solids is reported by 30% to 60% of patients with spastic disorders. [181], [190] Dysphagia is usually intermittent, sometimes related to swallowing specific substances or liquids at extreme temperatures. Dysphagia is usually not progressive, and weight loss is rare. In some instances, patients with spastic disorders experience episodes of esophageal obstruction while eating that persists until relieved by emesis; these instances are probably related to simultaneous prolonged DES-type contractions. More commonly, the dysphagia reported by patients with spastic disorders does not prevent or prolong eating. Intermittent substernal chest pain is reported by 80% to 90% of patients with spastic disorders. [181], [190] Esophageal chest pain is very similar to angina; usually described as crushing or squeezing, often radiating to the neck, jaw, arms, or midline of the back. Pain episodes may last from minutes to hours, but swallowing is usually not impaired during these episodes. Severe pain episodes may require narcotics or nitroglycerin for relief, further confusing the distinction between esophageal and cardiac pain. The mechanism producing pain is poorly understood; transient ischemia, lumenal distention, and altered visceral sensitivity have all been hypothesized. [200], [203], [204] More likely, the mechanism responsible for esophageal pain is variable among individual patients.

Endoscopic, radiographic, and manometric findings. Spastic motor disorders of the esophagus have no pathognomonic endoscopic features. However, endoscopy is useful in the evaluation of patients with dysphagia or suspected esophageal pain to identify either structural lesions or reflux esophagitis. Typically, spastic disorders are defined by manometry or barium radiography, the abnormal motor events are usually intermittent, and there are no uniform radiographic or manometric definitions. In the unequivocal case, nonperistaltic, high-amplitude, prolonged contractions are seen during esophageal manometry, and these are associated with the patient's experiencing pain (Fig. 59-12). These unequivocal cases are probably associated with a defect in the neuronal architecture of the myenteric plexus, placing them along the continuum of vigorous achalasia and achalasia (see Table 59-2). [100] The LES typically functions normally. Radiographically, "corkscrew esophagus," "rosary bead esophagus," pseudodiverticula, or curling are indicative of DES (Fig. 59-13). It must be emphasized, however, that neither tertiary contractions (nonperistaltic, simultaneous esophageal contractions) on radiographs nor occasional simultaneous contractions on manometry are pathognomonic of esophageal spasm; both may be seen in asymptomatic persons. [164]

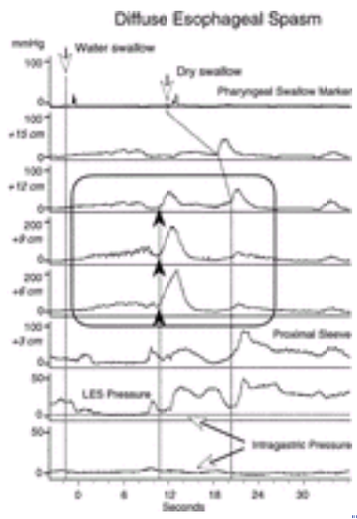

FIGURE 59-12. Esophageal manometric recording in a patient with symptomatic diffuse esophageal spasm. The timing of the swallow is indicated by the *first vertical dotted line*. The *italicized numbers* to the **left** of the pressure calibrations indicate the position of each recording site relative to the midpoint of the sleeve sensor that is centered within the lower esophageal sphincter (LES). The resting LES pressure is 20 mm Hg relative to intragastric pressure (indicated by the *horizontal dotted line*) and demonstrates normal deglutitive relaxation. The *rectangle* surrounds a section of the tracing demonstrating high-amplitude, prolonged, simultaneous, repetitive contractions in the smooth muscle esophagus. The most prominent simultaneous contraction is indicated by the *solid arrowheads* connected by a *vertical dotted line*. After the subsequent dry swallow, there is a propagated contraction in the proximal (striated muscle) esophagus, but this also terminates with simultaneous contraction waves in the smooth muscle. This patient's symptoms were dysphagia and chest pain.

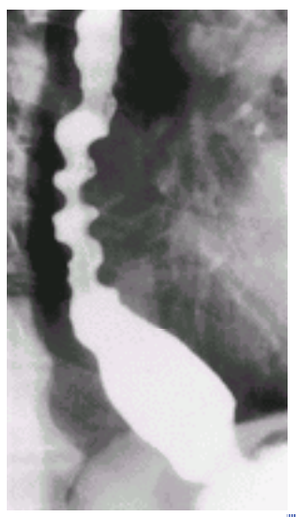

FIGURE 59-13. Corkscrew esophagus on barium radiography in a patient with symptomatic diffuse esophageal spasm.

One hypothesized explanation for the limited sensitivity of esophageal manometry in detecting spasm is that abnormal motor events escape detection because of sampling error. Because both chest pain and spasm are sporadic events, the likelihood of documenting both in a brief bedside study seems slim. This perception fostered the development of ambulatory esophageal manometry systems capable of longer recording intervals with the hope of correlating spontaneously occurring symptoms with abnormal esophageal motility. Unfortunately, despite multiple examinations of this technology, no consensus exists among investigators regarding scoring techniques or on the utility of this technology in establishing abnormal esophageal motility as the cause of "noncardiac" chest pain. One study, using combined ambulatory manometry and pH studies on a highly selected group of patients acutely hospitalized for attacks of chest pain, showed that up to 43% of patients have pain associated with episodes of acid reflux, but there was little additional yield from the manometric data. [205] Thus, at present, ambulatory manometry remains an investigational technique, with scoring criteria and symptom-association criteria remaining to be established. Variability in results evident in published trials can easily be explained by differences in patient populations studied and analysis schemes used. Furthermore, the evolving picture suggests that motor abnormalities play a less significant role than previously suggested in chest pain, and GERD disease plays a much more significant role. [206] Bancewicz and associates [191] found that intensive antireflux therapy was the most useful therapy for a large group of symptomatic patients without a specific motor disorder. Similarly, in another study, Achem and colleagues [207] found that antireflux therapy benefited patients with unexplained chest pain, regardless of the presence or absence of nonspecific motor abnormalities.

Differential Diagnosis Although abnormal peristalsis can potentially cause dysphagia and chest pain, significant abnormalities are rare, as suggested by the data in Table 59-5. Furthermore, esophageal dysmotility is not life-threatening, as is angina pectoris, the pain of which it can closely mimic. Features suggesting an esophageal as opposed to a cardiac etiology include the following:

- Pain that is nonexertional and prolonged
- Pain that interrupts sleep
- Pain related to meals
- Pain relieved with antacids
- The presence of additional esophageal symptoms of heartburn, dysphagia, or regurgitation.

However, each of these characteristics still exhibits overlap with cardiac pain in some instances. Thus, an esophageal origin of chest pain should be considered only after careful consideration and evaluation of potential cardiopulmonary causes. Furthermore, even within the spectrum of esophageal diseases, neither chest pain nor dysphagia is specific for a spastic disorder because both symptoms are also characteristic of common esophageal disorders including peptic or infectious esophagitis. *After these more common diagnostic possibilities have been excluded* by appropriate radiographic evaluation, endoscopic evaluation, and in some instance, a therapeutic trial of antisecretory medications, spastic disorders should be considered as the cause of the still unexplained symptoms.

Treatment Ironically, the medical therapies of esophageal spasm are similar to those of coronary artery disease, a disease with which it can be confused. However, despite the dogma of treatment with smooth muscle relaxants, there is a paucity of data on the medical treatment of esophageal spasm. Long-term outcome studies of the medical treatment of DES with smooth muscle relaxants are not available. Nitrates, [208] calcium channel blockers, [209] and hydralazine [210] have all been shown to be beneficial in small trials. In addition, botulinum toxin injected at the esophagogastric junction has also been used with some success in patients with nonachalasic esophageal spasm. [211] The only double-blind placebo-controlled trial showing efficacy with medical therapy was in the case of the anxiolytic trazodone, suggesting that reassurance and control of anxiety are important therapeutic goals. [184] Consistent with this conclusion, successful management of symptoms associated with spastic motility disorders have also been reported using behavioral modification programs and biofeedback. [212] Although the rationale is unclear, esophageal dilation with standard mercury-filled dilators has also been suggested as a therapy for dysphagia or chest pain in patients with spastic disorders. However, in the only controlled trial of this therapy, dilation with an 8-mm ("placebo") dilator was as effective as an 18-mm dilator in producing transient symptom relief. [213] Alternatively, pneumatic dilation has been used in patients with DES and severe dysphagia. [102], [214] In one practitioner's experience, 45% of patients with DES noted relief, compared with 80% of patients with achalasia. [102] In another series of nine patients with DES and LES dysfunction, dysphagia but not chest pain was improved during 37 months of observation. [214] However, it is not clear what distinguishes that group of patients from patients with vigorous achalasia, implying that patients likely to derive benefit from pneumatic dilation are those with mixed features of achalasia and DES, as described by Vantrappen and colleagues. [111] If dysphagia becomes so severe that weight loss is observed or if pain becomes unbearable, surgical therapy consisting of a Heller myotomy across the LES with proximal extension of the incision to include the involved area of spasm should be considered. [215], [216] However, there are no controlled studies of this treatment in patients with well-defined DES, and the indication for this procedure is extremely rare. In summary, at this point, the therapy of esophageal spastic disorders is as poorly defined as are the spastic disorders themselves. Clearly, most esophageal pain is attributable to reflux, irrespective of the presence or absence of minor motility abnormalities, and antireflux therapy should be extensively pursued before attempting therapy of a spastic disorder. Within the universe of motility disorders, achalasia stands alone as a well-defined

disease. Partially overlapping achalasia is DES, a disorder characterized by a severe peristaltic defect with functional and symptomatic consequences in some cases. Interestingly, DES most likely responds to specific therapy when it exhibits characteristics indicative of vigorous achalasia, implying that it is part of a pathophysiological continuum in these cases (Fig. 59-14). Alternatively, episodic esophageal spasm may be a manifestation of GERD, a disorder for which very effective therapy exists.

FIGURE 59-14. The universe of esophageal motility disorders. Some overlap exists among adjacent entities, as suggested by the Venn diagram. The attributes indicated on the **left** are increasingly relevant going down the diagram, whereas those at the **right** are increasingly applicable moving up the diagram. (From Kahrilas PJ. Esophageal motility disorders: current concepts of pathogenesis and treatment. Can J Gastroenterol 2000;14:221.)

With respect to other esophageal motility disorders, the current therapy is as poorly defined as are the disorders themselves. Although in extreme circumstances these disorders (nutcracker esophagus, hypertensive LES, and nonspecific disorders) may mimic DES with regard to symptoms and can exhibit profound esophageal hypercontractility, there are no significant controlled data suggesting that these patients benefit from antispasmodic therapy. In view of the unproven value of detecting these manometric aberrations, practice guidelines do not support pursuing these findings in the evaluation of patients with chest pain. Rather, until the meaning of these aberrations of esophageal motility are clarified, we should not overlook therapy aimed at the most common esophageal disorder, GERD, or more global conditions such as depression or somatization neurosis that are coexistent in these patients

Esophageal Involvement in Systemic Disease

Esophageal dysmotility occurs as a manifestation of several disease processes with the potential to affect smooth muscle or the autonomic nervous system. Included are collagen-vascular diseases, infiltrative disease such as amyloidosis or malignant diseases, metabolic disorders such as thyrotoxicosis and diabetes, and caustic injury as occurs with GERD. However, esophageal involvement is well characterized only with collagen-vascular diseases, diabetes, and GERD. Dysmotility associated with GERD is discussed in Chapter 60; the following discussion focuses on esophageal involvement in the collagen-vascular diseases and diabetes.

Scleroderma *Scleroderma* causes diffuse fibrosis and degenerative changes in the skin and synovium. The disease also has the potential to involve the heart, kidneys, lungs, intestines, and esophagus. White women between 30 and 50 years of age are the most commonly afflicted. Two forms of scleroderma are recognized: progressive systemic sclerosis with diffuse scleroderma (the more fulminant form with early involvement of internal organs) and the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia). The basic disease process is of smooth muscle atrophy with subsequent fibrosis. With either form of scleroderma, the esophagus is involved in 75% to 85% of cases. [217], [218] Pathological changes are confined to the smooth muscle portion of the esophagus resulting in aperistalsis and atony of the LES. [219] The main clinical manifestations of scleroderma esophagus are dysphagia and heartburn. Symptomatic patients usually have Raynaud phenomenon, but the severity of the esophageal disease does not covary with the disease severity in other organs. [220] The prevalence of erosive esophagitis may be as high as 60%, with reported cases of Barrett metaplasia and Barrett adenocarcinoma. [221], [222] Dysphagia may be attributable to poor peristalsis or to a stricture complicating the peptic esophagitis (seen in as many as one third of patients). [222] Radiographic findings typically consist of a slightly dilated aperistaltic esophagus and free reflux. Wide-mouth diverticula of the esophagus, similar to those described in the intestines, have also been seen. [223] Manometric abnormalities consist of a hypotensive or absent LES pressure, hypotensive to absent distal esophageal peristalsis, and normal proximal esophageal peristalsis. [217] There is no specific treatment for the esophageal involvement in scleroderma. Gastroesophageal reflux should be identified and treated commensurate with its severity. Strictures may require frequent dilation, and in rare cases of intractable esophagitis, antireflux surgery may be required. [224]

Other Collagen Vascular and Connective Tissue Diseases Esophageal symptoms are uncommon in *systemic lupus erythematosus,* although 25% to 35% of unselected patients have the manometric findings of hypotensive peristalsis and a hypotensive LES. [225], [226] *Mixed connective tissue disease* exhibits a mixture of clinical features found in scleroderma, polymyositis, and systemic lupus erythematosus and is characterized by high titers of a circulating antibody for a nuclear ribonucleoprotein antigen. More than 60% of patients with mixed connective tissue disease have esophageal involvement defined by cineradiography, [227] and up to 82% of patients have manometric findings. [225] Abnormalities of both smooth and skeletal muscle are found. In the largest report to date, 5 of 17 patients had a manometric pattern consistent with scleroderma, and 10 patients had aperistalsis of the entire esophageal body along with low pressures in both the UES and LES. [225]

Diabetes Mellitus More than 60% of patients with *diabetes* with peripheral or autonomic neuropathy and an occasional patient without neuropathy have esophageal manometric abnormalities. [228] Reported manometric abnormalities associated with diabetes include hypotensive peristalsis, frequent failed peristalsis, hypotensive LES with impaired deglutitive relaxation, simultaneous contractions, and repetitive contractions. [228], [229] and [230] The significance of these abnormalities is uncertain because most of these patients are asymptomatic. [228] Histological and pharmacological studies suggest that the esophageal abnormalities are secondary to the degenerative effects of diabetes mellitus on the autonomic nervous system, rather than smooth muscle dysfunction.

Presbyesophagus Manometric studies from the 1960s on men more than 80 years old suggested that aging was associated with failed peristalsis, decreased LESR, and an increase in spontaneous contractions. [231] Symptoms correlated poorly with these findings, leading to introduction of the term *presbyesophagus* to describe incidental asymptomatic peristaltic abnormalities in elderly patients. In 1974, a study of patients who were more than 70 years old and who were carefully screened to rule out diabetes or neurological disease found no increased incidence of peristaltic abnormalities in elderly persons compared with young control subjects. [232] The only difference found was decreased peristaltic amplitude in the elderly group, suggesting that age in of itself does not lead to peristaltic dysfunction. Thus, cases of “presbyesophagus” are likely related to comorbid conditions commonly encountered in elderly patients.

CHAPTER 60

Joel E. Richter

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) results from the failure of the normal antireflux mechanism to protect against frequent and abnormal amounts of gastroesophageal reflux (GER), that is, the effortless movement of gastric contents from the stomach to the esophagus. GER is not itself a disease, but a normal physiological process. It occurs in virtually everyone, multiple times everyday, especially after large meals, without producing either symptoms or signs of mucosal damage. In contrast, GERD is a spectrum of disease usually producing symptoms of heartburn and acid regurgitation. Most patients have no visible mucosal injury at the time of endoscopic examination (nonerosive GERD), whereas others have esophagitis, peptic strictures, Barrett esophagus, or evidence of extraesophageal diseases such as chest pain, pulmonary symptoms, or ear, nose, and throat symptoms. GERD is a multifactorial process, one of the most common human diseases, and of economic importance, contributing to the expenditure in the United States of 4 to 5 billion dollars per year for antacid medications.

EPIDEMIOLOGY

The prevalence of GERD differs, depending on whether the analysis is based on symptoms (primarily heartburn) or signs (i.e., esophagitis) of disease. When based on symptoms, GERD is common in Western countries. For example, in a nationwide population-based study by the Gallup Organization in the United States, 44% of the population reported heartburn at least once a month. [1] More convincing data were obtained by Locke and colleagues, [2] who mailed out 2200 validated self-report questionnaires to a predominantly white population residing in Olmsted County, Minnesota. The prevalence of heartburn and acid regurgitation in the past 12 months was noted to be 42% and 45%, respectively. Frequent symptoms (at least weekly) were reported by 20% of respondents, with an equal gender distribution across all ages. The majority reported that heartburn was of moderate severity and had a duration of 5 years or more, and only 5.4% reported a physician visit for reflux complaints within the previous year. More variable prevalence rates for symptomatic GERD have been reported from Europe, ranging from 5% in Switzerland to 27% in Finland. [3]

Conversely, the true prevalence of esophagitis is very difficult to define because healthy persons rarely undergo endoscopic procedures. Studies suggest that 7% of persons in the United States have erosive esophagitis, whereas European studies identify prevalence rates ranging from 2% to 10%. [4] Analyses of the gender ratio of GERD show nearly equal proportions of affected men and women, but a male predominance occurs in esophagitis and Barrett esophagus. [4] Increasing age is an important factor in the prevalence of GERD complications, probably the result of cumulative acid injury to the esophagus over time. [5]

In contrast, the prevalence of GERD and its complications is relatively low among residents of Africa and Asia. For example, a cross-sectional study in Singapore reported prevalence rates for reflux symptoms of 7.5% in Indians, 0.8% in Chinese persons, and 3.0% in Malays. [6] Possible reasons for the lower GERD prevalence includes low dietary fat, lower body mass index, and lower maximal acid output related to infection with *Helicobacter pylori.* [7], [8]

The prevalence of GERD is increasing in Western countries. El-Serag and Sonnenberg [9] observed opposing time trends in the prevalence of peptic ulcer disease and GERD in the United States: rates of peptic ulcer and gastric cancer fell between 1970 and 1995; the prevalence of GERD and esophageal adenocarcinoma rose significantly. The authors speculated that the decreasing prevalence of *H pylori* may be playing a contributory role to the increasing prevalence of GERD. Data suggest that *H pylori*–induced gastritis involves both the antrum and corpus, affecting the parietal cells and thus reducing acid secretion and elevating gastric pH. [8] This may have a protective influence on the esophageal mucosa in patients susceptible to GERD. Long-term epidemiologic studies will be required to address this question more appropriately.

Other noteworthy epidemiologic observations about GERD are that it is more common in whites than in African Americans or Native Americans, [4] family clustering has been reported, [10] and it is rarely the cause of death. [4] GERD, however, is associa- ted with considerable morbidity and with complications such as esophageal ulcerations (5%), peptic stricture (4% to 20%) and Barrett esophagus (8% to 20%). Furthermore, GERD as a chronic disease significantly impairs quality of life. As compared with other chronic medical conditions, the impairment of quality of life resulting from GERD is similar to, or even greater than, that resulting from arthritis, myocardial infarction, heart failure, or hypertension [11] (Fig. 60-1).

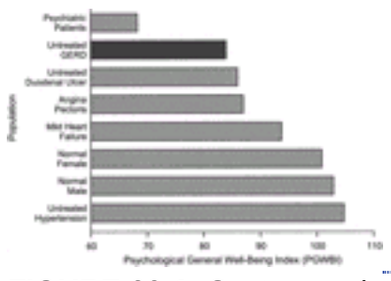

FIGURE 60-1. Gastroesophageal reflux disease (GERD) and quality of life. GERD has a greater negative impact on the sense of well-being than many common chronic diseases including hypertension and angina. The only illness having a greater effect than GERD on quality of life is psychiatric disease. (Data from ref. [11].)

PATHOPHYSIOLOGY

The pathophysiology of GERD is complex and results from an imbalance between defensive factors protecting the esophagus (antireflux barriers, esophageal acid clearance, tissue resistance) and aggressive factors from the stomach contents (gastric acidity and volume and duodenal contents). The intermittent nature of symptoms and esophagitis in many patients suggests that the aggressive and defensive forces are part of a delicately balanced system.

Antireflux Barriers

The first tier of the three-tiered esophageal defense against acid damage consists of the *antireflux barriers.* This is an anatomically complex region that includes the intrinsic lower esophageal sphincter (LES), the diaphragmatic crura, the intra-abdominal location of the LES, the phrenoesophageal ligaments, and the acute angle of His (Fig. 60-2).

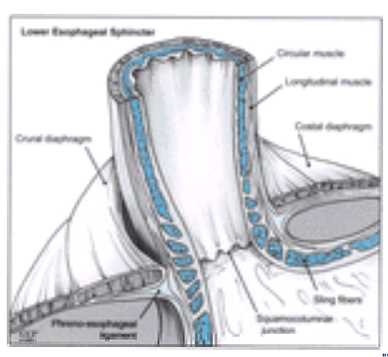

FIGURE 60-2. Anatomy of the gastroesophageal junction illustrating the major elements of the antireflux barrier. (From ref. [17].)

The LES is a tonically contracted segment of distal esophagus about 3 to 4 cm in length. [12] It is the major component of the antireflux barrier and is capable of preventing reflux even when it is completely displaced from the diaphragmatic crura because of a hiatus hernia. [12] The proximal margin of the LES is normally about 1.5 to 2.0 cm above the squamocolumnar junction, whereas the distal segment, about 2 cm in length, lies within the abdominal cavity. [13] This location of the distal LES contributes to the maintenance of gastroesophageal competence during intra-abdominal pressure events. Resting LES pressure ranges between 10 to 30 mm Hg and includes a generous reserve capacity, because a minimal basal LES pressure in the range of 5 to 10 mm Hg usually prevents GER. [14] The LES maintains a high-pressure zone by the intrinsic tone of its muscle and by cholinergic excitatory neurons. [15] There is considerable diurnal variation in basal LES pressure; it is lowest after meals and highest at night. It is also influenced by certain circulating peptides and hormones, foods (particularly fat), and numerous drugs (Table 60-1). During swallowing, LES relaxation (LESR) occurs for 5 to 10 seconds, thus permitting esophageal peristalsis to sweep the swallowed bolus into the stomach.

	INCREASE PRESSURE	DECREASE PRESSURE
Hormones	Gastrin Motilin Substance P	Secretin Cholecystokinin Somatostatin Vasoactive intestinal polypeptide
Neural agents	α-Adrenergic agonists β-Adrenergic antagonists Cholinergic agonists	α-Adrenergic antagonists β-Adrenergic agonists Cholinergic antagonists
Foods	Protein	Fat Chocolate Peppermint
Miscellaneous	Histamine Antacids Metoclopramide Domperidone Prostaglandin $F_{2\alpha}$ Cisapride	Theophylline Prostaglandins E_2 and I_2 Serotonin Meperidine Morphine Dopamine Calcium blockers Diazepam Barbiturates

TABLE 60-1 Substances that Modulate Lower Esophageal Sphincter Pressure

Anatomically, the LES lies within the hiatus created by the right crus of the diaphragm, and it is anchored by the phrenoesophageal ligaments, which inserts at about the level of the squamocolumnar junction (see Fig. 60-2). [16] Developmentally, the crural diaphragm arises from the dorsal mesentery of the esophagus and is innervated separately from the costal part of the diaphragm. It is inhibited by esophageal distention, during vomiting, and in association with transient LESRs, but not during swallowing. The crural diaphragm provides extrinsic squeeze to the intrinsic LES, contributing to resting pressure during inspiration and also augmenting LES pressure during periods of increased abdominal pressure such as coughing, sneezing, or bending. [17] Crural contractions impose rhythmic pressure increases of about 5 to 10 mm Hg on the LES pressure recording. [18] During deep inspirations and some periods of increased abdominal straining, these changes may reach 50 to 150 mm Hg. [19]

The oblique entrance of the esophagus into the stomach creates a sharp angle on the greater curve aspect of the gastroesophageal junction, the angle of His. This angle has been shown in cadavers to create a flap valve effect that contributes to gastroesophageal junction competency. [20]

Mechanisms of Reflux

Transient Lower Esophageal Sphincter Relaxations This is the most common mechanism underlying GER and also accounts for the reflux of gases during belching. Figure 60-3 illustrates an example of a transient LESR and highlights differences from swallow-induced LESRs: transient LESRs are not associated with antecedent pharyngeal contractions, are unaccompanied by esophageal peristalsis, persist for longer periods (>10 seconds) than swallow-induced LESRs, and are always accompanied by inhibition of the crural diaphragm. [21] Transient LESRs account for nearly all reflux episodes in healthy persons and for 50% to 80% in patients with GERD, depending on the severity of associated esophagitis (Fig. 60-4). [22] However, one study suggested that low basal LES pressure, rather than transient LESRs, may be the primary mechanism of GER in patients with nonreducible hernias. [23] Transient LESRs are not always associated with GER. In healthy persons, about 40% to 60% of transient LESRs are accompanied by reflux episodes, compared with 60% to 70% in patients with GERD. [15], [22], [24], [25] The rate of transient LESR is increased by gastric distention, whether by gas or a meal, by stress, and, to a lesser extent, by subthreshold (for swallowing) stimulation of the pharynx. [26] Under normal circumstances, meals are the major stimuli for transient LESRs, but the importance of specific foods is unknown. [27] Transient LESRs are inhibited by the supine position, sleep, general anesthesia, and vagal cooling. [26] Various drugs also impair transient LESRs including cholecystokinin A antagonists, anticholinergic drugs, morphine, somatostatin, nitric oxide inhibitors, 5-hydroxytryptamine $_3$ (5-HT $_3$) antagonists, and d-aminobutyric acid $_B$ (GABA $_B$) agonists. [28] Current evidence indicates that transient LESRs are mediated through vagal pathways. [26] Gastric distention activates mechanoreceptors in the proximal stomach adjacent to the gastric

cardia that send signals to the brainstem center through vagal afferent pathways. The structured sequence of motor events including LESR, inhibition of the crural diaphragm, and contractions of the esophageal body suggest that this process occurs in a programmed manner, probably controlled by a pattern generator within the vagal nuclei. The motor arm is in the vagus nerve and shares common elements with swallow-induced LESR. [30]

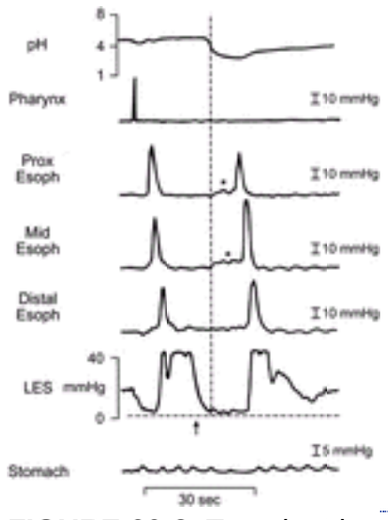

FIGURE 60-3. Transient lower esophageal sphincter (LES) relaxation (*arrow*) occurring immediately after the completion of a swallow-induced LES relaxation. Note the substantially longer duration of the transient LES relaxation (TLESR) compared with the preceding swallow-induced LES relaxation. A reflux episode (*dotted line*) associated with a common cavity (*asterisk*) occurs after complete LES relaxation has been achieved and is cleared by secondary peristalsis. (From ref. [26].)

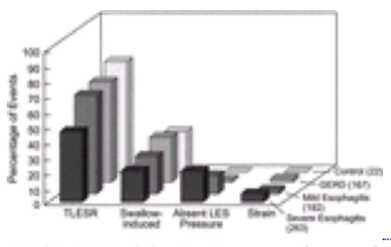

FIGURE 60-4. Proportion of reflux episodes in the spectrum of gastroesophageal reflux disease (*GERD*) occurring by the mechanisms of transient lower esophageal sphincter relaxation (*TLESR*), swallow-induced LES relaxation, absent basal LES pressure, and straining in the presence of low LES pressure (Data from ref. [22].)

Swallow-Induced Lower Esophageal Sphincter Relaxations About 5% to 10% of reflux episodes occur during swallow-induced LESRs. Most of these episodes are associated with defective or incomplete peristalsis. [22], [28] During a normal swallow-induced LESR associated with normal peristalsis, reflux is uncommon because of the absence of concomitant crural diaphragm relaxation, the relatively short duration of LES relaxation (5 to 10 seconds), and the prevention of reflux by the oncoming peristaltic wave (see Fig. 60-3). Reflux during swallow-induced LESR is more common in the presence of a hiatus hernia because of pooling of gastric liquids in the hernia sac and the absence of any residual diaphragmatic support during the LESR. [31]

Hypotensive Lower Esophageal Sphincter Pressure Stress reflux and free reflux are two mechanisms by which GER can be associated with diminished LES. [14], [22] *Stress reflux* results when a relatively hypotensive LES is overcome and is "blown open" by an abrupt increase in intra-abdominal pressure from coughing, straining, or bending. Stress reflux is unlikely when the LES pressure is greater than 10 mm Hg. *Free reflux* is characterized by a fall in intraesophageal pH without an identifiable change in intragastric pressure, and it usually occurs when the LES pressure is 0 to 4 mm Hg. Reflux as the result of low or absent LES pressure is uncommon. It is found mostly in patients with severe esophagitis, in whom it may account for up to 23% of reflux episodes (see Fig. 60-4), and rarely in patients without endoscopic evidence of esophagitis. [14], [22], [24], [25] The mechanisms of a low LES pressure are poorly understood. The presence of a hiatus hernia reduces LES pressure because the intrinsic support of the crural diaphragm is lost. [12] Some LES weakness may be secondary to impairment of the excitatory cholinergic pathways to the LES as a result of esophagitis. Induction of experimental esophagitis in cats affects the release of acetylcholine and lowers LES pressures; changes that are reversible on healing of the esophagitis. [32] However, healing of esophagitis in humans is rarely accompanied by an increase in LES pressure. [33]

Hiatus Hernia

P>The relationship between *hiatus hernia* and GERD remains controversial. Mainstream opinion has shifted widely from one that virtually equated hiatus hernia with GERD to one that denied it a causal role. Currently, both epidemiologic and physiological data confirm the importance of the hiatus hernia in patients with more severe esophagitis, peptic stricture, or Barrett esophagus. Hiatus hernias, identified endoscopically or radiologically, are reported in 54% to 94% of patients with reflux esophagitis; a rate strikingly higher than in the healthy population. [34]

The functional impact of the hiatus hernia has been clarified by elegant combined manometry and videofluoroscopic studies that show that hiatus hernia impairs LES function through several mechanisms as well as impairing esophageal clearance (Fig. 60-5). [31], [35], [36] Reflux is worse in patients who have a nonreducible as opposed to a reducible hiatus hernia. Nonreducing hernias are those in which the gastric rugal folds remain above the diaphragm between swallows. [36] Furthermore, statistical modeling has revealed a significant interaction between hiatus hernia and LES pressure, such that the likelihood of GER is increased as basal LES pressure decreases, an effect that is substantially amplified by the presence of a hiatus hernia and as hernia size increases. [12]

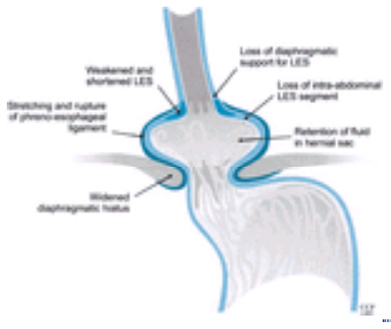

FIGURE 60-5. The impact of a hiatus hernia on the antireflux barrier. (From ref. [29].)

Displacement of the LES from the crural diaphragm into the chest reduces basal LES pressure and shortens the length of the high-pressure zone primarily because of the loss of the intra-abdominal LES segment. [35] Both these effects are caused by the loss of the extrinsic support of the diaphragmatic crura resulting in increased GER. [23] Hiatus hernia virtually eliminates the increase of LES pressure that occurs during straining and may increase the triggering of transient LESRs during gastric insufflation with gas. [35], [37] Large, nonreducible hernias also impair esophageal acid clearance because of increased tendency for reflux to occur from the hernia sac during swallow-induced LESRs. [31], [36]

The origin of hiatus hernia remains unclear. Familial clustering of GERD [10] suggests the possibilities of inherited muscle weakness in this area. Animal studies propose that reflux itself causes esophageal shortening promoting the development of a hiatus hernia. [38] Other studies find an association with obesity [39] and lifting of

heavy weights, [40] raising the possibilities that over time, chronic intra-abdominal stressors may weaken the esophageal hiatus and may cause the development of a hiatus hernia. This theory is attractive because it helps to reconcile the increased prevalence of hiatus hernias as the population ages. [34]

Esophageal Acid Clearance

The second tier against reflux damage is *esophageal acid clearance.* Reflux events determine the frequency and extent that gastric contents enter the esophagus, but esophageal acid clearance time determines the duration the mucosa is exposed to acid and probably the severity of acid damage. Esophageal acid clearance involves two related but separate processes: *volume clearance,* which is the actual removal of the reflux material from the esophagus, and *acid clearance,* which is the restoration of normal pH in the esophagus after acid exposure through titration with base, rather than true removal of the refluxed material.

Volume Clearance Esophageal peristalsis operates to clear the acid volume in both the upright and supine positions, but it is inoperative during deep rapid eye movement sleep. [45] Helm and colleagues [41] showed that one or two primary peristaltic contractions will completely clear a 15-mL fluid bolus from the esophagus. Primary peristalsis is elicited by swallowing, which occurs with a frequency of once per minute in awake subjects, regardless of whether reflux occurs. Secondary peristalsis, initiated by esophageal distention from acid reflux, is much less effective in promoting clearance of refluxate, thus offering only an ancillary protective role. Peristaltic dysfunction, that is, failed peristaltic contractions and hypotensive (<30 mm Hg) peristaltic contractions that incompletely empty the esophagus, increases in frequency with the severity of esophagitis. Kahrilas and colleagues [42] found that the prevalence of peristaltic dysfunction rose from 25% in patients with mild esophagitis to more than 50% in patients with severe esophagitis (Fig. 60-6). Failed peristalsis results in very poor volume clearance because the foci of feeble contractions clear most, but not all, of the refluxate from the esophagus. Whether esophagitis leads to peristaltic dysfunction or whether an underlying motility disorder predisposes to the development of reflux disease is not clear. Animal studies find that esophageal dysmotility associated with active esophagitis is reversible, but that associated with stricture or extensive fibrosis is not. [32] Clinical observations suggest that impaired motor function does not revert to normal after either effective medical or surgical therapies. [33]

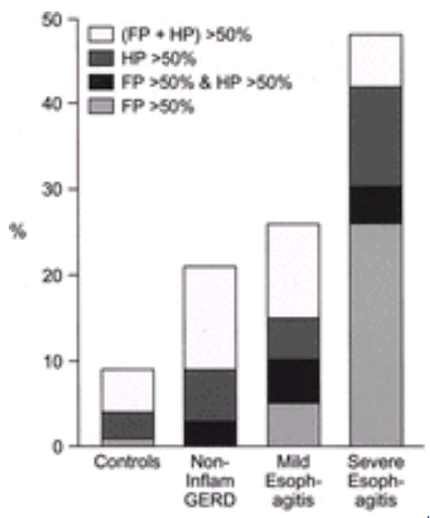

FIGURE 60-6. The prevalence of peristaltic dysfunction in controls and in patients with increasing severity of gastroesophageal reflux disease (GERD). The criteria for motility abnormalities was the occurrence of either failed, nontransmitted primary peristalsis (*FP*) or hypotensive peristalsis (<30 mm Hg) in the distal esophagus (*HP*) with more than half of the swallows. Note the increased prevalence of peristaltic dysfunction as the severity of GERD increases. (From ref. [42].)

Gravity contributes to bolus clearance when reflux occurs in the upright position. At night, when patients are supine, this mechanism is not operative unless the head of the bed is elevated. This time-honored treatment of GERD markedly improves acid clearance time and is most beneficial in those patients with aperistalsis (i.e., scleroderma). [43]

Salivary and Esophageal Gland Secretions *Saliva* is the second essential factor required for normal esophageal clearance of acid. Saliva has a pH of 6.4 to 7.8 and therefore is a weak base compared with the acidic gastric contents. [44] The high rate of spontaneous swallowing results in saliva production of approximately 0.5 mL per minute. Although saliva is ineffective in neutralizing large volumes of acid (5 to 10 mL), it can neutralize small residual amounts of acid remaining in the esophagus after the volume of refluxed material has been cleared by several peristaltic contractions. [41] The importance of swallowed saliva is supported by findings that increased salivation induced by oral lozenges or bethanechol is associated with a significant decrease in acid clearance time. In contrast, suction aspiration of saliva is accompanied by a marked prolongation of esophageal clearance, despite the presence of normal peristaltic contractions. [44] Physiological or pathological compromises of salivation may contribute to GERD. Diminished salivation during sleep explains why nocturnal reflux episodes are associated with markedly prolonged acid clearance times. [45] Similarly, chronic xerostomia is associated with prolonged esophageal acid exposure and esophagitis. [46] Cigarette smoking may promote GER. This was originally attributed to the effects of nicotine on lowering LES pressure, but more recent studies suggest that cigarette smokers have hyposalivation, which may also prolong esophageal acid clearance. [47] Finally, the esophagosalivary reflex may be impaired in patients with reflux esophagitis. This is a vasovagal reflex demonstrated by perfusing acid into the esophagus, thereby stimulating increased salivation. [48] This reflex may explain the symptoms of water brash (copious salivation) observed in some patients with reflux disease. The esophagosalivary reflex is very active in healthy persons, with a doubling or tripling of the salivary flow rate on exposure to acid. However, this reflex is diminished in patients with esophagitis and in those with strictures. [48] In addition to the role of saliva, dilution and neutralization of residual acid are achieved by the aqueous bicarbonate (HCO_3^-)-rich secretions of the esophageal submucosal glands. These glands have been identified in the opossum as well as in the human esophagus. [49] /SUP>Reflux of acid into the esophageal lumen stimulates these glands and helps to neutralize the acid, even if swallowing does not occur. [50]

Tissue Resistance Although clearance mechanisms minimize acid contact time with the epithelium, even healthy persons may have their esophagus exposed to acid 1 to 2 hours during the day and sometimes at night. Nevertheless, only a few persons experience symptomatic GER, and even fewer suffer GERD. This is the result of a third tier for esophageal defense, known as *tissue resistance.* Tissue resistance is not a single factor, but a group of dynamic mucosal structures and functions that interact to minimize mucosal damage from the noxious gastric refluxate. [51] Conceptually, tissue resistance can be subdivided into preepithelial, epithelial, and postepithelial factors. The preepithelial defense in the esophagus, in contrast to the stomach and duodenum, is poorly developed. There is neither a well-defined mucous layer nor a buffering capacity by the surface cells to secrete HCO_3^- into the unstirred water layer. This results in a lumen-to-surface pH gradient in the esophagus of 1:10, in contrast to the stomach and duodenum, where the gradient can range from 1:1000 to 1:10,000. [52] The epithelial defenses in the esophagus consist of both structural and functional components. Structural components include the cell membranes and intercellular junctional complexes of the esophageal mucosa. This structure is a 25- to 30-cell-thick, nonkeratinized squamous epithelium functionally divided into a proliferating basal cell layer (stratum basalis), a midzone layer of metabolically active squamous cells (stratum spinosum), and a 5- to 10-cell-thick layer of dead cells (stratum corneum). The esophageal mucosa is a relatively “tight” epithelium with resistance to ionic movement at the intercellular as well as the cellular level as the result of both tight junctions and the matrix of lipid-rich glucoconjugates in the intercellular space. [53] The functional components of tissue resistance include the ability of the esophageal epithelium to buffer and extrude hydrogen ions (H^+). Intracellular buffering is accomplished by negatively charged phosphates and proteins, as well as HCO_3^-. When the buffering capacity is exceeded and intracellular pH falls, it has the capacity actively to remove H^+ from the cells. This is possibly by the action of two transmembrane proteins, one a sodium (Na^+)/H^+ exchanger and the other a Na^+-dependent chloride (Cl^-)/HCO_3^- exchanger. [54], [55] After reflux-induced cell acidification, these transporters restore the intracellular pH to neutrality by exchanging H^+ for extracellular Na^+ or by exchanging Cl^- for extracellular HCO_3^-, respectively. Additionally, esophageal cells contain within their membrane a Na^+-independent Cl^-/HCO_3^- exchanger that extrudes HCO_3^- from the cytoplasm when the intracellular pH is too high. [54] When the epithelial cells are no longer able to maintain intracellular pH, they lose their ability to regulate volume, edema occurs, and balloon cells develop. The postepithelial defense is provided by the esophageal blood supply. Blood flow delivers oxygen, nutrients, and HCO_3^- and removes H^+ and carbon dioxide, thereby maintaining normal tissue acid-base balance. Blood flow to the esophageal mucosa increases in response to the stress of lumenal acid. [56] Cellular injury also stimulates cell proliferation, [57] which results in thickening of the basal cell layer of the epithelium. Unlike the stomach, in which superficial mucosal injury is repaired in hours, the esophagus repairs itself more slowly over days to weeks.

Gastric Factors

Gastric factors (particularly gastric volume and certain aggressive factors found in the refluxate) are potentially important in the production of reflux esophagitis. Gastric volume is determined by the

basal acid secretion rate, concomitant *H pylori* infection, duodenogastric reflux, and the rate of gastric emptying. Increased gastric volume not only provides more gastric contents available for reflux, but also increases the rate of transient LESRs.

Gastric Acid Secretion The primary importance of *gastric acid* is indisputable in the production of reflux esophagitis, but its mechanism may involve activation of pepsin rather than direct damage from acid alone (Fig. 60-7). In animal studies, acid causes minimal injury at a pH of less than 3.0, primarily by protein denaturation. However, the combination of acid and even small amounts of pepsin disrupts the mucosal barrier resulting in increased H^+ permeability, histological changes, and gross hemorrhage. [58] Complementing the animal studies, a series of clinical reports showed that patients with various grades of esophagitis, including Barrett esophagus, have increased frequency and duration of esophageal exposure to gastric refluxate of pH lower than 4. [59], [60] Conversely, perfusing the esophagus of animals with a pepsin solution of pH 7.5 produces minimal mucosal disruption or changes in permeability. [58] These observations are the cornerstone of acid suppressive therapy in the treatment of GERD.

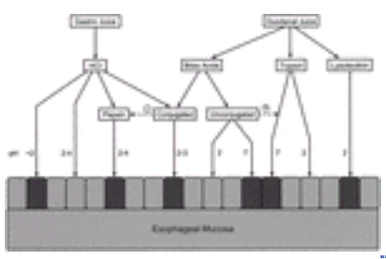

FIGURE 60-7. The postulated injurious agents responsible for esophageal mucosal damage. Mucosal injury is illustrated by the *darker boxes* representing the epithelial surface.

Some studies have suggested that patients with reflux, especially those responding poorly to conventional antisecretory therapy, may have higher rates of acid secretion than controls. [61] However, most evidence finds no abnormality of gastric acid secretion in patients with GERD. For example Hirschowitz [62] compared the gastric secretion of 115 patients with esophagitis with 508 age-, gender- and disease-matched control patients without esophagitis. Fasting basal or maximal secretion of either acid or pepsin was the same in both groups, and the severity of esophagitis was not related to any of these factors. Factors that reduce gastric acid secretion naturally, for example, concomitant infection with *H pylori,* especially if it is the cagA $^+$ virulent strain, may protect from the development of severe esophagitis and Barrett esophagus. [63], [64] *H pylori* infection, particularly infection with this virulent strain, is a biologic *antisecretory agent* that lowers gastric acidity. It produces severe corpus gastritis and accelerates the progression to multifocal atrophic gastritis and intestinal metaplasia, with concomitant lower acid output (Fig. 60-8). In addition, the bacteria produce ammonia that acts as a powerful neutralizing agent at elevated pH conditions. [8], [65] The corpus mucosa returns to normal when the *H pylori* infection is cured, increasing acid secretion and possibly contributing to the reports of esophagitis after successful treatment of *H pylori* infection. [66], [67] The consequences of long-term normalization of parietal cell function and return to higher intragastric acidity is unknown, but they could promote the development of more severe GERD, Barrett esophagus, and adenocarcinoma in Western populations. [8]

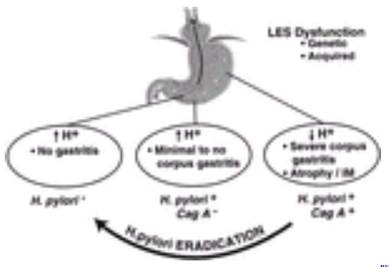

FIGURE 60-8. The acidity and volume of the gastric refluxate are modulated by the presence or absence of *Helicobacter pylori* and the cagA $^+$ virulence strain through the development of chronic corpus gastritis and gastric atrophy or intestinal metaplasia. Among persons susceptible to gastroesophageal reflux disease (GERD), the more acidic refluxate may increase the probability of esophagitis, Barrett esophagus, and adenocarcinoma, whereas the less acidic refluxate may protect against these complications of GERD. Conceivably, *H pylori* eradication could shift this delicate balance and could increase the potential for the development of more severe forms of GERD. (From ref. [8].)

Duodenogastric Reflux Bile acids have been implicated in the development of esophagitis, especially in the presence of increased *duodenogastric reflux.* Studies in animals demonstrate that conjugated bile acids produce their greatest injury in the presence of acid and pepsin, whereas trypsin, deconjugated bile salts, and the conjugated bile salt taurodeoxycholate are more damaging in the absence of acid [68] (see Fig. 60-7). Several surgical reports have suggested that duodenogastric reflux into the esophagus is frequent and may predispose to complications of GERD. [59], [69] However, accurate measurement of duodenogastric reflux is difficult. Duodenogastric reflux may be indirectly estimated by ambulatory pH studies using an esophageal pH of less than 7 to indicate *alkaline reflux.* [70] However, the reliability of this indirect marker is now questioned by newer techniques, which either spectrophotometrically measure bilirubin, the most common pigment in bile, [71] or measure esophageal impedance of the flow of liquids and gases independent of pH. [72] These studies show that acid reflux and bile reflux increase together across the spectrum of GERD, making it nearly impossible to incriminate one agent over the other in the development of esophagitis. [73] In addition, aggressive acid suppression with proton pump inhibitors (PPIs) decreases both acid and duodenogastric reflux probably by decreasing the volume of gastric contents available to reflux into the esophagus. [74] Finally, the absence of membrane microvesiculation and intracellular bile deposits in human esophageal biopsies, two distinctive morphologic features of experimental acid-bile salt injury, also argue against an important role for bile salts in GERD. [75]

Delayed Gastric Emptying The importance of *delayed gastric emptying* in the pathogenesis of GERD is controversial. Early studies observed a delay in the gastric emptying of solids in up to 50% of patients with reflux. [76] However, methodological problems including conducting the study with the patient supine, scanning only in the anterior position, and unstable radioisotopes may have influenced the results of these studies. More recent studies of patients in the upright position, in whom scanning was done both anteriorly and posteriorly, found only a 6% to 38% rate of delayed gastric emptying, regardless of the severity of the esophagitis. [77], [78] Nevertheless, delayed gastric emptying may be a major factor contributing to GERD in some groups, such as diabetic patients with autonomic peripheral neuropathy.

ASSOCIATED CONDITIONS

Certain medical and surgical conditions can predispose a person to GERD. The most common is *pregnancy;* 30% to 50% of pregnant women complain of heartburn, especially in the first trimester. Pregnancy increases the risk for reflux by the relaxing effects of circulating estrogens and progesterones on LES pressure. [79] Although symptoms may be severe, esophagitis is uncommon, and this type of “situational” GERD is cured with childbirth.

Up to 90% of patients with *scleroderma* have GERD as the result of smooth muscle fibrosis causing low LES pressure and weak or absent peristalsis. Severe disease is common; up to 70% of patients have esophagitis, many have peptic strictures, and Barrett esophagus and carcinoma of the esophagus have been reported. [80]

Unlike the previous two conditions that are characterized by LES dysfunction, hypersecretion of acid and increased gastric volume are the major factors causing GERD in patients with the *Zollinger-Ellison syndrome.* In these patients, the esophagitis and complications may be more difficult to treat than the ulcer disease. [81] After Heller myotomy, 10% to 20% of patients may develop GERD. [82] Finally, prolonged *nasogastric tube intubation* may contribute to the development of reflux esophagitis, in part because acid tracks orad along the tube and because the tube mechanically interferes with LES barrier function. [83]

CLINICAL MANIFESTATIONS

Classical Reflux Symptoms

Heartburn is the classical symptom of GERD, with patients generally reporting a burning feeling, rising from the stomach or lower chest and radiating toward the neck, throat, and occasionally the back. [84] Usually, it occurs postprandially, particularly after large meals or the consumption of spicy foods, citrus products, fats, chocolates, and alcohol. Recumbency and bending over may exacerbate heartburn. When heartburn dominates the patients' complaints, it has very high specificity (89%), but low sensitivity (38%) for GERD as diagnosed by abnormal 24-hour esophageal pH testing. [85] The diagnosis of GERD usually is based on the occurrence of heartburn on 2 or more days a week, although less frequent symptoms do not preclude the disease. [86] Although this symptom is an aid to diagnosis, the frequency and severity of heartburn do not predict the degree of esophageal damage. Heartburn is caused by acid stimulation of sensory nerve endings in the deeper layers of the esophageal epithelium. These nerve endings are normally protected by a relatively impermeable epithelium, but with epithelial changes caused by reflux, they may be stimulated by H^+ or spicy foods. [87]

Other common symptoms of GERD are acid regurgitation and dysphagia. The effortless regurgitation of acidic fluid, especially after meals and exacerbated by stooping or recumbency, is highly suggestive of GERD. [85] Among patients with daily regurgitation, the LES pressure usually is low, many have associated gastroparesis, and esophagitis is common. For these reasons, acid regurgitation may be more difficult to control medically then classical heartburn complaints. Dysphagia is reported by more than 30% of patients with GERD. [88] It usually occurs in the setting of long-standing heartburn, with slowly progressive dysphagia primarily for solids. Weight loss is uncommon because patients have good appetites. The most common causes are a peptic stricture or Schatzki ring, but other causes include severe esophageal inflammation alone, peristaltic dysfunction, and esophageal cancer arising from Barrett esophagus.

Less common reflux-associated symptoms include water brash, odynophagia, burping, hiccups, nausea, and vomiting. [89] *Water brash* is the sudden appearance in the mouth of a slightly sour or salty fluid. It is not regurgitated fluid, but rather secretions from the salivary glands in response to acid reflux. [44] *Odynophagia,* pain on swallowing, can occasionally be seen with severe ulcerative esophagitis. However, its presence should raise the suspicion of an alternative cause of esophagitis, especially infections (candidiasis, herpes) or pills (tetracycline, potassium chloride, quinine, vitamin C, alendronate).

In contrast to the previously described symptomatic presentations, some patients with GERD are asymptomatic. This is particularly true in elderly patients because of decreased acidity of the reflux material or decreased pain perception. [5] Many elderly patients present first with complications of GERD because of long-standing disease with minimal symptoms. For example, up to one third of patients with Barrett esophagus are insensitive to acid at the time of presentation. [90]

Extraesophageal Manifestations

It has been suggested that GER may be the cause of a wide spectrum of conditions including noncardiac chest pain, asthma, posterior laryngitis, chronic cough, recurrent pneumonitis, and even dental erosion. [91] Some of these patients have classical reflux symptoms, but many are "silent refluxers," contributing to problems in making the diagnosis. Furthermore, it may be difficult to establish a causal relationship even if GER can be documented by testing (e.g., pH studies), because patients may simply have two common diseases without a cause-and-effect relationship.

Chest Pain GER-related *chest pain* may mimic angina pectoris. The chest pain is usually described as squeezing or burning, substernal in location, and radiating to the back, neck, jaw, or arm. It often is worse after meals, awakens the patient from sleep, and may worsen during periods of emotional stress. Heavy exercise, even treadmill testing, may provoke GER. [92] Reflux-related chest pain may last minutes to hours, often resolves spontaneously, and may be eased with antacids. Most patients with GERD-induced chest pain have heartburn symptoms. [93] Early studies suggested that spastic motility disorders were the most common esophageal cause of chest pain. However, more recent studies using ambulatory esophageal pH and pressure monitoring suggest that about 25% to 50% of patients with noncardiac chest pain have GERD. [94] Overall, these series of reports found that 41% of patients had abnormal 24-hour pH test results, whereas 32% had chest pain that was clearly associated with acid reflux. Patients with coronary artery disease commonly have coexisting esophageal diseases, but the evidence that GER causes ischemic pain is controversial. [95] The mechanism for GERD-related chest pain is not clearly understood and probably is multifactorial, related to H^+ ion concentration, volume and duration of acid reflux, and secondary esophageal spasm.

Asthma and Other Pulmonary Diseases The association of GERD and *pulmonary diseases* was recognized by Sir William Osler, [96] who recommended that asthmatic patients should "learn to take their large daily meal at noon to avoid nighttime asthma which occurred if they ate a full supper." More recent studies suggest the coexistence of the two diseases in up to 80% of asthmatic patients, irrespective of the use of bronchodilators. [97], [98] GERD should be considered in asthmatic patients who present in adulthood, those without an intrinsic component, and those not responding to bronchodilators or steroids. [99] Up to 30% of patients with GERD-related asthma have no other esophageal complaints. Other pulmonary diseases associated with GERD include aspiration pneumonia, interstitial pulmonary fibrosis, chronic bronchitis, bronchiectasis, and possibly cystic fibrosis, neonatal bronchopulmonary dysplasia, and sudden infant death syndrome. Proposed mechanisms of reflux-induced asthma are either aspiration of gastric contents into the lungs with secondary bronchospasm or activation of a vagal reflex from the esophagus to the lungs causing bronchoconstriction. Animal [100] and human [101] studies report bronchoconstriction after esophageal acidification, but the response tends to be mild and unpredictable. In contrast, intratracheal infusion of even small amounts of acid induces profound and reproducible bronchospasm in cats. [100] The reflux of acid into the trachea as compared with the esophagus alone predictably caused marked changes in peak expiratory flow rates in asthmatic patients. [102] Although either mechanism may be responsible for reflux-induced asthma, most patients probably suffer from intermittent microaspiration.

Ear, Nose, and Throat Diseases GERD may be associated with a variety of laryngeal conditions and symptoms, of which *reflux laryngitis* is perhaps the most common. [103], [104] These patients present with hoarseness, globus sensation, frequent throat clearing, recurrent sore throat, and prolonged voice warmup. Ear, nose, and throat signs attributed to GERD include posterior laryngitis with edema and redness, vocal cord ulcers and granulomas, leukoplakia, and even carcinoma. These changes usually are limited to the posterior third of the vocal cords and interarytenoid areas, both in close proximity to the upper esophageal sphincter. GERD is the third leading cause of chronic cough (after sinus problems and asthma), accounting for 20% of cases. [105] *Dental erosion,* defined as the loss of tooth structure by chemical processes not involving bacteria, can be caused by GER in healthy persons and in patients with bulimia. [106] Despite the association between ear, nose, and throat diseases and GERD, overt esophagitis usually is absent, and most patients have only mild reflux symptoms, if any. [103] Microaspiration of gastric contents is the most likely cause of these complaints. Animal studies find that the combination of acid and pepsin is very injurious to the larynx. [103] Human studies report that proximal esophageal acid exposure, especially at night while sleeping, is significantly increased in patients with laryngeal symptoms and signs. [107]

DIAGNOSTIC EVALUATION

Many tests are available for evaluating patients with suspected GERD. These tests are often unnecessary because the classical symptoms of heartburn and acid regurgitation are sufficiently specific to identify reflux disease and to begin medical treatment. However, this may not always be the case, and the clinician must decide which test to choose to arrive at a diagnosis in a reliable, timely, and cost-effective manner, depending on the information desired (Table 60-2).

Tests for Reflux
Intraesophageal pH monitoring
Ambulatory bilirubin monitoring
Radionuclide ^{99m}Tc scintiscanning
Barium esophagram
Tests to Assess Symptoms
Empiric trial of acid suppression
Intraesophageal pH monitoring
Acid perfusion (Bernstein) test
Tests to Assess *Esophageal* Damage
Endoscopy
Esophageal biopsy
Barium esophagram
Tests to Assess *Pathogenesis*
Esophageal manometry
Gastric analysis
Radionuclide ^{99m}Tc scintiscanning

*Order of presentation represents the order of diagnostic usefulness.

TABLE 60-2 Commonly Used Tests for Assessing the Presence, Mechanism, and Consequences of Gastroesophageal Reflux Disease*

Empiric Trial of Acid Suppression

The simplest and most definitive method for diagnosing GERD and assessing its relation to symptoms (either classical or atypical) is the empiric trial of acid suppression. Unlike other tests that only suggest an association (e.g., esophagitis at endoscopy or positive symptom index on pH testing), the response to antireflux therapy ensures a cause-and-effect relationship between GERD and symptoms. Therefore, it has become the "first" test used in patients with classical or atypical reflux symptoms without "alarm" complaints. The popularity of this approach was aided by the introduction

of the PPIs, which, unlike the histamine $_2$ receptor antagonists (H $_2$RAs), could drastically reduce the amount of acid reflux into the esophagus. Symptoms usually respond to a PPI trial in 7 to 14 days. If symptoms disappear with therapy and then return when the medication is stopped, GERD may be assumed.

In the reported empiric trials with heartburn, the initial dose of PPI was high (e.g., omeprazole 40 to 80 mg/d) and was given for not less than 14 days. A positive response is defined as at least 50% improvement in heartburn. Using this approach, the PPI empiric trial had a sensitivity of 68% to 83% for determining the presence of GERD. [108, 109] In noncardiac chest pain, Fass and colleagues [110] found that a 7-day trial of omeprazole, 40 mg in the morning and 20 mg at night, had a sensitivity of 78% and specificity of 86% for predicting GERD, when compared with traditional tests. Likewise, Ours and colleagues [111] found omeprazole, 40 mg twice a day for 2 weeks, to be a very reliable method for identifying acid-related cough. Empiric trials using a 2- to 4-month regimen of PPIs taken twice a day also are commonly used in patients with suspected GERD-associated asthma and GERD complaints related to the ear, nose and throat.

An empiric trial of PPIs for diagnosing GERD has many advantages. The test is office based, is easily performed, is relatively inexpensive, is available to all physicians, and avoids many needless procedures. For example, Fass and associates [110] showed a savings of more than $570 per average patient because of a 59% reduction in the number of diagnostic tests performed for noncardiac chest pain. Disadvantages are few, including a placebo response and uncertain symptomatic end point if symptoms do not resolve totally with extended treatment.

Endoscopy

Upper *endoscopy* is the current standard for documenting the type and extent of mucosal injury to the esophagus (see Chapter 138). It identifies the presence of esophagitis and excludes other causes of the patient's complaints. However, only 40% to 60% of patients with abnormal esophageal reflux by pH testing have endoscopic evidence of esophagitis. Thus, the sensitivity of endoscopy for GERD is 60% at best, but it has excellent specificity, at 90% to 95%. [112]

The earliest endoscopic signs of acid reflux include edema and erythema. Neither finding is specific for GERD, and both are very dependent on the quality of endoscopic visual images. [112] More reliable are the findings of friability, granularity, and red streaks. Friability (easy bleeding), occurring with gentle pressure on the mucosa, results from the development of enlarged capillaries near the mucosal surface in response to acid. Red streaks may extend upward from the esophagogastric junction along the ridges of the esophageal folds. In studies evaluating these stigmata, nearly all patients had GERD. [113] With progressive acid injury, erosions develop (Fig. 60-9A, see also Color Fig. 60-9A). These are characterized by shallow thinning of the mucosa associated with a white or yellow exudate surrounded by erythema. Commonly located just above the esophagogastric junction, erosions may be either single lesions or coalesced regions. Typically, they occur along the tops of mucosal folds, areas most prone to acid exposure. Erosions may also be caused by nonsteroidal antiinflammatory drug use, heavy smoking, and infectious esophagitis. [113] Ulcers reflect more severe esophageal damage. They penetrate the mucosa, tend to have either a white or yellow discolored base, and may be seen either isolated along a fold or surrounding the esophagogastric junction.

FIGURE 60-9. (See Color Fig. 60-9A.) Endoscopic and histological signs of esophagitis. (**A**) Two linear erosions extending proximally from the squamocolumnar junction at the proximal border of a hiatal hernia. This would be classified as grade II esophagitis by the Savary-Miller and Hetzel systems and as grade B by the Los Angeles scale. (**B**) Reparative changes secondary to reflux disease characterized by basal cell hyperplasia (*dark cells* crowding the papillae) and marked elongation of the rete pegs (*pale papillae* with fingerlike projections).

Endoscopic grading of GERD depends on the endoscopist's interpretation of these visual images. Unfortunately, there exists no standard classification scheme for endoscopic findings. Instead, several grading systems are available, but none are completely satisfactory (Table 60-3). In Europe, the most popular scheme is the *Savary-Miller classification,* [114] which is based on degree of mucosal erosions. In the United States, the Hetzel and Los Angeles systems are most popular. The *Hetzel system* grades severity not by the number of erosions but by the area of mucosal injury. [115] In the *Los Angeles system,* the number, length, and location of mucosal breaks determine the degree of esophagitis. [116] These different classification systems diverge the most when defining the subtlest degree of injury. When erythema, edema, and an indistinct Z-line are included, the sensitivity of diagnosing GERD rises at the expense of specificity.

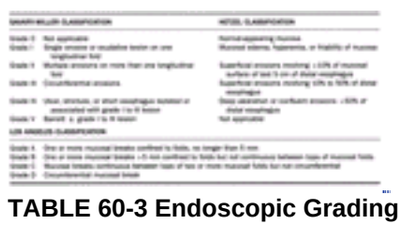

TABLE 60-3 Endoscopic Grading Systems for Esophagitis

Most patients with GERD are treated initially without endoscopy. The important exception is the patient experiencing alarm symptoms: dysphagia, odynophagia, weight loss, and gastrointestinal bleeding. With such symptoms, endoscopy should be performed early to rule out other entities such as infections, ulcers, cancer, or varices.

The role of endoscopy in GERD in the absence of alarm symptoms is more controversial and is evolving in the era of PPI therapy. Initially, endoscopy was used to place patients into two groups—those with nonerosive or mild disease and those with severe erosive disease—and to direct their treatment more precisely. However, this practice is now less popular with the use of PPIs as the first line of therapy for GERD. Because these drugs treat both groups equally well, early endoscopy has less impact on the choice of therapy. Currently, the most important reason for performing endoscopy in patients with GERD is to identify peptic strictures or Barrett esophagus. Using this rationale, most patients with chronic GERD need only one endoscopic examination while they are receiving therapy.

Esophageal Biopsy

The ability to obtain tissue during endoscopy is very important. *Biopsies* of the esophagus help to identify reflux injury, exclude other esophageal diseases, and confirm the presence of complications, especially Barrett esophagus (see Chapter 142). Microscopic changes indicative of reflux may occur even when the mucosa appears normal endoscopically. [117] In patients with classical esophagitis, biopsies are usually not taken unless they are needed to exclude other diagnoses such as neoplasm, infection, pill injury, or bullous disease. When Barrett esophagus is suspected, biopsies are

mandatory and are best done when esophagitis is healed.

The most sensitive histological markers of GERD are reactive epithelial changes characterized by an increase in the basal cell layer greater than 15% of the epithelium thickness or papilla elongation into the upper third of the epithelium (see Fig. 60-9B). These changes represent increased epithelial turnover of the squamous mucosa. Papilla, or rete peg, height increases as a result of loss of surface cells from acid injury, whereas basal cell hyperplasia is indicative of mucosal repair. Unfortunately, these changes are also noted in up to 50% of healthy persons when biopsies are taken from the distal 2 to 3 cm of the esophagus. [118] Hence, the changes are sensitive markers for GERD but have poor specificity.

Acute inflammation characterized by the presence of neutrophils and eosinophils is very specific for esophagitis. [118] Acid reflux injury to the vascular bed of the esophagus releases vasoactive substances that promote edema and migration of neutrophils and eosinophils into the area. Neutrophils are specific for acute esophagitis but are an insensitive marker, being present in only 15% to 40% of patients with GERD. [119] Eosinophils are found more often on biopsy (19% to 63% of subjects) but are less specific, present in up to 33% of healthy adults. [120] Interestingly, the sensitivity and specificity of eosinophils in children are much stronger, reflecting the lack of eosinophils in the juvenile inflammatory response. [118, 121]

Esophageal pH Monitoring

Ambulatory intraesophageal pH monitoring is now the standard for establishing pathological reflux (see Chapter 150). [122, 123] The test is performed with a pH probe passed nasally and positioned 5 cm above the manometrically determined LES. The probe is connected to a battery-powered data logger capable of collecting pH values every 4 to 6 seconds. An event marker is activated by the subject in response to symptoms, meals, and body position changes. Patients are encouraged to eat normally and to pursue regular daily activities. Monitoring is carried out usually for 18 to 24 hours. Reflux episodes are detected by a drop in pH to less than 4. Commonly measured parameters include the percentage of total time that the pH is less than 4, the percentage of time upright and supine that the pH is less than 4, the total number of reflux episodes, the duration of longest reflux episode, and the number of episodes longer than 5 minutes. [122] The total percentage of time that the pH is less than 4 is the most reproducible measurement for GERD, with reported upper limits of normal values ranging from 4% to 5.5%. [123] Ambulatory pH testing can discern positional variations in GER, meals, and sleep-related episodes and helps to relate symptoms to reflux events (Fig. 60-10). As the result of its reliability for measuring GER across normal activities, ambulatory pH testing has replaced other older studies, such as the standard acid reflux (Tuttle) test and radionuclide scintigraphy.

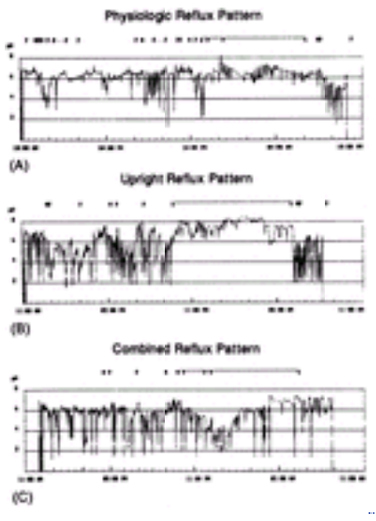

FIGURE 60-10. Common patterns of 24-hour esophageal pH monitoring. **(Top)** The physiological pattern of gastroesophageal reflux (*GER*) in healthy persons. Reflux is noted after meals (*m*) but not while asleep (*s*). A reflux episode is defined as a pH drop to less than 4. **(Middle)** Upright reflux pattern with extensive GER during day but not at night. These patients have frequent symptoms, but esophagitis is uncommon. **(Bottom)** Combined pattern with GER during day and at night (one episode lasted 3 hours). Most of these patients have esophagitis.

One important problem with esophageal pH monitoring is that there exists no absolute threshold value that reliably identifies pathological GER. Validation studies comparing the presence of esophagitis with abnormal pH test report sensitivities ranging from 77% to 100% with specificities from 85% to 100%. [123] However, these patients rarely need pH testing; rather, the patients with normal endoscopic findings and suspected reflux symptoms should benefit most from ambulatory pH monitoring. Unfortunately, the data are much less conclusive in this group, with considerable overlap between controls and patients with nonerosive reflux. [123] Other drawbacks of pH testing include possible equipment failure, the pH probe's missing a reflux event because it is buried in a mucosal fold, and false-negative studies resulting from dietary or activity limitations from poor tolerability of the nasal probe.

An important advantage of ambulatory esophageal pH monitoring is its ability to record and correlate symptoms with reflux episodes over extended periods. For this indication, it has essentially replaced the shorter acid perfusion (Bernstein) test. Because only about 10% to 20% of reflux episodes are associated with reported symptoms, different statistical analyses have evolved attempting to define a significant association between these two variables including the symptom index, symptom sensitivity index, and symptom association probability. [124] Unfortunately, no studies to date have defined the accuracy of any of these symptom scores in predicting response to therapy. Therefore, pH testing and symptom correlation can define an association between complaints and GER, but only treatment trials address the true definition of a causal relationship.

Definite clinical indications for ambulatory pH monitoring have been established. [123] *Before fundoplication,* pH testing should be performed in patients with normal endoscopic findings to identify the presence of pathological reflux. If esophagitis is present, pH testing is not necessary because the disease has been established. *After antireflux surgery, persistent or recurrent symptoms* warrant repeat pH testing. In these situations, pH monitoring is performed with the patient discontinuing all antireflux medications (PPIs for 1 week, H_2RAs for 2 days). Esophageal pH testing is particularly helpful in the evaluation of patients with *reflux symptoms resistant to treatment with normal or equivocal endoscopic findings*. For this indication, pH testing is usually done in patients receiving therapy to define two populations: those with and those without continued abnormal esophageal acid exposure times. The group with persistent GER needs intensification of the medical regimen, whereas those patients with symptoms and adequate acid control have another cause of their complaints. Finally, ambulatory pH testing may help in *defining patients with extraesophageal manifestations of GERD*. In this situation, pH testing is usually done with additional pH probes placed in the proximal esophagus or pharynx. [125] Initially, most of these studies were done when patients were not taking antireflux medications, to confirm the coexistence of GERD; however, this does not guarantee symptom causality. Therefore, the current approach is to treat the patients aggressively with PPIs first and to reserve pH testing only for those patients not responding after 4 to 12 weeks of therapy. [126]

Barium Esophagram

The *barium esophagram* is an inexpensive, readily available, and noninvasive esophageal test (see Chapter 152). It is most useful in demonstrating structural narrowing of the esophagus and in assessing the presence and reducibility of a hiatal hernia. Subtle findings such as Schatzki rings, webs, or minimally narrowed peptic strictures are often seen only with an esophagram; they are missed by endoscopy, which may not adequately distend the esophagus. This test, which involves consuming a 13-mm radiopaque pill or marshmallow along with the barium liquid, is the most sensitive for detecting esophageal narrowing, with values reported between 95% and 100%. [127] By giving the patient in the prone oblique position swallows of barium, the barium esophagram also allows good assessment of peristalsis and is helpful preoperatively in identifying a weak esophageal pump. [128]

The ability of the barium esophagram to detect esophagitis varies considerably. Although sensitivities of 79% to 100% have been reported with moderate to severe esophagitis, mild esophagitis is usually missed. [128] Barium testing also falls short when addressing the presence of Barrett esophagus. Barium studies can identify GER when contrast moves in a retrograde fashion from the stomach into the esophagus. If this occurs spontaneously, repeatedly, or to a significant degree into the middle or proximal esophagus, the test is positive, but it has a sensitivity of only about 40% for defining GERD. [129] Provocative maneuvers such as leg lifting, coughing, the Valsalva maneuver, or the water-siphon test can be used to elicit stress reflux. Although these tests can improve the sensitivity of

the barium esophagram, some argue that they also decrease its specificity. [129], [130]

The barium esophagram is primarily used in evaluating the patient with GERD with new-onset dysphagia because it can define subtle strictures and rings as well as assess motility. Conversely, endoscopy is preferred in the patient with recurrent dysphagia known to have a stricture or for the assessment of esophagitis or Barrett esophagus.

Esophageal Manometry

Esophageal manometry allows accurate assessment of LES pressure and relaxation, as well as peristaltic activity including contraction amplitude, duration, and velocity (see Chapter 150). However, esophageal manometry is generally not indicated in the evaluation of the patient with uncomplicated GERD because most of these patients have a normal resting LES pressure. [42] It is an integral component of pH testing to define the LES location accurately, a task poorly performed by endoscopy, fluoroscopy, or the pH pull-through technique. Esophageal manometry is an essential test in the preoperative evaluation of patients for antireflux surgery. [131] A normal LES pressure does not preclude surgery for the reasons discussed, yet occasionally an alternative diagnosis such as achalasia or scleroderma is made, which may change the clinical approach. Most importantly, the presence of ineffective peristalsis characterized by either low-amplitude (<30 mm Hg) peristaltic contractions or frequent failed peristalsis [132] suggests a weak esophageal pump. In these patients, a loose 360° fundoplication or an incomplete fundoplication will minimize the risk of postoperative dysphagia.

Miscellaneous Tests

Radiolabeled technetium-99m sulfur colloid scintiscanning is useful as a semiquantitative test for detecting GER. [133] After instilling 300 mL of radioisotope in saline through a nasogastric tube into the stomach, gamma counts over the esophagus are obtained in the supine position before and after provocation with abdominal compression. Although test specificity approaches 90%, the sensitivity is quite variable, from 14% to 90%. [134]

The *acid perfusion (Bernstein) test* is useful for detecting the relationship of symptoms to esophageal acidification. [135] The study is done with the patient upright with a nasogastric tube positioned in the midesophagus. Initially, normal saline is infused at 120 drops/min for 5 to 15 minutes, followed by an infusion of 0.1 N hydrochloric acid. If symptoms develop with acid infusion, saline is reinfused to assess symptom relief. Symptoms during acid infusion, but not saline infusion, constitute a positive test. The sensitivity of the Bernstein test for GERD ranges from 32% to 100%, and its specificity ranges from 40% to 100%. [136] In clinical practice, 24-hour esophageal pH testing has generally replaced both these tests.

Bile reflux can be measured using *ambulatory esophageal bilirubin monitoring* (Bilitec: Medtronics, Minneapolis, MN), [71] which uses the spectrophotometric property of bilirubin, the most common pigment in bile. As in pH testing, a fiberoptic light source is introduced into the esophagus with a data collection system worn on a waist belt. A spectrophotometer measures the wavelength absorption at 450 nm (bilirubin) and at 565 nm (reference) every 8 seconds. An integrated microcomputer calculates the difference of the absorbances, which is directly proportional to the bilirubin concentration in the sample. [71], [73] This allows a pH-independent assessment of duodenogastroesophageal reflux, which is preferable to the older method employing an esophageal pH of more than 7. [70] In the future, ambulatory measurements of esophageal impedance, [72] which measures the electrical activity of liquid and gas moving up and down the esophagus, combined with pH monitoring may be the preferred technique for measuring nonacidic reflux.

DIFFERENTIAL DIAGNOSIS

Symptoms associated with GERD may be mimicked by other esophageal and extraesophageal diseases including achalasia, Zenker diverticulum, gastroparesis, gallstones, peptic ulcer disease, functional dyspepsia, and angina pectoris. These disorders usually can be identified by failure to respond to aggressive antisecretory therapy and by diagnostic tests such as endoscopy, barium esophagram, esophageal manometry, ultrasound, nuclear emptying studies, and various cardiac tests. Although GERD is the most common cause of esophagitis, other causes (esophagitis, infections, or radiation esophagitis) need to be considered in cases that are difficult to manage cases and in older or immunocompromised patients.

CLINICAL COURSE

The clinical course of reflux esophagitis depends to a great extent on whether the patient has erosive or nonerosive GERD on initial presentation. Furthermore, patients tend not to cross over from one group to another unless they are treated medically or surgically: in follow-up ranging from 6 months to more than 5 years, only 15% of patients with nonerosive disease evolved over time to having esophagitis or complications of GERD. [137], [138]

Nonerosive Reflux Disease

Although early studies from tertiary referral centers suggested that nearly half of patients with GERD had esophagitis, [139] studies carried out in community practices reveal that up to 70% of the patients with GERD had a normal endoscopic examination. [140], [141] Furthermore, another community-based study of antacid users found that 53% of patients with GERD had nonerosive disease, and two thirds of the remaining had only minimal erosive changes at endoscopy. [142] Endoscopy-negative patients with GERD are more likely to be female, younger, thin, and without hiatal hernia. Despite their mild mucosal damage, these patients demonstrate a chronic pattern of symptoms with periods of exacerbation and remission. [143]

Nonerosive GERD is suspected by the presence of typical reflux symptoms with a normal endoscopic examination and is confirmed by the patient's response to antisecretory therapy. When performed, 24-hour esophageal pH monitoring identifies three distinct subset of patients with nonerosive disease. First, there are the patients with abnormal acid exposure time who are usually responsive to antisecretory therapy. Second are the patients with normal reflux parameters but a good relationship between acid reflux episodes and symptoms. This group represents 30% to 50% of patients with nonerosive GERD [179] and has "functional heartburn." [143] These patients probably have heightened esophageal sensitivity to acid and are less likely to respond to antireflux therapy. [144] The third group is characterized by normal acid exposure times and poor symptom correlation. Despite sometimes having classical reflux symptoms, other diseases such as achalasia, gastroparesis, bile reflux, or functional dyspepsia are the cause of their symptoms. Overall, patients with nonerosive GERD do not respond to antireflux treatments as well as do patients with erosive GERD, probably because these three subsets are not carefully defined before treatment. [143]

Erosive Reflux Disease

The clinical course of patients with *erosive esophagitis* is more predictable and is associated with complications of GERD. Controlled studies have shown that in the absence of ongoing maintenance therapy, up to 85% of patients with erosive GERD will have a relapse within 6 months, and the relapse rate is highest in those with the more severe grades of esophagitis. [145], [146] This observation, however, should not prevent at least one attempt to withdraw medication, because 20% of patients remain in remission for up to 1 year, especially those with milder esophagitis grades. Although the natural history of untreated erosive GERD is well studied, two European studies suggest that these patients are more prone to reflux complications. In a Finnish study, 20 patients with erosive GERD treated with lifestyle changes, antacids, and prokinetic drugs were followed up for a median of 19 years. Fourteen patients continued to have erosions, and 6 new cases of Barrett esophagus were detected. [147] Likewise, a large retrospective European study with 6.5 years of follow-up found a high rate of complications (21%) including 13 esophageal ulcers, 15 with strictures, and 45 patients with Barrett epithelium. [148] However, these data must be contrasted with other studies in which no patients with erosive esophagitis developed Barrett esophagus in a 2-year trial in the United States, [149] and over a 12-year period, in 3800 French patients, development of stricture was reported in only 0.26%. [150]

COMPLICATIONS

Hemorrhage and Perforation

Hemorrhage and esophageal perforation are rare complications of reflux esophagitis and are usually associated with deep esophageal ulcers or severe diffuse esophagitis. Clinically important hemorrhage has been reported in 7% to 18% of patients with GERD. [151] Esophageal perforations are very rare in the PPI era, but they can result in mediastinitis and can be fatal if they are not rapidly recognized and treated.

Peptic Esophageal Strictures

Strictures occur in 7% to 23% of patients with untreated reflux esophagitis, especially in older men. [152] They usually evolve over many years and may be linked to the long-term use of nonsteroidal

antiinflammatory drugs. [153] The mechanism of stricture formation is complex, starting as a reversible inflammatory process with edema, cellular infiltration, and vascular congestion, progressing to deposition of connective tissue and collagen, and ending in irreversible fibrosis. With the onset of dysphagia, there is often less heartburn, reflecting the stricture's acting as a barrier to reflux. Dysphagia is usually limit to solids, but it may progress to liquids. Unlike malignant strictures, patients with peptic strictures have a good appetite, alter their diet, and lose little weight.

Radiographically, peptic strictures are smooth-walled, tapered, circumferential narrowings in the lower esophagus, which are usually less than 1 cm long, but occasionally they extend to 8 cm in length (Fig. 60-11). In these unusual cases, the clinician should suspect a predisposing condition, such as the Zollinger-Ellison syndrome, superimposed pill esophagitis, or prolonged nasogastric intubation. [152] A stricture in the middle to upper esophagus should raise the suspicion of Barrett esophagus or malignant disease. Although once controversial, most data today suggest that a Schatzki ring is a forme fruste of an early peptic stricture. [154] In all cases, the nature of a peptic stricture needs to be confirmed by endoscopy with biopsies because some patients may have Barrett esophagus or unsuspected cancer.

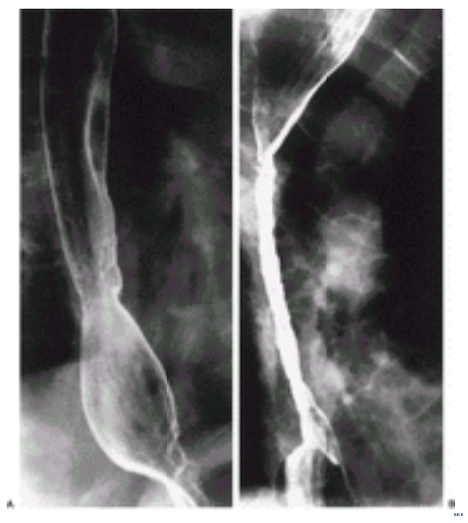

FIGURE 60-11. Barium esophagram of several forms of esophageal strictures. (**A**) Double-contrast study showing distal linear erosive esophagitis, an ulcer with a short stricture, and a large hiatus hernia. (**B**) A long, irregular distal stricture in a patient with Zollinger-Ellison syndrome. The stricture occurred after prolonged nasogastric intubation following head and neck surgery.

Barrett Esophagus

In some patients with GERD, the squamous epithelium of the distal esophagus is replaced by specialized columnar epithelium, resembling that of the intestine and containing goblet cells. Although Dr. Norman Barrett thought this lesion was a congenitally shortened esophagus, [155] studies consistently show that these patients have severe GERD with low LES pressures, poor esophageal motility, large hiatal hernias, and extensive acid and bile reflux. [156] Furthermore, most patients have had chronic reflux symptoms for at least 10 years. [157] Animal experiment show that, if the mucosal lining of the distal esophagus is excised in the setting of free acid reflux, columnar epithelium will regenerate in the area previously occupied by squamous epithelium. [158] If reflux is controlled, the mucosal lining will regenerate with squamous epithelium. Pluripotential stem cells derived from the stratified squamous epithelium are the origin of the specialized columnar epithelium. [159]

Barrett esophagus was once considered an uncommon condition, but estimates of its frequency at autopsy (1 in 57 to 1 in 105 cases), on general endoscopy survey (1 in 100 cases) and on endoscopic surveys of patients with GERD (10 in 100 to 15 in 100 cases), indicate that it is not uncommon, and it affects nearly 700,000 adults in the United States. [155] An autopsy series from Olmsted County, Minnesota found that most cases of Barrett esophagus go undetected during life and thus are not accessible for cancer surveillance programs. [160] Barrett esophagus is principally a disorder of white men; it is three times more frequent in men than in women and is rare in African Americans and Asians. [161] It is found predominantly in middle-aged and older adults; the mean age at diagnosis is approximately 55 years, but it has been reported in children older than 5 years of age. [162] The prevalence of Barrett esophagus increases with age, paralleling that of reflux esophagitis, but the length of the columnar-lined segment remains remarkably stable, even over years of endoscopic follow-up. [161] This finding suggests that it arises rapidly in the susceptible reflux damaged esophagus and early in the course of disease. Families have been reported with multiple members having Barrett esophagus, some with cancer affecting more than one generation. [10], [163] Although the columnar-lined esophagus in itself does not cause symptoms, most patients complain of heartburn and regurgitations. Approximately 25% of patients with Barrett esophagus discovered at endoscopy have no esophageal symptoms. [90]

Barrett esophagus is suspected at endoscopy and is confirmed by biopsy and histological examination. The columnar epithelium of the stomach is reddish pink, and the junction between the glossy white squamous mucosa and the columnar mucosa (Z-line) is normally found at the lower end of the tubular esophagus, just above the proximal folds of a hiatal hernia, if present. In Barrett esophagus, the distal esophagus is lined with columnar epithelium, extending upward for a variable distance, often 3 to 10 cm, but occasionally involving most of the esophagus (Fig. 60-12A, see also Color Fig. 60-12A). The proximal margin may be horizontal, or there may be irregular, often tongue-shaped upward extensions of columnar mucosa. Some patients have pale islands of regenerative or residual squamous epithelium, whereas others have punched-out benign ulcers in the columnar area. Strictures and esophagitis may be seen at the new squamocolumnar junction. The endoscopist should especially look for evidence of adenocarcinoma, such as nodularity or masses.

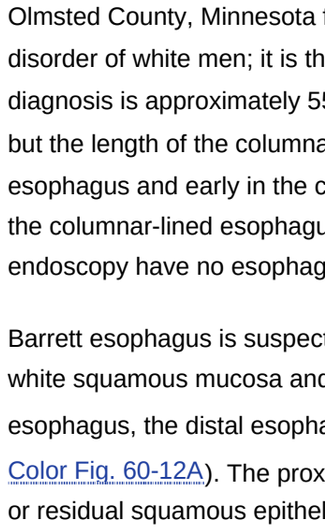

FIGURE 60-12. (See Color Fig. 60-12A.) Barrett esophagus. (**A**) Reddish pink columnar mucosa with tonguelike projections 3 to 4 cm into the tubular esophagus. (**B**) Specialized intestinal metaplasia with glandular epithelium and characteristic goblet cells.

The characteristic histological finding in Barrett esophagus is a distinctive specialized intestinal epithelium. This is a glandular epithelium with mucin-type cells and the distinguishing presence of goblet cells (see Fig. 60-12B). These are easily seen on hematoxylin and eosin–stained sections and can be demonstrated more prominently in sections stained with Alcian blue. It occupies most or all of the columnar-lined area and is the type of epithelium in which adenocarcinoma arises. [164] Other types of epithelia seen with Barrett esophagus include gastric fundic and cardia-type epithelia, but these alone do not make the diagnosis of Barrett esophagus, nor are they associated with adenocarcinoma.

Currently, there is some controversy over the classification of Barrett esophagus. [155] The classical or *long-segment Barrett esophagus* requires at least 3 cm of esophagus to be lined with columnar epithelium. This is the best-studied subset of Barrett esophagus, with traditional demographic features and a definite increased risk of becoming adenocarcinoma. *Short-segment Barrett esophagus* refers to shorter lengths or tongues of columnar epithelium, less than 3 cm, in the distal esophagus, with intestinal metaplasia on biopsy. This entity is three to five times more common than the long-segment variant, but, based on anecdotal reports, the risk of cancer appears to be lower. [165] *Intestinal metaplasia at the esophagogastric junction* refers to microscopic findings on biopsy but no visible columnar epithelium in the esophagus at endoscopy. [155] This finding has been reported in 10% to 32% of biopsies from unselected patients, many of whom have no reflux symptoms. [165] The percentage of woman and African Americans is also higher with this lesion than with either long- or short-segment Barrett esophagus. The cause is controversial; some investigators suggest that this is the earliest form of GERD, [166] whereas others believe these changes are secondary to *H pylori* infection. [167] Cancer risk is minimal, if it exists at all.

Patients with long-segment Barrett esophagus have an estimated 30 to 125 times increased risk of developing esophageal cancer compared with the general population. [168] Early studies suggested that the median cancer incidence was 1 per 100 patient-years of follow-up, [155] but more recent studies with longer follow-up suggest a lower cancer rate of 1 per 200 to 250 patient-years. [169], [170] This is an annual incidence of approximately 0.5%, with about 500 cases of adenocarcinoma diagnosed annually. However, since the early 1980s, the incidence of squamous cell carcinoma has stayed constant, whereas the incidence of adenocarcinoma of the esophagus and esophagogastric junction has risen fivefold—a growth rate exceeding that of any other cancer. [171] Currently, adenocarcinoma accounts for more than half of all esophageal cancers in the United States. Despite this cancer risk, most patients with Barrett esophagus die of unrelated causes. [170] More than 90% of patients who develop cancer present with symptoms caused by the tumor itself and are unaware of their antecedent Barrett esophagus. [172] Epidemiologic data suggest that the mean interval from developing Barrett esophagus to evolution to cancer may be 20 to 30 years. [161]

MEDICAL AND SURGICAL THERAPY

The rationale for GERD therapy depends on a careful definition of specific aims. In patients without esophagitis, the therapeutic goals are simply to relieve the acid-related symptoms and to prevent frequent symptomatic relapses. In patients with esophagitis, the goals are to relieve symptoms and to heal the esophagitis while attempting to prevent further relapses and the development of complications. These goals are set against a complex background: GERD is a chronic disease that may wax and wane in intensity, and relapses are common.

Nonprescription Therapy

Although GERD is common in the United States, very few persons seek medical care for their complaints, instead choosing to change their lifestyles and self-medicate with over-the-counter (OTC) antacids and low doses of H_2RAs. These observations have led to the “iceberg” model of the GERD population. Most heartburn suffers are invisible because they self-medicate and do not seek professional help; only those at the tip of the iceberg, typically patients with severe symptoms or reflux complications, are seen by physicians. [173]

Lifestyle Modifications Sensible *changes in lifestyle,* especially if their rationale is explained to the patient, should be part of the initial management of all subjects. These include head of the bed elevation, avoidance of tight-fitting clothes, weight loss, restriction of alcohol, elimination of smoking, dietary therapy, refraining from lying down after meals, and avoidance of evening snacks before bedtime. Physiological studies show that these maneuvers enhance esophageal acid clearance, minimize acid-reflux related events, or ease heartburn symptoms, but their therapeutic efficacy in controlled trials usually has not been evaluated. [174] The head of the bed can be elevated either by putting 6- to 8-inch blocks under the legs of the bed or by using a Styrofoam wedge under the mattress to elevate the upper torso. Eating several hours before retiring and avoiding evening snacks keep the stomach empty at bedtime, thereby decreasing the number of nocturnal reflux episodes. These three lifestyle changes are recommended for patients with nocturnal GERD symptoms or laryngeal complaints. One study found that head of the bed elevation was nearly as effective as ranitidine therapy in healing esophagitis. [175] Avoidance of tight-fitting clothes and weight loss are interventions aimed at reducing the incidence of reflux by the abdominal stress mechanism. The efficacy of weight reduction is especially controversial, [176] but it may be helpful when discrete periods of weight gain can be associated with exacerbation of reflux symptoms. Cessation of smoking and elimination of alcohol are valuable because both agents lower LES pressure, reduce acid clearance, and impair intrinsic squamous epithelial protective functions. [47], [177], [178] Dietary changes include reducing the size of the meal and intake of fats, carminatives, and chocolate, to reduce the frequency of reflux by decreasing gastric distention and by reducing the episodes of transient LESRs, and avoiding foods that lower basal LES pressure. [173], [176] Additionally, some patients complain of heartburn after consuming citrus drinks, spicy foods, tomato-based products, coffee, tea, or cola drinks. Stimulation of gastric acid or esophageal sensitivity to low pH or hyperosmolar liquid solutions may account for these symptoms. [179] However, the indiscriminate prohibition of food products should be avoided, but rather tailored to those foods that bring on individual symptoms, to promote dietary compliance. Finally, patients should avoid, if possible, drugs that lower LES pressure or can promote localized esophagitis.

Over-the-Counter Medications Over-the-counter antacids, Gaviscon, and H_2RAs (Table 60-14) are useful in treating mild and infrequent heartburn symptoms, especially when symptoms are brought on by lifestyle indiscretions. Antacids increase LES pressure but work primarily by buffering gastric acid in the esophagus and stomach, albeit for relative short periods. Heartburn symptoms are rapidly relieved, but patients need to take antacids frequently, usually 1 to 3 hours after meals and at bedtime, depending on symptom severity. Gaviscon, containing alginic acid and antacids, mixes with saliva to form a highly viscous solution that floats on the surface of the gastric pool and acts as a mechanical barrier. Both antacids [180] and Gaviscon [181] are more effective than placebo in relieving symptoms induced by a heartburn-promoting meal. However, these agents do not heal esophagitis, and long-term trials suggest effective symptom relief in only 20% of patients using antacids. [182], [183] Side effects of antacids and Gaviscon are minimal but include diarrhea from magnesium-containing antacids, constipation from aluminium-containing antacids, salt overload, magnesium or aluminium toxicity in patients with renal disease, and the milk-alkali syndrome (hypercalcemia, alkalosis, renal failure) from long-term and excessive use of calcium-containing antacids. H_2RAs are available in an OTC form at doses that are usually one half of the standard prescription dose. Although there are some differences in potency, duration, and rapidity of action, these drugs may be used interchangeably. Although their onset of relief is not as rapid as that of antacids, the OTC H_2RAs have a longer duration of action, up to 6 to 10 hours. [184] Therefore, they are particularly useful when taken before a potentially refluxogenic activity, such as a heavy meal or exercise. Like antacids, the OTC H_2RAs are ineffective in healing esophagitis and should not be used regularly for more than 2 weeks. [184]

Prescription Medication Therapy

Patients with frequent heartburn, esophagitis, or complications of GERD usually see a physician and receive prescription medications for their disease (see Table 60-4). Although prokinetic drugs attempt to correct the motility disorder associated with GERD, the most clinically effective medications for short- and long-term reflux treatment are the acid suppressive drugs.

TABLE 60-4 Drug Therapy for Gastroesophageal Reflux Disease

Prokinetic Drugs Until recently, three prokinetic drugs were available for the treatment of GERD: bethanechol, a cholinergic agonist; metoclopramide, a dopamine antagonist; and cisapride, a serotonin (5-HT_4) receptor agonist, which increases acetylcholine release in the myenteric plexus. These drugs improve reflux symptoms by increasing LES pressure, acid clearance, or gastric emptying. [185] However, none alter the frequency of transient LESRs, and their physiological activity decreases as the disease severity worsens. [186] Therefore, all the current prokinetics provide modest benefit in controlling heartburn, but they have little efficacy in healing esophagitis unless they are combined with an acid inhibiting drug. [185] The use of prokinetic drugs is limited by their side effect profiles. Bethanechol commonly causes flushing, blurred vision, headaches, abdominal cramps, and urinary frequency. Metoclopramide, which crosses the blood-brain barrier, has a 20% to 50%

incidence of fatigue, lethargy, anxiety, and restlessness and rarely causes tremor, parkinsonism, or tardive dyskinesia. It is possible to decrease the frequency of these side effects by dose reduction, by increasing the dosing regimen to twice a day, by taking a larger single dose before dinner or at bedtime, or by using a sustained-release tablet. Domperidone, another dopamine antagonist and one that does not cross the blood-brain barrier, has fewer side effects, but it is not available in the United States. Although the best prokinetic drug for treating GERD with an excellent safety profile, cisapride was withdrawn from the United States market because of increased reports of serious cardiac arrhythmias (ventricular tachycardia, ventricular fibrillation, torsades de pointes, and QT prolongation) with associated cardiac arrest and deaths related to possible drug interactions. [187] These drugs included common antibiotics (clarithromycin, erythromycin), antifungals (fluconazole, itraconazole, ketoconazole), and some antiviral agents. When taken with cisapride, these drugs inhibited the cytochrome P450 3A4 enzyme that metabolizes cisapride, thereby increasing cisapride blood levels to potentially dangerous values.

Histamine $_2$ Receptor Antagonists Cimetidine, ranitidine, famotidine, and nizatidine reduce acid secretion by competing with histamine receptors on the parietal cell. They are most effective in controlling nocturnal, as compared with meal-related acid, secretion because the parietal cell may also be stimulated postprandially by acetylcholine and gastrin. [188] All the H $_2$RAs are equally effective when used in proper doses, usually twice a day before meals. Clinical GERD trials show that heartburn, both day and night, can be significantly decreased by H $_2$RAs, when compared with placebo, although symptoms are rarely abolished (Fig. 60-13A). [189] Trials and a metaanalysis found that the overall esophagitis healing rates with H $_2$RAs rarely exceeded 60% after up to 12 weeks of treatment, even when higher than standard doses were used (see Fig. 60-13B). [189] , [190] Healing rates differ in individual trials, depending primarily on the degree of esophagitis being treated: grade I and II esophagitis heals in 60% to 90% of patients, whereas grade III and IV heals in 30% to 50% of patients despite high-dose regimens. [190]

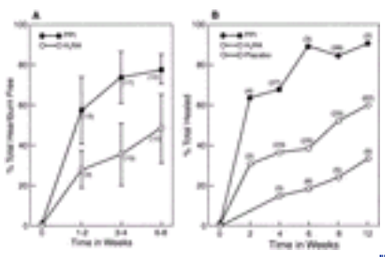

FIGURE 60-13. (**A**) Symptom relief-time curve expressed as the mean total heartburn relief for proton pump inhibitors (*PPIs*) or histamine $_2$ receptor antagonists (*H $_2$RA*) corrected for patients free of heartburn at baseline and over 8 weeks. By week 2, more patients treated with PPIs are asymptomatic compared with patients treated with H $_2$RAs even after a much longer duration of treatment (8 weeks). (**B**) Esophagitis healing-time curve as the mean total healing for PPIs, H $_2$RAs, and placebo over 12 weeks. By 4 weeks, PPIs healed esophagitis in more patients than the other two drug classes over 12 weeks, implying a substantial therapeutic gain. The number of studies is shown in *parentheses*. (From ref. [190] .)

Reflux symptoms associated with nocturnal gastric acid breakthrough during PPI therapy have been recognized. [191] At bedtime, H $_2$RAs successfully eliminated this problem, suggesting a new indication for H $_2$RAs in the PPI era. [192] However, this study used only a single evening dose and did not account for the tolerance that frequently develops to H $_2$RAs over weeks to months. [193] This may impair the ability of chronic long-term nocturnal dosing of H $_2$RAs to eliminate acid breakthrough symptoms, [194] but it suggests an important clinical role as medications used on an as-needed basis when lifestyle indiscretions may promote nocturnal symptoms. As a class of drugs, the H $_2$RAs are very safe, with a side effect rate (most of which are minor and reversible) of about 4%. [188] There have been some concerns about drug interactions with these agents. Serum concentrations of phenytoin, procainamide, theophylline, and warfarin are altered after the administration of cimetidine and, to a lesser degree, ranitidine, whereas this interaction is not reported with the other two H $_2$RAs. The former concern that these agents could alter blood ethanol levels has been discounted. [188]

Proton Pump Inhibitors This class of drugs markedly diminishes gastric acid secretion by inhibiting the final common pathway of acid secretion, the H $^+$, K $^+$-ATPase pump. PPIs inhibit daytime, nocturnal, and meal-stimulated acid secretion to a significantly greater degree than H $_2$RAs, [195] but they rarely make patients achlorhydric. Unlike H $_2$RAs, the degree of acid inhibition with PPIs does not correlate with plasma concentration, but it is related to the concentration and duration (area under the curve). After oral ingestion, acid inhibition is delayed because PPIs need to accumulate in the secretory canaliculus of the parietal cell to bind irreversibly to actively secreting proton pumps. [196] Therefore, the slower a PPI is cleared from the plasma, the more of it is available for delivery to the proton pumps. PPIs are best taken before the first meal of the day, when most proton pumps are active. Because not all pumps are active at any given time, a single PPI dose does not inhibit all pumps. A second dose, if needed, can be taken before the evening meal. The five available PPIs are omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole, the S-isomer of the racemic omeprazole. Their superior efficacy compared with H $_2$RAs is based on their ability to maintain an intragastric pH high than 4 between 15 to 21 hours daily compared with approximately 8 hours daily with the H $_2$RAs. [197] Multiple studies show that the PPIs are superior to H $_2$RAs in completely relieving heartburn symptoms in most patients with severe GERD, usually within 1 to 2 weeks (see Fig. 60-13A). [190] Symptom relief is slightly better in patients with erosive as compared with nonerosive disease. [198] Controlled studies and a large metaanalysis report complete healing of even severe ulcerative esophagitis after 8 weeks in more than 80% of patients taking PPIs compared with 51% of patients taking H $_2$RAs and 28% receiving placebo (see Fig. 60-13B). [199] , [200] , [201] and [202] In those patients not healing initially, prolonged therapy with the same dose or an increased dose usually resulted in 100% healing. [203] Studies with PPIs consistently show that they are superior to both regular and high-dose H $_2$RA therapy, but therapeutic efficacy among PPIs is similar. However, a large study found that the newest PPI, esomeprazole, at a dose of 40 mg, was superior to the parent compound (omeprazole, 20 mg) for complete healing of esophagitis at 4 and 8 weeks. [204] This superiority over omeprazole is related to higher systemic bioavailability and less interpatient variability with esomeprazole. One PPI, pantoprazole, is available in the United States for intravenous use. [205] All the PPIs, are well tolerated with headaches and diarrhea described as the most common side effects in clinical trials. Although increased gastrin levels are reported with all the PPIs, the elevations generally do not exceed the normal range for gastrin and return to normal values within 1 week of stopping the drug. Omeprazole may decrease the clearance of diazepam and warfarin because of competition for the cytochrome P450 isoenzyme P2C19. [206] The four newer PPIs have minimal or no important drug-drug interactions.

Maintenance Therapy

GERD tends to be a chronic relapsing disease, especially in patients with low LES pressure, severe grades of esophagitis, and difficult to manage symptoms. [183] Although almost all patients with severe esophagitis can be healed with PPI treatment, recurrence can be anticipated in more than 80% of patients within 6 months of drug discontinuation. [145] The chronicity of less severe forms of GERD is less certain, but relapses probably occur in 15% to 30% of patients over 6 months. [207] Therefore, maintenance therapy is needed for many patients.

One-year maintenance studies always find the PPIs superior to H $_2$RAs or prokinetics, with remission rates higher than 75%. [146] , [208] , [209] H $_2$RAs and prokinetic drugs have lower overall remission rates (20% to 50%) and are most useful in patients with mild or no esophagitis. [146] , [210] The United States Food and Drug Administration (FDA) has approved all the PPIs, sometimes at half the short-term dose, for maintenance therapy (see Table 60-4), but only ranitidine, 150 mg twice daily, has maintenance indications for mild esophagitis. Conversely, clinicians are now placing their patients with severe erosive esophagitis on long-term PPI therapy indefinitely. The efficacy of this approach is supported by open, compassionate use data, primarily from the Netherlands and Australia. [211] , [212] In a study of 230 patients with severe esophagitis healed initially with 40 mg omeprazole, all subjects were kept in remission for up to 11 years. More than 60% were maintained on omeprazole, 20 mg a day, whereas higher doses of 60 mg or more were needed in only 12% of patients, suggesting a lack of tolerance to PPIs. Relapses were rare (1 per 9.4 years of follow-up), strictures did not occur, and Barrett esophagus did not progress. [212]

There was concern about the long-term safety of PPIs because of their profound acid suppression. Current evidence suggests this fear is unjustified because sufficient gastric acid is produced allowing for normal protein and carbohydrate digestion, iron and calcium absorption, and the prevention of bacterial overgrowth. The clinical effect of omeprazole on vitamin B $_{12}$ absorption is controversial. [213] Therefore, it may be prudent to monitor B $_{12}$ levels in patients receiving long-term PPI therapy, especially elderly patients or those with poor or unusual diets. The main concern with the long-term safety of PPIs stemmed from reports of omeprazole's producing hypergastrinemia and gastric carcinoid tumors in rats, changes also subsequently demonstrated with long-term ranitidine therapy and subtotal resection of the gastric fundus. [214] However, the rat has a high density of enterochromaffin-like cells and an exaggerated response to achlorhydria; long-term omeprazole therapy in species (mice, dogs, humans) with lower densities of enterochromaffin-like cells has not caused carcinoid tumors. Furthermore, other groups with massive hypergastrinemia (five to ten times the gastrin values on omeprazole), such as patients with pernicious anemia or Zollinger-Ellison syndrome, rarely develop carcinoid tumors. [214] Finally, one study suggested that patients taking long-term

omeprazole who are infected with *H pylori* develop atrophic gastritis, a precursor to gastric adenocarcinoma at a more rapid rate than noninfected patients. [215] Nevertheless, a subsequent FDA panel determined that the available data were insufficient for recommending screening and treatment of *H pylori* infection in patients receiving long-term PPI therapy. [216]

Treatment in Elderly or Pregnant Patients

Older patients often complain of less severe reflux symptoms than their younger cohorts, but because of prolonged acid exposure over years, the elderly may have more complicated disease. [5] Treatment of the older patient with GERD follows the same principles as in other adults, although they may require more aggressive acid suppression therapy. [217] Pill-induced esophagitis may complicate their treatment. Metoclopramide must be used with caution because of frequent side effects in the elderly. H_2RAs can be associated with mental changes in older patients, and doses need to be decreased in patients with renal insufficiency. Fewer drug interactions are seen with famotidine and nizatidine. Alternative methods of administering PPIs may be necessary in debilitated older patients who cannot swallow intact omeprazole or lansoprazole capsules. Both capsules can be opened and the granules taken with water, an HCO_3^--based suspension, or apple or orange juice, or the granules can be sprinkled on applesauce or yogurt. [218]

Teratogenicity or fetal harm from absorption of medications across the placenta is the foremost consideration in the treatment of GERD during pregnancy. [219] Lifestyle modifications and antacids or Gaviscon remain the cornerstones of treatment, providing adequate relief to the majority of women with mild symptoms. Although rarely used in adults, sucralfate is a nonabsorbable mucosal binder that has been found superior to lifestyle changes in a controlled study in pregnant women. [220] Metoclopramide, H_2RAs, and most PPIs (except omeprazole) have a Category B FDA safety profile for use during pregnancy, based on animal studies showing no risk, as well as on small case series and anecdotal human reports. Ranitidine is the only one of these drugs shown to be effective during pregnancy. [221] PPIs may be safe for aspiration prophylaxis before anesthesia for elective cesarean sections. Antacids, sucralfate, and most H_2RAs (except nizatidine) are safe to use during lactation, even though the latter group of drugs is excreted in breast milk. PPIs are not recommended during breast-feeding, based on safety concerns in animal studies. [219]

Treatment of Complications

Extraesophageal Presentations Acid reflux–related chest pain is easily treated by H_2RAs or PPIs, with efficacy substantiated by placebo-controlled studies. [222] The efficacy of acid suppression therapy in asthma, cough, and other pulmonary complications of GERD is more mixed. [98] Medical antireflux therapy improves asthma symptoms and reduces the need for asthma medications in more than 60% of patients, but objective improvement of peak expiratory flow rates is observed in only 25% of patients. Best results are found with higher doses of PPIs (usually twice-daily administration) given for 2 to 3 months. Potential positive predictors of PPI response include asthma that is difficult to control, associated acid regurgitation, proximal reflux on pH testing, and healing of esophagitis with antireflux therapy. Case studies report that 60% to 96% of patients with suspected acid-related ear, nose, and throat symptoms and signs improve with acid suppression. [104] Here again, PPIs are more effective than H_2RAs, and extended therapy for up to 3 months may be required. Predictors of response have not been identified, although patients with milder laryngeal signs show better symptom improvement. In all these possible extraesophageal presentations of GERD, failure to respond to aggressive PPI therapy, confirmed by adequate acid control by pH testing, suggests a cause of these complaints other than acid.

Esophageal Strictures Dysphagia in patients with esophageal strictures is related to stricture diameter and severity of esophagitis. [223] When the esophageal lumen diameter is less than 13 mm, dysphagia is a major complaint and esophageal dilation is required. Simple short strictures can be dilated by blind peroral passage of rubber Hurst (round ends) or Maloney (taper ends) mercury-filled dilators of increasing sizes (16 to 60 French, 3 French = 1 mm) to disrupt the fibrous bands producing the obstruction. Complicated longer, tighter, or more irregular strictures will require bougienage over a guidewire using hollow-centered Savary plastic-covered polyvinyl dilators or balloon (Gruentzig) dilators. The techniques of esophageal dilation are discussed in detail in Chapter 145. [224] Before and after dilation, medical therapy with PPI is indicated; it has been shown to be superior to H_2RAs in relieving symptoms and in reducing the frequency for repeat dilations. [225] Maintenance PPI therapy for patients with strictures has dramatically reduced the incidence of repeat esophageal dilations and the cost of treating these patients. [152] Recalcitrant strictures, requiring surgery, are now very uncommon and suggest another aggravating factor such as chronic pill injury.

Barrett Esophagus In general, esophagitis in the presence of Barrett esophagus can be easily healed with PPI therapy, but meaningful regression of Barrett epithelium, except for small squamous islands, is rarely reported even with high-dose PPI therapy. [226] Recent ex vivo studies [227] have suggested that intermittent “pulses” of acid result in enhanced Barrett epithelial cell proliferation, possibly increasing the risk of dysplasia and cancer. Some have suggested the need to eliminate all acid reflux in patients with Barrett esophagus, [228] but this would require high and frequent doses of expensive medications and serial pH monitoring to document efficacy of therapy. Pending further clinical studies, patients with Barrett esophagus should be treated like others with chronic GERD. Esophageal resection of Barrett esophagus can prevent the progression to cancer, but this requires a total esophagectomy with high mortality, except in selected surgical centers. Therefore, ablation of Barrett epithelium in the setting of strict PPI anacidity has been proposed. Photodynamic therapy, laser, multipolar electrocoagulation, argon plasma coagulation, and endoscopic mucosal resection have been used for this purpose. [229] In these studies, Barrett mucosa can be reversed completely in 70% to 80% of patients, but intestinal metaplasia underlying the new squamous mucosa is reported in almost all series, with the occasional residual foci of metaplasia developing adenocarcinoma. [230] Adverse effects of ablation therapy have ranged from mild chest pain, sore throat, or odynophagia to esophageal perforation and death. The incidence of adenocarcinoma in patients with Barrett esophagus without dysplasia is probably so low that endoscopic ablation cannot be advocated outside of study protocols. Endoscopic therapy for patients with high-grade dysplasia or early cancer holds more promise, especially in the older patients with comorbid illnesses. [231] Because there is currently no way of eliminating the malignant risk of Barrett esophagus, regular endoscopic surveillance is recommended. Biopsies should be taken from each quadrant every 2 cm axially within the metaplastic tissue. The rationale is that dysplasia within Barrett epithelium is often multifocal, and obtaining fewer tissue samples increases the risk of missing dysplastic areas. [232] Brush cytology can compliment endoscopic biopsies. [233] Biomarkers, [234] such as p53, and flow cytometry [235] may augment the yield of histological examination of biopsy specimens. Although prospective studies are not available, case series confirm that esophageal adenocarcinomas detected by endoscopic surveillance are at an earlier stage with a more favorable survival than cancers detected at the time of diagnosis of Barrett, typically when patients present with dysphagia. [236] The appropriate surveillance interval for patients with Barrett esophagus has not been studied prospectively. However, current programs, such as proposed by the American College of Gastroenterology, are based on the grade of dysplasia (Table 60-5). [237] In these recommendations, the management of high-grade dysplasia remains most controversial. Some groups suggest that high-grade dysplasia may regress to lesser grades, and an intensive biopsy protocol every 3 months will differentiate high-grade dysplasia from cancer. [238], [239] The surgical literature contrasts with this experience. Of 126 cases with high-grade dysplasia alone by endoscopic biopsies, 41% had cancer, although usually an early stage, at the time of esophagectomy. [237] Nevertheless, most patients with Barrett esophagus never progress to important degrees of dysplasia. Predictors of cancer progression at the initial diagnosis of Barrett esophagus are needed to define individual surveillance programs more appropriately. One study suggested that patients whose baseline biopsies are negative or show only low-grade dysplasia without increased 4N or aneuploidy on flow cytometry may have surveillance deferred for up to 5 years. [239] Another prospective multivariate analysis revealed that progression to high-grade dysplasia or cancer was significantly and independently associated with dysplasia at diagnosis or anytime during follow-up, hiatal hernia size greater than 2 cm, and Barrett esophagus length greater than 2 cm. [240] These patients may warrant more frequent surveillance programs.

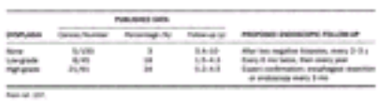

TABLE 60-5 Barrett Esophagus: Grade of Dysplasia and Proposed Follow-Up

Surgical Treatment

Antireflux surgery reduces GER by increasing basal LES pressure, decreasing episodes of transient LESRs, and inhibiting complete LESR. [241] This is accomplished by reducing the hiatal hernia back into the abdomen and thereby restoring an adequate length of intra-abdominal sphincter, reconstructing the diaphragmatic hiatus, and reinforcing the LES. [242] Before the explosion of laparoscopic surgery, the three most common operations were the Nissen fundoplication, the Belsey Mark IV repair, and the Hill posterior gastropexy repair. Since the advent of minimally invasive surgery, the two most popular procedures are the Nissen fundoplication and the Toupet partial fundoplication (Fig. 60-14). The former is a superior operation with more long-term durability, but it has a higher frequency of postoperative dysphagia and gas bloat symptoms. [243], [244] Both are now routinely performed laparoscopically through the abdomen. The hospital stay is 1 to 2 days, and many patients return to normal activity in 7 to 10 days. Patients with more severe disease and a short esophagus manifested by a large nonreducible hernia, a tight stricture, or a long-segment Barrett esophagus require a Collis lengthening procedure creating a 3- to 5-cm neoesophagus, so the fundoplication can be placed in the abdomen under minimal tension. [245]

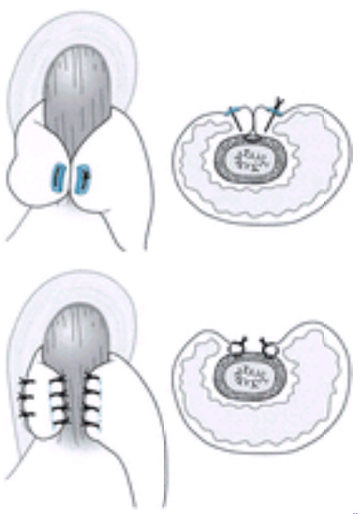

FIGURE 60-14. Appearance and cross-sectional views of the Nissen fundoplication, a full 360° wrap (**top**), and the Toupet partial fundoplication (**bottom**). These are the two most popular fundoplications used in laparoscopic antireflux surgery.

The common indications for antireflux surgery have evolved with the availability of more powerful medications for treating GERD. In the PPI era, the resolution of symptoms on treatment helps to predicate the success of antireflux surgery for both classical and atypical symptoms. [246] Antireflux surgery is a reasonable option in the following situations:

1. Healthy patients with GERD well controlled on PPIs who want alternative therapy because of drug expense, poor medication compliance, or a fear of unknown long-term side effects
2. Patients with atypical GERD symptoms responding to PPIs
3. Patients with volume regurgitation and aspiration symptoms not controlled on PPIs.

Patients recalcitrant to PPI therapy need to be approached cautiously with surgery because they may have another cause of their disorder (i.e., pill esophagitis, gastroparesis, functional heartburn).

Extensive physiological testing should be done before antireflux surgery is performed. All patients need endoscopy to exclude stricture, Barrett esophagus, and dysplasia. A barium esophagram can help define a nonreducible hernia, shortened esophagus, and poor esophageal motility. Esophageal manometry will identify ineffective esophageal peristalsis and previously misdiagnosed achalasia or scleroderma. Twenty-four hour pH testing is needed in all patients with nonerosive GERD or in those with esophagitis not responding to PPI therapy. Gastric analysis and gastric emptying studies may be indicated in selected patients. Careful testing will result in modification of the original operation or an alternative diagnosis in approximately 25% of patients. [131]

Antireflux surgery relieves reflux symptoms and reduces the need for stricture dilation in more than 90% of patients, [243] but Barrett esophagus rarely regresses, and the influence of surgery on the development of esophageal adenocarcinoma is controversial. [247] Comparison studies have found antireflux surgery superior to lifestyle changes, antacids, and H_2RA and prokinetic therapy, [149], [182] but not PPI therapy, especially when dose titration is permitted. [248] Mortality is rare (<1%) after antireflux surgery, but new postoperative complaints can occur in up to 25% of patients including dysphagia, gas bloat, diarrhea, and increased flatus. [249] Most symptoms improve over 1 year, but persistent complaints suggest too tight a wrap, a displaced fundoplication, or inadvertent damage to the vagus nerve. Successful antireflux surgery, however, does not guarantee a permanent cure. The best surgical results are obtained by experienced surgeons in high-volume centers who report long-term symptom recurrence in only 10% to 15% of patients. [243] However, most operations are performed by community or Veterans Affairs hospital surgeons. Here the results are not as good with studies finding relapse of esophagitis in 30% of patients [250] and return to regular use of antireflux medications in 62% of patients [251] 10 to 15 years after fundoplication. Potential factors contributing to these high relapse rates include inexperienced surgeons, low numbers of operations yearly per surgeon, and persistence of abdominal stressors (i.e., obesity, heavy isometric exercise or work) that gradually weaken the fundoplication. A suboptimal operation or severe symptom relapse may necessitate a second operation, which has less likelihood of a successful outcome. [242] Because optimal medical therapy is available to all patients with GERD, the risk and benefits of both long-term medical treatment and antireflux surgery must be carefully discussed with patients, so they can take part in this important decision.

New Treatments

The future medical treatment of GERD involves drugs that interfere with transient LESRs but do not cause dysphagia. Baclofen, a $GABA_B$ agonist, has been shown to decrease reflux symptoms and to improve pH studies in healthy persons and in patients with GERD. [252] Newer endoscopic treatments of GERD have been approved by the FDA. These techniques include an endoscopic suturing system, radiofrequency energy delivery to the gastroesophageal junction, and the injection of nonabsorbable polymers into the submucosa surrounding the LES. To date, these techniques have been applied only to patients with small (<2 cm) or no hernias and mild esophagitis. Results are encouraging, with improvement of symptoms and decreased medication requirements, but follow-up is short (<1 year), and a comparison with sham surgery has not been done. [253]

ESOPHAGEAL INFECTIONS AND DISORDERS ASSOCIATED WITH ACQUIRED IMMUNODEFICIENCY SYNDROME

Remarkable progress has been made in the treatment of human immunodeficiency virus (HIV) infection as well as in the care of immunosuppressed patient. For patients with acquired immunodeficiency syndrome (AIDS), the efficacy and widespread adoption of highly active antiretroviral therapy (HAART) have resulted in a marked reduction in the incidence of opportunistic infections including those involving the esophagus. [1] Likewise, in the setting of organ transplantation, further advancements in immunosuppressive therapy and targeted antimicrobial prophylaxis for patients at high risk of developing infection, such as cytomegalovirus (CMV) infection, have also resulted in a reduction in esophageal infections. Nevertheless, the number of patients at risk of opportunistic infections remains high, especially as our population grows older, immunosuppressive therapy becomes more widely employed to treat other diseases, and the use of organ transplantation expands. Timely and accurate diagnosis of esophageal infections is critical because treatment is highly effective and usually results in rapid symptomatic improvement and often clinical cure. This chapter focuses on the specific causes of esophageal infections, in particular epidemiology, pathology, presentation, diagnosis, and therapy. Esophageal disorders associated with HIV infection and AIDS are also reviewed here.

EPIDEMIOLOGY AND PREDISPOSING FACTORS

Primary esophageal infection is rare in an otherwise healthy person in whom no permissive factor is present. In this setting, the most common pathogen is herpes simplex virus (HSV), [2] although candidiasis may be observed in elderly patients without other predisposing factors. [3] In general, immunocompetent patients who develop esophageal infection have conditions, either local or systemic, that weaken esophageal defense mechanisms. Normal oroesophageal flora may be altered by the use of antimicrobial agents, thus allowing overgrowth of *Candida.* Disorders of esophageal emptying including achalasia, progressive systemic sclerosis, benign or malignant esophageal strictures, and diverticula predispose to esophageal infection, usually with *Candida,* because of stasis of esophageal contents. Infection in adjacent structures may spread into and involve the esophagus secondarily.

More commonly, some form of humoral or cellular immunodeficiency leads to esophageal infection. Underlying conditions that predispose to infections include diabetes mellitus, alcoholism, malnutrition, malignant diseases, and advanced age. Hyperglycemia impairs granulocyte function and leads to candidal disease. Corticosteroid therapy predisposes to infection by suppressing lymphocyte and granulocyte function. Mucosal disruption commonly follows chemotherapy or radiation and provides a portal of entry for pathogens. Transplantation predisposes to infections through variable mechanisms, most of which affect both B-cell and T-cell number and function, including use of immunosuppressive agents, chemotherapy, and neutropenia. Episodes of rejection in recipients of solid organ transplants are also commonly complicated by infection, because these patients are given more immunosuppression including powerful agents such as antithymocyte globulin. Broad-spectrum antibiotics, antisecretory therapy, and surgical trauma further predispose to esophageal infections.

Infection after transplantation has a predictable time course. Bacterial and fungal infections are most common during the initial months after transplantation, because it is during this period that granulocyte number or function is most severely compromised. HSV infection also tends to occur early after transplantation because of reactivation of disease, whereas CMV typically presents 2 to 6 months after transplantation at a time when neutropenia is common and T-cell function is most severely impaired. The development of opportunistic infections in HIV-infected patients reflects severe immunodeficiency; esophageal infections usually become clinically manifest when the CD4 lymphocyte count is less than 200/mm ^{3}. [4], [5]

FUNGAL INFECTIONS

Candida Species

Epidemiology *Candida* species are the most common esophageal pathogens, primarily *C albicans,* but occasionally *C tropicalis, C parapsilosis, C glabrata,* and *C dublinensis.* These organisms are normal components of the oral flora, and their growth is kept in check by bacterial commensals. Conditions predisposing to *Candida* esophagitis in the "normal" host include antibiotic use, inhaled or ingested corticosteroids, antisecretory therapy (histamine H_2 receptor blockers, proton pump inhibitors or hypochlorhydric states, diabetes mellitus, alcoholism, malnutrition, old age, head and neck radiotherapy, and esophageal motility disturbances. [6] Alterations in cellular immunity lead to candidal colonization and superficial infection, whereas granulocytes function to prevent invasive disease and dissemination. The congenital immunodeficiency chronic mucocutaneous candidiasis may also be complicated by *Candida* esophagitis. Improvements in immunosuppressive regimens, targeted prophylactic antifungal therapy, and empiric use of fluconazole in symptomatic patients have dramatically reduced the incidence of candidal infections in recipients of solid organ and bone marrow transplants. [7] Candidiasis remains the most common esophageal infection in patients with AIDS; it represents approximately 50% of esophageal infections, [8], [9] and it frequently coexists with other esophageal diseases. [10]

Pathology The gross pathological appearance of esophageal candidiasis can range from a few white or yellow plaques on the mucosal surface to a dense, thick plaque that coats the esophageal mucosa (Fig. 61-1A; see also Color Fig. 61-1). This plaque material is composed of desquamated squamous epithelial cells, admixed with fungal organisms, inflammatory cells, and bacteria [11] (Fig. 61-1B,C; see also Color Fig. 61-1). True ulceration is infrequent and has been documented most commonly in immunosuppressed patients with granulocytopenia (Table 61-1). [12]

TABLE 61-1 Pathologic Findings of Esophageal Infections

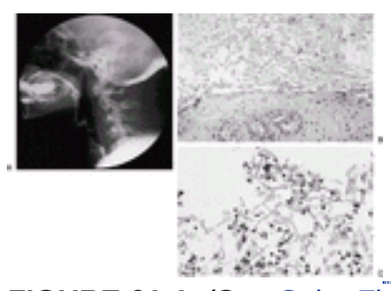

FIGURE 61-1. (See Color Fig. 61-1.) *Candida* esophagitis. (**A**) Endoscopic photograph shows multiple raised plaques involving the esophagus with normal intervening mucosa. (**B**) Desquamated squamous epithelial cells admixed with fungi and inflammatory cells adherent to the mucosa. The underlying squamous epithilium appears normal. (**C**). Close-up view of the plaque material demonstrates mycelia and spores typical of *Candida.*

Clinical Manifestations and Complications Although this infection is detected on occasion incidentally in an asymptomatic patient, the usual clinical presentation of esophageal candidiasis is dysphagia, with odynophagia less prominent (Table 61-2). Esophageal symptoms range from mild difficulty with swallowing to severe pain resulting in an inability to eat and secondary dehydration. When odynophagia is very severe, one must consider other causes or co-infections, particularly in patients with AIDS.

TABLE 61-2 Symptoms and Signs of Esophageal Infection

Physical examination may be helpful. Approximately two thirds of patients with AIDS and esophageal candidiasis have oral candidiasis (thrush). [13] Patients with chronic mucocutaneous candidiasis may have fungal involvement of various mucous membranes, hair, nails, and skin with a history of adrenal or parathyroid dysfunction. Complications of esophageal candidiasis are very rare. Esophageal hemorrhage may occur when the disease is severe (erosion or ulcer) and there is associated coagulopathy. Lumenal obstruction secondary to mycetoma, fibrosis and stricture formation, and fistulization into the bronchial tree have been described, [14] but these usually represent *Candida* colonization of these anatomic abnormalities caused by other underlying disorders.

Diagnosis Esophageal candidiasis should be suspected in any patient at risk of esophageal infection who complains of dysphagia or odynophagia. The presence of thrush further supports this diagnosis, but the absence of oral involvement does not exclude esophageal disease. Before the availability of endoscopy, radiographic examination (barium esophagram) was commonly used for initial evaluation. *Candida* esophagitis is characteristically manifested by multiple plaquelike lesions, often in a linear configuration; when severe, these lesions become confluent to cause a “shaggy” appearance of the esophagus resembling ulcerations (see Fig. 61-1). [15] Additional radiographic findings include pseudomembranes, cobblestoning, polypoid nodules, fungus balls, strictures, esophagopulmonary fistulae, mucosal bridges, or large, neoplastic-appearing esophageal ulcers and masses. [16] A large, well-circumscribed ulceration should not be attributed to *Candida.* Importantly, a normal barium esophagram does not exclude esophageal candidiasis. The presence of severe odynophagia may limit the ability of the patient to drink barium and thus hampers the utility of barium studies. Endoscopic examination of the esophagus is the most accurate method of diagnosing esophageal candidiasis. The gross endoscopic appearance of *Candida* esophagitis is usually diagnostic and may be graded according to published criteria. [11] During endoscopy, mucosal lesions can be brushed and submitted for cytologic evaluation or examined by biopsy for histological diagnosis. Multiple biopsies are essential to exclude coexisting disorders when ulceration is identified endoscopically. The use of periodic acid-Schiff or Gomori methenamine silver stain helps to highlight the organisms. Cytologic examination of esophageal brushings is more sensitive than histological examination of biopsy specimens because organisms may be washed off tissue surfaces in mild superficial candidiasis (i.e., grades 1 and 2) during processing of biopsy specimens. [3] Rarely, positive cytology but negative histology indicates colonization rather than infection. Skin testing and serologic tests for candidiasis are not useful in the diagnosis of *Candida* esophagitis. In patients with AIDS and thrush, the presence of dysphagia or odynophagia usually indicates *Candida* esophagitis. [5], [9] Given the prevalence of *Candida* esophagitis in AIDS, in the symptomatic patient with associated thrush, an empiric trial of antifungal therapy may be instituted, reserving endoscopy for those patients who fail to respond. However, this symptom complex does not exclude co-infection with other pathogens, and one third of patients with esophageal candidiasis do not have thrush. Further evaluation should not be delayed longer than 1 week in patients with severe persistent symptoms because the response to antifungal therapy is rapid, with clinical improvement occurring in most patients within days. [9], [17] When patients fail to improve with empiric antifungal therapy, endoscopy should be performed, given that disorders other than candidiasis are identified in most patients. [18], [19] The role of empiric antifungal therapy in symptomatic immunosuppressed patients who do not have AIDS has not been well studied, although this approach is commonly practiced.

Treatment Both oral and intravenous medications are available that are highly effective for the treatment of *Candida* esophagitis (Table 61-3). In general, oral therapies should be first initiated, reserving intravenous treatment for refractory disease or for patients who have contraindications to orally administered medication. Although candidal species other than *C albicans* may cause esophagitis, speciation is not widely employed because reliable culturing and sensitivity testing are lacking at most centers. For those patients with mild disease, minimal immunocompromise, or readily reversible immunodeficiency, an abbreviated course of therapy with an oral azole should be given. Immunocompromised transplant recipients and patients with AIDS with *Candida* esophagitis are best treated with systemically absorbed agents (azoles). In addition, patients with granulocytopenia are at significant risk of disseminated candidal infection, thus warranting the use of systematically acting intravenous agents such as the azoles or amphotericin B.

TABLE 61-3 Treatment Regimens for Common Esophageal Disease in AIDS

Orally administered systemically agents include ketoconazole (Nizoral), fluconazole (Diflucan), and itraconazole (Sporanox). All have efficacy for the treatment of *Candida* esophagitis. These agents, like other azoles, alter fungal cell membrane permeability by cytochrome P450–dependent interference with ergosterol biosynthesis resulting in fungal cell injury and death. The newer triazoles (itraconazole and fluconazole) have greater affinity than the imidazoles (miconazole and ketoconazole) for fungal cytochrome P450 enzymes. [20] Although other agents such as clotrimazole and nystatin may be effective for oral candidiasis and for prophylaxis against esophageal involvement, [21] these agents are less effective as primary therapy for esophageal candidiasis. Ketoconazole therapy (200 to 400 mg/d) is effective for the treatment of esophageal candidiasis. The dose may be increased, nausea permitting, to a maximum of 800 mg/d. Patients with AIDS usually require higher doses of ketoconazole, and a starting dose of 400 mg/d in divided doses has been recommended. Optimal absorption requires an acid milieu; thus, situations of gastric hypoacidity, such as pernicious anemia or iatrogenic hypochlorhydria, through the use of antisecretory agents, will reduce bioavailability. [22] Because patients with AIDS may have reduced gastric acid secretion that decreases absorption and thus impairs the efficacy of this agent, [23] ketoconazole is not generally recommended for initial therapy. The dose of itraconazole is 200 mg/d, and as with ketoconazole, further dose increases lengthen the drug’s half-life and improve efficacy. Itraconazole absorption is also reduced by increasing gastric pH. [24] Ketoconazole and itraconazole are extensively metabolized in the liver and are excreted in the bile. The half-life of these two agents are 7 to 10 hours and 24 to 42 hours, respectively. [20] Dose adjustments are not required in the patient with renal failure. Large randomized studies suggest that fluconazole (100 mg/d), the absorption of which does not depend on pH, has significantly greater efficacy for the treatment of *Candida* esophagitis in AIDS than ketoconazole (200 mg/d) [25] and itraconazole. [26] Fluconazole is available in oral and intravenous preparations. It is minimally metabolized and is excreted unchanged in the urine. Unlike ketoconazole and itraconazole, fluconazole is highly water soluble and is minimally protein bound. The half-life is approximately 30 hours if renal function is normal, and the presence of food or hypochlorhydria does not alter absorption. Both fluconazole and

itraconazole are also available in oral solutions. [27] The adverse effects of ketoconazole, fluconazole, and itraconazole are primarily dose dependent and include nausea, hepatotoxicity, and inhibition of steroid production and cyclosporine metabolism. [20] Minor increases in aminotransferases are common with these three agents but do not warrant drug discontinuation. Reversible inhibition of gonadal and adrenal steroid synthesis by ketoconazole may occur with doses of 400 mg/d or greater. [28] In recommended doses, fluconazole and itraconazole do not affect steroidogenesis. Finally, because of the effects on hepatic microsomal enzymes, all three azoles inhibit the metabolism of cyclosporine and result in an increase in cyclosporine blood levels, and this effect is most pronounced with ketoconazole. [20] Other important drug interactions with these agents have been noted, although these tend to be more common with ketoconazole. The other major family of antifungal agents consists of the polyene antibiotics, represented by amphotericin and nystatin (see Table 61-3). These agents bind irreversibly to sterols in fungal cell membranes, thereby altering the permeability characteristics of the membrane and causing cell death. Nystatin is effective for treating thrush but less so for esophageal disease. Furthermore, the efficacy, safety, and ease of administration of azole derivatives have made nystatin a second-line therapy. Although amphotericin B (Fungizone) is the most effective treatment for systemic mycoses, its severe side effects, coupled with the availability of azoles, have limited its use for the treatment of esophageal candidiasis. This agent is now available in an oral solution. Patients with esophageal candidiasis resistant to treatment with fluconazole or other azoles can be treated effectively with lower doses of intravenous amphotericin B (10 to 20 mg/d). Renal toxicity, which is usually reversible, is the most serious adverse effect of continued use of amphotericin B. The total dose for the treatment of esophageal candidiasis is approximately 100 to 200 mg. Combination therapy of flucytosine with amphotericin has been used in some patients with treatment-resistant disease.

Prophylaxis The use of ketoconazole or nystatin for the prevention of esophageal candidiasis in patients with cancer and in transplant recipients has yielded mixed results, and it can be problematic, especially in those receiving cyclosporine. [29] Primary prophylaxis has not been recommended in patients with AIDS, [30] although the long-term use of fluconazole in AIDS has been associated with a reduction in cryptococcal disease. [31]

Drug Resistance Because of widespread use, azole resistance has become an increasing problem in HIV-infected patients. Both the cumulative dose of azole and severe immunodeficiency have been shown to be highly associated with the development of resistance. [32] In patients with AIDS, clinical resistance correlates with in vitro resistance. When resistance occurs, increasing the dose of azole is often helpful. If higher doses fail, switching to another azole or use of oral solution of itraconazole [33] may be tried in higher doses because cross resistance is often present. Intravenous amphotericin B is usually required when high dose (>400 mg/d fluconazole) therapy fails. Resistance to amphotericin is rare. Improvement in immune function with HAART is also effective for the treatment of resistant candidiasis. [34]

Other Fungi

Epidemiology Esophageal involvement with other fungi is rare. Most instances of histoplasmosis and blastomycosis esophagitis represent secondary esophageal involvement from mediastinal lymph nodes rather than primary esophageal infection. [35], [36] Although no particular geographic distribution within the United States has been reported for aspergillosis or blastomycosis, histoplasmosis is endemic in the midwestern states and the Mississippi Valley. Mucormycosis has also been described in a patient with AIDS. [37]

Pathology, Clinical Manifestations, and Complications Other than the development of fistula, there are no unique pathological features of these fungal infections (see Table 61-1). Pulmonary symptoms may predominate when there is fistula formation to the tracheobronchial tree. Recognition depends on appropriate staining of biopsy specimen with the identification of the characteristic fungal elements. Histoplasmosis and blastomycosis are more likely to cause focal lesions as a consequence of extension from mediastinal lymph nodes, although mucosal infection occurring during the course of disseminated histoplasmosis has been noted in patients with AIDS. [38]

Diagnosis Although esophageal aspergillosis is rare, it should be considered in cases of apparent *Candida* esophagitis that are resistant to appropriate therapy. [39] Histoplasmosis should be considered in endemic areas and if extraesophageal manifestations such as hilar adenopathy, calcification or atelectasis of adjacent pulmonary tissue, or splenic calcification are present. Esophageal blastomycosis should be considered in patients with skin involvement and dysphagia. Endoscopy with biopsies and histological examination (with cytologic brushings) may establish the diagnosis if the pathologist is able to differentiate the septate hyphae of *Aspergillus* species from the pseudohyphae of *Candida* species. Culture of biopsy material using fungal media can be diagnostic. Barium esophagraphy or endoscopy may show a focal area of extrinsic compression of the esophagus, usually in the region of the carina, ulcer, or fistula. Because *Histoplasma capsulatum* does not generally invade the esophageal mucosa, endoscopic brushings or biopsies may not be diagnostic. Serologic tests are not useful because of the high prevalence of positive results in endemic areas. A urine antigen test has been developed that is highly specific for disseminated histoplasmosis.

Treatment Although histoplasmosis may resolve without antifungal therapy in the normal host, therapy should be administered. Ketoconazole, itraconazole, and amphotericin B are effective against histoplasmosis and blastomycosis. [20] Because of the toxicity associated with amphotericin, this agent should probably be reserved for severe infections or for cases of failure of ketoconazole therapy. Systemic aspergillosis should be treated with high-dose amphotericin B, although itraconazole has significant in vitro activity. Surgery may be required for drainage of abscesses or excision of fistulae.

VIRAL INFECTIONS

With the administration of *Candida* prophylaxis in selected patients undergoing transplantation coupled with the increasing use of oral antifungal therapies in AIDS, viral esophagitis is assuming more etiologic importance. Nevertheless, in the transplant setting, the incidence of clinically apparent viral esophageal disease has been decreasing as a result of targeted antiviral prophylaxis for herpesviruses in high-risk transplant recipients, the use of CMV-seronegative organs and blood products for seronegative recipients, and the use of leukocyte-depleted platelets for patients after bone marrow transplantation.

Herpes Simplex Virus

Epidemiology HSV type 1 (HSV-1) is one of three herpesviruses that affect the esophagus, the others being CMV and varicella-zoster virus (see later). HSV-2 rarely involves the esophagus. After *Candida* species, HSV-1 is the next most frequent agent that causes infectious esophagitis. Although well recognized as an esophageal pathogen in otherwise healthy people, HSV-1 esophagitis has been reported most often in patients with immunosuppression or other predisposing factors. After transplantation, HSV occurs as frequently as CMV as a cause of esophageal disease, [40] whereas in patients with AIDS, HSV esophagitis is relatively uncommon and is much less frequent than CMV infection. [41] In one study of 100 HIV-infected patients with esophageal ulcer, HSV was found in only nine patients, in four of whom it was a co-pathogen with CMV. [41]

Pathology HSV infection is generally limited to squamous mucosa, where the earliest manifestation is a vesicle. As these vesicles enlarge and ulcerate, they may coalesce to form larger lesions. Usually, the intervening mucosa between these lesions is normal. Microscopic examination of the squamous epithelial cells at the edge of the ulcers reveals multinucleation, ground-glass nuclei, and eosinophilic Cowdry type A inclusion bodies that may take up half of the nuclear volume. These inclusion bodies may be surrounded by haloes, and with time, become more basophilic, filling, enlarging, and deforming the nucleus.

Clinical Manifestations and Complications HSV-1 esophageal infection commonly presents with the sudden onset of severe odynophagia, often resulting in an inability to swallow liquids or solids. Herpes labialis (i.e., cold sores) and oropharyngeal ulcers may frequently coexist, antedate, or develop during the esophageal infection, whereas skin infection is rare. [40] In untreated immunocompetent persons, spontaneous resolution of HSV-1 esophageal infection occurs 1 to 2 weeks after the onset of symptoms. Complications are rare and include bleeding, tracheoesophageal fistula, [42] or dissemination. [43]

Diagnosis Esophageal disease caused by HSV-1 usually appears in radiographic studies as focal ulceration on a background of normal mucosa; vesicles are infrequently present (Fig. 61-2). These ulcers have been described as stellate or volcanic in appearance, with less propensity to form the longitudinal or linear lesions that are commonly seen in CMV infection. [44] Severe, diffuse herpetic esophagitis may result in a cobblestone or “shaggy” mucosal appearance resembling *Candida* esophagitis. [44] Although the radiographic appearance may be suggestive, definitive diagnosis of herpetic esophagitis requires endoscopic mucosal biopsies. The endoscopic appearance of herpetic esophagitis reflects the pathological changes (see Table 61-1) appearing as discrete, usually small (<2 cm) well-circumscribed ulcers, [45] diffuse erosive esophagitis, or, rarely, vesicles. Small scattered lesions covered with exudates can mimic esophageal candidiasis. Given the pathophysiological mechanism of disease, deep ulcers, as seen with CMV, are very rare. Cytologic or histological brushings or biopsies should be taken from the edge of an ulcer because the viral cytopathic effect is best identified here, rather than the granulation tissue in the ulcer bed. Immunohistochemistry on biopsy samples using specific monoclonal antibodies to HSV will help to confirm the diagnosis when the viral cytopathic effect is infrequent. Viral culture may also help to establish a definitive diagnosis. As with other causes of infectious esophagitis, serologic tests are unhelpful in establishing the diagnosis.

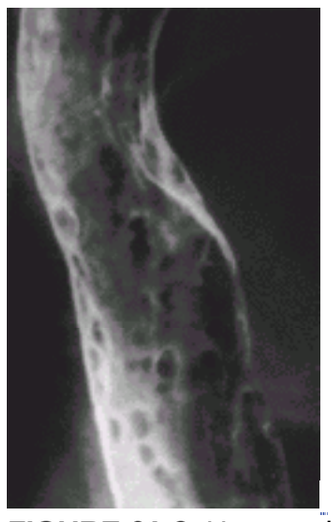

FIGURE 61-2. Herpes simplex virus esophagitis. Multiple vesicles and ulcers are present throughout the esophagus. (Courtesy of Robert Koehler, MD.)

Treatment Uncontrolled trials and vast clinical experience in both immunocompetent and immunodeficient patients suggest efficacy of acyclovir, a nucleoside analog, for the therapy of esophageal disease. In the largest study evaluating 34 patients with AIDS and HSV esophagitis, a clinical response was seen in essentially all treated patients. [46] Although spontaneous resolution of HSV-1 esophagitis is common in the immunologically normal host, because of its safety and efficacy, acyclovir therapy is commonly instituted in all patients regardless of immune status. When oral intake is hampered by severe odynophagia or when there is a question of drug absorption, intravenous administration is required. Side effects of intravenous acyclovir therapy are few and appear limited to irritation of veins used for drug infusion and rash. Although rare, drug resistance should suspected when there is clinical failure of acyclovir; in this setting, foscarnet (see Table 61-3) is the drug of choice and will lead to clinical cure in most patients. [47] Acyclovir is effective prophylaxis for HSV-antibody positive patients undergoing transplantation. Long-term secondary prophylaxis may be required when immunodeficiency persists because the relapse rate is high. More recently, valacyclovir, a prodrug of acyclovir, and famciclovir were released. Large studies of valacyclovir use in patients with genital HSV disease have shown equivalency to acyclovir and, as with acyclovir, minimal toxicity. [48] The advantage of this agent is that it can be administered three times per day, and the cost is equivalent to that of acyclovir.

Cytomegalovirus

Epidemiology Over the last several decades, CMV has become one of the most common opportunistic infections. Serologic studies from developed countries have shown seropositivity rates of 50% or greater; studies of homosexual men have found seropositivity up to 90% reflecting sexual transmission of the virus. [49] In transplant recipients who receive no antiviral prophylaxis, CMV and HSV are equally common esophageal pathogens. [40] In contrast, CMV is the most frequent cause of esophageal ulcer in patients with AIDS. [41]

Pathology The most prominent histological feature of CMV esophagitis is mucosal ulceration (see Table 61-1). Although there is variability, deep ulcers are very characteristic of disease in AIDS, whereas in immunosuppressed transplant recipients, lesions tend to remain more superficial. In contrast to HSV, the viral cytopathic effect of CMV is present in endothelial and mesenchymal cells in the granulation tissue of the ulcer base and not in the squamous epithelium. Inclusions are large (*cytomegalo*) and often have an eosinophilic appearance that may be present in the nucleus and cytoplasm (Fig. 61-3A; see also Color Fig. 61-3.). Because these inclusions may be atypical in appearance in patients with AIDS, [50] immunohistochemical stains are useful in confirming the presence of CMV and often highlight more infected cells than can be appreciated on routine hematoxylin and eosin staining. As with other esophageal infections, CMV may coexist with HSV or *Candida,* especially in patients with AIDS. [10] Whereas HSV leads to disease by a direct cytopathic effect on squamous epithelium, the pathogenesis of disease caused by CMV is not well understood. It has been speculated that CMV mucosal disease is the result of ischemia caused by endothelial cell involvement. More recently, inflammatory cytokines, such as tumor necrosis factor-a, have been suggested as playing an etiologic role. [51]

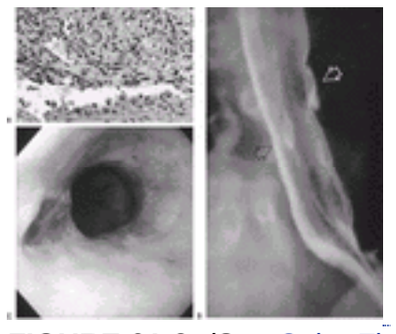

FIGURE 61-3. (See Color Fig. 61-3.) Cytomegalovirus esophagitis. (**A**) Biopsies from an ulcer base demonstrate granulation tissue with one large cell with intranuclear and intracytoplasmic inclusions diagnostic for cytomegalovirus. (**B**) Barium swallow demonstrates two well-circumscribed ulcers in the distal esophagus (*arrows*). (**C**) Endoscopic photograph shows the two ulcers, which are well circumscribed and have some depth, and the surrounding mucosa is normal.

Clinical Manifestations and Complications In contrast to HSV esophagitis, CMV esophagitis has very rarely been documented in immunocompetent persons. [52] Odynophagia is almost uniformly present and is typically severe (see Table 61-2). A prior or coexistent diagnosis of CMV infection in another organs (e.g., retinitis or colitis) is not infrequent. Although rare in transplant recipients, retinitis may be observed in approximately 15% of patients with AIDS at the time of diagnosis of gastrointestinal disease. [53] Complications include gastrointestinal bleeding (~5% of patients) and, rarely, strictures [54] or fistulae to the tracheobronchial tree. [55]

Diagnosis As with HSV-1, the radiologic appearance of CMV esophagitis is that of either focal or extensive ulceration. The radiographic characteristics of the ulcer depend in large part on the epidemiologic setting. Barium esophagraphy of CMV esophagitis may reveal thickening of mucosal folds or more typically ulcers; these ulcers may be vertical, linear with central umbilication, solitary, and deep, or occasionally they may manifest as diffuse superficial ulceration (see Fig. 61-3B). [44] In patients with AIDS, these ulcers are often large and deep and may exceed 2 cm in size. Rarely, the exuberant inflammatory response mimics a malignant disease. [56] The endoscopic appearance of CMV esophagitis is variable, ranging from multiple shallow ulcers, solitary giant ulcers, to diffuse superficial esophagitis (see Fig. 61-3C; see also Color Fig. 61-3). [57] Given the high rate of prior exposure to CMV, serologic testing is not helpful. In addition, some immunosuppressed transplant recipients fail to develop a brisk antibody response. Currently, identification of viral cytopathic effect in mucosal biopsies is the best diagnostic method. Multiple biopsies (up to ten) may be required to establish the diagnosis in patients with AIDS and should be taken from the ulcer base because the viral cytopathic effect is found here. [58] Viral culture of mucosal biopsies is less sensitive and specific than histology. [59] The identification of an isolated inclusion found by immunohistochemical staining should not be considered CMV disease but rather infection, and other causes of mucosal disease should be sought. [60] In contrast to *Candida* and HSV infections, cytologic specimens from esophageal lesion have very poor sensitivity. Because retinitis may coexist with gastrointestinal disease, and, when present, alters the duration of antiviral therapy, a diagnosis of CMV gastrointestinal disease in any patient with AIDS warrants ophthalmologic examination.

Treatment The therapies available for the treatment of CMV disease require intravenous administration and include ganciclovir, foscarnet, and, more recently, cidofovir. The most widely used therapy, ganciclovir, is an acyclovir derivative. A large prospective open-label trial of ganciclovir in 35 patients with AIDS documented clinical and endoscopic improvement in 77%. [53] The time course of the clinical response to ganciclovir is variable; a week of therapy may be required before there is symptomatic improvement. The total treatment duration should be based on the clinical and endoscopic response, and a 2- to 4-week treatment course is usually adequate. If retinitis is absent and there has been a complete response, the patient may be followed closely without maintenance therapy. Because of low bioavailability (<10%), oral ganciclovir is not effective for the treatment of active infections including those of the gastrointestinal tract. [61] After acute CMV disease in transplant recipients, treatment with ganciclovir should be given for approximately 1 to 2 months until the immunosuppressive regimen is either discontinued (bone marrow transplant) or significantly reduced (solid organ transplant). Ganciclovir is well tolerated, with its major side effect being myelosuppression, which may be severe when other bone marrow suppressive drugs, such as zidovudine (formerly known as azidothymidine or AZT), are coadministered. Clinical and virologic resistance has been documented, usually in patients receiving prolonged therapy. In this setting, foscarnet is often effective. [62] Ganciclovir has been used in conjunction with foscarnet to treat refractory disease or when side effects are limiting, because lower doses may be employed. [63] Foscarnet is a pyrophosphate analog that inhibits viral DNA polymerase and reverse transcriptase. A randomized trial comparing ganciclovir with foscarnet for patients with AIDS and gastrointestinal disease found clinical improvement in more than 80%, and there was no significant difference in efficacy between the two agents. [64] There are fewer data on its use in immunosuppressed patients who do not have AIDS. Foscarnet has been most frequently used when there is clinical resistance or intolerance to ganciclovir. The major side effect of foscarnet is reversible renal insufficiency. [65] This may be prevented by vigorous saline hydration before and during drug administration in combination

with dose adjustments based on creatinine clearance. Electrolyte disturbances, which include hypocalcemia and hypophosphatemia, are also common during or shortly after infusion, and slowing the rate of infusion may alleviate the mild cramps induces by these electrolyte shifts. All drugs for herpesviruses only inhibit viral replication; thus, relapse is frequent when therapy is discontinued. The relapse rate for transplant recipients also remains high until immunosuppressive therapy is reduced. Cidofovir is the newest systemic agent available for the therapy of CMV, but it has undergone evaluation only for the treatment of retinitis in AIDS. [66] Because of its long half-life, once-weekly administration is adequate. Like foscarnet, this drug is associated with renal insufficiency. In patients with AIDS, the relapse rate of CMV esophagitis is approximately 50% and is similar for HSV. [46], [53], [64] Initiation of HAART, when associated with significant improvement in CD4 count, may abrogate the need for long-term maintenance therapy. [67]

Prophylaxis High-dose acyclovir has been used with moderate success for the prophylaxis of CMV infection in transplant recipients, although ganciclovir has been shown to be superior. [68] Because of its cost, potential side effects, and intravenous route of administration, at many transplant centers, ganciclovir prophylaxis is limited to high-risk patients including CMV-seropositive patients, CMV-seronegative transplant recipients who receive CMV-seropositive organs or blood products, and patients receiving potent immunosuppression for episodes of transplant rejection. Oral ganciclovir is effective prophylaxis for CMV retinitis in patients with AIDS and a CD4 lymphocyte count less than 200/mm [3] but is untested for either primary or secondary prophylaxis of gastrointestinal CMV disease. There are also no data regarding the efficacy of oral ganciclovir prophylaxis in high-risk transplant recipients. Fortunately, despite long-term administration, resistance of CMV to ganciclovir and foscarnet is uncommon.

Other Viruses

The frequency of esophageal involvement caused by varicella-zoster during the course of chickenpox or herpes zoster infections is unknown but clinically uncommon. [69] Papillomavirus may infect the esophagus and may cause small polypoid lesions. [70] Esophageal ulcers have been reportedly caused by papovavirus and Epstein-Barr virus in patients with AIDS. [71], [72]

MYCOBACTERIAL INFECTIONS

Epidemiology

Mycobacterial involvement of the esophagus is very rare, even in immunosuppressed patients. Previously, tuberculous involvement of the esophagus was considered a rare autopsy finding seen in less than 0.15% of necropsies. [73] In developing countries, the rate of tuberculosis (TB) is much higher, and extrapulmonary manifestations, including esophageal disease, are more common. The combination of the AIDS epidemic with the upsurge in reported cases of systemic TB have increased the incidence of esophageal infection in developed countries. *Mycobacterium avium* complex (MAC) remains primarily a small bowel pathogen with only rare cases of esophageal involvement reported. [74], [75]

Pathology

Most commonly, TB affects the middle third of the esophagus at the level of the carina. Esophageal disease is caused by spread of infection from tuberculous-infected mediastinal lymph nodes by way of a draining fistula or obstructed lymphatics, often resulting in tracheoesophageal fistula. TB can also involve the upper third of the esophagus by direct extension from tuberculous pharyngitis or laryngitis. Primary esophageal TB in the absence of extraesophageal disease is exceedingly rare. [76] Granulomata are often present in ulcer tissue, with bacilli identifiable by mycobacterial staining.

Clinical Manifestations and Complications

The symptoms of esophageal TB depend on the degree and type of involvement. Pulmonary complaints often predominate because of the common occurrence of fistula to the trachea, bronchus, or pleural space. Rarely, formation of long strictures or traction diverticula resulting from the fibrotic response causes dysphagia. Upper gastrointestinal hemorrhage from tuberculous esophageal ulcers [77] and tuberculous arterioesophageal fistulae [78] has been reported.

Diagnosis

Esophageal TB should be suspected in patients with pulmonary or systemic TB who develop esophageal symptoms. Barium esophagram findings, including ulceration and stricture, are nonspecific. A sinus tract or fistulous connection to the bronchial tree or mediastinum is highly suggestive of TB but can also be seen with malignant disease or other infections; in this setting, the diagnosis may often be made by sputum staining and culture. [73], [75] An ulcerated tuberculous granulomatous mass may suggest an esophageal neoplasm on barium esophagraphy. [79] Although the gross appearance of ulcers or strictures is not diagnostic of TB, endoscopic biopsies from the edge of the lesions may reveal granulomata or acid-fast bacilli, and biopsy material may be cultured for further confirmation of the diagnosis and determination of sensitivities to antimycobacterial agents.

Treatment

Regardless of the presence of immunodeficiency, a 9-month course of multidrug therapy (in the absence of drug resistance) will cure esophageal TB and will often close fistulae. If fistulae do not close with medical therapy, surgical intervention will be required. The prevalence of multidrug-resistant TB is becoming an increasingly complex problem; thus, drug sensitivities to antituberculous therapy are essential to guide therapy. The most effective agents for the treatment of MAC are clarithromycin and ethambutol. [80] Although a clinical and bacteriologic response is common, long-term therapy for MAC is required in AIDS unless HAART is effective. [81]

BACTERIAL INFECTIONS

Epidemiology

Bacterial esophagitis is a rare cause of esophageal disease in immunocompromised patients. It has been described almost exclusively in patients with hematologic malignant disease complicated by severe granulocytopenia and occasionally after bone marrow transplantation and diabetic ketoacidosis. [82], [83], [84] and [85] For the most part, the infecting pathogens are oral flora, particularly gram-positive organisms, including viridans streptococci, staphylococci, and other bacilli. It is likely that these pathogens colonize and then invade mucosa damaged by reflux disease, radiation, or chemotherapy leading to local infection; dissemination may occur when granulocyte function is poor or there is absolute granulocytopenia. Reports in patients with AIDS have broadened the etiologic spectrum to include *Bartonella henselae,* the cause of catscratch disease, [86] actinomycoses, [87], [88] and *Nocardia*. [89]

Pathology

The gross pathological appearance of the esophagus in bacterial infection ranges from normal mucosa (colonization) to ulcers associated with erythema, plaques, pseudomembranes, or hemorrhage. [82] Microscopic examination reveals pseudomembranes and bacterial invasion that may be superficial and invade only the squamous epithelium or may be invasive and transmural with infiltration of blood vessels (i.e., phlegmonous esophagitis). Actinomycosis is characterized by ulcerative esophagitis and drainage of sulfur granules from sinuses leading from abscess cavities or with sulfur granules and filamentous gram-positive branching bacteria seen on tissue biopsies. [87] *Nocardia* has been reported to cause esophageal ulcer in AIDS. [89] *Bartonella henselae* esophagitis causes multiple nodules of the esophagus resulting from a lobulated proliferation of capillary vessels lined by plump endothelial cells. [86]

Clinical Manifestations and Complications

Bacterial esophagitis is usually found in a neutropenic patient with esophageal complaints who has undergone chemotherapy for a hematogenous malignant disease. Esophageal infection may serve as a focus for bacteremia and seeding of other organs. [82] No unique complications have been reported.

Diagnosis

The diagnosis of bacterial esophagitis should be considered in the clinical setting described earlier. Radiographic findings are nonspecific, and endoscopic biopsy and culture are required to establish this diagnosis. Additional stains including Gram stain are required to identify the etiologic bacteria. Positive blood cultures also pinpoint the bacterial pathogens and direct antimicrobial therapy.

Treatment

Broad-spectrum antibiotics that effectively treat both gram-positive and gram-negative oropharyngeal flora are required for treatment. Treatment of other bacterial infection found in these patients is similar to treatment of disease in other locations.

Treponema pallidum

Although esophageal involvement by *Treponema pallidum* was well recognized many years ago, this disease is now only of historical interest. Tertiary syphilis of the esophagus may present as a submucosal gumma or diffuse inflammatory reaction with fibrosis that often affects the upper third of the esophagus, and it may be associated with mucosal ulcers and structures. [90] Given the rarity of esophageal syphilis, most patients with infectious esophagitis and positive serologic tests for syphilis have another cause of esophagitis.

PROTOZOAL INFECTIONS

In developed countries, protozoal infections of the esophagus are very rare, occurring almost exclusively in patients with AIDS. In these patients, pathogens include *Pneumocystis carinii,* [91] *Cryptosporidium parvum,* [92] *Leishmania donovani,* [93] and *Trichomonas.* [94] In immunologically normal hosts from endemic areas in South America, *Trypanosoma cruzi* may involve the myenteric plexus of the esophagus resulting in Chagas disease. This disease is indistinguishable clinically, radiographically, endoscopically, and manometrically from idiopathic achalasia. The diagnosis may be established by antibody testing.

SPECIFIC HIV-RELATED ESOPHAGEAL DISORDERS

In addition to the infections described earlier, certain unique disorders cause esophageal disease in these patients.

Disorders Associated with Primary HIV Infection

Although primary HIV infection is largely asymptomatic, in some patients, a mononucleosis-like illness occurs around the time of infection consisting of fever, sore throat, and myalgias associated with a maculopapular rash. [95] Spontaneously resolving oropharyngeal and esophageal ulceration or candidal infection may also be observed during this seroconversion illness. [96], [97] Endoscopically, these esophageal ulcerations are multiple, small, and shallow. [96] In some of these patients, electron microscopic examination of biopsy specimens revealed enveloped viruslike particles with morphologic features compatible with retroviruses. [96] The diagnosis can be established at the time of presentation by the detection of HIV RNA in serum. [95] Antibody positivity to HIV occurs within 3 to 18 months after the illness.

Idiopathic Esophageal Ulcer

Epidemiology Early in the AIDS epidemic, large esophageal ulcerations were recognized in which no specific cause could be identified despite extensive histopathological examination of ulcer tissue. These ulcers are now termed *idiopathic esophageal ulcers* (IEU) or aphthous ulcers. These ulcers are very common and were found in 41% of HIV-infected patients with esophageal ulcer in a large prospective study. [41] They are seen in the later stages of immunodeficiency when the CD4 lymphocyte count is less than 100/mm [3]. [41]

Pathology These ulcers are variable in size, may be large, and are uniformly well circumscribed; diffuse superficial esophagitis has not been described. [98] Ulcer tissue resembles that seen in CMV and HSV infection, except viral cytopathic effect is absent. The presence of a superficial candidal infection overlying a large well-circumscribed lesion with histopathological findings of granulation tissue without viral cytopathic effect should still lead to the diagnosis of IEU. [10] Although HIV has been suggested as the direct cause of these lesions, there is little histopathological evidence to support a direct cytopathic role for HIV. [99], [100]

Clinical Manifestations and Complications IEU presents in a fashion indistinguishable from CMV esophagitis. Coexistent oropharyngeal aphthous ulcers are infrequent, [13] whereas thrush is common, especially if the patient has not been given empiric antifungal therapy. Complications include bleeding and fistula to the stomach but not to the tracheobronchial tree, [101] and strictures. [54]

Diagnosis The findings of IEU on barium esophagram are typically large, well-circumscribed, and often deep ulcers. [102] Because of the similarity to CMV infection, a definitive diagnosis cannot be based on the radiographic appearance alone. Because IEU is a diagnosis of exclusion, endoscopy and biopsy are the only definitive diagnostic tests. These ulcers are variable in size and appearance, and larger ulcers are endoscopically indistinguishable from CMV infection. [98] Distal esophageal ulcer may suggest gastroesophageal reflux disease; the histopathological features alone also cannot distinguish IEU from gastroesophageal reflux disease. Pill-induced esophagitis must be excluded by history because the pathological findings of esophageal biopsies are similar. These ulcers respond rapidly to either prednisone or thalidomide, with clinical and endoscopic cure seen in more than 90%. [103], [104]

Neoplasms Associated with AIDS

Kaposi Sarcoma With the advent of HAART, Kaposi sarcoma (KS) has been decreasing in frequency. Gastrointestinal KS is common in those with cutaneous disease. [105] Clinical experience suggests that gastric or duodenal involvement is more common than esophageal disease, and esophageal lesions, like other areas of the gastrointestinal tract, are most frequently an incidental finding. Findings on barium esophagram of KS have not been clearly characterized are well-circumscribed submucosal lesions that may ulcerate. [106] Small lesions are easily missed on barium studies. The endoscopic features of esophageal KS are characteristic and resemble their cutaneous appearance: violaceous macular or plaquelike lesions. These tumors typically involve the submucosa; therefore, mucosal biopsy must sample deeper tissue. Bleeding may occur when the tumor becomes large and ulcerated. Effective relatively nontoxic chemotherapy includes Doxil, a liposomal form of doxorubicin (Adriamycin). HAART therapy alone has been associated with lesion regression. Radiation therapy is effective to treat local lesions of the head and neck including the oropharynx.

Non-Hodgkin Lymphoma Unlike with other opportunistic processes, the advent of HAART has not altered the incidence of lymphoma in AIDS. Although gastrointestinal involvement is common, esophageal disease remains rare. Extraesophageal disease is common at the time of diagnosis. [107] In two studies comprising 23 patients with AIDS and gastrointestinal lymphoma, only 2 patients had esophageal involvement. [107], [108] The lesions appear radiographically as large ulcers or mass lesions typical of any carcinoma. [109] The endoscopic appearance of these lesions has been described as an ulcerated polypoid mass, often with a central ulceration, a submucosal lesion or extensive disease resulting in lumenal narrowing resembling an adenocarcinoma, [110] or a solitary ulcer. [111] Complications are rare and include bleeding. [109] Multidrug chemotherapeutic regimens are usually given for non-Hodgkin lymphoma in AIDS, and complete remission may be realized in approximately 50% of patients. Complications are frequent because of chemotherapy-induced neutropenia. The median survival in most series of AIDS-associated non-Hodgkin lymphoma is less than 8 months. Radiation therapy may be a potential option when the disease is localized.

Miscellaneous Neoplasms Despite the profound immunodeficiency seen in these patients, there does not appear to be an increase in the incidence of other esophageal neoplasms including squamous cell cancer and adenocarcinoma. Adenocarcinoma of the esophagus associated with Barrett esophagus has been reported in an HIV-infected patient. [112] Squamous cell esophageal carcinoma is uncommon in HIV-infected patients, and it has been reported in two patients with AIDS, [113] probably because of the relative young age of these patients.

ESOPHAGEAL NEOPLASMS

SQUAMOUS CELL CARCINOMA

Epidemiology and Etiology

Esophageal *squamous cell carcinoma* (SCC) is the most common form of esophageal malignancy worldwide and is one of the leading causes of cancer mortality in men, especially African American men. The incidence of esophageal SCC varies according to geographic location, with a global range from 2.5 to 5.0 for men and 1.5 to 2.5 for women for 100,000 population. High-incidence regions, where rates may exceed 100 per 100,000 population, include northern China, India, northern Iran, areas north and east of the Caspian Sea, and the Transkei area of South Africa. [1], [2], [3], [4] and [5] Indeed, nearly 50% of all cancers are esophageal in southeastern South Africa. [1] In the United States, African Americans have a four- to fivefold increased risk compared whites, especially African American men, in whom the risk is 15.1 per 100,000 compared with 2.9 per 100,000 in white men. [6], [7]

The geographic variation in esophageal SCC strongly hints at the contribution of environmental factors, although its genetic basis is now being elucidated. Genetic predisposition to esophageal SCC is rare. The incidence of esophageal SCC is very low in persons less than 40 years of age, but it increases with each succeeding decade of life. [7] It is more common in men than in women, a two to three times increased risk, regardless of ethnicity and age. [7] However, there are some exceptions to this general finding. In northern Iran, the rate is 263 per 100,000 for women and 206 per 100,000 for men, [8] and upper esophageal cancers in association with the Plummer-Vinson syndrome are found in women.

Tobacco and Alcohol Together, tobacco and alcohol constitute the largest risk factors for the development of esophageal SCC in North America and Western Europe. [9], [10], [11] and [12] Because tobacco and alcohol are commonly consumed together, their individual contribution may be difficult to ascertain. However, a comprehensive study of alcohol consumption in nonsmokers and tobacco use in nondrinkers found that each acts independently as risk factors. [13] The relative risk was 2.0 for those who smoked fewer than 15 cigarettes per day, and 6.2 for patients who smoked more than 25 cigarettes per day. [13] Not surprisingly, there is a documented substantial increase in risk with patients who consume both tobacco and alcohol, with the amount and duration of use being pivotal factors. [14], [15], [16], [17] and [18] Thus, smokers who have a large intake of beer and whiskey harbor a ten- to 25-fold increased risk in esophageal SCC compared with smokers who do not drink alcohol. [18], [19] Additionally, the risk may be greater for pipe and cigar smokers than for cigarette smokers. [18] In a manner reminiscent of lung cancer, cessation of smoking does lead to a decreased risk of esophageal SCC after 10 years. [18], [20], [21] Although cigarette smoking is a key risk factor in North America and Western Europe, chewing tobacco, betel, or combinations of these with lime accounts for the high incidence of esophageal SCC in southern and Southeast Asia. [22], [23] and [24] Tobacco tars and cigarette smoke contain various chemical carcinogens, such as aromatic amines, lactones, peroxy compounds, halo ethers, *N*-nitroso compounds, polycyclic aromatic hydrocarbons, and peroxy compounds, [25], [26], [27] and [28] that individually or in combination likely lead to esophageal epithelial hyperproliferation and eventual malignant transformation. The type of alcohol (beer, whiskey) and the fashion in which it is distilled, but not the duration of ingestion, are risk factors for esophageal cancer. Groups of people who do not consume alcohol have a substantially decreased risk. There are several reasons underlying alcohol's contribution to the pathogenesis of esophageal cancer, as well as other cancers. [29] Alcohol may contain congeners or other ingredients, such as *N*-nitroso compounds, urethane, mycotoxins, tannins, pesticide residues, and asbestos products that are directly or indirectly carcinogenic. Ethanol itself, because it is a solvent for fat-soluble compounds, may facilitate the absorption of other carcinogens. Carcinogens that are oxidants may increase the risk of DNA damage. Acetaldehyde, a metabolite of

ethanol, can inhibit DNA methyltransferase activity. [30] Consequently, a state of methyl deficiency may ensue that may potentiate the carcinogenic effect of a methyl-deficient diet.

Diet and Nutrition Vitamins and deficiencies, especially of vitamins A and C, folic acid, vitamins E and B_{12}, and riboflavin, are crucial as risk factors. [31], [32], [33], [34] and [35] Diets containing high amounts of green and yellow vegetables that are rich in ß-carotene and citrus fruits that are high in vitamin C decrease the incidence of esophageal SCC. [35] Lower plasma levels of folic acid have been documented in patients with esophageal SCC. [33] Riboflavin deficiency manifested by cheilosis and glossitis is common in the Linxian Province of China, where esophageal cancer is endemic. [36] It is likely that vitamins A, C, and E exert antioxidant effects; the latter two vitamins are known to influence the formation of nitrosamines. The levels of certain trace elements, such as selenium, molybdenum, and zinc, show an inverse association with mortality from esophageal cancer in high-incidence areas in the world. [37], [38] and [39] Furthermore, in animal models, a significant increase in esophageal tumors is induced by *N*-nitrosomethylbenzylamine (NMBA) in rats with zinc-deficient diets. Mechanistically, zinc deficiency enhances the microsomal activation of NMBA to a methylating agent that yields *O*-6-methylguanine adduct in esophageal DNA. [40] As a component of superoxide dismutase, zinc also protects against oxygen-derived radical damage and free-radical formation. [33] Similarly, selenium has protective effects, in part mediated through inhibition of lipid peroxidation of cell membranes through the action of glutathione peroxidase, which is dependent on selenium. [32] The Linxian and adjoining provinces in China have foodstuffs low in molybdenum and documented reduced levels of this trace element in patients' serum and urine. It is conceivable that molybdenum deficiency leads to the accumulation of nitrates that are precursors of nitrosamines because this trace element is a key constituent of nitrate reductase. [24]

Achalasia Patients with long-standing achalasia have a prevalence of esophageal SCC of 5%. [41], [42], [43], [44], [45] and [46] The interval from dysphagia, weight loss, and chest pain ascribable to achalasia to the development of cancer is approximately 17 to 20 years. [46], [47] In a study of 195 consecutive patients with achalasia, the incidence of esophageal SCC was 3.4 per 1000 patients per year, representing a 33-fold increase when compared with age- and sex-matched controls. [48] A follow-up study of 146 of 147 patients with achalasia treated with myotomy revealed that 10 patients progressed to esophageal cancer, with a mean interval of 16.7 years; the predicted frequency was less than 1. [49] Thus, the condition of achalasia eventually may lead to cancer; however, the exact risk and mechanism remain to be determined. Although endoscopic surveillance of patients with achalasia has been advocated, the frequency of examinations remains the subject of debate.

Head and Neck Squamous Cell Carcinoma Reflecting use of both alcohol and tobacco, patients with head and neck SCC are at an increased risk of developing esophageal cancer. [50], [51] Either coexisting or sequential esophageal cancers may develop annually at a rate of 3% to 7%. [52], [53], [54] and [55] As a result, endoscopic surveillance of the esophagus has been advocated in this setting. Toluidine blue staining has been demonstrated to enhance the detection of indolent esophageal cancers in patients with head and neck cancers. [56] Not surprisingly, survival of patients with head and neck cancer is adversely affected by the coexistence of esophageal cancer. [57] A reduction in second primary tumors from 24% to 4% in patients with head and neck cancers has been observed with the use of isotretinoin, a chemopreventive agent that induces epithelial differentiation. [58]

Tylosis Although some studies from China have suggested familial aggregation of esophageal cancers, [59] it is difficult to discriminate between a common environmental exposure and an actual genetic basis for these observations. However, a genetic predisposition to esophageal cancer is clear in tylosis palmaris, an autosomal dominant disorder manifested by hyperkeratosis of palms and soles. [60], [61], [62], [63], [64], [65] and [66] Approximately 50% of patients with tylosis palmaris will develop esophageal cancer by the age of 45 years, and perhaps 95% by age 65 years. [61], [62] There is linkage between esophageal SCC and oropharyngeal leukoplakia. In endoscopic surveillance studies over a 5-year period, 4 of 29 patients were found to have dysplasia, and 1 patient had carcinoma in situ. [67] The gene responsible for tylosis has yet to be identified, but once achieved, it may provide insights into sporadic esophageal cancer as well.

Other Factors Lye ingestion, which results in stricture formation, has been postulated as a risk factor for esophageal cancer, mostly appearing at level of the bronchial bifurcation. [68], [69] and [70] Lye strictures constitute only a small proportion of esophageal cancer cases, and the progression to cancer after initial exposure requires 4 to 5 decades. Other factors implicated in the pathogenesis of esophageal cancer include ionizing radiation, [71], [72] celiac sprue, [73], [74] and [75] human papillomavirus (HPV), [76], [77] and [78] Plummer-Vinson syndrome, [79] esophageal diverticula, [80] and maté drinking. [81], [82] Experimentally, induction of radiation injury is associated with cancer formation. [83] In patients who have undergone high-dose radiation treatments, esophageal cancer is the most frequently observed malignant disease. [84], [85], [86], [87], [88], [89] and [90] DNA tumor viruses that have a tropism for squamous epithelial cells, such as HPV and Epstein-Barr virus, have been associated with esophageal SCC. Polymerase chain reaction techniques have demonstrated an association of the oncogenic variants of HPV, namely HPV-16 and HPV-18, as well as a novel HPV genotype with esophageal SCC. [77], [78] The same has been observed with Epstein-Barr virus. [91] Both viruses infect squamous epithelial cells, replicate, and produce oncogenic proteins that contribute to hyperproliferation and malignant transformation. Hot maté drinking is common in Uruguay and southern Brazil, [81], [82] and hot liquid ingestion is prevalent in China. [92] These findings suggest that thermal injury of the mucosa may increase the risk of esophageal cancer.

Biology and Genetics

Based on the colon cancer paradigm, it is thought that the development of cancer results from the accumulation of alterations in oncogenes, tumor suppressor genes, and DNA mismatch repair genes. This is probably true for esophageal cancer as well. However, a genetic basis for the pathogenesis of esophageal cancer by no means precludes the importance of environmental factors; rather, more than likely, there is cooperativity among these factors. For example, some of the environmental factors injure the esophageal epithelium, which, in turn, may act to signal changes in key genes through point mutations or augmented gene expression.

Perhaps the most critical oncogene in esophageal SCC pathogenesis is cyclin D_1. Mammalian cyclins represent a large family of cell cycle regulatory proteins that associate, in turn, with their catalytic subunit partners, designated cyclin-dependent kinases or CDK. (The cell cycle is reviewed in the literature. [93]) The activity of cyclin D_1 is restricted to the G_1 phase, and it preferentially associates with cyclin-dependent kinase 4 or 6 (CDK4 or CDK6). The complex of cyclin D_1 and CDK4 or CDK6 then phosphorylates the retinoblastoma tumor suppressor gene product (pRb). This relieves the negative regulation of pRb on the G_1 phase through release of key transcriptional factors, such as E_2F. It has been shown that cyclin D_1 is overexpressed in more than 50% of esophageal SCCs and is associated with a poor prognosis. [94], [95] and [96] A subset of esophageal cancers also show c- *myc* and epidermal growth factor receptor overexpression as a result of gene amplification. [97], [98] Knowledge of the association of cyclin D_1 and esophageal cancer has been used to develop a transgenic mouse model in which one of the Epstein-Barr virus promoters has been used to target cyclin D_1 specifically to the oral-esophageal squamous epithelia, resulting in dysplasia and cell cycle abnormalities. [99], [100]

The key tumor suppressor gene *p53* has many functions, including cell cycle regulation, response to environmental insults to induce apoptosis, transcriptional regulation of genes, and DNA replication. *p53* is mutated in up to 70% of esophageal cancers. [101], [102], [103] and [104] One of the functional consequences of *p53* mutation is the transcriptional downregulation of *p21,* a general CDK inhibitor. In addition, *p16,* also referred to as *INK4a* (designated $p16^{INK4a}$), is an inhibitor of CDK4. Located on chromosome 9p22-23, *p16* can be deleted, mutated, or hypermethylated, resulting in loss of its inhibitory function in esophageal cancer. [105], [106] A paradigm that emerges in esophageal SCC is that either cyclin D_1 is overexpressed or *p16* is altered to accelerate the cell through the G_1 phase. Loss of heterozygosity in other tumor suppressor gene loci, such as pRb (chromosome 11) and APC (Adenomatous Polyposis Coli) (chromosome 5q), does not appear to occur in esophageal cancer, [107], [108] suggesting that other genes in proximity to pRb and APC are the key targets.

Clinical Manifestations

Early esophageal SCC may be asymptomatic or may be associated with only mild specific symptoms. [109], [110], [111], [112] and [113] As the cancer grows, dysphagia occurs in nearly 90% and odynophagia in 50% of patients. [114], [115] and [116] This is usually a reflection of partial or total lumenal obstruction. Anorexia and weight loss from malnourishment may be observed in about 75% of patients. [116], [117] Retrosternal pain or radiation of pain to the back suggests mediastinal involvement by the cancer. Nausea, vomiting, and hematemesis may occur. Cough may reflect aspiration pneumonia or, rarely, tracheoesophageal fistula. Recurrent laryngeal nerve involvement may result in hoarseness. Skeletal metastases may cause bone pain. Physical examination may reveal cachexia, lymphadenopathy, hepatomegaly (if distant metastatic disease is present), and the presence of fecal occult blood.

Evaluation of dysphagia is imperative and is discussed in Chapter 31. The differential diagnosis may include peptic acid esophagitis with stricture, caustic ingestion resulting in stricture, malignant disease (either squamous or adenocarcinoma), and motility disorders such as achalasia or scleroderma.

Natural History and Complications

Esophageal cancer in Western countries usually presents in an advanced stage, and consequently, nearly 75% of untreated patients succumb to the disease within 1 year. [118] Biologically, esophageal SCC is not a rapidly growing tumor, and there is a prolonged period of time between dysplasia and cancer. [119], [120] Early stages of esophageal cancer have been shown to persist for more than 2 decades in China and Iran. [121], [122] Additionally, balloon cytologic examinations, used to monitor the

natural history of esophageal squamous dysplasia in China, indicate that dysplasia may progress to cancer (26.6% of cases), but it may regress to mild dysplasia or a normal state (40.5% of cases). Furthermore, of the mild dysplastic cases, nearly 15% progressed to severe dysplasia and about 45% regressed. [123] Other studies in China indicate that early superficial cancers remain in this state in 58% of cases for a follow-up period of 19 to 78 months. [120] Patients with untreated early esophageal cancer in China have a median survival time of 75 months.

There are probably biologic differences superimposed on environmental factors in the high-incidence areas versus Western countries that may account for the apparently lengthy period from dysplasia to cancer in China and the good prognosis of resected early esophageal cancer with a 5-year survival approaching 90%. [112] Reminiscent of the high prevalence of early gastric cancer in Japan relative to Western countries, it is not entirely clear whether early esophageal cancer is prevalent in North America and Western Europe. Several nonbiologic explanations could be evoked: use and accuracy of balloon cytology in China, definition of early esophageal cancer, and proper staging with aggressive therapy. [124], [125]

The average survival of untreated patients with advanced, symptomatic cancer is approximately 9.5 months. [118], [122] Patients may develop aspiration pneumonia complications of esophageal cancer from extension into the tracheobronchial tree or other mediastinal structures. [126] Fistulae have a 4.5% prevalence and most often communicate with the trachea, the main stem bronchi, and the lung parenchyma. Fistulae carry a poor prognosis. [127], [128] The fistula may cause presenting symptoms, such as cough, chest pain, dyspnea, hoarseness, and hemoptysis, or it may occur within 2 months of initial diagnosis in untreated patients. [127], [129] As a result of fistula formation, patients may develop pneumonia and sepsis. Direct extension, as opposed to fistula formation, of the esophageal cancer may involve the lung and tracheobronchial tree, aorta, pericardium, and upper abdomen. Hoarseness suggests recurrent laryngeal nerve involvement. Apart from direct extension or fistula formation, esophageal cancer may metastasize to lymph nodes, lung, and liver as frequent sites. [130], [131], [132], [133] and [134]

Diagnostic Evaluation

Implicit in a diagnostic evaluation is a complete history and physical examination. A laboratory profile may reveal anemia, hypoalbuminemia, elevated prothrombin time reflecting vitamin K deficiency, and possibly elevated liver function tests if metastatic disease is present. Serologic markers of cancer, such as carbohydrate antigen 72.4 in gastric cancer, carbohydrate antigen 19-9 in pancreatic cancer, carcinoembryonic antigen in colorectal cancer, and a-fetoprotein in hepatocellular carcinoma, have not proven to be of high sensitivity and specificity in esophageal cancer. Evaluation is driven by establishment of tissue diagnosis through biopsy and cytology, followed by staging for prognosis and therapeutic planning. Initial diagnostic tests usually entail barium swallow supplemented with a tablet and flexible fiberoptic endoscopy. Staging requires computed tomographic (CT) scan, endoscopic ultrasound (EUS), and radionuclide bone scan. Bronchoscopy should be considered if tracheal invasion is suspected.

Fiberoptic Flexible Endoscopy and Barium Esophagography The diagnosis of esophageal cancer requires endoscopy with biopsy and cytology. Multiple biopsies increase the diagnostic yield up to 96%; cytology identifies the remaining cases. For example, in a retrospective study of 155 patients with endoscopic biopsy and cytology of upper gastrointestinal lesions, 2 of 28 patients with malignant disease had the diagnosis through cytology alone. [135] Because endoscopy may prove too costly in some regions of the world, barium esophagrams are advocated by some experts, especially in patients with dysphagia. Intrinsic advantages include reduction in cost, noninvasiveness, and reduced complication rate. Additionally, a barium study allows information about motility as well as challenge with a solid bolus. Ultimately, endoscopy is a better diagnostic test for patients in whom one suspects esophageal cancer because of the availability to obtain tissue in one test and a greater positive predictive value of upper endoscopy: 100% for endoscopy and 33% for barium swallow. [136] The endoscopic appearance of early esophageal cancer includes superficial erosive ulcer, a raised plaque, a “congestive” lesion marked by red spots on the mucosa, and a small polypoid lesion. Vital staining dyes such as toluidine blue, aniline blue, or Lugol iodine may be used to enhance detection and simultaneously to discriminate early cancers from normal adjacent mucosa. In a study of 178 patients who underwent endoscopy and vital staining, 9 esophageal cancers were found, of which 7 were early cancers. [137] In contrast, endoscopy without vital staining only detected 4 of 9 cancers. Limiting the usefulness of vital staining is its inability or failure to distinguish inflammation from dysplasia. [138] Advanced esophageal SCCs typically are exophytic, ulcerated, and even circumferential. Submucosal invasion may produce friable nodules or strictures. Whenever possible, the endoscope should be advanced through the stricture to determine the proximal-distal extent of tumor and any distal abnormalities. The preponderance of SCCs is found in the proximal esophagus to the midesophagus. Radiologically, early esophageal cancer may have a granular mucosal appearance with single or multiple small ulcerations with tiny filling defects. Polypoid lesions are characterized by small intralumenal filling defects affecting one wall of the esophagus with ulcerations. [139] An infiltrative or an ulcerative appearance can be one of the defining features of advanced esophageal cancer, but the most common presentation of advanced esophageal carcinoma is that of a polypoid mass within the lumen produced by an exophytic cancer. [140] The mass may have the characteristic appearance of an “apple-core” lesion with circumferential involvement by the cancer (Fig. 62-1). Infiltrating carcinomas may result in diminished esophageal motility with or without stricture. Such a stricture may be symmetric or asymmetric and, in fact, can sometimes be difficult to distinguish from a benign stricture. The primary ulcerative type of esophageal cancer is rare, although ulceration can be a component of either polypoid or infiltrating cancer. Ulcerative cancers are characterized by a well-demarcated meniscoid ulcer with a thin rim of lucency representing neoplastic tissue. [141]

Screening High-incidence areas, such as in northern China, may merit endoscopic screening in the general population. In China, 5-year survival was nearly 90% after operative resection for cancer cases detected through screening. [142], [143] Surprisingly, nearly 80% of patients declined therapy because of noncompliance, unavailability of medical resources, and coexisting medical illnesses. [144] Although balloon cytology has achieved success in China, its applications in United States veterans did not prove very successful. [145] The reasons were the low prevalence of esophageal cancer and the low specificity of dysplasia because of a confounding factor such as inflammation resulting from reflux esophagitis. In this United States veterans study, follow-up measures included biannual endoscopy with vital staining and biopsy, balloon cytology, laryngoscopy, and chest radiography. [146] However, the results of cytology in more than 95% of screened patients were false-positive results. Thus, mass screening in the United States is probably not feasible for esophageal SCC, given the lack of cost effectiveness. However, institution of screening and surveillance endoscopic programs may be applied to certain clinical situations, such as patients with tylosis, achalasia, and head and neck cancer.

Staging and Staging Systems

After establishment of the diagnosis of cancer, staging is necessary to optimize treatment options and management. This should ideally commence with CT scanning of the chest and abdomen and should be supplemented with EUS for esophageal wall and local lymph node involvement.

The critical determinants of survival in nearly 4000 surgical specimens from Japanese patients were depth of invasion, the presence or absence of lymph node metastases, and the presence or absence of distant metastases in a retrospective study. [147] Five-year survival was 46% with submucosal invasion, 29.5% with invasion of the muscularis propria, 21.7% with invasion into the muscularis propria, and 7% with involvement of adjacent tissues and organs. [147] Worsening survival rates also correlate with involvement of distant lymph nodes and with metastasis to distant organs (3.0%). Although several staging systems have been recommended for esophageal cancer, an overriding consideration is that surgical pathological staging is more accurate for predicting survival than pretreatment clinical staging.

Thus, staging involves clinical evaluation before therapy and then pathological staging of the surgical resected esophagus and dissected lymph noes. A staging system that is widely used because of its accuracy is depicted in Table 62-1.[148]

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria or submucosa		
T2	Tumor invades muscularis propria		
T3	Tumor invades adventitia		
T4	Tumor invades adjacent structures		
Lymph Node (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
Distant Metastasis (M)			
MX	Presence of distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis

TABLE 62-1 TNM Staging System for Cancer of the Esophagus (American Joint Committee on Cancer criteria)

Imaging Studies: Computed Tomography and Magnetic Resonance Imaging CT scanning has proven useful in the preoperative staging of esophageal cancer,[149],[150],[151],[152],[153],[154] and [155] especially in defining lymph node, pulmonary, and hepatic involvement. Accuracy of CT staging has a broad range, from 39% to 100%.[150],[151],[154],[156] Even documentation of aortic invasion, which precludes surgical resection, has a sensitivity of 80% to 100% and a specificity of 50% to 100% through CT scanning.[150],[151],[154] Tracheobronchial involvement is also discernible with CT scanning.[150],[151] and [152],[154] Comparisons between CT and magnetic resonance imaging (MRI) have shown little difference between the two modalities.[157],[158],[159] and [160] For example, sensitivity, specificity, and accuracy rates between CT scanning (100%, 80%, and 84%, respectively) and MRI (100%, 84%, and 87%, respectively) are comparable.[157] Early spread beyond the esophageal wall, regional lymph node involvement, and aortic invasion have led to problems with both false positivity and false negativity with both imaging modalities.[150],[151],[153],[154],[156],[158],[159] and [160] Thus, CT scanning remains the primary staging modality.

Endoscopic Ultrasound EUS has emerged as a key component of staging. It is particularly useful in gauging depth of esophageal invasion and local lymph node involvement(Fig. 62-2). EUS is superior to CT scanning in determination of T and N of the staging classification scheme and has been compared with surgical pathological and CT staging in several studies.[161],[162],[163] and [164] EUS accuracy in staging depth of tumor invasion varies from 87% to 92%, making it more accurate than CT. The overall accuracy of EUS in detecting regional lymph node status ranges from 80% to 88%. In these studies, EUS sensitivity varied from 92% to 95% and specificity varied from 50% to 54%, whereas CT accuracy ranged from 51% to 74%, with sensitivity of 34% and specificity of 88%.

Note the prominent muscularis propria (*m.p.*) (**B**) T2N1 stage. The mass is directly adjacent to the muscularis propria. (**C**) T3N0 stage. Note invasion into the muscularis propria (*arrow*). (**D**) T3N1 stage. A mass with a large lymph node in mediastinal fat.

EUS is useful in the assessment of resectability. It was able to predict resectability in 147 of 167 patients (89%), more accurately for adenocarcinoma (82%) than for SCC (64%).[165] Lumenal stenosis, which prevents passage of the scope, portends a higher stage, either III or IV (older staging system), in nearly 90% of cases; conversely, 58% of cancers without stenosis were not stage III or IV.[166] Overstaging (T1 to T3) or understaging (T1 or T2) may be a problem with EUS; 73% of T2 lesions are overstaged, and 71% of T3 lesions are understaged.[167] EUS is superior to CT scanning for T and N repeat staging after preoperative chemotherapy, although some difficulty in differentiating between residual tumor and fibrosis may ensue.[168] Cost-effectiveness studies of EUS staging are needed.

Laparoscopy Abdominal metastases are more common from distal esophageal tumors, and these subdiaphragmatic metastases may be confirmed by laparoscopy.[169] Nonetheless, laparoscopy is not common practice for staging of esophageal cancer.

ESOPHAGEAL ADENOCARCINOMA

Epidemiology

Barrett esophagus is the most important precursor to esophageal *adenocarcinoma*.[170],[171] Esophageal adenocarcinomas arising from esophageal glands [171],[172] or heterotopic gastric mucosa [173] are rare. Furthermore, many of the adenocarcinomas of the gastric cardia probably arise in short segments of Barrett metaplasia rather than from the gastric epithelium.[174],[175] and [176] Once considered rare,[177],[178],[179] and [180] the incidence of esophageal adenocarcinoma (both of esophageal and gastroesophageal junctional origin) has increased at a rate of 4% to 10% annually in different regions of the United States.[180] This rapid increase is greater than that of any other cancer.[9],[180] Although adenocarcinoma of the esophagus is among the top 15 malignant diseases and is more common than esophageal SCC in the United States, the latter remains more common worldwide than adenocarcinoma.

Esophageal adenocarcinoma affects mostly whites. The incidence typically begins to increase after the age of 40 years,[175],[177],[181],[182] and [183] and it rises with each succeeding decade.[9] It is a disease of men, with a male-to-female predominance of 3 to 5.5:1.[170],[180],[182] The annual age-adjusted incidence rates of adenocarcinoma of the esophagus and gastric cardia in white men is 1.3 and 2.8 per 100,000, respectively.[180]

Etiology

Barrett esophagus is a premalignant condition and is the most important risk factor for esophageal adenocarcinoma (see Chapter 60). Alcohol and cigarette smoking are not key risk factors in the development of Barrett esophagus, but they may be important once the condition is established.

Patients with Barrett esophagus are identified at an average age of 55 years. It typically affects whites, a feature shared with esophageal adenocarcinoma. Barrett esophagus may develop as a complication of chronic gastroesophageal reflux, and it is defined as the replacement of the normal squamous epithelium of the esophagus by metaplastic columnar epithelium.[183],[184],[185],[186],[187],[188],[189],[190] and [191] Patients with cystic fibrosis and scleroderma may be at increased risk of Barrett esophagus.

The incidence of adenocarcinoma arising in Barrett esophagus varies from 1 cancer per 55 to 441 patient years, or about 500 cases per 100,000.[192],[193],[194],[195],[196],[197],[198],[199],[200] and [201] This incidence rate is a figure greater than that for esophageal SCC in high-risk areas of the world, and it corresponds to nearly a 125-fold increased risk when compared with the general population in the United States. The prevalence of adenocarcinoma at the time of initial diagnosis of Barrett esophagus is approximately 8%.[177],[183],[191],[192],[193],[194],[195] and [196] Incidence estimates of esophageal adenocarcinoma arising in Barrett esophagus are highly

variable, probably because of problems with classification of Barrett esophagus as only affecting gastric cardia mucosa, with designating distal esophageal cancers as primary gastric cancers, and with whether the study was retrospective or prospective. [197] In any case, the incidence estimates for esophageal adenocarcinoma provide a compelling need for the detection of Barrett esophagus and associated dysplasia. [202], [203] Historically, investigators believed that long-segment Barrett esophagus (>3 cm) carries a higher risk of cancer than the more prevalent short-segment Barrett esophagus (<3 cm); however, one study found that the risk of cancer in short-segment Barrett esophagus is not much lower than in the long-segment variant. [204]

Apart from Barrett esophagus, symptomatic gastroesophageal reflux [205] and increased body mass index are reported to be associated with esophageal adenocarcinoma. [206] Additionally, there may be an association between medications that relax the lower esophageal sphincter and the risk of esophageal adenocarcinoma. [207]

Biology and Genetics

The transition of Barrett metaplasia to adenocarcinoma [208] involves progression through low-grade dysplasia, high-grade dysplasia, and carcinoma *in situ*. The molecular mechanisms underlying this progression are being elucidated. Abnormal DNA content, as reflected by aneuploidy measured through flow cytometry, is associated with dysplasia and adenocarcinoma, [209], [210], [211] and [212] as well as with metaplastic or dysplastic populations of cells or clones in close proximity to adenocarcinoma. [213], [214] Abnormalities in cell proliferation, as assessed by proliferating cell nuclear antigen (PCNA) and Ki-67 expression, are noted in Barrett metaplasia, dysplasia, and esophageal adenocarcinoma.

As with many cancers, esophageal adenocarcinoma involves the activation of oncogenes, inactivation of tumor suppressor genes, and mutations in DNA mismatch repair genes (Fig. 62-3). A key mechanism affecting tumor suppressor genes and putative tumor suppressor genes is loss of heterozygosity of chromosomal regions 17p (*p53*), 5q (*APC, MCC*), 18q (*DCC*), and 13q (*RB1*). [215], [216], [217], [218] and [219] Loss of heterozygosity of 17p (*p53*) typically occurs before 5q (*APC*) loss during neoplastic progression in Barrett esophagus, [308] rather than the reverse sequence, as in colon cancer. Furthermore, actual DNA mutational analysis indicate that *p53* gene alterations precede the onset of DNA aneuploidy and cancer. [220], [221] and [222] As in SCC, cyclin D_1 oncogene overexpression has been described. [223] Increased expression of epidermal growth factor and its receptor and expression of transforming growth factor-a are found in Barrett-associated adenocarcinoma. [224] Microsatellite instability, a reflection of changes in DNA mismatch repair genes, was found in 2 of 27 patients with Barrett metaplasia and in 8 of 36 patients with esophageal adenocarcinomas. [225] In fact, microsatellite instability can develop as an early event in metaplasia and in diploid tumor cells. *Ras* mutations are not present in esophageal adenocarcinoma.

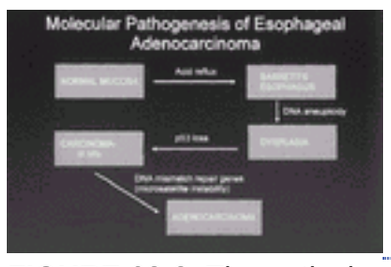

FIGURE 62-3. Theoretical genetic model of esophageal adenocarcinoma.

Clinical Manifestations

Early esophageal adenocarcinoma may be silent or may present with symptoms and signs of gastroesophageal reflux and its complications, including heartburn, regurgitation, benign strictures with dysphagia, and bleeding from ulcerations. [226], [227] and [228] Consequently, these manifestations merit meticulous endoscopic mucosal biopsies. [229], [230], [231] and [232] There are conflicting reports on the correlation between symptoms and the presence of esophageal dysplasia or early adenocarcinoma. An analysis of 741 patients in 15 published series indicated that 98% of patients had symptoms of gastroesophageal reflux or its complications. [233] An autopsy study, however, suggested that most cases of Barrett esophagus remain clinically unrecognized in the general population. [234] Symptoms referable to advanced esophageal adenocarcinoma are similar to those of advanced SCC: dysphagia, odynophagia, weight loss, chest pain, nausea, vomiting, cough, and usually occult gastrointestinal bleeding. Laboratory evaluation may reveal anemia (secondary to gastrointestinal bleeding) and signs of malnutrition (hypoalbuminemia or elevated prothrombin time secondary to vitamin K deficiency).

Natural History and Complications

Although the period of progression from Barrett metaplasia to adenocarcinoma remains undefined, and in fact may vary, [196], [201], [229], [230] it is clear that only a subset of patients with Barrett esophagus will develop adenocarcinoma. This is probably the result of the interplay of gastroesophageal reflux with genetic alterations. Metaplasia appears to migrate proximally with ongoing reflux but not with advancing age. [187], [188] and [189]

The events involved in the progression of Barrett esophagus to adenocarcinoma have been extrapolated from studying the high-grade dysplasia in mucosa surrounding the cancer. [182], [229], [230] Although it is clear that gastroesophageal reflux contributes to the development of dysplasia and adenocarcinoma, other factors, yet to be identified (e.g., bile reflux), are also important. This is underscored by the finding that pharmacological therapy or antireflux surgery does not convert the metaplastic epithelium back to normal squamous epithelium, nor does it prevent the development of adenocarcinoma.

Low-grade dysplasia may progress or regress at endoscopic follow-up. However, one third of patients with high-grade dysplasia who undergo esophagectomy have foci of adenocarcinoma in the resected specimens. [231], [235], [236], [237], [238], [239], [240], [241], [242], [243], [244], [245], [246], [247] and [248] Obviously, many cases of high-grade dysplasia do not progress to adenocarcinoma. [201], [229], [230] and [231] Given the absence of clinical parameters or biomarkers to stratify patients with high-grade dysplasia, esophagectomy is warranted whenever possible.

If undetected in its early stages, esophageal adenocarcinoma may invade the muscularis propria as well as the adventitia and metastasize to adjacent organs such as regional lymph nodes, lung, liver, peritoneum, bone, and brain. There is also an increased incidence of synchronous cancers in the esophagus.

Diagnostic Evaluation

Endoscopy The mainstay of diagnosis is endoscopy, with confirmation of Barrett esophagus by histopathology, and the establishment of metaplasia or dysplasia (Fig. 62-4, Fig. 62-5 and Fig. 62-6; see also Color Fig. 62-4 and Color Fig. 62-5). Suspicion of Barrett esophagus or adenocarcinoma warrants endoscopy with biopsy. In Barrett esophagus, the squamocolumnar junction is displaced proximal to the region of the lower esophageal sphincter and represents the junction between squamous epithelium and specialized metaplasia. [236] It is important to recognize hiatal hernias, so biopsies from the gastric hernia are not mistakenly classified as Barrett esophagus (see Chapter 60 and Chapter 138).

Early cancers may be associated with superficial erosions, plaquelike elevations, or areas of nodularity. As the cancer becomes more advanced, it may appear as an intralumenal polypoid mass, a stricture (which may be asymmetric), or a deep ulceration. Esophageal adenocarcinomas may be detected in short-segment or long-segment Barrett esophagus. Furthermore, adenocarcinomas that appear to be in the gastric cardia may, in fact, have developed in short segments of Barrett metaplasia.

Endoscopic Biopsy and Cytology When either short-segment or long-segment Barrett esophagus is suspected, four-quadrant endoscopic biopsies should be performed at 2-cm intervals in a systematic fashion. Multiple biopsies also should be taken of any erosions, nodules, ulcers, or strictures, no matter how insignificant they appear. [230] In addition, biopsies should be obtained from “control” areas, namely, the gastric cardia and the normal-appearing squamous epithelium. This protocol has been shown consistently to detect high-grade dysplasia or early adenocarcinoma arising in Barrett esophagus. Endoscopic cytology has been advocated, but it has a variable high false-negative rate, [249], [250], [251] and [252] making it unacceptable as a primary diagnostic tool for clinical practice, although its role in screening has been resurrected. [253] Caution must be exercised in interpreting the histological diagnosis of dysplasia in Barrett esophagus. Although the diagnosis of high-grade dysplasia or carcinoma can be made with confidence, interobserver variability may exist for indefinite dysplasia or low-grade dysplasia. Such cases may require independent pathological confirmation. When biopsies reveal high-grade dysplasia from a mass, ulcer, or a malignant-appearing stricture, endoscopy and repeat biopsies should be performed to exclude malignancy. As outlined earlier, high-grade dysplasia may dictate esophagectomy anyway. Sometimes, high-grade dysplasia and well-differentiated adenocarcinoma may be difficult to distinguish histologically because the muscularis mucosae is not obtained with endoscopic mucosal biopsies, and its invasion is necessary to define adenocarcinoma. Flow cytometric detection of aneuploidy or increased G_2-tetraploid fractions may provide additional important information concerning patients at risk of esophageal adenocarcinoma. The prevalence of aneuploid cell populations increases with metaplasia to different grades of dysplasia. [254], [255] Moreover, some patients may have aneuploidy without histological evidence of high-grade dysplasia or adenocarcinoma. In 9 of 13 patients (cohort of 62 patients) whose biopsies initially showed aneuploid cell populations or increased G_2 fractions, but who later had high-grade dysplasia or adenocarcinoma, the detection of aneuploidy seems to have been an excellent prospective marker. This was not the case in the remaining 49 patients without aneuploidy or increased G_2 fractions who progressed ($P < 0.0001$). The value of increased G_2 fractions has been debated, but with proper processing of mucosal biopsies and appropriate extraction of nuclei, there does appear to be an association of high G_2 fractions with progression to dysplasia and adenocarcinoma. [256]

Barium Esophagography Barium swallow may raise the index of suspicion of Barrett esophagus in the presence of stricture or ulcer. Uncomplicated Barrett esophagus may be difficult to discern, except for mucosal irregularities. [257], [258], [259], [260] and [261] Advanced esophageal adenocarcinoma usually has the same radiographic signs as observed with SCC, except SCCs are more common in the proximal or midesophagus, whereas adenocarcinomas are typically in the distal esophagus (Fig. 62-7).

FIGURE 62-7. Adenocarcinoma represented by an ulcerated mass in the distal esophagus. (Courtesy of Deborah Hall, MD.)

Staging

Preoperative CT scans are useful in staging esophageal and gastroesophageal junction adenocarcinomas, and they carry the same advantages and limitations as in the staging of SCC. [262] EUS is also an important diagnostic tool, with the same technical issue as in SCC.

Surveillance of Barrett Metaplasia and Dysplasia

A decision model comparing no surveillance with surveillance every 1 to 5 years with surgical resection for high-grade dysplasia or cancer found two important variables for the selection of a particular surveillance strategy: the incidence of cancer arising in Barrett esophagus and the quality of life after surgical resection. [263] Notwithstanding these important considerations and the absence of definitive surveillance recommendations, certain guidelines from leading expert centers may help to guide clinical practice. Endoscopic biopsies taken systematically that are negative for histological dysplasia and are without flow cytometric and cytologic abnormalities should lead to repeat endoscopic evaluation at 2-year intervals. [264] This protocol can be modified on an individual basis if the clinical situation warrants it. If high-grade dysplasia is detected histologically without any endoscopic abnormalities, then early repeat endoscopy with multiple biopsies should be pursued to document the extent of high-grade dysplasia and to exclude coexisting cancer. Treatment recommendations for high-grade dysplasia need to be individualized. Surgical resection has to be balanced against the patient's performance status, coexisting illnesses, compliance with endoscopic surveillance, and institutional experience with surgical resection. For patients with high-grade dysplasia who do not opt for surgical resection but who would do so if cancer were diagnosed, then endoscopic surveillance biopsies should be repeated 3 months after the initial two endoscopies and at 6-month intervals thereafter. Adenocarcinoma can develop in small or large areas of high-grade dysplasia, and thus systematic biopsies must be taken.

In a provocative study of the use of balloon cytology in the surveillance of Barrett esophagus for dysplasia, adequate columnar epithelium was obtained in 52 of 63 patients with balloon cytology and in 59 of 61 patients with brush cytology. [253], [265] Balloon cytology obtained abnormal cells in 6 of 8 patients with adenocarcinoma, in 2 of 2 of patients with high-grade dysplasia, but in only 2 of 8 patients with low-grade dysplasia. Brush cytology was abnormal in all 11 patients with high-grade dysplasia but in only 2 of 9 patients with low-grade dysplasia. The authors concluded that balloon cytology may be adequate and cost effective for the detection of high-grade dysplasia or carcinoma, provided sampling is adequate and a more abrasive balloon could be pursued. Although these results are promising, more studies are needed.

The search for markers of intestinal metaplasia as a means of identifying patients who may develop high-grade dysplasia and adenocarcinoma has yielded promising results with the measurement of small intestinal brush border enzymes such as sucrose isomaltase and aminopeptidase N. [214] Additionally, markers of proliferation such as PCNA, Ki-67, tritiated thymidine uptake, and ornithine decarboxylase may be useful as well, but they have not been extended to wide-scale clinical application. [214]

THERAPY FOR ESOPHAGEAL SQUAMOUS CELL CARCINOMA AND ADENOCARCINOMA

The therapeutic approaches for esophageal SCC and esophageal adenocarcinoma are becoming increasingly indistinguishable, and therefore they are considered together. The presentation of esophageal cancer at advanced stages mitigates against curative surgical resection on a consistent basis. In fact, although nearly 60% of patients may undergo surgical exploration, only two thirds of such patients will undergo resection. Thus, more than 40% of patients will require palliative therapy. Overall, 1- and 5-year survival rates are approximately 18% and 5%, respectively. [266] The following discussion is divided into categories of potential curative modalities as well as palliative measures.

Surgery

Surgery remains the mainstay of treatment of esophageal cancer with curative intent for respectable, local, and locoregional disease. Advances in surgical therapy, staging techniques, patient selection, and supportive care in recent years have resulted in a marked improvement in surgery-related mortality and morbidity. Even if cure is not accomplished, palliative surgical bypass procedures may also have some impact on patients with advanced unresectable disease to relieve symptoms and to improve the quality of life.

There are various surgical approaches for esophageal cancer, including transthoracic, transhiatal, and radical en bloc resections. Despite the different advantages and disadvantages of each, and the controversies surrounding them, there is no evidence to suggest improved survival with any particular one. [267] Factors that may influence the decision of selecting a particular technique include tumor location, depth of tumor invasion, status of lymph node involvement, overall performance status and body habitus of the patient, previous treatment (e.g., radiation or chemoradiation therapy), and the preference and biases of the surgeon and institution.

In the 1940s, midesophageal tumors were approached through the left side of the chest. The benefits of a right-sided approach (Ivor-Lewis) have been advocated since then and include enhanced accessibility to the upper two thirds of the esophagus, location of the aorta as a barrier to the left pleural space, and visualization of the entire esophagus after division of the azygous vein. This approach has been applied as well for distal esophageal cancers, thus allowing for a longer segment of esophageal resection with a higher anastomosis. A cervical anastomosis has some inherent advantages, namely, decreased morbidity and mortality, reduced reflux, and a better opportunity for postoperative radiation if pursued. The left thoracoabdominal approach may be used for distal esophageal and gastroesophageal cancers.

The early complications of transthoracic esophagectomy include anastomotic leak (0%–13%), pulmonary problems such as pneumonia, retained secretions, and pulmonary emboli (6%–50%), recurrent laryngeal nerve injury (1%–13%), and cardiac problems such as myocardial infarction, arrhythmia, and congestive heart failure (2%–27%). The mortality ranges from 1% to 13%, with a 5-year survival of 1% to 35%.

Owing to high rates of morbidity and mortality associated with the thoracotomy associated with transthoracic esophagectomy, the transhiatal approach has also been advocated. Complications are the same as with transthoracic approach, but with a higher incidence of anastomotic leak (9%–36%). Mortality ranges between 2% and 13%, and 5-year survival ranges from 12% to 27%. [272], [273], [274], [275], [276], [277], [278], [279], [280] and [281]

The en bloc resection for cancers of the distal esophagus and the cardia involves removal of 10 cm of the esophagus on either side of the tumor along with contiguous tissues, vascular supply, and lymph nodes. Various series reported a 1.4% to 11% operative mortality, with a 5-year survival of 18% to 35%. [283], [284] En bloc resection as a curative procedure is controversial, and most surgeons in Western countries favor a transthoracic or transhiatal approach. [285], [286] and [287]

An important consideration during surgery is the choice of esophageal replacement. [288], [289], [290], [291], [292] and [293] The stomach, by virtue of its rich blood supply, length, and muscular wall, is preferred, whereas the left colon, because of its similarity to the esophagus in caliber, can be used to replace the esophagus when the stomach cannot be used. Jejunal interposition may be used for reconstitution of the hypopharynx and the cervical esophagus. Overall, complications of esophageal replacement include anastomotic leaks (2%–5%), anastomotic stricture (9%–29%), gastric dysfunction, and chylothorax.

Unresectable esophageal cancer may warrant a bypass procedure using a portion of stomach, jejunum, or colon as a conduit. However, bypass surgery is fraught with high morbidity and mortality rates, and it should be reserved for patients with a tracheoesophageal fistula or those in whom conservative medical measures have failed. Effective palliative resection of the cervical esophagus usually requires total laryngectomy and esophagectomy (transhiatal approach).

Radiation Therapy

Radiation (External Beam) Alone The uses of radiation as a single modality are limited to patients who are not candidates for surgical resection because of unresectable disease or patients who are medically unable to tolerate a surgical procedure and multimodality treatment. [294], [295] and [296] Limited experience with patients treated with radiation therapy alone indicate a 1-year survival of 18% and a 5-year survival of 6%, reminiscent of survival data after surgical resection. [297], [298] and [299] Favorable 5-year survival rates may be observed in women and in patients with cancers less than 5 cm in length (22.4% and 17.7%, respectively). [294], [295], [296], [297], [298] and [299] Radiation alone may lead to amelioration of dysphagia, with 50% of patients receiving relief for 2 months or more and 15% of patients for more than 1 year. In the acute setting, radiation-induced esophagitis may lead to dysphagia, and fibrotic strictures may form. Unusual complications of radiation therapy include pulmonary fibrosis, myelitis, and cutaneous burns.
Brachytherapy Intralumenal radiation (brachytherapy) can ameliorate symptoms resulting from obstructing cancers. Higher doses of radiation can be delivered with this technique without inducing injury to pulmonary, cardiac, and mediastinal structures. [300] A cobalt-60 source is commonly used, either alone or after external beam radiation therapy, and treatment is typically administered over 2 weeks. Overall and complete response rates with brachytherapy range between 74% and 85% and 9% and 53%, respectively. [301], [302] Most patients experience a prompt subjective response to brachytherapy. Complications of brachytherapy include ulcers, strictures, and tracheoesophageal fistula in up to 25% of patients. [301], [302]

Preoperative (Neoadjuvant) and Postoperative (Adjuvant) Radiation Therapy The potential advantage of neoadjuvant radiation therapy includes increased respectability, decreased tumor seeding at the time of surgery, and increased radiosensitivity as a result of more oxygenated cells. Neoadjuvant radiation has not been shown to improve overall survival of patients with potentially respectable disease. [303], [304], [305], [306] and [307] A metaanalysis of 1147 patients from 5 randomized neoadjuvant radiation therapy trials (median follow-up of 9 years) showed no statistically significant benefit in either the 2-year survival rate (34% versus 30%) or the 5-year survival rate (18% versus 15%). [307] There was benefit demonstrated in radiation treatment, with an overall reduction in the risk of death by 11%. Adjuvant radiation therapy provides the advantages of accurate pathological staging, and treatment is directed to areas with a high risk of disease recurrence. Postoperative radiation therapy is often given when the surgical margins are positive or the resection is incomplete. A slightly higher total dose range (4500 to 5500 cGy) than that administered in the neoadjuvant randomized trials has not yielded a survival advantage. [308]

Chemotherapy

Because approximately 30% of patients present initially with metastatic disease and at least 50% of others present with stage II and III disease, chemotherapy holds promise for local control of disease, increased survival, and prevention of distant metastasis. Cisplatin and 5-fluorouracil (5FU) have been used as a standard regimen, and they have produced response rates of 35% to 40% in advanced disease with a median survival of 33 weeks and a 1-year survival of 38%. Other active agents are mitomycin and bleomycin, as well as many newer agents such as taxans (paclitaxel and docetaxel), irinotecan, gemcitabine, and oxaliplatin.

Neoadjuvant (Preoperative) Chemotherapy The rationale of neoadjuvant chemotherapy is to eradicate occult metastases before surgery. No advantage of neoadjuvant therapy was demonstrated in the 1980s or 1990s. [311], [312], [313], [314] and [315] More recently, data from a large (802 patients), randomized, and well-controlled study of neoadjuvant chemotherapy in esophageal cancer conducted by the United Kingdom Medical Research Council upper gastrointestinal tract cancer group has been very encouraging. [316] Patients with esophageal cancer, 67% of whom had adenocarcinoma, were randomized to neoadjuvant chemotherapy before surgery or to surgery alone. Resectability was significantly higher in the treatment arm (78% versus 70%; $P < 0.001$), as was the overall survival ($P = 0.003$). Two-year survival rates were 43% in the neoadjuvant chemotherapy arm versus 34% in the surgery-alone arm. Postoperative complications were similar (40%–41%).
Adjuvant (Postoperative) Chemotherapy A trial to evaluate the efficacy of postoperative chemotherapy in resectable lesions showed an advantage of disease-free survival in the treatment arm ($P = 0.05$), but there was no overall survival benefit. [317] Several clinical trials are ongoing to evaluate this approach further, using newer chemotherapy agents and regimens.

Primary Chemoradiation Therapy

Cisplatin and 5FU combined with radiation therapy can substantially improve the 5-year survival in patients with esophageal cancer compared with radiation alone. Cisplatin and 5FU are radiosensitizers and improve the response to radiation therapy not only in the cancer cells, but unfortunately in normal tissues as well.

Definitive primary chemoradiation therapy for locoregional esophageal carcinoma is considered an alternative to surgical resection, although there are no large prospective randomized trials comparing it directly with surgery. The largest single-institution trial of primary chemoradiation was conducted by Coia [318] on 57 patients with stage T1 and T2 esophageal cancer. These patients were treated with radiation, 6,000 cGy, and two cycles of 5FU delivered as a continuous 4-day infusion during the first and fifth week of radiation therapy, and a single bolus of mitomycin C on day 2. The median survival was 18 months, and 3-year and 5-year survival rates were 29% and 18%, respectively.

A phase III multiple-institution randomized trial compared combined modality with radiation therapy alone. [319] Patients randomized to combination therapy received a total dose of 5000 cGy radiation and 5FU for 4 consecutive days and cisplatin on day 1 in weeks 1, 5, 8, and 11. Patients in the radiation-alone group were given a total dose of 6400 cGy. This trial was stopped early after an interim analysis demonstrated a survival advantage for patients in the combination therapy group. The 5-year survival rate for patients who had chemoradiation was 26% versus 0% for those receiving radiation only ($P < 0.001$), with median survival of 14.1 months versus 9.3 months, respectively. There was no statistical difference in survival related to histology of cancer (adenocarcinoma versus SCC).

Neoadjuvant Chemoradiation Therapy

Data from several nonrandomized studies suggest that neoadjuvant therapy with chemotherapy (5FU and cisplatin) plus radiation before surgery yielded complete response rates of 24% to 42%, with median survival of 12 to 23 months. [319], [320], [321] and [322] One hundred patients (25 with SCC and 75 with adenocarcinoma) were randomized to concurrent continuous infusion of 5FU, cisplatin, and vinblastine with radiation 45 Gy followed by surgery versus surgery alone in a University of Michigan study. Twenty-eight percent of patients in the neoadjuvant chemoradiation arm achieved pathological complete response. Three-year survival rates were 30% in the combination therapy arm versus 16% in the surgery alone arm, but this difference was not statistically significant ($P = 0.15$). Median survivals were similar in both arms of the trial. [323] A phase III trial had 113 patients with esophageal adenocarcinoma randomized to 5FU infusion and cisplatin with radiation (40 Gy) plus surgery or surgery alone, [324] and a trial of 297 patients with SCC (with surgery alone, and cisplatin with radiation followed by surgery) was inconclusive. [325] Large randomized trials are needed to address this approach further.

Adjuvant Chemoradiation Therapy

Medical and radiation oncologists have also administered combined modality chemoradiation therapy postoperatively to patients with esophageal cancer, based on the proven benefit observed in other gastrointestinal malignancies, such as rectal cancer. Several small or retrospective studies suggested a survival benefit of adjuvant chemoradiation for patients with esophageal and gastroesophageal junction cancer. [326], [327], [328] and [329] A large intergroup study from the United States demonstrated the survival benefit of adjuvant chemoradiation in such patients. [330] Six hundred and three patients with complete resections, negative surgical margins, and no evidence of residual disease were randomized to receive surgery alone or surgery plus postoperative chemotherapy with 5FU and leucovorin and concurrent radiation therapy. The median survival was 36 months for patients in the adjuvant chemoradiation arm versus 26 months for patients in the surgery-only arm ($P = 0.005$). The 3-year overall survival rates were 50% versus 40%, and disease-free survival rates were 48% versus 31%, for the treatment group versus the observation group. The median disease-free survival rates were 30 months for chemoradiation-treated patients and 19 months for surgery-only patients ($P < 0.001$). The toxicities of the chemoradiation were acceptable, with hematologic and gastrointestinal toxicities comprising the predominant adverse events. Three patients (1%) died as a result of toxicities. This study is the first large well-controlled study demonstrating an advantage to adjuvant therapy, with respect to both disease-free survival and overall survival. Unfortunately, the study was not designed specifically for answering the role of adjuvant therapy in esophageal cancer.

Summary

For patients with stage T1 and T2 lesions without any evidence of nodal involvement, surgery alone may be curative in more than 60%. For patients with locally advanced disease, the emerging recommendation entails perioperative chemotherapy and/or radiation therapy plus surgical resection. Patients should be encouraged to enter large randomized clinical trials whenever possible, because definitive survival benefits of either neoadjuvant or adjuvant multimodality therapy with surgery need further study.

Palliation Treatment

Local Disease Because fewer than 50% of patients are candidates for a curative approach after careful staging and preoperative assessment of comorbid disease, palliative approaches are mandatory. Because total esophagectomy is fraught with high mortality in palliative situations, bypass should be considered for those patients with expected survival of more than 6 months. External beam radiation therapy (with or without chemotherapy) may be suitable for annular or nearly obstructive lesions, but radiation-induced esophagitis may be problematic. Lower does may be an option. Endoscopic dilation can be employed to relieve the stricture and is associated with a low complication rate. [331], [332] However, repeated dilations may be necessary. Expandable metal stents are a good option to maintain patency; additionally, laser and bipolar electrocoagulation therapy may be helpful (see Chapter 145). It is worth emphasizing the exciting potential of photodynamic therapy. An intravenously administered photosensitizer, porfimer sodium (approved by the Food and Drug Administration for use in the palliation of esophageal cancer) is administered, and then light of a specific wavelength (630 nm) is shone on the tumor. Cell toxicity is believed to occur through release of singlet oxygen resulting in ischemia and, eventually, necrosis. Photodynamic therapy's depth of destruction is 2 to 5 mm, and it is preferred to laser in tumors longer than 8 cm (Fig. 62-8; see also Color Fig. 62-8).

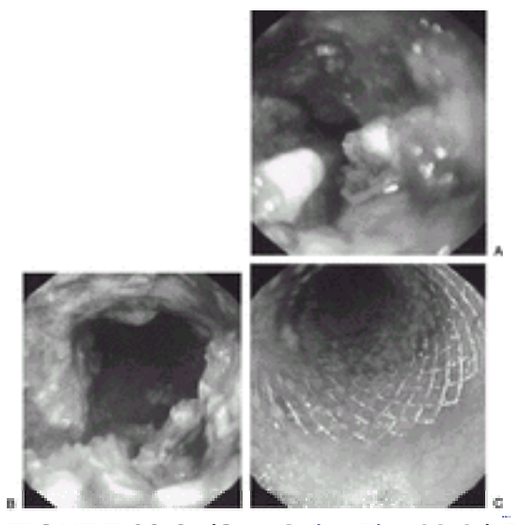

FIGURE 62-8. (See Color Fig. 62-8.) Photodynamic therapy of esophageal cancer with laser after administration of porfimer sodium, a photosensitizer. Light of 630 nm from a laser acts on cells that accumulate the photosensitizer (**A**). After 6 days, there is some decrease in the mass size (**B**). After 12 days, the mass is diminished in size significantly, and a metallic endoprosthesis is endoscopically inserted (**C**). (Courtesy of Norman Nishioka, MD.)

Metastatic Disease For distant metastatic disease, systemic chemotherapy with 5FU and cisplatin is the main modality for palliative care response, and survival rates are not impressive. With newer agents such as paclitaxel, docetaxel, gemcitabine, irinotecan, and oxaliplatin, response rates have improved to 50% to 60%, and median survival has increased to 10 to 14 months, with gains in quality of life. [333], [334] and [335]

Prognostic Factors

It would be helpful to be able to identify patients a priori who would benefit from certain types of therapeutic modalities. Performance status, weight loss than 10% of body weight, the tumor stage, and lymph node involvement from primary tumor are also very important. [336], [337]

The chances for curative surgical resection are optimized for lesions less than 5 cm, confined to the mucosa and without lymph node involvement. Poor prognosis is correlated with aneuploidy and histology. For those patients who achieve pathological complete response to neoadjuvant chemotherapy, long-term survival has been significantly improved. [338] Increased cyclin D_1 expression and reduced E-cadherin expression portend a less favorable outcome. [339] A high serum vascular endothelial growth factor (VEGF) was associated with tumor progression, poor treatment response, and poor survival in patients with SCC. [340] It is also suggested that high expression of *BAX* and *p16* ^{INK4a} are associated with a favorable prognosis. [341] Importantly, patients need to abstain from tobacco and alcohol during treatment.

The extent of disease is an important prognostic factor for esophageal adenocarcinoma. After resection, negative surgical margins are important for improving prognosis; conversely, the development of distant metastasis during treatment portends a poor prognosis. The type of operation is not an independent prognostic factor, nor is ultrasound assessment after neoadjuvant therapy. Identification of micrometastatic disease in lymph nodes of patients with esophageal cancer may permit stratification to better or worse survival. [342]

BENIGN EPITHELIAL TUMORS (SQUAMOUS CELL PAPILLOMA)

Squamous cell papillomas are usually discovered incidentally at endoscopy on radiography. Generally, they are small, sessile, and polypoid growths of normal or hyperplastic squamous epithelium covering a core of connective tissue. [343], [344] On removal, they typically do not recur. [345], [346] The average age of patients is 51.5 years, with a male-to-female ratio of 1.8:1. These tumors occur more frequently in Japan. Most are solitary and located in the distal third of the esophagus. Papillomas may result from chronic irritation from reflux esophagitis. Morphologic features suggest that papillomas result from HPV infection, and HPV DNA has been found in a subset of papillomas. Actual development of cancer has not been documented in these tumors. This may reflect that the nononcogenic genotypes of HPV may be associated with esophageal papillomas as in the skin. NMBA administered subcutaneously in rats leads to the development of esophageal squamous dysplasia and papillomas.

MALIGNANT EPITHELIAL TUMORS

Squamous Cell Carcinoma with a Spindle Cell Component

SCC with a spindle cell component is also referred to as carcinosarcoma, pseudosarcoma, spindle cell carcinoma, and polypoid carcinoma. [347], [348], [349], [350], [351], [352] and [353] Originally, carcinosarcoma was believed to be malignant, whereas pseudosarcoma was designated benign without metastatic potential. Local and distant metastasis of spindle cells, however, has been reported.

Spindle cell carcinomas are either solitary or multiple and are large and polypoid. Histologically, the squamous component at the surface is associated with dysplasia or carcinoma in situ. One may also see adenocarcinoma or undifferentiated epithelial components. The spindle cell component may range from mild proliferation to marked proliferation with pleomorphism, giant cells, and mitoses. Differentiation into smooth or skeletal muscle, bone, or cartilage may be rarely observed. Immunohistochemical and electron microscopic analyses indicate that the spindle cells stem from mesenchymal metaplasia of malignant squamous cells. Although there are reports that spindle cells contain epithelial cell markers such as cytokeratins, suggesting multiclonality, most pathologists believe that spindle cell carcinomas arise from SCCs that produce a spindle cell component.

Clinically, men are affected more than women, and most patients are middle aged or elderly. Located in the middle to distal esophagus, these cancers can produce obstruction and dysphagia by virtue of their large size. Most patients present with esophageal wall invasion and lymph node involvement.

Verrucous Squamous Cell Carcinoma

Verrucous SCC of the esophagus classically is a slow-growing malignant tumor that may be limited to local invasion but without distant metastasis. [354], [355] Some, however, do metastasize to other organs, with resulting poor prognosis.

Adenocanthoma and Adenosquamous Carcinomas

These rare tumors feature adenocarcinoma with squamous metaplasia (*adenocanthoma*) or with squamous carcinoma (*adenosquamous carcinoma*). [356], [357] These lesions can arise in the setting of Barrett esophagus or de novo. It is likely that these tumors arise in the squamous epithelium that has the ability to achieve squamous and glandular differentiation. Alternatively, squamous metaplasia or transformation within an adenocarcinoma may have occurred. Clinically, these tumors behave like adenocarcinomas.

Adenoid Cystic Carcinoma

This is a rare tumor that resembles salivary adenoid cystic carcinomas. Carrying a male predilection at an advanced age, these tumors are multilobulated or ulcerated and located in the midesophagus. [358], [359], [360], [361], [362] and [363] Histologically, *adenoid cystic carcinomas* contain many cystic spaces and are primarily submucosal.

Mucoepidermoid Carcinoma

This cancer consists of glandular and squamous elements; however, the mixture is more pronounced than in adenosquamous carcinoma. Found in the middle to distal

esophagus, *mucoepidermoid carcinomas* probably arise from submucosal glands or their ducts and carry a dismal prognosis.

Melanoma

Melanoma is a rare esophageal cancer that can be primary or metastatic, although the esophagus is less commonly a metastatic target than the stomach, small intestine, or colon. [364], [365], [366], [367], [368], [369] and [370] The mean age of patients is 60 years, and there are more cases in Japan than in other countries. Melanomas are polypoid and may be multiple, with a propensity for lateral spread. Primary esophageal melanomas arise from melanocytes in the basal layer. There must not be evidence of melanoma in the skin or internal organs to call an esophageal melanoma a primary tumor. Additionally, in situ or junctional melanoma must be evident in the mucosa adjacent to the tumor. Some cases are amelanotic and may require confirmation with immunohistochemical demonstration of S100 protein or homatropine methylbromide 45; alternatively, electron microscopy may reveal premelanosomes. Overall, the prognosis of malignant melanoma is dismal; most patients succumb to the disease within 2 years.

Neuroendocrine Tumors

Small cell carcinoma of the esophagus may include a small cell variant of SCC as well as oat cell carcinoma. [371], [372], [373] and [374] Oat cell carcinoma of the esophagus can be primary or secondary, but it is rare in either situation. A disease of the elderly who present with dysphagia, primary small cell carcinoma of the esophagus (typically distal and sometimes multiple) carries a dismal prognosis, with an average survival of 4.7 months. These tumors may occasionally secrete ectopic antidiuretic hormone or calcium. Microscopically, this tumor is an anaplastic small cell carcinoma resembling what is observed in the lung, with solid sheets of small anaplastic cells with mitoses. There can be evidence of squamous or glandular differentiation. Neuroendocrine markers employed are chromogranin and synaptophysin, as well as electron microscopic evidence of neurosecretory granules.

Esophageal carcinoid tumors are rare [375], [376], [377] and [378]; most occur at the gastroesophageal junction. Carcinoid syndrome has not been reported. There is little or no malignant potential, and, consequently, prognosis is very good.

Choriocarcinoma of the esophagus is an exceedingly rare tumor that may be primary or an adenocarcinoma with trophoblastic differentiation. [379], [380] Secretion of human chorionic gonadotropin has been reported.

BENIGN NONEPITHELIAL TUMORS

Leiomyoma

Leiomyomas are the most common benign esophageal tumors. [381], [382], [383], [384], [385] and [386] Men are affected more frequently than women, with a ratio of 2:1. These tumors typically are single, and most occur in the distal esophagus and in the inner circular layer of the muscularis propria. Typically, most leiomyomas are not associated with symptoms and are found incidentally. Symptoms, if present, include dysphagia and chest pain; gastrointestinal bleeding is rare.

The diagnosis is usually suggested by barium esophagography, which shows a smooth, round defect with sharp margins (Fig. 62-9), or endoscopy, in which there is a well-circumscribed, rounded mass with normal overlying mucosa. Biopsy is usually not necessary because of its nondiagnostic nature and also because of the potential for complication.

FIGURE 62-9. Leiomyoma of the esophagus represented by a smooth intramural mass outlined with air-contrast barium. (Courtesy of Deborah Hall, MD.)

Granular Cell Tumor

Granular cell tumors are derived from neural or Schwann cell elements, as evidenced by positive staining for S100 protein and neuron-specific enolase. Endoscopically, it is characterized as a smooth, sessile polyp with overlying normal mucosa. [387] Most tumors occur in the distal esophagus and may be single or sometimes multiple. [387] The tumors have an endoscopic appearance of being small, sessile, and intramural nodules or plaques. Patients are typically asymptomatic. Malignant transformation is rare. Microscopically, there are sheets of monomorphic histiocyte-like cells.

Fibrovascular Polyp

Intralumenal *fibrovascular polyps* of the esophagus are rare tumors that may grow and may prolapse into the larynx. Other symptoms include dysphagia, nausea, vomiting, and, occasionally, gastrointestinal bleeding from ulceration. The polyps are covered by a smooth mucosa and are composed of fibrous and vascular tissue, although adipose tissue may occasionally predominate, prompting the designation of a fibrolipoma or pedunculated lipoma. Fibrovascular polyps do not have any malignant potential.

Hemangioma

Hemangiomas are small, asymptomatic lesions found incidentally. [388]

Lymphangioma

Lymphangiomas are rare, with an appearance of a translucent, easily compressed mass on endoscopy. [389] Histologically, they contain dilated endothelial spaces.

Lipoma and Fibroma

Sessile submucosal nodules composed of adipose or fibrous tissue are called *lipomas* and *fibromas,* respectively. In aggregate, they constitute fewer than 5% of all benign esophageal tumors.

MALIGNANT NONEPITHELIAL TUMORS

Leiomyosarcoma and Other Sarcomas

Leiomyosarcoma is an uncommon tumor of the esophagus. [390], [391], [392] and [393] These tumors may be polypoid or infiltrative, and they can occur in all segments of the esophagus. Other esophageal sarcomas include soft tissue sarcoma, rhabdomyosarcoma, neurogenic sarcoma, and Kaposi sarcoma.

Metastatic Carcinoma

Metastatic carcinoma to the esophagus is unusual, representing 3% of esophageal malignancies in an autopsy series. [394] The most common metastatic tumor to the esophagus is melanoma, followed by breast cancer and, less commonly, gastric, renal, liver, prostate, testicular, bone, skin, lung, and head and neck cancer. Primary esophageal and head and neck squamous cancers may coexist or may develop sequentially. Metastatic carcinomas to the esophagus cause extrinsic compression. In this context, the esophageal stricture is extrinsic, without mucosal involvement.

Lymphoma

Primary esophageal *lymphoma* may be Hodgkin's or non-Hodgkin's type, [395], [396], [397] and [398] although, clearly, primary gastrointestinal lymphomas more commonly affect the stomach and small intestine. Symptomatic esophageal lymphoma may be present in immunocompromised patients, as in those with acquired immunodeficiency syndrome. Alternatively, lymphoma of the esophagus may be attributable to disseminated disease or infiltration from adjacent lymph nodes.

CHAPTER 63

Douglas O. Faigel

MISCELLANEOUS DISEASES OF THE ESOPHAGUS: SYSTEMIC, DERMATOLOGIC DISEASE, FOREIGN BODIES AND PHYSICAL INJURY

FOREIGN BODIES

Risk Factors

The esophagus is the most common site of *foreign body impaction* in the gastrointestinal (GI) tract, accounting for 75% of all impactions (see Chapter 138). [1] Most cases occur in pediatric patients between the ages of 6 months and 3 years who ingest coins, toys, crayons, buttons, and batteries. [1], [3], [4], [5] and [6] In adults, those who wear dentures, prisoners (seeking secondary gain), those with mental retardation, alcohol and drug abusers, and psychiatric patients are at increased risk, and most often they present with meat and bone impactions. [1], [2], [3], [4], [5] and [6] Multiple foreign bodies may be present, and recurrence occurs in 3% to 10% of patients. [1] Typically, these items become lodged in areas of esophageal narrowing: the cervical esophagus (cricopharyngeus), aortic arch, distal esophagus just above the gastroesophageal junction, or any area of structural abnormality. Most patients with food impactions have an underlying esophageal disorder such as a Schatzki ring (Fig. 63-1; see Color Fig. 63-1.). [4] Esophageal bezoars have been described in elderly patients with esophageal dysmotility or in those receiving tube feedings and sucralfate. [7], [8] and [9]

FIGURE 63-1. (See Color Fig. 63-1.) Food impaction in the distal esophagus (**A**). When cleared by advancing the bolus into the stomach (**B**), a Schatzki ring is evident (**C**).

Diagnosis

A careful history usually provides the diagnosis. Most older children and fully conscious adults are able to recognize the ingestion at the time of the incident and convey this information to the physician. Patients usually complain of a sharp pain in the neck or chest, and they may be able to localize the level of obstruction, although this is not always reliable. [10] Dysphagia is the most common symptom, followed by odynophagia, choking, and drooling. [2] Respiratory symptoms (e.g., coughing, dyspnea, wheezing, stridor) occur in 5% to 15% and are primarily seen in children with foreign objects lodged proximally [3], [5], [11] A history of prior impactions is common. [1] Rarely, the diagnosis may be delayed for months or even years. [12]

The physical examination is often unremarkable. Neck swelling, erythema, tenderness, or crepitus are signs of oropharyngeal or proximal esophageal perforation. Radiographs of the neck and chest may reveal a radiopaque foreign object, whereas subcutaneous air or soft tissue swelling suggests the presence of a radiolucent object. [2], [13] A contrast examination should not be routinely performed when high-grade obstruction is suspected, owing to the risk of aspiration. Furthermore, opaque contrast agents such as barium coat the foreign body and esophagus and hamper subsequent endoscopy, whereas Gastrografin, a transparent contrast agent, causes severe pneumonitis if it is aspirated. [14] Metal detectors have been used to detect metallic foreign bodies and may be useful as a screening tool in the pediatric population. [15], [16]

Complications

Most ingested foreign bodies pass through the GI tract uneventfully. Complications depend on the size, shape, presence of sharp points, and location of the object. Esophageal perforation may cause mediastinitis and abscess formation. [17], [18] Hemorrhage, which may be life-threatening, occasionally occurs and, when massive, suggests the presence of damage or fistulization to surrounding vasculature such as the aorta or innominate artery. [19], [20] and [21] Long-standing foreign bodies in the esophagus may induce cricoid perichondritis, periesophagitis, esophageal diverticula, or esophageal stenosis. [22] Fistulization to the airway and pericardium have also been reported. [23], [24] Disc batteries are particularly noxious, because of direct pressure, leakage of alkali, and generation of electrical current, which causes liquefaction necrosis and perforation. [25], [26]

Management

Treatment of an esophageal foreign body depends on the object's physical characteristics, its location, and the length of time it has been in place. In all cases, the risk of pulmonary aspiration and airway obstruction must be minimized. Urgent intervention is indicated for sharp objects, disc batteries, and coins in the proximal esophagus, or when impactions result in high-grade obstruction causing the patient difficulties in handling secretions. [1], [2] Coins in the distal esophagus can be observed for 12 to 24 hours to see whether they will pass into the stomach. Once in the stomach, most objects pass through the remainder of the GI tract without problem. Food impactions or foreign objects should not be allowed to remain in the esophagus for more than 24 hours. [2] Flexible endoscopy performed by an experienced endoscopist forms the mainstay of therapy and has a success rate in foreign object removal of up to 98% and very low morbidity. [1], [14], [27] Nonendoscopic removal of blunt radiopaque esophageal foreign objects has been accomplished by use of a Foley catheter under fluoroscopic guidance, but it provides no control of the object as it is being removed, provides no airway protection, and does not allow for assessment of underlying esophageal disorders. [28] Blind bougienage carries a perforation risk and should be avoided. [2], [29]

Food usually impacts in the distal esophagus and is almost always associated with underlying esophageal disease (see Fig. 63-1). [1], [2] Glucagon, 1 mg intravenously, may relax the esophagus and allow spontaneous passage of the bolus, [30] but it does not obviate the need for subsequent esophageal examination. The use of effervescent agents is of limited efficacy, carries a perforation risk, and interferes with subsequent endoscopy. [31], [32] The use of enzymatic digestion of the meat with papain (Adolph's Meat Tenderizer) is especially discouraged because perforation and death have been associated with its use. [33]

The principles for the endoscopic management of impacted foreign objects and food boluses are similar. Successful removal requires the availability of a variety of endoscopic instruments employed by an experienced endoscopist. [34] An esophageal overtube is usually employed to protect the airway. An ex vivo trial with a similar foreign body helps to determine which endoscopic accessories would be most useful in the actual removal. Coins are most easily removed with grasping forceps, a polypectomy snare, or a retrieval basket. [35] Difficult to remove smooth, round objects, such as disc batteries, are most easily removed by capturing them with a polypectomy snare fitted with a net (Roth Retrieval Net, U.S. Endoscopy Group, Inc., Mentor, OH) [34] Advancing small (<2.0 cm), smooth objects under direct vision into the stomach can aid in their retrieval. [1] Endoscopic retrieval of sharp objects is accomplished with use of retrieval forceps or a polypectomy snare. [34] The risk of mucosal injury during sharp object retrieval can be minimized by orienting the object with point trailing during extraction, using an overtube, or fitting a protector hood to the end of the endoscope. [2], [36] In managing food bolus impactions, it is sometimes possible to distend the esophageal lumen with air and gently push the bolus into the stomach. [37], [38] Otherwise, by using a variety of snares, baskets, graspers, and forceps, the food bolus can usually be removed as a whole or in piecemeal fashion through an esophageal overtube. [2] A friction-fit adaptor fitted to the end of the endoscope can also be used as a direct-vision suction device to remove the impacted food. [39] The underlying esophageal stricture may be dilated at the time of the disimpaction, provided bolus removal has not been delayed and severe esophagitis is not present. [1], [37], [38]

Surgery is rarely needed to remove an impacted object or food bolus. [1] It is generally performed in patients with large objects in whom endoscopic management has failed, when the object has become embedded in the esophageal wall, or when there has been perforation. [1], [2], [21], [40] Objects in the high cervical esophagus or pharynx may require rigid laryngoscopy for removal. [4]

SYSTEMIC DISEASES

Sarcoidosis

Sarcoidosis is a systemic granulomatous condition that rarely involves the GI tract (2 of 1254 cases in one series). [41] Granulomata may be found in the submucosa of the GI tracts in 10% of patients with known sarcoidosis, but this is rarely associated with symptoms. [41] Granulomatous esophagitis usually presents in conjunction with generalized sarcoidosis.

Dysphagia, the most common clinical manifestation of esophageal sarcoidosis, may be caused by extrinsic esophageal compression from enlarged lymph nodes, an achalasia-like dysmotility syndrome, or stricture formation caused by granulomatous esophagitis, and it may resolve with steroid treatment. [42], [43] and [44] It may be difficult to differentiate esophageal sarcoidosis from Crohn's disease because both are characterized by the presence of granulomata. [45]

Therapy is aimed at the systemic disease and typically includes the use of corticosteroids. Esophageal strictures may require dilation, and rarely, esophagojejunal interposition. [44]

Crohn's Disease

Crohn's disease of the esophagus is rarely encountered, with one series reporting only one case of Crohn's esophagitis among 383 patients. [46] In a 4-year study of 500 patients with Crohn's disease, only nine had esophageal involvement. [47] The true prevalence may be higher, as suggested by one study of 41 consecutive children, 16 of whom were found to have esophagitis and 2 had esophageal ulcers. [48] Additionally, in 33% of patients with Crohn's disease, there is abnormal expression of HLA-DR in the esophageal mucosa associated with increased epithelial content of T cells, B cells, natural killer cells, and macrophages, even though clinical Crohn's esophagitis may be absent. [49]

Patients with Crohn's disease with esophagitis almost invariably have active disease elsewhere in the GI tract. Extraintestinal manifestations are common, and the degree of inflammation usually parallels the activity in the other involved segments. [50], [51] Dysphagia has been the presenting symptom of Crohn's disease, and isolated esophageal involvement without disease elsewhere has been reported. [51], [52] and [53] Esophageal epidermolysis bullosa acquisita, a rare autoimmune subepidermal bullous disorder, is associated with Crohn's disease, and in one case it responded to treatment of the intestinal disease with sulfasalazine. [54]

Patients with Crohn's esophagitis complain of dysphagia, odynophagia, pyrosis, or substernal chest pain. [47], [51] Perforation and fistulization to the bronchi, mediastinum, pleura or stomach may occur. [52], [55], [56] Barium radiography may reveal a variety of lesions. Aphthous ulceration is present early in the course of the disease but is nonspecific. Later in the course, cobblestoning and deep linear ulcerations may be present, along with decreased motility and distensibility (Fig. 63-2). There may be esophageal stricturing and the formation of sinus tracts, fistulae, or mucosal bridges. [50], [51], [57]

FIGURE 63-2. Crohn's esophagitis. Filiform polyps (*white arrowheads*) are associated with mucosal nodularity, deep ulcers, and intramural sinus tracts (*black arrowheads*). (From Eisenberg RL. Gastrointestinal radiology: a pattern approach. 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003).

Endoscopy with biopsy is helpful in delineating the degree of inflammation and in ruling out other causes of esophagitis. [50] Endoscopic biopsies are not able to demonstrate the transmural nature of the inflammation, however, and granulomata are rarely found. [47], [51] Endoscopic ultrasound may have a role in diagnosing esophageal Crohn's disease by demonstrating the transmural nature of the inflammatory process. [58]

Most patients respond to treatment with corticosteroids and have resolution of their symptoms with healing of the esophageal lesions in 2 to 4 weeks. [47], [50], [51] At least half of patients will then remain free of both esophageal lesions and upper GI symptoms, whereas the others will have either persistent lesions or recurrence after initial healing. [50] Progressive stricturing may respond to medical management and bougie dilation. Extensive mucosal bridges may be endoscopically excised with a papillotomy knife. [57] Medical therapy may be improved by the placement of a percutaneous endoscopic gastrostomy to provide nutrition and aid in healing. [99] Surgical resection may be required for the treatment of fistulae, extensive refractory strictures, and perforation, and for when malignancy cannot be excluded. [53]

Behçet Syndrome

Behçet syndrome is characterized by oral and genital aphthous ulcers and ocular inflammation, and it may have multiorgan involvement including the GI tract. [60] Rare in northern Europeans, Behçet syndrome is most common in the eastern Mediterranean, Middle East, and East Asian populations, primarily affecting young adults. [61]

Esophageal Behçet syndrome has been reported since 1973. [62], [63], [64] and [65] Patients may present with dysphagia, odynophagia, chest pain, and hematemesis. Lesions found include superficial erosions, diffuse esophagitis, perforated ulcers with mediastinal abscess, and esophageal strictures. Most of the lesions have been found in the middle and distal esophagus. All these patients had other concomitant manifestations of Behçet syndrome. Barium esophagrams and endoscopy in symptomatic patients may reveal the mucosal lesions, aphthous ulcerations, perforations, or strictures. [63] Biopsies show ulceration with nonspecific inflammation and neutrophilic infiltration. [60]

The clinical course parallels that of the multisystem disease with unpredictable exacerbations and remissions. Dysphagia caused by esophageal ulcers may resolve spontaneously. [60] Patients generally require systemic immunosuppression to prevent blindness from uveitis or death from cerebral vasculitis. [61] Corticosteroids may markedly improve the symptoms of esophageal involvement, and the intestinal and esophageal ulcers have been successfully treated with sulfasalazine and low-dose cyclosporine. [64], [65]

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) occurs after successful bone marrow implantation when immunologically competent cells from the grafted marrow target antigens in the recipient. It can occur in both acute and chronic forms. It also rarely occurs after a blood transfusion in an immunologically impaired patient. GVHD is primarily manifested by skin rash, liver test abnormalities, and GI involvement usually presenting as diarrhea. [66]

Esophageal involvement is relatively uncommon and is primarily seen in patients with chronic GVHD who have multisystemic disease. [67], [68] Upper GI involvement may occur in the absence of lower GI GVHD but is uncommon. [69], [70] Patients with GVHD esophagitis complain of odynophagia, dysphagia, pyrosis, and retrosternal chest pain.

GVHD esophagitis needs to be differentiated from opportunistic infection of the esophagus such as with herpesvirus, cytomegalovirus, and *Candida,* and endoscopy with biopsy should be performed. [70] In patients with confirmed GVHD esophagitis, the esophageal mucosa has appeared erythematous and friable, and strictures, webs, bullae, or an esophageal cast have been noted (Fig. 63-3). [68], [71], [72]

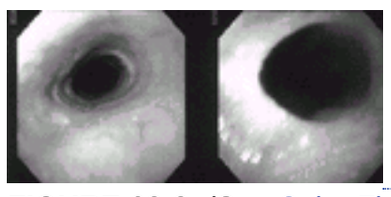

FIGURE 63-3. (See Color Fig. 63-3.) Graft-versus-host disease. Multiple fine mucosal webs are present in the esophagus.

Therapy consists of controlling the underlying immunologically mediated inflammatory process with the use of immunosuppressants such as prednisone, azathioprine, and cyclosporine. [66] Esophageal symptoms may respond to antireflux medications and to dilation of webs and strictures, although the risk of iatrogenic perforation may be increased in these patients. [67] Strictures and webs usually recur unless the underlying inflammatory process is controlled.

Eosinophilic Esophagitis

Idiopathic eosinophilic esophagitis (IEE) may occur alone or in conjunction with idiopathic eosinophilic gastritis. [73] In IEE, there is full-thickness infiltration of the esophagus by eosinophils. Most patients are male, with onset in childhood or early adulthood, and have an allergic disorder or peripheral blood eosinophilia, suggesting that the condition is a hypersensitivity reaction. [74] Patients complain of dysphagia or chest pain. [75], [76] Proximal esophageal stricture is the most common abnormality, followed by distal stricture and abnormal motility. Multiple esophageal rings have been noted. [77], [79] One case of esophageal rupture has been reported. [80] Skin testing may document an underlying food allergy, and patients may respond to elimination diets. [74], [76] IEE responds well to corticosteroids at a dosage of 1.5 mg/kg for 4 weeks, but topical treatment with inhaled steroids has also been described. [78], [79] Reflux esophagitis, which can also have eosinophilic infiltration noted on biopsy, may be differentiated from IEE by a more marked infiltration of eosinophils (5 to 20/high power field); on electron microscopy, the eosinophils demonstrate signs of activation, lack of adequate response to gastroesophageal reflux disease therapy, and normal esophageal pH testing. [74], [81], [82], [83] and [84] Additional causes of esophageal eosinophilic infiltration include parasitic and fungal infections, systemic connective tissue disorders, esophageal leiomyomatosis, inflammatory bowel disease, lymphomas and myeloproliferative disorders, vasculitis, and food allergy. [85]

Miscellaneous Autoimmune Diseases

Several other systemic autoimmune diseases rarely affect the esophagus. In *Sjögren syndrome,* more than half of affected patients complain of dysphagia, which does not appear to correlate with the degree of xerostomia. [86] Ten percent have upper esophageal webs. [87] Dysphagia may [88] or may not [89] correlate with the presence of peristaltic abnormalities on esophageal manometry.

Amyloidosis, either primary or secondary, may cause dysphagia. Amyloid deposition in the esophageal muscle or nerves produces motility abnormalities that may mimic achalasia and respond to pneumatic dilation. [90], [92] Amyloid deposition may predispose to esophageal rupture. [93]

The *anticardiolipin antibody syndrome* is associated with numerous thromboembolic phenomenon. Esophageal involvement includes ischemic necrosis from esophageal vascular thrombosis (which may perforate), and the formation of varices caused by portal vein thrombosis. [94], [95] and [96]

DERMATOLOGIC DISEASES

Pemphigus Vulgaris

Diseases that affect the squamous epithelium of the skin also affect the esophagus (Table 63-1). *Pemphigus vulgaris* is a chronic blistering autoimmune disease of older adults manifested by flaccid intraepidermal blisters and intraoral erosions caused by IgG autoantibodies directed against desmoglein 3 in keratinocyte membranes and keratinocyte acetylcholine receptors. [97], [98] and [99]

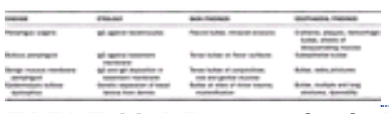

TABLE 63-1 Dermatologic Diseases with Esophageal Manifestations

Patients may be symptomatic, but at least 50% have esophageal involvement even if there are no symptoms. [100] Isolated esophageal involvement with no or minimal skin manifestations has rarely been reported. [101], [102] and [103] Endoscopy with biopsy is necessary to establish the diagnosis and to rule out other causes of esophageal symptoms (see Table 63-1). Complete sloughing of the esophageal mucosa (esophagitis dissecans superficialis) has rarely been reported. [104] Diagnosis is made by immunofluorescence microscopy, but this does not differentiate between idiopathic pemphigus vulgaris and drug-induced pemphigus. [99], [104], [105] Serologic testing for pemphigus antibodies and antibodies against desmoglein 3 support the diagnosis. [106]

Treatment of pemphigus vulgaris relies on the use of high-dose corticosteroids, but other immunosuppressive drugs (azathioprine, cyclophosphamide, cyclosporine, methotrexate) may be necessary to achieve a complete remission or as a steroid-sparing agent. [99] Plasmapheresis has been used successfully in severe cases. [99] A medication history should be sought for drugs associated with pemphigus, especially thiol compounds (e.g., penicillamine), angiotensin-converting enzyme inhibitors, and antibiotics (penicillins, rifampin, cephalosporins). [102]

Bullous Pemphigoid

Bullous pemphigoid is distinguished from pemphigus vulgaris by the presence of tense bullae with a predilection for the flexor surfaces. [99] Involvement of the oropharynx occurs in 20%. [107] The incidence of esophageal involvement in bullous pemphigoid is unknown and is likely underestimated because symptoms are infrequent, even in the presence of active disease. [107] The formation of bullae is the result of IgG autoantibodies directed against the basement membrane of the squamous epithelium and activation of the complement cascade. [99], [108] Immunofluorescence microscopy demonstrates linear deposits of IgG or C3 along the basement membrane of the involved epithelium. [108]

Esophageal involvement with bullous pemphigoid is usually asymptomatic, although rarely dysphagia and odynophagia occur. Massive upper GI hemorrhage has been reported. [109] Scarring, mucosal sloughing, and hemorrhage are rare. Treatment with prednisone is highly effective, but azathioprine, cyclophosphamide, cyclosporine, or methotrexate are sometimes required. [99]

Benign Mucous Membrane Pemphigoid

Benign mucous membrane pemphigoid (BMMP), also known as cicatricial pemphigoid, is a chronic blistering disease of the conjunctivae, oral mucosa, genital mucosa, and adjacent areas of skin. It occurs in late adulthood, usually after the sixth decade, producing tense blisters with scarring and strictures of the esophagus, trachea, anus, or vagina. [110] The pathogenesis of BMMP is idiopathic autoimmune deposition of IgG or IgA autoantibodies in the basement membrane zone, with specific antigens recently identified. [99], [111], [112]

Esophageal involvement in BMMP occurs in 2.3% to 13% of affected patients and can be seen initially or up to 10 years later in the course of the disease. Patients complain of dysphagia, odynophagia, and chronic cough resulting from aspiration. [113] Rarely, patients have been found with isolated esophageal BMMP with no other manifestations or with active esophageal disease without symptoms. [114] Esophagrams may show bullae as seen in bullous pemphigoid and epidermolysis bullosa dystrophica. More typical is the presence of webs and strictures, primarily of the cervical esophagus but also of the middle and lower esophagus (Fig. 63-4 and Fig. 63-5; see Color Fig. 63-5.). [115] Secondary manifestations include nasopharyngeal reflux, tracheal aspiration, and intramural pseudodiverticulosis. [115] Bullae are rarely seen endoscopically, but in one case endoscopy induced the formation of bullae. [114] Severe dysphagia may require dilation, which carries an increased risk of esophageal injury in these patients. [115] The medical management of severe BMMP requires prednisone, whereas milder cases respond to treatment with dapsone. [99] Surgical treatment has rarely been required. [116]

FIGURE 63-4. Benign mucous membrane pemphigoid. Postinflammatory scarring caused a long, irregular area of narrowing suggestive of a malignant process. (From Eisenberg RL. Gastrointestinal radiology: a pattern approach. 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003).

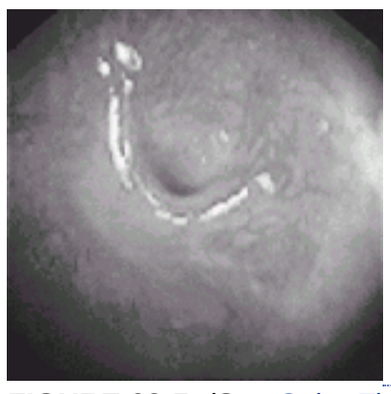

FIGURE 63-5. (See Color Fig. 63-5.) Benign mucous membrane pemphigoid. Also known as cicatricial pemphigoid, this endoscopic photograph depicts a tight esophageal stricture.

Epidermolysis Bullosa Dystrophica

Epidermolysis bullosa dystrophica is a rare inherited blistering condition primarily affecting squamous epithelium. Both dominant and recessive forms of the disease exist. Esophageal involvement is clinically important in the recessive form and is rarely seen in the dominantly inherited form. [117] The disease is produced by mutations in the collagen type VII gene (*COL7A1*). [118], [119] and [120]

Beginning in early childhood, cutaneous bullae are evident and form at sites of minor trauma. Histopathologically, there is a separation of the basal lamina from the underlying dermis. [121] This is caused by a marked reduction or absence of the anchoring fibrils that are normally present between the lamina densa and dermis. [121] The pathogenesis appears to be disordered transport or assembly of type VII collagen, which is absent from the anchoring fibrils in affected patients. [122] Healing is by scar formation. Over time, there are loss of hair and nails and formation of contractures and syndactyly by the scarring and healing process, a process termed *mummification.*

The same bullae formation and healing with scar formation occur in the esophagus as a result of the trauma of mastication and swallowing. The esophagus is involved primarily at the upper esophageal sphincter, carina, and distal esophagus. [123] Strictures, which are often multiple, are observed at all these sites, along with esophageal shortening and motility abnormalities. [123], [124] Dysphagia, pain with eating, and food impaction are the main symptoms in these patients and result from the strictures, bullae, or impacted food. [123], [124] Malnourishment is common, particularly in younger patients, and may necessitate the use of parenteral nutrition.

Owing to the striking cutaneous manifestations, the diagnosis of epidermolysis bullosa dystrophica is rarely difficult. Endoscopy should not be done in uncomplicated cases because of the risk of traumatic bullae formation. Barium esophagraphy is the test of choice and usually reveals typical strictures or webs (Fig. 63-6). [123], [124]

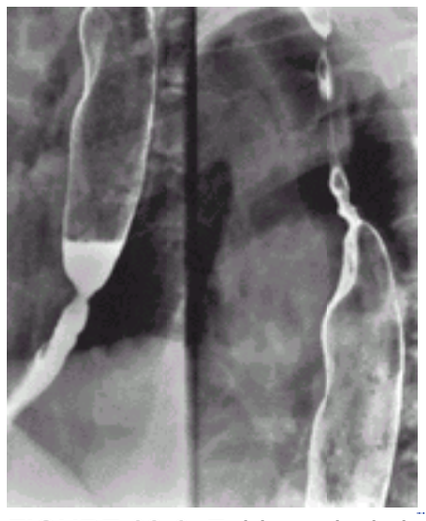

FIGURE 63-6. Epidermolysis bullosa dystrophica. Esophagram in patient with a recessive form of the disease demonstrating strictures of the proximal and distal esophagus.

The prognosis of esophageal involvement in epidermolysis bullosa dystrophica is poor. [123] Complications include esophageal perforation (which may be spontaneous or a result of therapeutic esophageal dilation) and complete occlusion. [123], [124] Patients should avoid coarse or hot foods. A pureed or nutritionally complete liquid diet may be necessary to avoid malnutrition. Medical management with corticosteroids or phenytoin is often used, but treatment failures are not uncommon. [123], [124], [126] Careful dilation of strictures with balloons or bougies may be successful, but there is an increased risk of esophageal trauma and perforation. [123], [127] In children, balloon dilation and intensive nutritional support may successfully relieve dysphagia and may lead to weight gain and overall clinical improvement. [128], [129] In patients with severe esophageal stenosis causing malnutrition or with esophageal perforation, esophagectomy and esophageal replacement, usually with colon interposition, should be performed, which improves dysphagia and nutritional status. [123], [126], [130]

An acquired form of epidermolysis bullosa (*epidermolysis bullosa acquisita*) may cause nonscarring bullous lesions of the esophagus. It is likely an autoimmune disease and has been seen in association with autoimmune thrombocytopenia and hypothyroidism and with Crohn's disease. [54], [131] In one case, circulating IgG anti-type VII collagen antibodies were identified. [132] Treatment is with steroids and dapsone. [131]

ESOPHAGEAL TRAUMA

Mallory-Weiss Syndrome

In 1929, Mallory and Weiss described patients with alcoholism who had retching and emesis followed by massive, in some cases fatal, upper GI hemorrhage caused by linear lacerations at the gastroesophageal junction. [133] Termed *Mallory-Weiss tears,* these lacerations account for 5% to 15% of upper GI bleeding episodes. [134], [135] and [136] The tears are nonpenetrating mucosal lacerations, 3 to 20 mm long and 2 to 3 mm wide, and are oriented along the long axis of the esophagus (Fig. 63-7; see Color Fig. 63-7). [137]

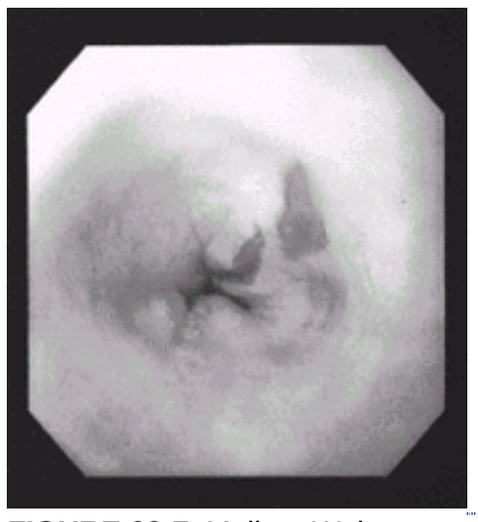

FIGURE 63-7. Mallory-Weiss tear. A nonpenetrating mucosal laceration occurred as a result of retching in a 53-year-old woman.

The pathogenesis of Mallory-Weiss tears involves the sudden rise of intra-abdominal pressure such as seen in vomiting, retching, and coughing. They are most commonly associated with alcoholic binges, but they may occur after retching or vomiting for any reason including the ingestion of emetogenic chemotherapeutic agents [135] or medical conditions such as diabetic ketoacidosis. [138] Mallory-Weiss tears may also occur as a result of seizures, hiccups under anesthesia, blunt trauma, straining at stool, asthma, heavy lifting, cardiopulmonary resuscitation, primal scream therapy, changes in air pressure, and complications of carbon monoxide poisoning. [140], [142] Mallory-Weiss tears rarely complicate upper endoscopy (0.5% of all endoscopies) and occur in patients with excessive retching or struggling during the procedure. [144] and [145] Nausea and vomiting from polyethylene glycol electrolyte lavage solutions used in preparation for colonoscopy have also been associated with Mallory-Weiss tears. [146], [147]

Hiatal hernias are found in a large proportion of patients with Mallory-Weiss tears and may be a risk factor. When the gastroesophageal junction is located above the diaphragm, a large pressure gradient between the intragastric and intrathoracic compartments may result in sudden dilation and laceration of the mucosa at the gastroesophageal junction. [137] An alternative hypothesis is that the tears are the result of prolapse of the stomach into the esophagus during retching. [137]

Patients with Mallory-Weiss tears present with upper GI bleeding. The classic presentation is of repeated, violent retching, vomiting, or coughing followed by hematemesis, although 40% of patients have no antecedent explanation for the tear, and 50% have hematemesis on first emesis. [135], [137] The syndrome can occur at any age, with a mean age at presentation in the 40s. [137], [139], [143] Male patients are affected more frequently (4:1) than female patients. [135], [137] Spontaneous cessation of bleeding is seen in 90%. [185], [186] However, a need for blood transfusion, endoscopic intervention, and surgery and up to a 12% mortality have been reported. [134], [135] Patients with portal hypertension and coagulation defects are at increased risk of bleeding from Mallory-Weiss tears and may have a poorer prognosis. [134], [148], [190] Twenty-seven percent of patients have multiple lacerations, and up to 77% have other associated upper GI lesions. [134], [135]

Endoscopy is the preferred modality for diagnosing and treating actively bleeding Mallory-Weiss tears. Endoscopic hemostasis has been achieved by the injection of anhydrous ethanol, polidocanol, or 1:10,000 epinephrine, cautery with multipolar coagulation or heater probe, or endoscopic band ligation. [135], [150], [151], [152], [153] and [154] Esophageal balloon tamponade may be successful but carries the considerable risk of extending the tear or rupturing the hiatal hernia. [136], [149] Surgery is occasionally required when bleeding cannot be controlled. [135] Vasopressin administered either systemically or by direct infusion into the celiac or left gastric artery has, in a few cases, been reported to control hemorrhage. [155], [156] Angiographic embolization has been used with success. [157] The long-term prognosis has not been well studied, but recurrences have been noted and may be related to continued alcohol abuse. [133], [135]

Esophageal Intramural Hematomas

Esophageal intramural hematoma (also termed esophageal apoplexy) is a rare but well-recognized clinical entity consisting of hematomas in the wall of the esophagus produced by local trauma. [158], [159], [160] and [161] Similar to Mallory-Weiss tears and Boerhaave syndrome, they typically occur in the setting of vomiting or retching, although spontaneous hematomas have occurred, particularly in patients with coagulopathies or undergoing treatment with anticoagulants or aspirin. [158], [159], [160], [161], [162], [163], [164] and [165] Iatrogenic hematomas have occurred after endoscopic sclerotherapy and cardioversion. [166], [167]

The pathogenesis is most likely mechanical injury to the esophageal wall from internal pressure (retching, coughing, or sneezing) or from blunt external trauma. [158], [159], [160] In several cases, there has been suspicion of esophageal damage from ingestion of a medication or foreign body. [168], [169] A history of a recent meal is also frequently noted. [170], [171] In most cases, an identifiable mucosal tear is present. [160]

Patients complain of the abrupt onset of substernal or epigastric pain followed by hematemesis. Dysphagia is present, and swallowing aggravates the pain. [158], [162], [168], [170] The amount of bleeding is usually not large, but up to 10% of patients require blood transfusions. [161], [170] In some cases, the degree of esophageal obstruction can be pronounced. [172]

Patients presenting with hematemesis and substernal chest pain should first undergo a chest radiograph to rule out perforation and then endoscopy. Typically, an esophageal mass with bluish or violet color protruding into the lumen is seen, associated with a mucosal tear. [160], [173], [174] Varying degrees of lumenal narrowing are present that can include complete esophageal obstruction. [172] An esophagram with a water-soluble contrast agent should be performed to rule out esophageal perforation before endoscopy. [172] The esophagram shows a filling defect in the esophagus as the most common abnormality, but leiomyoma, carcinoma, and metastatic disease can have similar radiographic appearances. [175] Computed tomography with contrast or magnetic resonance imaging may reveal a nonenhancing esophageal mass that has the density of blood. [163], [165], [168], [174], [175] and [176] Endoscopic ultrasound shows an intramural hypoechoic submucosal mass. [174]

Most patients respond well to conservative management and have complete resolution in 2 to 3 weeks with no long-term sequelae. [170] Aspiration precautions should be observed, but parenteral nutrition is rarely needed because most patients are able to swallow within a few days. Blood transfusion is sometimes required. Surgery is needed in 19% of cases to control bleeding or repair perforations. [170] Patients should be monitored for the development of fever or pleural effusions indicating an esophageal perforation not detected during the initial evaluation. [175]

Esophageal Injury and Rupture

Esophageal perforations and ruptures are life-threatening injuries that require prompt surgical intervention. Perforation is most commonly iatrogenic after instrumentation of the esophagus, but it may be secondary to external trauma or may occur spontaneously (Boerhaave syndrome). Esophageal rupture affects all age groups, with a mean age of 28 to 43 years, and it lacks a gender or race predominance. [177] Although diagnosis may sometimes be difficult, successful management depends on early diagnosis and intervention.

Medical instrumentation is the most common cause of esophageal perforation, accounting for at least half of all cases. [177], [178] and [179] Iatrogenic rupture is a well-recognized complication of rigid and flexible endoscopy and of therapeutic esophageal dilation. [177] It is most commonly seen after bougie or balloon dilation of benign and malignant strictures or for treatment of achalasia. [180], [181], [182], [183] and [184] Perforation has also been seen after placement of nasogastric tubes, erroneous inflation of a gastric balloon in the esophagus, sclerotherapy, and balloon tamponade for bleeding esophageal varices and as a complication of anesthesia. [177], [185], [186]

Both penetrating and blunt trauma to the neck, chest, and upper abdomen may cause esophageal perforation. Penetrating knife and gunshot wounds in these areas should raise the suspicion of esophageal injury. [187], [188] Blunt thoracoabdominal and cervical trauma may result in perforation of the midthoracic or cervical esophagus (less commonly the distal esophagus), most likely caused by rapid changes of the esophageal transmural pressure and rapid increases of intrathoracic pressure

against a closed glottis. [177], [189], [190], [191] and [192] The degree of associated trauma may be severe, as from blast and crush injuries, or more innocuous, as from assault, child abuse, or the Heimlich maneuver. [189], [190], [191], [192], [193], [194] and [195]

Spontaneous transmural rupture of the esophagus was first described in 1724 by Herman Boerhaave. His patient, Baron von Wassenauer, died suddenly after severe retching and was found at autopsy to have an esophageal rupture and food contaminating the thorax. [196] Boerhaave syndrome was largely a pathological curiosity diagnosed at autopsy until Barrett's first successful surgical repair in 1946. [197] As with Boerhaave's original patient, most patients have antecedent retching and vomiting, although any maneuver that transiently raises the intra-abdominal pressure may result in rupture. [198], [199] Esophageal rupture from vomiting caused by colonoscopy preparation has also been described. [200] Ninety percent of spontaneous ruptures occur in the distal esophagus, with more than two thirds on the left side, where studies have demonstrated an anatomic weakness of the left posterolateral aspect of the esophagus just above the diaphragm. [199], [201] The normal esophagus lacks a serosa, making it more prone to rupture than other parts of the GI tract. [198] In addition, some patients with spontaneous rupture have been found to lack a muscularis mucosae, which may make them anatomically predisposed to Boerhaave syndrome. [202] Recurrent spontaneous esophageal rupture has been reported. [203]

The clinical manifestations of esophageal perforation depend on the extent, acuity, and cause of the rupture. Iatrogenic perforations may remain asymptomatic for up to 8 hours in as many as 50% of patients. [177] Upper esophageal perforations may be accompanied by chest pain, dysphagia, odynophagia, nausea, vomiting, hoarseness, or aphonia. [177] Lower esophageal perforations may also cause abdominal pain, pneumothorax or hydropneumothorax (usually on the left side), and pneumomediastinum. Hematemesis (seldom severe) is noted in 55%. [198], [199], [200], [201], [202], [203] and [204] The classic Mackler triad of vomiting, chest pain, and subcutaneous emphysema in patients with spontaneous rupture should not be relied on, because it is found in only one third of patients with Boerhaave syndrome. [205], [206] and [207] Two patients with early spontaneous esophageal rupture had intense thirst for small sips of cold water, and this may be an early clue to the diagnosis. [208]

On physical examination, patients appear acutely ill with tachypnea and tachycardia. Fever may or may not be present. Sudden massive esophageal rupture may be dramatic, presenting with tension pneumothorax, hypotension, and shock. [205], [207], [209] Subcutaneous emphysema is present in 30% of patients. [210] Auscultation may reveal absence or reduced breath sounds on the side of the perforation if there is pleural involvement. Hamman sign (mediastinal crunch) may be noted in patients with mediastinal air. This mediastinal crackling occurs with each heartbeat and has been likened to the sound of boots walking through dry snow. It is best appreciated with the patient lying in the left lateral decubitus position.

The diagnosis of esophageal rupture requires a high index of suspicion. Early diagnosis and treatment are mandatory to avoid the high mortalities associated with patients presenting beyond 24 hours from the rupture. [204], [207] Misdiagnosis and treatment delays occur in more than 50% of patients with spontaneous rupture. [205], [211] Corticosteroid use may mask the symptoms of esophageal perforation, leading to delays in diagnosis. [212] The differential diagnosis includes pulmonary embolus, myocardial infarction, aortic dissection, Mallory-Weiss laceration, esophageal intramural hematoma, spontaneous pneumothorax, pneumonia, lung abscess, pericarditis, pancreatitis, strangulated diaphragmatic hernia, and perforated peptic ulcer. [198], [213] Chest and abdominal radiographs usually suggest the presence of a perforation by demonstrating subcutaneous emphysema, pneumomediastinum, mediastinal widening or air-fluid level, pleural effusion, pneumothorax, hydropneumothorax, or air in the peritoneal cavity. [198], [199] A completely normal chest radiograph is present in fewer than 5% of patients, although in fewer than one third of patients is the radiograph diagnostic of esophageal rupture. [214] Esophagrams employing water-soluble contrast (e.g., Gastrografin) with multidirectional views are diagnostic in most cases. [177], [198], [199] If these are negative, a barium esophagram should be obtained to provide better definition. If an esophagram cannot be obtained (e.g., uncooperative or severely ill patient), a noncontrast computed tomography scan may be useful in identifying minute amounts of air and oral contrast in the pleural space and in the evaluation of the mediastinum, pleura, and aorta. [198] However, computed tomography does not allow for localization of the exact site of perforation. [215] Flexible upper endoscopy is a highly accurate modality and has been advocated in patients with suspected blunt or penetrating esophageal trauma. [216], [217] Disadvantages of endoscopy include missing small defects and the risk of extending the perforation.

Complications of esophageal perforation include tension pneumothorax and infection. The diagnosis may be delayed for several days until the patient develops fever, mediastinitis, pleural effusion, empyema, or sepsis. Examination of the pleural fluid reveals an exudate with a pH as low as 6.0 owing to a combination of gastric acid refluxed through the defect and the metabolism of leukocytes. [218] The pleural fluid amylase is elevated and may raise the suspicion of pancreatitis with pancreaticopleural fistula. The pleural fluid amylase in esophageal rupture is of salivary origin, and obtaining isoenzyme levels may aid in the diagnosis. [219] Bacterial infection of the pleural fluid, empyema, is common, and both clostridial myonecrosis of the chest, and invasive candidiasis have been reported. [220], [221]

Treatment of both spontaneous rupture (Boerhaave syndrome) and traumatic perforation is primarily surgical. All patients should take nothing by mouth, and broad-spectrum antibiotics should be administered. Aggressive resuscitation and cardiopulmonary support may be needed. Specific therapy depends on the site of the rupture, the cause, the length of time between the perforation and the diagnosis, and the overall health status of the patient. Small cervical perforations can be treated with antibiotics and without surgery or with surgical drainage of the neck without esophageal repair. [222] Free intrathoracic perforations are treated aggressively with debridement and irrigation of the mediastinum, followed by primary closure of the defect. [223], [224] In patients operated on early, the mortality is less than 10%, but this rate triples in those treated more than 24 hours later. [225] Nonetheless, most authors recommend surgery with primary esophageal repair even in patients with a delayed diagnosis. [223], [224], [225], [226], [227] and [228] Children do particularly well, with less than a 5% mortality. [229] Esophagectomy is rarely required. It is primarily indicated when the diagnosis has been delayed and infectious complications have ensued, but it also may be indicated in patients with distal esophageal obstruction who have suffered iatrogenic perforation. [181], [230] Patients with perforation caused by endoscopy with dilation do well, with very low mortalities owing to prompt diagnosis and treatment, although recurrent dysphagia is common. [231] Nonoperative management of thoracic esophageal ruptures may be successful in selected cases. [198], [214], [232], [233] Minimally invasive interventions, such as thorascopic repair of the ruptured esophagus and endoscopic repair of a small dilation-induced perforation using metal clips, have been described. [234], [235] The use of covered expandable metal stents to treat esophageal perforation successfully has been reported. [236], [237], [238], [239] and [240] Although stents may be useful in patients with significant comorbidity (e.g., cancer), they are generally not removable and should not be used in patients who are otherwise operative candidates.

PILL ESOPHAGITIS

Epidemiology

The incidence of *pill esophagitis* is estimated to be 0.004% per year and ranges from 0.04% for alendronate to 20% or more for nonsteroidal antiinflammatory drugs (NSAIDs). [241], [242] and [243] More than 700 cases involving more than 70 different substances (Table 63-2) have been documented, although most cases have been caused by tetracyclines, potassium chloride, and quinidine. [244], [245]

Nonsteroidal antiinflammatory drugs (including aspirin)
Tetracyclines (including doxycycline)
Quinidine
Emepronium
Papain
Bisphosphonates (alendronate, pamidronate, etidronate)
Potassium chloride and citrate
Isotretinoin
Theophyllines
Oxybutynin
Captopril
Ascorbic acid
Iron preparations
Penicillins
Sodium valproate
Cromolyn sodium
Clindamycin
Chloral hydrate
Rifampin
Zidovudine, Zalcitabine
Alprenolol

TABLE 63-2 Medications Implicated in Pill Esophagitis

The risk of pill esophagitis appears to be related to patient, esophageal, and drug factors. Activities that increase the risk include lying down immediately after

ingesting the agent and the lack of adequate oral intake after medication ingestion to ensure prompt delivery of the drug into the stomach. Esophageal factors include dysmotility of the esophagus (e.g., achalasia and presbyesophagus) or mechanical narrowing of the esophagus (i.e., an esophageal stricture or extrinsic compression). Drug factors include intrinsic caustic characteristics of the medication and systemic effects, such as with NSAIDs.

Elderly patients are at increased risk of pill esophagitis resulting from more frequent use of high-risk medications (NSAIDs, potassium, quinidine, iron), an increased prevalence of esophageal dysmotility, and decreased salivation. However, esophageal medication-induced injury may occur at any age. Esophageal transit of standard-size medication tablets can be as long as 5 minutes in 50% or more of healthy persons (Fig. 63-8; see Color Fig. 63-8.). [246], [247] and [248] This was especially true with capsules or sticky tablets because of adherence to the esophageal wall, whereas nonadherent tablets ingested with adequate fluid while the patient is in an upright position usually pass through the esophagus without delay. [245] Transit is also delayed if pills are taken when the patient is supine or without sufficient (=15 mL) of fluid. Women have been injured twice as frequently as men in reported cases, probably because women are more likely to be treated with high-risk medications such as alendronate, antibiotics, NSAIDs and emepronium bromide (used for bladder irritability). [249]

FIGURE 63-8. (See Color Fig. 63-8.) Dissolution of a medication in the midesophagus.

Pathogenesis

The pathogenesis of pill esophagitis generally involves prolonged, direct contact of the medication with esophageal mucosa. Some substances (quinidine, potassium) act directly as caustic substances, whereas others (tetracycline, ferrous sulfate) probably injure the esophageal epithelium as a result of their acidic pH, alkaline pH, or hyperosmolarity on dissolution. [250] Other agents (NSAIDs) appear to be absorbed by the esophageal mucosa and injure the mucosa from within. [243]

Sites within the esophagus at greatest risk are the middle and distal thirds. The middle third is at risk because of extrinsic compression by the left atrium and aortic arch that slow transit and increase contact time with the medication. However, the greatest incidence of pill esophagitis occurs in the distal, acid-exposed region of the esophagus related to concomitant acid reflux, as demonstrated by injury from NSAIDs and other drugs. [251] The most commonly encountered agents are detailed in Table 63-3.

AGENT (REFERENCE)	MECHANISM	ENDOSCOPIC FINDINGS
Bisphosphonates (254,257)	Direct chemical injury	Ulceration, exudate
Tetracyclines (250,258)	Acidic pH, inhibition of protein synthesis	Mild ulceration
Quinidine (250,259)	Direct chemical injury	Severe inflammation with stricture formation
Potassium (249,250)	Hyperosmolar injury	Severe inflammation
Nonsteroidal anti-inflammatory drugs (241,243, 251, 260)	Intracellular damage, prostaglandin inhibition	Distal erosive esophagitis

TABLE 63-3 Common Medications Associated with Pill Esophagitis

Symptoms

Patients with medication-induced esophageal injury usually complain of retrosternal chest pain, odynophagia, and dysphagia. [250] Pain and odynophagia are found in nearly all cases, and they may be severe enough to inhibit adequate oral intake of fluids leading to dehydration. Dysphagia is less common, usually is related to ulceration, and is rarely indicative of a stricture in this clinical situation. Patients may rarely present with hematemesis or other signs of upper GI hemorrhage. Even more unusual is a presentation of perforation with signs of sepsis, mediastinitis, or shock. [244]

Diagnosis

The diagnosis of pill esophagitis is based on the typical history of medication ingestion, risk factors, and symptoms. When confirmation the diagnosis is required, because of atypical or persistent symptoms, endoscopy is the most sensitive test. Endoscopy usually demonstrates erosions or ulcers, usually in the middle or distal third of the esophagus. Focal epithelial damage sparing the distal esophagus is nearly pathognomonic of pill esophagitis and effectively excludes gastroesophageal reflux as a cause of the esophagitis. Strictures or evidence of hemorrhage are rarely observed. If a stricture is found, it more likely is the cause of the esophagitis (pills lodging at that site) than a result of the esophagitis. Air contrast barium radiography demonstrating discrete ulcers in the midesophagus is suggestive of drug-induced esophagitis, although it is nonspecific. [252], [253], [260]

Prevention and Treatment

Adequate patient education is key to the prevention of medication-induced esophageal injury. Patients should be instructed to ingest medications in an upright position, to consume at least 100 mL of fluid at the same time, and to remain upright for 15 to 30 minutes after ingestion. Pills frequently implicated in esophageal injury should be avoided in bedridden patients and in those with esophageal compression, stricture, or dysmotility. [249]

Treatment of pill esophagitis is nonspecific and empiric. Most patients resolve their symptoms and heal mucosal lesions rapidly within days to weeks of withdrawal of the offending agent. [245] However, some patients have such severe symptoms that intravenous fluids or dietary modifications are needed to avoid dehydration and malnutrition. Although there are no data documenting the efficacy of antisecretory therapy (H_2-receptor antagonists, or proton pump inhibitors), the use of these agents can be supported to protect esophageal mucosa further from injury related to physiological or pathological reflux of gastric contents. Whether other mucosal “healing” agents, such as sucralfate suspension, are of benefit in treating pill esophagitis is unknown.

CORROSIVE ESOPHAGITIS

Epidemiology

There are more than 26,000 cases of *ingestion of corrosive substances* per year in the United States, and 17,000 or more of these cases occur in children. [261] Fifty percent of childhood ingestion cases occur in children less than 4 years of age. In children, corrosive esophageal injury usually represents accidental ingestion,

whereas most ingestions in adolescents and adults represent suicide attempts. Industrial accidents involving more concentrated agents continue to account for a small percentage of cases of corrosive esophagitis. Overall, ingestion of corrosive substances remains a leading cause of pediatric death in both developed and developing nations. Nearly one half of caustic ingestions injure the esophagus, frequently resulting in serious long-term sequelae. [261, 262]

Pathogenesis

In general, alkaline substances (lye, detergents) produce a greater depth of injury than acidic substances. [261, 263] A review of 115 Danish children hospitalized over an 18-year period revealed complications only in those ingesting strong alkali agents such as lye, whereas detergent ingestion (a weak alkali) caused a complication in only a single case. [264] Conversely, in Finland, where lye has not been available to the public for 30 years, 56 of 98 children treated over a 14-year period for caustic ingestion had ingested dishwashing detergent. [262] The severest location of caustic injury generally occurs in the narrowest portion of the esophagus, usually the midesophagus in the region of the aortic arch.

Alkaline substances tend to injure the esophageal mucosa more severely than acids because of the rapidity of the injury (seconds) and the nature of the injury (liquefaction necrosis). Previous studies have shown that the requisite pH for esophageal injury is 12.5 (0.4% sodium hydroxide has a pH of 13). [261] The severity of injury is dependent both on concentration and on mucosal contact time. Liquid lye is more injurious than the granular or nonalkaline corrosives because the granules often adhere to the mucous membranes of the mouth, thereby preventing further movement of lye into the esophagus. Nonalkalines or acidic corrosives produce coagulation necrosis and eschar formation, which protects the deeper esophageal epithelial layers from further injury. As with alkalis, the concentration of the acidic agent determines the degree of injury. Acidic substances are also cleared by esophageal peristalsis and are neutralized by swallowed salivary bicarbonate, further limiting their ability to injure the esophagus. [261] Pathologically, within 10 days of caustic esophageal injury, granulation tissue begins to replace the necrotic epithelium, and by 21 days fibroblasts are producing epithelial strictures.

Diagnosis

The diagnosis is usually based on history as well as physical findings. However, symptoms (vomiting, dysphagia, abdominal pain, oral mucosal injury) do not directly correlate with endoscopic findings, leading some to recommend that all patients with evidence of ingestion manifested by either symptoms of injury or physical findings involving the mouth should have endoscopy to stage the esophageal injury. [261, 263, 264] Asymptomatic patients are not at risk for further complications and do not require a staging endoscopy. [264]

Common findings on endoscopy, after caustic ingestion, include edema, hemorrhage, epithelial sloughing, and ulceration (Fig. 63-9; see Color Fig. 63-9.). Unfortunately, these endoscopic findings are not reliable in predicting the depth of injury. Nevertheless, some investigators have classified endoscopic esophageal injury as being first degree (superficial injury manifested by erythema), second degree (deeper injury manifested by ulceration), and third degree (penetration of injury through the esophageal wall and manifested by necrosis). Endoscopic ultrasound may provide better determination of the depth of injury and may prove to be adjunctive or even superior to endoscopy in staging caustic esophageal injury. [265] Plain abdominal or chest radiographs may reveal evidence of pleural fluid, mediastinitis, or frank perforation indicating severe esophageal injury. Barium swallow may demonstrate esophagitis, gastric abnormalities, and poor distention. [267]

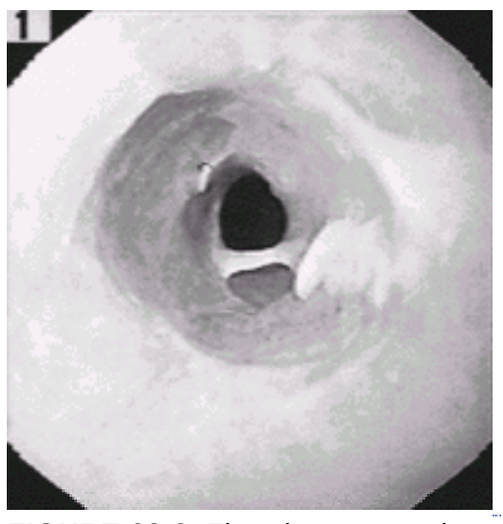

FIGURE 63-9. First-degree esophageal injury after alkali caustic ingestion with sloughing of the superficial mucosa without ulceration.

Long-term sequelae of caustic ingestion include formation of an esophageal stricture, which is usually long and rigid and is most commonly found at the region of the aortic arch. Distal esophageal peristalsis may be adversely affected, [266] and may result in decreased esophageal clearance of refluxate leading to esophagitis and a peptic stricture that would otherwise not occur. Stricture after caustic ingestion occurs only in patients with more severe injury (second and third degree) and is more likely in those with circumferential injury.

Symptoms

The esophageal symptoms of caustic ingestion include abdominal pain, retrosternal chest pain, dysphagia, and odynophagia. These symptoms usually last days to weeks and can be accompanied by other nonesophageal symptoms such as refusal to drink and increased salivation in children who are unable to describe their symptoms further. Late symptoms related to caustic ingestion include dysphagia and food impactions related to esophageal stricture.

Association with Cancer

Squamous cell esophageal cancer is estimated to be a thousandfold more common in patients having suffered caustic injury of the esophagus than in the general population. [261] The mean delay between the time of the caustic ingestion and the onset of the carcinomas is approximately 50 years. Because of the marked increased incidence of cancer in these patients, yearly endoscopic surveillance beginning 20 years after caustic esophageal injury has been recommended, although there is no outcome study showing the value of endoscopic and biopsy surveillance in this situation, and whether biopsy or cytology is useful in detecting early esophageal cancer is unproven. However, routine endoscopic biopsy of normal-appearing mucosa or biopsies guided by tissue staining with Lugol solution may increase the detection of dysplasia or early cancer and can be justified in this clinical situation.

Treatment

There is no value in attempting removal of the caustic substance by inducing vomiting, lavage, or other neutralizing attempts. In fact, those manipulations have the potential for inducing further mucosal damage. [261]

Steroids have been the most extensively investigated palliative modality. [268, 269] Steroid use remains controversial in the treatment of caustic esophageal injury because there have been no well-designed placebo-controlled trials showing an advantage of steroids over placebo treatment. Despite this, many authors continue to advocate the use of steroids in clinical practice. In a review of 13 publications of 361 patients, Howell and colleagues [269] calculated a 19% stricture rate in those treated with steroids versus a 41% rate in those not receiving treatment. Stricture never occurred in either group in patients with only first-degree esophageal burns, but it was significantly reduced in those with advanced injury who received steroids. A retrospective review of data suggested that dexamethasone (1mg/kg/d) is superior to prednisolone (2 mg/kg/d) in this setting. [268] Given that concomitant reflux may also contribute to stricture formation, antisecretory agents, such as proton pump inhibitors, should probably be given. [270]

Chronic strictures secondary to caustic esophagitis should be dilated, and approximately one third to one half of these patients will respond to this treatment. Placement of a gastrostomy has been advocated to facilitate so-called endless-loop bougienage in which a continuous string loop with plummets of progressively larger size is positioned to be passed through the mouth and esophagus to the gastrostomy. [271] Patients with severe strictures not responding to dilation require surgical therapy, most commonly with a colonic interposition. [270], [272], [273]

CHAPTER 64

Jean-Pierre Raufman

STOMACH: ANATOMY AND STRUCTURAL ANOMALIES

ANATOMY OF THE STOMACH AND DUODENUM

As with most organs, the gross anatomy and microscopic anatomy of the stomach and duodenum are intrinsic to their function. Because in this case function relates primarily to digestion and nutrition, the structure and organization of these organs facilitate sequential physiological events that promote the fragmentation, enzymatic digestion, and absorption of nutrients. Moreover, appropriately timed autocrine, paracrine, and hormonal secretions of gastric and duodenal endocrine cells recruit other cells and organs to the digestive process. Our understanding of these complex integrated physiological events, which include secretory, peristaltic, and absorptive actions, remains incomplete. In this chapter, the anatomy and structural anomalies of the stomach and duodenum are considered together because these organs are structurally and functionally related.

Gross Anatomy

Anatomic Relationships and Divisions The stomach, a large, distensible bag with the largest diameter of any part of the gastrointestinal tract, is located in the mid-upper abdomen, just beneath the diaphragm (Fig. 64-1). The size and shape of the stomach vary greatly from person to person, depending on age, body habitus, posture, and interval since eating. The ability of the stomach to enlarge and to accommodate to meals is facilitated by its free mesentery and its distensibility, as well as location because its dilation is not constrained by other abdominal organs. Although fixed proximally to the esophagus and distally to the duodenum, and by the gastrocolic and gastrophrenic ligaments, the stomach has great latitude in distention and motion. When the stomach is nearly empty, gastric volume approximates a few hundred milliliters; when distended with food, the stomach can accommodate 2 L. The full stomach may reach from the diaphragm to the pelvic brim.

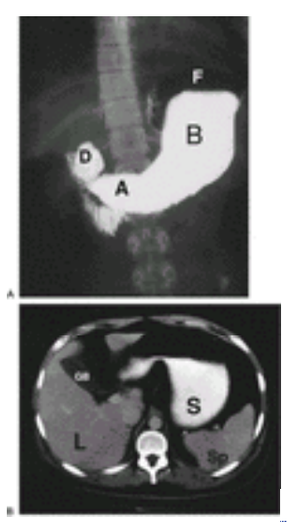

FIGURE 64-1. (**A**) Barium contrast radiograph of the stomach and duodenum (*F,* fundus; *B,* body; *A,* antrum; *D,* duodenal bulb). The pyloric channel can be seen connecting the antrum to the duodenal bulb. The second and third parts of the duodenum can be seen as well as the plicae circulares. (**B**) A computed tomogram of the abdomen shows the stomach in relation to adjacent organs. *S,* stomach; *GB,* gallbladder; *L,* liver; *Sp,* spleen. (Courtesy of Drs. Timothy Carter and Hemendra R. Shah, University of Arkansas for Medical Sciences, Little Rock, AR.)

In consequence of its size and central location in the abdomen, the stomach abuts many organs. These include the diaphragm superiorly, the liver and biliary tree to the right, the spleen to the left, and the pancreas and transverse colon posteriorly (see Fig. 64-1). The anterior surface of the stomach approximates the abdominal wall. The stomach is separated from these organs by the peritoneal lining. By convention, the somewhat J-shaped stomach is divided into the following: the cardia, a 1- to 2-cm segment adjacent to the esophagogastric junction; the fundus, the superior portion of the stomach lying above and slightly posterior to the rest of the stomach; the body or corpus, the voluminous portion of the stomach below the fundus; the antrum, the distal region of the stomach; and, finally, the pylorus or pyloric channel, a narrow (1- to 2-cm) channel that connects the stomach to the duodenum (Fig. 64-2). The shorter, right side of the stomach is the lesser curvature; the opposite, longer left side is the greater curvature. An intrusion, about two thirds of the way along the distal lesser curvature, near the junction of the body and antrum, is designated the angular notch or incisura angularis.

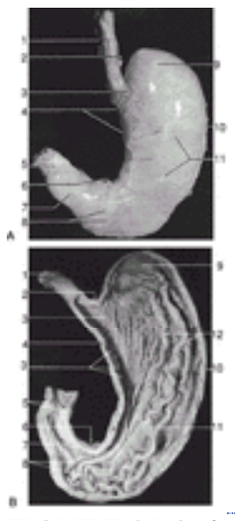

FIGURE 64-2. (**A**) Ventral aspect of the exterior of the stomach. (**B**) Ventral aspect of the posterior mucosa of the stomach. *1,* esophagus; *2,* cardiac notch; *3,* cardiac part of the stomach; *4,* lesser curvature; *5,* pyloric sphincter; *6,* angular notch; *7–8,* antrum; *9,* fundus; *10,* greater curvature; *11,* body (corpus); *12,* gastric folds (rugae). (From Rohen JW, Yokochi C. Color atlas of anatomy. New York: Igaku-Shoin, 1993.)

The tubular, C-shaped duodenum, nestling the head of the pancreas, starts at the pylorus and extends to the ligament of Treitz (Fig. 64-3). The word *duodenum* derives from its length, approximately the same as the breadth of 12 fingers (about 25 to 30 cm). The duodenum has no mesentery, and, in contrast to the stomach, it is largely retroperitoneal and fixed in position.

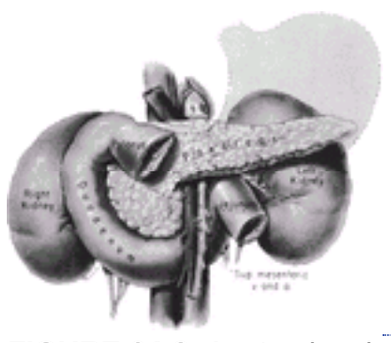

FIGURE 64-3. Anatomic relationships of the four parts of the duodenum to adjacent organs. The stomach is shown in outline. (From Rosse C, Gaddum-Rosse P. Hollinshead's textbook of anatomy. Philadelphia: Lippincott–Raven, 1997.)

The first, or superior, part of the duodenum is about 5 cm long, starts at the pylorus, and passes posteriorly, upward, and to the right. The initial 2 to 3 cm of the first part is the duodenal bulb. In contrast to the rest of the duodenum, which is lined by circular folds (plicae circulares), the lining of the bulb is relatively flat. The second, or descending, part of the duodenum takes a sharp curve and descends along the head of the pancreas for 7 to 10 cm. The common bile and pancreatic ducts, together or separately, enter the medial aspect of the second part of the duodenum at the posteromedial ampulla of Vater (Fig. 64-4). The accessory pancreatic duct (Santorini) enters the duodenum approximately 2 cm proximal to the ampulla (see Fig. 64-4). The third, or horizontal, part of the duodenum passes from right to left across the spine, inclining upward about 5 to 8 cm. The final, fourth, or ascending part of the duodenum starts left of the spine, ascends leftward, and terminates at the ligament of Treitz, where the intestine angles anteriorly and downward as the jejunum.

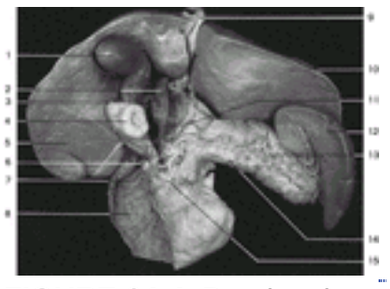

FIGURE 64-4. Duodenal papillae. The liver is slightly reflected upward. The duodenum (*8*) has been opened, and the pancreatic duct (*13*) has been dissected. A probe identifies the minor duodenal papilla (*6*), which is about 1.5 cm above the major papilla (probe, *7*). *1,* gallbladder; *2,* common hepatic duct; *3,* cystic duct; *4,* pylorus (cut); *5,* right lobe of liver; *9,* ligamentum teres; *10,* left lobe of liver; *11,* proper hepatic artery; *12,* spleen; *14,* pancreas; *15,* duct of Wirsung. (From Yokochi C, Rohgen JW, Weinreb EL. Photographic anatomy of the human body. New York: Igaku-Shoin, 1989.)

Circulation Gastric and duodenal blood supply derive from the celiac artery and the superior mesenteric artery (SMA). Both vessels arise from the abdominal aorta. The short celiac artery branches to form the splenic, left gastric, and common hepatic arteries. A dense anastomotic network that encircles the stomach is formed by vessels that branch from these major arteries. These vessels include the following: the left gastric artery, which feeds the anterior and superior portions of the stomach; the right gastric, gastroduodenal, and right gastroepiploic arteries, which arise from the hepatic artery and feed the lower right portion of the stomach and the lower greater curvature; and the short gastric and left gastroepiploic arteries, which arise from the splenic artery to feed the fundus and the upper greater curvature. The distal stomach, pylorus, and duodenum are supplied by the inferior pancreaticoduodenal branch of the SMA (see Fig. 64-3). The duodenum is also nourished by the right gastric and superior pancreaticoduodenal arteries that arise from the hepatic artery. Venous drainage from the stomach and duodenum leads directly or indirectly to the portal vein. From the stomach, the left and right gastric veins drain the lesser curvature, and the right and left gastroepiploic and short gastric veins drain the greater curvature. From the duodenum, the anterior inferior and superior pancreaticoduodenal veins drain into the superior mesenteric vein (see Fig. 64-3). The posterior superior pancreaticoduodenal vein drains directly into the portal vein.

Lymphatics The pattern of lymphatic drainage of the stomach is similar to that for its vasculature, with most lymph draining ultimately into celiac nodes. Submucosal, muscular coat, and serosal lymphatics join to drain into four major groups from the stomach and two from the duodenum. The first group of gastric lymphatics follows the left gastric artery, receives branches from the upper stomach, and ends in the superior gastric nodes surrounding the gastroesophageal junction. The second group drains the fundus and proximal stomach, follows the short gastric and left gastroepiploic arteries, and ends in the pancreaticolienal and splenic nodes, which drain into celiac nodes. The third group drains the distal greater curvature into inferior gastric nodes connected to subpyloric nodes. The final group of gastric lymphatics drains the pyloric area into superior gastric, hepatic, and subpyloric nodes. In the duodenum, anterior and posterior lymphatics drain into a series of small pancreaticoduodenal nodes near the boundary between the pancreas and duodenum. Efferents from these lymph nodes run superiorly and inferiorly to hepatic and pancreatic nodes, respectively, and to preaortic (superior mesenteric) nodes near the origin of the SMA.

Innervation The stomach and duodenum are innervated by sympathetic and parasympathetic neurons that comprise the autonomic nervous system. Sympathetic neuron cell bodies are located in the gray matter of the anterior columns of spinal thoracic segments T6 to T12; those innervating the stomach arise primarily from T7 and T8. Neural axons exit the spinal cord by the ventral roots and unite to form the greater and lesser splanchnic nerves that synapse in the celiac ganglia. Postganglionic fibers follow the hepatic, splenic, and left gastric arteries to the stomach, where they form perivascular intramural autonomic plexuses. Gastric afferent fibers follow the same course as efferent fibers; they pass through the celiac ganglia without synapsing, however, thereby reaching cell bodies in dorsal root ganglia of the spinal cord. Afferent fibers transmit visceral pain sensation from the stomach and duodenum. The vagus nerve, originating in the dorsal motor nucleus of the medulla, provides parasympathetic innervation to the stomach and duodenum. Vagal fibers course along the esophagus and enter the abdomen as the posterior and anterior vagal trunks. These neural trunks contain preganglionic efferent and visceral afferent fibers. Efferent fibers synapse with gastric cholinergic and peptidergic neurons in the wall of the stomach and duodenum that innervate various cells directly. Although afferent vagal fibers predominate, little is known about their function. After entering the abdomen at the esophageal hiatus of the diaphragm (Fig. 64-5), the anterior vagal trunk divides almost immediately into anterior gastric and hepatic branches. The anterior branch innervates the cardia and provides a branch running to the right of the lesser curvature as the anterior nerve of Latarjet. The hepatic branch innervates the liver, gallbladder, pylorus, and proximal duodenum. The posterior vagal trunk divides into celiac and posterior gastric branches. The former innervates the pancreas and other abdominal viscera. The posterior gastric branch innervates both surfaces of the stomach and forms the posterior nerve of Latarjet. The anterior and posterior nerves of Latarjet proceed along the lesser curvature, give off branches to the fundus and body, and terminate in a crow's foot neural distribution to the antrum and pylorus.

FIGURE 64-5. Distribution of the anterior (**left**) and posterior (**right**) vagal trunks. (**Left**) The anterior vagal trunk separates into (*a*) a principal branch along the lesser curvature of the stomach, (*b*) a branch that runs through the lesser omentum to reach the pyloric end of the stomach, and (*c*) a branch running higher in the lesser omentum to join the hepatic plexus. The unlabeled branch at the top innervates the liver, gallbladder, and pancreas. (**Right**) The posterior vagal trunk (seen through the stomach) separates into (*a*) a major branch along the posterior lesser curvature and (*b*) a branch to the celiac plexus. (From Rosse C, Gaddum-Rosse P. Hollinshead's textbook of anatomy. Philadelphia: Lippincott–Raven, 1997.)

Preganglionic vagal fibers synapse with ganglia in the intrinsic plexuses of the gastric wall: the myenteric (Auerbach) plexus, and the submucosal (Meissner) plexus. Postganglionic fibers from these plexuses innervate secretory and muscle cells.

Microscopic Anatomy

The stomach and duodenum have four tissue layers: mucosa, submucosa, muscularis propria, and serosa. The submucosa re- presents a connective tissue layer beneath the mucosa that is composed of a loose framework containing vasculature, lymphatics, and nerves. The muscularis propria of the stomach consists of a series of three muscle layers between the submucosa and the serosa (Fig. 64-6). The oblique muscle layer overlies the submucosa. The more substantial circular muscle layer, which thickens at the pylorus to form the pyloric sphincter, is covered by an outer longitudinal muscle layer that is a feature of the muscularis propria of the entire gastrointestinal tract. The thin serosa, the outer layer of the stomach that serves as the visceral peritoneum, is composed of areolar tissue covered by a monolayer of squamous mesothelial cells.

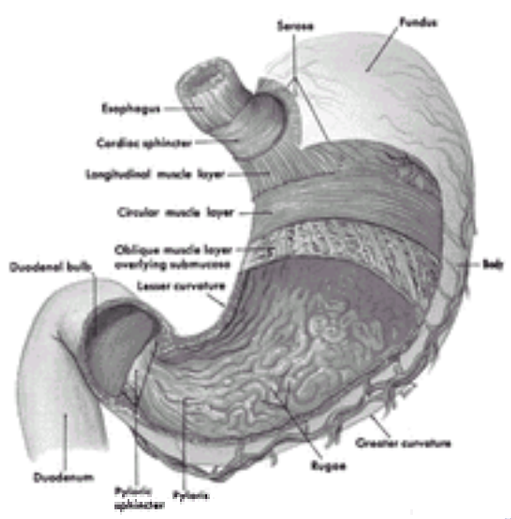

FIGURE 64-6. Muscle layers and rugal folds of the stomach. (From Thibodeau GA, Patton KT. Anthony's textbook of anatomy and physiology. St. Louis: Mosby–Year Book, 1996.)

Stomach The gastric mucosa is divided into epithelium, lamina propria, and muscularis mucosae. At the gastroesophageal junction, the mucosal boundary between the stratified squamous epithelium of the esophagus and the glandular columnar epithelium of the stomach can be seen as an irregular line (Z-line) encircling the lumen. When the stomach is empty, the mucosa and submucosa contract into thick folds called *rugae* (see Fig. 64-2, *right*). In the fundus and body, most rugae are aligned in a honeycomb pattern, whereas along the lesser curvature and in the antrum, they are arranged longitudinally (see Fig. 64-6). As the stomach distends, the rugae flatten and eventually disappear. Gastric pits (foveolae gastricae), which serve as exit channels for underlying gastric glands, stud the gastric mucosal surface. This surface epithelium is lined by a single layer of columnar epithelial cells that extends into the gastric pits and glands. Differences in the cellular makeup of glands permits histological division of the gastric mucosa into three types that differ in structure and function: cardiac (junctional), fundic, and antral (pyloric) (Fig. 64-7). The lamina propria is an area of loose connective tissue containing strands of collagen and smooth muscle, lymphatics, blood vessels, nerves, and a variety of cells, including lymphocytes, plasma cells, mast cells, fibroblasts, macrophages, and eosinophils. The muscularis mucosae, a smooth muscle layer, forms the inferior margin of the mucosa and separates it from the submucosa, which contains dense connective tissue, arterioles, venules, lymphatics, and neural plexuses.

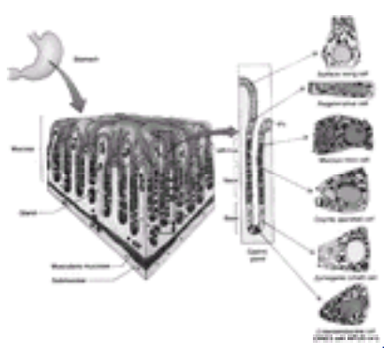

FIGURE 64-7. Drawing of gastric glands from fundus/body region of stomach showing approximate location within a representative gastric gland and typical histology of surface epithelial, mucous neck, parietal, chief, and enterochromaffin-like cells. (From Gartner LP, Hiatt JL. Color textbook of anatomy. Philadelphia: WB Saunders, 1997.)

Proceeding from the surface epithelium into the pits, the mucosal cells considered in detail in the following subsections include the following: mucous cells and mucous neck cells, which line the surface and extend into the pits, respectively; parietal cells, which secrete hydrochloric acid and intrinsic factor; endocrine cells, which secrete a variety of mediators; and, toward the base of the pits, chief cells, which secrete pepsinogens (see Fig. 64-7). [1], [2] and [3]

Mucous cells. The rectangular *mucous cells* are polarized (Fig. 64-8). Apically located mucous granules contain mucin, a neutral glycoprotein that can be stained with mucicarmine and periodic acid-Schiff. The mucous cell nucleus, Golgi complexes, and endoplasmic reticulum are located at the base of the cell. Like other columnar epithelial cells, mucous cells are attached at their apical margins by tight junction complexes and are connected by gap junctions and desmosomes at other cellular sites. Mucous neck cells are similar to the mucous cells just described, but they contain more rough endoplasmic reticulum and are found predominantly in the neck of glands and scattered deeper within glands. Because mucous neck cells contain acidic mucus (glycosaminoglycan), their granules are generally less dense than granules in surface mucous cells. Mucus is released by stimulated exocytosis; hence the degree of granule filling depends on the stage of digestion.

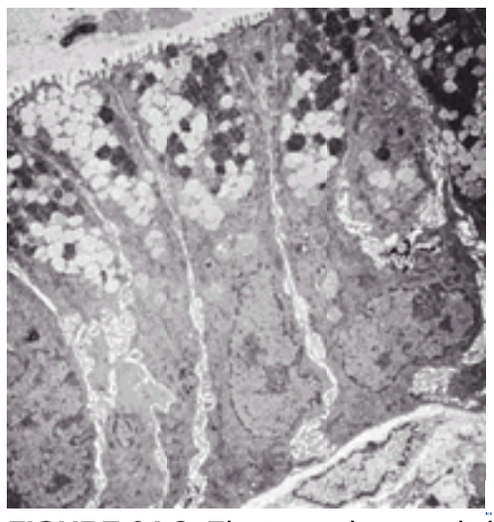

FIGURE 64-8. Electron micrograph (original magnification ×3200) of gastric mucous cells. Microvilli protrude from the apical surface, mucous granules fill the apical cytoplasm, and the nucleus lies near the base of the cell. (From Misiewicz JJ, Forbes A, Price A, et al. Atlas of clinical gastroenterology. London: Wolfe, 1994.)

Parietal (oxyntic) cells. *Parietal cells,* situated in the lower two thirds of fundic-type glands, secrete hydrochloric acid and intrinsic factor (see Fig. 64-7). In glands of the fundus and body, these cells have a concentric nucleus and appear pyramidal, with the tubular apical end abutting the glandular lumen. Numerous mitochondria and tubulovesicles occupy much of the cytoplasm (Fig. 64-9, *left*). When parietal cells are stimulated, tubulovesicles expand into microvillus-lined canaliculi that course through the cytoplasm and fuse with the apical membrane to connect with the lumen of the gastric gland (see Fig. 64-9, *right*). [4] In unstimulated cells, H^+,K^+-ATPase, which mediates the electroneutral exchange of cytoplasmic hydronium ion for potassium in the canalicular lumen, is found in the tubulovesicle membranes, whereas in stimulated cells, this enzyme is relocated to canalicular membranes. Translocation of the proton pump and expansion of the canaliculi are necessary for the acid-secreting function of parietal cells.

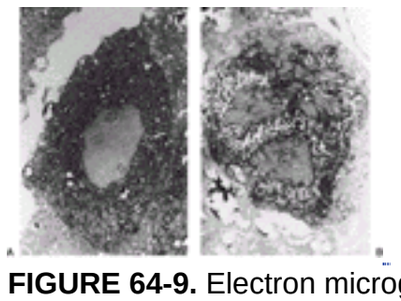

FIGURE 64-9. Electron micrographs of parietal cells. (**Left**) Resting parietal cell showing concentric nucleus and abundant mitochondria and tubulovesicles. (**Right**) Activated parietal cell with expanded canaliculus (approximate magnification ×4000). (From Prinz C, Kajimura M, Scott D, et al. Acid secretion and H,K-ATPase of stomach. In: Modlin IM, ed. Current clinical and scientific perspectives in gastroenterology. Yale J Biol Med 1992;65:170.)

Chief cells. *Chief cells,* found predominantly in the lower third of gastric glands (see Fig. 64-7), secrete proenzyme pepsinogens that are hydrolyzed in an acid environment to the acid protease pepsin. Chief cells are polar, with apically located dense pepsinogen-containing secretory granules. The basal pole contains granular endoplasmic reticulum, the nucleus, and prominent Golgi complexes (Fig. 64-10). When chief cells are stimulated, the zymogen granules migrate to the apical pole, fuse with the cell membrane, and release their contents into the lumen of the gastric gland.

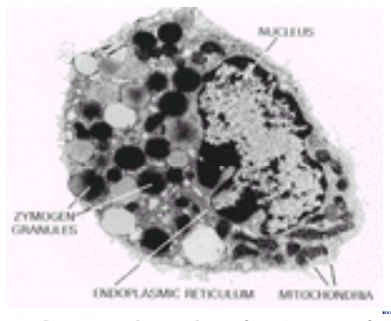

FIGURE 64-10. Electron micrograph of a dispersed chief cell from a guinea pig stomach (original magnification ×21,000). (From Raufman JP. Gastric chief cells: receptors and signal transduction mechanisms. Gastroenterology 1992;102:699.)

Endocrine cells. *Enterochromaffin-like (ECL) cells* are small, irregularly shaped cells scattered near parietal cells in fundic-type gastric glands. ECL cells, which do not connect with the lumen of the glands, are packed with histamine-containing granules. Histamine release from ECL cells has been shown to be a major regulator of parietal cell function. [5] *G cells,* located in the midportions of antral glands and in duodenal crypts, are characterized by a broad base resting against the basement membrane that runs beneath the epithelium. [6] Dense secretory granules containing gastrin cluster near the base. A narrow apex extends to the lumen of the gland. These cells secrete the hormone gastrin in response to stimuli associated with eating, such as vagal stimulation, antral distention, and the lumenal presence of aromatic amino acids. G-cell microvilli that protrude into the gland lumen sense secretory and, possibly, inhibitory lumenal stimuli. *D cells,* located in fundic and antral glands, contain the inhibitory peptide somatostatin. These cells have neuronlike extensions that terminate near other gastric mucosal cells, particularly G cells, ECL cells, parietal cells, and chief cells. Evidence indicates that inhibitory actions of D cells are mediated by paracrine actions of somatostatin released from these extensions. [7] Scattered gastric endocrine cells contain pancreatic polypeptide, glucagon, serotonin, and other secretory products whose actions are less well understood.

Duodenum In the pylorus, the mucosal pattern changes from the pits and glands (typical of gastric mucosa) to the villi and crypts (typical of intestinal mucosa). [8] From the proximal to distal duodenum, the villi become progressively taller and thinner until a ratio of villus to crypt of 4:1 or 5:1, characteristic of jejunal mucosa, is achieved. A monolayer of epithelial cells, consisting of absorptive, mucous, Paneth, and endocrine cells, covers the villi and lines the crypts. The lamina propria, composed of loose connective tissue, contains lymphatics (lacteals), blood vessels, nerves, and smooth muscle fibers, as well as varying numbers of plasma and mast cells, lymphocytes, fibroblasts, macrophages, and eosinophils. The muscularis mucosae lies below and perpendicular to the crypts. The submucosa of the duodenum provides a connective tissue framework for blood vessels, lymphatics, and nerves and contains Brunner glands that secrete alkaline mucus. Brunner glands extend through the muscularis mucosae, occupy part of the mucosa, and empty into the crypts. The muscularis propria consists of a layer of inner circular fibers surrounded by a layer of fibers arranged longitudinally. The myenteric plexus is located between these muscle layers.

Cellular Interactions Gastric and duodenal microscopic anatomy is central to the regulation of digestion; that is, the juxtaposition of secretory cells and neurons is crucial to their physiological interactions. For example, in the fundus and body, ECL cells, D cells, and cholinergic neurons must be sufficiently close to parietal cells to allow paracrine secretory products, such as histamine, somatostatin, and acetylcholine, respectively, to reach receptors on the acid-secreting cells. [5] Likewise, in the antrum, the interplay among neurons containing gastrin-releasing peptide and vasoactive intestinal polypeptide, histamine-containing mast cells, somatostatin-containing D cells, and gastrin-containing G cells requires physical proximity. [7]

Cellular Renewal Gastric and duodenal mucosal epithelial cells undergo continuous, rapid renewal, a process involving proliferation, migration, differentiation, senescence, and loss of epithelial cells. [9] To replace surface mucous cells, nascent cells migrate upward from the base of gastric pits or duodenal crypts to the mucosal surface or villous tip. In humans, migration of basal cells to the surface takes 2 to 6 days. [10] In contrast, parietal and chief cells are replaced by cells, possibly mucous neck cells, in the upper proliferative zone of the gastric glands, a process that takes weeks to months. [11] Senescent gastric or duodenal mucosal cells are sloughed into the lumen. Aspirin, indomethacin, and ethanol stimulate epithelial proliferation, perhaps by causing mild injury. [12], [13], [14], [15], [16] and [17] Epithelial proliferation is also increased by chronic inflammation, as in chronic superficial gastritis, gastric atrophy associated with pernicious anemia, and other hypergastrinemic states, such as Zollinger-Ellison syndrome. [18] In these conditions, the zone of proliferating cells is expanded. In contrast, corticosteroids and physiological stress, such as water immersion and restraint in rats, suppress epithelial proliferation. [15] Prostaglandins appear to delay senescence and loss of epithelial cells. [19] The result is mucosal thickening, which contributes to the cytoprotective effects of prostaglandins.

EMBRYOLOGY OF THE STOMACH AND DUODENUM

The primitive stomach and proximal duodenum derive from the foregut caudal to the developing lung, whereas the duodenum beyond the origin of the liver bud (the future ampullary papilla) derives from the cephalic end of the midgut. [20], [21] After the fourth week of intrauterine development, the primitive stomach rotates 90° clockwise around its longitudinal axis, ending with the left side facing anteriorly and the right side posteriorly. [22] This accounts for the course of the left vagus along the anterior wall and the right vagus along the posterior wall. The left wall of the stomach grows faster than the right, resulting in the size difference between the curvatures. The dorsal mesentery, which attaches the stomach to the posterior body wall, forms the omental bursa, or lesser peritoneal sac. The ventral mesentery attaches the stomach and duodenum to the liver.

As the stomach grows and rotates, the cephalic end moves leftward and downward, forming the fundus and cardia. The caudal end moves upward and to the right, forming the antrum and pylorus. Hence, the long axis of the stomach runs from above left to below right.

The duodenum also grows rapidly, forms a C-loop projecting ventrally, rotates to the right, and becomes retroperitoneal. Because of rapid epithelial proliferation during the fifth and sixth weeks, the duodenal lumen is temporarily obliterated. The duodenal lumen recanalizes over the ensuing weeks as some cells degenerate.

The epithelium and glands of the stomach and duodenum derive from the embryonic endoderm. The connective tissue, muscle, and serosa derive from the mesoderm.

CONGENITAL ABNORMALITIES OF THE STOMACH

Atresia

Gastric atresia results in a blind end in the antrum or pylorus. Atresia may involve only the mucosa and submucosa, with normal muscle and serosa, or it may involve the entire gastroduodenal wall. The cause is unknown, but complete atresia is familial, with autosomal recessive transmission. [23] In many cases, polyhydramnios complicates pregnancy. Complete pyloric atresia may be associated with junctional epidermolysis bullosa. Atresia probably results from failure of the antrum and pylorus to recanalize after transient occlusion by epithelium during embryogenesis.

In the newborn, gastric atresia is suggested by persistent, nonbilious vomiting, upper abdominal distention, dehydration, and hypochloremic, hypokalemic metabolic alkalosis. Gastric rupture may occur. Diagnostic abdominal radiographs demonstrate gaseous gastric distention without intestinal gas.

Initial therapy includes nasogastric suction and fluid resuscitation. Surgical treatment of a short atretic segment, involving only the mucosa, requires resection of the membrane and pyloroplasty. Extensive atretic segments require resection with gastroduodenostomy. Gastrojejunostomy should be avoided because, in the absence of vagotomy, peptic stomal ulceration may occur. Careful exploration must exclude unsuspected distal atresias.

Mucosal Membranes

Congenital mucosal membranes, which are probably related to atresias, occur in the antrum or pylorus and generally encircle, but do not occlude, the lumen. The membrane may contain either squamous or columnar epithelium. Peptic ulceration can result in acquired membranes. Vomiting may occur in infancy, but symptoms usually develop in late childhood or adulthood, depending on the diameter of the aperture.

Plain abdominal radiographs usually appear normal, but barium studies reveal a bandlike defect in the prepyloric antrum. Gastric emptying may be slowed, and the antrum between the mucosal membrane and the pylorus may simulate a second duodenal bulb. Previously, treatment was surgical, with excision of the membrane with or without pyloroplasty. More recently, endoscopic lysis of membranes has been reported. [24]

Gastric Duplication

Gastric duplications, containing mucosa, submucosa, and muscle, usually involve the greater curvature and share a common wall, but they are separate from the main part of the stomach. They sometimes connect with the gastrointestinal tract, usually the stomach or pancreas. Gastric duplications vary tremendously in size, occur more commonly in girls, and may coexist with other duplications of the digestive tract.

Patients usually present in the first year of life. Symptoms depend on size, location, and the presence or absence of communication with the gastrointestinal tract. Small children may present with vomiting, failure to thrive, and weight loss. Projectile vomiting may mimic that seen in pyloric stenosis. In older children, epigastric pain, abdominal fullness or mass, gastrointestinal bleeding, or symptoms of gastric obstruction may occur. Rarely, peritonitis results from cyst perforation, hemoptysis results from fistulation to the lung, or cancer develops in the duplication. [25] Gastrointestinal radiographs may show a mass that protrudes into the lumen, extrinsic compression of the stomach, or filling of the cyst with barium. Ultrasonography, computed tomography, or magnetic resonance imaging may demonstrate the abnormality. [25] Treatment usually consists of complete surgical excision, but this may not be feasible if a large part of the gastric wall is involved. Partial excision, partial gastrectomy, and cyst gastrostomy are other options.

Microgastria

Microgastria represents a rare failure of the stomach to enlarge after its development from the foregut. The structure becomes tubular, with a small capacity. Esophageal dilation may provide some storage area, but patients with microgastria generally present soon after birth with vomiting, diarrhea, aspiration pneumonia, malnutrition, and anemia. Microgastria is associated with developmental cardiac abnormalities, upper limb and spinal deformities, micrognathia, and asplenia. [26], [27] Many patients die within weeks to months. Supportive treatment requires frequent, small, high-caloric feedings and parenteral alimentation. If the child survives, surgical formation of a jejunal reservoir should be attempted, but anastomotic ulcers may occur. [28] Other anomalies should be sought and corrected at surgery.

Gastric Teratoma

These congenital tumors contain all three primary embryonic germ layers. They can occur anywhere, but they are rare in the stomach. *Gastric teratomas* may cause gastrointestinal bleeding, obstruction, or an upper abdominal mass. They occur almost exclusively in male patients. Although usually diagnosed in children, gastric teratomas may not be discovered until adulthood.

Plain abdominal radiographs may show calcified teeth or bone in the tumor, and barium contrast studies confirm a gastric mass. The large size of these teratomas may require total gastrectomy and formation of a jejunal pouch. [29] Gastric teratomas are not associated with other congenital anomalies, and the prognosis is good. [30]

Gastric Diverticula

Congenital *gastric diverticula* are rare, comprise all layers of the gastric wall, and arise primarily from the posterior gastric wall near the gastroesophageal junction. Gastric diverticula also may be found in the antrum and pylorus. Their cause is unknown, but they may be associated with ectopic pancreatic tissue, hiatus hernia, and diverticula in another part of the gastrointestinal tract. Ectopic pancreatic tissue, or pancreatic rests, may occur in the mucosa or submucosa of the duodenum or stomach and may mimic tumors, or they may ulcerate and bleed. Acquired diverticula may result from the scarring and dilation that accompany peptic ulceration, intestinal obstruction, cancer, or gastric surgery.

Gastric diverticula are commonly asymptomatic and are discovered as incidental findings on endoscopy or barium contrast studies. [31] These must be distinguished from acquired false diverticula, peptic ulcers, ulcerated neoplasms, and prominent folds. [32] Occasionally, epigastric or chest pain, heartburn, and vomiting may be reported. Severe symptoms or, rarely, bleeding and perforation require surgical excision and closure of the defect. Otherwise, no treatment is necessary.

Ectopic Gastric Mucosa

Rests of *ectopic gastric mucosa* can be found in any part of the gastrointestinal tract and may cause ulceration, obstruction, or bleeding. In the upper esophagus, this condition has been reported in as many as 5% of people. [33] In the small intestine, colon, and rectum, ectopic gastric mucosa may form bleeding masses resembling polyps. [34], [35] Meckel diverticula in the distal ileum may contain gastric mucosa with acid-secreting parietal cells that cause ulceration and bleeding in children and young adults. [36]

Hypertrophic Pyloric Stenosis

Neonates In *neonatal hypertrophic pyloric stenosis,* a congenital condition, muscular hypertrophy and mucosal edema of the pylorus result in gastric outlet obstruction. This disorder, the most common indication for surgery during the first 6 months of life, is more frequent in boys than in girls—1 per 150 births versus 1 per 750 births, respectively. [37] It has a genetic basis, clusters in families, and is more common in whites than in other races, but the mode of inheritance is unclear. Although the cause is unknown, lack of nitric oxide synthase in pyloric tissue may contribute to pylorospasm. [38], [39] Cases cluster in families and can be associated with other disorders, including maternal myasthenia gravis, fetal rubella, phenylketonuria, Hirschsprung disease, Turner syndrome, Smith-Lemli-Opitz syndrome, Cornelia deLange Amsterdam dwarf syndrome, and esophageal atresia. [37] Although the symptoms of pyloric stenosis, particularly regurgitation and nonbilious projectile vomiting, typically do not occur until 3 to 4 weeks after birth, up to 20% of infants may be symptomatic earlier. [37] Vomiting may occur immediately after eating or may be delayed until the stomach is full. Although the vomitus is classically nonbilious, it may contain blood. Despite vomiting, the infant remains hungry until malnutrition and weakness cause interest in feeding to wane. Decreased delivery of food and fluid to the intestines results in constipation, oliguria, and failure to thrive. The baby generally appears thin, weak, and dehydrated. Abdominal examination is likely to reveal gastric dilation, visible gastric peristalsis, and a palpable pyloric mass. Whereas gastric dilation and visible peristalsis are more evident during feeding, the olivelike pyloric mass is more likely to be palpable immediately after vomiting, when the abdominal wall is more flaccid. Typically, erect, plain abdominal radiography demonstrates a large gastric air bubble with little or no intestinal air. Studies indicate that, in most cases, the detection of an “olive” on physical examination in babies with typical symptoms is sufficient for diagnosis. [40] If further testing is needed, barium radiography appears to be more cost effective than ultrasonograpy. [41] When contrast radiography is performed, the stomach should be emptied with a nasogastric tube before barium is slowly instilled. Barium studies are likely to show a long, narrow pyloric channel, typically giving the appearance of a double channel, and a mass effect that indents the prepyloric antrum and duodenal bulb (Fig. 64-11).

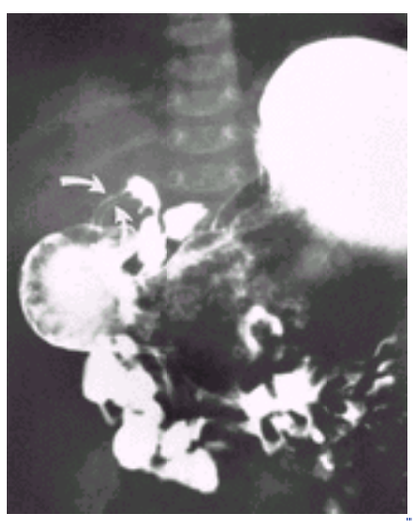

FIGURE 64-11. Barium contrast upper gastrointestinal series shows the long, narrow, double channel of the pylorus (*arrows*) in a patient with hypertrophic pyloric stenosis.

Initial therapy, before surgery is considered, requires replacement of fluid and electrolytes, as well as correction of the alkalosis resulting from repeated vomiting. Nevertheless, definitive therapy is surgical. The preferred operation is Ramstedt pyloromyotomy: longitudinal division of the anterior pyloric muscle from the serosa to the submucosa. Mild vomiting may persist, but symptoms usually disappear within several days. After surgical correction of the defect, growth and development are normal, and long-term results are excellent.

Adults Rarely, adults demonstrate signs and symptoms of congenital hypertrophic pyloric stenosis. In adults, however, most cases result from chronic peptic ulcer disease, severe gastritis, or cancer involving the pyloric area. In adults with congenital pyloric stenosis, common symptoms, usually dating from infancy, include early satiety, nausea, vomiting, epigastric pain, weight loss, and anorexia. The diagnosis is generally delayed, in part because physical findings observed in infants, such as a pyloric mass, are not present. Barium contrast radiography may reveal gastric dilation, delayed emptying, and a long, narrow pyloric channel. To exclude predisposing conditions, such as cancer or ulcer disease, upper endoscopy is helpful. Endoscopic dilation or surgical pyloromyotomy may be therapeutic, but, to exclude a small focus of cancer, pyloric resection with gastroduodenostomy may be preferable. [42]

CONGENITAL ABNORMALITIES OF THE DUODENUM

Atresias, Stenosis, and Membranes

The duodenal lumen is obliterated by epithelium during the fifth to sixth weeks of development. *Duodenal atresia, stenosis, or membranes* probably result from subsequent failure of the lumen to recanalize. This rare cause of duodenal obstruction occurs distal to the ampulla in 80% of cases, has no sexual or racial predilection, and is frequently associated with other congenital anomalies, including Down syndrome, intestinal malrotation, tracheoesophageal fistula, annular pancreas, cardiac and renal anomalies, and anorectal malformations.

In newborns with compete obstruction caused by a duodenal membrane or atresia, vomiting develops within hours to a few days after birth. The vomitus is nonbilious if obstruction is proximal to the ampulla and generally indistinguishable from that associated with pyloric stenosis. With partial obstruction, symptoms may be delayed and less severe. Rarely, duodenal membranes that persist or develop in adulthood cause upper abdominal distention, vomiting, and weight loss.

When obstruction is distal to the duodenal bulb, plain abdominal radiographs or ultrasonograms show a double bubble, caused by a distended stomach and duodenal bulb (Fig. 64-12). [43] The absence of distal intestinal gas suggests complete obstruction. Upper gastrointestinal contrast radiography may not be necessary but can confirm the site of obstruction.

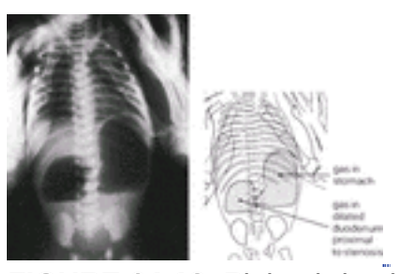

FIGURE 64-12. Plain abdominal radiograph in an infant with duodenal atresia shows the double bubble sign. The stomach and the proximal duodenum are distended with air. (From Misiewicz JJ, Forbes A, Price A, et al. Atlas of clinical gastroenterology. London: Wolfe, 1994.)

Immediate treatment requires nasogastric suction, with fluid and electrolyte resuscitation. Definitive treatment is surgical, with gastrojejunostomy or

duodenojejunostomy, depending on the level of obstruction. [44] At surgery, other correctable anomalies should be sought. The prognosis usually depends on the outcome of associated anomalies. In adults, endoscopic lysis of duodenal membranes may be successful. [45], [46]

Annular Pancreas

Annular pancreas is a rare condition that affects the sexes equally and may result in complete or partial obstruction of the second part of the duodenum. [47] The cause is unknown but probably involves incomplete migration of the ventral pancreatic bud during embryogenesis. This results in a pancreatic remnant within the duodenal wall or pancreatic encirclement of the duodenum. Annular pancreas is associated with intestinal malrotation, Down syndrome, facial cleft, imperforate anus, and cardiac and tracheoesophageal malformations. [48]

Neonates present with intractable vomiting. Children or young adults have abdominal pain and distention with less dramatic vomiting. The clinical presentation and plain abdominal radiographs are similar to those for duodenal obstruction caused by duodenal atresia, including a double bubble sign. Upper gastrointestinal contrast radiography or endoscopy confirms the level of duodenal obstruction but cannot distinguish among various causes of obstruction (Fig. 64-13). Computed tomography or ultrasonography may establish the diagnosis. In adults, endoscopic retrograde cholangiopancreatography can establish the diagnosis if the duct from the annular pancreas joins the main pancreatic duct. Impaired pancreatic ductal flow may result in acute or chronic pancreatitis.

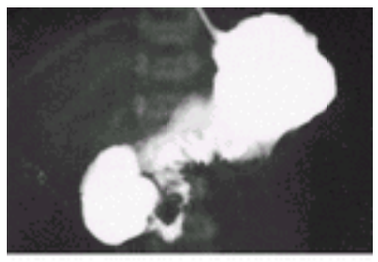

FIGURE 64-13. Barium contrast upper gastrointestinal series shows partial occlusion of the second part of the duodenum, consistent with annular pancreas, duodenal atresia, or other causes of duodenal obstruction. (From Misiewicz JJ, Forbes A, Price A, et al. Atlas of clinical gastroenterology. London: Wolfe, 1994.)

Treatment includes nasogastric decompression and correction of fluid and electrolyte disturbances. Resection or division of the annular pancreatic segment may cause pancreatitis or pancreatic fistula and should not be attempted. Definitive therapy requires duodenostomy or duodenojejunostomy. Surgical results are good, and long-term prognosis depends on the outcome of associated anomalies.

Duplication

Duplications are cystic or tubular malformations that contain all layers of the normal duodenum and may communicate with the main lumen. Intestinal obstruction may occur secondary to compression by a mass effect and may cause upper abdominal distention, early satiety, and vomiting. Duodenal duplications may ulcerate and bleed and, rarely, perforate into the head of the pancreas and cause pancreatitis. [49] Diagnosis can be established by ultrasonography, contrast radiography, or computed tomography. Treatment is surgical, and the approach depends on the relationship of the cyst with the biliary and pancreatic ducts, as well as the vasculature. If total resection is not possible, cystenterostomy may suffice.

Malrotation

In children, *intestinal malrotation* is the most common cause of duodenal obstruction. [50] This may occur in utero if the duodenojejunal loop does not rotate normally around the SMA and the duodenum fails to complete its rotation. Consequently, the ligament of Treitz may be situated to the right, rather than left, of midline, thereby kinking the duodenum. If the cecum fails to rotate completely into the right lower abdomen or when the hepatic flexure lies medial to the duodenum, mesenteric bands may compress the second or third parts of the duodenum. Other developmental anomalies, such as duodenal atresia, annular pancreas, or Hirschsprung disease, are present in 30% to 60% of patients with intestinal malrotation.

Patients with malrotation present within the few weeks of life with bilious vomiting and abdominal distention. Intestinal peristalsis may be visible on the abdominal wall. Occasionally, lax mesentery results in intestinal or cecal volvulus. If the vasculature is twisted, intestinal ischemia can result in bleeding, perforation, peritonitis, and sepsis. A few patients with malrotation present later in life with weight loss, hypoproteinemia, chylous ascites, increased susceptibility to infection, intermittent postprandial vomiting, and abdominal distention. Others, with minor malrotations, remain asymptomatic throughout life.

Plain abdominal radiographs demonstrate a large gastric air bubble and distended duodenum proximal to the obstruction. An upper gastrointestinal series can confirm the obstruction and, if barium is able to pass this area, may identify the type and extent of malrotation. Ultrasonography may reveal obstruction or volvulus caused by malrotation in utero.

Treatment is surgical: division of obstructing bands, resection of infarcted bowel, and fixation of the cecum to prevent further episodes of volvulus. When extensive bowel resection is required, mortality approaches 20%, and survivors may develop short bowel syndrome with profound malabsorption requiring long-term parenteral alimentation.

Superior Mesenteric Artery Syndrome

Rarely, the SMA obstructs the third portion of the duodenum by compressing it against fixed retroperitoneal structures, particularly the spine. Although *SMA syndrome* has been attributed to an acute angle between this vessel and the aorta, thereby trapping the duodenum, the exact cause is unknown. This syndrome also has been associated with rapid childhood growth, major weight loss in adults, immobilization in a cast that increases lordosis and accentuates the angle of the SMA with the aorta, abdominal surgery, and inflammatory diseases of the abdomen. [51], [52]

Symptoms are nonspecific, and documenting SMA compression of the duodenum as the cause is difficult. Symptoms, including episodic epigastric pain associated with vomiting, may be acute or chronic, sometimes lasting many years.

In adults, plain abdominal radiographs are usually unremarkable, but in children a double bubble sign may be seen (see Fig. 64-12). Upper gastrointestinal contrast studies may show dilation behind an abrupt cutoff in the third portion of the duodenum (see Fig. 64-13). On abdominal angiography, lateral views may show the narrowed angle of the SMA with the aorta. Because controversy exists about the clinical importance of SMA syndrome, it is important to exclude other causes of abdominal pain before making this diagnosis and initiating treatment.

Medical therapy includes small feedings or a liquid diet. Patients may benefit from lying prone or on their left side postprandially. In some cases, weight gain or removal of a body cast improves symptoms. Laparoscopic lysis of the ligament of Treitz has been reported beneficial in a few cases. [53] Duodenojejunostomy may be

required in refractory cases.

Preduodenal Portal Vein

A *preduodenal portal vein,* sometimes associated with a preduodenal common bile duct, can obstruct the duodenum. Only about 50 cases have been reported. In early embryonic life, both retroduodenal and preduodenal veins drain the primitive gut. The preduodenal vein usually atrophies, leaving a normal retroduodenal portal vein. When the retroduodenal branch atrophies, the preduodenal vein remains patent and may compress the duodenum. A preduodenal vein is associated with other congenital malformations, such as duodenal stenosis or atresia, annular pancreas, intestinal malrotation, and biliary tract abnormalities. [54]

Duodenal Diverticula

Congenital *duodenal diverticula* occur within a few centimeters of the ampulla of Vater (Fig. 64-14). [55] The ampulla may empty into a diverticulum. These diverticula are usually asymptomatic, incidental findings on barium contrast studies. Rarely, duodenal diverticula obstruct the common bile duct by external compression on the duct or distortion of its entry into the duodenum. Most cases of biliary obstruction associated with a duodenal diverticulum result from another cause, such as an obstructing common bile duct stone or neoplasm. Acquired diverticula in the duodenal bulb may result from peptic ulcer disease. When one is reasonably certain that diverticula are causing symptoms, the best procedure is choledochoduodenostomy or jejunostomy with Roux-en-Y anastomosis, not excision of the diverticulum.

CHAPTER 65

Henry P. Parkman and Robert S. Fisher

DISORDERS OF GASTRIC EMPTYING

Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying (as seen in dumping syndrome), and disorders with motor and sensory abnormalities (e.g., functional dyspepsia). Each disorder can present with a spectrum of symptoms that may be mild, leading to empiric treatment, or severe and incapacitating. Refractory symptoms often lead to a comprehensive evaluation including gastric emptying scintigraphy, antroduodenal manometry, electrogastrography (EGG), and possibly tests of gastric accommodation or compliance (satiety testing). Evaluation may guide treatments that target the underlying pathophysiology. Management of these patients requires an understanding of the pathophysiology, clinical tests, and new treatment options.

DELAYED GASTRIC EMPTYING (GASTROPARESIS)

Symptoms and Clinical Presentation

Gastroparesis is a chronic motility disorder of the stomach characterized by delayed gastric emptying in the absence of mechanical obstruction. The clinical presentation of gastroparesis may vary. Symptoms include early satiety, nausea, vomiting, bloating, and upper abdominal discomfort. Late postprandial vomiting of undigested food is typical. In 146 patients with gastroparesis, nausea was present in 92%, vomiting in 84%, abdominal bloating in 75%, and early satiety in 60%. [1] These symptoms, however, are nonspecific and may mimic structural disorders such as ulcer disease, partial gastric or small bowel obstruction, gastric cancer, and gallbladder or pancreatic disorders. [2] There is also an overlap of symptoms of gastroparesis and functional dyspepsia. At times, vomiting can be difficult to distinguish from regurgitation of gastroesophageal reflux disease (GERD) or rumination syndrome.

Abdominal discomfort or pain is present to varying degrees in gastroparesis, but it is not usually the predominant symptom. In the series of 146 patients with gastroparesis reported by Soykan and colleagues, [1] 46% had abdominal pain, whereas in another series, [3] 89% of 28 patients with gastroparesis had abdominal pain. Abdominal discomfort is generally described as burning, vague, or crampy. Visceral hypersensitivity to gastric distention has been suggested as a cause of pain in gastroparesis, analogous to that described in functional dyspepsia. [4], [5] In diabetic gastroparesis, abdominal pain may represent a visceral equivalent of autonomic neuropathy. Potential explanations for diabetic neuropathy include nerve injury from ischemic microangiopathy or abnormal metabolic function. [6] Abdominal pain from gastroparesis responds poorly to prokinetic agents and gastric electrical stimulation. [3]

Symptoms do not correlate well with delayed gastric emptying in diabetic gastropathy, idiopathic gastroparesis, and functional dyspepsia. [7], [8], [9] and [10] Early satiety, abdominal fullness or distention, and vomiting may, however, predict delayed emptying. [11], [12] Treatment with the prokinetic cisapride improved emptying and reduced symptoms of epigastric pressure and bloating with borderline improvement in early satiety, nausea, and vomiting. [13] In 343 patients with functional dyspepsia, 34% of whom had gastroparesis, the severity of postprandial fullness and vomiting correlated with delayed emptying. [12]

Most gastroparetic patients are women. In the series of Soykan and colleagues, [1] 82% of gastroparetic patients were female. Female gender and the later portion of the menstrual cycle (the luteal phase) have been associated with slower gastric emptying, [14], [15] thought to result from reduced gastric muscle contractility caused by female reproductive hormones, primarily progesterone. In the study by Stanghelleni and colleagues [12] of functional dyspepsia, female gender was an independent risk factor for delayed gastric emptying.

Evaluation of Patients with Suspected Gastroparesis

Gastroparesis is diagnosed by demonstrating delayed gastric emptying in a symptomatic patient after exclusion of mechanical obstruction by endoscopy or upper gastrointestinal (GI) series (Table 65-1). Although abdominal pain may be present in patients with gastroparesis, this is usually evaluated separately using other tests such as ultrasonography.

1. Initial investigation
   A. History and physical examination
   B. Blood tests
      Complete blood count
      Complete metabolic profile including glucose, potassium, creatinine, total protein, albumin, calcium
      Amylase, if abdominal pain is significant symptom
      Pregnancy test, if appropriate
   C. Abdominal obstruction series, if vomiting or pain is acute or severe
2. Evaluate for organic disorders
   A. Upper endoscopy to evaluate for mechanical obstruction or mucosal lesions (alternative: barium upper gastrointestinal series often with small bowel follow through)
   B. Biliary ultrasound, if abdominal pain is a significant symptom
3. Evaluate for delayed gastric emptying
   A. Solid phase gastric emptying test
   B. Screen for secondary causes of gastroparesis
      Thyroid function tests
      Antinuclear antibody
      Glycosolated hemoglobin
4. Treatment trial with prokinetic agent or antiemetic agent
5. If no clinical response, consider further investigation
   A. Electrogastrography
   B. Antroduodenal manometry
   C. Small bowel evaluation with enteroclysis

TABLE 65-1 Evaluation of Patients Suspected to Have Gastroparesis

The first step is taking a careful history. Understanding the patient's symptoms often leads to a clinical suspicion of gastroparesis. Typical symptoms in a young female patient may suggest idiopathic gastroparesis, just as typical symptoms in a patient with long-standing insulin-dependent diabetes should suggest diabetic gastroparesis. After abdominal surgery, patients can develop delayed gastric emptying, especially if the vagus nerve has been damaged. On physical examination, the presence of foul breath or a succussion splash may suggest gastroparesis. A succussion splash, detected by auscultation over the epigastrium while moving the

patient from side to side or by rapidly palpating the epigastrium, indicates excessive fluid in the stomach from gastroparesis or mechanical gastric outlet obstruction. [16] Dehydration and weight loss suggest chronic or severe symptoms.

The second step in evaluating gastroparesis is to exclude mechanical obstruction or ulcers by performing an upper endoscopy or upper GI series. Mechanical gastric outlet obstruction can be caused by pyloric stenosis, an active duodenal, pyloric channel, or prepyloric ulcer, scarring from prior ulcers, or neoplasia of the stomach. Gastroparesis is suggested on endoscopy by presence of food particles in the stomach after an overnight fast. In severe gastroparesis, bezoars may occur, especially if the gastric phase III migrating motor complex (MMC) is absent. Endoscopy is more sensitive for detection of mucosal lesions. [16]

Double-contrast techniques have increased the sensitivity of radiologic studies. When an upper GI series is ordered, a small bowel follow-through (SBFT) can look for small bowel lesions. The SBFT is accurate for detection of high-grade small bowel obstruction and usually provides an adequate assessment of the terminal ileum. However, it may fail to detect low-grade obstruction and smaller mucosal lesions. An SBFT may rarely suggest superior mesenteric artery syndrome as a possible cause or consequence of symptoms. Enteroclysis (small bowel enema) can be obtained after placement of a nasoduodenal or oroduodenal tube. Compared with SBFT, enteroclysis is more accurate in detecting small intestinal mucosal lesions, mild to intermediate grades of obstruction, and small bowel cancers. [17] Computed tomographic scanning with oral and intravenous contrast may also be useful for detection and localization of intestinal obstruction.

The third step is to obtain a gastric emptying scintigram using a radiolabeled solid meal. Patients should discontinue medications that may affect gastric emptying for 48 hours before this test (Table 65-2). An abnormal gastric emptying test suggests, but does not prove, that the symptoms are caused by gastroparesis. If gastric emptying is normal, other causes for symptoms should be sought. However, a gastric motility disorder should not be totally dismissed because localized motor dysfunction, such as impaired fundic relaxation or gastric dysrhythmias, may be associated with symptoms and normal gastric emptying. [18]

Delay Gastric Emptying
Opiate analgesics
Anticholinergic agents
Tricyclic antidepressants
Calcium channel blockers
Progesterone
Octreotide
Proton pump inhibitors
Histamine H_2 receptor antagonists
Interferon-α
L-Dopa
Fiber
Sucralfate
Aluminum hydroxide antacids
β-Adrenergic receptor agonists
Glucagon
Calcitonin
Dexfenfluramine
Diphenhydramine
Alcohol
Tobacco/nicotine
Tetrahydrocannabinol
Accelerate Gastric Emptying
Prokinetic agents
Metoclopramide
Erythromycin and related antibiotics
Cisapride
Domperidone
β-Adrenergic receptor antagonists

TABLE 65-2 Medications that Affect Gastric Emptying

Evaluation of a patient should not stop once delayed gastric emptying is demonstrated; an underlying cause should be sought. Thyroid function tests should be obtained to evaluate for hypothyroidism. A glycosylated hemoglobin level evaluates long-term glycemic control; poor glucose control can worsen gastric emptying. If a patient does not have diabetes mellitus and has not had gastric surgery, a search should be undertaken to evaluate some other causes of gastroparesis including smooth muscle, neurological, or metabolic or endocrinologic disorders. Idiopathic gastroparesis is diagnosed after other causes are excluded.

Evaluation of Gastric Emptying, Motor Function, and Myoelectric Activity

Radiographic contrast techniques: upper gastrointestinal series. The upper GI series is an insensitive method for measuring gastric emptying because it is difficult to quantitate, and barium is not a “physiological” meal (Table 65-3). [19] Gastric retention may be suggested by poor emptying of barium from the stomach, gastric dilation, and the presence of retained food or a gastric bezoar. Little or no emptying of barium at 30 minutes and minimal barium remaining at 6 hours are suggestive of delayed gastric emptying. [20] The upper GI series is primarily helpful in detecting mucosal lesions and mechanical outlet obstruction.

TABLE 65-3 Tests to Assess Gastric Motor and Myoelectric Function

Radionuclide gastric emptying scintigraphy. Gastric emptying scintigraphy remains the best current test for measuring gastric emptying because it is sensitive, quantitative, and physiological. It is used to confirm the presence of gastric stasis after excluding structural or mucosal disorders. The usefulness of emptying tests, however, in directing therapy and predicting response is debated. [13], [21] Measurement of gastric emptying of solids is more sensitive for detection of gastroparesis because normal emptying of liquids is often preserved until the disorder is advanced. In patients who have undergone gastric surgery, a dual solid and liquid emptying test may be indicated because symptoms may result from slow solid emptying or rapid liquid emptying. Most centers use a technetium-99m sulfur colloid–labeled egg sandwich as a test meal. [19] A meal using the processed food Egg Beaters has been proposed for standardization among centers. [22] Whatever meal is employed, the radiolabel needs to be cooked into it so the radioisotope binds to the solid phase, thus preventing elution of the radiotracer into the liquid phase with an erroneous measurement of the faster liquid phase gastric emptying. [23] Gastric emptying should be carried out to at least 2 hours after meal ingestion. For shorter durations, the test is less reliable because of large variations of normal gastric emptying. Extending scintigraphy to 4 hours increases the detection of delayed gastric emptying. [24], [25] The simplest approach for interpreting gastric emptying study is to report the percentage of retention at defined times after meal ingestion (usually 2 and 4 hours) (Fig. 65-1). Curve fitting techniques can calculate the half-emptying time, the time at which half of the stomach contents have emptied from the stomach. Extrapolation of the emptying curve to predict the half-emptying time is unreliable if the emptying had not reached 50% during the actual imaging. [26] Other parameters of potential use are the lag phase for solids, which represents the time required for trituration of solid food into 1- to 2-mm particles that can then empty through the pylorus. A prolonged lag phase suggests antral hypomotility. The slope of the gastric emptying curve after the lag phase represents the rate at which solids leave the stomach once emptying begins. A decreased slope suggests antral hypomotility or small intestinal dysmotility. [27]

FIGURE 65-1. Gastric emptying scintigraphy using a technetium-99m–labeled egg sandwich. The percentages of gastric retention are shown for 0, 30, 60, 120, 180, and 240 minutes after meal ingestion. (**A**) Normal gastric emptying with only 30% retention at 2 hours after meal ingestion (normal <50%) and complete emptying at 4 hours (normal <10%). (**B**) Markedly delayed gastric emptying with little emptying at 4 hours.

Advances in scintigraphy may provide information on fundic and antral abnormalities. Dynamic antral scintigraphy with frequent 1-second imaging can evaluate antral wall contractility. [19] Regional gastric emptying can assess intragastric meal distribution and transit from the proximal to distal portions of the stomach. Proximal

retention may be seen in GERD, distal retention in functional dyspepsia, and global retention in gastroparesis. The gastric emptying response to intravenous prokinetic agents was suggested to predict the response to long-term oral therapy. More recent studies have not supported this. [28] Most clinicians follow the symptomatic response to therapy. Glucose and gender are factors that affect gastric emptying. Premenopausal women empty the stomach more slowly than men. [14], [15] Some investigators have advocated separate reference values for premenopausal women. [29] Hyperglycemia delays gastric emptying. Checking blood glucose concentrations of diabetic patients before a gastric emptying test has been suggested, but it is not usually done.

Breath tests for gastric emptying. Breath testing can be used to measure gastric emptying with the nonradioactive isotope, ^{13}C, to label octanoate, a medium-chain triglyceride, which can be bound into a solid meal. [30], [31] and [32] Studies have also reported labeling ^{13}C to proteinaceous algae (*Spirulina*). [23] Octanoate, after ingestion and emptying from the stomach, is absorbed by the small intestine. The octanoate is metabolized to carbon dioxide in the liver that is excreted from the lungs during respiration. The rate-limiting step for excretion of ^{13}C is gastric emptying. By measuring ^{13}C in breath samples, gastric emptying can be indirectly determined. The octanoate breath test is reproducible and correlates with gastric emptying scintigraphy, and it offers promise as a clinical test for gastric emptying. The ^{13}C breath test does not use ionizing radiation; it can be used to study patients away from gamma camera facilities in community doctor's offices or at the patient's bedside, and breath samples can be shipped to a laboratory for analysis. The octanoate breath test has been used in clinical research and pharmaceutical studies, but not often for patient evaluation. Validation of this test in patients with emphysema, cirrhosis, celiac sprue, and pancreatic insufficiency is needed, because it is not clear whether substrate metabolism in these disorders may also be a rate limiting step for $^{13}CO_2$ excretion.

Ultrasonography. Transabdominal ultrasonography can measure several parameters of gastric motility. Serial changes in antral cross-sectional area are measured as an index of gastric emptying; emptying is considered complete when the antral area returns to the fasting baseline. [33] Duplex sonography may be used to evaluate transpyloric flow of liquid gastric contents. Ultrasonography has also been employed to measure accommodation in the proximal and distal stomach. [23] Unfortunately, ultrasonography for gastric emptying is operator dependent and generally measures liquid emptying only. The test is suboptimal in obese people.

Electrogastrography. EGG is the recording of gastric myoelectric activity, using cutaneous electrodes on the anterior abdomen overlying the stomach. [34] The dominant frequency of the EGG corresponds to the gastric electrical rhythm or frequency of the gastric slow wave. The normal gastric slow wave frequency is approximately 3 cycles/min. Meal ingestion increases the amplitude of the EGG signal by increases in gastric electrical activity and contractility or gastric distention from the meal. EGG measures the frequency and regularity of gastric myoelectric activity, detects abnormal rhythms of gastric myoelectric activity, and assesses the amplitude or power increase after a meal. [26] Gastric dysrhythmias (tachygastria, bradygastria) and decreased postprandial amplitude (or power) of the EGG have been described in idiopathic and diabetic gastroparesis [35] (Fig. 65-2). Gastric myoelectric abnormalities have also been described in patients with unexplained nausea and vomiting, motion sickness, and nausea and vomiting of pregnancy. [26] Studies have suggested a good correlation between delayed gastric emptying by scintigraphy and an abnormal EGG. [35] An abnormal EGG is present in 75% of patients with gastroparesis compared with only 25% of symptomatic patients with normal gastric emptying. Gastric dysrhythmias may be better predictors of symptoms than delayed gastric emptying and may correlate better with symptomatic response to medications. [8] In diabetic patients, hyperglycemia may itself provoke dysrhythmias, primarily tachygastrias. [36]

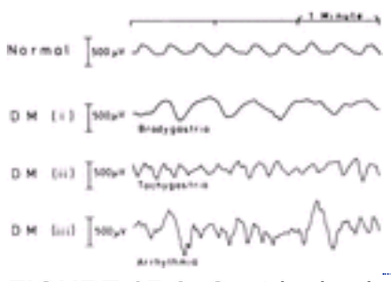

FIGURE 65-2. Gastric dysrhythmias recorded with electrogastrography from diabetic patients. The **top tracing** shows normal 3 cpm activity. The **next tracings** show examples of bradygastria, tachygastria, and arrhythmia (tachybradygastria). (From Hongo M, Okuno Y, Nishimura N, Toyota T, Okuyama S. Electrogastrography for prediction of gastric emptying state. In: Chen JZ, McCallum RW, eds. Electrogastrography: principles and applications. New York: Raven Press, 1994:257.)

EGG is used to demonstrate gastric myoelectric abnormalities in patients with unexplained nausea and vomiting or functional dyspepsia. The EGG is generally used as an adjunct to gastric emptying scintigraphy as part of a comprehensive evaluation of patients with refractory symptoms suggestive of an upper GI motility disorder. [26]

Antroduodenal manometry. Antroduodenal manometry, although somewhat invasive and lengthy (requiring at least 5 hours of recording), provides information about coordination of gastric and duodenal motor function in both fasting and postprandial periods. [26] Ambulatory studies, performed over 24 hours using solid-state transducers, allow correlation of symptoms with abnormal motility; catheter migration in the stomach prevents quantitation of antral contractility. The main indications for antroduodenal manometry are to evaluate the following:

- Unexplained nausea and vomiting
- The cause of gastric or small bowel stasis (e.g., neuropathic or myopathic disorders)
- Suspected chronic intestinal pseudoobstruction when the diagnosis is unclear. [26]

Decreased antral contractility and phase III MMCs originating in the small intestine rather than in the stomach can be seen in gastroparesis. Occasionally, pylorospasm or irregular bursts of small intestinal contractions, which increase outflow resistance, can be seen. Antroduodenal manometry can help to confirm or exclude a GI motility disorder if the gastric emptying test is normal or borderline. With an accurate stationary recording, a reduced postprandial distal antral motility index is correlated with impaired gastric emptying of solids. [27] An average of less than one antral contraction per minute postprandially has been suggested as a simple estimate of significant hypomotility. [37] A normal study with a normal transit test strongly suggests that motor dysfunction is not the cause of symptoms. [26] Antroduodenal manometry may differentiate between a neuropathic or myopathic motility disorder, and it may suggest unexpected small bowel obstruction or rumination syndrome. [26], [38] Myopathic disorders, such as scleroderma or amyloidosis, have low-amplitude contractions with normal propagation. Neuropathic disorders have normal amplitude but abnormal propagative contractions, seen readily in the phase III MMC, such as bursts and sustained uncoordinated pressure activity, and a failure of a meal to induce the fed-type pattern. Occult mechanical obstruction of the small intestine is suggested by two types of patterns: postprandial clustered contractions for more than 30 minutes' duration separated by quiescence and simultaneous prolonged (>8 seconds) or summated contractions suggesting a common cavity phenomenon from a dilated segment of intestine. [39] Antroduodenal manometry may demonstrate a characteristic pattern of rumination with an increase in intra-abdominal pressures at all levels of the upper gut (R waves), especially postprandially. [40] In pediatric studies, the absence of MMCs is an indicator of a poor response to prokinetic agents. [41] Some investigators perform the study with infusions of erythromycin or octreotide to predict the patient's response to long-term treatment of these agents. [42]

Gastroparesis and Disorders with Delayed Gastric Emptying

Gastroparesis occurs in many clinical settings (Table 65-4); the most common are idiopathic conditions, diabetes mellitus, and sequelae of gastric surgery. The relative prevalence depends on referral patterns of reporting investigators. In a series of 146 patients, gastroparesis was idiopathic in 36%, diabetic in 29%, and postsurgical in 13% of patients. [1]

Idiopathic
Endocrine or metabolic
Diabetes mellitus
Thyroid disease
Renal insufficiency
After gastric surgery
After resection
After vagotomy
Central nervous system disorders
Brainstem lesions
Parkinson disease
Peripheral neuromuscular disorders
Myotonia dystrophica
Duchenne muscular dystrophy
Connective tissue disorders
Scleroderma
Polymyositis/dermatomyositis
Infiltrative disorders
Lymphoma
Amyloidosis
Diffuse gastrointestinal motility disorder
Chronic intestinal pseudoobstruction
Medication-induced (see Table 65-2)
Electrolyte imbalance
Potassium, calcium, magnesium
Miscellaneous conditions
Infections (especially viral)
Paraneoplastic syndrome
Ischemic conditions
Gastric ulcer

Adapted from ref. 19.

TABLE 65-4 Etiology of Gastroparesis (Nonobstructive Delayed Gastric Emptying)

Diabetic Gastroparesis Gastroparesis is a well-known complication of *diabetes,* most commonly associated with long-standing, insulin-dependent diabetes mellitus with other complications of retinopathy, nephropathy, and peripheral neuropathy. Frequently, it occurs with autonomic neuropathy as identified by orthostatic hypotension. Longitudinal studies suggest that delayed gastric emptying is present in 30% to 50% of patients with long-standing type 1 or type 2 diabetes but is not necessarily associated with diabetic complications. [43] Diabetic gastroparesis is clinically important because it is associated with GI symptoms, alterations in glycemic control, and changes in oral drug absorption. [43] Symptoms from diabetic gastroparesis include primarily nausea and vomiting, but also early satiety, fullness, and abdominal discomfort. The presence of abdominal bloating or fullness in particular appears to be associated with diabetic gastroparesis. [44] Symptom severity, however, does not necessarily correlate well with the degree of gastric stasis. [7], [45] Patients with severe symptoms may have only a mild delay or even normal gastric emptying. One study, examining the effect of the prokinetic agent, domperidone, in diabetic gastroparesis suggested that symptom improvement did not correlate with improvement in gastric emptying, but rather with resolution of dysrhythmias. [8] Diabetic gastroparesis has been considered to be associated with a poor prognosis; more recent studies suggest this may be incorrect. [43] The motor dysfunction is typically confined to the stomach (gastroparesis), but sometimes a diffuse GI motility disorder may be present. Diabetic "gastropathy" has been used to include a range of gastric pathophysiological abnormalities observed in diabetic patients with dyspeptic symptoms. Gastric motor abnormalities include impaired fundic relaxation with antral dilation, gastric dysrhythmias, antroduodenal incoordination, antral hypomotility, and visceral hypersensitivity [4]; gastroparesis may be the end stage of gastric dysfunction. The term *gastropathy* has also been used because symptoms do not predict delayed gastric emptying, and the response to prokinetic treatment is not necessarily related to improvement in emptying. Diabetic gastroparesis likely results from impaired neural control of gastric motor function, possibly resulting from a vagal neuropathy. Morphologic abnormalities of the gastric myenteric plexus in diabetic patients have not been identified by conventional histology. [46] Abnormal neural innervation and neurotransmission of both inhibitory and excitatory neurotransmitters and underlying muscle dysfunction have been described in animal models of diabetes. Impairment of the inhibitory nitric oxide–containing nerves [47] and damage of the interstitial cells of Cajal, [48] the electrical pacemaker cells, have been described in animal models and in patients with diabetic gastroparesis. [49] Gastroparesis has also been described in type 2 diabetes mellitus. [7] However, it is also not uncommon in this disease for gastric emptying to be accelerated. [50] Usually, this change occurs early in the disease. This may be related to a lack of a fundic receptive relaxation response, a vagally mediated response. [51] Hyperglycemia itself may reversibly affect gastric motility. Hyperglycemia decreases antral contractility, decreases antral phase III MMC activity, increases pyloric contractions, causes gastric dysrhythmias (primarily tachygastria), and delays gastric emptying. [36], [52] Normalization of serum glucose in hyperglycemic patients has been shown to improve gastric myoelectric activity, to improve gastric emptying, and to restore antral phase III activity. [53] It is not clear how hyperglycemia adversely affects gastric motility. Hyperglycemia appears to cause a reversible impairment of vagal efferent function. [54] Glucose-responsive neurons have been identified in the central nervous system (CNS) that may modify vagal efferent activity. [55] Prostaglandins may also be involved, because indomethacin can reverse abnormal gastric electrical rhythms that occur during hyperglycemia. [56] Patients with insulin-dependent diabetes mellitus have an increased perception of gastric distention, with more nausea, fullness, and upper abdominal pain. [4] Hyperglycemia increases nausea and fullness during proximal gastric distention. [52], [57] Increased sensitivity of the proximal stomach may be responsible for dyspeptic symptoms postprandially when the stomach is distended by a meal. [4], [57] This is also reflected in studies showing that the prevalence of GI symptoms in insulin-dependent diabetes mellitus is greater in patients with poor glycemic control. [58] Changes of gastric motility may affect postprandial blood glucose concentrations. Delayed gastric emptying may contribute to poor glucose control because of unpredictable delivery of food into the duodenum. [52] Impaired gastric emptying with continued administration of exogenous insulin may produce hypoglycemia. Conversely, acceleration of emptying has been reported to cause hyperglycemia. [50] Problems with glucose control may be the first indication that a diabetic patient is developing gastroparesis. [52] Interestingly, gastroparetic symptoms may be mild or absent. Long-term oral administration of the prokinetic agents levosulpiride and erythromycin, which accelerate gastric emptying, were shown to decrease plasma glucose and glycosylated hemoglobin (HbA_{1c}) levels in diabetic patients. [59], [60]

Postsurgical Gastroparesis *Postsurgical gastroparesis* generally occurs after peptic ulcer surgery, [61] most commonly when a truncal vagotomy is performed. Vagal nerve stimulation causes both fundic relaxation and antral contractions; the effect of a total vagotomy is to accelerate gastric emptying of liquids and to delay emptying of solids. A gastric drainage procedure such as a pyloroplasty or gastroenterostomy is usually performed in an attempt to offset the gastroparetic effects of vagotomy. In most patients, the net result is that vagotomy combined with a drainage procedure produces little alteration in gastric emptying. The results of different gastric surgical procedures on gastric emptying are shown in Table 65-5.

TABLE 65-5 Gastric Emptying Alterations after Different Types of Gastric Surgery

About 5% of patients undergoing vagotomy with antral resection and gastrojejunostomy develop severe postsurgical gastroparesis; the antrum is not present to triturate solids, and the proximal stomach is unable to generate sufficient pressure to empty solids. [61] Patients with gastric outlet obstruction undergoing surgery may also develop postsurgical gastric stasis; the chronic gastric dilation may have led to irreversible gastric muscle dysfunction. The Roux-en-Y stasis syndrome is characterized by postprandial abdominal pain, bloating, nausea, and vomiting. [61] The combination of vagotomy, distal gastric resection, and Roux-en-Y gastrojejunostomy predisposes to gastric stasis. Gastric stasis is the esult of both slow emptying from the gastric remnant and delayed small bowel transit in the Roux efferent limb. [61] Ectopic jejunal pacemakers may develop in the transected and reattached jejunal segment. In addition, myoelectric and motor activity in the Roux limb is slower than normal and may be retrograde, causing reverse peristalsis toward the stomach and allowing the Roux limb to cause a functional obstruction. [62] Gastroparesis is unusual in patients with a highly selective parietal cell vagotomy. Transient myoelectric abnormalities may occur, but they usually disappear with time. [63] Development of delayed gastric emptying after highly selective vagotomy may suggest complete vagotomy. [64]

Post-Nissen fundoplication gastric motor dysfunction. Mild acceleration of gastric emptying can occur after Nissen fundoplication. [65], [66] Regional scintigraphy suggests rapid proximal gastric emptying after fundoplication. This has been attributed to an increase in intragastric pressure resulting from the fundic wrap preventing receptive relaxation. This may lead to symptoms of early satiety. [66] In patients with GERD and delayed gastric emptying, there can be normalization of emptying after fundoplication. [66] Emptying has been reported to improve after radiofrequency ablation of the LES. [67] *Gas bloat syndrome* refers to postoperative symptoms including inability to belch, pain, and bloating. It is more common in patients with preoperative delayed gastric emptying. [68] Early satiety, postprandial fullness, nausea, and vomiting may develop after fundoplication. [69] In some of these patients, postprandial antral hypomotility or a delay in gastric emptying can be seen. [70], [71] Delayed gastric emptying may have been present before surgery but not recognized because of the GERD symptoms. The development of postoperative gastroparesis after an open or laparoscopic Nissen fundoplication is uncommon but at times may result in significant morbidity. [71] Vagal nerve injury has been reported in 4% to as many as 40% of patients undergoing laparoscopic fundoplication. [72], [73]

After bariatric surgery. Surgical therapy for morbid obesity has increased since the late 1990s. Several procedures are designed to restrict stomach size. [74] The most commonly performed surgical procedure is the Roux-en-Y gastric bypass. The stomach is partitioned into a small proximal fundic pouch, and a bypassed distal stomach; a loop gastrojejunostomy through a small gastroenterostomy, drains the proximal pouch. [74] Ingestion of large meals is prevented by early satiety resulting from the small gastric pouch. The gastrojejunostomy configuration produces a relative malabsorptive state and can result in dumping if a high-carbohydrate liquid meal is ingested. Solid emptying is slower, and liquid emptying is faster after gastric bypass surgery. [75] Less commonly performed are gastric restrictive procedures

including vertical banding gastroplasty and adjustable gastric banding. [74] Vomiting can occur after vertical banding gastroplasty, reported in 21% of patients. [76] Another study found that emptying from the proximal pouch was normal and could not explain the early satiety. [77]

Idiopathic Gastroparesis *Idiopathic gastroparesis* refers to symptomatic gastroparesis in patients with no primary underlying abnormality. In most series, idiopathic gastroparesis is the most common form of gastroparesis. [1] Symptoms may fluctuate, with episodes of pronounced symptoms interspersed with relatively symptom-free intervals. Patients with idiopathic gastroparesis are typically young or middle-aged women. Even after adjusting for gender differences in gastric emptying, gastroparesis occurs more commonly in women. [12] A potential cause in some patients includes viral injury to the nerves or muscles of the stomach. Postviral gastroparesis was suspected in 23% of patients with idiopathic gastroparesis reported by Bityutskiy and associates. [78] This clinical diagnosis is suggested in previously healthy persons with an acute onset of viral illness with nausea, vomiting, diarrhea, fever, and cramps who have persistence of symptoms (nausea, vomiting, early satiety) for more than 3 months, with a delay in gastric emptying but no evidence of mechanical obstruction, metabolic disease, or systemic illnesses. Viruses suspected as potential causes are cytomegalovirus, (CMV) Epstein-Barr virus, and herpes varicella-zoster. Symptoms of idiopathic gastroparesis after a presumed viral illness tend to be less severe than in gastroparesis from other causes. Overall, these patients appear to have good prognosis, with many patients having a slow resolution of their symptoms. [78]

Other Disorders Associated With Delayed Gastric Emptying

Gastrointestinal Disorders

Gastroparesis associated with gastroesophageal reflux disease. Delayed gastric emptying can be seen in patients with GERD. Gastric stasis with distention may promote transient lower esophageal sphincter relaxation with subsequent gastroesophageal reflux. Some investigators have found delayed emptying in 40% of patients with GERD [79]; others have not shown this high prevalence. [80] Delayed emptying occurred equally in patients with and without reflux on esophageal pH monitoring, was independent of severity of reflux symptoms, and was independent of the presence of esophagitis. [80] Studies suggest that slow emptying from the proximal stomach, but not from the overall stomach, may correlate with esophageal acid exposure. [81] Ultrasound studies have shown that proximal gastric distention after a meal promotes GERD by increasing transient lower esophageal sphincter relaxations. [82]

Achalasia. Gastric emptying is difficult to study in achalasia because the ingested meal is often retained in the esophagus. Gastric emptying studies in these patients have been variable; several reported no abnormalities in gastric emptying. [83] Studies delivering liquid meals into the stomach through a nasogastric tube have shown rapid emptying of liquids. [84] After successful pneumatic dilation, gastric emptying of solid meals was delayed in 50% of patients with achalasia. [85] These emptying abnormalities may be related to abnormalities of the vagus nerve and dorsal motor nuclei of the vagus, which have been reported in some achalasia patients.

Gastric ulcer. Delayed gastric emptying has been reported in some patients with gastric ulcers. In some patients, the gastroparesis has resolved after ulcer healing. It may be difficult to determine whether the ulcer caused the gastric emptying delay or the gastric stasis caused the ulcer.

Atrophic gastritis. Atrophic gastritis is characterized by a decrease in gastric acid secretion usually leading to hypergastrinemia through acid-gastrin feedback regulation. Atrophic gastritis may result from pernicious anemia or may occur on a nonautoimmune basis. Delayed gastric emptying is present in two thirds of patients with achlorhydric atrophic gastritis and in one third of those with preserved acid secretion. Delayed gastric emptying in atrophic gastritis is associated with reduction of gastric acid output and hypergastrinemia, rather than severity of mucosal atrophy. [86]

Functional dyspepsia. See section “ Functional Dyspepsia” later in the chapter.

Hypertrophic pyloric stenosis. Infantile hypertrophic pyloric stenosis (IHPS), occurring in up to 0.3% of births, is the most common disorder during the first 6 months of life that requires abdominal surgery. A typical infant begins to vomit within the first 4 weeks of age. Hypertrophy of the inner circular muscle of the pylorus produces pylorospasm or functional gastric outlet obstruction resulting in nonbilious vomiting, dehydration, and metabolic alkalosis. An enlarged pylorus (pyloric olive) can be palpated or detected radiologically. Pylorospasm occurs from a defect in pyloric sphincter relaxation and not from a true obstruction. A lack of inhibitory nerves of the pylorus, primarily nitric oxide–containing nerves, and interstitial cells of Cajal has been shown in IHPS. [87], [88] Treatment with surgical pyloromyotomy is effective. Patients usually remain symptom free after surgical treatment; the muscle hypertrophy resolves. The nitric oxide and interstitial cells of Cajal abnormalities partially reverse, [89] although on manometry, the pyloric tone is higher and the phasic pyloric pressure waves are less frequent than in physiologically normal infants. [90] Medical treatment with atropine has been suggested by European groups. Hypertrophic pyloric stenosis with achalasia has been reported in the same patient. IHPS has been associated with the use of erythromycin for pertussis prophylaxis in neonates. [91] IHPS in adults is rare. [92] Diagnostic criteria for adults have been variable. Early reported cases were related to local inflammation and fibrosis from previous gastric or duodenal ulcer. In the uncommon idiopathic form, there is hypertrophy of the smooth muscle without any underlying disease. A certain proportion of these primary cases may represent persistence of the juvenile form, presenting later in life. Endoscopic dilation and laparoscopic pyloroplasty have been used for treatment. [93]

Celiac disease. Delayed gastric emptying is seen in 50% of patients with celiac disease, which normalizes with a gluten-free diet and recovery of small bowel mucosa. Delayed gastric emptying has been suggested to explain some of the dyspeptic symptoms in celiac disease. [94] Delayed emptying has been demonstrated by scintigraphy [95] and ultrasonography in assessing the antral area. [96] This was also reported with the ^{13}C-octanoate breath test for gastric emptying [94]; however, the small bowel malabsorption may “prolong” the gastric emptying values obtained, because excretion of ^{13}C is dependent on small bowel absorption.

Gallbladder disease. Delayed gastric emptying, in addition to delayed gallbladder emptying, may be present in cholelithiasis. [97] Studies have reported delayed solid phase gastric emptying in 20% to 42% of patients with gallstones, [98] whereas others have not found alterations in liquid phase emptying. [97] Interestingly, cholecystectomy has been shown to normalize gastric emptying. [98]

Chronic pancreatitis. Some patients with chronic pancreatitis have delayed gastric emptying. [99] Some of the abdominal pain, nausea, and vomiting seen in patients with presumed or documented chronic pancreatitis may result from gastroparesis; this may be related to the increased serum levels of endogenous cholecystokinin (CCK). [99] One study showed impaired gastric myoelectric activity in chronic pancreatitis [100]; this abnormality was restored toward normal with pancreatic enzyme replacement. Gastric emptying is variable in cystic fibrosis: early in the disease, it may be rapid; later in the disease, it is delayed. [101]

Liver disease. Abnormal scintigraphic gastric emptying has been reported in up to 78% of patients with cirrhosis of the liver. [102] The delay in gastric emptying is correlated with the severity of liver disease, as indicated by either Child-Pugh status, bilirubin level, prothrombin time, and presence of esophageal varices. [102] Secretin and endothelin have been suggested as playing a role in the gastric dysmotility with cirrhosis and portal hypertension. [103], [104] Delayed emptying has also been reported in patients with portal hypertension of either intrahepatic or extrahepatic pathology and does not correlate with corrected wedged hepatic venous pressure. [105] Other studies have not shown significant changes in gastric emptying [106] and have even reported acceleration of liquid phase gastric emptying. [107] Gastric emptying using the octanoate breath test may be prolonged in patients with cirrhosis, but normal with scintigraphy, because hepatic metabolism of octanoate may be abnormal. [108] Interferon-a treatment may delay gastric emptying and may cause dyspeptic symptoms; interferon treatment delayed gastric emptying in 12 of 14 patients and was associated with development of anorexia and abdominal discomfort. [109] Prokinetic therapy improved gastric emptying and GI symptoms during interferon-a therapy.

Constipation. Delayed gastric emptying is not uncommonly observed in patients with constipation. The finding of delayed gastric emptying suggests the possibility of a diffuse GI disorder. [110] This has implications for treatment; patients with chronic severe constipation and proximal GI tract dysmotility often have poor responses to colectomy. Volitional suppression of defecation can delay gastric emptying, suggesting a “cologastric brake” or the effects of stress. [111]

Diffuse gastrointestinal motor disorders. Gastroparesis can occur as a part of a diffuse GI motility disorder. *Chronic intestinal pseudoobstruction* is a syndrome with recurrent symptoms suggestive of intestinal obstruction in the absence of mechanical blockage. Symptoms are caused by ineffective peristalsis and include nausea, vomiting, and abdominal pain with abdominal distention. Radiologic findings consist of air-fluid levels within the small intestine. The term *diffuse GI motility disorder* rather than chronic intestinal pseudoobstruction, is often used if several portions of the GI tract have delayed transit but no air-fluid levels seen on abdominal radiographs. [19] Chronic intestinal pseudoobstruction can be caused by several systemic diseases including scleroderma, amyloidosis, myxedema, and long-standing diabetes mellitus. Often, it is idiopathic, with no known cause. The two main forms of idiopathic pseudoobstruction are myopathic and neuropathic. The bowel wall in the myopathic form (e.g., hollow visceral myopathy) shows thinning and degeneration of smooth muscle with replacement by fibrous tissue. The neuropathic form (e.g., visceral neuropathy) has normal smooth muscle histologically but abnormalities in neurons and glial cells within the splanchnic ganglia or myenteric plexus. Small bowel manometry may help to differentiate these two forms. In intestinal myopathy, low-amplitude contractions that propagate normally are seen. In intestinal neuropathy, individual contractions are of normal amplitude but disorganized: disruption of the phase III MMC, bursts of nonpropagating activity during fasting, and failure to convert from the fasting to the fed pattern with a meal are typical.

Nongastrointestinal Disorders Associated with Delayed Gastric Emptying

Eating disorders: anorexia, bulimia, rumination. *Anorexia nervosa* is a psychiatric disorder occurring primarily in adolescent and young adult women characterized by distorted body image and fear of obesity with compulsive dieting and self-imposed starvation to maintain a profoundly low body weight. GI symptoms are common and include lack of appetite, early satiety, epigastric fullness, abdominal bloating, nausea, and vomiting. [112], [113] Patients with anorexia nervosa often have delayed gastric emptying primarily for solids. [113] Interestingly, realimentation and maintenance of normal body weight improve gastric emptying and GI symptoms. [112], [114] Prokinetic therapy had been suggested to improve gastric emptying and to facilitate refeeding [113]; other studies have not shown an effect on weight gain. [115] Pathogenesis of gastric dysfunction in anorexia is probably multifactorial; starvation and malnutrition with marked endocrine disturbances may play a role; others have suggested a CNS disturbance related to the psychiatric abnormality. *Bulimia nervosa* is characterized by recurrent episodes of binge eating with a feeling of lack of control over the eating behavior during the binges, often followed by self-induced vomiting, the use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise to prevent weight gain. [116] Self-induced vomiting allows bulimic patients to continue eating or to terminate the binge. In contrast to anorexia nervosa, concern about weight and body size does not lead to a fall in weight below normal. Symptoms of postprandial fullness, early satiety, bloating, nausea, and epigastric pain may

be occur. [117] Depression may be an important determinant of GI symptoms. [117] Gastric emptying studies in bulimia have conflicting results; some (37%) of bulimic patients appear to have delayed emptying. [116] *Rumination syndrome* is the effortless regurgitation of recently ingested food into the mouth with subsequent remastication and reswallowing or expectorating of food. Initially described in children and mentally retarded institutionalized persons, there is an increasing awareness of this disorder in adults of normal intelligence. Rumination can become a habit, often initiated by a belch, a swallow, or by stimulation of the palate with the tongue. Abdominal muscle contraction with LES relaxation in the early postprandial period is responsible for regurgitation. [118] Typically, the effortless repetitive regurgitation occurs within 15 minutes of starting a meal, in contrast to vomiting from gastroparesis, which occurs later in the postprandial period. [40] Symptoms often cease when regurgitated food becomes acidic to taste. Difficulty in diagnosis results from lack of awareness and the difficulty differentiating rumination from vomiting caused by gastroparesis or regurgitation from GERD. Gastric emptying and esophageal pH monitoring are usually normal. Gastroduodenal manometry shows characteristic brief simultaneous increases in gastric and small bowel pressure (R waves) seen in all abdominal recording ports during the postprandial period. These represent abdominal wall contractions, and, if performed with esophageal pH monitoring, they are associated with a decrease in distal esophageal pH. These characteristic findings are seen in only one third of patients with clinical symptoms of rumination. [40] Making the patient aware of this habit may be beneficial. Treatment is with behavioral modification and biofeedback therapy administered in a formal eating-regulation program. Concentration on diaphragmatic breathing after eating may help. Biofeedback techniques help to teach patients to relax abdominal muscle during and after eating. [119] Chewing gum postprandially has been suggested to be helpful.

Cyclic vomiting syndrome. *Cyclic vomiting syndrome* refers to recurrent episodes of intense nausea and vomiting lasting hours to days separated by symptom-free periods of variable lengths. Typically, each episode is similar. Vomiting often starts abruptly, although a prodrome of nausea and abdominal pain can occur. The vomiting reaches highest intensity during the first hours, diminishes thereafter, and ends rapidly. The duration of vomiting averages 3 to 4 days and can lead to marked dehydration. This disorder is well characterized in children, but it has also been described in adults. [120], [121] In adults, the vomiting episodes are longer (3 to 5 days), less frequent (every 3 to 4 months), and triggering events are less evident [121]; there is usually a long delay in diagnosis. Abnormal upper GI motility can be demonstrated by gastric emptying scintigraphy, antroduodenal manometry, and EGG even in the asymptomatic state; however, these tests are often normal. [122] Precipitating events, identified in a few patients, include onset of menstrual periods and stress. Cyclic vomiting syndrome, also referred to as *abdominal migraine or abdominal epilepsy,* is associated with migraine headaches in patients and other family members. The cause of this disorder is unknown: a mechanistic relationship to migraine, underlying hypothalamic-pituitary axis derangement, or an inappropriate activation of vomiting reflex has been suggested. [120] Mitochondrial disorders have been identified in some patients. [123] There is no standard management for this disorder. Sleep, a quiet environment, and the use of benzodiazepines such as lorazepam may be effective. [121] Tricyclic antidepressants (e.g., amitriptyline or doxepin) in low doses may prevent attacks [121]; others have suggested that ß-blockers such as propranolol may prevent attacks. Antiemetics such as ondansetron and prokinetic agents such as metoclopramide or erythromycin may provide temporary relief during vomiting episodes. Antimigraine therapies such as the 5-HT $_{1D}$ receptor agonist sumatriptan, given subcutaneously, may reduce the severity of attacks. The use of nonsteroidal antiinflammatory drugs, such as indomethacin or ketorolac, given intramuscularly, has been reported to prevent or reduce the intensity of attacks if these drugs are given during the prodromal period. [120] These agents inhibit prostaglandin formation and may correct gastric dysrhythmias or act centrally.

Neurological disorders. CNS causes of gastroparesis are rare. Any condition associated with increased intracranial pressure may produce emesis, with or without nausea, by activation of brainstem structures mediating vomiting. [16] Focal lesions including tumors, especially those involving the brainstem and posterior fossa, can cause nausea and vomiting and can even present with gastroparesis. Demyelinating diseases such as multiple sclerosis and other demyelinating disorders have been reported to cause gastroparesis. [124] An adult patient with vomiting from a central mass lesion usually has CNS symptoms or signs, such as headache, cranial nerve findings, long tract signs, or papilledema. [125] Rarely, objective neurological findings may be absent. [126] Magnetic resonance imaging is better than computed tomography for visualization of the posterior fossa. Gastroparesis is common in Parkinson disease, reported in 70% of patients. [127] The stomach can be affected by the underlying parkinsonian neurodegenerative pathology; Lewy bodies have been reported in the myenteric plexus of the stomach. [128] Medications used to treat Parkinson disease such as L-dopa can delay gastric emptying. Impaired gastric emptying with delayed levodopa absorption may be a reason for a poor response to medical therapy for Parkinson disease. [127] Domperidone may be a useful prokinetic agent in Parkinson disease; domperidone does not cross the blood-brain barrier and should not interfere with centrally acting antiparkinsonism medications. [129]

Collagen vascular disorders. *Scleroderma* (systemic sclerosis) is a systemic inflammatory disorder affecting the skin and other organs. GI manifestations usually follow cutaneous and other systemic manifestations. [130] The esophagus is involved in about 75% of patients, especially when Raynaud phenomenon is present. Myogenic abnormalities from smooth muscle fibrosis are seen: feeble middle and distal esophageal contractions and a low LES pressure. Gastric involvement is less frequent than that of the esophagus, small intestine, or colon. Gastric involvement has been reported in 10% to 75% of patients, commonly as delayed gastric emptying. Watermelon stomach is also reported associated with scleroderma. [131] Gastric emptying of radiopaque pellets was delayed in 50% of patients with systemic sclerosis. [131] Delayed gastric emptying is usually seen only in patients with esophageal transit abnormalities [132]; it can occur in some normal esophageal manometry. [131] Antroduodenal manometry classically reveals very low-amplitude antral and duodenal contractions with normal MMC propagation. [130] *Polymyositis and dermatomyositis* classically affect only the skeletal muscle, as recognized on esophageal manometry with dysfunction of the upper esophageal sphincter and upper esophagus. However, polymyositis and dermatomyositis may be associated with other GI motor dysfunction. Gastric emptying was found to be delayed in 8 of 13 patients and correlated with the severity of the peripheral (skeletal) muscle weakness. [133] Systemic lupus erythematosus rarely affects gastric motility. Delayed gastric emptying has been reported in a patient with systemic lupus erythematosus; functional gastric outlet obstruction with antral narrowing from thickened folds resolved with prednisone treatment. [134] *Amyloid-associated GI dysmotility* can be manifested as intestinal pseudoobstruction, diarrhea, or achalasia. [135] GI symptoms typically include anorexia, difficulty with eating from macroglossia, and altered bowel habits. Nausea may occur in up to 40% of patients with amyloidosis. [135] Clinical gastroparesis occurs rarely in patients with amyloidosis; one study reported only 3 cases in 769 patients. [136]

Endocrine and metabolic disorders: thyroid, parathyroid, renal failure. *Hypothyroidism* should be excluded in all patients with gastroparesis. Although it represents only a small percentage of patients with gastroparesis, it is easily treated with thyroid supplementation. There is poor correlation between the gastric emptying and the elevated thyroid-stimulating hormone level. [137] Intestinal pseudoobstruction has also been described in hypothyroidism. *Hyperthyroid* patients may be expected to have rapid gastric emptying; studies have reported normal, rapid, and delayed gastric emptying. [138], [139] Delayed gastric emptying with gastric dysrhythmias have been reported; these resolve with treatment of the hyperthyroidism. [139] The delayed gastric emptying has been suggested to result from associated autonomic dysfunction. [139] In both hyperthyroidism and hypoparathyroidism, small intestine pseudoobstruction has been reported. Parathyroid hormone has been shown to relax gastric and other GI smooth muscle directly. [140] Whether it influences gastric emptying is not known.

Chronic renal failure. GI symptoms, especially anorexia, nausea, and vomiting, are often present in renal failure. Symptoms may be from uremia, medications, gastric mucosal ulceration, or gastroparesis. Gastric emptying studies have yielded conflicting results. Delayed emptying has been seen in patients with symptomatic uremia. [141] Normal emptying is most commonly seen in patients undergoing hemodialysis. Delayed emptying has been reported to be associated with changes in nutritional status and autonomic neuropathy. [142], [143] Using the octanoate breath test, delayed gastric emptying was present in 62% of patients undergoing long-term hemodialysis; delayed emptying was present in 91% of patients with dyspeptic symptoms and in 40% of those without symptoms. [144] Chronic ambulatory peritoneal dialysis delays emptying, primarily when the abdomen contains the dialysate; emptying normalizes after the dialysate is emptied. [145]

Gastric infections. Delayed gastric emptying can be seen during a variety of acute *viral infections* including herpes zoster and infections with Epstein-Barr virus, CMV, rotavirus, and parvoviruses. [146] Nausea and vomiting have been associated with altered gastric motor function [147]; this has been shown during acute viral gastroenteritis with parvovirus-like agents (Norwalk and Hawaii viruses). Delay in gastric emptying is usually transient and returns to normal with recovery from the viral infection. In rare patients, chronic symptoms and delayed gastric emptying may result [148], [149]; this may be one cause of idiopathic gastroparesis. Gastric CMV occurs often in immunosuppressed persons, particularly organ transplant recipients. [150] Upper GI CMV infection has been reported to occur in one third of patients after liver transplantation, often associated with typical symptoms of gastroparesis including nausea and abdominal fullness. Endoscopy can show large antral folds, gastric inflammation including acute superficial gastritis, and duodenal erosions and ulcerations. Viral cultures of gastric biopsies and histological presence of CMV inclusions in the gastric mucosa are used for diagnosis. [150] The CMV infection can be treated with ganciclovir. GI infection with CMV is unusual in immunologically normal persons. A case report documents acute CMV infection causing GI dysmotility in an immunocompetent patient; the disturbance in GI motor function persisted for years after viral infection had been eradicated. [148] Gastric emptying may be delayed in one third of persons seropositive for human immunodeficiency virus (HIV), [151] particularly those with advanced disease evidenced by low CD4 counts, marked weight loss, and enteric infections. [152] In immunocompromised patients, the acute stage of gastritis and gastroparesis from viruses and other infectious agents, especially with CMV and *Mycobacterium avium-intracellulare,* may persist for prolonged times. Some investigators have found delayed gastric emptying of solids with diminished postprandial antral motility but rapid emptying of the liquids, suggesting an autonomic neuropathy that is common in HIV infection. [153] It had been speculated that *Helicobacter pylori* causes GI motor abnormalities. Although a few studies have suggested an association, [154] most show that *H pylori* does not cause delayed gastric emptying or functional dyspepsia. [155] One study reported that chronic antral *H pylori* gastritis was associated with a lower incidence of the phase III MMC starting in the antrum in dyspeptic patients. [156] One study suggests that dyspeptic patients with *H pylori* infection have a high prevalence of gastric dysrhythmias; eradication of *H pylori* normalized gastric myoelectric activity and improved symptoms. [157]

Chronic mesenteric ischemia (ischemic gastroparesis). Gastric ischemia may occur in chronic *atherosclerotic disease;* the gastric ischemia is insidious and often is not recognized. Ischemic gastropathy secondary to atherosclerosis may present as gastritis, ulceration, or gastroparesis. [158] Angiography demonstrates arterial occlusion. Cases of chronic *mesenteric ischemia* with chronic gastric ischemia causing gastroparesis and gastric dysrhythmias have been reported. [159] Surgical

revascularization may improves gastric emptying and corrects gastric dysrhythmias in select patients.

Gastroparesis after lung and heart lung transplantation. Gastroparesis has been reported after heart and lung transplantations. [160], [161] After lung transplantation, gastroparesis may predispose to gastroesophageal reflux with microaspiration and subsequent pulmonary infection, which can have deleterious effects on the transplanted lungs. Symptomatic delayed gastric emptying was present 25% of patients after single lung transplantation and in 50% of patients after combined heart and lung transplantation. [160] A more recent study reported delayed gastric emptying in eight of ten patients after combined heart and lung transplantation. [161] Several causes may explain gastroparesis after heart and lung transplantation: vagal nerve dysfunction, viral infection, and immunosuppressive medications. Vagal nerve dysfunction from thermal or ischemic injury or dissection of posterior mediastinum during surgery has been suggested as the most likely cause. [160], [161]

Gastroparesis secondary to malignant disease (tumor-associated gastroparesis). Tumor-associated gastroparesis has been described with esophageal, gastric, pancreatic, breast, and lung carcinoma. The pathophysiology is unknown, but frequently it is attributed to paraneoplastic effects, neural invasion of the tumor, or the side effects of chemotherapy. In *gastric cancers* that are nonobstructing, tumor infiltration into the stomach wall may disrupt smooth muscle or neural innervation. The symptoms and delay in gastric emptying can be responsive to prokinetic agents, including metoclopramide. [162] *Small bowel tumors* are rare and can be difficult to diagnose. Infrequently, patients initially diagnosed with gastroparesis are found, on further evaluation, to have a small bowel adenocarcinoma causing symptoms from partial obstruction. [163] These tumors can be missed on an SBFT examination. Enteroclysis provides a more detailed evaluation. In *pancreatic cancer,* delayed gastric emptying has been reported in 40% to 60% of patients without gastroduodenal invasion or obstruction. Usually, the gastroparesis is asymptomatic, but it may be responsible for the nausea, vomiting, and abdominal or back pain that occur. [164] Retroperitoneal nerve invasion of the tumor has been postulated as a cause of the gastroparesis, although gastroparesis can also occur with resectable cancers. *Pseudoobstruction with delayed gastric emptying* may represent a paraneoplastic syndrome that occurs primarily with small cell lung carcinoma. [165] Intestinal dysmotility is suspected to have an autoimmune basis, reacting with the myenteric plexus. Pathological studies have shown degeneration of the myenteric plexus with infiltration by plasma cells and lymphocytes and markedly reduced numbers of neurons. [166] The onset of GI dysmotility not infrequently precedes the diagnosis of cancer [165]; patients may have a normal chest radiograph at presentation with subsequent diagnosis of cancer by computed tomography, magnetic resonance imaging, or bronchoscopy. Antroduodenal manometry may show neuropathic abnormalities with incoordination of contractions. Type 1 antineuronal nuclear antibody (ANNA-1 or anti-Hu) can often be detected in paraneoplastic pseudoobstruction from small cell lung carcinoma. [165] Delayed gastric emptying with nausea and vomiting can occur during treatment of malignant disease. Gastroparesis can occur after radiation therapy for treatment of tumors, [167] during treatment with chemotherapeutic agents, [168] after bone marrow transplantation, [169] and after celiac plexus block for chronic pain from pancreatic cancer. [170]

Medication-induced gastroparesis. Nausea and vomiting can be side effects of medications. Nausea and vomiting in response to a drug are likely to present early in its use; medications usually cause acute rather than chronic nausea and vomiting. [16] Many drugs including anticholinergics, narcotic analgesics, tricyclic antidepressants, and calcium channel blockers are known to delay gastric emptying (see Table 65-2). Drug-induced gastroparesis may be asymptomatic, but it needs to be considered when delayed gastric emptying is found in a symptomatic patient; symptoms may not be from delayed gastric emptying. Gastric acid suppressing agents, such as histamine H_2 receptor antagonists and proton pump inhibitors, have been shown to delay gastric emptying. [171] Some studies, however, suggest that nizatidine, an H_2 receptor antagonist with cholinergic properties, may induce antral contractility and may promote gastric emptying. [172] Gastric emptying of solids is delayed in patients receiving total parenteral nutrition (TPN). [173] It is suggested that if assessment of gastric emptying and motility is performed in a patient who is receiving TPN, the TPN should be converted to saline for the test. [26] Slowing of gastric emptying during TPN is correlated with increase in blood glucose by the intravenous nutrients; hyperglycemia inhibits gastric emptying of solids. The inhibitory effect of hyperglycemia on gastric emptying may be mediated by a suppression of the vagal-cholinergic system. [173] Oral ingestion of fat is well known to delay gastric emptying through intestinal feedback and release of CCK. Intravenous infusion of fat emulsions also delays gastric emptying. [173], [174] The mechanism by which intravenous fat influences gastric motility is poorly understood; increased plasma CCK concentrations was reported in an initial study but was not confirmed in subsequent studies. [173], [174]

Treatment of Symptomatic Gastroparesis

The general principles for treatment of symptomatic gastroparesis are as follows: first, to correct fluid, electrolyte, and nutritional deficiencies; second, to identify and treat the underlying cause of gastroparesis; and third, to reduce symptoms. [16] The specific treatment depends on the severity of symptoms and the underlying disorder. For mild gastroparetic symptoms, dietary modifications and a low-dose prokinetic agent may be used. Medicines are reviewed to ensure that the patient is not taking an anticholinergic agent or narcotic analgesic that could delay gastric emptying or prevent the action of a prokinetic agent. For diabetic patients, blood glucose should be regulated carefully to prevent hyperglycemia. In severe cases of gastroparesis with vomiting, signs of dehydration, and poor glucose control, treatment may include hospitalization, intravenous hydration, nasogastric suction to decompress the stomach, regulation of blood glucose, and intravenous administration of antiemetic and prokinetic agents.

Dietary Treatment In gastroparesis, the diet should be modified to promote faster gastric emptying. Liquid nutrients in the diet should be increased, because emptying of liquids is usually less affected than solids. Because fat intake releases CCK, which can delay gastric emptying, low-fat meals with complex carbohydrates are suggested. Meals should be small to allow time for emptying to occur; gastric emptying of meals is regulated for a set number of calories to be emptied into the duodenum. [175] To compensate for small meals, patients may need to eat four or five times daily. A diet low in indigestible fiber and roughage will reduce the chance of bezoar formation. Alcohol and carbonated beverages should be avoided. Even low doses of alcohol can decrease antral contractility and impair gastric emptying. Carbonated beverages release carbon dioxide gas, which can aggravate gastric distention. Commercial or self-prepared liquid homogenized meals may be tolerated in small quantities. Larger volumes needed to cover daily caloric needs are often not. Sometimes enteral alimentation may be helpful. In some severe cases, TPN may be needed. This is not a long-term solution because of catheter-induced bacteremia, clot formation, and cost.

Glucose Control Diabetic patients with gastroparesis may have abnormally high glucose concentrations both after fasting and postprandially. Hyperglycemia itself has been shown to delay gastric emptying. [52], [53] This slowing is associated with reduced antral contractility and increased pyloric pressure. Hyperglycemia can inhibit the accelerating effects of prokinetic agents. [176] Improvement of glucose control can increase antral contractility, correct gastric dysrhythmias, and accelerate gastric emptying.

Antiemetic Agents Nausea and vomiting are treated with antiemetic agents. [16] Drug classes used to treat nausea and vomiting are phenothiazines, antihistamines, anticholinergics, dopamine receptor antagonists, and serotonin receptor antagonists. Phenothiazine compounds possess antiemetic properties. Their actions are mediated primarily through a central antidopaminergic mechanism at the chemoreceptor trigger zone in the area postrema of the medulla oblongata. [16] Commonly used agents include prochlorperazine (Compazine), trimethobenzamide (Tigan), and promethazine (Phenergan). These agents are commonly used for severe episodes of nausea and vomiting and are available as tablets, capsules, liquid suspensions, suppositories, and for injectable use. Sedation and extrapyramidal side effects may develop with these agents. [179] Antihistamines with H_1 receptor antagonistic properties have central antiemetic effects. [16] These include diphenhydramine (Benadryl), dimenhydrinate (Dramamine), and meclizine (Antivert). These agents exert antinausea effects by blocking H_1 receptors in the vestibular apparatus and the chemoreceptor trigger zone within the area postrema. In vection-induced motion sickness, dimenhydrinate reduced tachygastria, decreased symptoms, and caused drowsiness, suggesting that symptom improvement is by improvement of gastric myoelectric activity or depression of CNS activity. [178] Serotonin ($5\text{-}HT_3$) receptor antagonists, such as ondansetron (Zofran) and granisetron (Kytril), are useful in chemotherapy-induced nausea and vomiting. The primary site of action is likely the chemoreceptor trigger zone because of the high density of $5\text{-}HT_3$ receptors in the area postrema. [16] They may also act peripherally because $5\text{-}HT_3$ receptors are present in the GI tract. [16] If used, they are best given on an as needed basis because of the lack of evidence of prolonged efficacy and their expense. Benzodiazepines such as lorazepam and diazepam have been shown to be effective as adjunctive agents in the treatment of chemotherapy-related nausea and vomiting. [16]

Prokinetic Agents Prokinetic agents enhance contractility of the GI tract and accelerate the aboral movement of lumenal contents (Table 65-6). In general, prokinetic agents increase gastric antral contractility, correct gastric dysrhythmias, and improve antroduodenal coordination. Some of the prokinetic agents, metoclopramide and domperidone, also have antiemetic properties.

TABLE 65-6 Prokinetic Agents for Gastroparesis

Usually, prokinetic agents are administered 30 minutes before meals to maximize blood levels and gastric prokinetic effects at meal ingestion. In addition, a bedtime dose is often used so indigestible solids can be emptied from the stomach. Medications with anticholinergic activity may block the effects of prokinetics that work by facilitating acetylcholine release. In gastroparesis, pharmacological therapy with prokinetic agents is often needed on a prolonged basis. Because GI symptoms

correlate poorly with gastric emptying, the response to treatment is usually judged clinically; repeating gastric emptying tests is not necessary. Prokinetic therapeutic options are limited now that cisapride is not routinely available (see Table 65-6). Prokinetics available for clinical use are metoclopramide and erythromycin.

Metoclopramide. Metoclopramide (Reglan), a substituted benzamide structurally related to procainamide, has been used since the 1970s to treat gastroparesis. [179] Metoclopramide has both prokinetic and antiemetic effects. Metoclopramide releases acetylcholine from intrinsic cholinergic neurons and blocks peripheral dopamine receptors, where dopamine acts as an inhibitory agent of smooth muscle contraction. The prokinetic properties of metoclopramide are limited to the proximal GI tract. Metoclopramide increases amplitudes of esophageal contractions, resting lower esophageal sphincter pressure, gastric fundic and antral contractions and improves antropyloroduodenal coordination. Metoclopramide has antiemetic effects resulting both from dopamine antagonism in the chemoreceptor zone and from a central action at the vomiting center. Metoclopramide is approved for use in diabetic gastroparesis and for prevention of postoperative and chemotherapy-induced nausea and vomiting. Controlled trials have shown that metoclopramide may provide symptomatic relief while accelerating gastric emptying of solids and liquids in patients with idiopathic, diabetic, and postvagotomy gastroparesis and in patients with GERD. [180], [181] Metoclopramide has been reported to be effective in the short-term treatment of gastroparesis for up to several weeks. [180], [181] Long-term efficacy for metoclopramide has not been clearly demonstrated; its effect on gastric emptying may diminish during long-term treatment. [182] In diabetic gastroparesis, acute administration of metoclopramide accelerates emptying, but not after 1 month of treatment. [182] Metoclopramide may continue to relieve symptoms because of its antiemetic effects. The usual starting dose of metoclopramide in adults is 10 mg 30 minutes before meals and at bedtime. In patients not responding, the dose can be increased to 20 mg. In severe gastroparesis, oral metoclopramide may not be adequately absorbed because of vomiting or delayed gastric emptying; metoclopramide administered intravenously may improve gastric emptying. Metoclopramide may also be administered subcutaneously, by suppository, or even intraperitoneally in patients undergoing peritoneal dialysis. [183] Side effects of metoclopramide, resulting from its antidopaminergic properties, may occur in up to 30% of patients and are the major factor restricting its use. Acute dystonic reactions—facial spasm, oculogyric crisis, trismus, and torticollis—occur in 0.2% to 6% of patients. [184] These effects are usually observed during the first 48 hours of treatment and are more frequent with higher doses. Drowsiness, fatigue, and lassitude occur in 10% of patients. Mental depression may occur and may range from mild to severe. Metoclopramide can aggravate underlying depression. Other side effects may include restlessness, agitation, irritability, and akathisia. Increased prolactin release may result in breast engorgement, lactation, and menstrual irregularity. Side effects of long-term use of metoclopramide are of concern. Prolonged treatment with metoclopramide may result in parkinsonian-like symptoms, more commonly within the first 6 months after beginning treatment, but occasionally after longer periods. [184] These symptoms usually subside within 2 to 3 months after discontinuation of metoclopramide. Patients with Parkinson disease should be given metoclopramide cautiously, if at all. Tardive dyskinesia, consisting of involuntary movements of the face, tongue, or extremities, may occur with prolonged use and may not reverse after stopping the medication. The prevalence of tardive dyskinesia may range from 1% to 2% to as high as 15% when patients take metoclopramide for at least 3 months. [184] This effect is more common in elderly women.

Erythromycin and motilides. Erythromycin has prokinetic effects because it is a motilin receptor agonist. [185] Motilin, an endogenous GI peptide, plays a role initiating the gastric phase III of the MMC and is a potent stimulator of antral contractility. Erythromycin binds to motilin receptors located on smooth muscle and on cholinergic neurons; the latter appear to be important for actions in vivo. [185], [186] Erythromycin stimulates gastric emptying in diabetic gastroparesis, idiopathic gastroparesis, and postvagotomy gastroparesis. Erythromycin is the most potent prokinetic agent in accelerating gastric emptying. Erythromycin accelerates gastric emptying by increasing the amplitude and frequency of antral contractions. Interestingly, erythromycin has been reported to accelerate stomach emptying in postsurgical gastroparesis in which the antrum, the primary site of its motor effect, has been resected. [187] The prokinetic effect in this situation may result from a stimulatory effect on the fundus. Erythromycin is reported to be most effective when it is used intravenously during acute exacerbations of gastroparesis. [188] Intravenous infusion of erythromycin lactobionate (200 mg) accelerated emptying of solids in patients with diabetic gastroparesis. [189] In these same patients, after 4 weeks of oral erythromycin ethylsuccinate (250 mg orally three times daily, 30 minutes before meals), the magnitude of the acceleration was less than that observed in response to the single intravenous dose. Studies carried out over longer observation periods have reported a reduction of benefit over time with oral administration. Hyperglycemia attenuates the stimulation of antral contractility and gastric emptying by erythromycin. [176] The motilin receptor agonist ABT-229 was not efficacious in relief of postprandial dyspeptic symptoms in diabetic gastroparesis or functional dyspepsia. [190] This lack of efficacy has been attributed to motilin's propensity to increase fundic tone, impairing accommodation. Oral administration of erythromycin should be initiated at low doses, such as 125 to 250 mg three times daily. Many physicians prefer using erythromycin suspension; it takes less time to reach peak concentrations and is easier to adjust dosages. [191] One center reports use of intravenous erythromycin (100 mg every 8 hours) for severe refractory gastroparesis. [192] Side effects of erythromycin include nausea, vomiting, and abdominal pain.

Cisapride. Cisapride (Propulsid) is a serotonin (5-HT $_4$) agonist that facilitates release of acetylcholine from cholinergic nerves in the myenteric plexus throughout the GI tract. Cisapride stimulates antral and duodenal contractions, improves antroduodenal coordination, and accelerates gastric emptying. Cisapride accelerates gastric emptying and decreases symptoms in patients with gastroparesis, an effect that may last for a year. Cisapride also increases esophageal contractions and resting LES pressure. Cisapride was approved by the United States Food and Drug Administration (FDA) for nocturnal heartburn in patients with GERD. There have been rare instances of cardiac arrhythmias and sudden death. [16], [177] These were not due to cisapride's 5-HT $_4$ agonist properties, but rather they were an effect of the its molecular structure on cardiac potassium channels, prolonging the QT interval and predisposing to ventricular arrhythmias, particularly torsades de pointes. Cisapride is metabolized by the cytochrome P450 3A4 system; use of medications that interact with this enzyme system leads to increased cisapride blood levels and increased cardiac toxicity. Besides cardiac risks, side effects include diarrhea, lightheadedness, and abdominal cramps. In patients with a seizure focus, cisapride may rarely increase seizure activity. Cisapride is not available for routine clinical use in the United States; it can be obtained only through limited-access investigational study protocols.

Domperidone. Domperidone (Motilium) is a benzimidazole derivative and is a specific dopamine-2 receptor antagonist. The effects of domperidone in the upper GI tract are similar to those of metoclopramide. Domperidone stimulates upper GI motility by enhancing gastroduodenal contractions and coordination. Domperidone does not readily cross the blood-brain barrier; therefore, it is much less likely to cause extrapyramidal side effects than metoclopramide. [193] Domperidone has antiemetic properties by its actions at the chemoreceptor trigger zone on the blood side of the blood-brain barrier. Domperidone has been studied primarily in diabetic gastroparesis. It increases both solid and liquid emptying, especially in those patients with a severe delay in gastric emptying. [194] Symptomatic improvement may not correlate with improvement in emptying [8], [194]; symptom improvement may result from antiemetic effects. Symptomatic benefit of domperidone can occur in diabetic patients with normal gastric emptying. [195] The effect of long-term treatment with domperidone has been variable. At 6 weeks, the effect of domperidone on solid phase gastric emptying was lost, whereas that on liquid gastric emptying was maintained. [194] Another study found that nausea and vomiting were improved compared with baseline values after 6 weeks of treatment, but there was no change in solid phase gastric emptying. [195] Other studies have suggested that improvement in gastric emptying and symptoms was still present after 1 year of treatment. [129] Double-blind studies examining the effects of long-term treatment with domperidone on chronic nausea and vomiting have revealed symptomatic benefit; these observations, however, have not been uniform. [195] Domperidone has been suggested for therapy of nausea and vomiting in Parkinson disease, in which symptoms could be related to the dopaminergic agents (e.g., L-dopa) used for the gastroparesis associated with the disorder. [129] Domperidone would work peripherally for GI dysmotility and symptoms; L-dopa would still work centrally for the parkinsonian symptoms. The side effects of domperidone are usually secondary to increased prolactin levels, such as breast engorgement and galactorrhea. CNS side effects are minimal. Domperidone is not FDA approved in the United States, but it is available in Europe, Canada, Mexico, and Japan; in some countries it is an over-the-counter drug.

Bethanechol. Bethanechol (Urecholine) is a nonspecific cholinergic muscarinic receptor agonist. It enhances amplitude of contractions throughout the GI tract. Unfortunately, bethanechol does not coordinate contractions; gastric emptying and small bowel transit are not necessarily accelerated. Most gastroenterologists do not consider bethanechol to be a true prokinetic agent. [177] Occasionally, it may be helpful as adjuvant treatment in combination with prokinetic agents. The typical dose is 25 mg orally four times daily. The direct cholinergic action of bethanechol may also stimulate secretion of gastric acid and saliva. Potential side effects of bethanechol include increased salivation, blurred vision, abdominal cramps, and bladder spasm.

Octreotide. Somatostatin has variable effects on GI tract motor activity. Somatostatin inhibits antral motor contractions. In the intestine, somatostatin initiates ectopic myoelectric and motor fronts under basal conditions but inhibits fed motility. Octreotide is a cyclic analog of somatostatin administered by subcutaneous injection and induces small intestinal phase III–like contractile activity. It may improve small intestinal motor function in patients with scleroderma with small bowel involvement. [196] In patients with gastroparesis, octreotide initiates phase-III activity, which originates in the small intestine and inhibits postprandial antral contractility. [197] Thus, octreotide delays gastric emptying and may worsen symptoms in patients with gastroparesis. Clinically, it may be used for small bowel dysmotility. In this case, prokinetic agents are administered before meals and octreotide is given at bedtime. Prolonged usage may result in gallstones from inhibition of gallbladder emptying.

Refractory Gastroparesis There is no uniform way to handle patients with refractory gastroparesis—patients not responding to antiemetic and prokinetic agents or with side effects preventing their use. In one study, of 110 patients with "refractory" gastroparesis, [1] 74% responded to use of another prokinetic agent, and only 26% were refractory to all prokinetic agents. These truly refractory patients underwent enteral or parenteral feedings and gastric electrical stimulation, and some underwent gastrectomy. Poor responders to prokinetic agents include postgastrectomy patients, those with myopathic connective tissue disorders, juvenile-onset diabetic patients with severely delayed gastric emptying, and patients with idiopathic gastroparesis with abdominal pain. [1] An initial approach to refractory gastroparesis includes ensuring that gastroparesis is responsible for the patient's symptoms, optimizing the patient's current therapy, and changing prokinetic agents. [177] Why some patients respond to one prokinetic agent and not another is uncertain. Different prokinetic agents have different mechanisms of action (see Table 65-6). The efficacy of most prokinetic agents diminishes with prolonged use. A "drug holiday," as used for L-dopa in Parkinson disease, can be used for prokinetic agents. In patients who remain refractory to treatment, one may consider placement of a venting gastrostomy or a feeding jejunostomy. Newer therapies include gastric electric stimulation and injection of botulinum toxin into the pylorus. Double-blind studies are not available to demonstrate efficacy of these modalities. TPN, if used, should be temporary, owing to the risk of infection and deep venous thrombosis. Surgical subtotal gastric resection, usually accompanied by a Roux-en-Y diversion, should generally be

discouraged. Completion gastrectomy can be considered for selected patients with postsurgical gastroparesis.

Combination prokinetic therapy. Prokinetic agents have different mechanisms to enhance gastric emptying (see Table 65-6). Addition of a second prokinetic agent may augment the response of another. Combination prokinetic therapy with two different agents may be useful to accelerate emptying and reduce symptoms in some refractory gastroparetic patients. [198] The combination of the available prokinetic agents, metoclopramide and erythromycin, has not been studied.

Newer prokinetic agents. Newer prokinetic agents being tested for gastroparesis include 5-HT $_4$ receptor agonists (tegaserod and cilansetron), dopamine antagonists (levosulpiride), CCK antagonists (loxiglumide and dexloxiglumide), and several motilin agonists. Tegaserod, a partial 5-HT $_4$ receptor agonist, reduces symptoms in patients with constipation-predominant irritable bowel syndrome. Tegaserod has been shown to accelerate gastric emptying and small bowel transit. [199] It is being evaluated for gastroparesis. Levosulpiride, an antidopaminergic agent, has antiemetic and prokinetic effects. [200] In diabetic gastroparesis, levosulpiride has accelerated gastric emptying and improved symptoms; however, there was no correlation between the two. Loxiglumide, a CCK-A receptor antagonist, has been shown to increase antral contractility and to accelerate gastric emptying in normal subjects. [201] This also suggests that endogenous CCK may have a role in slowing gastric emptying. New studies are being conducted with its dextroisomer, dexloxiglumide. [202] Clonidine, an a $_2$-adrenergic agonist, has been reported to decrease symptoms and to accelerate gastric emptying in patients with diabetic gastroparesis. [203] Other studies have shown that clonidine reduces dyspeptic symptoms by improving gastric accommodation. [204] Some studies report clonidine delays gastric emptying. [205] A side effect is hypotension; clonidine should be used cautiously, especially in diabetic patients with autonomic dysfunction. Acetylcholinesterase inhibitors, such as physostigmine and neostigmine, may stimulate GI contractility by increasing acetylcholine levels with subsequent muscarinic receptor activation. Anticholinesterase agents may increase contractility, but they may not increase antroduodenal coordination; therefore, they may not increase emptying. [206] In animal studies, GI transit is affected in an inverted U-shaped dose response curve with acceleration at lower doses but inhibition at higher doses. [207] This dual effect may be related to activation of different muscarinic receptor subtypes. Some H $_2$ receptor antagonists, such as ranitidine and nizatidine, have been reported to have anticholinesterase activity. [171], [172]

Gastric electric stimulation. Gastric electric stimulation is an emerging treatment for refractory gastroparesis. There are several techniques for stimulating the stomach. First is gastric electrical pacing; the goal is to entrain and pace the gastric slow waves with high-energy, long-duration pulses. Pacing at 10% higher than the basal rate has been shown to accelerate gastric emptying and to improve dyspeptic symptoms. [208] Second is high-frequency, low-energy, short-pulse-duration stimulation. This has been shown to decrease symptoms with little effect on gastric emptying [209], [210]; it may activate sensory afferent nerves to reduce symptoms. Finally, sequential muscle stimulation using bursts of suprahigh-frequency stimulation to induce direct gastric muscle contractions in a peristaltic sequence has accelerated emptying in animal studies. [211] High-frequency gastric electric stimulation at 12 cpm has FDA humanitarian approval for treatment of chronic, refractory nausea and vomiting secondary to diabetic or idiopathic gastroparesis. Stimulating wires are placed into the gastric muscle at the greater curvature during laparoscopy or laparotomy. These leads are attached to an electric stimulator ("pacemaker"), which is placed in a subcutaneous abdominal pouch. An initial study demonstrated effectiveness in 20 of 26 patients with decrease in nausea and vomiting at 3 and 6 months; gastric emptying of liquids, but not for solids, was improved. [209] In long-term follow-up, 3 of 24 patients underwent total gastrectomy because of unsatisfactory results, and 3 had the stimulator removed because of erosion or infection. A subsequent study reported on 33 patients with chronic gastroparesis. [210] After implantation, the electrical stimulator was turned on or off in a randomized, double-blind, crossover design. Patients felt better when the stimulator was on, although the decrease in vomiting that occurred was not statistically significant. Long-term follow-up over 1 year showed a decrease in the mean vomiting frequency from 25 to 6 times per week. In addition, there was an improvement in the overall quality-of-life score and a mild improvement in gastric emptying. Complications were infection in 3 patients and electrode penetration of the stomach wall in 1 patient. An open-label study in 25 patients reported an overall improvement of 40% from "severe" to "moderate" in symptoms of nausea and vomiting. [212] There was an infection rate of 15%, requiring removal of the stimulator. Carefully designed studies are needed to determine the overall effectiveness of gastric electrical stimulation, which type of patient will likely respond, and optimal stimulation parameters.

Botulinum toxin injection into the pyloric sphincter. Gastric emptying is a highly regulated process reflecting the integration of propulsive forces of proximal fundic tone and distal antral contractions with inhibitory forces of pyloric sphincter resistance. Few studies have been performed to see whether inhibition of the pyloric sphincter muscle accelerates gastric emptying. Early studies with surgical pyloromyotomy did not show benefit; more recent studies have shown a beneficial response in diabetic gastroparesis. [212] Pyloromyotomy may be helpful in preventing gastric stasis after truncal vagotomy. Botulinum toxin is a potent inhibitor of neuromuscular transmission and has been used to treat spastic disorders of muscles by local injection into effected muscles. Injection of botulinum toxin directly into the LES reduces pressure and improves symptoms in patients with achalasia. [213] In several small series of four to eight patients with gastroparesis, botulinum toxin has been injected into the pyloric sphincter in an attempt to reduce gastric outlet resistance and to accelerate gastric emptying in patients with idiopathic and diabetic gastroparesis. [214], [215] Overall, these open-label studies have shown a mild improvement in gastric emptying and modest improvement in symptoms that may last for several months.

Alternative and unconventional medical therapy primarily for nausea and vomiting. Tricyclic antidepressants may be of some benefit in patients with functional vomiting. [216] Low doses may have an effect to reduce afferent sensory transmission. Some of these agents, especially the tertiary amines such as amitriptyline (Elavil), have anticholinergic properties and may delay gastric emptying. Stimulation of the PC6 acupuncture point on the wrist with conventional acupuncture, electroacupuncture, or acupressure with a wrist band (e.g., Sea-band) may help to control postoperative nausea, chemotherapy-induced nausea, and nausea associated with morning sickness. [217], [218] and [219] These studies also suggested acupressure had similar efficacy to standard antiemetic therapy for postoperative nausea. [217] Another acupuncture point that has been used for influencing gastric motility is the Zusanli point (ST36), located on the leg below the patella. [220] Electroacupuncture reduces the severity of symptoms of vection-induced motion sickness while decreasing gastric tachyarrhythmias. [221] Animal studies suggest that electroacupuncture enhances gastric emptying by vagal stimulation. Electroacupuncture has been postulated to modulate serotonin, substance P, and endogenous opiates along CNS pathways. [223] Naloxone, an opiate receptor antagonist, blocks the analgesic effect of acupuncture and worsens symptoms of motion sickness. [223] Ginger, a traditional Chinese herbal remedy, reduces nausea and associated tachygastria caused by circular vection, an experimental model of motion sickness. Ginger also has been shown to reduce hyperglycemia-induced gastric dysrhythmias and nausea. [224]

Venting gastrostomy and feeding jejunostomy tubes. In the treatment-refractory patient with severe nausea and vomiting, placement of a gastrostomy tube for intermittent decompression by venting or suctioning may provide relief to the patient who has prominent abdominal distention. The gastrostomy tube can be opened for drainage or aspirated to decompress the stomach; this can be employed when symptoms are distressing to alleviate nausea, pain, and bloating. Venting gastrostomy tubes may be placed by the endoscopist, surgeon, or interventional radiologist. In one series, six of eight patients were able to return to full-time work or school. [225] The percutaneous endoscopic gastrostomy tube can be converted to a button. Use of a gastrostomy tube for feeding may aggravate gastroparetic symptoms. A feeding jejunostomy is usually preferred. Although a J-tube extension can be placed through the gastrostomy, these often prolapse into the stomach. To prevent this, enteral feedings through a direct jejunostomy tube can be helpful. Jejunostomy tubes are effective for providing nutrition, fluids, and medications, provided the small intestine is functioning. [226], [227] Carefully regulated nutrient enteral infusion may allow better glucose control in diabetic patients whose glycemic control is otherwise poor because of vomiting and gastroparesis. [227] Jejunostomy tubes are usually inserted laparoscopically or at laparotomy [228]; in some centers they are placed endoscopically.

Surgical treatment. Surgical treatment of idiopathic and diabetic gastroparesis has generally been disappointing. [16] Surgery is performed only as a last resort. The procedure usually employed is a partial gastrectomy and Roux-en-Y gastrojejunostomy. For selected patients with postsurgical gastroparesis in whom medical therapy has failed, further resection of the stomach may occasionally be considered. Usually, these patients have had prior vagotomy. Postsurgical gastroparesis patients require radical surgery to eliminate hold-up in the atonic stomach and creation or revision of a Roux limb to prevent enterogastric reflux. The resection is performed as a completion of the gastrectomy or a near-total gastrectomy, rather than as a less extensive resection. [229], [230] In near-total gastrectomy, only a small rim of proximal stomach (<1 cm) is retained. Reconstruction is achieved by a Roux loop of at least 45 cm to the rim of the stomach. The extensive gastrectomy is to eliminate the gastroparetic stomach and to allow ingested nutrients to pass directly from the esophagus into the small intestine. The Roux-en-Y jejunal segment helps to prevent reflux of small intestinal contents into the remaining stomach and esophagus. This extensive surgery may lead to improvement in two thirds of patients in specialized centers. [229] In a series of 62 patients who underwent completion gastrectomy for severe postvagotomy gastric stasis, good symptomatic improvement in nausea, vomiting, and postprandial abdominal pain was obtained in only 43% of patients, without improvement in chronic pain, diarrhea, and dumping symptoms. [231] The combination of nausea, need for TPN and retained food at endoscopy predicted a poor outcome. In another series of 81 patients with severe postsurgical gastroparesis, near-complete gastrectomy with a 55-cm Roux-en-Y reconstruction was performed. Follow-up averaged 56 months for 52 patients; 78% reported improvement of their GI symptoms, 7% believed that there was no change, and 15% stated that their condition had worsened. [232] A subtotal (70%) gastrectomy with resection of antrum and pylorus, closure of the duodenum, and restoration of GI continuity with a 60-cm Roux-en-Y jejunal loop was reported in four patients with insulin-dependent diabetes with intractable vomiting from gastroparesis. [233] Three of the four patients did well, eliminating frequent hospital admissions.

Pancreatic transplantation for diabetic gastroparesis. Pancreatic transplantation and simultaneous kidney and pancreatic transplantation are being performed more often for insulin-dependent diabetes mellitus. With successful pancreatic transplantation, postprandial hyperglycemia resolves, and insulin therapy can be discontinued. [234] Simultaneous pancreatic and kidney transplantation helps to correct both uremia and hyperglycemia. Pancreatic transplantation has been shown to halt progression and slightly improve diabetic polyneuropathy. [235] Improvement during the first year after pancreatic transplantation may be primarily the result of correction of hyperglycemia, which affects nerve function. A relatively small degree of improvement in peripheral nerve function has been reported over time. [235] Gastric emptying may be improved in some patients after pancreatic transplantation, although the literature is sparse. One study reported, at 6 months after pancreatic transplantation, an improvement in liquid emptying in six of eight patients with previously delayed emptying, but no improvement in solid phase emptying. [234] Another study found emptying improved 1 year after pancreatic and kidney transplantation in 8 of 23 patients. [236] Despite limited improvement in gastric emptying,

symptoms and gastric dysrhythmias improved in diabetic patients after organ transplantation. [234], [236]

DISORDERS WITH RAPID GASTRIC EMPTYING

Postsurgical Dumping Syndrome

Description and Clinical Features Rapid gastric emptying and its consequences are responsible for *dumping syndrome,* symptoms of which include postprandial sweating, weakness, orthostasis, tachycardia, and diarrhea. Symptoms can be debilitating. Dumping syndrome, especially of liquids, occurs almost exclusively after gastric surgery and is the most common postgastrectomy syndrome, occurring in up to 20% of patients after gastrectomy (usually antrectomy) or truncal vagotomy with a drainage procedure (see Table 65-5). Postsurgical pathophysiological abnormalities causing the dumping syndrome include the following:

- Loss of proximal stomach receptive relaxation and accommodation secondary to vagotomy
- Decreased gastric capacity after gastrectomy
- Loss of controlled emptying from bypass or ablation of pyloric sphincter
- Loss of duodenal feedback inhibition resulting from a bypassed duodenum from gastrojejunostomy. [237], [238]

Dumping symptoms are often characterized as early or late relative to their time course after meal ingestion. Early dumping symptoms occur in the first 30 minutes and result from accelerated early gastric emptying of liquids with rapid filling of the intestine with hypertonic fluid, leading to bloating, crampy abdominal pain, and explosive diarrhea. Rapid filling of the intestine is associated with osmotic fluid shifts into the gut lumen and reduction of plasma volume resulting in secondary release of vasoactive substances that cause vasomotor symptoms such as lightheadedness, sweating, flushing, and palpitations with tachycardia. Late dumping symptoms occur 2 to 3 hours after a meal and are associated with reactive hypoglycemia (weakness, palpitations, and diaphoresis); these result from the hyperinsulinemic response to an overwhelming carbohydrate load. [239] Because of its relatively long half-life, increased serum concentrations of insulin and associated hypoglycemia persist for relatively long periods. Enteroglucagon is also released excessively in response to the high carbohydrate concentrations in the small bowel, and it sensitizes pancreatic ß-cells to hypersecrete insulin. [239]

Diagnosis Dumping syndrome is usually diagnosed clinically, based on the characteristic symptoms occurring in patients after gastric surgery. Another postsurgical disorder is postvagotomy diarrhea; in this disorder, the diarrhea is not related to meals, and postprandial hypotension and hypoglycemic are not seen. Scintigraphic studies of both solid and liquid phase can document rapid gastric emptying. The rapid emptying is most notable immediately after the meal, occurring in the first 15 minutes. [240] In patients with suspected dumping syndrome, gastric emptying of liquids may be the preferable measurement. Orocecal transit time may also be helpful. Responses to an oral hypertonic glucose load (50 g in 300 mL) have been suggested to be helpful in diagnosing dumping syndrome [241]; responses consistent with dumping include the following:

- A rise in hemoglobin in the early postprandial period suggesting hemoconcentration
- An increase in heart rate greater than or equal to 10 beats per minute
- Elevated plasma glucose early postprandially
- Low plasma glucose concentrations late postprandially.

Treatment Postsurgical dumping symptoms may resolve over time with conservative management. Specific treatment of the dumping syndrome is aimed at slowing delivery of nutrients into the small intestine and minimizing release of endogenous vasoactive substances. Initial dietary recommendations are to eat small, dry, frequent meals, to increase protein and fat content in the diet, to reduce the intake of carbohydrates by avoiding simple sugars, and to minimize liquid intake. [237] Lying down in a supine position after drinking liquids may delay liquid emptying. Increasing the viscosity of liquid meals by adding gel-forming carbohydrates (pectin or guar gum) may delay transit time and may slow carbohydrate absorption. Late dumping symptoms from hypoglycemia are usually relieved by ingestion of simple carbohydrates. Medical therapy has centered on delaying gastric emptying. Anticholinergic agents have been employed, but they are usually not beneficial. The somatostatin analog, octreotide, is the primary pharmaceutical treatment. Octreotide has a much longer half-life than somatostatin and is administered subcutaneously to prevent breakdown by gastric acid. Octreotide has effects on both GI transit and GI peptide release. Octreotide delays gastric emptying and prevents the accelerated emptying seen in dumping syndrome. [237] Octreotide also inhibits the release of enteric hormones and insulin secretion; this may actually be the primary mechanism of its symptomatic benefit. [239] Octreotide, 50 µg subcutaneously 30 minutes before meals, reduces symptoms (diarrhea, lightheadedness, and palpitations) and signs (orthostatic hypotension, tachygastria) and metabolic alterations (late hypoglycemia) with dumping syndrome. [239] This dose may be increased to 100 µg three times a day if needed. Side effects of octreotide when administered subcutaneously include injection site pain, iatrogenic diabetes, malabsorption with a worsening of diarrhea, and cholelithiasis. Less information is available regarding the long-term utility of octreotide and use of the newer long-acting depot form of octreotide. The fatty acid oleic acid, administered before a meal, may slow GI transit and may decrease diarrhea in patients with rapid GI transit including dumping syndrome. Oleic acid activates nutrient-triggered intestinal inhibitory feedback mechanisms (jejunal-ileal brake). [242] Revisional gastric surgery is performed in a few patients with severe dumping symptoms, with the aim to delay stomach emptying to alleviate symptoms. The results are variable and often disappointing. [237] Because of the risk of causing severe gastric stasis, surgery is recommended only when other measures have failed. Surgical procedures include takedown of a prior gastrojejunostomy with conversion to Billroth I gastroduodenostomy. A commonly used surgical procedure is creating a Roux-en-Y diversion, which has been reported to slow gastric emptying. [243] Insertion of an antiperistaltic jejunal segment between the stomach and the small bowel has been performed to produce a functional delay of nutrient outflow from the stomach. [243] Pyloric reconstruction has also been attempted.

Other Disorders with Rapid Gastric Emptying

Type II Diabetes Mellitus Accelerated gastric emptying has been reported early in *type 2 diabetes* and rarely in early type I diabetes. [50], [51] Although this condition primarily applies to liquids, rapid emptying of a high-carbohydrate solid meal may occur. Rapid emptying may result from impaired fundic accommodation from vagal neuropathy with reduction of inhibitory nitric oxide nerves. [47] Accelerated gastric emptying may result in faster intestinal absorption of glucose and increased postprandial glucose levels in part owing to a mismatch between absorbed food and insulin release. Excessive hepatic glucose release also contributes to postprandial hyperglycemia. [51] Slowing gastric emptying has been suggested to improve control of postprandial glucose in type 2 diabetes. [244] This may be the means by which the addition of dietary soluble fiber has been shown to improve glucose control. [245], [246] Agents that slow gastric emptying are being developed to improve glucose tolerance for diabetic patients; these include amylin and its analog pramlintide, CCK analogs, protease inhibitor II, and glucagon-like peptide 1. [244]

Pancreatic Exocrine Insufficiency In *pancreatic insufficiency,* accelerated gastric emptying of fatty meals has been reported. [247] Maldigestion and malabsorption of lipids may lead to the inability of unhydrolyzed fats to release CCK, which serves as a feedback inhibitor of gastric emptying. Pancreatic enzyme replacement slows the rapid gastric emptying. [247] Other studies report normal gastric emptying in pancreatic insufficiency. [248] Chronic pancreatitis has also been reported associated with delayed gastric emptying (see earlier). [99]

Duodenal Ulcer Some patients with duodenal ulcer have rapid gastric emptying of liquids with increased acid secretion. [249] Rapid gastric emptying of acid may exceed duodenal buffering capacity leading to mucosal injury. One study reported that enhanced gastric emptying was still present in patients with healed duodenal ulcers. Many of these studies were performed before the recognition that *H pylori* is an important factor in ulcer disease and acid secretion.

Zollinger-Ellison Syndrome Patients with *Zollinger-Ellison syndrome,* characterized by hypergastrinemia and increased gastric acid secretion, can have duodenal ulcers, diarrhea, or marked esophagitis. The diarrhea is usually attributed to massive gastric acid secretion leading to an increased amount of liquids propelled into the small intestine. These patients may have accelerated gastric emptying of liquids. However, gastric acid suppression may not normalize the rapid gastric emptying, suggesting the rapid emptying may not be related to gastric acid hypersecretion. [250] Pentagastrin administration also does not accelerate gastric emptying in physiologically normal subjects; instead, it seems to delay stomach emptying of solids. [250]

Hyperthyroidism Orocecal transit time is rapid in *hyperthyroidism* and may be a factor in hyperthyroid-associated diarrhea. [251] It returns to normal after reestablishment of the euthyroid state. Rapid gastric emptying and intestinal transit of barium have been reported. There are case reports of rapid gastric emptying using scintigraphy in hyperthyroidism [138]; most patients with hyperthyroidism appear to have normal gastric emptying [252]; some have delayed. [139]

Obesity *Morbidly obese patients* may have accelerated gastric emptying. [253] Dieting with weight loss has been shown to decrease this accelerated gastric emptying to a near-normal rate. [253] Gastric volumes are also larger than in normal-weight persons; this may cause satiety signals not to be triggered in response to meal ingestion and gastric distention. In addition, intestinal absorption of nutrients may be more efficient in obesity. [254]

FUNCTIONAL DYSPEPSIA

Definition and Subgroups

Dyspepsia refers to symptoms originating in the upper GI tract; the term is used to describe upper abdominal pain or discomfort often exacerbated with eating, early satiety, postprandial abdominal bloating or distention, and nausea. [255] Structural or organic disorders causing dyspepsia are gastroduodenal ulcer, gastritis, GERD, medication side effects, and gastric cancer. In most patients, no cause is apparent, and the dyspepsia is idiopathic, that is, functional or nonulcer dyspepsia. The 1999 Rome II criteria [256] for diagnosing functional dyspepsia include the following:

- Persistent or recurrent pain or discomfort centered in the upper abdomen
- Symptoms for at least 12 of the preceding 52 weeks
- No evidence of organic disease (including upper endoscopy) that is likely to explain the symptoms
- No evidence that dyspepsia is exclusively relieved by defecation or associated with the onset of a change in stool frequency or stool form (i.e., not irritable bowel syndrome). [256]

The Rome group [256] suggested that it may be useful to subcategorize functional dyspepsia into ulcer-like, dysmotility-like, and nonspecific dyspepsia based on the predominant or most bothersome symptom. In ulcer-like dyspepsia, pain in the upper abdomen is the predominant symptom. Dysmotility-like dyspepsia is characterized by symptoms of fullness, early satiety, bloating, and nausea. Nonspecific dyspepsia is used if there is no predominant symptom. In the 1991 Rome I criteria, reflux-like dyspepsia, predominantly heartburn or regurgitation accompanying dyspeptic symptoms, had been a subcategory of functional dyspepsia, but this symptom complex is now considered to be primarily GERD. The usefulness of these symptom-based subgroups has been questioned because there is overlap among them, and they are not helpful in predicting treatment responses. [257] The Rome II modifications of predominant symptoms for subcategorization may help to reduce this overlap. [258]

Pathogenesis with Emphasis on Gastric Dysmotility

Numerous mechanisms have been proposed for the pathogenesis of functional dyspepsia. [259] The *gastric acid or inflammation hypothesis* suggests that gastric acid or inflammation from acid, bile, or *H pylori* infection is responsible for symptoms. This acid hypothesis also includes occult GERD and postinfectious dyspepsia. [260] The *motor disorder hypothesis* suggests that gastric dysmotility disorders such as gastroparesis, impaired fundic accommodation, antral distention, or gastric dysrhythmias are important. The *visceral hypersensitivity hypothesis* suggests exaggerated symptoms in response to physiochemical stimuli such as distention, contraction, acid, and bile. The *psychological or psychiatric hypothesis* proposes that symptoms are related to depression, anxiety, or a somatization disorder.

Gastrointestinal Dysmotility Motility and sensory abnormalities of the stomach and upper small bowel have been found in many patients with unexplained dyspepsia. Delayed gastric emptying, impaired gastric accommodation to a meal, gastric dysrhythmias, and visceral hypersensitivity are important pathophysiological factors in functional dyspepsia. One or more of these factors may be detected in one half to two thirds of patients with functional dyspepsia. [261]

Delayed gastric emptying and antral hypomotility. Delayed gastric emptying is present in approximately 35% of patients with functional dyspepsia, with studies ranging between 25% and 80%. [12], [261] Differentiation between the dysmotility-like dyspepsia form of functional dyspepsia and idiopathic gastroparesis may be arbitrary. Specific dyspeptic symptoms and their severity have correlated poorly with the degree of gastric stasis. [10], [262] However, in a series of 343 patients with functional dyspepsia, the severity of postprandial fullness and vomiting correlated with delayed gastric emptying, which was present in 34% of the dyspeptic patients. [12] Detection of delayed gastric emptying in functional dyspepsia may have prognostic importance because these patients may respond better to prokinetic agents than patients with normal emptying. [13] However, this link of prokinetic agents in improving gastric emptying and symptoms is inconsistent; both delayed emptying and symptoms may be improved by prokinetic therapy; at other times, emptying or symptoms have improved, but not both. [13] Antroduodenal manometry has been used to study patients with functional dyspepsia. The most common abnormality, present in about half of patients, is postprandial antral hypomotility. [263] Antral hypomotility correlates with delayed gastric emptying. Several studies have suggested that small bowel motor dysfunction occurs in a large proportion of patients with nonulcer dyspepsia [263]; other investigators have reported small intestinal dysmotility in only a small percentage. [264] Small intestinal abnormalities may include retrograde, simultaneous, or reduced frequency of fasting MMC activity, as well as a reduced percentage of MMCs that start in the antrum. In the fed state, decreased or low-amplitude duodenal contractions may occur. In a study of 41 consecutive patients with severe chronic dyspepsia, a neuropathic disorder (contractions of normal amplitude but abnormal propagation) was present in 39%, myopathy (low-amplitude contractions with normal coordination) in 2%, and normal small bowel motility in 59%. [265]

Regional gastric dysfunction: impaired fundic accommodation and antral distention. Regional gastric function abnormalities may be present in many dyspeptic patients and appear to correlate with dyspeptic symptoms. Normally, the stomach accommodates a meal by the relaxation of the gastric fundus and corpus, providing the meal with a reservoir and enabling a volume increase without a rise in intragastric pressure. Reduced postprandial fundic relaxation and accommodation were found in 40% of patients with functional dyspepsia. [266] Impaired proximal gastric accommodation was associated with early satiety and subsequent weight loss and may be related to a vagal defect. Other studies have not found a clear relationship between postprandial symptoms and proximal stomach function. [267] Scintigraphy and ultrasound studies have shown that, in functional dyspepsia, the intragastric distribution of the meal is characterized by rapid transit of ingested food from the proximal stomach to the distal stomach (Fig. 65-3). [268] Rapid transit from the proximal stomach may result from poor receptive relaxation or accommodation of the proximal stomach. Rapid proximal gastric transit causes abnormally large quantities of food to enter the antrum immediately after ingestion. Early antral distention occurs in many dyspeptic patients. [268], [269] The degree of postprandial abdominal discomfort has been related to the degree of impaired accommodation of the proximal stomach and antral distention. [270]

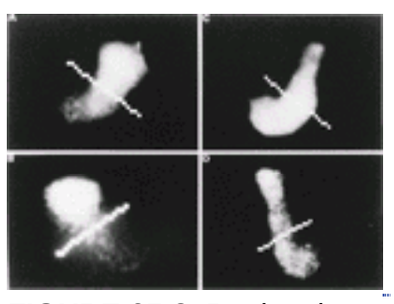

FIGURE 65-3. Regional gastric emptying abnormalities in functional dyspepsia. (**A** and **B**) Anterior and posterior views taken immediately after food ingestion from a physiologically normal subject. (**C** and **D**) Similar views from a dyspeptic patient. In normal subjects (**A** and **B**), food remained predominantly in the proximal half of the stomach after ingestion and then redistributed to the distal half over time. In dyspeptic patients (**C** and **D**), initial activity on the proximal half was lower because of rapid progression to the distal portion of the stomach. (From ref. [268].)

Radionuclide imaging of the gastric wall with single photon emission computed tomography (SPECT) to calculate gastric volumes has been used as a noninvasive measure of gastric accommodation. [271] SPECT imaging in 32 patients with functional dyspepsia suggested that impaired gastric accommodation (41%) may occur more commonly than delayed emptying (9%) in dyspeptic patients referred to tertiary centers. Most of the dyspeptic patients were found to have normal gastric emptying and accommodation. [271] Satiety testing with water or a nutrient drink has been suggested as a noninvasive technique to evaluate impaired accommodation and sensation. One example is the water load test, in which the subject drinks water until full. [272] Functional dyspeptic patients have reduced consumption. Another is a slow caloric drinking test in which Nutridrink (N. V. Nutricia: Zoetermeer, The Netherlands) is ingested at 15 mL/min. [273] This satiety test is correlated with gastric accommodation to a meal, as measured by the barostat. These satiety tests offer the potential to evaluate gastric accommodation in a noninvasive way. A reduced tolerated volume, however, may reflect either impaired accommodation or hypersensitivity of the stomach. [23]

Gastric myoelectric abnormalities. Gastric myoelectric abnormalities measured by EGG, such as tachygastria and bradygastria and decreased ratio of postprandial to fasting power, are found in about 40% of patients with functional dyspepsia. [11], [272], [274], [275] The prevalence of EGG abnormalities is similar to delayed gastric emptying in functional dyspepsia. EGG and gastric emptying tests appear to complement each other in correlating symptoms to gastric dysmotility. [11] How EGG results affect patient management is controversial. In two small studies, dyspeptic patients with an abnormal EGG had a more favorable response to treatment with prokinetic agent than patients with a normal EGG. [276], [277] Multichannel EGG recording using electrodes placed at several positions overlying the stomach has been suggested to assess slow wave propagation and coupling. Patients with functional dyspepsia were found to have inconsistencies in frequency and regularity of gastric slow waves suggesting impaired slow wave propagation and coupling. [278]

Visceral Hypersensitivity Augmentation of visceral afferent sensation (nociception) may be a major cause of symptoms in functional dyspepsia. Thirty five to 50% of the patients with functional dyspepsia have increased sensation to gastric and small intestinal distention. [5], [279] When the stomach is stimulated by increasing volumes or increasing intragastric pressures, patients with functional dyspepsia experience symptoms at volumes that physiologically normal subjects do not (allodynia), and they have greater amount of pain at levels when the physiologically normal subjects begin to have pain (hyperalgesia). The symptoms in functional dyspepsia may result from altered gastric perception with an exaggerated visceral sensory perception of normal physiological events. In addition to hypersensitivity to distention, some dyspeptic patients may be hypersensitive to intragastric or intraduodenal acid, bile salts, or even nutrients. [280] In other functional GI disorders, such as irritable bowel syndrome, different CNS regions are activated to process visceral pain when compared with physiologically normal subjects. Brain activation by visceral stimulation with gastric distention is being studied in functional dyspepsia using positron emission tomography and functional magnetic resonance imaging. In physiologically normal subjects, distal gastric distention produces symptoms of abdominal pain, nausea, and bloating, and it activates some of the same cortical and subcortical CNS regions implicated in processing somatic pain. [281] Thus, there are several pathophysiological alterations of gastric motility and sensation in functional dyspepsia. Distinct pathophysiological abnormalities may be present in subgroups of patients, perhaps causing different symptoms, and may predict different responses to treatment. One study found that 23% of patients with functional dyspepsia had delayed gastric emptying with associated symptoms of nausea, vomiting, and postprandial fullness, 35% of patients had hypersensitivity to gastric distention associated with symptoms of pain, belching, and weight loss, and 40% had impaired accommodation associated with symptoms of early satiety and weight loss. [261] Twenty three percent of patients had two or three of these abnormalities, whereas 26% had none, suggesting still another as yet unidentified mechanism of functional dyspepsia. Unfortunately, individual symptoms do not strongly predict underlying pathophysiology. [261] These disorders may be interrelated: reduced fundic accommodation may lead to increased wall tone in response to distention or meal ingestion and may lead to stimulation of visceral afferents and cerebral perception of gastric events/symptoms. [271]

Treatment: Focusing on Gastric Dysmotility and Nociception

There is much literature, although inconsistent, on treatment of functional dyspepsia. Methodological shortcomings are present in many studies including suboptimal study design, unclear inclusion criteria, unvalidated outcome measures, and a short duration of follow-up. [282] In addition, the placebo response in functional dyspepsia can be substantial, approximating 45%. [283] Treatment modalities that have been tested extensively include acid suppressive agents, promotility compounds, and *H pylori* eradication.

Promotility Agents The lack of available promotility compounds limits this treatment modality. Promotility agents including metoclopramide, cisapride, and domperidone have improved dyspeptic symptoms more effectively than placebo in the majority of studies [282], [284]; improvement in symptoms with promotility agents has been 40% to 45% greater than with placebo. [284] The few studies that compare the effects of acid suppressing and promotility agents on dyspeptic symptoms have favored the promotility agents. [285] Several metaanalyses of the prokinetic agent studies in functional dyspepsia have been published. [284], [286], [287] In a metaanalysis of 17 cisapride studies and 4 domperidone studies, both cisapride and domperidone seemed to be efficacious. [287] For cisapride, there were overall reductions in epigastric pain, early satiety, abdominal distention, and nausea. Another metaanalysis found a funnel plot of study results to suggest that publication bias may be skewing the data on the efficacy of prokinetic agents. [288] Erythromycin and other motilin receptor agonists are potent stimulants of gastric motor function. They have not yet demonstrated efficacy in functional dyspepsia. The motilin receptor agonist, ABT-229, was ineffective in dyspeptic patients with delayed gastric emptying. [289] It is speculated that because motilin receptor agonists increase proximal gastric tone, they may aggravate the impaired fundic accommodation in functional dyspepsia, and this could explain the worsening of postprandial symptoms with ABT-229. [289]

Psychotropic Medications and Antinociceptive Agents Strategies to inhibit pain or symptom perception (sensory modulators) are receiving attention because of the augmented visceral hypersensitivity in dyspepsia. Psychotropic medications including antidepressants and serotonin reuptake inhibitors are being studied. Anxiolytic agents, such as benzodiazepines, should be avoided because of their potential for addiction. Low-dose tricyclic antidepressants appear to have analgesic effects that are independent of psychological effects. The mechanism of these agents in functional bowel disorders is not known, but it may include reduction in visceral sensitivity. [290] Tricyclic antidepressants have been beneficial to treat abdominal pain syndromes, noncardiac chest pain, and irritable bowel syndrome. [291] Two studies using low-dose tricyclic antidepressants for functional dyspepsia [292], [293] reported a decrease in dyspeptic symptoms, primarily abdominal pain. In clinical practice, psychotropic medications have been suggested for patients with severe, intractable, refractory dyspeptic symptoms that interfere with daily activities. Dosages required for symptomatic improvement are usually lower than those used to treat psychiatric disorders. [290] Starting at low doses, with gradual dose increments, is the approach used. Typically, for amitriptyline, a starting dose is 10-25 mg at bedtime. If benefit is not observed in several weeks, doses are increased by 25-mg increments up to 75 to 100 mg. The positive effects are rapidly noticed by many patients, in contrast to the prolonged treatment needed to improve depression. Significant side effects of antidepressant agents are common, can interfere with management, and may lead to a change in medication in 25% of patients. [290] The sedative effects of many tricyclic compounds may be helpful for patients with difficulty in sleeping. Agents with strong anticholinergic properties, such as amitriptyline, may adversely affect gastric motility. The secondary amines, nortriptyline (Pamelor) and desipramine (Norpramin), have fewer side effects than amitriptyline (Elavil). There are no published studies demonstrating the utility of the selective serotonin reuptake inhibitors for functional dyspepsia. Some studies are reported for irritable bowel syndrome. [294] Interestingly, paroxetine appears to enhance gastric accommodation rather than improve the visceral hypersensitivity. [295]

Other Treatments Complementary and alternative medicines are used frequently by patients with functional dyspepsia. In a prospective German study of 3001 patients with functional dyspepsia, 40% of the patients used alternative medicine regimens including special diets, herbal teas, yoga, and acupuncture. [296] In Germany, commercially available herbal preparations such as Iberogast, with extracts from bitter candy tuft, [297] and Enteroplant, containing peppermint oil and caraway oil, [298] have been shown in placebo-controlled trials to improve symptoms. Psychodynamic interpersonal psychotherapy and hypnotherapy are being reported as effective in the treatment of functional dyspepsia. [299], [300] Interestingly, one preliminary study has shown that posthypnotic relaxation with gut-oriented suggestions is effective in accelerating gastric emptying in dyspeptic patients. [301]

Future Treatment

Prokinetic agents. Future treatments being evaluated for functional dyspepsia include newer prokinetic agents. These include 5-HT $_4$ agonists (tegaserod and cilansetron), dopamine receptor antagonists (levosulpiride), CCK antagonists (loxiglumide and its dextroisomer, dexloxiglumide), and several motilin agonists. The 5-HT $_4$ agonist tegaserod has been found to accelerate gastric emptying as well as to have an effect on visceral afferent sensation. [199]

Fundic relaxing agents. Agents that relax the fundus and improve the accommodation response may be helpful in some patients with functional dyspepsia, perhaps those with early satiety. 5-HT $_1$ agonists (sumatriptan, buspirone), a-adrenergic receptor agonists (clonidine), and nitric oxide donors (glyceryl trinitrate) have been tried in several small series. [204] The 5-HT $_1$ agonists, such as sumatriptan, induce relaxation of the gastric fundus through a nitric oxide–mediated pathway. Sumatriptan allows larger volumes to be accommodated before perception or discomfort is reached, and it improves meal-induced satiety in patients with functional dyspepsia. [302] It is given primarily by injection. Buspirone, an oral 5-HT $_1$ agonist, may have effects similar to those of sumatriptan. It also has anxiolytic properties. The a-adrenergic agonist clonidine reduces proximal gastric tone and pain perception during gastric distention in healthy subjects. [204] Thus, clonidine has the potential to reduce gastric sensation or increase gastric compliance without altering other physiological motor functions. Some studies have suggested that clonidine may delay gastric emptying. [205] Sildenafil (Viagra) has been shown to increase gastric accommodation. [303] In animal models, it also relaxes the pylorus and improves gastric emptying. [304] In humans, however, it slows gastric emptying. [303] Studies suggest that 5-HT $_3$ receptor agonists relax the gastric fundus without inhibiting antral motility. [305] These agents may be useful for impaired accommodation.

Sensory modulators. Strategies to inhibit pain or symptom perception include use of ?-opioid agonists and 5-HT $_3$ receptor antagonists. Fedotozine, a ?-opioid agonist, has visceral analgesic properties, blunting perceptions of gut distention. Fedotozine has been evaluated in Europe for functional dyspepsia and has demonstrated mild symptom benefit in two trials. [306], [307] Fedotozine provided relief of epigastric pain and nausea with a trend to reduced fullness when compared with placebo. [307] It is not available in the United States; concern has been expressed on the fairly modest symptom improvement and the exact mechanism of action. [308] Fedotozine may act through peripheral opiate and cholinergic pathways to stimulate antral and small intestinal contractility. [309] 5-HT $_3$ receptors are located on vagal afferents and dorsal root ganglion neurons. In physiologically normal subjects, the 5-HT $_3$ receptor antagonist, alosetron, reduced postprandial nausea and vomiting in response to a dyspepsia-inducing meal, without an effect on gastric accommodation or the amount of ingested food. [310] Preliminary studies suggest that alosetron may be mildly effective in decreasing symptoms of functional dyspepsia. [311] Alosetron was FDA approved for treating irritable bowel syndrome. It was sanctioned because of reports of cases of ischemic colitis and is currently not available for clinical use in the United States.

Gastric antidysrhythmics. This area has been receiving attention because of the increased availability of EGG. Many of the prokinetic agents such as metoclopramide, cisapride, [9] and domperidone [8] have been shown to correct gastric dysrhythmias. Prostaglandin inhibitors have been shown to resolve tachygastrias in vitro and in vivo during hyperglycemia. [56] In several patients, indomethacin has improved symptoms and gastric myoelectric abnormalities. [312] Unfortunately, indomethacin is also ulcerogenic.

OVERVIEW

This chapter reviews gastric motility disorders and focuses primarily on the pathophysiology, diagnosis, and treatment of gastroparesis, dumping syndrome, and the gastric dysmotility seen in functional dyspepsia. Refractory symptoms may lead to a comprehensive evaluation including gastric emptying scintigraphy, antroduodenal manometry, EGG, and possibly tests of gastric accommodation or compliance. This evaluation may guide treatments that target the underlying pathophysiology.

CHAPTER 66

John Del Valle, William D. Chey, and James M. Scheiman

ACID PEPTIC DISORDERS

Sour eruptions, gas, and epigastric pain radiating to the back with occasional splashing noises and vomiting are familiar to most physicians who have treated patients with acid peptic disorders of the stomach. In fact, the early Greek Diocles of Carystos (350 BCE) described these as symptoms of a melancholic gassy illness originating in the stomach. [1] *Acid peptic disorders or peptic ulcer disease* (PUD) represent a common group of pathological states that affect as many as 4.5 million persons per year (new cases and recurrences) in the United States. [2], [3] The cost of health care for these common disorders has been substantial, with estimated annual direct (physician visit, diagnostic studies, treatment) and indirect (time lost from work) costs of more than $9 billion per year. [4], [5] The past several decades have witnessed dramatic advances in the diagnosis and therapy of acid-related disorders. The development of histamine (H_2)–receptor antagonists and H^+,K^+-ATPase inhibitors and an understanding of how the gastroduodenal protective equilibrium is altered by such culprits as nonsteroidal antiinflammatory drugs (NSAIDs) and *Helicobacter pylori* have changed how we think of peptic disorders. This chapter provides a comprehensive overview of the epidemiology, pathogenesis, diagnosis, and therapeutic approach to patients with PUD.

IMPACT OF PEPTIC ULCER DISEASE

Approximately 500,000 new cases and 4 million recurrences of gastric and duodenal ulcers in the United States led 4 million patients to visit physicians in 1995. [2], [3] Cost-analysis data published in 1998 revealed that there were more than 2.6 million PUD-related physician office visits, resulting in a total cost of $196.3 million. [5], [6] The inpatient setting was the second most common site of care, with 470,000 PUD-related visits. The total cost (facility and physician fees) was $1.8 billion, mostly for facility costs ($1.6 billion). PUD-related visits to hospital-based outpatient departments (250,000) and emergency departments (190,000) created a total cost of $370.2 million and $66.8 million, respectively. In the year 2000, the cost of drugs (prescription and over the counter) to treat ulcer disease was approximately $620.5 million. Taken together, the total direct cost of PUD is approximately $3.3 billion per year.

The indirect costs related to PUD, that is, the per person loss of productivity over a 3-month period, is estimated at $606. [7] Because more than 75% of patients with PUD are of working age (18 to 65 years old), the estimated productivity loss is estimated at $6.2 billion.

EPIDEMIOLOGY AND NATURAL HISTORY

Two major epidemiologic observations have markedly changed how we approach PUD: the association between *H pylori* and gastric duodenal mucosal ulceration, which leads one to consider peptic ulcer as an infectious disease; and the relationship between ingestion of NSAIDs and the production of mucosal damage, which has generated an acute awareness of preventive measures.

Incidence, Prevalence, Risk Factors, and Odds Ratios

Epidemiologic studies regarding acid peptic disorders are often derived from large databases in which the actual diagnostic criteria for establishing an ulcer are not available to the investigators. Despite this, the qualitative trends are valid because similar observations have been made by several investigative groups. [4], [8], [9] Ulcer complications, such as perforation and hemorrhage, usually require hospitalization and therefore can be assessed more accurately. The 1-year point prevalence of active gastric and duodenal ulcer in the United States is approximately 1.8%, [10] whereas lifetime prevalence ranges from approximately 11% to 14% for men and 8% to 11% for women. [11], [12], [13] and [14] In young Norwegians, the annual incidence of duodenal ulcer was approximately 2 in 1000 men and 0.9 in 1000 women, with similar annual rates for gastric ulcer in both sexes. [15] In Japan, the male-to-female ratio for peptic ulcer was 2:1, but the overall gastric ulcer rate was about 1.5 times greater than that for duodenal ulcer. [16] In 1998, it was estimated that there were 6.8 million cases of PUD in the United States, representing a prevalence rate of 2490 cases per 100,000 persons. [6] The male-to-female ratio for deaths from duodenal ulcer has decreased from 5:1 to about 1.3:1.2, in part because of a decrease in the rate of duodenal ulcer among men, with little change among women. It will be interesting to observe the impact of *H pylori* eradication on these statistics.

Temporal, Gender, and Mortality Trends

Before the 20th century, duodenal ulcer disease was distinctly unusual. [17] The major form of ulcer disease in the 1800s was gastric ulcer, particularly in women, and it was often associated with perforation. Duodenal ulcer disease increased progressively during the early 1900s, reaching a peak in about 1950. [18] Susser and Stein [19] introduced the key concept of birth cohorts (i.e., those born during the same time period) and attributed the changes in ulcer incidence to the urbanization of United States society. These investigators proposed that factors introduced to the birth cohort born between 1868 and 1908 predisposed this group to develop duodenal ulcers and those born about 10 years earlier to develop gastric ulcers. Those born before and after these dates had a lower lifetime prevalence of ulcer disease. This finding suggests that some environmental factor (e.g., *H pylori*) was introduced during the latter part of the 19th century and the early 20th century that increased the incidence of ulcers, and the risk factors were introduced early in life and decreased thereafter. [20] The birth cohort phenomenon applies to data collected in the United States, Britain, Europe, and Japan. [9]

The number of physician office visits for duodenal ulcer decreased between 1958 and 1993. [3] In 1998, there were almost 450,000 outpatient visit (office and emergency department) for PUD-related issues. Hospitalizations for duodenal and gastric ulcer disease decreased in the United States from 1965 through 1980, but there has been little change in the hospitalization rates for perforated duodenal ulcer and for gastrointestinal (GI) hemorrhage. [10] Similar statistics have been reported from Europe. [21]

The mortality rate for duodenal ulcer in 1962 was 3.1 per 100,000, and for gastric ulcer, it was 3.5 per 100,000; these rates had decreased to about 1 per 100,000 each by 1979. [22], [23] Data from the United States Centers for Disease Control and Prevention in 1998 estimate a crude mortality rate of ulcer disease of 1.74 deaths per 100,00 persons. [6] Gastric ulcer has a higher mortality rate than duodenal ulcer because of its prevalence in older patients. [24], [25] and [26]

Surveys in the United States and Europe have documented a substantial increase in hospitalizations of elderly patients for bleeding and perforation. [27], [28] Although the overall mortality rate remained stable throughout the 1970s, it rose significantly in patients older than 75 years of age, presumedly because of increased consumption of NSAIDs by an expanding geriatric population. In Australia, a twofold increase in the intake of nonaspirin NSAIDs from 1979 to 1988 by those older than 65 years of age was associated with a striking increase in peptic ulcer hospitalization rates. [29], [30] and [31] The availability of H_2-receptor antagonists, H^+,K^+-ATPase inhibitors, and prostaglandin analogs has not decreased the rate of ulcer complications.

Genetics of Ulcer Disease

Earlier studies that suggested a potential genetic predisposition to ulcer development [32] have been reconsidered in light of the role of *H pylori* in the pathogenesis of peptic disease. The concordance for peptic ulcer among identical (i.e., monozygotic) twins is approximately 50% and is increased among nonidentical twins, although not to the same degree. [33] The lifetime prevalence of developing an ulcer in first-degree relatives of patients with ulcers is about threefold greater than that in the general population. [34] Approximately 20% to 50% of patients with duodenal ulcer report a positive family history, contrasted with only about 10% of patients who do not have ulcers. [33], [35] Gastric ulcer also clusters in families, but the prevalence of gastric ulcer is not increased among families with duodenal ulcers or vice versa.

The increased incidence of ulcer disease in first-degree relatives is likely from clustering of *H pylori* within families, rather than secondary to genetic factors. Similarly, the theory that elevated levels of serum pepsinogen I may be a genetic marker for familial duodenal ulcer was explained by infection with *H pylori*. [36] In addition, reported genetic markers for PUD, such as blood group O antigen (1.3-fold increase is induced), [37] inheritance of nonsecreting blood group status, [38] and human leukocyte (HLA) subtypes (HLA-B5, HLA-B12, HLA-Bw35), were challenged. The lifetime prevalence of PUD was found to be equally high in persons with O and A phenotypes, but the Lewis phenotype Le (a-b-) and the ABH nonsecretor trait are relevant markers of peptic ulcer. [39] It is thought that these traits may confer an increased susceptibility to infection with *H pylori.* Rare genetic syndromes associated with duodenal ulcer include multiple endocrine neoplasia type I (MEN I) and systemic mastocytosis. [35]

PATHOPHYSIOLOGY

The development of gastroduodenal ulcerations is thought to result from an imbalance between endogenous noxious agents, including hydrochloric acid, proteolytic enzymes, and bile (aggressive factors), and the mucosal defense and repair mechanism that keep the surface intact. Geometric growth in basic science knowledge has facilitated our understanding of the aggressive and defensive factors involved in this equation.

Gastric Secretion

Two secretory products with the potential of producing mucosal damage include hydrochloric acid and pepsinogen. The mechanisms regulating secretion of acid and pepsinogen are reviewed in detail in Chapter 13.

Basal acid secretion follows a circadian pattern, with the lowest secretion in the morning and the greatest at night. [40] Cholinergic input through the vagus nerve and histaminergic input from locally released histamine are the main determinants of basal gastric acid output; food is the principal physiological stimulant of increased acid production. Meal-stimulated acid secretion occurs in three phases referable to origin of the stimulant: the cephalic, gastric, and intestinal phases. The principal determinants of the cephalic phase include sight, smell, and taste of food, which operate through cholinergic input through the vagus nerve. Once food enters the stomach, the gastric phase is activated by amino acids and amines that directly stimulate gastrin release, which, in turn, increases the secretory response. As nutrients enter the intestine, the principal stimulatory factors include distention and proteins and their breakdown products. Series of inhibitory pathways are activated during the different phases of gastric secretion and serve as a counterbalance for the secretory process. The GI hormone somatostatin seems to be an important element in this inhibitory process.

The parietal cell is found in the oxyntic gland in close proximity to the histamine-containing enterochromaffin-like (ECL) cell. The ECL cells express receptors for gastrin and acetylcholine, both of which stimulate histamine release. [41], [42]

The acid-secreting parietal cell contains receptors for histamine (H_2 class), gastrin, and acetylcholine (M_3) (Fig. 66-1). [43], [44] Histamine stimulates adenylate cyclase, whereas acetylcholine and gastrin activates the phosphoinositide–intracellular calcium cascade. The increase in intracellular cyclic adenosine monophosphate (cAMP) or cytosolic calcium leads to activation of various protein kinases, which, in turn, regulate the acid-secreting pump on the canalicular surface of the parietal cell: H^+,K^+-ATPase. The combination of these different signaling pathways leads to a significant increment in gastric secretion (*potentiation*). Potentiation explains why receptor blockade of one pathway with an antagonist also diminishes acid secretion derived from an alternate pathway. [45]

FIGURE 66-1. Gastric parietal cell in the resting and stimulated state. Parietal cells express receptors for gastrin, acetylcholine (*ACh*), and histamine (H_2 subtype). Ligand-mediated parietal cell stimulation leads to a marked increase in canalicular membranes containing H^+,K^+-ATPase. (Adapted from ref. [46].)

H^+,K^+-ATPase is a membrane-embedded protein consisting of two subunits: an a subunit (the active catalytic site) and a ß subunit, whose function is not fully elucidated. This enzyme uses the chemical energy of ATP to transport (pump) protons from the cytoplasm of the parietal cell into the secretory canaliculi in exchange for K^+. The pumps are located in the cytoplasmic membrane of the secretory canaliculus and in cytoplasmic tubulovesicles. [46], [47] They depend on the degree of parietal cell stimulation. The cytoplasmic vesicles are impermeable to K^+, thus rendering the proton pump inactive. In the resting state, only 5% of pumps are active and are located within the canaliculi. During stimulation, cytoplasmic tubulovesicles are rapidly transferred to the membrane of the secretory canaliculus, where 60% to 70% are activated. After stimulation of the parietal cell ceases, the proton pumps return to their inactive state in the cytoplasmic vesicles. [46], [47] The half-life of the proton pumps is 48 hours. [48]

Pepsinogen, the inactive precursor of the proteolytic enzyme pepsin, is produced by the chief cell, which is found primarily in the gastric fundus. The pathogenetic importance of derangements in pepsinogen secretion in PUD remains to be established (see Chapter 13).

Mucosal Defense and Repair

Defensive elements that prevent the gastroduodenal mucosa from damage can be divided into preepithelial, epithelial, and subepithelial factors (Table 66-1). This division is arbitrary, because the entire mucosa functions in concert to prevent injury. The term *cytoprotection* was coined by Andre Robert and colleagues [49], [50] to describe the ability of prostaglandins, independent of their ability to inhibit acid secretion, to protect rat gastric mucosa against a variety of noxious agents. They also observed that low doses of mild irritants released endogenous prostaglandins that could reduce or prevent deep epithelial injury produced by higher concentrations of these or other agents, [50] a phenomenon termed *adaptive cytoprotection.* The term cytoprotection itself is a misnomer, because histological studies of the cytoprotection model demonstrate superficial epithelial injury with preservation of deep mucosal integrity. [51] However, the cytoprotection phenomenon prompted an explosion of investigation into the role of endogenous prostaglandins, nitric oxide (NO), mucus and bicarbonate (HCO_3^-) secretion, maintenance of mucosal blood flow, stabilization of mucosal mast cells and lysosomes, and effects on gastric motility and cellular proliferation. No single mechanism entirely explains the cytoprotection phenomenon. [52]

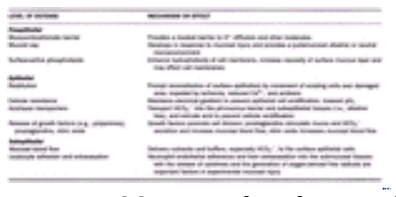

TABLE 66-1 Mechanisms of Gastroduodenal Mucosal Defense

Cyclooxygenase Isoenzymes The depletion of endogenous prostaglandins appears to play an essential role in the development of mucosal injury resulting from NSAIDs. Cyclooxygenase (COX) is the rate-limiting catalytic enzyme in the production of endogenous prostaglandins from membrane-esterified arachidonic acid released under physiological stimulation. Two isoforms of the enzyme have been identified (Fig. 66-2): COX-1, which is constitutively expressed and plays an important role in the maintenance of normal gastric (as well as other organ) function; and COX-2, which is an inducible form that is up-regulated in areas of inflammation. [53] COX-2 is also constitutively expressed in a variety of organ systems, including the brain, kidney, and reproductive tract. The normal stomach has very low levels of COX-2 expression, predominantly in parietal cells, endothelial cells, and macrophages. However, in the setting of *H pylori* gastritis, COX-2 is induced in the epithelial cells, and the degree of induction correlates with the extent of inflammation. [54] NSAIDs nonspecifically inhibit both COX isoforms, leading to both beneficial (antipyretic and antiinflammatory) and toxic (GI injury) effects. Differences in the selectivity of various NSAIDs for COX-2 versus COX 1 (Fig. 66-3) may partially explain differences in ulcer and complication risks associated with specific NSAIDs. [55] The reduced ulceration demonstrated in clinical trials with the COX-2–specific inhibitors, agents that provide similar efficacy to NSAIDs without affecting gastric prostaglandins, have further emphasized the critical role of COX-1 in gastric mucosal defense and repair. [56]

FIGURE 66-2. Tissue distribution and biologic actions of the cyclooxygenase (*COX*) isoenzymes. COX-1 is constitutively expressed in platelets, endothelium, stomach, and kidney, whereas COX-2 is inducible in sites of inflammation in macrophages, leukocytes, fibroblasts, and endothelial cells. COX-2 is also constitutively expressed in vascular endothelial cells and in the kidney, ovary, and brain. Nonsteroidal antiinflammatory drugs nonselectively inhibit both COX isoforms, whereas COX inhibitors inhibit COX-2 only.

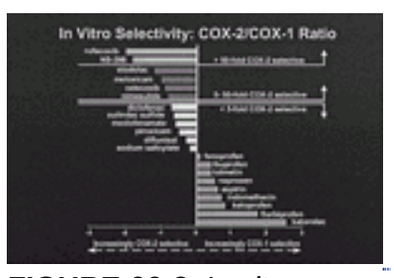

FIGURE 66-3. *In vitro* comparison of selectivity of various nonsteroidal antiinflammatory drugs and cyclooxygenase-2 (COX-2)–specific inhibitors. Drugs with selectivities toward the positive direction (**right**) are more COX-1 selective, and those toward the negative direction (**left**) are more COX-2 selective. These ratios vary depending on assay conditions, but the pattern is generally preserved. (Data from ref. [55].)

Preepithelial Defensive Factors The stomach and duodenum are covered by a mucous- HCO_3^- barrier that provides primary defense against the strongly acidic gastric lumenal contents (Fig. 66-4). The surface epithelial cells secrete mucus and form a gastric layer of mucus 100 µm thick. Gastric acid is secreted in a pulsatile manner through the mucous gel, allowing the formation of short-lived channels within the mucous gel that rapidly close to prevent lumenal acid back-diffusion. This maintains the pH at the mucosa near neutrality despite the low lumenal pH. [57] Gastroduodenal mucus is a viscous glycoprotein that serves as a modest barrier for H^+ diffusion (about fourfold compared with water), although it is an effective barrier to the diffusion of pepsin and other large molecules. Histamine, acetylcholine, and gastrin coordinately stimulate mucin production, whereas prostaglandin appears to increase mucin release by epithelial cells. [58] Dipalmitoylphosphatidylcholine, the predominant surface-active phospholipid found in pulmonary surfactant, is secreted to high levels by the gastric mucous cell. [59] Gastric surfactant, a complex of mucin glycoprotein with these surface-active phospholipids, appears to play an important physiological role in mucosal defense by forming a hydrophobic surface with nonpolar fatty acids that extend from the cell membrane into the lumen, increasing the viscosity of the surface mucous layer. [60] Topical administration of phospholipids to the gastric mucosa can prevent NSAID-induced mucosal damage in animals; efficacy in humans is under investigation. [61]

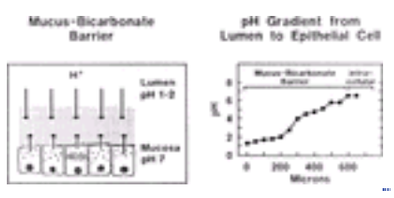

FIGURE 66-4. A layer of mucus overlies the gastroduodenal mucosa. This provides a barrier against the diffusion of acid (H^+) from the lumen to the mucosa. The surface epithelial cells secrete bicarbonate into the base of this barrier. The **right panel** depicts the pH gradient as measured by a pH microelectrode passed from the stomach gradually into the mucous-bicarbonate barrier. The lumenal pH is about 1.3, and the pH immediately adjacent to the surface cell is near 7.0. (Adapted from Flemstrom G, Kivilaakso E. Demonstration of a pH gradient at the luminal surface of rat duodenum in vivo and its dependence on mucosal alkaline secretion. Gastroenterology 1983;84:787.)

HCO_3^- secretion, the other preepithelial defensive factor, is secreted by the surface epithelial cells into the mucous gel to provide a protective pH gradient that maintains a neutral pH at the epithelial cell surface. Lumenal acidification and prostaglandins are potent stimulants of mucosal HCO_3^- secretion. [62] Because

epithelial HCO_3^- secretion requires the presence of HCO_3^- at the nutrient side of the basolateral membrane, states of acidosis, such as shock on decreased gastroduodenal blood flow, lead to marked suppression of surface epithelial HCO_3^- secretion.[63] This phenomenon is likely an important factor in stress-induced gastroduodenal mucosal injury.

Epithelial Defensive Factors The properties of the surface epithelial cells that provide the second line of gastroduodenal defensive factors include restitution, epithelial cell metabolism (e.g., transmembrane, transcellular resistances), acid-base transporters that maintain intracellular pH, and mucus secretion. The apical barrier of the gastric mucosal surface is maintained by tight junctional complexes. When superficial mucosal damage occurs, the surface epithelium rapidly repairs epithelial continuity through the migration of existing epithelial cells from the mucous neck cell area over the basal lamina. This process, known as *mucosal restitution,* can repair small epithelial defects.[64] Restitution occurs rapidly without cell division, depends on microfilaments, and is blocked in the presence of mucosal ischemia or low pH.[64],[65] Damage to the gastroduodenal mucosa results in a layer of gelatinous mucus, fibrin, and cellular debris, referred to as the *mucoid cap,*[66] that forms an alkaline microenvironment conducive to restitution and healing. When this first-line barrier of HCO_3^- and mucus is dissipated, however, the surface epithelial cells remain capable of maintaining intracellular pH, provided there is adequate HCO_3^- supplied through circulation and the Na^+/H^+ and Cl^-/HCO_3^- exchangers and a Na^+/HCO_3^- cotransporter on the cell membranes.[67],[68] When epithelial cells become acidified because of a failure of the overlying pH-mucous barrier, these mechanisms provide the capacity to extrude acid and maintain normal intracellular pH. The epithelial growth factor (EGF) family and trefoil peptides appear to play important roles in gastric physiology.[69] The two most important members are EGF and transforming growth factor-a (TGF-a). EGF is produced in saliva, by Brunner glands in the duodenum, by cells in chronically inflamed mucosa.[70] TGF-a is produced by gastric parietal cells, and it also binds to the EGF receptor. Activation of the EGF receptor leads to inhibition of gastric acid secretion, stimulation of mucin production, and epithelial cell migration and proliferation. Trefoil peptides, so named because of their unique three-leaf structure, are up-regulated at sites of GI injury and include human spasmolytic peptide, pS2, and intestinal trefoil factor.[71] Both human spasmolytic peptide and intestinal trefoil factor protect against experimental injury resulting from ethanol and indomethacin.[72],[73] The colocalization of trefoil factors with mucous cells and their close association with gastric mucin have led to the hypothesis that these peptides enhance the barrier function of mucus. *Regeneration,* the process by which larger epithelial defects that destroy the basal lamina (e.g., ulcers) heal, requires cellular proliferation. Regeneration is at least partly dependent on tissue prostaglandins and growth factors, including the EGF family,[69],[74] and by angiogenic factors such as fibroblast growth factor[75] and hepatocyte growth factor.[76] The regenerative and angiogenic ulcer healing response appears regulated, at least in part, by prostaglandins derived from COX-2.[77] This supports the clinical observation that NSAIDs may impair ulcer healing by their effects on both isoforms of COX, a concern that applies as well to the COX-2–specific inhibitors. The adverse impact on healing can be overcome when gastric acid is markedly reduced, such as with a proton pump inhibitor (PPI).

Subepithelial Defensive Factors The key subepithelial process that prevents mucosal injury is adequate mucosal blood flow. Diminished blood flow or acidosis markedly impairs preepithelial and epithelial defensive factors. The rich vascular anatomy within gastric mucosa is designed to carry the HCO_3^- released by actively secreting parietal cells at the base of the gland to the epithelial surface, where it can neutralize protons that breach the earlier lines of defense.[78] For each molecule of H^+ secreted by the parietal cells, one molecule of HCO_3^- is transported across the basolateral membrane, producing this *alkaline tide* in the submucosa. When gastric acid secretion is suppressed, by H_2-receptor antagonists or H^+,K^+-ATPase inhibitors, acidification of the gastric mucosa results in greater injury than in the acid-secreting mucosa because of the absence of this alkaline tide. Maintenance of endothelial integrity appears to define the cytoprotection phenomenon and, as discussed later, is a critical component of NSAID-induced GI injury.

Pathogenesis of Peptic Ulcer Disease

Pathophysiology of Duodenal Ulcers Before the role of *H pylori* was understood, many studies were published proposing a unifying, acid-driven hypothesis as fundamental to the genesis of peptic ulceration. Unfortunately, no single abnormality in the gastric secretory process has been found in all patients with ulcers. Despite this, acid is still an independent factor that negatively affects mucosal defense. The next section outlines some of the earlier work on the role of gastric secretion, motility, and mucosal abnormalities as primary pathogenic elements in ulcer development. This is followed by a review of *H pylori*–induced and NSAID-induced disease.

Acid dysregulation. The pathophysiology of duodenal ulcer disease has been examined in selected and often relatively small groups of patients and controls. Discrepancies exist among studies because of the heterogeneity of duodenal ulcer disease itself and the heterogeneity of study populations, especially the control groups. Despite these considerations, several abnormalities in gastric and duodenal secretion, gastrin release, and gastric emptying have been observed in patients with duodenal ulcer (Fig. 66-5).[79],[80] and[81] To what extent these abnormalities are associated with *H pylori* infection, which would have been present in almost 100% of patients with ulcers, but only in some control subjects, is unknown.

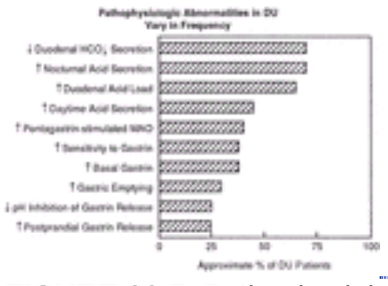

FIGURE 66-5. Pathophysiological abnormalities in patients with duodenal ulcer vary in frequency. Shown are the approximate percentages of patients with duodenal ulcers with some of the abnormalities that have been described. These data come from many separate studies with different experimental conditions and patient populations, and they represent approximations of these abnormalities. For example, approximately 70% of patients with duodenal ulcers have decreased proximal duodenal mucosal bicarbonate or increased nocturnal acid secretion.

Duodenal ulcer and duodenal pH. Attempts at establishing a role for altered duodenal pH as an important factor in ulcer formation has been fraught with technical difficulties; therefore, it is not surprising that the results of studies examining these parameters in patients with PUD are conflicting.[82],[83],[84] and[85]

Abnormalities in duodenal mucosal defense. Some patients with gastric or duodenal ulcer appear to have a mucous gel covering the mucosa that is somewhat structurally weaker than that of normal persons.[86] The mechanism for this is unknown, and these findings have not been confirmed. HCO_3^- production in the duodenal bulb, but not the distal duodenum, is markedly diminished in patients with active duodenal ulcer as compared with healthy persons (Fig. 66-6).[87] The mechanism of this defect is not established, but a cellular or subcellular defect in HCO_3^- secretion has been proposed.[87] Histological evaluation of the duodenum in patients with inactive duodenal ulcer fails to reveal any striking morphologic changes when compared with the mucosa of healthy persons.[88] Studies suggests that *H pylori* may alter duodenal mucosal HCO_3^- production.

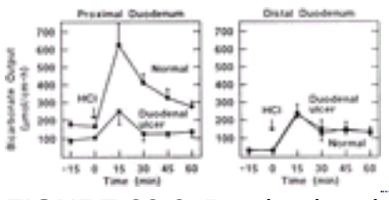

FIGURE 66-6. Proximal and distal duodenal mucosal bicarbonate secretion in patients with duodenal ulcers and in healthy persons. The proximal duodenal mucosal bicarbonate secretion is significantly impaired in patients with duodenal ulcers compared with healthy persons, and distal duodenal mucosal bicarbonate production is similar in both. Notice the gradient from the proximal to distal duodenum in the healthy persons. (Adapted from ref.[87].)

Pathophysiology of Gastric Ulcers Most (70%) of gastric ulcers are associated with NSAID use or *H pylori* infection. In an effort to develop a unified descriptive system, gastric ulcers have been classified into three groups. *Type I ulcers* occur in the body of the stomach and are not associated with other gastroduodenal disease. *Type II ulcers* are also located in the body of the stomach and are associated with a duodenal ulcer scar or active ulcer. *Type III ulcers* are located in the immediate prepyloric area. Acid secretion in types II and III is similar to that of duodenal ulcer, but ulcers located in the body of the stomach (type I) tend to be associated with normal or low levels of gastric acid secretion. Information about the *H pylori* status in these different types of gastric ulcer disease is not available. Widespread superficial gastritis often surrounds the ulcer and is present in the gastric antrum (i.e., chronic active gastritis or atrophic gastritis)[89] (see Chapter 68).

Motility abnormalities and duodenogastric reflux. Abnormalities in pyloric sphincter pressure and gastric motility have been reported in patients with gastric ulcers.

[90], [91] and [92] It seems unlikely that these effects are involved in ulcer pathogenesis because patients with gastroenterostomies and copious amounts of duodenogastric reflux often have superficial gastritis, particularly surrounding the anastomosis, but do not commonly develop gastric ulcers. Moreover, gastric ulcer healing is not enhanced by the bile salt–binding agent cholestyramine. [93]

Gastric secretion and gastric ulcers. Basal and stimulated gastric acid secretion is within normal limits in groups of patients with gastric ulcers. Unlike patients with duodenal ulcer, in whom there is a maximal acid output threshold of about 10 mmol/h for ulcers to develop, there is no minimal secretory response before gastric ulceration occurs, and gastric ulcers have been documented in the presence of achlorhydria. [94]

Mucosal blood flow. Gastric ulcers tend to occur near the gastric angulus, an area of prominent muscle bundles where the mucosa is directly supplied by the left gastric artery, rather than through a rich submucosal plexus, as observed throughout other portions of the stomach. [95]

Helicobacter pylori and Ulcer Disease

Background and history. Establishing the link between *H pylori* and the pathogenesis of PUD was one of the most exciting medical discoveries of the 20th century. We now know that *H pylori* causes most cases of histological gastritis, is the most important etiologic factor in most patients with PUD, has also been intimately linked to the pathogenesis of both low- and high-grade gastric mucosa-associated lymphoma (maltoma), and is a predisposing factor for the development of gastric adenocarcinoma. [96] Although some investigators have suggested that *H pylori* may be associated with nonulcer dyspepsia, eradication of this infection has been found to offer little, if any, benefit over placebo or a short course of PPI therapy [97], [98] (see Chapter 30 and Chapter 68). Although the recognition of *H pylori* colonization of the stomach has ushered in a new era in gastric microbiology, gastric urease activity [99] and spiral organisms have been observed in human stomachs since the turn of the 20th century. [100] Despite prior negative studies in 1975, [101] Steer and Colin-Jones [102] reported the presence of gram-negative bacteria in the gastric mucosa of approximately 80% of patients with gastric ulcers. In 1983, Warren and Marshall [103] published their landmark study characterizing the spiral-shaped *H pylori* bacterium and describing its correlation with histological gastritis. *H pylori* is a curved or S-shaped gram-negative rod approximately 0.5 by 3 µm in size, containing four to seven sheathed flagella at one pole. [104], [105], [106] and [107] Prolonged culture leads to coccoid forms of *H pylori,* which may represent a dormant state, allowing the survival of the bacterium in unfavorable environments. [108] Perhaps the most distinctive characteristic of *H pylori* is the ability to produce large amounts of highly active urease. [109]

Transmission. The natural habitat of *H pylori* is the human stomach, and perhaps the stomach of nonhuman primates, cats, and houseflies. [110], [111] and [112] It is probable that animals are secondary hosts and humans are the primary reservoir for the bacteria. Aside from colonization of gastric metaplasia or ectopic gastric mucosa in other parts of the GI tract, the organism is confined to the stomach. There are isolated reports of recovering the organism from the oral cavity, [113] but whether this represents true colonization or contamination by refluxed gastric contents remains unclear. Person-to-person transmission from a single environmental source is suggested by the increased prevalence among family members of patients with *H pylori* and among institutionalized patients. Moreover, DNA analysis reveals identical *H pylori* strains in infected members of the same family and in patients in a chronic care facility. [114], [115], [116], [117], [118], [119] and [120] *H pylori* can potentially be transmitted by three different modes. First, circumstantial evidence is most consistent with fecal-oral transmission. The organism has been isolated from feces, [121], [122] although several laboratories have not been able to duplicate these findings. Water has been suggested as a source, and, although polymerase chain reaction (PCR) assays have been positive, intact organisms have not been isolated from water. The age-related rise of *H pylori* infection, which follows a pattern similar to that of other diseases that are transmitted by the fecal-oral route, provides support for this mechanism of transmission. However, most believe that the age-related increase in *H pylori* prevalence is the result of the cohort effect (see section "Epidemiology" later). Oral-oral transmission of *H pylori* has also been postulated, based on isolation of *H pylori* from the oral cavity. This may be especially important among African infants whose mothers feed them premasticated food. [123] Moreover, it has been hypothesized that children who regurgitate or vomit infected gastric juice, especially during acute infection with *H pylori,* may transmit the infection to their contacts. [124] Finally, iatrogenic transmission has also been described in patients who have undergone acid secretory or endoscopic studies with a contaminated pH electrode, biopsy forceps, or endoscope. [125], [126] This is a rare occurrence.

Epidemiology. Gastritis, a common histological finding in the otherwise healthy population, closely parallels the presence of *H pylori* in a large percentage of persons in developing countries, with a high prevalence among children and young adults, indicating infection early in life. Indeed, in developing countries of Central and South America, Asia, and Africa, 80% of children are infected by 10 years of age. [127], [128] In contrast, the prevalence of *H pylori* and gastritis in the white population of the United States and other developed countries increases with age from approximately 10% at 20 years of age to about 50% at 60 years of age. [129], [130] These findings probably represent a cohort effect, in which most of the higher prevalence in older patients is the result of a high rate of infection earlier in life. Differences in hygiene and living conditions in the past may account for the higher rates of infection in older persons in the United States. [131] If this hypothesis proves true, the age-related *H pylori* prevalence in the United States will gradually decrease as younger persons with their lower *H pylori* prevalence advance in age. The prevalence of *H pylori* is influenced by environmental factors such as childhood socioeconomic status, domestic crowding, and the absence of a fixed hot-water supply during childhood. [131] Ethnicity may be risk factor, which may reflect childhood environmental factors or genetic susceptibility. In the United States, asymptomatic Latin Americans have approximately an 80% prevalence of *H pylori,* without significant variation in different age groups. [132] Asymptomatic African Americans have a rate of *H pylori* acquisition that parallels that of whites. However, the age-related prevalence is higher in African Americans than in whites. [130] More cogent evidence supporting genetic susceptibility comes from studies of monozygotic twins, in whom infection rates are higher than in matched dizygotic twins. [133]

Evidence that Helicobacter pylori causes peptic ulcer disease. There is no doubt regarding the central role of *H pylori* in both gastric and duodenal ulcers not otherwise associated with NSAIDs or acid hypersecretory states. Thus, nearly all non–NSAID-related ulcers should be considered manifestations of an infectious disease. This paradigm, however, needs to be understood within a changing milieu of the prevalence of *H pylori* infection. As the prevalence of *H pylori* infection declines to zero, the prevalence of ulcers will also decline, but an increasing percentage of ulcers that do occur will be unrelated to *H pylori.* [134] Three primary lines of evidence support the etiologic role of *H pylori* in PUD:

1. The natural history of *H pylori* infection. Follow-up of patients with gastritis (and therefore presumptively with *H pylori* infection) for up to 10 years revealed that 11% developed peptic ulcers (1% per year) compared with fewer than 1% of persons without gastritis. [135] The odds ratio for the association between peptic ulcer and *H pylori* infection was 3.4 (95% confidence interval = 1.8–6.3).
2. The consistent, age-independent worldwide association of *H pylori* and ulcer disease: approximately 90% of patients with duodenal ulcer and 70% to 90% of patients with gastric ulcers are infected with *H pylori.* [129], [136], [137]
3. The results of multiple prospective treatment trials indicate that eradication of *H pylori* significantly reduces the likelihood of gastric and duodenal ulcer recurrence. [138], [139], [140] and [141]

This is the best evidence supporting the concept that *H pylori* is an important contributing factor in PUD. Moreover, treatment of *H pylori* infection leads to more rapid and reliable ulcer healing than does treatment with antisecretory therapy alone. [141], [142] The beneficial effect of curing *H pylori* infection also extends to patients who present with bleeding ulcers; the rebleeding rate is significantly lower compared with patients in whom infection persists. [143] Data from the United States, however, suggest that the proportion of *H pylori*–negative ulcers is increasing. A multicenter treatment trial in the United States of patients with duodenal ulcer suggests that no more than 80% of patients had *H pylori* infection. [144] Moreover, despite cure of *H pylori* infection, the pooled recurrence rate of duodenal ulcers at 6 months after therapy in seven rigorously designed multicenter trials in the United States was 20%. [145] Similar results have been reported from Hong Kong. [146] Complicating matters further, in some populations with a very high prevalence (>80%) of *H pylori* infection; the occurrence of PUD may be mistakenly attributed to this infection. In addition, the prevalence of *H pylori* infection in complicated ulcers may be lower than that found in uncomplicated ulcer disease. Two centers found that approximately 70% of patients with bleeding duodenal ulcers were infected with *H pylori,* whereas another center observed that 50% of patients with perforated duodenal ulcers had *H pylori* infection. [146], [147], [148] and [149] In these reports, the prevalence of NSAID use could not be incriminated as an explanation for the low prevalence of *H pylori* infection. The swinging of the pendulum, from skepticism regarding the concept that PUD is an infectious disease to universal agreement regarding the importance of *H pylori* infection to a more circumspect qualified endorsement of a central etiologic role of *H pylori,* should not diminish the clinician's enthusiasm for diagnosing and treating *H pylori* infection in the setting of PUD. Nevertheless, the foregoing data lead to some uncertainty regarding the best management for patients with PUD. For patients (e.g., the elderly, those with severe comorbidity) in whom recurrence of an ulcer, especially a bleeding ulcer, may be associated with severe morbidity, full-dose antisecretory therapy may be appropriate, despite cure of *H pylori* infection. In most cases, maintenance antisecretory therapy is unnecessary in view of the low recurrence rate and morbidity of PUD after *H pylori* eradication.

Helicobacter pylori and nonsteroidal antiinflammatory drug interactions. Available data can be interpreted to support three potential interactions between NSAIDs and *H pylori*: no influence, increased adverse outcome, and beneficial effects. Most of the data suggest that NSAIDs and *H pylori* are independent risk factors for PUD. Circumstantial evidence favors the concept that NSAIDs increase the risk of developing complicated or otherwise symptomatic ulcers in patients with a prior history of ulcer disease. [150], [151] Although NSAIDs alone appear to cause more endoscopically detected simple ulcers in the stomach than in the duodenum, NSAID-associated ulcers occur with similar frequency in both these locations. [152], [153], [154], [155] and [156] Moreover, most NSAID-associated complications occur within 1 month after initiation of NSAID therapy. These findings suggest that NSAIDs induce complications in patients with preexistent clinically silent ulcers. More limited data suggest that in patients without a history of PUD, there is a higher incidence of peptic ulcers in association with NSAID use in patients infected with *H pylori* as compared with those without *H pylori* infection. This is based on a trial suggesting that cure of *H pylori* diminishes the incidence of peptic ulcers in patients beginning NSAIDs. [157], [158] In contrast to those studies, which focused on NSAID-naive subjects, two studies assessed the effect of *H pylori* eradication on ulcer healing and relapse in patients who were already taking long-term NSAIDs. [159] Eradication of *H pylori* did not influence the rate of ulcer healing, and there was only a trend

favoring *H pylori* eradication in reducing ulcer recurrence. [164] *H pylori*–positive long-term NSAID users who had ulcers at baseline (41 gastric and 46 duodenal ulcers) were randomly assigned to receive omeprazole with or without eradication therapy. Relapse was defined as recurrent ulcer and/or dyspepsia. Contrary to the findings in NSAID-naive subjects, curing *H pylori* infection did not reduce the relapse rate in long-term NSAID users. [160] How could *H pylori* affect NSAID-naive patients and long-term NSAID users in a different way? One explanation is that *H pylori* contributes to an excessive ulcer risk in NSAID-naive subjects, whereas NSAIDs cause most of the ulcers in long-term users of these agents irrespective of *H pylori* status. Epidemiologic studies have consistently shown that the risk of ulcer disease is substantially higher among patients who recently start taking NSAIDs than among long-term NSAID users. [161] This excessive ulcer risk may occur in a subgroup of *H pylori*–infected persons who are prone to develop ulcer on exposure to NSAIDs; that is, initiation of NSAID treatment aggravates or precipitates ulcer disease in these susceptible patients. Weeding out of susceptible patients will select a group of patients who can tolerate long-term NSAIDs irrespective of the *H pylori* status, and this explains why some studies did not find *H pylori* as a risk factor in long-term NSAID users. [162] One study raised concern that curing *H pylori* could impair ulcer healing. [163] In a subgroup of 163 patients with gastric ulcers, eradication of *H pylori* was associated with delayed ulcer healing; however, this finding was not confirmed by another larger randomized trial using ulcer healing as the predefined end point. [164] The lack of convincing evidence that curing *H pylori* infection has an adverse impact on the healing of NSAID ulcers supports the concept that antibiotic therapy should be offered to all patients. A randomized trial compared eradication of *H pylori* with maintenance omeprazole for secondary prevention of recurrent ulcer bleeding in patients with *H pylori* infection who were taking NSAIDs or low-dose aspirin. [165] Among long-term users of NSAIDs, eradication of *H pylori* alone was not sufficient to prevent recurrent bleeding. In contrast, among users of low-dose aspirin, eradication of *H pylori* alone was comparable to maintenance omeprazole in reducing the incidence of recurrent bleeding. Preliminary data have suggested that the combination of *H pylori* eradication and long-term treatment with a PPI may be superior to *H pylori* eradication alone for secondary prevention of ulcer bleeding associated with low-dose aspirin. [166] The divergent outcomes between low-dose aspirin and NSAIDs suggest that the increased ulcer risk with NSAIDs appears to overshadow the *H pylori*–attributable risk. Because low-dose aspirin has a much lower overall risk, *H pylori* may play a more important role in ulcer bleeding associated with this therapy than in bleeding associated with NSAIDs. Based on these observations, it appears that eradication of *H pylori* may be considered a cost-effective strategy to reduce ulcer risk in low-dose aspirin users and among NSAID users at high risk. [167] It remains clear that the residual increased risk associated with the aspirin and NSAIDs is not eliminated, and the use of cotherapy to prevent ulcers in these situations should be individualized based on clinical circumstances. In the case of the COX-2–specific inhibitors, the weight of current evidence suggests minimal interactions with *H pylori* infection. However, the elimination of this risk factor in patients taking these agents has the potential to reduce their overall risk of ulceration further.

Pathogenesis of Helicobacter pylori–induced peptic ulcer disease. The mechanism by which *H pylori* leads to gastric and duodenal ulceration has not been established. The organism colonizes many persons, yet the percentage of carriers who develop clinical sequelae is rather small. This discrepancy in carrier rates and development of disease results from multiple factors, including bacterial characteristics, variations in the host inflammatory response to the organism, and varying types of interactions between the host and the bacteria.

Gastric colonization. One of the most intriguing aspects of *H pylori* is its ability to inhabit and survive within the highly acidic conditions found within the stomach. Sachs and colleagues [168], [169] shed significant insight into *H pylori*–mediated acid resistance, a key feature of which is the expression of urease. Synthesis of this enzyme accounts for 15% of protein produced by the organism. The urease gene cluster consists of seven genes (*UreA* and *UreB* and *UreE* to *UreI*) that encode the structure and regulate portions of the enzyme. [170] *UreI* is a proton-gated urea transporter, which increases access of gastric juice urea to the intrabacterial urease by 300-fold. The steady entry of urea facilitates the rapid and continuous buffering of the bacterial periplasm to 6.0. Maintenance of a pH in this range (~6) permits acid resistance and growth of the organism in an acidic pH. [168], [169]

Virulence factors. Various *H pylori* factors contribute to the ability of the bacterium to colonize gastric mucosa, to evade host defenses, and to damage host tissue. These virulence factors are encoded by specific gene sequences located in a so-called *pathogenicity island. H pylori* is genetically a highly diverse bacterial organism, and some of these genes may [171], [172], [173] and [174] affect the ability of this organism to colonize and ultimately induce disease in its host. One such gene is the expression of the Cag island, a 35- to 40-kb genetic element, that is associated with human disease (see later) and is present in approximately 60% of strains in the United States. Persons infected with CagA $^{+}$ strains are at increased risk of peptic disorders as well as distal gastric cancer. *CagA,* which encodes CagA (cytotoxin-associated gene protein), and a gene (*picB*), which encodes a product that promotes induction of cytokines, are essential for induction of proinflammatory cytokine activation as well as for transporting proteins into host cells. [176], [177] and [178] Approximately 50% of *H pylori* strains produce a vacuolating cytotoxin (VacA), which is related to the pathogenicity island. The *vacA* gene has a very variable structure and is near, but not within, the pathogenicity island. Expression of the VacA cytotoxin usually is associated with the presence of *cagA* in the pathogenicity island. Thus, in general, those strains that are CagA $^{+}$ are VacA $^{+}$. The function of CagA is unknown, but once in the host cell, CagA is phosphorylated and is activated by a eukaryotic tyrosine kinase. [175], [179], [180] Once activated, CagA causes alteration in cell cycle and morphology, and it induces inflammation through regulation of interleukin-8 (IL-8) production by nuclear factor-?b and mitogen-activated protein kinases signaling pathways. The question remains whether these cellular changes indeed lead to peptic injury and malignant transformation. CagA expression was initially reported to represent an enhanced risk for the development of both gastric cancer and duodenal ulcer disease. However, the proportion of *H pylori* bacteria that possess the *cagA* gene varies in different geographic areas and populations infected with *H pylori.* In addition, other studies have not demonstrated an increased risk of severe gastroduodenal disease in association with CagA expression. Despite such data, the possibility that specific strains may be associated with specific diseases, especially duodenal ulcer disease, remains attractive. [181]

Mucosal immune responses. Paradoxically, *H pylori* induces host responses that promote inflammation and epithelial damage without conferring immunity against infection. Responses to *H pylori* infection include increased IL-1, IL-6, IL-8, and tumor necrosis factor-a expression (TNF-a), [182], [183] which may recruit and activate monocytes and neutrophils. Release of neutrophil mediators may, in turn, further disrupt epithelial cells and contribute to ulcer formation. *H pylori* may also induce B-cell–mediated autoimmune response. [184] *H pylori* lipopolysaccharide expresses antigens that cross-react with epithelial cell antigens. [185] Antibodies to *H pylori* may recognize these antigens and induce gastritis. *H pylori* infection is also associated with increased apoptosis. [186], [187]

Gastrin release and acid secretion. *H pylori*–positive patients have significantly higher basal, 24-hour, meal-stimulated, bombesin-stimulated, and gastrin-releasing peptide (GRP)– stimulated gastrin levels than do persons cured of *H pylori* infection. [188], [189], [190], [191], [192], [193], [194] and [195] Although ammonia produced by *H pylori* urease may raise the pH at the epithelial surface, increased gastrin is found when gastric contents are buffered to eliminate the pH effects, [188], [196] and acutely giving urea by mouth, by intragastric instillation, or by reducing urease activity does not alter serum gastrin level. [192], [197], [198] Hypergastrinemia in *H pylori*–infected patients may result from a decrease in acid secretion inhibiting antral somatostatin-producing D cells. Cure of *H pylori* reverses the decline in somatostatin mRNA. [199], [200] Decreased release of somatostatin is a plausible explanation for increased gastrin release. *H pylori* factors that inhibit somatostatin release have not been identified, although TNF-a has been implicated. [201] It is also possible that constituents of *H pylori* and proinflammatory cytokines may have direct stimulatory effects on gastrin release. [202] Basal and GRP-stimulated acid secretion is increased in patients with *H pylori*–associated duodenal ulcer disease as compared with asymptomatic infected volunteers, suggesting a greater acid response to gastrin in patients with duodenal ulcer disease. After cure of *H pylori* infection in patients with duodenal ulcer, acid secretion may either decrease by approximately 50%, into the range of uninfected healthy volunteers, or remain unchanged. [190], [191], [195], [203], [204], [205] and [206] Acid secretion is also decreased in response to GRP stimulation. In most, but not all studies, however, pentagastrin-stimulated acid output did not decline after cure of *H pylori* infection. A complete understanding of the complex effect of *H pylori* on acid secretion is hampered by the heterogeneity of duodenal ulcer disease. A summary of the potential impact of *H pylori* on gastric acid secretion is given in Figure 66-7.

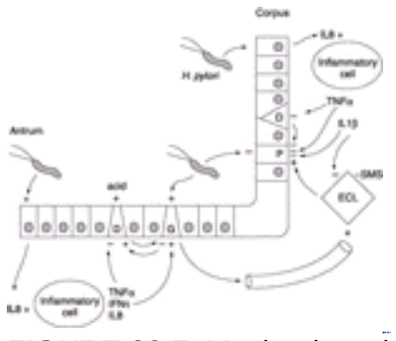

FIGURE 66-7. Mechanisms by which *Helicobacter pylori* may induce abnormalities in gastric acid secretion. *H pylori* may have both direct and indirect (through proinflammatory cytokines) effects on gastric parietal cell activity. *SMS,* somatostatin; *ECL,* enterochromaffin-like cell. (Adapted from Calam J, Gibbons A, Healey ZV, Bliss P, Arebi N. How does *Helicobacter pylori:* cause mucosal damage? Its effect on acid and gastric physiology. Gastroenterology 1997;113:S43.)

Mucosal bicarbonate secretion. Both basal and stimulated HCO_3^- production in the proximal duodenum is markedly diminished in patients with active duodenal ulcer disease, but distal duodenal HCO_3^- production is normal. Unlike other pathophysiological defects, there is less overlap (about one fourth) between those with and without ulcers. The mechanism of this defect, whether cause or effect, is under investigation. Prostaglandin E_2 (PGE_2), a potent agonist of gastroduodenal HCO_3^- production, stimulates significantly less HCO_3^- production in patients with quiescent duodenal ulcers, suggesting a cellular or subcellular defect in HCO_3^-. [87] Moreover, histological evaluation of the duodenum in patients with inactive duodenal ulcer fails to reveal any striking morphologic differences from findings in healthy

persons, and cure of *H pylori* infection normalized duodenal HCO_3^- secretion in patients with duodenal ulcers. In contrast, HCO_3^- secretion is not impaired in persons with *H pylori* infection who do not have ulcers, and in this group, HCO_3^- secretion does not change after *H pylori* cure. [207]

Gastric metaplasia in the duodenum. One hypothesis linking *H pylori* to duodenal ulcer disease is that *H pylori* organisms can only colonize areas of gastric metaplasia in the duodenal bulb, leading to active duodenitis and eventually to duodenal ulcer formation. Indeed, gastric metaplasia with active duodenitis is found in most, [208], [209] and [210] but not all, [211], [212] and [213] patients with duodenal ulcers. Moreover, gastric metaplasia in the duodenum is a patchy, multifocal process that is commonly found in healthy persons. [212], [213] and [214] There are conflicting data correlating the possible relationship among pH, gastric metaplasia in the duodenal bulb, and duodenal ulcer disease. [205], [206] and [207] In addition, others have found a similar prevalence of gastric metaplasia among patients with duodenal ulcers and nonulcer dyspepsia. [215] Furthermore, these latter investigators observed that, although pH values decrease in parallel with a greater extent of metaplasia in patients with nonulcer dyspepsia, the converse is true in patients with duodenal ulcer disease. Such data suggest that gastric acid does not determine the prevalence or extent of duodenal metaplasia. Overall, the association between gastric metaplasia and *H pylori* in the pathogenesis of duodenal ulcer, although conceptually attractive, is as yet unsubstantiated.

Nonsteroidal Antiinflammatory Drugs and Ulcer Disease

Epidemiology. It is estimated that 14 million persons in the United States take NSAIDs daily. In 1991, more than 70 million NSAID prescriptions in the United States were filled, representing 278 prescriptions per 1000 population, with ibuprofen and naproxen the most commonly prescribed agents. [216] In 2000, after the introduction of the COX-2–specific inhibitors, more than 111 million prescriptions were written in the United States at a cost of more than $4.8 billion. [217] Furthermore, the evolving interest in the ability of low doses of aspirin to reduce cardiovascular events and to protect against colorectal cancer has likely led to increased patient exposure to aspirin and its potential for GI injury. Currently, annual sales in the United States of over-the-counter agents of NSAIDs and aspirin together approach $2 billion. [218] NSAID-induced patient morbidity can range from symptoms such as nausea and dyspepsia (experienced by as many as 60% of users) to serious adverse GI events such as bleeding and perforation (estimated to affect 2% to 4% of users per year). In the United States, [219] it is estimated that more than 100,000 hospitalizations (at a cost of at least $2 billion) and as many as 10,000 to 20,000 deaths annually can be attributed to NSAID-related complications. [220] Although the probability of a drug-related complication in an individual patient is low, the vast numbers of patients exposed to NSAIDs translate into a considerable problem from the health care economic perspective. Estimated costs for excess hospitalizations, outpatient physician visits for symptoms, laboratory testing, and diagnostic studies such as endoscopy for NSAID toxicity seriously underestimate the true societal impact of this condition because indirect costs such as work loss and other lost productivity tend not to be included in these calculations. [221] In an effort to inform clinicians better, the United States Food and Drug Administration (FDA) and its counterpart in the United Kingdom, the Committee on Safety of Medicines, issued formal warnings regarding the risk of adverse GI events in patients using these medications.

Mechanisms. The mechanisms by which NSAIDs induce mucosal injury remain incompletely understood but appear to involve both direct topical injury and systemic effects mediated by prostaglandin depletion.

Topical damage. Aspirin and most NSAIDs are weak organic acids with ionization constants (pK_a) in the range of 3 to 5. [222] In the strongly acid environment of gastric juice (pH <2.5), these lipidic drugs are soluble and nonionized and freely diffuse across cell membranes into mucosal cells. Once inside the cell, the elevated intracellular pH favors dissociation of the H^+ ion and trapping of the negatively charged acid moiety. Because the nonionized form remains in equilibrium across the cell membrane, the total intracellular drug concentration (ionized and nonionized) is much higher than outside the cell, an effect known as *ion trapping* (Fig. 66-8). Ion trapping promotes direct toxic cellular injury and leads to abnormal ion flux across the epithelium, with increased H^+ back-diffusion. The exact mechanisms by which high cellular levels of NSAIDs damage the surface epithelial cells are not known. Changes in membrane permeability may be secondary to impairment of energy metabolism as a result of uncoupling of oxidative phosphorylation with secondary inhibition of ion transport, [223] inhibition of mucosal prostaglandin secretion, reduction of mucus secretion, and interference with cell turnover. [224] NSAIDs also directly attenuate the hydrophobic, or “nonwettable,” properties of the mucous barrier independent of prostaglandin-mediated actions. In short-term studies in rats, preassociation of NSAIDs with surface-active phospholipids was shown to prevent ulceration even in the presence of prostaglandin depletion. [61]

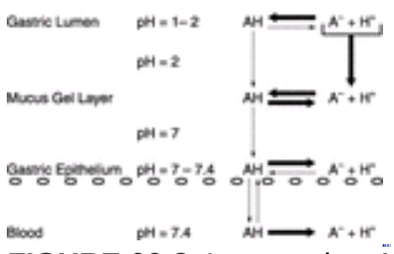

FIGURE 66-8. Ion trapping. Nonsteroidal antiinflammatory drugs (NSAIDs) are weak organic acids with ionization constants (pK_a) in the range of 3 to 5 and thus are soluble at the low pH in the stomach lumen. In the strongly acidic environment of gastric juice (pH of less than 2.5), these lipidic drugs are nonionized and freely diffuse across cell membranes into mucosal cells. Once inside the cell, the elevated intracellular pH favors dissociation of the H^- ion and trapping of the negatively charged acid moiety. Because the nonionized form remains in equilibrium across the cell membrane, the total intracellular drug concentration (ionized plus nonionized) will be much higher than outside the cell. Ion trapping allows direct cellular injury resulting from the toxicity of high intracellular levels of the NSAID. (Adapted from ref. [223].)

Systemic effects. The clinically important effects of NSAIDs–the production of ulcers with an increased risk of significant complications—appear to be largely caused by their systemic actions. [225] Inhibition of COX-1with a resultant decrease in endogenous prostaglandins, especially PGE_1, PGE_2, and PGI_2, is thought to be the most important mechanism of action. [225], [226] and [227] Traditional NSAIDs have been shown to inhibit plasma and mucosal prostaglandin production in humans, whereas COX-2 inhibitors lack this effect and are therefore associated with reduced rates of ulcers and complications. [228] Mucosal prostaglandins play an important role in normal mucosal defense, and, thus, NSAIDs may compromise mucosal mechanisms that prevent the development of gastroduodenal ulceration resulting from lumenal acid. [225] Platelet COX-1 is also inhibited irreversibly by aspirin and for as long as 18 hours by other NSAIDs. The resulting decreased platelet aggregation and prolonged bleeding times may potentiate GI bleeding from the upper and lower GI tract. [229] Three lines of evidence support the importance of mucosal prostaglandin depletion in the development of NSAID-induced ulcers. First, active or passive immunization against PGE_2, PGF_2a, or PGI_2 in animals leads to formation of ulcers that grossly and histologically resemble ulcers associated with long-term NSAID use. [230] Second, coadministration of the PGE_1 analog misoprostol with a variety of NSAIDs dramatically reduces the subsequent development of mucosal ulceration. [231], [232] Third, analgesic or antiinflammatory agents that do not inhibit COX or reduce prostaglandin production, such as acetaminophen or the COX-2–specific inhibitors, do not cause mucosal ulceration. [227], [228] Although inhibition of prostaglandin synthesis contributes significantly to NSAID-induced mucosal injury, there may be other important mechanisms of injury. Some studies have found a poor correlation between mucosal prostaglandin inhibition after NSAIDs and the degree of acute mucosal injury. [233], [234] Maximal mucosal prostaglandin and thromboxane inhibition occurs with doses of aspirin as small as 30 to 80 mg/d. However, clinical experience suggests that ulcer complications are less common at these low doses and appear to increase at higher aspirin doses. [234], [235] By inhibition of prostaglandin production, NSAIDs interfere with all three lines of mucosal defense: [236] mucous cell secretion of mucin and surface-active phospholipid, [237] basal bicarbonate secretion from gastric and duodenal mucosa (two defects that combine to form a mucous gel poorly suited to perform its role as a barrier to acid diffusion), and the mucosal proliferation critical to ulcer healing. [74] Prostaglandins also play an inhibitory role in the physiological regulation of acid secretion. [238] Feedback inhibition of gastric acid secretion is also dependent on endogenous prostaglandins; thus, NSAIDs may impair mucosal defense and increase acid secretion simultaneously. [239] Interruption of mucosal blood flow is an early event in experimental NSAID-induced mucosal injury, [240] which occurs, in part, by causing neutrophil adherence to the gastric vascular endothelium. This adherence is blocked by exogenous prostaglandin, neutrophil depletion, and antibodies to adhesion molecules, and it is characterized by up-regulation of intercellular adhesion molecule-1 (ICAM-1), an important endothelial adhesion molecule. [241], [242] Neutrophil adherence can also be blocked experimentally by administration of pentoxifylline, an agent that reduces TNF release and subsequent ICAM-1 expression. [243] Cytokines such as IL-1 reduce experimental NSAID injury, presumably by affecting neutrophil function. [244] The somatostatin analog octreotide also appears to have a similar capacity to block neutrophil-endothelial interaction and to reduce NSAID injury. [245], [246] Attention to the role of NO in the maintenance of epithelial integrity has focused on its role in mucosal blood flow. In animal models, inhibition of NO synthesis exacerbates NSAID injury, and NO donors reduce NSAID toxicity. [247] Data have demonstrated that induction of ulceration may be related to inhibition of COX-1 and COX-2 simultaneously. In an animal model, pure inhibition of either COX-1 or COX-2 did not cause damage, but only the combination led to ulceration. [248] Neutrophil adherence appears related to COX-2 inhibition, which also plays a role in regeneration. Furthermore, some studies have suggested that as a consequence of COX inhibition, arachidonic acid metabolism may be shunted toward the lipoxygenase pathway, resulting in increased synthesis of leukotriene B_4, a potent chemotactic agent for neutrophils. [243] Although the topical effects can be largely prevented by administering enteric-coated NSAID formulations or prodrugs, the failure of these agents to reduce the incidence of long-term NSAID-induced ulcers or complications implies that topical injury is not the most important component of NSAID-induced injury. [249] Parenteral administration of the NSAID ketorolac has been demonstrated to cause gastric ulceration, which proves that the systemic action of NSAIDs (in the absence of any direct topical

effects) is sufficient to cause mucosal ulceration. [250] Certain NSAIDs, such as indomethacin, piroxicam, oxaprozin, and ketorolac, may also have indirect topical effects because their entry into enterohepatic circulation results in repeated exposure to the GI mucosa. Increased intestinal concentrations of the active drug by this mechanism may contribute to small intestine and colonic ulcerations, strictures, and perforations, which are also noted with slow-release NSAID preparations such as diclofenac. [251], [252] Strategies to avoid local toxicity have included the use of enteric coating or prodrugs. although enteric-coated aspirin causes less gastroduodenal injury than plain or unbuffered aspirin, it can cause significant gastroduodenal ulceration. [253], [254] and [255] Prodrugs (such as sulindac) that avoid proximal GI absorption produce little acute superficial damage but appear to lack significant protective advantage against risk of upper GI bleeding compared with other NSAIDs. [256] Finally, acid may play an important secondary role for the development of NSAID-related ulceration of the proximal GI tract. The efficacy of high dose H_2 blockers and PPIs for the prevention of NSAID-induced ulcers has provided support for this concept. [257], [258] These agents primarily reduced ulcers, but, unlike misoprostol, they did not reduce the number of erosions, the presumed precursor lesion. This suggests that topical injury initiates the erosive disease induced by NSAIDs, and that acid and prostaglandin depletion are the essential components for the development of clinically important gastric and duodenal ulceration (Fig. 66-9).

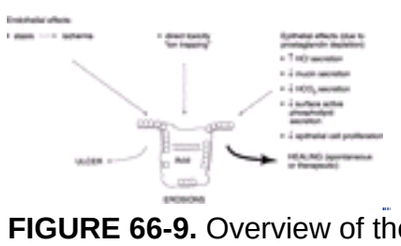

FIGURE 66-9. Overview of the pathogenesis of mucosal damage induced by nonsteroidal antiinflammatory drugs. (Adapted from Scheiman JM, Fendrick AM, Conaway DC. Optimizing outcomes for patients at risk for NSAID-induced ulcer disease. J Clin Outcomes Management 1996;3:23.)

Superficial mucosal lesions. Subepithelial petechiae or hemorrhages and erosions in the fundus may be seen with acute NSAID ingestion within 1 hour of ingesting a single dose of aspirin. Repeated doses of aspirin over a 24-hour period lead to gastric erosions, predominantly in the antrum. [233], [259], [260] If aspirin is continued for several days, the petechiae and erosions become less prominent, a process known as *gastric adaptation.* [261] Despite adaptation, gastric erosions are found at endoscopy in 30% to 50% of patients receiving long-term NSAIDs. [233], [259], [262] There is controversy with regard to the relationship between the presence or severity of superficial mucosal lesions and the subsequent development of clinically significant gastroduodenal ulceration, [263] although the presence of erosions at baseline endoscopic examination has predicted the development of larger endoscopic lesions in at least one study. [264] Scoring systems, devised to grade the severity of these superficial lesions, are useful in clinical investigation but have no utility in the clinical setting. [265] These superficial lesions appear to be caused largely by direct topical effects of the ingested agent and are of little clinical importance. No correlation exists between symptoms of dyspepsia and the number or severity of the lesions, [260], [262] and they are not associated with perforation or serious hemorrhage. [233] Although there may be considerable differences in incidence of superficial injury after short-term administration of enteric-coated or buffered NSAID formulations, these drug modifications have not significantly altered the incidence of chronic gastric ulceration or of NSAID-associated complications. [222], [224], [233] Studies of mucosal injury after acute NSAID administration do not provide uniformly reliable information for predicting the likelihood of clinically significant gastroduodenal injury after long-term administration of any given NSAID. [224]

Ulcers. Long-term NSAID ingestion may cause gastroduodenal ulcerations, but the relative risk appears to depend on the definition of an endoscopically confirmed ulcer, the dose and duration of NSAIDs used, and the characteristics of the patient population. Although the histological definition of an ulcer is a defect that penetrates the muscularis mucosa, endoscopic definitions typically are based on the size of the lesion. [233] The selection of a cutoff size, usually 3 to 5 mm, greatly influences the reported ulcer prevalence; studies that include 3-mm lesions probably include too many erosive lesions as ulcers. [266] Using a 5-mm criterion, the incidence of acute gastric ulcers was 6% to 12% and that of duodenal ulcers was 4% to 8%. [267], [268] It is unclear whether the endoscopically defined ulcers developing acutely during short-term NSAID therapy have the same natural history as do long-term NSAID-induced ulcers. In cross-sectional studies in which endoscopy is performed in medical patients receiving long-term NSAIDs, the prevalence of gastric ulcers ranged from 9% to 31%, and the prevalence of duodenal ulcers was 0% to 19%. [233], [266], [269], [270] The crude prevalence rate of gastric ulcer in long-term NSAID users is about 13%, and that of duodenal ulcer is about 11%; therefore, roughly 25% of patients taking long-term NSAIDs can be expected to have an endoscopically demonstrable gastric or duodenal ulcer. [233], [266] The calculated relative risk compared with that of a healthy population is a 46-fold increase for gastric ulcers and an 8-fold increase for duodenal ulcers. [266] In case control studies that have evaluated the risk of NSAID-induced ulceration relative to a matched control population, the relative risk of gastric ulceration was 4.0 and of duodenal ulceration was 1.7. [233], [271]

Associated symptoms. Dyspeptic symptoms, although extremely common in patients taking NSAIDs, [236], [262], [266], [272] do not reliably differentiate those who have ulceration. [235], [273] In the Aspirin Myocardial Infarction Study, severe dyspepsia was observed in 24% of patients taking aspirin (0.5 g, three times daily) and in 15% of patients given placebo. [274] Dyspepsia is more common in the first few weeks of therapy, and it tends to decline over time, regardless of treatment, [236] but it may be relieved by food, antacids, sucralfate, and antisecretory agents. [225], [275] Symptoms that are unrelieved by H_2 antagonists or lead to cessation of NSAID therapy may indicate underlying ulcers. [256] Patients with NSAID-induced ulcer complications appear less likely to have antecedent symptoms than do other patients with ulcers. [259] Thirty to 40% of patients with significant mucosal ulcerations are asymptomatic; [259], [262], [270], [276] and 60% who develop bleeding are asymptomatic, compared with 25% of asymptomatic bleeding ulcers occurring without NSAID use. [277] In a cross-sectional population study of long-term NSAID users, the positive predictive value of dyspepsia for the presence of an ulcer was only 26%, but the negative predictive value was 93%. [270] Thus, dyspepsia has little discriminatory value in identifying the subsets of long-term NSAID users most likely to have mucosal ulceration or ulcer complications. Dyspeptic symptoms may prompt a diagnostic evaluation or therapy, but the clinically silent ulcer usually remains undiagnosed, untreated, and at risk of complications.

Risk of developing complications. NSAID ingestion is associated with a significantly increased risk of GI complications, as determined by case control and cohort studies in which the frequency of the complication in NSAID users is compared with a matched control group of persons who do not use NSAIDs. [233] In most studies, the risks reported reflect GI bleeding, perforation, surgery, or death. [225] The differences in the reported relative risks may reflect differences in the study population, definition of outcome measures, type and dosage of NSAID, method of ascertaining use of NSAIDs, duration of treatment, and exclusion criteria. [225], [233], [276], [277], [278] and [279] The overall odds ratio of the risk of adverse GI events of all types related to NSAID use appears to be increased approximately threefold to fivefold. [161], [279] The estimation of relative risk may be assessed with prospective studies. The risk of developing an ulcer complication in a group of patients without a previous history of PUD is estimated variably as 5.5 for every 1000 patient-years, [274] or 22 for every 1000 patient-years, or 2% annually. This figure is in accord with observed complication rates of 1% to 3% per year in a Tennessee Medicaid population, of 1.6% per year from the Arthritis, Rheumatism and Aging Medical Information System (ARAMIS) study of patients with rheumatoid arthritis, of 2% to 4% per year from NSAID premarketing investigational new drug studies, and 1.5% in the 4000 subject, 3-year, Aspirin Myocardial Infarction Study. [276] It is estimated that approximately 30% of cases of upper GI bleeding and 29% of ulcer-related deaths are directly attributable to the effects of NSAIDs. [280], [281] and [282]

Risk factors for complications. Most NSAID users derive benefit from these agents and do not develop complications. To optimize clinical management, it would be helpful to predict which patients are at increased risk. Although the factors that predispose patients to complications are not well understood, clinical studies have identified several potentially important risk factors (Table 66-2).

Age > 60 years
Previous ulcer disease or bleeding
Concomitant corticosteroid therapy
High-dose, multiple-NSAID therapy
Chronic major organ impairment, e.g., cardiovascular disease
Concomitant anticoagulant use

*Possible: duration of NSAID therapy, Helicobacter pylori infection, dyspepsia on NSAID therapy, and extent of disability with rheumatoid arthritis. Unclear: cigarette smoking.
NSAID, nonsteroidal antiinflammatory drug.

TABLE 66-2 Risk Factors for Ulcers Induced by Nonsteroidal Antiinflammatory Drugs and Their Complications*

Prior history of peptic ulcer disease or gastrointestinal bleeding. The incidence of NSAID-induced ulcer complications, especially hemorrhages, is as much as 14-fold higher in those with a previous history of GI bleeding or ulcer disease. [161], [225], [276], [282], [283] The risk is highest in the first 1 to 3 months after initiation of NSAID therapy, suggesting that the NSAIDs exacerbate an underlying ulcer condition. [161], [280] Because most prospective, controlled NSAID trials have excluded patients with a known history of ulcer disease or GI bleeding, this high initial risk was not noticed. [225], [274] Extreme caution is advised in using NSAIDs in patients with a history of prior ulcers or ulcer complications, and prophylactic antiulcer therapy is recommended for this group of patients.

Increased risk in the elderly. Advancing age is a strong risk factor for NSAID-associated complications; [233], [276], [281] it is greater than 5 in NSAID users older than 60 years of age, but less than 2 in younger patients. [161] In the prospective Aspirin Myocardial Infarction Study, there was a linear relation in the aspirin-treated group

between ulcer complications and the age of the patient. [233], [274]

Relation to drug dose. The overall risk of NSAID-associated complications is dose related, [256], [279], [280] although complications occur even at low NSAID doses, particularly with aspirin. In the Physician's Health Study, healthy male physicians given aspirin (325 mg/d) had twice the rate of symptomatic duodenal ulcer and a 1.7 times higher rate of GI bleeding than placebo-treated persons, [284] whereas an aspirin dose three times that amount (the Aspirin Myocardial Infarction Study) was associated with an eightfold increased risk of ulcer complications compared with placebo. [274] The Dutch TIA Trial compared 30- and 283-mg doses of aspirin and found some major GI bleeding episodes even at 30 mg. [285] There may not be a truly safe aspirin dose for the GI tract, and the small antithrombotic effect may be offset by bleeding complications. [278] The doses of aspirin associated with hemorrhage are far lower than those generally associated with developing a gastric ulcer. An increased risk of developing GI bleeding is demonstrable within 30 days of initiating NSAID therapy, presumably before most NSAID-induced ulcers would develop de novo. [161] Although the incidence of de novo NSAID-induced gastric ulcers is greater than that of duodenal ulcers, the incidence of bleeding from these two sites is equivalent. [225], [233] These observations suggest that NSAIDs, even in low doses, can potentiate bleeding from preexisting, perhaps *H pylori*–associated, lesions, likely through their ability to reduce platelet function. In a study of consecutive patients admitted with upper or lower GI bleeding, evidence of current overt or covert NSAID ingestion (determined from platelet COX inhibition) was found in 80% of cases, compared with 24% of a matched control population. [229] Peptic ulcers accounted for 42% of upper GI bleeding; 80% of patients with bleeding duodenal ulcers and 100% of those with bleeding gastric ulcers had evidence of NSAID ingestion. NSAIDs were also implicated in 60% of the remaining cases of upper GI bleeding and in 85% of those with lower GI bleeding. [229]

Nonsteroidal antiinflammatory drugs and corticosteroids or anticoagulants. Despite a widespread impression among clinicians that corticosteroids cause peptic ulcers, the results of previous studies evaluating this association have been conflicting. [286], [287] The risk of developing an ulcer is not increased in corticosteroid users who are not taking NSAIDs, [288] and relative risk of complicated PUD in corticosteroid users is increased only in those concurrently taking NSAIDs (2X). [161] Thus, routine use of prophylactic antiulcer medications is not indicated for patients receiving steroid therapy, unless the patients are taking corticosteroids with NSAIDs. [289] The use of NSAIDs in combination with anticoagulants has been demonstrated to increase GI bleeding risk markedly, [290] presumably through exacerbation of bleeding from NSAID-induced lesions. NSAIDs should be used with extreme caution in patients receiving long-term anticoagulants.

Other possible risk factors. Several other factors have been implicated in the potentiation of NSAID-induced GI complications, including the use of tobacco and alcohol, as well as gender. [161] In the Misoprostol Ulcer Complications Outcomes Safety Assessment Trial (MUCOSA), cardiovascular disease was identified as a risk factor for complications. [291] Rheumatoid arthritis appears to be associated with increased risk in several studies. [291], [292] and [293] The observation that NSAID users in the ARAMIS database who had rheumatoid arthritis and who were taking antacids and H *2* blockers were at increased risk of GI complications requires further study, particularly given the observation that these agents have demonstrated efficacy to reduce ulcers. [294] The role of comorbid conditions, such as renal disease or other serious medical illness, requires further study.

Specific drugs and relative frequency of injury. NSAIDs are categorized in several chemical classes, which relate to their absorption, pharmacokinetics, and therapeutic performance, but there is little evidence of substantial differences in clinical efficacy or adverse GI side effects for most nonsalicylate NSAIDs. [256], [279], [295], [296] At equipotent antiinflammatory doses, there remains uncertainty with regard to differences in the frequency of upper GI complications among most users of NSAIDs. [259] However, some patterns have arisen with regard to difference among NSAIDs in clinical practice. In general, the potency and duration of COX-1 isoenzyme inhibition and subsequent depletion of upper GI prostaglandins correlate with development of ulcer disease and complication risk. [225], [295] This has been confirmed by metaanalysis [161] and by large, population-based, retrospective case cohort studies. [279] As shown in Table 66-3, there is considerable overlap in the risk ratios for complications among the various NSAIDs and their confidence intervals, demonstrating significant variations in individual NSAID risk. [296] It remains unclear whether there are truly substantial differences among NSAIDs when they are given at equivalent antiinflammatory doses.

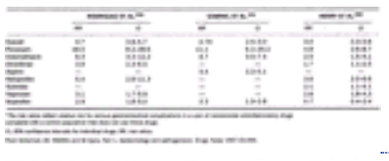

TABLE 66-3 Relative Risk Associated with Different Nonsteroidal Antiinflammatory Drugs*

The nonacetylated NSAIDs, as well as several newer NSAIDs, may be associated with a significantly decreased incidence of ulceration and serious GI side effects. The nonacetylated salicylates (salicylsalicylic acid) such as salsalate and the salicylate salts have minimal inhibition of COX and therefore do not diminish mucosal or systemic prostaglandin levels and do not affect platelet function. [227] In the absence of significant systemic prostaglandin inhibition, it is unclear how the antiinflammatory efficacy of salsalate and aspirin appear to be comparable in patients with rheumatoid arthritis. [297] Salsalate is insoluble in gastric acid, is not absorbed by the gastric mucosa, and produces minimal direct mucosal injury compared with other NSAIDs. [298] When compared with other commonly used NSAIDs, salsalate appeared to produce fewer adverse side effects. [255], [298], [299] Nabumetone and etodolac are purported to have a significantly decreased incidence of ulceration and serious GI side effects. [300], [301] Although these agents can inhibit systemic prostaglandin production, gastric and duodenal prostaglandin production appears to be relatively spared. [300], [302] The explanation for this has not been determined, but it may to be related to the relative selectivity of these agents for COX-2 compared with the COX-1 isoenzyme. These agents may have less inhibition of platelet aggregation, potentially decreasing the likelihood of bleeding complications. [301] In prospective endoscopic trials of patients with arthritis, the incidence of peptic ulceration after 3 months of nabumetone was 2% to 5%, compared with 14% to 25% in patients treated with naproxen or indomethacin. [303], [304] Other short-term endoscopic studies with etodolac also suggest a lower incidence of mucosal injury with these agents than with other NSAIDs. [300], [305] Postmarketing surveillance studies of large cohorts of patients who are taking these agents report an incidence of clinically evident ulcers of less than 1% and of major GI complications of less than 0.1%. [306] It appears from these limited data that these newer NSAIDs may result in a lower incidence of gastroduodenal ulceration and serious GI complications. However, differences in study design preclude a direct comparison with the results of studies of older NSAIDs. Thus, although these agents appear promising, a true determination of their safety will depend on large case control studies that assess ulcer complications in patients taking newer NSAIDs versus those taking older NSAIDs.

Gastrointestinal safety of COX-2–specific inhibitors. Pharmacologists took advantage of subtle differences in the active site of the two forms of COX to develop molecules (celecoxib, rofecoxib) that are highly selective inhibitors of COX-2. As predicted, these drugs, even at very high doses, spare GI prostaglandins. When studied with endoscopy, both celecoxib and rofecoxib produce rates of injury nearly equivalent to those of placebo (Fig. 66-10). [307] Rofecoxib also has been shown to be equivalent to placebo in fecal blood loss and intestinal permeability studies in humans. [308] The ulcer risk associated with celecoxib has been evaluated by endoscopy in patients with osteoarthritis and rheumatoid arthritis in studies lasting 3 to 6 months. In a 3-month study of patients with osteoarthritis and rheumatoid arthritis, celecoxib, 200 mg twice daily, caused fewer endoscopic ulcers than naproxen, 500 twice daily, and ibuprofen, 800 three times daily, but not fewer than diclofenac, 75 mg twice daily. [309] One report compared the incidence of endoscopic ulcers in patients with rheumatoid arthritis who were taking celecoxib, traditional NSAIDs, and placebo. [310] The incidence of upper GI tract ulcers was 4 of 99 (4%) in the placebo group, 9 of 148 (6%) on 100 mg twice daily, 6 of 145 (4%) on 200 mg twice daily, 8 of 130 (8%) on 400 mg twice daily, and 36 of 137 (26%) on naproxen 500 mg twice daily. The ulcer rates with celecoxib were not significantly different from those with placebo, but they were significantly less than those with naproxen.

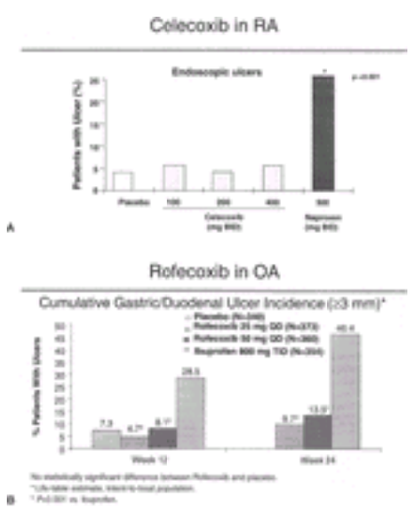

FIGURE 66-10. Incidence of peptic ulcers associated with selective cyclooxygenase-2 inhibitors. (**A**) Celecoxib leads to ulcer formation at a rate comparable to

placebo. (**B**) Rofecoxib is also associated with a rate of ulcer formation comparable to that seen with placebo. (*A,* Adapted from ref. [310]; *B,* adapted from ref. [311].)

Two 6-month, placebo-controlled, endoscopy studies were performed with rofecoxib, 25 and 50 mg, compared with ibuprofen, 800 mg three times daily, with a baseline endoscopy and endoscopies at 6, 12, and 24 weeks. In one study of 742 patients, at 12 weeks, 7.3% of patients receiving placebo developed an endoscopic ulcer compared with 4.7% taking 25 mg of rofecoxib, 8.1% taking 50 mg of rofecoxib, and 28.5% in the ibuprofen group. [56] The incidence of 5-mm lesions was similar in these two studies. In a second study (775 patients) of identical design, similar safety with rofecoxib was observed. When the two studies were combined, the incidence of endoscopic ulcers met predefined criteria for equivalence to placebo. [311] In an analysis of predictors of gastroduodenal ulcer development, the presence of erosions at baseline endoscopy, prior history of ulcer disease, age greater than 65 years, and the presence of *H pylori* were significant risk factors. The rofecoxib clinical trials examined the incidence of clinical ulcers (the so-called perforation, ulcer, and bleed or PUB rate) over 12 months, in more than 5000 patients. The drug was associated with a relative risk reduction of 0.51, [306] representing a PUB rate of 1.33 per 100 patient-years with rofecoxib compared with 2.60 with traditional NSAIDs. Most important, the incidence of clinically significant GI bleeding was also markedly reduced. In an analysis of the celecoxib clinical trials, the annualized incidence of upper GI complications with celecoxib was 0.20% compared with 1.68% with NSAIDs. [312] To confirm long-term safety and clinically important reduction in GI toxicity, both manufacturers performed long-term safety trials with the COX inhibitors. In a trial known by the acronym VIGOR, the safety of rofecoxib, 50 mg, was studied in comparison with naproxen, 500 mg twice daily, in more than 7000 patients treated worldwide over 6 to 12 months. [293] The primary and secondary end points of this study were the occurrence of symptomatic and complicated upper GI events. The results of the trial are shown in Table 66-4. The COX inhibitor was associated with a 50% to 60% reduction in ulcers, bleeding, or both.

TABLE 66-4 Event Rates in the Vioxx Gastrointestinal Outcomes Study (VIGOR)

In the celecoxib outcomes study, known by the acronym CLASS, 8000 patients worldwide with osteoarthritis (90%) and rheumatoid arthritis (10%) were randomized to celecoxib, 400 mg twice daily, ibuprofen, 800 mg three times daily, or diclofenac, 75 mg twice daily, in a study of 12 months' duration; an analysis of the first 6 months was published. [313] In this trial, the primary end point was also the development of complicated upper GI events. The secondary end point was the development of symptomatic plus complicated ulcers. Although the primary end point in all patients was not met in the CLASS trial (Table 66-5a), it was likely because of the inclusion of low-dose aspirin (Table 66-5b). A complete analysis of the entire 12 months of trial failed to show efficacy or safety of celecoxib compared with diclofenac, likely because of high dropout rates in the trial. [314] Despite the study design limitations, this work (see Table 66-5) suggests that the impressive GI safety of COX-2–specific inhibitors could be significantly impaired by the concomitant use of low-dose aspirin. Further studies to address this question are ongoing.

TABLE 66-5A Celecoxib Gastrointestinal Outcomes Study (CLASS): All Patients (Rates per 100 Patient-Years; 6-Month Data)

TABLE 66-5B Celecoxib Gastrointestinal Outcomes Study: Non-aspirin Users (Rates per 100 Patient-Years; 6-Month Data)

Extended scope of drug-induced complications. The GI complications of NSAIDs include a variety of lesions throughout the GI tract. [314], [315] and [316] Small bowel ulcerations have been identified at surgery, radiographically, and by enteroscopy. [316], [317] In a postmortem study, small bowel ulceration was found in 8% of NSAID users, compared with 0.6% of nonusers. [317] These ulcerations may be associated with occult GI blood loss and an increased risk of small bowel perforation. [317] NSAIDs also are associated with the development of weblike small bowel and colonic strictures that may produce clinically significant lumenal narrowing. In the colon, NSAIDs have been associated with the precipitation of relapses of established inflammatory bowel disease, and the development of acute colitis, strictures, and perforations. [318], [319] Whether COX-2–specific inhibitors have a reduced risk of intestinal complications is uncertain and requires further study. [314]

Summary of drug-induced complications. NSAIDs can cause acute and chronic gastroduodenal injury. The acute topical injury seen is dose dependent, varies with different NSAID formulations, declines with continued NSAID administration, is unrelated to symptoms, is not predictive of the development of chronic gastroduodenal ulceration or complications, and is of little clinical significance in most patients. Gastric or duodenal ulcers develop in approximately 25% of long-term NSAID users. In histologically normal mucosa or in mucosa inflamed because of infection with *H pylori,* NSAIDs may cause ulcers de novo or may exacerbate an underlying ulcer diathesis, but it remains unclear whether *H pylori* infection predisposes to NSAID-induced ulceration. The presence or absence of symptoms is of limited clinical utility in predicting which patients have ulceration or will have complications. Dyspepsia tends to decline with time and is relieved by antisecretory agents in most patients. Complications such as hemorrhage, perforation, and death occur in approximately 2% of long-term NSAID users per year. As many as 60% of complications may occur in asymptomatic patients, and these problems are more common in the elderly, in patients with prior peptic disease or ulcer complications, and in those receiving higher NSAID doses and concomitant corticosteroids. Complications arise from NSAID-induced ulcers and from exacerbations of preexisting (*H pylori*–related) ulcer disease. GI hemorrhage is potentiated by NSAID-induced platelet dysfunction. [320] Although COX-2 inhibitors have a favorable safety profile regarding GI toxicity, some reports have aroused concern regarding the potential prothrombotic and cardiovascular toxicity of these agents. [321]

Smoking and Peptic Ulcer Disease

Epidemiology and natural history. Although a large body of evidence demonstrates that cigarette smokers are at an increased (twofold) risk of developing ulcer disease with its related complications and, in addition, tend to have impaired ulcer healing rates. [322], [323], [324], [325], [326] and [327] This association was placed in doubt by Aldoori and associates. [328] In a prospective cohort of 47,806 men (40 to 75 years old), these investigators observed that neither current nor past smokers were at increased risk of development of a duodenal ulcer. The reason for this discrepancy may be the method of screening patients by questionnaire, which could be rather insensitive. Using metaanalysis of English-language papers, Kurata and Nogawa [329] examined the risk ratios for several factors, including cigarette smoking, and found that the attributable risk for cigarette smoking and peptic ulcer–related GI events was 23%. Cigarette smoking and *H pylori* are cofactors for peptic ulcer formation. [329] Svanes and colleagues [330] observed a tenfold increased risk of perforation in smokers, with a significant dose response relationship. An endoscopic study in patients with rheumatoid arthritis who were taking NSAIDs revealed that 63% of patients with gastric ulcers smoked, but only 33% without ulcers smoked. [330] This suggests that smoking and NSAID intake may be independent or additive risk factors for PUD.

Pathophysiological mechanisms. Despite the clear association between cigarette smoking and PUD, the pathophysiological basis for this association is not established. Smoking does not appear to have a consistent effect on gastric acid or pepsin secretion, [331] but it does appear to decrease the effectiveness of histamine H_2-receptor antagonists in duodenal ulcer healing. [332], [333] and [334] Cigarette smoking may increase the risk for infection with *H pylori,* especially in African Americans, [335], [336], [337] and [338] and it may potentiate the injurious effect of this pathogen on the gastric mucosa. [339] Additional factors that lead to mucosal injury and appear to be increased by smoking include free oxygen radicals, platelet-activating factor, pituitary vasopressin, gastric endothelin, and pituitary vasopressin. [331] Altered gastric motility has also been associated with smoking, with concomitant relaxation of the pylorus and reflux of duodenal contents into the stomach. [340], [341] Finally, smoking may also alter processes important in gastric and duodenal mucosal integrity or protection such as prostaglandin content, mucosal blood flow, or epidermal growth factor. [331]

Diseases Associated with Peptic Ulcer Disease Epidemiologic evidence demonstrates that duodenal ulcers occur more commonly in patients with certain chronic illnesses. However, studies reporting these associations did not consider *H pylori* status in the patients evaluated. Table 66-6 lists diseases associated with duodenal ulcer. The pathophysiological mechanisms by which some of these disorders increase peptic disorders are not clear.

Evidence Strongly Supports an Association
Zollinger-Ellison syndrome (gastrinoma)
Systemic mastocytosis
Multiple endocrine neoplasia type I
Chronic pulmonary diseases
Chronic renal failure
Hepatic cirrhosis
Kidney stones
α-antitrypsin deficiency
Evidence Only Suggests an Association
Crohn's disease
Hyperparathyroidism without multiple endocrine neoplasia type I
Coronary artery disease
Polycythemia vera
Chronic pancreatitis
Cystic fibrosis

Data from references: 361 to 373.

TABLE 66-6 Diseases Associated with Duodenal Ulcer

Role of Psychological Factors The role of psychological factors in the pathogenesis and natural history of PUD has been the subject of numerous studies, with conflicting conclusions. Early unblinded studies described certain personality characteristics thought to be markers for ulcer risk, including conflicts about dependency needs, hypochondriasis, and low ego strength. [342], [343], [344], [345] and [346] However, studies of patients in whom the diagnosis of duodenal ulcer disease was established endoscopically and with adequate controls (at least 50 persons in each study arm) concluded that several emotional factors (e.g., anger, anxiety, unhappiness, emotional control, hostility) were not different between patients with duodenal ulcer and well persons. [344], [345] Furthermore, even if personality traits are overrepresented in patients with PUD (e.g., neuroticism), it must be shown that neuroticism is a consequence of PUD and not a causal factor, and that these traits should be considered a manifestation of coping with the illness. Adami and colleagues [345] assessed the relationship between subject-perceived stress and the development of peptic ulcer in about 4500 adults in the United States. At baseline, 68% perceived themselves as stressed. Over the 13-year follow-up, 208 developed ulcers: 7% of those in the stressed group and 4% of the nonstressed group. The investigators observed that the relative risk increased from 1.4 to 2.9 with increasing degrees of stress. The pathophysiological factors underlying psychological stress and the development of ulcer disease warrant further investigation.

Other Factors Associated with Peptic Ulcer Disease

Alcohol. The data supporting a role for alcohol in the pathogenesis of PUD are quite limited. Alcohol is an agent commonly used to induce gastric mucosal damage in experimental animals, [347] but in these models, alcohol is often administered as absolute ethanol (i.e., pure ethanol, or 200 proof), which is hypertonic and lipid soluble and traverses the gastric mucosa promptly, resulting in frank acute mucosal damage. [347] Therefore, the practical implications of this model are nonexistent. In fact, mucosal injury does not occur at all in humans at ethanol concentrations of less than 10% (20 proof). [348] At concentrations of 20% (40 proof) and greater, the transmucosal gastric potential difference decreases, and endoscopic evidence of acute injury is observed. Because of prompt epithelial restitution, it is unlikely that these acute and transient mucosal changes result in chronic mucosal damage. Retrospective analysis of alcohol intake in patients with ulcer disease revealed that those who consumed modest amounts of alcohol had a decreased prevalence of ulcer disease compared with nondrinkers. [349]

Diet. Despite the observation that some types of foods and beverages are reported to cause dyspepsia, there are no convincing data indicating that any specific diet causes ulcers. Highly spiced foods are often reported to result in indigestion or dyspepsia by unknown mechanisms. Duodenal ulcer is more common in the south of India, an area of rice-eating, low-fiber diets, than in the northern part, a wheat-eating area; [350] again, the cause is unknown. Both decaffeinated and caffeinated beverages (e.g., tea, coffee) are potent stimulants of gastric acid secretion, [351], [352] as are cola-type beverages, beer, and milk. [351] However, epidemiologic studies have failed to reveal an increased risk of ulcer disease in persons who consume these beverages. Although bland meals and the frequent ingestion of milk were commonplace in ulcer treatment in the early 1900s, they neither expedite ulcer healing nor prevent recurrences or complications. In fact, they stimulate greater amounts of gastric acid secretion than three regular daily meals. Dietary alterations, other than instructions to avoid pain-causing foods, are unnecessary for patients with ulcers.

Miscellaneous factors. Peptic ulcer appears to have some seasonal variations; for example, duodenal ulcers occur more frequently in January and February than during the rest of the year. [353] Regional differences exist: ulcer perforation is greater in Scotland than in England, and the incidence of duodenal ulcer is significantly less in northern India than in southern India. [10] These geographic differences are not fully understood. PUD, especially gastric ulcer, seems to be somewhat more common in persons of lower economic status, [354] possibly related to a higher incidence of *H pylori* in this population. The mortality rate for ulcer disease is greater in nonwhites younger than 65 years of age. The differences, however, are minor in elderly persons, in whom the rates for races tend to equalize.

CLINICAL MANIFESTATIONS

Abdominal Pain

Abdominal pain is the most common symptom, leading a patient to seek medical attention for a perceived peptic ulcer. On careful questioning, most patients with PUD report abdominal pain, but epigastric discomfort is more commonly associated with diseases other than an ulcer. [353] Esophageal, cardiac, biliary, pancreatic, and intestinal disorders may cause epigastric distress and often produce pain that is localized to the epigastrium, mimicking ulcer pain. The sensitivity (i.e., symptom-positive and disease-positive) and the specificity (i.e., symptom-negative and disease-negative) of abdominal pain as a marker for ulcer disease are low. In a large survey of patients in a dyspepsia clinic, abdominal pain occurred in 94% of patients with ulcers, but it was also present in 82% of the larger group of patients without ulcer disease. [354] The diagnosis and management of nonulcer dyspepsia are discussed in Chapter 30.

Abdominal pain in ulcer disease is classically described as having a burning quality, localized to the epigastrium, nonradiating, occurring 2 to 3 hours after a meal or at night, and relieved by food or antacids. The most discriminating symptom is the presence of pain that awakens the patient from sleep (especially between 12 and 3 AM), [355] which is present in approximately two thirds of patients with duodenal ulcer and one third of patients with gastric ulcers. Unfortunately, it is also present in about one third of patients with nonulcer dyspepsia, which is at least twice as common as ulcer disease. [81] In the United States, fewer than 30% of patients with dyspepsia who undergo upper GI endoscopic examination have ulcer disease. [356] However, of those with classic ulcer dyspepsia, 40% have an ulcer crater, and 40% have endoscopic gastroduodenitis without an ulcer crater. This observation suggests that careful questioning may slightly improve diagnostic accuracy. [356] Although abdominal pain is the major presenting symptom of an ulcer, it is not possible to diagnose this entity with any significant degree of accuracy based on symptoms alone. However, some clinical clues may suggest ulcer disease: prior documented ulcer, nocturnal pain, family history of ulcer, and the intake of antacids or antiulcer drugs that result in pain relief. [354]

Approximately 10% of patients with PUD, particularly those with NSAID-associated ulcers, present with complications (e.g., hemorrhage, perforation) without an antecedent history of ulcer pain. Either they are insensitive to pain or ulcers can be present without producing pain.

Mechanisms of Abdominal Pain The genesis of abdominal pain in patients with ulcer disease is undefined. In a blinded, prospective study, no consistent association was found between pH of gastric infusate and production of pain in patients with active duodenal ulcer. [357] In an unblinded study, direct duodenal infusions of hydrochloric acid tended to induce pain in patients with duodenitis and duodenal ulcer. [358] Infusion of acid caused pain in only 40% of patients with active symptomatic duodenal ulcers, but a placebo-saline infusion resulted in ulcer-type pain in 10%. Other factors, such as pepsin, bile acids, and motility events, possibly could contribute to ulcer-type pain.

Pain Relief Pain of any type is very responsive to placebo therapy. In all clinical trials of therapy for peptic ulcer, abdominal pain resolved promptly in patients treated with placebo or an active drug. [359] Nonetheless, most studies suggest that active treatment with antacids, H_2-receptor antagonists, or omeprazole is somewhat superior to placebo. Furthermore, the proportion of patients (~30%) who have nonhealed ulcers and are symptom free equals the proportion who have healed ulcers but who continue to have ulcer symptoms. [356], [360]

Ulcer Complications

Complications of PUD include hemorrhage, perforation, penetration, and obstruction. Intractability, previously considered a complication of ulcer disease, has become exceedingly rare subsequent to the development of more effective antiulcer drugs (e.g., H^+,K^+-ATPase inhibitors).

Hemorrhage *Hemorrhage,* the most common complication of ulcer disease, occurs in approximately 15% of patients. [361] It tends to be more common in patients during the sixth decade of life and beyond, largely because of the increased use of NSAIDs in this age group. [362], [363] Approximately 10% to 20% of patients bleed from a gastric or duodenal ulcer without any antecedent symptoms. Approximately one third of patients treated with H_2-receptor antagonists have recurrent hemorrhage. [361] Studies suggest that eradication of *H pylori* prevents duodenal ulcer and non-NSAID gastric ulcer recurrences and may prevent recurrent hemorrhage. The diagnosis and management of GI hemorrhage are discussed in Chapter 33, Chapter 34, Chapter 70, and Chapter 148.

Perforation Ulcer-related *perforation* is less common than hemorrhage but more common than obstruction, occurring in approximately 7% of patients with PUD.

Duodenal ulcers tend to perforate anteriorly, and gastric ulcers tend to perforate along the anterior wall of the lesser curvature of the stomach. With the increased use of NSAIDs, the incidence of perforation is increasing, particularly in women more than 60 years of age.
Penetration *Penetration* is similar pathologically to perforation, except the ulcer crater burrows through the entire wall of the intestine, and instead of leaking digestive contents into the peritoneal cavity, the crater bores into an adjacent organ. Gastric ulcers most commonly penetrate into the left lobe of the liver, whereas duodenal ulcers penetrate posteriorly into the adjacent pancreas, sometimes leading to pancreatitis. Rarely, gastric ulcers may penetrate into the colon, resulting in a gastrocolic fistula.
Gastric Outlet Obstruction *Gastric outlet obstruction,* also referred to as gastric retention or pyloric stenosis, can result from functional impairment of antral motility caused by the effects of acute inflammation and edema or from mechanical obstruction caused by scarring near the gastroduodenal junction. The former tends to resolve with medical treatment, and the latter usually requires surgical or endoscopic (i.e., balloon dilation) intervention. The prevalence of gastric retention is approximately 2% in patients with PUD. The symptoms of gastric outlet obstruction tend to be insidious and can manifest as gastroesophageal reflux, early satiety, weight loss, abdominal pain, and vomiting. As the degree of retention increases, the quantity of vomitus also increases, often containing food ingested 12 or more hours previously.

Differential Diagnosis

Nonulcer Dyspepsia *Nonulcer dyspepsia,* which is abdominal pain or discomfort that occurs in the upper abdomen without the presence of an ulcer, is a major complaint that affects about 15% of the population annually, most of whom do not seek medical care. [364], [365], [366], [367], [368] and [369] In the United States, more than 2 million people seek outpatient evaluations each year for dyspepsia. For a detailed review of this entity, see Chapter 30.
Other Gastrointestinal Diseases GI diseases that mimic PUD include upper GI neoplasms (i.e., gastric and pancreatic cancer), mesenteric ischemia, which is sometimes referred to as abdominal angina, and pancreatitis or cholecystitis. Gastric or duodenal involvement with Crohn's disease or with typical and atypical strains of *Mycobacterium tuberculosis* can produce gastric retention and ulcer-type symptoms.

DIAGNOSTIC STUDIES

History and physical examination are not reliable tools for establishing a diagnosis of PUD; documentation of true ulcer disease depends on the use of radiographic or endoscopic methods. The high cost of endoscopic and radiographic procedures have led to attempts at developing a surrogate marker for ulcer diagnosis, such as the response to an empiric trial with antisecretory agents or the evaluation of *H pylori* status with serologic markers. The following section reviews the different diagnostic modalities that assist the clinician in assessing a patient with signs or symptoms of PUD.

Treat-First Strategies

A major tenet of the practice of medicine—establishing the precise diagnosis so specific therapy can be prescribed—has been questioned for patients with dyspepsia. [370], [371] Most physicians prescribe highly effective antiulcer drugs without further investigation, and it is unusual in today's environment to encounter a patient with untreated dyspepsia. This approach has been endorsed in a policy statement by the American College of Physicians. [370] This policy of "treat first" is appropriate for the patient younger than 45 to 50 years of age with mild and intermittent epigastric symptoms and no other systemic symptoms or evidence of ulcer complications. However, the therapeutic response should be evaluated to ensure prompt symptomatic relief and the absence of recurrence after therapy has been discontinued. For patients older than approximately 50 years of age, those in whom symptoms have been of long duration, those with systemic symptoms (e.g., anorexia, weight loss, back pain), or those in whom there is any suggestion of an occult malignant disease or another disease process (e.g., pancreatic or biliary tract disease), a specific diagnosis should be established.

Endoscopy and Radiography

The diagnostic procedure to be used depends, in large part, on the skill and experience of available personnel. In a center with superb GI radiography, this may be a reasonable first course to pursue. However, because of its superior sensitivity and specificity for significant organic disease and the ability to obtain biopsies, endoscopy is the preferred diagnostic test in most cases. There is no justification for the routine use of one procedure followed by the other. When a lesion such as a gastric ulcer has been observed radiographically, however, endoscopy with biopsy may be warranted. Conversely, there can be endoscopic lesions, such as extrinsic displacement of the stomach or duodenum, that require radiographic studies. Therefore, these two procedures may be complementary in specific circumstances.

Traditionally, endoscopy with biopsies was considered the standard of practice in patients with gastric ulcer. However, with the increased intake of NSAIDs, the finding of a clearly benign-appearing gastric ulcer on the radiograph in a 40-year-old patient with a history of recent NSAID intake does not necessarily warrant endoscopic examination with biopsies. However, all gastric ulcers should be observed until complete endoscopic healing because of the potential of an occult malignant disease. [372], [373]

Cost comparisons are complicated. Overall, the acquisition cost for routine upper GI endoscopy is approximately three to four times greater than the cost for upper GI radiography. Gastric biopsies for *H pylori* add further endoscopic and laboratory costs. Some endoscopists consider current professional fees to be excessive, and this has led to the proposal of a "screening endoscopy" at a cost similar to that of radiography. [374] Regrettably, this has not become generally accepted. It is likely that, with the changes in health care delivery, the costs for endoscopy will decrease substantially. Additional cost-benefit studies are needed in patients with acid peptic symptoms. The goals of any diagnostic test are to be sensitive and specific and to have high diagnostic accuracy. Although studies comparing air-contrast barium meals performed by expert GI radiologists with endoscopy reveal equal accuracy in the diagnosis of an ulcer, [375] extrapolation of these studies to the clinical practice is not warranted because the radiography and endoscopy studies were performed by experts. Such reports are often biased in favor of endoscopy because this test is commonly used as the standard. For example, lesions found on x-ray films but not observed endoscopically are assumed to be radiographic false-positive results, although they may represent endoscopic false-negative results (i.e., the ulcer was missed at endoscopy). With modern wide-angle endoscopic television chip and endoscopic instruments, visualization of the stomach and duodenum should be complete in almost all patients. Nonetheless, as many as 10% of duodenal ulcers have been missed by endoscopy. [376], [377] Postbulbar duodenal ulcer disease may be missed by the endoscopist, but these lesions can be seen with the use of longer endoscopes. Patient risk with endoscopy, although minimal, is greater than that associated with radiography.

Although there is generally good agreement between the diagnostic results of endoscopy and those of a double-contrast barium meal for gastric ulcers when each test is performed by skilled personnel, there are fewer radiologists skilled at contrast studies, and radiography does not permit biopsies or cytologic brushings of the lesion to determine whether a gastric ulcer represents an ulcerating carcinoma. [378], [379] Therefore, radiography has largely become obsolete in the evaluation of gastric ulcers. This modality is most useful for examining gastric and duodenal distensibility or for the presence of extrinsic compression.

Diagnosis of *Helicobacter pylori*

Endoscopic Tests From a pragmatic standpoint, the first decision regarding the choice of diagnostic testing for *H pylori* revolves around the need for endoscopy. It is also important to consider whether a test will be performed before (pretreatment test) or after the completion of treatment (posttreatment test). At the time of endoscopy, specific findings, such as a duodenal ulcer, are highly predictive of *H pylori* infection. Antral nodularity is also a specific, but insensitive, marker of *H pylori* infection. The critical role of endoscopy for the diagnosis of *H pylori* therefore is to obtain gastric mucosal biopsies that are used for both *direct tests* (culture and histology) and *indirect tests* (urease testing). The biopsy-based tests are dependent on the actual bacterial load and identify only patients with active *H pylori* infection. Medications that affect the density or viability of *H pylori* organisms within the stomach decrease the sensitivity of these tests by increasing the possibility of sampling error. For this reason, bismuth compounds and antibiotics should be withheld for 4 weeks, and PPIs should be withheld for 1 to 2 weeks before endoscopic *H pylori* testing.
Culture. At the current time, the importance of culture, a direct test, is more historic than practical. Although some laboratories achieve sensitivities of more than 95% for culture, other methods for the diagnosis of *H pylori* infection are less costly, simpler, and prone to less variability or error, and they provide results more rapidly. Culture, however, has the advantage of allowing for the determination of antibiotic sensitivity. Culture may also be of importance in research. Saline is a simple acceptable short-term (<6 hours) transport medium, whereas refrigerated Stuart medium or glycerol-containing media will be more appropriate if culture will be delayed. [380], [381] Glycerol-containing media are also suitable for long-term storage of biopsy specimens at -70°C. [381] Various selective and nonselective media are suitable for culture, such as brain-heart infusion agar plates with other supplements and media used for *Campylobacter.* Attempted culture on more than one medium may be helpful to increase sensitivity. In general, culture incubation is performed under microaerophilic conditions at 37°C, with positive cultures usually detected after 3 to 5 days. Identification of *H pylori* is made on the basis of colony morphology (approximately 3-mm translucent colonies) that contain gram-negative, curved rods that test positive for urease, catalase, and oxidase.

Histological assessment. The standard for the diagnosis of *H pylori* is the detection of the organism on gastric biopsies that have been processed using a variety of histological stains (see Chapter 68). The distribution of *H pylori* in the stomach is not uniform, nor are organisms usually found in areas of intestinal metaplasia. [382] Therefore, normal gastric mucosa should be sampled to minimize sampling error, and to help with interpretation of the specimen, jumbo biopsy forceps are recommended, although the effect of biopsy size on the sensitivity of histology has not been studied. Multiple biopsies should be obtained to achieve close to 100% sensitivity and specificity. The use of special stains is outlined in Chapter 68.

Rapid urease tests. Developed by Marshall, the CLOtest (Ballard Medical Products, Draper, UT) was the first of the commercially available biopsy urease tests designed specifically for *H pylori* detection. It is an indirect test for the presence of *H pylori. H pylori* urease hydrolyzes the urea contained in the agar gel of the test packet and leads to production of ammonia, a pH rise, and a color change of the phenol red indicator. The test is interpreted up to 24 hours after insertion of the gastric biopsy sample into the well containing the agar gel. The overall sensitivity of the test in the pretreatment setting is approximately 90%. However, sensitivity seems to vary from one study to another, even within the same institution, [383], [384] because of the use of different standards for the diagnosis of *H pylori,* the subjective nature of test interpretation, different biopsy sizes or number in different studies, or different protocols employed in the incubation of the biopsy. Two studies found that the sensitivity of the CLOtest at 24 hours was equivalent for different biopsy sizes, [384], [385] but in one of the studies, the CLOtest became positive more quickly with a larger biopsy size. Although warming also hastened the time to a positive result, no significant difference at 24 hours was noted between warmed and room temperature testing. [383] In addition, the sensitivity of the CLOtest is not affected by preimmersion of biopsy forceps in formalin. [386] Specificity of the CLOtest is uniformly excellent (95% to 100%), but when read at 24 hours, false-positive results may be infrequently encountered. Another gel test, Hpfast (GI Supply, Comphill, PA), is similar to the CLOtest, but it uses a different pH indicator. Hpfast also is interpreted up to 24 hours. PyloriTek (Horizons International Corp., Ponce, Puerto Rico) is a strip test. In the presence of urease, ammonia is produced from urea impregnated into a reaction strip. An overlying pH indicator detects the diffusion of ammonia through a membrane. A potential advantage of this test is that interpretation may be performed only 1 hour after tissue inoculation. Simultaneous studies of the three tests have been performed, and the results have been comparable. [387], [388] Another rapid urease test that provides an answer in 1 hour and requires no incubation or reagents (Pronto Dry [Endo-Surg Medical Inc., Columbia, TN]) is now available. In addition, it is anticipated that faster versions of the CLOtest and Hpfast will become available in the near future. As such, the choice of test should be based on factors such as cost, availability, or physician preferences. Rapid urease tests have been reported by some to be falsely negative in the setting of ulcer bleeding. [389], [390] and [391] Studies suggest that a mixture of blood and gastric and duodenal contents including bile may render the test falsely negative. [392] Conversely, false-positive results do not occur with increased frequency in the setting of acute ulcer bleeding. To maximize the yield of biopsy-based testing in patients with acute ulcer bleeding, the clinician should obtain tissue samples from the gastric body and antrum for rapid urease testing and histology. Some have advocated banking biopsies in formalin for histology and sending them for assessment only if the rapid urease test is negative. Unfortunately, this practice is difficult to implement in the clinical setting. An alternative strategy is to perform a rapid urease test and, if negative, to obtain a nonendoscopic test, such as serology, urea breath test, or stool antigen, to confirm the presence or absence of infection.

Polymerase chain reaction. PCR assays, which have been shown to be sensitive and specific, have been developed for the detection of *H pylori* in gastric mucosal biopsies. However, the diverse genetic organization of *H pylori* may affect the sensitivity of the assay. Uncertainty also exists about the specificity of some of the primer molecules used in PCR. Moreover, specimen preparation and conditions during PCR are not necessarily standardized among different laboratories, and successful detection of *H pylori* may require an uncertain minimum bacterial load. Currently, PCR assays should be restricted to the research setting for identification of different *H pylori* strains.

Nonendoscopic Tests

Antibody test. Many commercially available serologic tests that detect the presence of anti– *H pylori* IgG antibodies have received FDA approval, which ensures some likelihood of quality control and more uniform results across a spectrum of patients from different regions and demographic backgrounds of the United States. Despite FDA approval, however, the performance characteristics of the tests may vary widely. [393] Availability, cost, and ease of use may influence the choice of test. In general, in the United States, only FDA-approved tests detecting anti– *H pylori* IgG antibody should be used. Unfortunately, because there is no widely agreed on minimum standard for performance, even FDA-approved serologic tests are not necessarily consistently highly accurate. Individual reports of serologic antibody tests may suggest accuracies of approximately 95%, but these results may be misleading. Indeterminate results, the gray zone, may be excluded, or considered positive or negative at the discretion of investigators. [394] A metaanalysis of studies of 11 commercial enzyme-linked immunoadsorbent assay kits and one latex agglutination kit found an average sensitivity of 85% and specificity of 79%. [395] Thus, antibody tests both underdiagnose (false-negative results) and overdiagnose (false-positive results) *H pylori* infection with some frequency. In addition, the pretest probability of infection should be considered when using antibody tests as a screening tool. Patients with a high probability of having *H pylori* infection (e.g., patients with PUD) who have negative serologic tests deserve further evaluation. If the likelihood of infection is low, the predictive value of a positive test is low, and the test may need confirmation. Conversely, a negative test predicts a low probability of infection in patients who have a low likelihood of infection, and further evaluation for infection is unnecessary. Despite the foregoing commentary, antibody testing offers numerous advantages: it is noninvasive, relatively inexpensive, and avoids some of the pitfalls inherent to methods that identify patients with active infection such as the urea breath test or stool antigen test. The active tests depend on and reflect the current bacterial load and may be falsely negative because of temporary suppression of *H pylori* infection by ingested bismuth compounds, PPIs, or antibiotics. These medications do not cause false-negative serologic test results. However, there may be a small, transient fall in antibody titer even after failed antibiotic treatment of *H pylori,* presumably reflecting the decreased bacterial load. The fall in titer, however, is insufficient to lead to a negative result. In addition to the previously described limitations of antibody testing, patients with gastric atrophy, but no ulcers, may have false-positive results because of serologic evidence of prior *H pylori* infection that has spontaneously resolved. [396] Conversely, the serologic test may be more sensitive than the standards against which it is being evaluated, especially if the bacterial load is small. Although this may be true on occasion, [397] this seems unlikely in most discrepant cases, especially in studies including a large battery of different diagnostic tests. In addition, a few patients with *H pylori* infection who are treated with antibiotics for unrelated indications (e.g., bronchitis, pharyngitis, urinary tract infection) will experience successful cure of their infection. For example, clarithromycin used alone can lead to cure of *H pylori* infection in as many as 30% to 40%. Such patients will have a true-positive antibody test result (the test detects *H pylori* antibody) but no active *H pylori* infection. Given the widespread and often indiscriminate use of antibiotics, this phenomenon is likely to erode the utility of antibody testing further, particularly in countries where the prevalence of active *H pylori* infection is falling or is already low. [398] In addition to laboratory antibody tests, rapid qualitative antibody tests (in-office or near-patient tests) using either serum or fingerstick whole blood are commercially available. They are inexpensive (<$15), results are available in 5 to 15 minutes, and they are simple to use. Unfortunately, published reports suggest that the current generation of whole-blood tests may be less accurate than some laboratory-based tests. [399], [400] It is possible that newer whole-blood tests will offer greater accuracy than the currently available tests. [401] The office-based tests are only qualitative, precluding their use for early follow-up testing for assessment of cure after anti– *H pylori* treatment. Other antibody tests using saliva have not proven to be as accurate as those using serum or whole blood. [402] Numerous urine antibody tests for *H pylori* have been reported and may yield results comparable to those of traditional serologic testing. [403] At this time, saliva- and urine-based tests are not commercially available in the United States.

Breath and stool tests

Nonendoscopic urease tests. The ^{13}C and ^{14}C urea breath and blood tests identify only actively infected patients through *H pylori's* urease activity. Patients ingest ^{13}C- or ^{14}C-labeled urea. If *H pylori* is present in the stomach, urease hydrolyzes the labeled urea and releases labeled HCO_3^-, which is transported by the bloodstream to the lungs and is exhaled as labeled carbon dioxide. Breath or blood is collected, and either the radioactive ^{14}C isotope is detected using a scintillation counter or mass spectrometry or infrared spectroscopy is used to detect nonradioactive ^{13}C. [404], [405] Because oral organisms also hydrolyze urea, an early peak in labeled carbon dioxide may occur during the ^{13}C breath test because the urea is presented in liquid form. However, in practice, this is inconsequential, because breath samples are collected 15 to 30 minutes after urea ingestion. The ^{14}C test uses a capsule containing labeled urea. Because the solid form of the label minimizes any possibility of hydrolysis by oral bacteria, breath is collected after only 10 minutes. The normal background concentration of ^{13}C necessitates collection of a baseline breath sample to which subsequent samples are compared. In contrast, because there is almost no background concentration of ^{14}C, there is no need for a basal breath sample, and a very small dose of radioactive ^{14}C urea need be used. [406] Overall, the performance characteristics of both the ^{13}C and ^{14}C tests are similar. False-negative results can occur in patients taking certain drugs, such as PPIs, bismuth compounds, or antibiotics, that decrease the density of *H pylori* organisms or its metabolic activity. [407] There is also some evidence to suggest that H_2-receptor antagonists can rarely induce false-negative results of nonendoscopic urease tests. [408] For nonendoscopic urease tests to be reliable, acid-suppressive medications should be withheld for 1 to 2 weeks before testing. [409], [410] The minimum time interval required for a reliable breath test after the last dose of an incidentally prescribed bismuth compound or antibiotics has not been studied, but a period of 2 to 4 weeks appears to be adequate. [411] The choice of test (^{13}C versus ^{14}C) depends on availability, cost, and regulatory issues. The ^{13}C test is preferred for children and pregnant women. The ^{13}C and ^{14}C urea breath tests and ^{13}C urea blood test have been approved by the FDA.

Fecal antigen test. A test that identifies *H pylori* antigens in stool has become commercially available. The fecal antigen test uses polyclonal anti– *H pylori* capture antibody adsorbed to microwells. Diluted stool and a peroxidase conjugated polyclonal antibody are added, followed by substrate 1 hour later. In infected patients, enzyme-substrate binding leads to a color change, which can be detected visually or spectrophotometrically. After collection, stool samples can be stored at 2 to 8°C for 3 days and at -20°C indefinitely. Studies have reported sensitivity and specificity for the fecal antigen test of more than 90% in patients not previously treated for *H pylori* infection. [412], [413] Like the nonendoscopic urease tests, the stool antigen test identifies patients with active *H pylori* infection. Preliminary studies suggest that the stool antigen test may be useful as a means of establishing cure after antimicrobial therapy. [414] The sensitivity of the stool test is decreased by the recent use of antibiotics, bismuth, or PPIs, although to a lesser degree than the nonendoscopic urease tests. [415] The fecal antigen test is more accurate than antibody testing and is less costly than the nonendoscopic urease tests. Issues that have slowed the widespread use of this test include the inherent unpleasantness associated with the handling and storing of stool, limited availability, and highly variable state-to-state reimbursement. The fecal antigen test has been approved by the FDA.

Use of *Helicobacter pylori* Test for Initial Diagnosis

Should Helicobacter pylori status be determined in all patients with duodenal ulcer? Early reports indicated that *H pylori* could be identified in approximately 90% of patients with duodenal ulcers and in 70% of patients with gastric ulcers. However, studies in the United States suggest that the prevalence of *H pylori* infection in patients with ulcer disease may be 60%. [416], [417] Moreover, the prevalence of *H pylori* in bleeding ulcers is known to be lower than in uncomplicated ulcers. Because a substantial minority of patients (=40%) with ulcer disease do not have *H pylori* infection, testing to establish the presence of infection should be performed in all patients with an ulcer before the initiation of antibiotic therapy. The method of assessment of *H pylori* status depends on the clinical circumstances. If endoscopy is performed, biopsy-based methods can be used to establish the presence of *H pylori.* Because of a reduced sensitivity of rapid urease test in the setting of acute upper GI bleeding, [418] both rapid urease testing and histology should be performed in the setting of acute upper GI bleeding. If at the time of endoscopy, biopsies for *H pylori* were not obtained from a patient found to have a duodenal ulcer, or if diagnosis of a duodenal ulcer was made by radiographic studies or on the basis of a prior history of a documented duodenal ulcer, nonendoscopic tests are appropriate. Given the high pretest probability of *H pylori* infection in patients with ulcer disease, antibody testing is a reasonable diagnostic choice. The nonendoscopic urease tests and the fecal antigen test are also excellent options.

Should Helicobacter pylori be determined in patients taking nonsteroidal antiinflammatory drugs? If NSAIDs and *H pylori* together have additive deleterious effects on gastroduodenal injury, it would be appropriate to test and treat for *H pylori* before beginning NSAID treatment. Although some evidence favors this paradigm, [419] most of the data currently available do not support this approach. At this time, we do not recommend determining the *H pylori* status of patients who are taking NSAIDs unless these patients have a history or concurrent evidence of PUD. *H pylori*–infected patients in this latter category should be treated with anti– *H pylori* therapy.

Should Helicobacter pylori status be determined in all patients presenting with dyspepsia? Management options for patients with uncomplicated dyspepsia (in which patients do not have alarm features, such as vomiting, weight loss, bleeding, or anemia) include the "test-and-treat" strategy for *H pylori* and empiric antisecretory therapy. Several organizations, including the American Gastroenterological Association, [420] have supported the test-and-treat strategy, and large, randomized, controlled trials from Europe suggest that this strategy reduces endoscopic workload without compromising clinical outcomes in patients with uncomplicated, uninvestigated dyspepsia. [421], [422] Patients may be less satisfied with the test-and-treat strategy compared with early endoscopy, [421] a finding supporting the notion that patients are reassured by the more definitive diagnosis provided by endoscopy. In a study from the United States, clinical and economic outcomes of patients with a positive qualitative antibody test who were treated for *H pylori* compared with those with a negative antibody test who were treated with a PPI were similar. [423] Based on a large number of randomized trials, it appears that eradication of *H pylori* offers little, if any, benefit over placebo or a short course of PPI in patients with nonulcer dyspepsia [97], [98] (see Chapter 30). As such, the clinical benefits of the test-and-treat strategy are derived largely from improvement in patients with ulcer disease. Factors influencing the decision between the test-and-treat approach and empiric antisecretory therapy include the background prevalence of *H pylori* and PUD and the percentage of patients whose ulcers are caused by *H pylori.* [424] Populations with a low prevalence of *H pylori* or ulcer disease will derive less benefit from the test-and-treat strategy than populations where the opposite is true. The changing demographics of *H pylori* infection in the United States and many other Western countries will require ongoing reevaluation of the choice between the test-and-treat strategy and empiric antisecretory therapy in patients with uninvestigated dyspepsia.

Use of *Helicobacter pylori* Test for Posttreatment Diagnosis

Indications and timing. In patients with PUD, eradication of *H pylori* significantly reduces ulcer recurrence and rebleeding; therefore, all patients with *H pylori*–related ulcer bleeding, obstruction, or perforation should undergo testing to prove eradication of the pathogen after antibiotic therapy. Whether to pursue testing routinely after treatment of patients with an uncomplicated duodenal ulcer is less clear. Certainly, testing for *H pylori* infection should be pursued in patients who suffer with recurrent or persistent symptoms after antibiotic therapy. It is less clear whether patients with an uncomplicated ulcer who are rendered asymptomatic by *H pylori* therapy should be tested. One could argue that there is a risk of morbidity and even mortality associated with ulcer recurrence resulting from persistent *H pylori* infection; however, this risk is likely to be small, and the cost-effectiveness of posttherapy testing in patients with uncomplicated ulcer disease therefore remains controversial. Most patients with gastric ulcers undergo follow-up endoscopic evaluation, and at that time it is reasonable to test for cure of *H pylori* infection using biopsy methods. In general, evaluating for eradication of *H pylori* should be done with the same endoscopic and nonendoscopic tests used to identify active infection. Testing should be performed no less than 4 weeks after the completion of therapy, because up to 2 weeks after treatment that ultimately is shown to have failed, it may not be possible to detect *H pylori* as a result of temporary suppression or reduction of the bacterial load. This phenomenon, which has been termed *clearance,* can be appreciated only in retrospect, after recrudescence occurs. *Cure* (or eradication) is used to describe nondetection of organisms 4 or more weeks after treatment.

Endoscopic tests after treatment. Very limited data exist regarding the accuracy of biopsy-based methods for the detection of *H pylori* in the posttreatment setting. One study showed that two jumbo biopsies, one from the gastric angle and one from the greater curve of the gastric body, would suffice to detect bacteria in virtually all those patients who remained infected. [425] Interestingly, the least sensitive site was prepyloric, with a false-negative rate of approximately 10%. In the same study, rapid urease tests such as the CLOtest had a sensitivity of 95% based on a single antral biopsy. Because false-negative CLOtests may be associated with low *H pylori* density, [384] it is reasonable to anticipate that rapid urease tests may be less sensitive in the posttreatment setting, and this is supported by data from multicenter treatment trials in the United States. [426] In this study, it was found that biopsies from the antrum and body for histology obtained 8 weeks after therapy yielded a posttreatment sensitivity of 93%, whereas rapid urease testing alone yielded a sensitivity of only 78%. Combining histology and rapid urease testing yielded a posttreatment sensitivity of 98%. [427] Based on these results, we discourage the use of rapid urease testing as a sole means of establishing *H pylori* eradication. Rather, combining histology and rapid urease testing is appropriate when assessing for *H pylori* eradication using endoscopic methods.

Antibody test after treatment. After successful cure of *H pylori* infection, anti– *H pylori* antibody titers invariably fall, allowing quantitative serologic antibody methods to be used for follow-up evaluation of treated patients. A 50% decline in titer is reliably accurate in establishing cure. [428] Conventionally, convalescent and baseline serum samples are tested together, to minimize errors resulting from assay variation. Such variation, however, is minimal, and it is not likely to be consequential when evaluating for titer declines of approximately 50%. Therefore, provided the same assay is to be used on the convalescent sample as was used on the baseline sample, it is probably not essential to store the baseline sample. Of critical importance for determination of posttreatment cure is the timing of the convalescent assay. Distinguishing between treatment success and failure requires a 6-month posttreatment period before approximately 85% of patients will be correctly characterized. [428] Whether nonquantitative office-based tests may be useful for confirmation of cure is not well studied. However, most patients probably remain seropositive; in one report, only 36% of patients became seronegative during follow-up. [429] It is not known whether most patients eventually will become seronegative after cure (or spontaneous elimination) of *H pylori* infection, but this seems unlikely. Because the time frame is erratic for the antibody to decline sufficiently (usually 20% to 50% of the original titer) to assess cure, and it requires at least 6 to 12 months for acceptable sensitivities, antibody assays are impractical in the posttreatment clinical setting.

Nonendoscopic urease breath tests after treatment. In contrast to antibody tests, the nonendoscopic urease tests detect active infection and provide an indirect reflection of the *H pylori* bacterial load present at the time of the test. Intuitively, if the bacterial load has been reduced to zero by successful treatment, the nonendoscopic urease tests should accurately reflect this status and should be negative, as they are in patients who are uninfected in the first instance. Indeed, nonendoscopic urease tests have posttreatment sensitivity and specificity of greater than 90%. [430] As mentioned earlier regarding biopsy tests, it is currently recommended that nonendoscopic urease tests be performed no sooner than 4 weeks after completion of anti– *H pylori* therapy. There are some data to suggest that posttherapy testing can be performed as early as 2 weeks after therapy. [411] However, this finding requires confirmation in large clinical trials before being recommended for routine clinical care.

Fecal antigen test after treatment. The fecal antigen test can also be used to establish cure of *H pylori* after the completion of therapy. Original reports from Europe, using a standard of endoscopy-based methods and a urea breath test, suggested that the fecal antigen test had sensitivity and specificity that exceeded 90% as a test for eradication when done more than 4 weeks after the completion of therapy. [413] Unfortunately, more recent studies using less stringent standards have reported lower sensitivity and specificity of the fecal antigen test when it was done 1 month after the completion of therapy for *H pylori*. [413] Some investigators have suggested that it may be necessary to wait as long as 3 months to achieve acceptable accuracy in the posttherapy setting. At present, the optimal timing of stool testing to establish *H pylori* cure remains unclear.

Specialized Testing

Serum Gastrin Testing The incidence of gastrinoma (i.e., Zollinger-Ellison syndrome) in patients with ulcer disease is exceeding low, estimated at much less than 1% of all patients with ulcers (see Chapter 67). Clinical situations in which gastrin measurement should be considered include the following: patients with ulcer disease and endocrine tumors, especially hyperparathyroidism (possibility of MEN I); patients with ulcers located in the distal duodenum or jejunum; patients with diarrhea or weight loss (i.e., hyperacidity of the small intestine resulting in ulcer plus diarrhea and steatorrhea); patients with refractory ulcer disease; and patients with recurrent ulcer disease despite eradication of *H pylori* or satisfactory compliance with prophylactic therapy.

Gastric Secretory Testing Gastric secretory testing should be considered in patients with reproducible hypergastrinemia and in whom gastrinoma is suspected, in patients with gastrinoma who are receiving medical therapy and who should have gastric secretory testing to ensure adequate therapeutic suppression of gastric acid secretion, and patients with refractory ulcer disease.

THERAPY

History

Treatment of patients with acid peptic disorders before the 1970s relied on antacids, anticholinergics, a bland diet, and bed rest. In the latter part of the 1970s, Peterson and colleagues reported that a large dose of antacids (equivalent to 1000 mmol/d) resulted in healing of approximately 80% of duodenal ulcers after 4 weeks of therapy when compared with placebo. [401] As one would anticipate, large-dose antacid regimens were inconvenient and poorly tolerated by patients. In 1977, the first of four H_2-receptor antagonists, cimetidine, became available in the United States:. The availability of cimetidine, ranitidine, famotidine, and nizatidine, orally administered inhibitors of gastric acid secretion, revolutionized the treatment of acid peptic diseases. All the H_2-receptor antagonists produced ulcer healing rates of 80% to 95% after 6 to 8 weeks of therapy. [431] Their outstanding efficacy, ease of use, and excellent safety profile made them the drugs of choice for the treatment of acute ulcers throughout the 1980s.

More potent inhibition of acid secretion became possible with the advent of the H^+,K^+-ATPase inhibitors, which block the final step in H^+ secretion. [432] These potent PPIs appear to produce slightly more rapid ulcer healing than standard doses of H_2-receptor antagonists, an observation of uncertain clinical significance. Virtually all ulcers that are refractory to standard doses of H_2-receptor antagonists can be healed with PPIs, a dramatic confirmation of the importance of gastric acidity in ulcer pathogenesis. [432]

During this same period, other agents that did not affect acid secretion but appeared to expedite ulcer healing with an efficacy comparable to that of H_2-receptor antagonists were developed. These included sucralfate and bismuth (the latter not approved by the FDA for this purpose), which appear to enhance mucosal defense mechanisms. [433], [434] Despite their efficacy and safety, these agents did not initially achieve the widespread use for ulcer therapy enjoyed by H_2-receptor antagonists. Prostaglandin analogs of the E class, which stimulate gastroduodenal mucosal defense mechanisms and have a modest inhibitory effect on gastric acid secretion, were developed but have not been as effective as H_2-receptor antagonists in therapy of acute ulcers. However, the prostaglandin analog, misoprostol, has demonstrated dramatic efficacy in the prevention of NSAID-induced ulcers and is the only agent approved by the FDA for this purpose. [435]

Recognition of the importance of *H pylori* in the pathogenesis of acid peptic diseases precipitated another revolution in ulcer therapy. Historically, gastric and duodenal ulcer disease were chronic conditions with high recurrence rates. In the absence of continuous maintenance therapy, the endoscopically confirmed ulcer recurrence rates approach 60% to 90% at 1 year. [436] Long-term maintenance therapy with H_2-receptor antagonists or sucralfate reduces the recurrence rate to approximately 30% per year but does not alter the underlying predisposition to ulcer disease. Cessation of maintenance therapy is followed by rapid recurrence of symptomatic or asymptomatic ulcer disease in most patients. [437] Eradication of *H pylori* leads to a dramatic decrease in ulcer recurrence, thus affecting the natural history of this disorder.

Acid-Neutralizing and Acid-Inhibitory Drugs

Antacids Antacids were the mainstay of antiulcer treatment until the advent of H_2-receptor antagonists in the late 1970s, and these nonprescription agents continue to be used liberally by patients for the relief of dyspepsia of all causes. The clinical pharmacology and buffering effects of antacids have been reviewed extensively. [438] Antacids have their greatest benefit when administered 1 hour after meals.

Mechanisms of action. Until recently, antacids were believed to produce their therapeutic effect entirely through their acid-neutralizing action. The use of large doses (1000 mmol/d) of antacid administered in multiple doses in patients with duodenal ulcer was based on the principle of neutralizing secreted gastric acid. However, doses of aluminum-containing antacid as low as 120 mmol/d result in healing that is equivalent to larger doses. [439] The buffering effect of these doses of antacids is modest at best and cannot account for their therapeutic efficacy. Mucosal cytoprotective mechanisms have been postulated to explain the efficacy of low-dose antacids. Aluminum salts are thought to enhance mucosal prostaglandin levels, to bind EGF, to stimulate mucus and HCO_3^- secretion, to preserve microvascular flow, to bind bile acids, and to inhibit pepsin activity. [440], [441], [442] and [443]

Adverse effects. Antacids are well tolerated in patients with normal renal function. Sodium-containing antacids can result in significant sodium retention, which may be of concern in patients with hypertension or fluid overload. Large amounts of calcium carbonate can result in hypercalcemia, metabolic alkalosis, and renal insufficiency (i.e., milk-alkali syndrome). [444] Magnesium has a cathartic effect and can result in diarrhea. Conversely, calcium and aluminum may cause constipation. Many proprietary antacids contain a combination of magnesium and aluminum. In patients with renal insufficiency, magnesium-containing antacids can result in significant hypermagnesemia and should be avoided. Aluminum, like calcium carbonate, can bind with phosphate, leading to hypophosphatemia in some cases, and it is commonly used in chronic renal failure for this purpose. Plasma and urinary aluminum concentrations appear to increase in patients with chronic renal failure who take daily aluminum hydroxide. [445], [446] Aluminum absorption may be enhanced by concomitant citrate buffers (e.g., Shohl solution), which is also commonly used in chronic renal failure. Because of growing concerns that aluminum may cause chronic neurotoxicity in patients with chronic renal failure, aluminum-containing antacids are best avoided when possible. [446] Moreover, aluminum may inhibit the absorption of some drugs such as iron supplements and tetracyclines.

H_2-Receptor Antagonists The four H_2-receptor antagonists approved for clinical use by the FDA are cimetidine, ranitidine, famotidine, and nizatidine. These compounds share an aromatic ring system and a flexible side chain (Fig. 66-11). Cimetidine, like histamine, contains an imidazole ring; whereas ranitidine has a furan ring, and famotidine and nizatidine contain thiazole rings. [431]

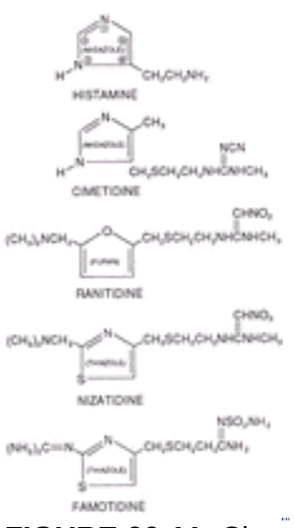

FIGURE 66-11. Chemical structures of histamine and H_2-receptor antagonists. All four antagonists share an aromatic ring system with a flexible side chain attached to a polar uncharged group.

H_2-receptor antagonists exhibit reversible competitive inhibition of histamine-stimulated acid secretion in vivo. [447], [448], [449], [450] and [451] Famotidine has a slower onset of dissociation from the receptor than other agents, suggesting some degree of noncompetitive inhibition; this may account for its longer half-life. [447], [448] H_2-receptor antagonists inhibit basal, histamine-, pentagastrin-, and meal-stimulated acid secretion in a linear, dose-dependent manner. [448], [449] and [450] As much as 90% inhibition of vagal- and gastrin-stimulated acid secretion occurs with H_2-receptor antagonists, reflecting the importance of histamine in potentiating or mediating the effects of cholinergic- and gastrin-stimulated acid secretion. [451] H_2-receptor antagonists lead to near-complete inhibition of nocturnal and basal acid secretion. On the basis of multiple pharmacological studies, famotidine is 20 to 50 times more potent, and ranitidine and nizatidine are 4 to 10 times more potent, than cimetidine on a molar basis (Table 66-7). [431] Increased potency does not necessarily confer a therapeutic advantage, provided the drugs can be administered in equipotent doses without toxicity. Once-daily bedtime dosing regimens of H_2-receptor antagonists are approved for the treatment of acute peptic ulcers. Once-daily morning administration of H_2-receptor antagonists is inferior to nighttime dosing in decreasing 24-hour intragastric acidity. [452]

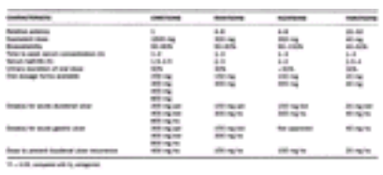

TABLE 66-7 Comparisons of H $_2$-Receptor Antagonists

Pharmacokinetics. All H $_2$ antagonists are absorbed rapidly from the small intestine (see Table 66-7). Absorption is not affected by food but may be decreased by antacids or sucralfate by as much as 30%. Peak blood levels occur within 1 to 3 hours after oral administration. Because of extensive first-pass hepatic metabolism, the bioavailability of oral cimetidine, ranitidine, and famotidine is between 40% and 65%. The bioavailability of nizatidine, which does not undergo first-pass metabolism, is almost 100%. The bioavailability of all intravenous H $_2$-receptor antagonist formulations is close to 100%. All H $_2$-receptor antagonists are well distributed throughout the body. [431], [448], [449], [450] and [451], [453] All agents cross the blood-brain barrier to a limited extent, yielding equivalent ratios of cerebrospinal fluid to serum of 0.07 to 0.20. [454] All H $_2$-receptor antagonists cross the placenta, and although they are believed to be safe, they are not recommended in the first trimester of pregnancy. [455] Cimetidine and ranitidine are concentrated 10- to 20-fold in breast milk; famotidine is not and appears in breast milk in clinically insignificant quantities. Nevertheless, H $_2$-receptor antagonists in general are not recommended in nursing mothers. H $_2$-receptor antagonists are eliminated by a combination of renal excretion (i.e., glomerular filtration and tubular secretion) and hepatic metabolism. With intravenous administration, 60% to 80% of drug is cleared largely unchanged by the kidney, and the remainder is cleared by the liver. After oral administration, 60% to 80% of cimetidine, famotidine, and ranitidine is metabolized by the liver, whereas oral nizatidine is excreted principally by the kidney. [431], [447], [448] and [449], [451] Plasma concentrations of H $_2$-receptor antagonists are affected by renal insufficiency. It usually is recommended that the doses be cut in half at a creatinine clearance of 15 to 30 mL/min for cimetidine and famotidine and less than 50 mL/min for nizatidine and ranitidine. [431] The percentage of H $_2$-receptor antagonist removed by dialysis is small, and replacement doses are unnecessary. Hepatic dysfunction has minimal impact on H $_2$-receptor antagonist pharmacokinetics, and dose adjustment is unnecessary in patients with compensated liver disease with normal renal function. It is unclear whether dose reductions are necessary in decompensated liver disease. [431], [456] The metabolism of H $_2$-receptor antagonists declines with age, and a dose reduction of as much as 50% may be indicated in the geriatric population. Unfortunately, the relation among serum drug levels, acid suppression, and ulcer healing has not been established in this population. [431]

Adverse effects. The H $_2$-receptor antagonists are well tolerated and have a remarkably low incidence of side effects (<3%). [448], [450], [457] In a metaanalysis of randomized clinical trials, the overall rate of untoward effects was no different between patients treated with H $_2$-receptor antagonists and those receiving placebo. [458] Risk factors for adverse effects include multiple medical illnesses, hepatic or renal disease, or advanced age. Much has been made in the clinical literature regarding the relative frequencies of adverse effects among the different H $_2$-receptor antagonists. Cimetidine, as the first H $_2$-receptor antagonist in clinical use, has undergone the most extensive postmarketing surveillance; the other H $_2$-receptor antagonists have had more limited surveillance. [459] With the exception of the increased potential for drug interactions associated with cimetidine, there is no evidence that any one H $_2$-receptor antagonist has a distinctly superior safety profile. In the only large study available, the adverse effects of cimetidine and those of ranitidine were found to be virtually identical. [460] Cimetidine exhibits weak antiandrogenic activity that may result in gynecomastia and impotence, but not the other H $_2$ antagonists effects. They occur in only 0.2% of patients receiving long-term cimetidine therapy at conventional doses, but they have been reported in as many as 44% of patients treated with high-dose therapy for hypersecretory conditions. [461], [462] The changes are readily reversed after discontinuing cimetidine or substituting another H $_2$-receptor antagonist. Various central nervous system (CNS) reactions have been reported with all H $_2$-receptor antagonists, including headache, lethargy, dizziness, depression, memory impairment, agitation, confusion, psychosis, and hallucinations. [463], [464] The incidence of CNS reactions in the outpatient setting is exceedingly low and is not clearly different from controls. [454], [458], [459] and [460] The prevalence of CNS side effects attributable to intravenous H $_2$-receptor antagonists is much more difficult to assess, [454] but trials suggest that the prevalence of CNS reactions definitely attributable to intravenous H $_2$-receptor antagonists is less than 1%. [454], [465] Toxicity does not correlate well with the H $_2$-receptor antagonist dose or serum concentration. [454] Although advanced age and severe hepatic or renal disease are commonly thought to be risk factors for CNS toxicity for these drugs, this has not been convincingly demonstrated. Although cimetidine has been most frequently associated with CNS reactions, there is no evidence that any one H $_2$-receptor antagonist has a higher rate of adverse reactions than another. Leukopenia, neutropenia, anemia, thrombocytopenia, and pancytopenia have been reported with H $_2$-receptor antagonists, with a prevalence ranging from 0.01% to 0.7%. [466] H $_2$-receptor antagonists have been associated with myelosuppression in as many as 5% of bone marrow transplant patients and should probably be avoided in this setting. [467] Reversible asymptomatic elevations of hepatic aminotransferase two to three times the normal level may occur, especially with intravenous therapy. [359], [456] Rare cases of acute hepatitis are generally mild and reversible, and no deaths have been reported. Case control studies and postmarketing surveillance studies do not detect an increased rate of gastric cancer or an increased mortality rate. [468], [469]

Drug interactions and metabolism. Drugs that require an acidic milieu for gastric absorption may have decreased uptake in the more alkaline milieu produced by H $_2$-receptor antagonists, but with the exception of ketoconazole, the impact of H $_2$-receptor antagonists on drug absorption is rarely clinically significant. [470] Cimetidine and, to a lesser extent, ranitidine bind to the hepatic cytochrome P450 microsomal mixed-function oxidase system, dose dependently inhibiting phase I oxidation and dealkylation. Phase II glucuronidation and sulfation reactions are not affected by these agents. [456], [470] Cimetidine is reported to interact with the metabolism of several medications that have a narrow therapeutic/toxic level ratio, including theophylline, phenytoin, lidocaine, quinidine, and warfarin. The metabolism of a variety of other P450-handled medications is also impaired by cimetidine. This may occasionally be significant for some ß-blockers (e.g., propranolol, metoprolol), calcium channel blockers (except diltiazem), tricyclic antidepressants, and benzodiazepines. [471], [472] It is more convenient and perhaps safer to use another H $_2$-receptor antagonist with less interactive potential. Ranitidine binds five- to tenfold less avidly to the P450 system than cimetidine and has far less potential for significant adverse drug interactions. Famotidine and nizatidine do not demonstrate significant avidity for the P450 system and are virtually devoid of significant related drug interactions. [471], [473] All H $_2$-receptor antagonists are secreted at the renal tubule, where they compete with the tubular secretion of creatinine and certain medications. With normal renal function, a clinically insignificant rise (15%) in serum creatinine may occur, but the actual glomerular filtration rate is unchanged. Cimetidine and ranitidine, but not famotidine, inhibit renal tubular secretion of procainamide by as much as 44%. [431]

H $^+$, K $^+$-ATPase Inhibitors

Structure and site of action. As reviewed in Chapter 13, the parietal cell H $^+$,K $^+$-ATPase is the key enzyme responsible for generating hydrochloric acid in the stomach. Its recognition as essential in the final step of acid secretion has made this enzyme a target for a category of drugs that block its activity, PPIs. Some PPIs with a common structural motif have been developed and include omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole. [47], [474], [475], [476], [477], [478], [479], [480], [481] and [482] These compounds are substituted benzimidazoles, which vary in their substitutions (Fig. 66-12), but share common mechanisms for inhibiting acid secretion. PPIs are acid-labile lipophilic compounds that are absorbed in the proximal small intestine, circulate in the blood, and cross the basolateral surface of the parietal cell. Esomeprazole is the S-enantiomer of omeprazole, which is a racemic mixture of both S- and R-optical isomers. Through a series of in vitro studies, esomeprazole has been shown to undergo less hepatic metabolism through cytochrome P450 2C19 and decreased intrinsic clearance than the R-enantiomer of omeprazole. The difference in clearance results in slower plasma elimination of esomeprazole as compared with omeprazole. Clinical studies have demonstrated greater acid inhibition and diminished interindividual variability of esoprazole over omeprazole.

FIGURE 66-12. Chemical structure and reaction pathways of four of the proton pump inhibitors used in the United States. (Adapted with permission from ref. [482].)

PPIs are weak bases (pK $_a$ from 4.0 for omeprazole, lansoprazole, and pantoprazole to 5.0 for rabeprazole), and this facilitates their accumulation in acid compartments such as the parietal cell acid secreting space. Once in the acidic compartment, PPIs are converted into the reactive thiophilic sulfenamide through an acid-catalyzed reaction (see Fig. 66-12). The sulfenamide derivatives are permanent cations that are trapped within the parietal cell, where they react rapidly to form a covalent disulfide bond with a cysteine residue on the a-chain of the H $^+$,K $^+$-ATPase rendering it irreversibly inactive, with the possible exception of rabeprazole, which has been shown to have a shorter activation time and partial reversible binding in vitro. Acid secretion is blocked until a new enzyme unit is synthesized, which usually occurs within 96 hours. [481] The rate with which the different PPIs are converted to the corresponding active form varies and is determined by their structure

and pK $_a$. Relative rates of conversion are rabeprazole > omeprazole + lansoprazole > pantoprazole. [483], [484]

Effects on acid secretion. PPIs, the most potent inhibitors of acid secretion available, block both basal and stimulated acid formation. Although different doses of these agents are recommended for treatment of several acid-related disorders, when they are used at equivalent doses, PPIs are quite comparable in terms of their efficacy. [485] Through metaanalysis, Burget and colleagues [486] concluded that, to obtain healing of a duodenal ulcer at 4 weeks, the intragastric pH should be maintained at 3 or greater for 18 to 20 hours per day. Therefore, this gastric pH has often been used as a target when comparing the efficacy of the various PPIs. A detailed review of the many studies published examining the relative efficacy of each PPI is available. [474] It appears that, after reviewing all the studies, omeprazole, lansoprazole, and pantoprazole have equivalent potency when they are considered on a milligram-by-milligram basis. Rabeprazole (20 mg) has a significantly quicker antisecretory effect and longer duration of action than omeprazole (20 mg). [487] Whether the slight difference in onset and duration of acid inhibition of the various PPIs has any significant impact on clinical outcomes has not been established.

Pharmacokinetics. The onset of action for PPIs is approximately 1 hour, with maximal inhibition and duration of inhibition being dose dependent. They all have short plasma half-lives (~1 hour) and are unlikely to accumulate even when clearance is significantly diminished. [480] In contrast, the duration of the inhibitory effect on acid secretion is prolonged (48 to 72 hours) because of the irreversible modification of the H^+,K^+-ATPase. Rabeprazole dissociates from the acid secretory pump to a greater extent than other compounds; therefore, its duration of action is shorter. The inhibitory effect of omeprazole is increased with daily dosing, with steady state in action achieved within 3 to 4 days. Availability improves to 60% with repeated dosing, which may reflect impaired absorption as the gastric pH increases. [488], [489] In contrast, lansoprazole and pantoprazole have a higher and constant bioavailability, the latter achieving this availability independent of the dose used. [490], [491] and [492] Although ingestion of food has been shown to decrease absorption of lasoprazole in some studies, this has not been a consistent observation. [480] Concomitant use of antacids has been shown to have no effect on omeprazole availability, but conflicting results have been observed with the other PPIs. [480] PPIs are concentrated and activated only in acidified compartments; thus, they inactivate only those proton pumps that are actively secreting acid. In the fasting state, roughly 5% of proton pumps are actively secreting, compared with 60% to 70% in the meal-stimulated state. The acid-inhibitory potential of both omeprazole and lansoprazole are maximized by taking them immediately before a meal, providing the drug at the time of stimulated acid secretion. [493], [494] Unlike H $_2$-receptor antagonists, which are commonly administered at bedtime, it is best to administer the PPIs in the morning before breakfast. [495] Omeprazole is less effective when given to patients during prolonged periods of fasting, such as in an intensive care unit. Evidence of this is provided from pharmacodynamic studies of the intravenous form of omeprazole, which is not yet available in the United States. [496], [497] For these reasons, H $_2$-receptor antagonists are likely to remain the preferred agents for the inhibition of gastric secretion in the intensive care unit setting.

Formulation. PPIs are acid labile; therefore, each compound is prepared in a specialized formulation to minimize degradation and protonation within the stomach. Omeprazole and lansoprazole are administered as enteric-coated, pH-sensitive granules in a gelatin capsule. The capsules dissolve in the stomach, and the granules dissolve within the proximal small intestine, releasing the drug where a more favorable pH of 6 is encountered. Pantoprazole and rabeprazole are available as enteric-coated tablets. Pantoprazole is also available in a parenteral formulation for intravenous use.

Elimination. All PPIs are avidly bound to protein (>95%) and are rapidly metabolized in the liver with minimal clearance by the kidneys. They are metabolized in the liver in a first-pass effect by the cytochrome P450 enzyme system, and negligible amounts of unchanged drugs are found in the urine and feces. [480], [481], [498], [499] and [500] The absorption of omeprazole and lansoprazole is reduced in patients with cirrhosis, but the bioavailability is not affected. [475] The absorption of PPIs is not altered by renal failure, and renal function does not affect the elimination of PPIs.

Adverse effects. PPIs are well tolerated, related to the high level of drug selectivity and efficient clearance of these compounds, with adverse effects occurring to a similar degree in patients receiving an H $_2$ blocker or placebo. [501], [502] and [503] The most common side effects include headache, constipation, nausea, abdominal pain, and diarrhea. The frequency of these side effects is similar for all the PPIs (1% to 3%), except in the case of diarrhea and headache, which are reportedly less common with rabeprazole and pantoprazole. Minimal elevation in aspartate aminotransferase and alanine aminotransferase has also been observed. Withdrawal of drug because of side effects is less than 1% to 2%. Serious adverse reactions from PPIs are rare, but there are case reports of hepatitis with lansoprazole and omeprazole and of interstitial nephritis with omeprazole. [504], [505] and [506] As is the case with H $_2$-receptor antagonists, PPIs may inhibit the gastric absorption of drugs that require an acidic gastric pH for absorption such as ketoconazole, ampicillin esters, and digoxin. PPIs are extensively metabolized by the cytochrome P450 system. Increasing evidence suggests that omeprazole partly inhibits those drugs metabolized by the P450 enzyme subfamily IIC, including diazepam, phenytoin, and warfarin. [507], [508] The clinical significance of these interactions has been minimal in most studies. Nevertheless, caution is warranted when omeprazole is used in combination with these agents. [507], [508] Unlike cimetidine, omeprazole has little or no significant effect on the elimination of drugs metabolized by the P450 subfamily IA (e.g., theophylline), subfamily IID (e.g., metoprolol, propranolol), or subfamily IIIA (e.g., cyclosporine, lidocaine, quinidine, nifedipine). [508], [509] No significant interference in alcohol metabolism has been demonstrated. Lansoprazole does not interact with diazepam, warfarin, phenytoin, or prednisone. [510], [511] and [512] There is a small increase in theophylline clearance (10%) when it is administered consistently with lansoprazole. Rabeprazole, pantoprazole, and esomeprazole do not appear to interact significantly with drugs metabolized by the cytochrome P450 system.

Impact of Antisecretory Drugs on Serum Gastrin Gastrin secretion depends on gastric intralumenal pH, with inhibition of release occurring at a pH 3.0. or less. Conversely, elevating the postprandial intragastric pH to more than 6.0 results in an enhanced, sustained rise in the serum gastrin response to meals. The elevation can be abruptly suppressed by intragastric infusion of acid. [513] Twenty-four-hour intragastric acidity and simultaneous plasma gastrin levels are significantly increased after therapy with H $_2$-receptor antagonists and PPIs. [513], [514] and [515] The greater the degree of gastric acid suppression produced by a particular drug regimen, the greater is the integrated serum gastrin. [514] The mean rise in fasting and meal-stimulated gastrin release induced by short-term courses of “standard” doses of H $_2$-receptor antagonists is small but significant, with values remaining well within the range of normal in almost all cases. [513], [514] After discontinuation of H $_2$-receptor antagonist therapy, fasting gastrin levels may remain slightly elevated (although well within normal limits) for several days to weeks before returning to pretreatment levels. The impact of long-term H $_2$-receptor antagonist therapy on serum gastrin levels has not been well studied. An elevated fasting gastrin level occurred in 19% of a small group of patients receiving long-term nighttime maintenance H $_2$-receptor antagonist therapy; this value returned to normal in all cases within 6 weeks after discontinuing therapy. [516] Another study reported no difference in basal or meal-stimulated gastrin levels in patients receiving maintenance therapy. [517] As a consequence of their greater degree of acid suppression, courses of therapy with PPIs produce greater rises in serum gastrin levels than H $_2$-receptor antagonists. Although selected reports suggest there is some variation in the ability of different PPIs to induce hypergastrinemia (pantoprazole less than omeprazole, lansoprazole more than omeprazole, and rabeprazole more than omeprazole), these difference are not clinically significant. [480] Within 2 weeks of initiating PPI therapy, fasting gastrin concentrations are increased two- to fourfold in most patients. [513], [518], [519] and [520] Gastrin levels returned to pretreatment values within 7 to 14 days after discontinuation of therapy. The largest experience with PPI-induced hypergastrinemia has been observed with omeprazole. Large clinical trials confirm a statistically significant rise in fasting gastrin levels after 4 weeks of omeprazole therapy, with as many as 12% of values exceeding the upper limits of normal. [521] Studies of 24-hour gastrin profiles in patients taking omeprazole show that the meal-stimulated physiological fluctuations in serum gastrin are preserved, and gastrin levels approach baseline at the end of the dosing interval. The rise in integrated gastrin levels is proportional to the total omeprazole dose. [522] With long-term omeprazole (>1 year), gastrin levels appear to increase threefold to fourfold over the first 1 to 2 months of therapy and then generally remain stable. [523], [524] However, a continued gradual rise over 30 months has been reported. [524], [525] Gastrin levels are elevated in as many as 23% of patients receiving long-term omeprazole treatment, [525] and they return to normal within 2 to 4 weeks after discontinuing the drug. [432] The increase in 24-hour gastrin profiles in patients given omeprazole (20 mg/d) is slightly less than that after proximal gastric vagotomy, even though omeprazole inhibits a mean of 94% of 24-hour acidity compared with 78% for vagotomy. Vagotomized patients have not developed adverse clinical consequences after prolonged hypergastrinemia. [522], [526] The rise in the 24-hour serum gastrin level caused by omeprazole is an order of magnitude lower than observed in patients with pernicious anemia. [527] The rise in serum gastrin levels may be pronounced, exceeding 400 pg/mL in 3% to 6% of patients receiving long-term omeprazole therapy. [523], [524] and [525] This degree of hypergastrinemia is attributable in most instances to profound drug-induced acid suppression and may respond to lower doses of omeprazole or alternative acid-inhibitory agents. [518], [528]

Consequences of Prolonged Acid Suppression In addition to its acid-stimulating effects, gastrin is a trophic hormone that stimulates mucosal growth in the stomach. The most prominent trophic effect of gastrin in the mucosa is on the endocrine ECL cell in the oxyntic mucosa. [529], [530] In humans, prolonged, severe hypergastrinemia associated with such conditions as type A chronic atrophic gastritis, pernicious anemia, or Zollinger-Ellison syndrome (especially patients with MEN I) may result in hyperplasia of the ECL cells and, in 3% to 5% of cases, the development of gastric carcinoid tumors. [531], [532] and [533] The finding that female rats treated for 2 years with omeprazole developed ECL hyperplasia and as many as 40% developed gastric carcinoid tumors raised legitimate concerns about the risks of carcinoid development in patients receiving long-term PPI therapy. [534], [535] To put this theoretical concern into clinical perspective, several observations are relevant. PPIs have not been found to induce mutagenicity or teratogenicity in multiple genotoxicology studies (i.e., no direct carcinogenic potential). [536], [537] In rats, ECL cell hyperplasia and carcinoids may be induced after prolonged, marked hypergastrinemia from several causes: partial fundectomy, antral exclusion, prolonged infusions of H $_2$-receptor antagonists, and PPIs. [530], [538], [539] Increases in the ECL cell density occur as early as 9 days after initiation of hypergastrinemia, stabilize after 10 to 20 weeks of hypergastrinemia, and revert to normal within 20 weeks if gastrin levels are normalized. [540], [541] In these models, ECL cell hyperplasia and carcinoids are prevented by antrectomy, which eliminates secondary hypergastrinemia. [540], [541] In human patients receiving long-term omeprazole therapy for as long as 10 years, hyperplasia of ECL cells has been observed, but there has been no reported progression to dysplasia or carcinoid, other than for patients with Zollinger-Ellison syndrome. [522], [525], [542], [543] In two long-term studies of more than 500 patients receiving long-term omeprazole, the ECL cells have been assessed quantitatively and

qualitatively by repeat biopsies of the gastric corpus. In the largest study, the proportion of patients with ECL hyperplasia rose from 10% pretreatment to 16% after omeprazole treatment. This primarily resulted from an increase in the micronodular pattern of hyperplasia from 2.5% to 10%. [542] In a smaller study, there was a 100% increase in the mean ECL cell volume density over a 5-year period. This increase was linearly related to the mean serum gastrin concentration. The increase in endocrine cell number and size was paralleled by a decrease in the normal endocrine cell growth pattern from 64% to 33% of patients and an increase in micronodular hyperplasia from 9% to 17%. [525] The qualitative and quantitative increases in the ECL cell population were mostly restricted to the subset of patients with more severe hypergastrinemia (>240 pg/mL). [543] Long-term therapy (>2 years) with lansoprazole led to a fourfold increase in ECL volume, with patients developing hyperplasia without evidence of dysplasia or neoplasia. [544], [545] and [546] In both omeprazole studies, a significant proportion of patients treated had chronic corpus gastritis, primarily caused by *H pylori* infection, with varying degrees of active mucosal inflammation or atrophic gastritis. The changes in the endocrine cell population correlated with the severity of the corpus gastritis. ECL cell micronodular hyperplasia was detected in both studies in almost 50% of patients with chronic atrophic gastritis, compared with only 2% to 4% of those without evidence of gastritis. The increase in ECL cell hyperplasia observed over time in these studies paralleled an increase in the incidence of chronic atrophic gastritis. A similar progression in chronic gastritis and ECL cell micronodular hyperplasia has been shown in normogastrinemic patients with gastric ulcers who were followed without antisecretory therapy for years. [543] Kuipers and colleagues [547] noted the acceleration of atrophic gastritis in a cohort of *H pylori*–infected patients treated with a PPI compared with a cohort of historical controls who underwent fundoplication. Whether this translates into an increased risk of gastric cancer and whether *H pylori* eradication can reduce that risk has not been examined. The greatest potential for the development of ECL cell hyperplasia and carcinoids appears to be in patients with chronic fundic atrophic gastritis. The level of hypergastrinemia seen in most patients treated with omeprazole is mild and (in the absence of chronic gastritis) causes little change in the ECL cell population. However, the development of ECL cell hyperplasia in patients with chronic atrophic gastritis is clearly potentiated by hypergastrinemia, especially at gastrin levels greater than 240 pg/mL. Significant hypergastrinemia does occur in a small subset of treated patients, especially in those with chronic atrophic gastritis. At this time, there is no agreement regarding the need or utility of periodic monitoring of serum gastrin levels in patients receiving long-term PPI therapy. There has also been concern regarding the development of colonic dysplasia and neoplasia secondary to PPI-induced hypergastrinemia. No evidence of this was observed in rats in which colonic carcinomas were induced and animals were subsequently rendered hypergastrinemic. [545] In 1996, the FDA reviewed these data along with data from major pharmaceutical companies in the United States and concluded that there was insufficient evidence to support a clear association among the use of PPIs, *H pylori* infection, and the accelerated development of atrophic gastritis. No product labeling changes were proposed, and further investigations regarding the observation by Kuipers and colleagues are needed to explore this observation. Despite the lack of data, many practitioners have adopted an approach to diagnose and treat *H pylori* infection in this patient cohort.

Drugs that Promote Mucosal Protection

Sucralfate

Structure and pharmacology. Sucralfate is a complex salt of sucrose in which the eight hydroxyl groups have been replaced by sulfate and aluminum hydroxide. [548] Within this acidic milieu, there is gradual dissociation of aluminum hydroxide into solution, leaving highly polar sulfate anions that may bind electrostatically to positively charged tissue proteins and mucins. Sucralfate has little acid-neutralizing capacity. [433] Because of its poor solubility, only 3% to 5% is absorbed (and renally excreted), with the remainder excreted in the feces. [548] Aluminum, which accounts for 21% of sucralfate by weight, dissociates to some extent into solution, but less than 0.01% is absorbed. [445] This is similar to what occurs with antacids containing aluminum hydroxide, causing a small but significant rise in serum and urine aluminum levels within 2 days. [433] In patients with normal renal function, the minor amounts of aluminum absorption with short-term therapy are of no clinical significance. Sucralfate appears to be extremely safe for short-term and long-term use, but its impact on the disposition of aluminum in the body has not been adequately studied.

Mechanisms of action. Sucralfate has several actions that are postulated to be important in ulcer therapy. [433], [549], [550] and [551] As the sulfate residues bind to the tissue proteins, sucralfate forms a protective barrier that may retard diffusion of acid, bile salts, and pepsin from the lumen to the ulcer. Sucralfate may bind to and stabilize the gastroduodenal mucous layer, as well as stimulating mucus and HCO_3^- secretion and gastric mucosal prostaglandin E_2 synthesis, and other trophic effects, which may promote mucosal defense.

Adverse effects. Because of its lack of systemic absorption and its inert chemical structure, sucralfate is virtually devoid of systemic toxicity. Gastric bezoar formation has been reported. [433] Constipation occurs in 3% of patients. [433] In patients with chronic renal insufficiency, significant aluminum accumulation may occur with standard doses of long-term aluminum hydroxide or sucralfate. Rarely, aluminum neurotoxicity with these agents has occurred in patients undergoing hemodialysis, [446] and it is recommended that long-term therapy with aluminum-containing compounds be avoided in this patient population. [446] Aluminum salts effectively bind phosphates in the GI tract and result rarely in hypophosphatemia, especially in patients who are already phosphate depleted. [433], [549]

Drug interactions. Sucralfate may bind to and may limit their absorption of several drugs, notably quinolone antibiotics, phenytoin, and warfarin. However, significant interactions are rare, and these may be avoided by administration of sucralfate separately from other medications. [433]

Bismuth-Containing Agents

Formulations. Physicians and patients have used bismuth salts for hundreds of years to treat sundry GI conditions, including dyspepsia, diarrhea, abdominal pain, and amebiasis. [434] Beginning in the 1970s, bismuth salts were demonstrated to be effective as single agents in the healing of peptic ulcers, but they never achieved widespread usage because of the excellent patient acceptance of H_2-receptor antagonists. These compounds have been used alone and in combination with antibiotics for the eradication of *H pylori,* and they have undergone a major resurgence in the treatment of PUD. Two colloidal preparations of bismuth have been most widely used: colloidal bismuth subcitrate (CBS; De-Nol) and bismuth subsalicylate (BSS). CBS is not available in the United States but has been used widely in Europe for the treatment of PUD. BSS is available as an over-the-counter agent, Pepto-Bismol, in the United States for the nonspecific treatment of dyspepsia and diarrhea. It is a fixture in the medicine cabinet of an estimated 60% of households in the United States, [434] and it has been approved by the FDA for treatment of *H pylori* infection. BSS may be administered as a liquid (303 mg of bismuth and 260 mg of salicylate/30 mL) or as a tablet (151 mg bismuth and 102 mg salicylate). [434], [552]

Pharmacokinetics. More than 99% of bismuth is excreted in the feces. Colonic bacteria convert the bismuth salts to bismuth sulfide, which imparts a black color to the stools. [552] Minimal bismuth absorption occurs from the proximal GI tract and is greater with CBS than with BSS. [553] This has not resulted in significant toxicity with short-term use. [554] Mean serum levels after 6 weeks of CBS therapy are elevated (17 g/L), although much less than the level thought to be toxic (50 g/L). An estimated 0.2% of bismuth from CBS is absorbed. [434] Absorbed bismuth is thought to be sequestered in multiple tissue sites in the body and is slowly excreted in the urine for 3 months or longer at approximately 2.6% per day. [434] Concomitant H_2-receptor antagonists enhance bismuth absorption from CBS but not from other bismuth formulations. Mean salicylate levels in patients given BSS in conventional doses (2.1 g/d) for 3 weeks produce a steady-state plasma salicylate level of only 2.4 mg/dL. [434]

Mechanisms of action. The mechanisms of action of bismuth salts are largely unknown, but they may involve binding and protecting ulcer crater or enhancing mucosal defense. They have no effect on gastric acid secretion and only a minimal effect on peptic activity. In endoscopic studies of patients given short-term aspirin therapy, bismuth markedly reduced the severity of mucosal lesions. [555], [556] Bismuth agents may also retard peptic degradation of epidermal growth factor. [557] Bismuth agents inhibit the growth of *H pylori* by causing detachment of the organism from the mucosa and bacterial lysis. [434]

Adverse effects. There have been no documented cases of bismuth toxicity from acute courses of BSS or CBS in recommended doses. There have been only three reported cases of bismuth neurotoxicity related to CBS and BSS, all involving patients who had used these agents in large doses or for extended periods. [434] In view of the documented absorption that occurs with CBS, its use should be restricted to short-term treatment only. In view of its salicylate content, BSS should be used with caution in patients with salicylate sensitivity, bleeding disorders, and renal failure, in elderly patients or in combination with other salicylate-containing drugs. The safety of long-term BSS has not been ascertained.

Prostaglandin Analogs

Structure and formulations. Prostaglandins are derivatives of 20-carbon–chain unsaturated fatty acids, also referred to as eicosanoids. The human GI mucosa contains and synthesizes several prostaglandins, but the primary prostaglandins are PGE_2 and PGF_2, which are produced in a ratio of about 2:1. Although they have a multitude of biologic effects, naturally occurring prostaglandins have a short biologic half-life of only a few minutes, and this limits their potential use as therapeutic agents. The only prostaglandin analog approved by the FDA for clinical use in PUD is misoprostol, a derivative of naturally occurring PGE_1.

Pharmacokinetics. Misoprostol is readily absorbed from the GI tract, with a peak plasma concentration at approximately 30 minutes after oral administration. The mean serum half-life is approximately 1.5 hours. Misoprostol metabolites are primarily excreted in the urine, but dose reduction is unnecessary in patients with chronic renal failure. [558], [559] Misoprostol does not affect hepatic cytochrome P450 drug metabolism.

Mechanisms of action. The therapeutic actions of misoprostol may be attributed to inhibition of gastric acid secretion and to stimulation of mucosal defense mechanisms. [435] The relative importance of these actions on the therapeutic efficacy is unclear. Direct mucosal contact appears to be necessary for its therapeutic action. After binding to the parietal cell, where there is a receptor for PGE, misoprostol exhibits dose-related inhibition of gastric acid secretion that is mediated through inhibition of histamine-stimulated cAMP production. [560] Although not as potent as H_2-receptor antagonists, misoprostol results in a significant reduction in nocturnal, basal, and meal-stimulated acid secretion at a standard therapeutic dose of 200 µg given four times daily. [561], [562] Prostaglandin analogs also stimulate mucus and HCO_3^- secretion, which enhances the pH mucous barrier, [561], [563], [564] enhances mucosal blood flow, and inhibits mucosal cell turnover. [565]

Adverse effects. Dose-related diarrhea is reported in 10% to 30% of patients receiving prostaglandin analogs. [435] This tends to occur early in the course of therapy and may be self-limited. Diarrhea may be the result of prostaglandin stimulation of intestinal sodium, chloride, and water secretion, or it may be secondary to changes in intestinal postprandial motility, resulting in accelerated orocecal transit time. [566], [567] Administration of misoprostol with food may decrease the incidence of diarrhea. Prostaglandins stimulate uterine smooth muscle, resulting in an increase in uterine pressure. Uterine bleeding has been reported with prostaglandin analogs in as many as one third of women during the first trimester of pregnancy. The use of these agents in women who may be pregnant is contraindicated. All women of childbearing potential should be warned of this risk before initiating misoprostol therapy. Vaginal bleeding may also occur in postmenopausal women. [435]

Miscellaneous Drugs

Anticholinergics. Anticholinergic agents are ineffective inhibitors of gastric acid secretion compared with H_2-receptor antagonists or PPIs, and they have been less effective than these agents in ulcer healing. Moreover, anticholinergic side effects (dry mouth, blurred vision, urinary retention) make these agents less desirable in the treatment of peptic disorders.

Tricyclic antidepressants. Antidepressant agents cause a mild decrease in acid and pepsin secretion, presumably mediated by inhibition of cholinergic and histamine H_2 receptors. Because of multiple side effects and the ready availability of superior agents, however, they have no role in the routine therapy of PUD. [568]

Carbenoxolone. Carbenoxolone is a licorice extract that was used many years ago to treat PUD, but it has no utility in the treatment of this disease. Its mode of action is unknown, but many of its effects resemble those of prostaglandins, and it has been shown to decrease prostaglandin metabolism. Carbenoxolone has aldosterone-like effects that can result in significant fluid retention and hypokalemia.

Treatment of Active Ulcers

The discovery of *H pylori* and of its role in PUD has had a major impact on the approach to treatment of gastric and duodenal ulcers. Before this discovery, annual ulcer recurrence rates after using antisecretory agents alone were as high as 80%, [569], [570] often requiring long-term maintenance therapy for ulcer prevention. Treatment concepts today should focus primarily on *H pylori*– and NSAID-induced mucosal disease. Most peptic ulcer trials have examined a relatively healthy patient population. Patients who are elderly, who have complicated ulcer disease (e.g., bleeding, perforation), who have large or multiple ulcers, who have severe underlying medical illnesses, or who are pregnant or lactating were specifically excluded from these trials; therefore, these data must be interpreted in the context of the defined population. These limitations notwithstanding, results of the randomized, double-blind, controlled trials are the standards on which clinical practice should be based.

Most patients with gastric ulcers have normal or reduced levels of acid secretion. It may seem paradoxical to treat such patients with acid-inhibitory agents. Overall, it is the duration of treatment that appears to be one of the most important factors in gastric ulcer healing. With or without therapy, there is a strong correlation between gastric ulcer healing and the duration of treatment or observation. Placebo healing rates increase over time, approaching 50% to 60% at 8 weeks. [571] In contrast, duodenal ulcer healing rates with placebo do not increase significantly after 4 weeks. Therefore, the duration of therapy may be more important than the potency of the pharmacological agent.

The following section first outlines, in general terms, the efficacy of the previously described drugs in the therapy of duodenal and gastric ulcers. Sections focusing on the therapy of *H pylori*– and NSAID-related disease follow.

Therapy for Duodenal and Gastric Ulcers

Acid-Neutralizing and Acid-Inhibitory Drugs

Antacids. Antacids have been found in multiple trials to be comparable to H_2-receptor antagonists in efficacy over a wide dose range of 120 to 1008 mmol/d, [572], [573] and [574] and they are superior to placebo and equivalent to H_2-receptor antagonists in relieving ulcer symptoms. [572], [573] There appears to be no advantage to using antacid regimens of more than two or three Mylanta DS or Maalox TC tablets four times daily. [572] Because of the need for four-times-daily dosing and the moderate incidence of diarrhea (secondary to magnesium) and constipation (secondary to aluminum), antacid therapy therefore should not be used as first-line ulcer therapy.

Acid-inhibitory drugs. Burget and colleagues [575] developed an elegant model of the relation between duodenal ulcer healing and antisecretory therapy. The rate of duodenal ulcer healing was found to depend on one of three variables: the degree of acid inhibition, the duration of acid inhibition, and the total duration of therapy. Antisecretory regimens that increase intragastric pH to more than 3.0 for more than 18 hours daily result in ulcer healing rates of 90% within 3 to 4 weeks. Regimens that raise the pH to more than 3.0 for only 8 to 10 hours daily can achieve similar healing rates after 6 to 8 weeks of therapy. Recognizing the association between duodenal ulcer healing and these three factors, the differences in healing rates among different antisecretory agents, doses, and dosing regimens become easily understood.

H_2-receptor antagonists. All four available H_2-receptor antagonists are efficacious in the treatment of gastric and duodenal ulcers. [431], [576], [577] Several randomized, double-blind trials have confirmed that once-daily bedtime dosing of H_2-receptor antagonists yields overall ulcer healing rates that are similar to twice-daily regimens. [571], [578] All the H_2-receptor antagonists have been approved by the FDA for once-daily administration in the treatment of duodenal ulcers: cimetidine (800 mg), ranitidine (300 mg), famotidine (40 mg), and nizatidine (300 mg) at bedtime. Healing rates for these regimens at 4 and 8 weeks of therapy are approximately 80% and 90%, respectively. Once-daily dosing also appears efficacious for treatment of gastric ulcers. [431], [448], [449] Higher doses of H_2-receptor antagonists, such as 300 mg of ranitidine twice to four times daily, result in higher 2- and 4-week duodenal ulcer healing rates, [639] but with the availability of PPIs, high-dose H_2-receptor antagonists appear to offer little advantage in the treatment of PUD. In general, gastric ulcers heal more slowly than duodenal ulcers, with average healing rates of 63%, 75%, and 88% after 4, 6, and 8 weeks, respectively. [431] The optimal H_2-receptor antagonist dosing regimen for gastric ulcers is undetermined. Trial results indicate that once-daily nocturnal H_2-receptor antagonist regimens are superior to placebo, and these nocturnal regimens are approved by the FDA. [431], [579] In summary, H_2-receptor antagonists should be administered between dinner and bedtime for 6 and 8 weeks to patients with duodenal and gastric ulcers, respectively.

H^+,K^+-ATPase inhibitors. PPIs result in gastroduodenal ulcer healing rates of more than 90% after 4 weeks of therapy. [427], [470], [474] The ulcer healing rate with omeprazole at 60 mg/d exceeds that of 20 mg/d at 2 weeks of therapy; however, at 4 weeks, these doses result in comparable healing rates in uncomplicated duodenal ulcers. [432] Omeprazole (20 to 40 mg/d) and lansoprazole (30 to 60 mg/d) have demonstrated efficacy in the treatment of acute gastric ulcers, with more than 90% healing after 8 weeks of therapy. [437], [475], [477], [479] The optimal dose has not been established, but healing may be slightly faster using the 40-mg dose. In several comparative trials, omeprazole resulted in significantly higher healing rates than H_2-receptor antagonists after 4 weeks and, in some trials, after 8 weeks of treatment. [579], [580], [581], [582] and [583] In a multicenter trial, 40 mg of omeprazole each day had significantly higher healing rates at 4 and 8 weeks of treatment than 20 mg of omeprazole each day or 150 mg of ranitidine twice daily. A metaanalysis suggests a slight advantage to omeprazole compared with H_2-receptor antagonists after 4 and 8 weeks of gastric ulcer treatment. [489] Pantoprazole has also been shown to be superior to ranitidine in gastric ulcer healing. [584] In deciding between H_2-receptor antagonists and PPIs, the clinician has two acceptable alternatives for uncomplicated ulcers. Both classes of drugs are efficacious in more than 90% of patients. They are safe and well tolerated, have excellent patient acceptance, and may be administered once daily. Although PPIs are more expensive than H_2-receptor antagonists on a daily basis, the cost of a 4-week treatment course of omeprazole compares favorably to a 6- to 8-week course of nongeneric H_2-receptor antagonists. PPIs may also provide more rapid pain relief than H_2-receptor antagonists, and this may be important to the patient. Although there are sparse data regarding patients with complicated gastric or duodenal ulcers, the superior efficacy of PPIs to other agents makes these the drug of choice for initial ulcer treatment in these patients. This includes patients with ulcers complicated by GI bleeding, ulcers larger than 1.5 to 2.0 cm in diameter, and patients with severe underlying medical disease. The advantage of PPIs over H_2-receptor antagonists in ulcer healing is especially pronounced in large ulcers (>1 cm). [585], [586] and [587] Although smoking retards ulcer healing, its impact may not be as great in patients treated with PPI as with H_2-receptor antagonists. [431], [585], [586], [587], [588], [589] and [590] Omeprazole and lansoprazole healed ulcers faster and relieved pain faster than H_2-receptor antagonists in most studies. [586], [588] Data with pantoprazole and rabeprazole demonstrate similar efficacy to omeprazole and lansoprazole in regard to ulcer healing. [584], [589] In patients with complicated ulcers who require hospital admission and nasogastric suction, a continuous intravenous infusion of H_2-receptor antagonists should be administered, rather than oral omeprazole. High, frequent doses of omeprazole are required in the fasting patient to maintain adequate acid suppression, thus limiting its utility in this setting. Similarly, in patients with peptic disease and gastric outlet obstruction, the absorption and bioavailability of omeprazole may be unpredictable. Future studies will clarify the utilities of intravenous pantaprazole in this patient population

Drugs that promote mucosal protection

Sucralfate. Sucralfate (1 g, four times daily) results in healing of 70% to 80% of duodenal ulcers after 4 weeks and 85% to 99% after 8 weeks of therapy. [433] In multiple comparative trials with H_2-receptor antagonists, there was no discernible difference in healing rates at 4 or 8 weeks between these agents. [433], [590] Sucralfate has also been shown to be effective at a dose of 2 g given twice daily in limited trials. Sucralfate has not been approved by the FDA for treatment of gastric ulcers. [591], [592] The development of more effective and easier to administer agents such as H_2-receptor antagonist and PPIs has made sucralfate somewhat obsolete.

Bismuth compounds. CBS is effective as a single agent in the short-term treatment of duodenal ulcer but is not approved by the FDA for use in the United States. BSS has not been adequately studied as a single agent in the treatment of duodenal ulcer disease. Limited data available on gastric ulcer healing with CBS suggest

that its superior to placebo and comparable to H_2-receptor antagonists in inducing gastric ulcer healing. [555]

Prostaglandin analogs. Prostaglandin analogs have little role in the treatment of acute duodenal or gastric ulcers.

Treatment of *Helicobacter pylori* Infection

The list of antimicrobial agents used to treat *H pylori* has grown exponentially since the 1990s. Moreover, studies reveal an improved clinical outcome and cost savings when patients with duodenal ulcer are successfully treated for *H pylori*. [593] It is important to realize that efficacy of any regimen for the treatment of this organism must be defined by demonstrating the absence of the microbe at least 4 weeks after completing therapy (eradication). [594], [595] Many agents may appear to be effective in clearing the organism within earlier time points, but this usually represents a decrease in the number of bacteria sufficient to render the diagnostic test falsely negative. The following is an overview of the different agents used for therapy of *H pylori.* A summary of treatment recommendations is outlined later in this chapter.

Antimicrobial Sensitivity Antimicrobial agents most commonly used for treatment of *H pylori* include amoxicillin, bismuth compounds, clarithromycin, metronidazole, and tetracycline. PPIs are also frequently part of the regimens used. Unlike other bacterial infections, susceptibility testing to antibiotics is not routine before initiating anti– *H pylori* treatment. Because metronidazole and clarithromycin are the mainstays of anti– *H pylori* treatment, knowledge regarding resistance to these and the other antibiotics may help to guide therapy. Metronidazole resistance is most common among *H pylori* isolates, occurring in approximately 10% to 60% of patients in developed countries, [114] with an even higher prevalence (e.g., 95% in South Korea) of resistance in developing parts of the world. [116] In contrast, the prevalence of clarithromycin resistance is generally not more than 10% to 15%, [596] with a tendency to be lower in countries where clarithromycin has only recently become available. In countries where clarithromycin has been available for some time, it appears that resistance rates are increasing. [597] Although resistance to tetracycline is rare, it has been noted to occur in up to 6% of isolates. [596] Resistance to amoxicillin is also rare. [598] Certain combination therapies may minimize the clinical impact of metronidazole resistance. Quadruple therapy, consisting of a PPI, metronidazole, tetracycline, and bismuth subcitrate, has been reported to be highly efficacious even against metronidazole-resistant strains. [599], [600] In vitro, ranitidine-bismuth citrate has been reported partially to overcome the effects of resistance to clarithromycin. [601] Unless sensitivity determinations are performed before initiating treatment, however, even initial regimens should probably exclude metronidazole or clarithromycin in patients known or suspected of having been exposed to these antimicrobials previously.

Current Treatment Regimens

Bismuth-based traditional therapy. In the United States, traditional triple therapy consists of BSS, two tablets (262 mg), metronidazole, 250 mg, and tetracycline, 500 mg, each taken four times daily for 10 to 14 days, providing a cure rate of approximately 85%. Substitution of amoxicillin for tetracycline results in a lower eradication rate and is not recommended. In Europe, bismuth subcitrate is often used instead of BSS, and treatment for 7 days has been shown to be effective. In the setting of an active ulcer, an acid-suppressive agent is added to hasten pain relief. Thus, traditional triple therapy for active ulcer disease is really quadruple therapy. Quadruple therapy, that is, combining traditional triple therapy, together with PPIs, preceded by a loading treatment phase of 3 days with a PPI alone, has been shown to be more efficacious and associated with fewer side effects than routine triple therapy. [600] More recent data suggest that pretreatment with PPIs for 3 days followed by 4 days of quadruple therapy is also efficacious. [602], [603] There is ongoing evaluation of a combination capsule containing tetracycline, bismuth, and metronidazole, which would significantly reduce the number of capsules taken per day. Preliminary studies have suggested that therapy with a PPI twice daily and three combination capsules three times daily for 10 days yields an eradication rate comparable to traditional quadruple therapy. As discussed in the section "Antimicrobial Resistance," a potential advantage of quadruple therapy for 7 days is the high cure rate of infection even with *H pylori* strains that are considered resistant to metronidazole.

Dual therapy. Clarithromycin is the single most effective anti– *H pylori* agent, and studies combining this antibacterial agent with either PPIs or ranitidine bismuth citrate have shown efficacy rates of approximately 65% to 80%. Specific FDA-approved regimens include the combination of clarithromycin, 500 mg three times daily, together with either omeprazole, 40 mg every day, or ranitidine–bismuth citrate, 400 mg twice daily for 14 days. Dual therapies with amoxicillin and a PPI have yielded variable cure rates in the United States and are thus not recommended. However, lansoprazole, 30 mg three times daily, together with amoxicillin, 1 g three times daily for 14 days, has been approved by the FDA for patients intolerant or allergic to clarithromycin or who are known to have organisms resistant to clarithromycin. This regimen has an eradication rate of approximately 70%. Because of their marginal efficacy relative to PPI triple antibiotic regimens and quadruple therapy, dual regimens have been relegated to the realm of historical interest.

Proton pump inhibitor–based and other triple therapies. The combination of two antibacterial agents with PPIs is among the most effective (approximately 85% to 90%) anti– *H pylori* regimens. Together with PPIs, combinations of clarithromycin and either amoxicillin or metronidazole are more effective than amoxicillin plus metronidazole. A standard dose of a PPI is taken together with clarithromycin, 500 mg, and either amoxicillin, 1 g, or metronidazole, 500 mg, all twice daily. In Europe, these regimens are effective if used for only 7 days, but in the United States, results are less clear. Therefore, 10 to 14 days of treatment are still recommended.

Adverse Effects Side effects of treatment relate to the particular regimen chosen. Patients should be educated about the importance of compliance and forewarned regarding minor side effects. Clarithromycin may cause taste disturbances, but this does not usually affect compliance. Metronidazole may be associated with side effects, particularly so at a dose greater than 1 g/d. Traditional triple therapy may be associated with mild side effects in about 50% of patients, and this includes vaginal moniliasis in up to 10% of women. Pseudomembranous colitis, a serious complication, occurs infrequently. In general, therapy is discontinued because of side effects in fewer than 5% of treated patients.

Considerations in Patients Who Remain Infected after a Course of Therapy

Primary treatment failure. There are only limited data addressing the management of patients in whom an initial attempt at eradicating *H pylori* infection fails. Therefore, most recommendations for management come from expert opinion. Dual therapy should not be used in the setting of treatment failure. In addition, it is prudent for a second course of therapy to be given for 10 to 14 days. After unsuccessful treatment of *H pylori* infection using metronidazole, the rate of secondary resistance is much higher than the primary resistance rate. An overall estimate for secondary metronidazole resistance is 80%. Data suggest that secondary resistance to clarithromycin after failed therapy develops in a significant percentage of patients treated with clarithromycin containing triple therapies. [604] Related to the high likelihood of secondary antibiotic resistance in the setting of primary treatment failure, if metronidazole or clarithromycin was used in the initial regimen, a second course of therapy should avoid these antibiotics. If clarithromycin was not used initially and there is no history of penicillin allergy, the combination of a PPI with clarithromycin and amoxicillin or tetracycline twice daily for 14 days is a reasonable choice. Ranitidine bismuth citrate (RBC) can be used in place of a PPI and may even provide improved efficacy in the setting of salvage therapy. [605] If the initial therapy contained clarithromycin but not metronidazole, a good choice would be quadruple therapy (PPI, tetracycline, bismuth, metronidazole) for 10 to 14 days. If both metronidazole and clarithromycin were included in the initial therapy, we have had success using a PPI, tetracycline, bismuth, and furazolidone (100 mg four times daily) for 14 days. Furazolidone appears to be effective even for most metronidazole-resistant *H pylori* strains. When furazolidone is used, patients should be warned not to consume alcohol or take monamine oxidase inhibitors concomitantly. In a study from Italy, the combination of a PPI twice daily, amoxicillin, 1 g twice daily, and rifabutin, 300 mg once daily for 10 days, yielded an eradication rate of 87% in patients in whom primary *H pylori* therapy had failed. [606] The role of antibiotic sensitivity testing as a means of selecting appropriate therapy in the setting of treatment failure remains poorly defined. At present, *H pylori* culture and antibiotic sensitivity testing are relatively time consuming and expensive. As a consequence, these techniques are not widely available. A decision analytic model comparing upper endoscopy with biopsy and culture and antibiotic susceptibility testing for *H pylori* with upper endoscopy with biopsy but no culture and antibiotic susceptibility testing found that pretreatment susceptibility testing could be cost effective depending on the prevalence of antibiotic resistance, the cure rate for sensitive strains, the cure rate for resistant strains, and the cost of diagnosing and treating *H pylori*. [607] It seems clear that as resistant strains of *H pylori* become more prevalent and culture and antibiotic sensitivity testing become more practical and accessible, these techniques could take on an important role in the management of treatment failures.

Reinfection. *Reinfection* is defined as the recurrence of *H pylori* infection after successful cure, as determined at least 4 weeks after treatment. A distinction is made between reinfection, in which a new strain is identified, and recrudescence, in which the strain is identical to the initial pretreatment organism. A very high recurrence rate may mitigate the desire for treatment. Recurrence rates probably relate to two factors. First, there may be an incorrect assessment of initial cure because of premature timing of the assessment and because of the possibility of decreased sensitivity of diagnostic tests in the posttreatment setting associated with a decreased bacterial load. Second, the prevalence of infection in the community or the particular living circumstances of patients (e.g., close contact, as in institutions) probably influences the rate of reinfection. Recurrences within the first 6 months after treatment are more likely to represent recrudescences, whereas reinfection may be more common thereafter. In general, it seems reasonable to assume that recurrence rates would be similar to the incidence rate of primary infection, which in the developed world is less than 1%/year. [608] However, even in a developing country such as China, where the prevalence of *H pylori* is more than twice that of the United States, the rate of reinfection was found to be low (average annual recurrence rate of approximately 1%) and similar to that found in developed countries. [609]

Treatment recommendations. At the present, peptic ulcers are the best established indication for *H pylori* treatment. Treatment of patients with nonulcer dyspepsia who are infected with *H pylori* and therapy for the sake of preventing gastric carcinoma remain controversial. In 1994, the National Institutes of Health (NIH) Consensus Conference concluded that all patients infected with *H pylori* with documented gastric or duodenal ulcers should receive antimicrobial therapy independent of whether NSAIDs had been ingested. [610] This recommendation included patients with newly diagnosed or recurrent ulcers. A similar consensus recommendation was put forth by the American College of Gastroenterology in conjunction with the American Gastroenterological Association and the American Society for Gastrointestinal Endoscopy. [611]

Treatment of Gastric and Duodenal Injury Related to Nonsteroidal Antiinflammatory Drugs

Treatment of Active Ulcers For patients with NSAID-associated gastroduodenal ulcers, the inciting agent should be discontinued if possible. When NSAIDs are being used for analgesic purposes rather than for their antiinflammatory effects, substitution of NSAIDs with acetaminophen or narcotics may provide analgesia. If NSAIDs are discontinued, gastric and duodenal ulcers respond rapidly to conventional therapy with H_2-receptor antagonists, omeprazole, or sucralfate. [612], [613], [614] and [615] In some patients with severe inflammatory rheumatic conditions, discontinuation of NSAIDs may be undesirable despite active ulceration. The use of COX-2–specific inhibitors or lower-risk NSAIDs such as salsalate, nabumetone, or etodolac may be useful in this situation. The safety with regard to clinical outcomes is more soundly established for the COX-2–specific inhibitors. Unfortunately, the optimal method of treating ulcers in patients who continue to take NSAIDs is not well established by randomized, controlled clinical trials. [616]

Antisecretory agents. It appears that H_2-receptor antagonists in conventional doses are capable of healing small (<5 mm) NSAID-related gastric and duodenal ulcers within 8 weeks, but the healing of larger ulcers, especially gastric ulcers, is markedly retarded. [617] Several trials have documented that the healing of NSAID-induced gastric and probably duodenal ulcers is delayed with H_2-receptor antagonist therapy if NSAID treatment is continued. [618], [619] In view of these findings, PPIs appear to be the preferred agent for the treatment of NSAID-associated ulcers. In a multicenter, double-blind, randomized trial comparing omeprazole with ranitidine, gastric ulcers healed within 8 weeks in 95% of a subset of 56 patients who continued NSAID therapy and who were treated with omeprazole (40 mg/d), in 82% with omeprazole (20 mg/d), and in 53% with ranitidine. [618] In a direct comparison of two doses of omeprazole, 20 and 40 mg, and ranitidine, 150 mg twice daily, in 541 patients, omeprazole was significantly more effective than H_2-blocker therapy. No advantage of 40 mg over 20 mg was seen. [619] The ability to heal NSAID-related ulcers rapidly while the drug is continued may have important clinical implications, given the number of anecdotal reports of serious GI complications of NSAIDs in patients receiving full-dose H_2-blocker therapy.

Misoprostol. In a randomized, double-blind study of patients, misoprostol demonstrated a 67% rate of healing of gastric and duodenal ulcers at 8 weeks when NSAIDs were continued, compared with 26% of patients treated with placebo. [620] A comparative study of misoprostol, 200 µg four times daily, and omeprazole, 20 and 40 mg/d, in 935 patients with NSAID-related ulcers demonstrated therapeutic success rates that were equivalent for all agents, with no advantage seen with high-dose omeprazole. Omeprazole, at either dose, was more effective in relieving NSAID-associated abdominal pain and indigestion, and it caused less diarrhea than misoprostol, leading to a reduced patient withdrawal rate compared with misoprostol and improved remission rate overall.

Mucosal protectants. Sucralfate does not appear to be effective in the presence of continued NSAIDs. [621]

Recommendations For patients with endoscopically documented uncomplicated gastric or duodenal ulcers, it is recommended that NSAIDs be discontinued, if possible. For patients with large or complicated NSAID-induced ulcerations, more rapid ulcer healing probably can be achieved with omeprazole, 20 to 40 mg/d, or its equivalent. The NIH Consensus Development Panel on *H pylori* recommended antimicrobial treatment of *H pylori*–infected patients with NSAID-induced gastric ulceration. Eradication of *H pylori* will not eliminate the likelihood that such a patient will have an ulcer recurrence if NSAID therapy is reinitiated; thus, preventive therapy is recommended in this situation. If NSAID therapy must be continued, the optimal approach supports potent acid suppression. It appears that small gastric and duodenal ulcerations heal with H_2-receptor antagonists, but larger or complicated ulcerations (>5 mm) may be better treated with a PPI. Because large ulcers are associated with a higher risk of complications, it should not be concluded that continued NSAID or COX-2–specific inhibitor therapy in the presence of large ulcerations is safe or advisable; the risks are unknown.

Prophylaxis for Ulcers Related to Nonsteroidal Antiinflammatory Drugs Because of the clear association between NSAID use and gastroduodenal ulcers, it would appear desirable to use an antiinflammatory agent with improved safety profile such as a COX-2–specific inhibitor or to administer prophylactic antiulcer therapy to prevent these ulcers and their complications. To address the efficacy of prophylactic therapy, several prospective endoscopic trials were performed. Most of these trials studied a population of patients with osteoarthritis or rheumatoid arthritis who were receiving long-term NSAID therapy but who did not have endoscopic evidence of a peptic ulcer at the start of the trial. Patients were then randomized to therapy with a prophylactic agent or placebo and followed with endoscopy over a 1- to 3-month period to determine the incidence of peptic ulcers. There are no prospective outcome trials to compare cotherapy approaches, so clinical judgment relies on data largely from endoscopic end points.

Prostaglandin analogs. Misoprostol has been shown to be an effective agent in the prevention of NSAID-induced gastric and duodenal ulcers and their complications. It is the only agent approved by the FDA for this purpose. However, despite its efficacy, its lack of impact on dyspepsia and its side effect profile make it the least commonly used cotherapy in clinical practice. In two large, multicenter, placebo-controlled studies of patients taking long-term NSAIDs, the 3-month incidence of gastric ulcers (>0.5 cm) among patients taking misoprostol (200 µg, four times daily) was less than 2%, compared with 8% to 12% among placebo-treated patients. [622], [623] In the larger trial, duodenal ulcers were found in fewer than 1% of patients receiving misoprostol but in almost 5% of placebo-treated patients. [622] It is worth emphasizing that 32% of patients treated with misoprostol developed diarrhea, compared with 18% of placebo-treated patients, although fewer than 4% of patients dropped out of the study because of this symptom. It is also noteworthy that the incidence of dyspepsia was similar among patients treated with misoprostol and those treated with placebo. Misoprostol has been found to be superior to H_2-receptor antagonists and sucralfate for the prevention of NSAID-induced gastric ulcers in randomized, prospective trials. [621], [623] Doses of 200 µg twice and three times daily significantly reduce rates of gastric and duodenal ulceration, with the higher dose more effective for gastric protection. [624] These data are of clinical relevance because the occurrence of diarrhea in up to 30% of patients on full-dose therapy is reduced by lower misoprostol doses. Studies up to 1 year in duration have confirmed the continued efficacy of misoprostol for the prevention of endoscopic ulcers. [625] The MUCOSA trial confirmed the ability of misoprostol to prevent the evolution to the complicated NSAID ulcer. In this randomized, double-blind trial of 8849 patients with rheumatoid arthritis who were taking long-term NSAIDs, misoprostol, 200 µg four times daily, reduced GI complications by 40% from 42 of 4439 (0.95%) in the placebo group to 25 of 4404 (0.57%) compared with placebo. [626] This study provided insight into numerous controversial issues. It confirmed the value of endoscopic ulcers as a surrogate marker for the development of clinically significant lesions. However, the reduction in GI complications was far less than the reduction in endoscopic lesions, making problematic the extrapolation from endoscopic lesion rates to reduction in clinically relevant outcomes for other agents or reduced misoprostol doses. There remains considerable debate in the literature regarding the cost effectiveness of misoprostol therapy for the prevention of NSAID ulcers. Current cost-effectiveness analyses have used reduction of endoscopic ulcers as the outcome of interest, and a pharmacoeconomic analysis of the MUCOSA data has not been published to date. A cost-utility assessment of misoprostol therapy in patients with rheumatoid arthritis demonstrated increased cost without additional quality-of-life benefits. [627] A critical review of the literature supports the idea that misoprostol is most cost effective when it is targeted to high-risk patient subgroups, [628] such as these with a history of previous PUD (52% reduction), significant cardiovascular disease history (38% reduction), significant functional disability (87% reduction), and those who required concomitant antacid use (48% reduction).

Mucosal protectants. A comparative study with misoprostol demonstrated the PGE_1 analog to be far superior for the prevention of NSAID ulcers, and ulceration rates in the sucralfate group were equivalent to rates in the placebo group in studies of similar design. [621]

H_2 antagonists: conventional dose. Studies have examined the ability of H_2 blockers, in traditional ulcer healing doses, to prevent NSAID-associated ulcers in arthritis patients. The findings in these studies probably apply to other H_2 blockers as well, because, when they are given in equivalent acid-suppressive doses, all have similar effects on GI ulceration. In studies with endoscopic ulcer end points, acid suppression with traditional-dose H_2 blockers did not provide clear-cut control of NSAID-induced GI toxicity compared with placebo. [629], [630] This is in contrast to nonendoscopy-based trials, which demonstrate efficacy for cimetidine and antacids compared with placebo for the prevention of NSAID-related dyspepsia. [631] The widespread coprescription of H_2 blockers in NSAID users reflects their efficacy for symptom control in clinical practice, despite the evidence that the major site of injury caused by NSAIDs, the stomach, is not protected.

High-dose acid suppression with H_2 blockers. In a 6-month study from the United Kingdom, [257] the reduction in the incidence of gastric ulcer in NSAID-users was dose dependent. The reduction in gastric ulcer rate was significant with only high-dose famotidine. There were trends for symptom improvement, and adverse event withdrawal was uncommon. Additional work by Hudson and colleagues [252] demonstrated that patients with prior NSAID ulcers are a high-risk group, and there is currently no cotherapy with 100% protective efficacy.

Potent acid suppression with proton pump inhibitors. Given that high-dose acid suppression with an H_2 blocker reduced NSAID ulcers in the stomach and duodenum, it follows that other, more potent acid inhibitors, should be as or more effective. Early experience with high-dose omeprazole in the acute prevention of aspirin-induced injury demonstrated that use of this PPI caused a remarkable reduction in both gastric and duodenal injury rates. [632] Researchers examined the long-term efficacy of omeprazole, 20 mg daily, in 177 higher-risk long-term NSAID users over a 3-month period in a Scandinavian multicenter study. [258] The patients studied had a history of PUD or ongoing dyspepsia. The reduction in peptic ulceration rates with omeprazole prophylaxis for NSAID-related ulcers was statistically significant. The peptic ulcer incidence was 4.7% with omeprazole versus 16.7% with placebo ($P < 0.05$), and dyspeptic symptoms persisted in 8.2% of the patients taking omeprazole compared with 20.0% taking placebo. This reduction was seen both for gastric ulcer (2 versus 6) and duodenal ulcer (2 versus 9); however, given the relatively small number of patients, significance was achieved only for the combined ulcer end point. Moreover, omeprazole significantly reduced the ulceration rate both in patients with previous ulcer and in those without. As shown in other studies, prior ulcer history was associated with an extremely high recurrence rate on placebo (approximately 50%). In another large multicenter study conducted in Europe, primary prophylaxis with omeprazole for NSAID-induced ulcers was studied in 169 patients requiring continuous NSAID therapy. [633] After 6 months, 78% of the omeprazole-treated group remained in remission, compared with 53% in the placebo group ($P = 0.004$). Two large randomized, double-blind studies evaluated the efficacy of omeprazole compared with ranitidine and misoprostol for both the healing and the subsequent recurrence of ulcers in individuals using NSAIDs. [614], [634] Omeprazole prevented ulcers more effectively (72% remission) than ranitidine (59%

remission) in patients who used NSAIDs regularly with similar rates of adverse events. Maintenance therapy of NSAID-associated ulcers with omeprazole was associated with a lower rate of relapse (61% remission) than misoprostol (48% remission) and was better tolerated. This difference was maintained when relapse was based on the development of both symptoms and endoscopic lesions. Thirty-two percent of patients taking placebo had gastric ulcers at relapse compared with 10% taking misoprostol and 13% taking omeprazole. Duodenal ulcers recurred in 12% of the placebo group, 10% in the misoprostol group, and 3% in the omeprazole group (Fig. 66-13). In addition, omeprazole was effective in reducing the symptoms in addition to reducing NSAID-associated endoscopic lesions, whereas misoprostol was ineffective and was associated with reductions in quality of life.

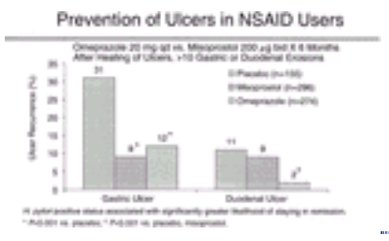

FIGURE 66-13. Prevention of ulcers in nonsteroidal antiinflammatory drug users with omeprazole or misoprostol. (Adapted from ref. 614.)

Studies that examined a pure NSAID-related ulcer group, namely, ulcers in NSAID users who are uninfected with *H pylori,* demonstrated that lansoprazole, 30 mg daily, was comparable to misoprostol,200 µg four times daily, with significantly fewer side effects, 635 supporting the widespread use of PPIs as an alternative strategy for prevention of NSAID-associated ulcers.

Recommendations. A prior history of peptic ulcer or ulcer complications increases the relative risk of NSAID therapy about 14-fold. It is axiomatic that NSAIDs should be avoided in such patients, and, if NSAIDs are to be used, extreme caution is urged. COX-2–specific inhibitors appear to be the drugs of choice in this situation. The use of the nonacetylated NSAIDs (e.g, salsalate) or the lower-risk NSAIDs (e.g., nabumetone, etodolac) may also be considered. Cotherapy with misoprostol or a PPI is recommended for all high risk patients taking NSAIDs. Because patients with major complications while taking NSAIDs were not studied in the outcome studies with the COX-2–specific inhibitors, cotherapy may also be considered for these patients. Patients who have a prior history of PUD or complications should be tested and treated for *H pylori* before initiation of NSAID therapy. It is unknown whether NSAID usage in such patients causes de novo ulcers, exacerbates the ulcer diathesis caused by *H pylori,* or both. It is unknown whether eradication of *H pylori* in these patients can lower the incidence of NSAID-induced ulcer complications. Pending further clinical study, ulcer prophylaxis is recommended for all patients with a history of symptomatic or complicated peptic ulcers, regardless of *H pylori* status. Because misoprostol has been shown to prevent gastric and duodenal ulcers and their complications, it is the preferred agent from the evidence-based medicine standpoint. In patients who are intolerant of misoprostol, alternatives should be considered. The use of lower doses of misoprostol is less expensive, is associated with less diarrhea, and may have significant efficacy in reducing ulceration. 623 In those situations, when misoprostol cannot be tolerated, potent acid suppression appears to be a reasonable alternative strategy to reduce ulcer risk. The benefits and cost effectiveness of prophylaxis in other situations are even more uncertain. Because outcome trials with the COX-2–specific inhibitors have established their superior GI safety compared with traditional agents, in the absence of head-to-head comparisons with cotherapy, either approach may be rational. The use of a single safer agent has obvious advantages for patient compliance. It is certain that the underlying patient risk and the likelihood of symptom-driven patient expenditures drive cost effectiveness among strategies to prevent symptomatic NSAID-related gastropathy. 636 Patients using concomitant corticosteroids with NSAIDs appear to be at greatly increased risk of developing NSAID-induced complications and should be considered for prophylactic or COX-2–specific inhibitor therapy. Similar considerations apply to those patients with serious underlying medical illness (marked disability, serious cardiac, pulmonary, renal diseases, rheumatoid arthritis, and patients receiving cotherapy with anticoagulants) 225 in whom an NSAID-induced complication would be poorly tolerated. Advancing age (>60 years) is also risk factor for NSAID-induced complications. However, it may not be cost effective to treat all elderly NSAID users prophylactically. 637

Prevention of Ulcer Recurrences and Complications

Natural History There is limited prospective information on the natural history of gastric and duodenal ulcers. Available data suggest that non–NSAID-related gastric ulcers have a relatively high recurrence rate of about 50% to 60% during the first 2 years after healing. The findings for duodenal ulcer suggest that about 70% to 80% of these patients have recurrences. Many of the reported duodenal ulcer recurrences represent asymptomatic ulcers found only at scheduled endoscopy in patients in ulcer trials, and the natural history of the asymptomatic duodenal ulcer requires further study.

Factors Associated with Ulcer Recurrence The major predictor of ulcer recurrence is the successful eradication of *H pylori,* which diminishes duodenal ulcer and gastric ulcer recurrences to 10% annually, in contrast to annual recurrence rates of 60% to 100% for those in whom *H pylori* is not eradicated. Because gastric and duodenal ulcer diseases are often associated with recurrences, it would be desirable to be able to predict and discriminately treat those who are destined for a recurrence. Several retrospective studies have attempted to relate various factors with ulcer recurrence rates. 638, 639 and 640 Many of these trials have been conducted in defined, sometimes small populations, such as teaching institutions or male veterans, and this makes the extraction of single predictive elements difficult and application of predictors to the general population questionable. Moreover, *H pylori* status was not determined in earlier studies. Despite these limitations, some tentative conclusions can be made about factors other than *H pylori* that can influence ulcer recurrence. Patients whose duodenal ulcers healed promptly, those who were younger, female, and nonsmokers, and those who had a more recent onset of ulcer disease, fewer pain episodes at entry, and a low basal or peak acid output had fewer ulcer recurrences than those without these features. 640 With follow-up periods as long as 6 years for 250 male veteran patients with duodenal ulcer with or without gastric ulcer, 11% of the total population developed ulcer complications, 639 and recurrences were threefold greater among those with prior ulcer complications requiring hospitalization than those without these criteria. Patient age, age at onset of ulcer disease, and family history were unrelated to the severity of disease. Van Deventer and colleagues 638 developed a risk index to predict the likelihood of ulcer recurrence. Cigarette smoking, alcohol intake, early disease onset (<40 years old), repeated duodenal ulcers, and endoscopic evidence of duodenal scarring or erosions were additive factors in the prediction of duodenal ulcer recurrence. 638 Each item has a value of 1, and patients with a risk index of less than 2 had about a 20% recurrence rate after 1 year, compared with a 100% recurrence rate for those with a score of 4. Although gastric ulcer disease is also associated with a high recurrence rate, there are no data, other than eradication of *H pylori,* that permit precise identification of specific factors associated with high or low ulcer recurrence rates. Continued NSAID intake, smoking, and possibly continued ethanol intake may contribute to gastric ulcer recurrences.

Role of Long-Term Maintenance Therapy Numerous clinical trials have confirmed the efficacy of continuous maintenance drug therapy in reducing the number of ulcer recurrences. 641, 642 and 643 It is our opinion, based on the available information, that long-term daily maintenance therapy with conventional medications has become obsolete. It has been estimated that the total cost of 2 weeks of triple therapy to eradicate *H pylori* is approximately $25. In the patient with recurrent ulcer disease, it is clearly cost effective to eradicate *H pylori* and to avoid the inherent costs of daily antiulcer drugs. Using a similar cost analysis, eradication therapy of *H pylori* is preferred to on-demand therapy. Based on the cost of approximately $3/d for a therapeutic dose of omeprazole, H_2-receptor antagonist, or sucralfate, and assuming that American patients with ulcers consumed doses comparable to those of Norwegian patients with ulcers (i.e., 10 weeks/y), the annual cost for antiulcer medications would exceed that of eradication of *H pylori.* These projections represent approximate estimates and do not include additional factors, such as the potential untoward effects of any medical program and indirect costs related to time lost from work. Careful cost analyses will be forthcoming.
