EDITORS

Contributors

Paul C. Adams, M.D., F.R.C.P.(C.)
Professor, Department of Medicine, University of Western Ontario; Chief, Department of Gastroenterology, London Health Sciences Centre, University Campus, London, Ontario, Canada

David A. Ahlquist, M.D.
Professor, Department of Internal Medicine, Mayo Medical School; Consultant, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota

Aijaz Ahmed, M.D.
Assistant Professor of Medicine, Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University School of Medicine; Staff Physician, Stanford University Medical Center, Palo Alto, California

David H. Alpers, M.D.
William B. Kountz Professor of Medicine, Department of Internal Medicine, Division of Gastroenterology, Washington University School of Medicine, St. Louis, Missouri

Dana K. Andersen, M.D.
Professor and Chairman, Department of Surgery, University of Massachusetts Medical School, UMass Memorial Medical Center, Worcester, Massachusetts

James M. Anderson, M.D., Ph.D.
Professor and Chair, Department of Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Dean L. Antonson, M.D.
Associate Professor of Pediatrics and Internal Medicine; Associate Director, Section of Pediatric Gastroenterology and Nutrition, University of Nebraska Medical Center, Omaha, Nebraska

Louis J. Aronne, M.D., F.A.C.P.
Clinical Associate Professor of Medicine; Medical Director, Comprehensive Weight Control Program, Weill Medical College of Cornell University, New York, New York

Mark W. Babyatsky, M.D.
Assistant Professor of Medicine and Gastroenterology, Mount Sinai Medical Center, New York, New York

Jeffrey L. Barnett, M.D.
Adjunct Professor, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan; Huron Gastroenterology Associates, Ypsilanti, Michigan

Kim E. Barrett, Ph.D.
Professor and Vice Chair for Research, Department of Medicine, University of California, San Diego, San Diego, California

Nathan M. Bass, M.D., Ph.D.
Professor of Medicine, Division of Gastroenterology, University of California, San Francisco; Medical Director, Liver Transplantation Program, UCSF Medical Center, San Francisco, California

Jose Behar, M.D.
Professor of Medicine, Brown Medical School, Gastrointestinal Motility Research Laboratory, Rhode Island Hospital, Providence, Rhode Island

Kevin Behrns, M.D.
Research Associate Professor of Surgery, Center for Gastrointestinal Biology and Disease, University of North Carolina School of Medicine, Chapel Hill, North Carolina

Tamir Ben-Menachem, M.D., M.S.
Director, Gastrointestinal Endoscopy, Department of Internal Medicine, Henry Ford Health Sciences Center, Detroit, Michigan

Michelle L. Bennett, M.D.
Piedmont Cosmetic Surgery and Dermatology, Winston Salem, North Carolina

Piero Biancani, Ph.D.
Professor of Medicine and Surgery (Research), Brown University; Director, Gastroenterology Motility Research Laboratory, Rhode Island Hospital, Providence, Rhode Island

Stephen J. Bickston, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology and Hepatology; Medical Director, Inpatient Digestive Health Center of Excellence, University of Virginia Health System, Charlottesville, Virginia

Elisa H. Birnbaum, M.D.
Associate Professor, Department of Surgery, Section of Colon and Rectal Surgery, Washington University School of Medicine at Barnes-Jewish Hospital, St. Louis, Missouri

David J. Bjorkman, M.D., M.S.P.H., S.M. (Epid.)
Senior Associate Dean, University of Utah School of Medicine; Professor, Division of Gastroenterology, University of Utah Health Sciences Center, Salt Lake City, Utah

Andres T. Blei, M.D.
Professor of Medicine, Department of Medicine, Division of Hepatology, Feinberg School of Medicine, Northwestern University, Chicago, Illinois

Richard S. Blumberg, M.D.
Associate Professor, Department of Medicine, Harvard Medical School; Chief, Gastroenterology Division, Brigham and Women’s Hospital, Boston, Massachusetts

C. Richard Boland, M.D.
Professor of Medicine; Chief, Division of Gastroenterology, Department of Medicine, University of California, San Diego School of Medicine, San Diego, California

Maurizio Bonacini, M.D.
University of Southern California, Keck School of Medicine, Los Angeles, California

Gregory A. Boyce, M.D.

Gastroenterology Clinic, St. Francis Medical Center, Monroe, Louisiana

H. Worth Boyce, Jr., M.D.
Professor of Medicine, Department of Internal Medicine; Director, Center for Swallowing Disorders, University of South Florida College of Medicine, Tampa, Florida

David A. Brenner, M.D.
John and Nina Sessions Distinguished Professor of Medicine; Chief, Division of Digestive Diseases and Nutrition, University of North Carolina, Chapel Hill, North Carolina

Robert S. Bresalier, M.D.
Chairman and Professor, Department of Gastrointestinal Medicine and Nutrition, University of Texas, M.D. Anderson Cancer Center, Houston, Texas

Mary P. Bronner, M.D.
Department of Pathology, University of Washington, School of Medicine, Seattle, Washington

Randall W. Burt, M.D.
Professor of Medicine, Division of Gastroenterology, Department of Internal Medicine, University of Utah School of Medicine; Senior Director for Prevention and Outreach, Huntsman Cancer Institute at the University of Utah, Salt Lake City, Utah

Michael Camilleri, M.D.
Professor of Medicine and Physiology, Mayo Medical School; Consultant in Gastroenterology, Mayo Clinic, Rochester, Minnesota

Mitchell S. Cappell, M.D., Ph.D.
Associate Professor, Department of Medicine, State University of New York Downstate Medical Center; Vice Chairman, Department of Medicine, Chief, Division of Gastroenterology, Woodhull Medical and Mental Health Center, Brooklyn, New York

John M. Carethers, M.D.
Associate Professor of Medicine, Department of Medicine, University of California, San Diego; Chief, Gastroenterology Section, Department of Medicine Services, Veterans Affairs San Diego Healthcare System, San Diego, California

Donald O. Castell, M.D.
Professor, Department of Medicine, Division of Gastroenterology and Hepatology, Medical University of South Carolina, Charleston, South Carolina

Lin Chang, M.D.
Associate Professor, David Geffen School of Medicine at UCLA; Head of Clinical Research Operations, UCLA/CURE Neuroenteric Disease Program, Los Angeles, California

William D. Chey, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology, Univerisy of Michigan Health System, Ann Arbor, Michigan

William Y. Chey, M.D.
Professor of Internal Medicine, Konar Center for Digestive and Liver Diseases, University of Rochester Medical Center, Rochester, New York

Denesh K. Chitkara, M.D.
Fellow in Pediatric Gastroenterology, Harvard Medical School, Cambridge, Massachusetts

Kyung J. Cho, M.D.
Professor, Department of Radiology, University of Michigan Health System, Ann Arbor, Michigan

Gregory M. Christman, M.D.
Assistant Professor and Assistant Research Scientist, Department of Obstetrics and Gynecology and Reproductive Sciences Program, University of Michigan Health System, Ann Arbor, Michigan

Paul J. Ciclitira, M.D., Ph.D., F.R.C.P.
Gastroenterology Unit, Rayne Institute, St. Thomas Hospital, London, United Kingdom

Nadine Clerc, M.D.
Directeur de Recherche 2éme classe CNRS, ITIS (InTégration des Informations Sensorielles), Centre Nationale de la Recherche Scientifique (CNRS), Marseille, France

Ray E. Clouse, M.D.
Professor of Medicine and Psychiatry, Department of Medicine, Division of Gastroenterology, Washington University School of Medicine; Physician, Department of Medicine, Barnes-Jewish Hospital, St. Louis, Missouri

Steven M. Cohn, M.D., Ph.D.
Paul Janssen Associate Professor of Medicine; Attending Physician, Digestive Health Center of Excellence, University of Virginia Health System, Charlottesville, Virginia

David W. Crabb, M.D.
John B. Hickam Professsor and Chair, Department of Medicine, Indiana University Medical Center, Indianapolis, Indiana

Karen D. Crissinger, M.D., Ph.D.
Professor, Department of Pediatrics and Physiology, University of South Alabama; Physician, USA Children’s and Women’s Hospital, Mobile, Alabama

Nicholas O. Davidson, M.D.
Professor of Medicine and of Molecular Biology and Pharmacology; Director, Division of Gastroenterology, Department of Medicine, Washington University Medical School; Attending Physician, Department of Medicine, Barnes-Jewish Hospital, St. Louis, Missouri

Khaldoun A. Debian, M.D.
Assistant Professor of Clinical Medicine, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine at the University of Southern California, Los Angeles, California

Laurie D. DeLeve, M.D., Ph.D.
Associate Professor, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine of the University of Southern California, Los Angeles, California

John Del Valle, M.D.
Professor and Senior Associate Chair of Internal Medicine, University of Michigan Health System, Ann Arbor, Michigan

Graham J. Dockray, Ph.D.

Professor, Physiological Laboratory, University of Liverpool, Liverpool, United Kingdom

John A. Donovan, M.D.
Assistant Professor of Clinical Medicine, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine of the University of Southern California, Los Angeles, California

Jeffrey A. Drebin, M.D., Ph.D.
Associate Professor, Division of General Sugery, Section of Hepatobiliary, Pancreatic, and Gastrointestinal Surgery, Washington University School of Medicine, St. Louis, Missouri

Douglas A. Drossman, M.D.
University of North Carolina-Chapel Hill, Digestive Diseases and Nutrition, Chapel Hill, North Carolina

Gerald W. Dryden, M.D.
Assistant Professor, Department of Internal Medicine, University of Louisville Health Sciences Center, Louisville, Kentucky

John P. Duffy, M.D.
Resident, Division of General Surgery, David Geffen School of Medicine at UCLA, Los Angeles, California

Brian J. Dunkin, M.D.
Assistant Professor; Chief, Section of Surgical Endoscopy, Department of Surgery, University of Miami School of Medicine, Miami, Florida

Frederic E. Eckhauser, M.D.
Section of Surgical Sciences, Johns Hopkins Bayview Medical Center, Baltimore, Maryland

H. Julia Ellis, S.R.D., B.Sc., Ph.D.
Gastroenterology Unit, Rayne Institute, St. Thomas Hospital, London, United Kigdom

Grace H. Elta, M.D.
Professor, Department of Internal Medicine, Division of Gastroentenology, University of Michigan Health System, Ann Arbor, Michigan

B. Mark Evers, M.D.
Professor and Robertson-Poth Distinguished Chair in Surgery, Department of Surgery, The University of Texas Medical Branch, Galveston, Texas

Douglas O. Faigel, M.D.
Associate Professor of Medicine, Department of Medicine, Division of Gastroenterology, Oregon Health and Science University, Portland Veterans Affairs Medical Center, Portland, Oregon

George T. Fantry, M.D.
Associate Professor; Director, Clinical Gastroenterology, Department of Medicine, University of Maryland, Baltimore, Maryland

Lori E. Fantry, M.D.
Assistant Professor, Department of Medicine, University of Maryland, Baltimore, Maryland

Richard N. Fedorak, M.D.
Professor of Medicine, Department of Medicine, University of Alberta; Director, Division of Gastroenterology, University of Alberta Hospital, Edmonton, Alberta, Canada

Alessandro Fichera, M.D.
Attending Surgeon, Department of Surgery, The University of Chicago, Chicago, Illinois

Robert S. Fisher, M.D.
Professor, Department of Medicine, Temple University School of Medicine; Chief of Gastroenterology, Temple University Hospital, Philadelphia, Pennsylvania

Ira J. Fox, M.D.
Professor, Department of Surgery, University of Nebraska Medical Center, Omaha, Nebraska

Martin L. Freeman, M.D.
Associate Professor, Department of Medicine, Division of Gastroenterology, Hennepin County Medical Center, Minneapolis, Minnesota

John B. Furness, Ph.D.
Professor, Department of Anatomy and Cell Biology, University of Melbourne, Parkville, Victoria, Australia

Malliga E. Ganapathy, M.D.
Associate Professor, Department of Medicine, Medical College of Georgia, Augusta, Georgia

Vadivel Ganapathy, Ph.D.
Regents’ Professor and Interim Chair, Department of Biochemistry and Molecular Biology, Medical College of Georgia, Augusta, Georgia

Robert M. Genta, M.D.
Adjunct Professor of Pathology and Medicine, Baylor College of Medicine, Houston, Texas; Professeur de Pathologie, Université de Gèneve, Division de Pathologie Clinique, Hopital Universitaire de Gèneve, Geneva, Switzerland

Marc G. Ghany, M.D.
Staff Clinician, Liver Diseases Section, Digestive Disease Branch, National Institute of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health, Bethesda, Maryland

Ralph A. Giannella, M.D.
Mark Brown Professor of Medicine; Director, Division of Digestive Diseases, University of Cincinnati College of Medicine, Cincinnati, Ohio

Robert G. Gish, M.D.
Associate Professor, Department of Medicine, University of California, San Francisco; Medical Director, Liver Disease Management and Transplant Program, California Pacific Medical Center, San Francisco, California

Fred S. Gorelick, M.D.
Professor, Department of Medicine and Cell Biology, Yale University School of Medicine, New Haven, Connecticut; and Staff Physician, Department of Medicine and Research, Veterans Affairs Healthcare, Connecticut, West Haven, Connecticut

Gregory J. Gores, M.D.

Professor, Department of Medicine, Mayo Clinic, Rochester, Minnesota

Sugantha Govindarajan, M.D.
Professor, Department of Pathology, Keck School of Medicine of the University of Southern California, Los Angeles, California

Richard J. Grand, M.D.
Professor of Pediatrics, Harvard Medical School; Director, Inflammatory Bowel Disease Program, Children's Hospital Boston, Boston, Massachusetts

D. Neil Granger, Ph.D.
Boyd Professor and Head, Department of Molecular and Cellular Physiology, Louisiana State University Health Science Center, Shreveport, Louisiana

Harry B. Greenberg, M.D.
Senior Associate Dean for Research, Stanford University School of Medicine, Stanford, California; and Professor of Medicine and Microbiology and Immunology, Department of Gastroenterology and Hepatology, Stanford University and Veterans Affairs Palo Alto Health Care System, Palo Alto, California

Charles H. Halsted, M.D.
Professor of Internal Medicine, Division of Clinical Nutrition, University of California, Davis School of Medicine, Davis, California

Karen M. Harnett, Ph.D.
Assistant Professor of Medicine and Molecular Pharmacology, Physiology and Biotechnology (Research), Brown Medical School, Gastroenterology Motility Research Laboratory, Rhode Island Hospital, Providence, Rhode Island

William L. Hasler, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan

Peter C. Hayes, M.D.
Professor of Hepatology and Internal Medicine, The University of Edinburgh, Royal Infirmary, Edinburgh, United Kigdom

E. Jenny Heathcote, M.B., B.S., M.D., F.R.C.P., F.R.C.P.(C.)
Professor of Medicine, Department of Medicine, University of Toronto; Staff Gastroenterologist, Department of Medicine, Toronto Western Hospital, Toronto, Canada

Gail Hecht, M.D.
Professor, Department of Medicine, University of Illinois at Chicago; Chief, Section of Digestive Diseases and Nutrition, University of Illinois Medical Center, Chicago, Illinois

Hans Herlinger, M.D.
Professor of Gastrointestinal Radiology, University of Pennsylvania Health System, Philadelphia, Pennsylvania

Richard A. Hodin, M.D.
Associate Professor of Surgery, Harvard Medical School; Chief, Division of General Surgery, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Mark Holodniy, M.D.
Associate Professor of Medicine, Infectious Diseases and Geographic Medicine, Stanford University School of Medicine, Stanford, California

Gerald J. Holtmann, M.D.
Professor of Medicine, Department of Gastroenterology, University of Essen, Essen, Germany

Simon Horslen, M.D.
Assistant Professor, Department of Pediatrics; Intestinal Failure Clinic, University of Nebraska Medical Center, Omaha, Nebraska

Arnold F. Jacobson, M.D., Ph.D.
Associate Director, Clinical Research, Amersham Health, Princeton, New Jersey

Russell F. Jacoby, M.D.
Associate Professor, Department of Medicine, University of Wisconsin; Director, Colon Cancer Prevention Program, University of Wisconsin Comprehensive Cancer Center, Madison, Wisconsin

Oliver F. W. James, F.R.C.P., F. Med. Sci.
Professor and Head, School of Clinical Medical Sciences, University of Newcastle upon Tyne; Physician, The Liver Unit, Freeman Hospital, Newcastle upon Tyne, United Kingdom

Stephen P. James, M.D.
Deputy Director, Division of Digestive Diseases and Nutrition, National Institute of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health, Bethesda, Maryland

Edward N. Janoff, M.D.
Professor, Department of Medicine, University of Minnesota; Division of Infectious Diseases, Veterans Administration Medical Center, Minneapolis, Minnesota

R. Brooke Jeffrey, M.D.
Professor, Department of Radiology, Associate Dean for Academic Medicine, Stanford University School of Medicine, Stanford, California

Robert T. Jensen, M.D.
Chief, Digestive Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, Maryland

Joseph L. Jorizzo, M.D.
Professor and Former (Founding) Chair, Department of Dermatology, Wake Forest University School of Medicine, Winston-Salem, North Carolina

Peter J. Kahrilas, M.D.
Gilbert H. Marquardt Professor of Medicine, Division of Gastroenterology, Department of Medicine, Feinberg School of Medicine, Northwestern University; Chief, Division of Gastroenterology, Department of Medicine, Northwestern Memorial Hospital, Chicago, Illinois

Robert A. Kane, M.D.
Professor, Department of Radiology, Harvard Medical School; and Director, Ultrasound Section, Radiology Department, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Gary C. Kanel, M.D.
Professor, Department of Pathology, Keck School of Medicine of the University of Southern California, Los Angeles, California; Associate Pathologist, Department of Pathology, Rancho Los Amigos National Rehabilitation Center, Downey, California

Philip O. Katz, M.D.

Director, Gastroenterology Division, Department of Medicine, Graduate Hospital, Philadelphia, Pennsylvania

Umaprasanna S. Karnam, M.D.
Consultant, Department of Gastroenterology and Hepatology, Central Utah Medical Clinic, American Fork, Utah

Emmet B. Keeffe, M.D.
Professor of Medicine, Department of Medicine, Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Palo Alto, California; Chief of Hepatology, Co-Director, Liver Transplant Program, Stanford University Medical Center, Stanford, California

Stephen J. Keely, Ph.D.
Assistant Project Scientist, Division of Gastroenterology, Department of Medicine, University of California, San Diego Medical Center, San Diego, California

Nyingi Kemmer, M.D.
Staff Hepatologist, Division of Gastroenterology and Hepatology, Scripps Clinic, La Jolla, California

Michael B. Kimmey, M.D.
Professor, Department of Medicine, Division of Gastroenterology, University of Washington; Chief of Gastroenterology, University of Washington Medical Center, Seattle, Washington

Samuel Klein, M.D.
William H. Danforth Professor of Medicine and Nutritional Science, Center for Human Nutrition, Washington University School of Medicine, St. Louis, Missouri

James A. Knol, M.D.
Associate Professor, Department of Surgery; Attending Surgeon, Division of Gastrointestinal Surgery, University of Michigan Health System, Ann Arbor, Michigan

Cynthia W. Ko, M.D., M.S.
Assistant Professor, Department of Medicine, Division of Gastroenterology, University of Washington, Seattle, Washington

Judith Korner, M.D., Ph.D.
Florence Irving Assistant Professor of Medicine, Department of Medicine, Columbia University, New York, New York

Joshua R. Korzenik, M.D.
Assistant Professor, Department of Medicine, Division of Gastroenterology, Washington University School of Medicine, St. Louis, Missouri

Richard A. Kozarek, M.D.
Clinical Professor of Medicine, University of Washington; Chief of Gastroenterology, Virginia Mason Medical Center, Seattle, Washington

Kristine Krueger, M.D.
Associate Professor, Department of Internal Medicine, University of Louisville, Louisville, Kentucky

Wolfgang A. A. Kunze, M.D.
Department of Anatomy and Cell Biology, University of Melbourne, Parkville, Victoria, Australia

Uri Ladabaum, M.D., M.S.
Assistant Clinical Professor, Department of Medicine, Division of Gastroenterology, University of California, San Francisco, San Francisco, California

James Y. W. Lau, M.D.
Consultant Surgeon, Departments of Medicine and Surgery, Prince of Wales Hospital, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

Igor Laufer, M.D.
Professor, Department of Radiology, Hospital of the University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Sum P. Lee, M.D., Ph.D.
Professor and Division Head, Department of Medicine, Division of Gastroenterology, University of Washington; Section Chief, Gastroenterology Section, Primary and Specialty Medical Care, Veterans Affairs Puget Sound Health Care System, Seattle, Washington

William M. Lee, M.D.
Professor, Department of Internal Medicine, University of Texas Southwestern Medical School; and Attending Physician, Department of Internal Medicine, Parkland Memorial Hospital, Dallas, Texas

Glen A. Lehman, M.D.
Professor of Medicine and Radiology, Department of Gastroenterology and Hepatology, Indiana University Medical Center, Indianapolis, Indiana

Frederick Leibach, Ph.D.
Professor and Chair Emeritus, Department of Biochemistry and Molecular Biology, Medical College of Georgia, Augusta, Georgia

Wai K. Leung, M.D.
Associate Professor, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, New Territories, Hong Kong

Marc S. Levin, M.D.
Associate Professor, Department of Medicine, Washington University School of Medicine; Staff Physician, Barnes-Jewish Hospital, St. Louis, Missouri

Joel S. Levine, M.D.
Professor of Medicine, Division of Gastroenterology and Hepatology, University of Colorado Health Sciences Center, Denver, Colorado

Marc S. Levine, M.D.
Professor of Radiology, Department of Radiology, University of Pennsylvania School of Medicine; Chief, Gastrointestinal Radiology Section, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Ellen Li, M.D., Ph.D.
Professor, Department of Medicine, Division of Gastroenterology, Attending Physician, Barnes-Jewish Hospital, Washington University School of Medicine, St. Louis, Missouri

T. Jake Liang, M.D.
Chief, Liver Diseases Section, Digestive Diseases Branch, National Institutes of Diabetes, Digestive and Kidney Diseases, National Institutes of Health; Chief Staff Physician, Hepatology Service, National Institutes of Health Clinical Center, Bethesda, Maryland

Stephen Locarnini, M.D., Ph.D.

Associate Professor, Research and Molecular Development, Victorian Infectious Diseases Reference Laboratory, North Melbourne, Victoria, Australia

John D. Long, M.D.
Assistant Professor of Medicine, Department of Medicine, Division of Digestive Diseases, University of Cincinnati College of Medicine; Director, GI Clinic, Department of Medicine, University Hospital, Cincinnati, Ohio

Bo L. Lönnerdal, Ph.D.
Professor, Department of Nutrition, University of California, Davis, Davis, California

Shelly C. Lu, M.D.
Professor of Medicine, Department of Medicine, Division of Gastroenterology and Liver Diseases, Keck School of Medicine of the University of Southern California, Los Angeles, California

Lawrence Lumeng, M.D.
Professor, Departments of Medicine and Biochemistry/Molecular Biology; Chief, Division of Gastroenterology and Hepatology, Indiana University School of Medicine, Richard L. Roudebush Veterans Affairs Medical Center, Indianapolis, Indiana

Finlay A. Macrae, M.G.S., M.D., F.R.A.C.P., F.R.C.P.
Professor, Department of Medicine, University of Melbourne; Head, Colorectal Medicine and Genetics, The Royal Melbourne Hospital, Parkville, Victoria, Australia

James L. Madara, M.D.
Dean and Richard T. Crane Professor, Division of the Biological Science, University Vice-President for Medical Affairs, Pritzker School of Medicine, University of Chicago, Chicago, Illinois

James K. Madison, Ph.D.
Assistant Professor, Department of Psychiatry, Creighton University School of Medicine, Omaha, Nebraska

Gabriel M. Makhlouf, M.D., Ph.D., F.R.C.P.
Professor of Medicine; Director of Gastroenterology Research, Department of Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia

Suzanne M. Matsui, M.D.
Assistant Professor, Department of Medicine, Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, California

Gary M. Mawe, Ph.D.
Professor, Department of Anatomy and Neurobiology, University of Vermont, Burlington, Vermont

Marlyn J. Mayo, M.D.
Assistant Professor, Department of Internal Medicine, University of Texas, Southwestern Medical Center at Dallas, Dallas, Texas

Craig J. McClain, M.D.
Professor, Department of Medicine, University of Louisville; Chief, Department of Hepatology, University of Louisville/Jewish Hospital and Louisville Veterans Affairs Medical Center, Louisville, Kentucky

Alec J. Megibow, M.D., M.P.H., F.A.C.R.
Professor, Department of Radiology, New York University School of Medicine, New York, New York

Michel H. Mendler, M.D.
Assistant Professor of Clinical Medicine, Division of Gatrointestinal and Liver Diseases, Keck School of Medicine of the University of Southern California, Los Angeles, California

Raphael B. Merriman, M.D., M.R.C.P.I.
Clinical Instructor of Medicine, Department of Medicine, University of California, San Francisco; Attending Hepatologist, UCSF Medical Center, San Francisco, California

Fabrizio Michelassi, M.D.
Thomas D. Jones Professor and Chief, Department of Surgery, University of Chicago, Chicago, Illinois

Laurence J. Miller, M.D.
Professor of Medicine; Professor of Biochemistry and Molecular Biology, Mayo Medical School; Director, Cancer Center, Mayo Clinic Scottsdale, Scottsdale, Arizona

Satoshi Minoshima, M.D., Ph.D.
Professor, Department of Radiology, University of Washington Medical School, Seattle, Washington

Donald G. Mitchell, M.D.
Professor, Department of Radiology, Jefferson Medical College; Director, Magnetic Resonance Imaging Division, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania

Marshall H. Montrose, M.D.
Professor, Department of Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, Indiana

Richard H. Moseley, M.D.
Professor, Department of Medicine, Division of Gastroenterology, University of Michigan Health System; Chief, Medical Service, Ann Arbor Veterans Affairs Medical Center, Ann Arbor, Michigan

Peter L. Moses, M.D.
Associate Professor of Medicine, Department of Gastroenterology and Hepatology, University of Vermont, Burlington, Vermont; Attending Physician, Department of Medicine/Gastroenterology and Hepatology, Fletcher Allen Health Care, South Burlington, Vermont

Michael W. Mulholland, M.D., Ph.D.
Chairman and Professor, Department of Surgery, University of Michigan Health System, Ann Arbor, Michigan

Mark E. Murphy, M.D.
Assistant Professor, Department of Internal Medicine, Division of Digestive and Liver Diseases, Mercer University School of Medicine, Savannah Campus, Savannah, Georgia

Deborah W. Neklason, Ph.D.
Research Instructor, Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah Health Sciences Center, Salt Lake City, Utah

Enders K. W. Ng, M.D.

Adjunct Associate Professor, Department of Surgery, The Chinese University of Hong Kong; Senior Medical Officer, Department of Surgery, Prince of Wales Hospital, Shatin, New Territories, Hong Kong

Timothy T. Nostrant, M.D.
Professor, Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan

Alex Novogrudsky, M.D.
Teaching Assistant, Department of Medicine, New York University School of Medicine, New York, New York

Eric K. Outwater, M.D.
Professor, Department of Radiology, The University of Arizona College of Medicine; Head, Cross-Sectional Imaging Section, Arizona Health Sciences Center, Tucson, Arizona

Chung Owyang, M.D.
Professor of Internal Medicine; H. Marvin Pollard Collegiate Professor and Chief, Division of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan

Stephen J. Pandol, M.D.
Professor, Department of Medicine, University of California, Los Angeles; Staff Physician, Veterans Affairs Greater Los Angeles Healthcare System, Los Angeles, California

John E. Pandolfino, M.D.
Assistant Professor of Medicine of Gastroenterology, Feinberg School of Medicine, Northwestern University, Evanston, Illinois

Julián Panés, M.D.
Assistant Professor, Department of Medicine, University of Barcelona; Consultant, Department of Gastroenterology, Hospital Clinic, Barcelona, Spain

Sareh Parangi, M.D., F.A.C.S.
Assistant Professor, Department of Surgery, Harvard Medical School; Attending Surgeon, Department of Surgery, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Henry P. Parkman, M.D.
Associate Professor, Department of Medicine, Temple University School of Medicine; Director, GI Motility Laboratory, Department of Medicine, Temple University Hospital, Philadelphia, Pennsylvania

Pankaj Jay Pasricha, M.D.
Professor, Department of Internal Medicine; Director, Division of Gastroenterology and Hepatology, The University of Texas Medical Branch, Galveston, Texas

Richard D. Pearson, M.D.
Professor, Departments of Internal Medicine and Pathology, Division of Infectious Diseases and International Health, University of Virginia Health System, Charlottesville, Virginia

Marion G. Peters, M.D.
Professor of Medicine; Chief of Hepatology Research, Department of Medicine, Division of Gastroenterology, University of California, San Francisco; Attending Physician, Department of Medicine, Moffitt-Long Hospital, San Francisco, California

Elizabeth M. Petty, M.D.
Associate Professor, Departments of Internal Medicine and Human Genetics, University of Michigan; Director, Medical Genetics Clinic, University of Michigan Health System, Ann Arbor, Michigan

Lana N. Pho, M.S.
Genetics Counselor, Huntsman Cancer Institute, University of Utah Health Sciences Center, Salt Lake City, Utah

Josep M. Piqués, M.D.
Associate Professor, Department of Medicine, University of Barcelona; Chief, Department of Gastroenterology, Hospital Clinic, Barcelona, Spain

Andrew G. Plaut, M.D.
Professor, Department of Medicine, Tufts University School of Medicine, Tufts-New England Medical Center, Boston, Massachusetts

Daniel K. Podolsky, M.D.
Mallinckrodt Professor of Medicine, Harvard Medical School; Division Chief, Gastroenterology; Director, Center of the Study of Inflammatory Bowel Disease, Massachusetts General Hospital, Boston, Massachusetts

Jeffrey L. Ponsky, M.D.
Director, Endoscopic Surgery, Department of General Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio

Don W. Powell, M.D.
Associate Dean for Research; Professor, Department of Internal Medicine, University of Texas Medical Branch, Galveston, Texas

Maria J. Pozo, Pharm.D., Ph.D.
Professor, Department of Physiology, University of Extremadura, Caceres, Spain

Dawn Provenzale, M.D., M.S.
Associate Professor of Medicine, Department of Medicine, Director, GI Outcomes Research, Department of Medicine/Gastroenterology, Duke University Medical Center, Durham, North Carolina

John C. Rabine, M.D.
Adjunct Professor; Chief of Gastroenterology, Department of Internal Medicine, Division of Gastroenterology, David Grant Medical Center, Travis Air Force Base, California

Emad Y. Rahmani, M.D., F.A.C.P.
Associate Professor, Department of Medicine, Indiana University; Director of Gastrointestinal Endoscopy, Wishard Memorial Hospital, Indianapolis, Indiana

David S. Raiford, M.D.
Associate Professor, Department of Medicine, Division of Gastroenterology, Hepatology, and Nutrition, Vanderbilt University School of Medicine; Director, Liver Service, Vanderbilt University Medical Center, Nashville, Tennessee

Philip W. Ralls, M.D.
Professor and Vice Chair, Department of Radiology, Keck School of Medicine of the University of Southern California, Los Angeles, California

Jean-Pierre Raufman, M.D.
Moses and Helen Golden Professor of Medicine; Head, Division of Gastroenterology and Hepatology, University of Maryland School of Medicine, Baltimore, Maryland

Helen E. Raybould, Ph.D.
Professor, Department of Anatomy, Physiology, and Cell Biology, School of Veterinary Medicine, University of California, Davis, Davis, California

Howard A. Reber, M.D.
Professor of Surgery, Division of General Surgery, Section of Gastrointestinal Surgery, David Geffen School of Medicine at UCLA, Los Angeles, California

K. Rajender Reddy, M.D.
Professor of Medicine and Surgery; Director of Hepatology, Medical Director of Liver Transplantation, University of Pennsylvania, Philadelphia, Pennsylvania

Douglas K. Rex, M.D.
Professor of Medicine, Division of Gastroenterology and Hepatology, Indiana University Medical Center; Director of Endoscopy, Department of Gastroenterology, Indiana University Hospital, Indianapolis, Indiana

Joel E. Richter, M.D.
Professor of Medicine, Cleveland Clinic Lerner College of Medicine, Case Western Reserve University; Chairman, Department of Gastroenterology and Hepatology, Cleveland Clinic Foundation, Cleveland, Ohio

Richard A. Rippe, Ph.D.
Associate Professor of Medicine, Division of Digestive Diseases and Nutrition, School of Medicine, University of North Carolina, Chapel Hill, North Carolina

Michelle L. Robbin, M.D.
Associate Professor; Chief of Ultrasound, Department of Radiology, University of Alabama at Birmingham, Birmingham, Alabama

Lewis R. Roberts, M.D., Ph.D.
Assistant Professor, Department of Internal Medicine, Mayo Medical School; and Senior Associate Consultant, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota

Jayanta Roy-Chowdhury, M.B.B.S.
Professor, Departments of Medicine and Molecular Genetics, Marion Bessin Liver Research Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York

Namita Roy-Chowdhury, Ph.D.
Professor, Departments of Medicine and Molecular Genetics, Marion Bessin Liver Research Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York

Stephen E. Rubesin, M.D.
Professor, Department of Radiology, University of Pennsylvania School of Medicine; and Radiologist, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Cyrus E. Rubin, M.D.
Professor Emeritus, Departments of Medicine and Pathology; Gastrointestinal Pathologist, Deparment of Anatomic Pathology, University of Washington Medical Center, Seattle, Washington

Deborah C. Rubin, M.D.
Associate Professor, Department of Medicine, Division of Gastroenterology, Washington University School of Medicine; Attending Physician and Gastroenterologist, Barnes-Jewish Hospital, St. Louis, Missouri

Bruce A. Runyon, M.D.
Professor of Medicine, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine of the University of Southern California; and Chief, Liver Service, Department of Medicine, Rancho Los Amigos National Rehabilitation Center, Los Angeles, California

Anil K. Rustgi, M.D.
T. Grier Miller Professor of Medicine and Genetics; Chief of Gastroenterology, Department of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Edward Rydzak, M.D.
Assistant Professor, Department of Internal Medicine, Division of Digestive and Liver Diseases, Mercer University Medical School, Savannah Campus, Savannah, Georgia

Michael G. Sarr, M.D.
Professor, Department of Surgery, Mayo Medical School; Consultant, Division of Gastroenterology and General Surgery, Mayo Clinic, Rochester, Minnesota

R. Balfour Sartor, M.D.
Professor, Department of Medicine, Microbiology, and Immunology; Director, Center for IBD Research and Treatment, Division of Digestive Diseases, School of Medicine, University of North Carolina, Chapel Hill, North Carolina

Adrienne M. Scheich, M.D.
Senior Research Fellow, Division of Pediatric Gastroenterology and Nutrition, Floating Hospital for Children at Tufts-New England Medical Center, Boston, Massachusetts

James M. Scheilman, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology; Director, Endoscopic Ultrasound Program, University of Michigan Health System, Ann Arbor, Michigan

Frank V. Schiødt, M.D.
Assistant Professor, Department of Gastroenterology, Rigshospitalet, Copenhagen, Denmark

Philip S. Schoenfeld, M.D., M.S.Ed., M.Sc.(Epi.)
Assistant Professor, Department of Internal Medicine, Department of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan

Neal E. Seymour, M.D.
Chief, Section of General Surgery, Vice Chairman of Surgery, Baystate Medical Center, Springfield, Massachusetts

Fergus Shanahan, M.D.
Professor and Chair, Department of Medicine, University College Cork, National University of Ireland; Professor, Department of Medicine, Cork University Hospital, Cork, Ireland

Elizabeth F. Sherertz, M.D.
The Skin Surgery Center, Winston-Salem, North Carolina

Stuart Sherman, M.D.
Professor of Medicine and Radiology, Indiana University School of Medicine; Director, ERCP Service, Indiana University Medical Center, Indianapolis, Indiana

Diane M. Simeone, M.D.
Assistant Professor, Department of Surgery; Attending Surgeon, University of Michigan Health System, Ann Arbor, Michigan

Kenneth J. Simpson, M.D., Ph.D.
Senior Lecturer, Department of Internal Medicine, The University of Edinburgh; Consultant Physician, Scottish Liver Transplant Unit, Royal Infirmary, Edinburgh, United Kingdom

Phillip D. Smith, M.D.
Mary J. Bradford Professor in Gastroenterology; Professor of Medicine and Microbiology, University of Alabama at Birmingham; Staff Physician, Birmingham Veterans Affairs Medical Center, Birmingham, Alabama

Ronald J. Sokol, M.D.
Professor and Vice Chair, Department of Pediatrics, University of Colorado Health Sciences Center, Program Director, Pediatric General Clinical Research Center, The Children's Hospital, Denver, Colorado

Cindy Solomon, M.S.
MELARIS Product Manager, Myriad Genetic Laboratories, Salt Lake City, Utah

Nathaniel J. Soper, M.D.
Professor, Department of Surgery, Washington University School of Medicine; Head, Minimally Invasive Surgery, Department of Surgery, Barnes-Jewish Hospital, St. Louis, Missouri

Samuel L. Stanley, Jr., M.D.
Professor, Department of Medicine, Washington University School of Medicine; Attending Physician, Department of Medicine, Barnes-Jewish Hopsital, St. Louis, Missouri

Martin J. Stebbing, Ph.D.
Senior Research Fellow, Department of Anatomy and Cell Biology, University of Melbourne, Parkville, Victoria, Australia

William F. Stenson, M.D.
Professor, Department of Medicine, Division of Gastroenterology, Washington University School of Medicine; Attending Physician, Department of Medicine, Barnes-Jewish Hopsital, St. Louis, Missouri

Steven M. Strasberg, M.D.
Professor and Section Head, Department of Surgery, Section of Hepatobiliary, Pancreatic, and Gastrointestinal Surgery, Washington University School of Medicine, St. Louis, Missouri

Robert W. Summers, M.D.
Professor of Internal Medicine, Division of Gastroenterology and Hepatology, University of Iowa Roy and Lucille A. Carver College of Medicine, Director of Clinical Activities, Center for Digestive Diseases, University of Iowa Health Care, Iowa City, Iowa

Weijung Sun, M.D.
Assistant Professor, Department of Medicine, Division of Hematology/Oncology, University of Pennsylvania; Attending Physician, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Joseph J. Y. Sung, M.D., Ph.D.
Professor of Medicine; Chief, Gastroenterology and Hepatology, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, New Territories, Hong Kong

Paul Swain, M.D.
Professor and Consultant Gastroenterologist, Department of Gastroenterology, The Royal London Hospital, Whitechapel, London, United Kingdom

John F. Sweeney, M.D.
Associate Professor, Michael E. DeBakey Department of Surgery, Baylor College of Medicine, Houston, Texas

Nicholas J. Talley, M.D., Ph.D.
Professor of Medicine, University of Sydney, Nepean Hospital, Penrith, New South Wales, Australia

Jayant A. Talwalkar, M.D., M.P.H.
Instructor of Medicine, Department of Internal Medicine, Mayo Medical School; and Senior Associate Consultant, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota

Rebecca A. Taub, M.D.
Executive Director, Biology Research, Bristol-Myers Squibb Company, Wallingford, Connecticut

Alicia M. Terando, M.D.
Resident in Surgery, Department of Surgery, University of Michigan Health System, Ann Arbor, Michigan

Dwain L. Thiele, M.D.
Professor of Internal Medicine; Interim Chief, Digestive and Liver Diseases, Chief of Hepatology, Department of Internal Medicine, University of Texas Southwestern Medical Center at Dallas, Chief, Liver Diseases, Parkland Memorial Hospital, Dallas, Texas

Andrea Todisco, M.D.
Associate Professor; Attending Physician, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan

Mark Topazian, M.D.
Associate Professor of Medicine, Department of Internal Medicine, Section of Digestive Diseases, Yale University School of Medicine, New Haven, Connecticut

Peter G. Traber, M.D.
GlaxoSmithKline, King of Prussia, Pennsylvania

Guido N. J. Tytgat, M.D., Ph.D.
Professor, Department of Gastroenterology and Hepatology, Faculty of Medicine, University of Amsterdam; and Chief, Department of Gastroenterology and

Hepatology, Academic Medical Center, Amsterdam, The Netherlands

Peter Vilmann, M.D.Sc.
Associate Professor, Copenhagen University; and Consultant Surgeon, Department of Surgical Gastroenterology, Gentofte University Hospital, Hellerup, Denmark

Fivos Vogalis, M.D., Ph.D.
C.R. Roper Research Fellow, Department of Anatomy and Cell Biology, University of Melbourne, Parkville, Victoria, Australia

Arnold Wald, M.D.
Professor of Medicine, Division of Gastroenterology, Hepatology, and Nutrition; Director, Fellowship Training in Gastroenterology, Hepatology, and Nutrition, Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Paul B. Watkins, M.D.
Verne S. Caviness Distinguished Professor of Medicine; Director, General Clinical Research Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Jerome D. Waye, M.D.
Clinical Professor of Medicine, Department of Medicine, Division of Gastroenterology, Mount Sinai Medical Center; Director of Endoscopic Education, Mount Sinai Hospital; and Chief, Gastrointestinal Endoscopy Unit, Lenox Hill Hospital, New York, New York

Steven A. Weinman, M.D., Ph.D.
Professor, Internal Medicine and Physiology and Biophysics, The University of Texas Medical Branch, Galveston, Texas

David C. Whitcomb, M.D., Ph.D.
Professor of Medicine, Cell Biology and Physiology, and Human Genetics; Chief, Division of Gastroenterology, Hepatology, and Nutrition; Director, Center for Genomic Sciences, University of Pittsburgh, Pittsburgh, Pennsylvania

Russell H. Wiesner, M.D.
Professor of Medicine, Mayo Clinic Transplant Center, Mayo Medical School; Director of Viral Hepatitis, Liver Transplant Program, Mayo Clinic, Rochester, Minnesota

C. Mel Wilcox, M.D.
Professor, Department of Medicine, Division of Gastroenterology and Hepatology, University of Alabama at Birmingham, Birmingham, Alabama

John W. Wiley, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System; and Program Director, General Clinical Research Center, University of Michigan, Ann Arbor, Michigan

Christopher B. Williams, M.B., B.S., M.D., F.R.A.C.P
Consultant Physician, St. Mark's Hospital, Wolfsone Unit for Endoscopy, London, United Kingdom

John A. Williams, M.D.
Professor, Departments of Internal Medicine and Physiology, University of Michigan Health System, Ann Arbor, Michigan

Francis Y. K. Yao, M.D.
Associate Clinical Professor, Department of Medicine, Associate Medical Director, Liver Transplantation, University of California, San Francisco, San Francisco, California

Hal F. Yee, Jr., M.D., Ph.D.
Assistant Professor of Medicine and Physiology, Division of Digestive Diseases, David Geffen School of Medicine at UCLA; Attending Physician, UCLA Medical Center, Los Angeles, California

Graeme P. Young, M.D.
Professor of Gastroenterology, Department of Medicine, Flinders University of South Australia; Director, Department of Gastroenterology, Flinders Medical Centre, Adelaide, South Australia, Australia

Renée L. Young, M.D.
Associate Professor of Internal Medicine, Section of Gastroenterology and Hepatology, Omaha Veterans Affairs Medical Center, University of Nebraska Medical Center, Omaha, Nebraska

Tonia M. Young-Fadok, M.D., M.S., F.A.C.S., F.A.S.C.R.S.
Associate Professor of Surgery, Mayo Medical School; Consultant Surgeon, Division of Colon and Rectal Surgery, Mayo Clinic, Rochester, Minnesota

Ellen M. Zimmermann, M.D.
Associate Professor, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor, Michigan

Gregory Zuccaro, Jr., M.D.
Director, Center for Endoscopy and Diseases of the Pancreas and Bile Ducts, Department of Gastroenterology and Hepatology, Cleveland Clinic Foundation, Cleveland, Ohio

PREFACE

In the 16 years or so since we initiated our project to develop a textbook that would serve the needs of students and practitioners of gastroenterology in the 1990s and beyond, the discipline has undergone changes that have exceeded our wildest predictions. The rate of progress in the science of gastroenterology has been so dramatic that the concepts of diagnosis and treatment by which we approached patients with the most common gastrointestinal disorders—such as peptic ulcer disease, cholecystitis, and colon cancer—in the 1980s have been changed fundamentally. *Helicobacter pylori, laparoscopic cholecystectomy,* and *DNA mismatch repair enzyme gene mutations* are terms that were not part of the standard lexicon of even academic gastroenterologists who were already experts in their field. With this challenge before us, we have taken every step to ensure that the fourth edition of the *Textbook of Gastroenterology* is appropriately current. As with the first three editions, every chapter has been updated; in addition, nearly 30 percent of the chapters have new authors to provide a fresh outlook to the material. More importantly, in this edition we have added new chapters to cover the topic of liver diseases, recognizing that most gastroenterologists are also hepatologists. In this regard, we are delighted to introduce our newest associate editor, Neil Kaplowitz, who has assumed responsibility for the hepatology chapters.

These changes have helped retain the major assets of the *Textbook,* namely its modernity, its freshness, and its up-to-date accuracy. Throughout this edition, we have taken great care to maintain the fundamental aims of the *Textbook* in its first and subsequent editions: to present the scientific basis of gastroenterology in such a fashion that it will provide insight into common clinical problems, to detail the basics of a clinician's approach to common clinical problems, to provide at its core an encyclopedic discussion of virtually all of the disease states encountered in practice, and to describe all of the major diagnostic and therapeutic technologies of gastroenterology, both the long standing and the very recent, available to clinicians today.

Above all, as in the first three editions, this edition of the *Textbook of Gastroenterology* is planned to integrate the various demands of science, technology, expanding information, good judgment, and common sense into the diagnosis and management of gastrointestinal patients. Because gastrointestinal complaints are among the most commonly encountered in clinical practice, the *Textbook* is not meant solely for the education of practicing or training gastroenterologists and surgeons but also, and most important in the changing health care environment, primary care physicians and physician extenders. We hope that the collective efforts of the authors of the 162 chapters and the six of us who have edited this edition have succeeded in achieving our goal to provide an outstanding educational work for students and practitioners of the medical science of gastroenterology.

Our efforts were especially facilitated by the expert assistance of Lori Ennis and Barbara Boughen, who collaborated as a team to complement editorial talents with interpersonal skills to maintain the high quality of the text and to deliver the manuscripts in a timely fashion. The authors are indebted to their administrative and secretarial assistants, Carol Arnold, Robbie Loftin, Terri Kirschner, Sue Sparrow, JoAnn Wilson, and Maria Vidrio. In addition, the faculty and fellows of the Gastroenterology Divisions at the University of Michigan, Health System in Ann Arbor, Washington University School of Medicine in St. Louis, and The University of Texas Medical Branch in Galveston provided valuable assistance in reviewing the chapters in the third edition of the *Textbook* as preparations for this, the fourth edition.

The editors wish to express their gratitude to their colleagues at Lippincott Williams & Wilkins who have continued to demonstrate their commitment to quality, integrity, and excellence. Of the many people at Lippincott who have contributed their best efforts to the success of this book, one person deserves special recognition: Beth Barry. This edition would not have been possible without her dedication and extraordinary talent.

Tadataka Yamada, M.D.

PREFACE TO THE FIRST EDITION

The practice of gastroenterology has changed dramatically during the past 20 years. We have witnessed a logarithmic growth in the volume of information concerning the basic biology and biochemistry of the gut. This wealth of new knowledge not only has provided fresh insight into the pathogenesis of gastrointestinal diseases but also has identified the critical role of the gut in the physiology and pathology of other organ systems. There is every reason to expect that the pace of our scientific growth will continue in the years ahead.

In many instances, advances in the science of gastroenterology have been incorporated directly into clinical practice. This has led to the evolution of a large and ever-expanding armamentarium of diagnostic and therapeutic modalities for management of patients with gastrointestinal diseases. The ability to see the organ of pathology and to treat lesions directly without invasive surgical procedures is an advantage almost unique to gastroenterology. As a result, today's clinicians must think in ways not even imagined by their predecessors. Although the textbooks of the past have served us well, modern gastroenterology dictates a more integrated approach to science, technology, and clinical practice. In the *Textbook of Gastroenterology* the Editors address this need.

The *Textbook* begins with a section of chapters describing the basic mechanisms of normal and abnormal gastrointestinal function. This section of the *Textbook* is written so that fundamental scientific concepts can be understood by a reader who is not scientifically oriented. We hope to present the scientific basis of gastroenterology in such a fashion that it will provide insight into common clinical problems. The section is intended to serve both as a guide for clinicians who need to understand the pathophysiology of their patients' disorders and as a resource for serious students of gastroenterology.

A major shortcoming of textbooks that consist solely of descriptions of diseases is the lack of guidance for the reader in applying the information to the management of patients who present with symptoms or signs rather than diagnoses. Therefore, a major section of the *Textbook* consists of detailed chapters on the clinician's approach to patients presenting with common gastrointestinal problems.

As a fully comprehensive textbook, the *Textbook of Gastroenterology* has at its core an encyclopedic discussion of virtually all of the disease states encountered in practice. These chapters, comprising the bulk of the Textbook, have a classical structure that ensures the uniform coverage of all important points.

After the initial evaluation, physicians must choose from a battery of diagnostic and therapeutic modalities as they proceed with patient management. A full section describing all of the major technologies, both the longstanding and the very recent, available to clinicians today comprises the last section of the *Textbook.* This section discusses not only the theory and practical uses of these procedures but also the contraindications and potential complications, the evaluation and assessment of the data obtained, and the future directions of the modality.

The purposes of the *Textbook of Gastroenterology,* then, are multiple: to teach the scientific basis of gastroenterology, to provide practical approaches to common gastrointestinal problems, to serve as an encyclopedic reference for gastrointestinal diseases, and to indicate the current applications and future directions of the technology of gastroenterology. Above all, the *Textbook* is planned to integrate the various demands of science, technology, expanding information, good judgment, and common sense in the diagnosis and management of gastrointestinal patients. The Editors intend the book to be as useful at the bedside as on an office shelf or a student desk. Because gastrointestinal complaints are among the most commonly encountered in clinical practice, we want our readers to include surgeons, primary care physicians, and nurses as well as gastroenterologists and other internists.

To achieve these goals, the finest experts in the field of gastroenterology have written this Textbook. Each chapter is prepared by an authority who is actively engaged in advancing our knowledge of the subject matter of the chapter. We believe that the expertise of this group of physicians and scientists has ensured that the *Textbook* will achieve its aims.

CHAPTER 1

Helen Raybould, Stephen J. Pandol, and Hal Yee

THE INTEGRATED RESPONSES OF THE GASTROINTESTINAL TRACT AND LIVER TO A MEAL

This chapter provides an overview of the mechanisms involved in the regulation of the various responses in the gastrointestinal (GI) tract and the liver to the ingestion of a meal. The coordination of these responses is essential to the overall function of the GI tract, which is to take in nutrients and eliminate wastes, and a key function of the liver, which is to coordinate the distribution and storage of vital nutrients. Each of the processes described in this introductory chapter is explored in greater depth and with extensive references to the literature elsewhere in the textbook.

The GI tract consists of the alimentary canal from the mouth to the anus and the associated glandular organs that empty their contents into the canal. In a general sense, the GI tract adds water, ions, and enzymes to a meal to convert it into an aqueous solution of molecules that can be transported into the blood. Importantly, most of the added substances are absorbed for reuse. The major physiological processes that occur in the GI tract are motility, secretion, digestion, absorption, and elimination. Food is taken into the mouth as large particles containing macromolecules that are not absorbable. The breaking down of food into absorbable material occurs by grinding and mixing the food (motility) with various secretions containing enzymes, ions, and water that enter the GI tract. The enzymes convert the macromolecules into absorbable molecules in a process termed *digestion*. The products of digestion, as well as the secretions from the upper parts of the GI tract, are then transported across the epithelium to enter the blood or lymph by a process termed *absorption*. Secretions and lumenal contents are moved from the mouth to the anus and eliminated by GI motility. The coordination of GI function is regulated in a synchronized way to maximize digestion and absorption by means of multiple control mechanisms.

The liver is anatomically coupled to the GI tract through the biliary tree and portal circulation. It has numerous vital functions, including bile formation and secretion; uptake, storage, and release of nutrients; generation of plasma proteins; detoxification; and immune surveillance. This chapter focuses on the crucial role that the liver plays in the integrated metabolic response to a meal.

The functions of the GI tract and the liver are regulated by three principal types of control mechanisms: paracrine, endocrine, and neural (Fig. 1-1). Paracrine regulation describes the process whereby a chemical released from a sensing cell diffuses through the interstitial space to influence the function of neighboring cells. An example of a paracrine mechanism is the inhibition of gastrin release by somatostatin. Somatostatin is released from cells in the gastric antral mucosa in response to low intragastric pH. Another example is the action of histamine, which is released from enterochromaffin cells in the gastric fundic mucosa, stimulating gastric acid secretion through direct action on the parietal cells.

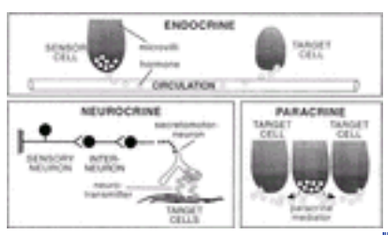

FIGURE 1-1. Three principal types of control mechanisms regulate the function of the gastrointestinal tract—paracrine, endocrine, and neurocrine (neural). Examples of paracrine mechanisms are numerous; in this figure, the target cell is shown as being adjacent to the sensor cell. However, paracrine mechanisms may be mediated over tens or hundreds of microns and may involve many different cell types, including epithelial cells, endocrine cells, nerve terminals, and smooth muscle. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

Endocrine regulation describes the process whereby the sensing cells respond to a stimulus by releasing their contents into the circulation to act on distant target cells. A particular cell responds because it possesses high-affinity receptors specific for the hormone. There are many examples of endocrine regulation in the GI tract and the liver, including the action of gastrin to increase gastric acid secretion, the action of cholecystokinin (CCK) to stimulate pancreatic enzyme secretion, and the action of glucagon to enhance hepatic glycogenolysis and gluconeogenesis.

A neurocrine or neural response is mediated by the release of transmitters from nerves. A neural reflex is the reaction of sensory neurons to stimuli, such as the presence of nutrients or acid in the intestinal lumen, or the stretch and contraction of smooth muscle in the gut wall, leading to the activation of intrinsic and extrinsic neurons that alter the secretory and motor behavior of the gut. An example of a neural reflex is the distention of the esophagus, which leads to the receptive relaxation of the stomach wall. Various sensory neural receptors in the GI tract detect both chemical and mechanical stimuli. The transmission to the target tissue may involve relatively short, neural reflex pathways within the intrinsic nervous system of the gut (i.e., the enteric nervous system) or longer pathways through the spinal cord and brain (Fig. 1-2). Efferent nerves from the brain and spinal cord that innervate the GI tract and the liver are both parasympathetic and sympathetic. In the integrated response of the GI tract to a meal, parasympathetic input is predominant in the regulation of function; these fibers synapse with enteric neurons to effect end-organ responses. Secretomotor enteric neurons are contained within the myenteric and submucosal plexuses—the two nerve plexuses that make up the enteric nervous system. These plexuses contain the neural elements capable of integrating entire reflex circuits without input from the central nervous system (CNS). In contrast to the GI tract, the autonomic nervous system plays a relatively modest role in the hepatic response to a meal, as affirmed by the success of liver transplantation, in which the liver is disassociated from the nervous system.

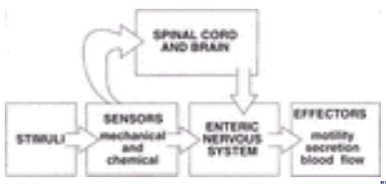

FIGURE 1-2. The control of gastrointestinal (GI) function during the response to a meal is regulated by neural reflexes. The various stimuli present in the meal or generated within the GI tract by digestion stimulate many different sensors. Activation of these sensors stimulates intrinsic and extrinsic afferent neurons, resulting in reflex activity mediated through the enteric nervous system, the prevertebral ganglia, or the central nervous system (spinal cord or brainstem). Activation of these reflexes alters effector function in the GI tract, including motility, secretion, and blood flow. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

The response of the GI tract to a meal is classically divided into phases: cephalic, oral, esophageal, gastric, duodenal, intestinal, and colonic. The liver's response to a meal permits a shift in metabolic conditions from the fasted state to the fed state. In each phase or state, the meal provides certain stimuli that activate control mechanisms resulting in changes in effector function, such as secretion, motility, and metabolism. A particular stimulus generated in an organ of the GI tract can activate effectors not only in the same organ but also in other regions of the GI tract or the liver. These coordinated effects allow for continuous adjustments in motility, secretions, or metabolism to match the unique characteristics of a meal to maximize its digestion, absorption, distribution, and storage.

GASTROINTESTINAL RESPONSE TO A MEAL

Cephalic and Oral Phases

The main feature of the cephalic and oral phases of the response to a meal is the activation of the GI tract. The cephalic phase consists of responses to the auditory, cognitive, visual, and olfactory stimuli induced by the meal. The oral phase includes responses to many of the same stimuli but also includes those initiated in the mouth, which are both mechanical and chemical. The effector responses are mediated through various higher brain centers but ultimately converge in the parasympathetic outflow to the GI tract through the cranial nerves and the vagus nerve (Fig. 1-3). This outflow activates both secretory and motor events, including salivary, gastric, and pancreatic secretions; gallbladder contraction; and relaxation of the sphincter of Oddi. These responses supply the intralumenal environment with water, ions, digestive enzymes, and bile, which are all necessary to initiate digestion and solubilize components of the meal in the aqueous phase so that complete digestion and absorption can occur.

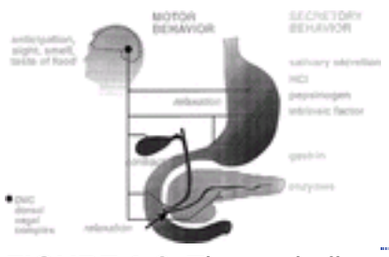

FIGURE 1-3. The cephalic and oral phases of the meal initiate a similar repertoire of responses to activate the digestive processes in the gastrointestinal (GI) tract. The stimuli from either cognitive cues or oropharyngeal stimulation result in activation of parasympathetic outflow, which activates secretory and motor events in both the proximal and distal GI tract. *HCl,* hydrochloric acid. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

During the oral phase, mechanical disruption of the food (i.e., chewing) and the addition of salivary secretions enable swallowing and initiate digestion (Table 1-1). Chewing subdivides the food and mixes it with salivary secretions, including amylase, lingual lipase, water, and mucus. Chewing also results in the formation of a rounded, smooth, and lubricated portion of food (i.e., a bolus) that can be swallowed. Mucus lubricates the food for both chewing and, more importantly, swallowing. The presence of material in the mouth provides both mechanical and chemical stimuli that initiate salivary, gastric, and pancreatic secretion through activation of parasympathetic pathways. Studies in humans indicate that the gastric secretory response to oropharyngeal stimulation is far more robust if the meal is palatable, although the action of chewing bland material will initiate both salivary and gastric secretion. These results indicate that both mechanical and chemical stimuli induced by the meal can mediate the secretory response.

Disruption of food resulting in smaller particles
Formation of bolus for swallowing
Initiation of starch and lipid digestion
Facilitation of taste
Cleaning of mouth and provision of antibacterial action
Clearance and neutralization of refluxed gastric material in the esophagus
Regulation of gastric and duodenal phase responses
Regulation of food intake and eating behavior
Assistance in speech

TABLE 1-1 Functions of Chewing and Salivary Secretion

The components of the cephalic and oral phases of the response to a meal are mediated by purely neural pathways. For example, the salivary secretory response is mediated by parasympathetic effector neurons. In the stomach, responses vary by region. In the proximal stomach, vagal activation stimulates pepsinogen secretion from chief cells, and proton and intrinsic factor secretion from parietal cells. In the distal stomach, vagal activation induces the release of gastrin from endocrine cells in the antrum (i.e., G cells). For this response, vagal efferents synapse with enteric neurons that release gastrin-releasing peptide, which in turn directly activates G-cell gastrin release. Gastrin acts as an endocrine agent on chief and parietal cells to promote their respective secretions. The parietal cell is also activated by histamine that is released from mucosal enterochromaffin-like (ECL) cells. Histamine release is regulated by cholinergic vagal inputs and by gastrin. The acid secreted into the stomach provides the appropriate conditions for the rapid activation of pepsin from its inactive precursor. Thus, protein digestion can be initiated rapidly as food enters the stomach. The overall effect is a complex interaction of neural, paracrine, and endocrine controls initiated by neural activation in the cephalic and oral phases of the responses to a meal.

In a similar manner, the motor effects on the gallbladder and the sphincter of Oddi are mediated by vagal efferent action on the enteric neurons in these organs. Gallbladder contraction is mediated at least in part by the direct action of acetylcholine, released from intrinsic neurons, on smooth muscle. The inhibitory action on the sphincter is mediated by vasoactive intestinal peptide (VIP) and nitric oxide (NO), which are also released from intrinsic neurons.

The responses of the exocrine secretory cells and smooth muscle previously described, as well as the responses in the pancreas and the intestine, result from agonist interaction with specific receptors on the cells, followed by activation of intracellular signaling systems. These signals, in turn, regulate ion transporters, exocytosis, and the contraction and relaxation of smooth muscles. The specifics of these intracellular signals and cellular responses are detailed elsewhere in this textbook.

Esophageal Phase

The pharynx, esophagus, and associated structures have two main functions: to transfer food from the mouth to the stomach, and to protect the gut from the potentially injurious effects of acid and digestive enzymes (Fig. 1-4).

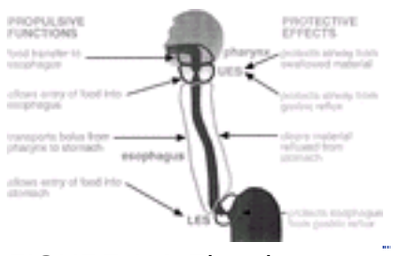

FIGURE 1-4. The pharynx, esophagus, and associated structures (*UES,* upper esophageal sphincter; *LES,* lower esophageal sphincter) subserve both transfer (i.e., propulsive) and protective functions. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

The stimuli provided by the meal in the esophageal phase are predominantly mechanical. Swallowing produces a mechanical stimulation of the pharynx, and the entry of the bolus into the esophagus produces esophageal distention. The sensors involved are mechanosensitive afferents innervating both the pharynx and the esophagus. Activation of these afferents initiates reflex pathways by way of the brainstem or solely by way of intrinsic pathways within the enteric nervous system. These pathways initiate a stereotypic response of muscle relaxation and contraction that is called *peristalsis*. In the pharynx and upper one third of the esophagus (striated muscle), motility is regulated from the nucleus ambiguus in the brainstem. Parasympathetic outflow through the vagus nerve terminating on intrinsic neurons regulates contraction and relaxation of the smooth muscle in the lower two thirds of the esophagus. However, the stimulation of the enteric nervous system of the esophagus is sufficient to produce peristalsis. Pharyngeal and esophageal stimulation and activation of reflex pathways (both intrinsic and extrinsic) produce striated and smooth muscle peristalsis, relaxation of the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES), and relaxation of the proximal stomach (i.e., receptive relaxation).

Another important reflex is a protective mechanism mediated by spinal afferents that terminate in the distal esophageal mucosa. These afferent terminals are sensitive to acid, and their activation leads to reflex closure of the LES and relaxation of the proximal stomach.

The pharynx, UES, esophagus, and LES act in a coordinated manner to propel material from the pharynx to the stomach. The movement of the bolus of food in the mouth, aided by the tongue, initiates a peristaltic wave that carries the bolus through the pharynx. With the coordinated relaxation of the UES, the bolus enters the esophagus, wherein peristaltic waves move it toward the stomach. With each swallow (i.e., pharyngeal stimulation), the LES and the proximal stomach relax, allowing the bolus to pass into the stomach. Distention of the esophagus by the bolus initiates another wave called *secondary peristalsis*. Repetitive secondary peristalsis is often required to clear the esophagus of the meal bolus. Like pharyngeal stimulation, esophageal distention produces relaxation of the proximal stomach and opening of the LES. This allows the stomach to accommodate large volumes of the meal with a minimal increase in intragastric pressure.

Gastric Phase

The gastric phase initiates several responses within the stomach and the other organs of the GI tract, including pancreatic secretion, gallbladder contraction, and relaxation of the sphincter of Oddi (Table 1-2). Stimuli provided by the presence of a meal in the stomach are both mechanical (i.e., distention and stretch of smooth muscle wall) and chemical (e.g., oligopeptides and amino acids produced by protein digestion in the lumen). The pathways mediating the effects of these stimuli are complex, involving neural, endocrine, and paracrine mechanisms. The gastric responses are both secretory (e.g., acid, intrinsic factor, mucus, pepsinogen, gastrin, lipase, bicarbonate) and motor (e.g., inhibition of proximal stomach motility and stimulation of antral peristalsis) (Fig. 1-5). Afferent (i.e., sensory) neurons respond to mechanical and chemical stimuli and activate both intrinsic pathways and parasympathetic outflow via vagovagal reflex pathways. Parasympathetic efferent neurons can be either excitatory or inhibitory, depending on the intrinsic secretomotor neurons on which they terminate. Those that terminate onto neurons that release either acetylcholine or other excitatory neurotransmitters (e.g., substance P) stimulate secretion and motility, and those that terminate on neurons that release VIP or NO generally inhibit function. These neural pathways mediate gastric motor and secretory responses, as well as responses further along the GI tract. The endocrine pathway consists of the release of gastrin, leading to the stimulation of gastric secretion. Paracrine pathways include the release of somatostatin, leading to the inhibition of gastric secretion, and the release of histamine, leading to the stimulation of gastric secretion. These endocrine and paracrine pathways activate responses only within the stomach.

Gastric Responses
Storage of the meal
Secretion of pepsinogen and lipase to initiate digestion
Secretion of H^+ to kill microorganisms and convert pepsinogen to active form
Secretion of intrinsic factor to bind vitamin B_{12} (cobalamin) for absorption
Secretion of mucus and bicarbonate for gastric mucosal barrier and lubrication
Secretion of water for aqueous suspension of nutrients and to make hypoosmotic
Mixing secretions with food and reduction of particle size (grinding) of the meal
Regulation of emptying of contents into duodenum
Distal Gastrointestinal Tract Responses
Stimulation of pancreatic secretion
Contraction of the gallbladder
Increased colonic motor activity
Relaxation of the sphincter of Oddi

TABLE 1-2 Major Functions of the Gastric Phase

FIGURE 1-5. The gastric phase. Once food reaches the stomach, the meal presents many mechanical and chemical stimuli to the gastric wall that initiate new responses or reinforce those that are ongoing. These stimuli initiate both neural and endocrine (humoral) pathways to bring about changes in function. The different regions of the stomach subserve different functions; the proximal stomach (fundus and body) secretes many factors and has a major role as a reservoir. The distal stomach (antrum and pylorus) secretes mucus and bicarbonate; motor coordination of this region is critical in the regulation of gastric emptying. *LES,* lower esophageal sphincter. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

The afferent innervation of the stomach consists of vagal and spinal afferents, the cell bodies of which are in the nodose and dorsal root ganglia, respectively. The central terminals lie in the brainstem and spinal cord, and the peripheral terminals lie in the muscle and mucosa. The sensory terminals in the muscle respond to stretch of the stomach wall, and afferents innervating the mucosa respond to lumenal contents. The terminals in smooth muscle respond to both stretch and active contraction in the terminal fields. They are predominantly vagal afferents; the majority of spinal afferents terminate in the serosa and mesenteric attachments. The mechanism by which mucosal afferents respond to changes in lumenal content is not clear, but it is characteristic of afferents along the length of the GI tract and may be similar to the process that mediates taste. Endocrine or EC cells may release their contents in response to apical stimulation by nutrients, acid, or osmotic stimuli. The release of contents from the basolateral portion of the cells, which are close to the terminals of afferents, stimulates the afferents to initiate neural reflexes.

As the meal enters the stomach, the stretch of the gastric wall activates vagal afferents, which results in vagovagally mediated receptive relaxation of the proximal stomach and an increase in gastric acid secretion, as well as the induction of pancreatic enzyme secretion, gallbladder contraction, and sphincter of Oddi relaxation. Parasympathetic innervation through the vagus nerve is the strongest stimulant of gastric acid secretion. Extrinsic efferent fibers terminate on intrinsic neurons that innervate not only parietal cells, but also ECL cells that release histamine and G cells that release gastrin. Acetylcholine induces acid secretion directly by acting on

parietal cells, and indirectly by stimulating ECL cells and activating neurons that release gastrin-releasing peptide, which, in turn, induces gastrin release from G cells. The complexity of the regulatory systems is further illustrated by the observation that gastrin also can act directly on parietal cells, or indirectly by stimulating ECL cells to release histamine (Fig. 1-6). If the vagus nerve is severed, acid secretion in response to gastric wall stretch is reduced but not abolished. Such results suggest that intrinsic neural reflexes also can mediate the secretory response. Thus, the same stimulus can activate the response through different effector mechanisms. In addition to gastric distention activating this reflex pathway, the products of protein digestion also can activate the same effector pathway, presumably by stimulating the sensory terminals in the mucosa. Furthermore, the products of digestion can activate acid secretion independently of neural pathways by directly stimulating gastrin release from G cells in the antral mucosa.

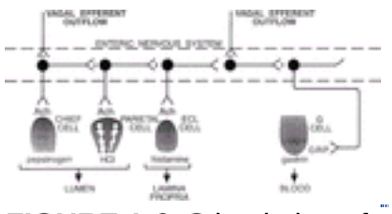

FIGURE 1-6. Stimulation of gastric acid secretion by increased parasympathetic utflow is effectively amplified by the intrinsic neuronal circuitry of the gastric wall. Vagal efferents synapse with intrinsic cholinergic neurons and with neurons containing gastrin-releasing peptide (*GRP*). Activation of these intrinsic neurons stimulates a number of cell types in the gastric mucosa. Neurocrine (GRP and acetylcholine [*Ach*]), paracrine (histamine), and endocrine (gastrin) pathways all contribute to this response. *ECL,* enterochromaffin-like cell; *G cell,* gastrin cell; *HCl,* hydrochloric acid. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

A negative feedback mechanism also exists, whereby a low pH in the gastric antral lumen stimulates the secretion of somatostatin from endocrine cells. Somatostatin exerts a paracrine effect on G cells, decreasing the release of gastrin, which indirectly leads to a decrease in acid secretion.

The motor functions of the stomach include acting as a reservoir for ingested food, fragmenting the food and mixing it with secretions, and emptying of the contents into the duodenum at controlled rates. In a consideration of the motor functions of the stomach, it is easiest to divide the stomach into proximal and distal regions. The proximal stomach produces slow changes in tone compatible with its reservoir function. During the first part of the meal, the proximal stomach relaxes to accommodate the volume of the meal, but later in the response to the meal, tone in the proximal stomach starts to increase, which accelerates gastric emptying by propelling the contents toward the distal stomach. Phasic contractions in the distal stomach are generated by myoelectric activity at a rate of three cycles per minute beginning in the midstomach and moving toward the pylorus. When the nutrient meal is in the stomach, antral contractions serve to mix and grind the gastric contents, resulting in a reduction in the size of solid particles. These contractions also contribute to the emptying phase of the response to a meal. As material is emptied from the stomach, antral contractions are associated with pyloric opening, and gastric chyme is emptied into the duodenum. Only particles less than 2 mm in diameter pass into the duodenum; larger particles are propelled back into the proximal stomach. Gastric motility in the gastric phase of the meal is controlled primarily by neural reflexes mediated by extrinsic circuits but also by the enteric nervous system. These neural reflexes are activated by receptors for chemical and mechanical stimuli in the duodenum, principally nutrients, osmotic load, acid, and stretch of the intestinal wall.

The gastric phase also consists of the activation of the more distal GI tract, including pancreatic secretion, gallbladder contraction, and relaxation of the sphincter of Oddi. These effects are mediated by the same vagal afferent and efferent pathways that mediate the gastric responses, and they prepare the intestine for the gastric emptying of the meal into the proximal small intestine.

Duodenal Phase

The main characteristics of the duodenal phase are the controlled delivery of chyme from the stomach, and the secretion of pancreatic juice and bile into the duodenum to match the digestive and absorptive capacity of the intestine (Table 1-3). The function of this region is highly regulated by feedback mechanisms (Fig. 1-7). The combination of organs regulated during this phase has been termed the *duodenal cluster unit:* stomach, duodenum, liver, biliary tract, gallbladder, and pancreas. Lumenal and wall stimuli activate neural and endocrine pathways to mediate the responses of these organs. The different organ systems in the duodenal cluster unit have a common embryologic origin and are regulated by similar sensory mechanisms and effector pathways. The gastric phase of the response to a meal provides some of the stimuli for the duodenal phase. For example, the products of gastric lipid and protein digestion are potent stimulants of regulation in the duodenum. The important duodenal stimuli are distention, acid, osmotic load, and different nutrients. The sensory pathways consist of spinal and vagal afferents and intrinsic sensory neurons that initiate reflex pathways. Hormonal pathways, especially those mediated by CCK and secretin, are also important. The effector systems regulated include the inhibition of gastric emptying and secretion, the stimulation of pancreatic secretion, gallbladder contraction, relaxation of the sphincter of Oddi, pancreatic and biliary water and bicarbonate secretion, intestinal secretion, and the conversion of small bowel motility from the fasted to fed patterns.

Inhibition of gastric acid secretion
Inhibition of gastric emptying
Stimulation of pancreatic enzyme secretion
Stimulation of pancreatic and biliary ductal ion and water secretion
Stimulation of gallbladder contraction
Relaxation of the sphincter of Oddi
Alteration of intestinal motility from the fasted to the fed state

TABLE 1-3 Major Functions of the Duodenal Phase

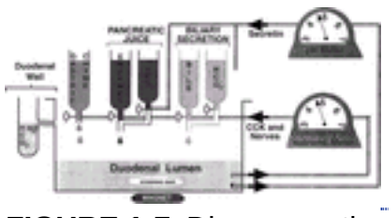

FIGURE 1-7. Diagrammatic representation of the duodenal cluster unit illustrates the control mechanisms and pathways involved in intestinal feedback regulation during the duodenal phase. The nutrient content and osmolality of the meal are sensed (represented as a *meter*) and activate predominantly neural pathways involving cholecystokinin (*CCK*) to open or close various stopcocks to increase pancreatic secretion or delay gastric emptying, for example. The acidity of the meal is sensed and activates secretin release and neural pathways to increase bicarbonate secretion from the pancreas and probably also from the duodenal wall. The contents of the duodenum are mixed with the secretions by the segmental contractions of the smooth muscle wall, represented as a *stirring bar* and *magnetic stirrer*. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

Gastric emptying in the duodenal phase depends on the chemical and physical composition of the gastric contents (i.e., chyme) entering the duodenum. Sensory neurons are both vagal and spinal, responding to nutrients, H^+, distention, and the hyperosmolality of chyme. The effector responses that result in the inhibition or slowing of gastric emptying are not completely understood but involve the activation of vagal efferent outflow, which produces a decrease in antral contractions, contraction of the pylorus, and a decrease in proximal gastric tone. In addition to these extrinsic neural pathways, there also may be local pathways, such as an intrinsic neural reflex, mediating the pyloric contraction induced by acid in the duodenum.

The availability of CCK antagonists has contributed to the understanding that CCK is physiologically important in regulating the function of the duodenal cluster unit in the duodenal phase. The administration of CCK-A receptor antagonists reverses the inhibition of gastric emptying, gallbladder contraction, relaxation of the sphincter

of Oddi, and stimulation of pancreatic enzyme secretion in response to either a meal or the infusion of nutrients into the duodenum. CCK is released from endocrine cells in the proximal intestine in response to lumenal lipid and protein. The action of CCK to inhibit gastric acid secretion and gastric emptying, and to increase pancreatic secretion, is dependent on neural pathways (Fig. 1-8). CCK stimulates specific CCK-A receptors on vagal afferent nerve terminals in the intestinal mucosa and activates vagovagal reflexes to modify gastric and pancreatic function. Thus, CCK, long thought of as a classic hormone, may actually function as a locally acting paracrine effector acting on nerve terminals to initiate reflex neural responses.

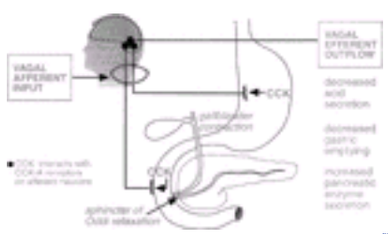

FIGURE 1-8. Cholecystokinin (*CCK*) acts predominantly by way of a vagal afferent pathway to integrate intestinal feedback regulation of the duodenal phase of the meal. (From Undergraduate Teaching Program of the American Gastroenterological Association, 1996.)

The physiological release of CCK in response to a meal is modulated by at least two peptides. One is monitor peptide, which is secreted by pancreatic acinar cells. In addition, there is at least one lumenal CCK-releasing factor. The proposed mechanism of action for both of these releasing factors is that they are constitutively secreted into the intestinal lumen. In the absence of protein or protein products in the intestinal lumen, both factors are efficiently broken down by digestive enzymes and thus are not available to stimulate CCK release. On ingestion of a meal, however, dietary proteins compete with the releasing factors as substrates for the digestive enzymes. The net effect is that the releasing factors escape digestion and become available to stimulate CCK secretion from endocrine cells in the mucosa.

The most important function of the pancreas in the integrated response to a meal is the production, storage, and secretion of digestive enzymes. The major control of pancreatic enzyme secretion is exerted by efferent fibers from the parasympathetic nervous system and by CCK. As indicated in the previous sections, parasympathetic activation of pancreatic enzyme secretion occurs during the cephalic, oral, gastric, and duodenal phases of the response. Secretion during the duodenal phase accounts for about 70% of the total response to a meal. In this phase, secretion is activated by the presence of chyme in the duodenum by way of extrinsic neural pathways, enteropancreatic neural pathways (i.e., through intrinsic neurons that terminate in both the duodenum and pancreas), and endocrine pathways (i.e., through CCK, secretin).

As the meal enters the intestine, it is acidic and hyperosmotic; however, by the time it leaves the duodenum, it has a neutral pH and is isosmotic. This conversion is achieved by the secretion of large volumes of water and bicarbonate ions by the intestinal mucosa, and by the pancreatic and biliary systems. Secretion is regulated mainly by the release from the duodenal mucosa of secretin, which acts as an endocrine agent to increase bicarbonate and water secretion from the pancreatic and biliary ductal systems. The existence of a releasing peptide for proton-induced release of secretin also has been proposed.

The contraction of the gallbladder and the relaxation of the sphincter of Oddi result in the addition of biliary secretion to the meal. During the cephalic, oral, and gastric phases, these responses are mediated by parasympathetic efferent nerves. During the duodenal phase, CCK acting either alone or through a vagal reflex pathway has a pronounced effect on the delivery of bile to the duodenum. Bile is composed of both inorganic and organic constituents. As previously indicated, the inorganic constituents (e.g., water, bicarbonate ions, and other electrolytes) serve to convert gastric chyme into a neutral isosmotic solution. The major organic constituents of bile are conjugated bile acids, phospholipids, cholesterol, and bilirubin; the latter two are excretory products. Both bile acids and phospholipids are essential in maintaining cholesterol in a soluble state and thereby preventing the formation of gallstones. Conjugated bile acids traverse the entire small intestine and are taken up by a receptor-mediated transport system in the terminal ileum. The conjugated bile acids return to the liver by way of the portal circulation and then are secreted back into the biliary system and stored in the gallbladder. This cycling of bile acids is termed the *enterohepatic circulation*. Bile acids have multiple important functions in the process of digestion and absorption of lipids and fat-soluble vitamins. They accomplish these functions in part by possessing polar (hydrophilic) and nonpolar (hydrophobic) regions that allow them to interface between aqueous and lipid environments. Thus, they are involved in the formation of emulsions and micelles and in the binding of lipolytic digestive products to the oil phase of the meal. All these effects enhance digestion and the absorption of fat in the meal.

The highly regulated duodenal phase is responsible for the addition of water, ions, enzymes, bile acids, and other secretions to the meal in proportions that result in an optimal environment for the digestion of nutrients. The process of digestion in the intestinal lumen is facilitated further by the induction of patterns of motility in the duodenum that promote the mixing of intestinal contents with digestive enzymes.

During the intervals between meals, motility of the GI tract is characterized by periods of intense contractions and periods of quiescence. In humans, these periods cycle at about 1.5 hours. The sequential contractions migrate aborally (i.e., toward the anus) and have been termed the *migrating motor complex* (MMC). This complex of migrating contractions starts in the stomach and moves through the intestine and into the colon, sweeping undigested material and contents through the GI tract in the interdigestive period. Initiation of the MMC is dependent on the integrity of the vagal innervation, which serves to release the hormone motilin, which, in turn, activates the MMC. Food in the intestine abolishes the MMC and changes intestinal motility from this fasted pattern to a fed pattern of motility.

Small Intestinal Phase

This phase of the meal is characterized by digestion and absorption. The small intestine is divided into three functional regions: duodenum, jejunum, and ileum. The jejunum is the major organ for intralumenal and surface digestion and absorption of meal nutrients. In addition, a significant portion of the water and ions from both exogenous and endogenous sources is absorbed in the jejunum. The ileum provides another site for absorption. The ileum has a specific role in the absorption of cobalamin (vitamin B_{12}) bound to intrinsic factor secreted by the stomach and bile acids. The ileum also releases hormones that have important functions in the gut. For example, the peptide YY (PYY) inhibits gastric function. The ileocecal valve prevents the large reservoir of colonic bacteria from entering the small intestine. Two characteristics of the small intestine make it especially well adapted for its critical role in nutrient assimilation. First, the small intestine has an enormous surface area as a result of folds in the mucosa, villi on the mucosa, and microvilli on the epithelial cells. Second, the blood flow to the intestine is very high after a meal; it can account for up to 25% of the cardiac output. The enteric nervous system is highly developed in the small intestine, enabling this region of the GI tract to function fairly independently of the extrinsic innervation.

The main responses initiated in the small intestinal phase are alterations in intestinal motility patterns, intestinal secretion, and blood flow, as well as regulation of tight junction permeability. The small intestine exhibits two motor patterns: peristalsis and segmentation. Both of these motility patterns are generated by the enteric nervous system and are independent of the extrinsic nervous system. Peristalsis is characterized by a wave of relaxation followed by a ring of contraction that develops at a point and moves aborally over variable distances. Peristalsis is the primary mechanism by which contents are moved along the intestine in the digestive period. Segmentation is characteristic of the fed state and is the process by which rings of contraction develop at uniform intervals, dividing the lumen into segments. Segmentation is the primary mechanism by which the contents of the intestine are mixed with secretions and moved across the mucosa to enhance absorption.

Other responses initiated in the small intestine are less well understood: for example, regulation of mucosal blood flow, regulation of tight junction permeability, and alteration in mucosal function.

The major changes in the chemical and physical characteristics of food, as well as the absorption of nutrients, trace elements, vitamins, water, and ions, occur in the intestinal phase. Hydrolysis of proteins and carbohydrates and the solubilization and hydrolysis of fats are catalyzed by enzymes in the intestinal lumen (from salivary, gastric, and pancreatic secretions) and in the intestinal brush border. Absorption is the process by which molecules produced by lumenal surface digestion are transported into epithelial cells and then carried into the blood or lymph. In addition to absorbing components of the meal, the small intestine absorbs much of the endogenous secretions. The duodenum and jejunum have the highest absorptive capacities; most absorption occurs in the upper small intestine, although some occurs in the ileum. Molecules are absorbed by two principal mechanisms: transcellular (i.e., passing through enterocytes) and paracellular (i.e., passing between enterocytes). Monosaccharides, amino acids, electrolytes, minerals, and water-soluble vitamins enter the portal circulation and pass through the liver into the systemic circulation. Lipids and fat-soluble vitamins and cholesterol esters (together with lipophilic drugs) enter the lymph, which drains into the systemic circulation.

Colonic Phase

The colonic phase of the response is important in the further reabsorption of water and ions and for the storage and elimination of waste products. The cecum and ascending colon receive about 2 L of ileal effluent daily. Absorptive transport mechanisms reduce the volume to about 200 mL per day. The transverse, descending, and sigmoid portions of the colon store fecal material and transport the material to the rectum. The rectum signals the defecation reflex. In addition, some fermentation of monosaccharides yields free fatty acids that can be taken up by colonic epithelial cells.

The stimuli induced in the colon are both mechanical (e.g., rectal distention) and chemical (e.g., free fatty acids). Extrinsic and intrinsic neural pathways mediate the motility responses of the colon and the defecation response. Hormonal pathways affecting other parts of the GI tract also may be excited in the colon. For example, PYY may be released from the colonic mucosa if the fat content of the meal is high and not all is absorbed by passage through the small intestine. PYY, in turn, slows gastric emptying and transit of the meal through the small intestine, resulting in increased fat digestion and absorption.

The effectors in the colonic phase are both motor and secretory. The colon exhibits both storage motor patterns (i.e., changes in tone) and propulsive motor patterns (i.e., phasic contractions). Rectal distention initiates the defecation reflex. This response consists of both involuntary and voluntary components. Propulsive motility in the descending colon and rectum is increased to move the feces to the anus, where relaxation of internal and external anal sphincters facilitates elimination.

HEPATIC RESPONSE TO A MEAL

An essential function of the liver is to coordinate the distribution of vital metabolic substrates to the tissues of the body. It must perform this task during both the fasted (i.e., postabsorptive) state, when the gut contains no nutrients, and the fed (i.e., absorptive) state, when nutrients ingested during a meal enter the circulation from the gut (Table 1-4). During the fasted state, the energy needs of the tissues must be satisfied by metabolic substrates generated from the body's stores, chiefly the liver, the adipose tissue, and the skeletal muscle. Conversely, during the fed state, the body's energy requirements are met by a portion of the ingested nutrients, and any remaining nutrients must be stored for later use. The integrated response of the liver to a meal directs the crucial metabolic transition from the fasted to the fed state and back.

FASTED STATE	FED STATE
No nutrients in the gut	Nutrient absorption from the gut
Energy needs met by using stored fuel	Energy needs met by using ingested nutrients
Net hepatic glucose release	Glucose is principal fuel source
Glycogenolysis by liver and muscle	Hepatic glucose uptake
Gluconeogenesis by liver	Glycogen synthesis by liver and muscle
Fat catabolism by adipocytes	Fat synthesis and storage by liver and adipocytes
Protein catabolism, especially by muscle	Repletion of depleted proteins
Enhanced fatty acid utilization by most tissues	
Long-term Fast	
Hepatic ketone generation	
Enhanced ketone use by brain and other tissues	
Proportional increase in renal gluconeogenesis	

TABLE 1-4 Major Characteristics of the Fasted and Fed States

Fasted State

During the fasted state, the liver must maintain the concentration of glucose in the blood even though no nutrients are being absorbed from the gut. This is imperative because, under ordinary circumstances, the brain and erythrocytes use only glucose as an energy source. The blood glucose concentration is sustained by hepatic glucose production and by the reduction of glucose utilization by most tissues and organs. An early event in the fasted state is the hydrolysis of glycogen (i.e., glycogenolysis) in the liver into glucose that is released into the blood. The hepatic stores of glycogen are, however, limited, so that during prolonged fasts the liver must synthesize glucose from a variety of precursors (i.e., gluconeogenesis), which include lactate, pyruvate, amino acids, and glycerol. These glucose precursors result from several extrahepatic metabolic processes that are stimulated during a prolonged fast. Glycogen is stored in skeletal muscle as well as in the liver. During a prolonged fast or when a muscle is working, skeletal muscle glycogen is hydrolyzed to form lactate and pyruvate. Lipid hydrolysis (i.e., lipolysis) in adipocytes is stimulated in the fasted state, resulting in the formation of glycerol as well as fatty acids. As the fasted state proceeds, protein mainly located in skeletal muscle is catabolized to amino acids. These precursors are circulated to the liver, where they are converted into glucose to help preserve the concentration of glucose in the blood. Consequently, during the fasted state, the liver is a site of net glucose release.

Gluconeogenesis is capable of supplying less than half of the energy necessary for survival. Therefore, the fasted state is also characterized by a substantial reduction in glucose utilization by most tissues and organs of the body. Glucose generated by the liver is, thus, spared for use by the CNS. Glucose use is reduced by an increase in fat utilization by other tissues. As previously discussed, enhanced lipolysis associated with the fasted state produces fatty acids in addition to the glucose precursor, glycerol. These fatty acids are released to the systemic circulation, where they are used as an energy source by nearly all tissues, except, most notably, the CNS. Fatty acids undergo ß-oxidation, producing hydrogen atoms, which undergo oxidative phosphorylation, and acetyl-CoA, which enters the Krebs cycle, where it is catabolized to generate energy.

During long-term fasts (i.e., longer than 24 to 48 hours), further metabolic changes occur that facilitate survival. The kidneys, which are also capable of performing gluconeogenesis, take on an increasingly more prominent role in glucose production. In addition, the liver converts acetyl-CoA, a product of fatty acid catabolism, as previously discussed, into ketones. These ketones are used as an energy source by many tissues, including the brain. A distinct advantage of shifting the fuel source from glucose to ketones is that muscle is spared as a source of amino acids for gluconeogenesis.

Fed State

The digestion and absorption of a meal drastically alter the metabolic conditions in the body because extrinsic nutrients enter the blood from the gut. During this period, termed the *fed state,* ingested glucose becomes the body's principal energy source. A small amount of this glucose enters the liver, where some of it is used to meet the liver's energy needs; the remainder is converted to glycogen, which will replete the hepatic stores, and to fatty acids and glycerol for synthesis of and storage as triacylglycerols in the adipose tissue. Thus, a key feature of the fed state is net glucose uptake by the liver. Glucose that reaches the skeletal muscle is catabolized for energy and converted to glycogen to replete muscle energy stores. Adipocytes catabolize glucose as well, but they also use it to form a-glycerol phosphate and fatty acids, which are triacylglycerol precursors. Ingested amino acids are taken up by all the body's tissues and organs, including the liver, for use in protein synthesis. Excess amino acids, however, are not stored as protein, but are converted by the liver to a-keto acids, which are catabolized or converted to fatty acids for storage as fat. Thus, the net protein synthesis during the fed state simply replenishes the protein degraded during the fasted state, except in growing children or vigorously exercising adults. The lipid contents of a meal are absorbed by the intestine as triacylglycerol-containing chylomicrons that are carried to the circulation by way of the lymphatics. Lipoprotein lipases in the endothelium hydrolyze the ingested triacylglycerols into fatty acids and glycerol, which the tissues use for energy, and adipocytes store the excess as fat.

Regulation of the Metabolic State

The hepatic response to a meal, which directs the transition from the fasted to the fed state, is regulated by endocrine and neural pathways, as is that of the GI tract, but also by the concentration of metabolic substrates in the sinusoidal blood. Insulin and glucagon, hormones produced in the islet cells of the pancreas, are the principal regulators of the metabolic state, such that the transition from the fasted to the fed state can be explained by an increase in the ratio of insulin to glucagon in the blood. Insulin, the secretion of which is increased during the fed state, affects primarily the metabolism of the liver, adipose tissue, and muscle. Insulin stimulates glucose uptake and use, net glycogen synthesis, net amino acid uptake, and net protein synthesis by muscle. The effect of insulin on adipocytes is to increase glucose uptake and use, and net fat synthesis. The hepatic response to insulin is enhanced glucose uptake, net glycogen synthesis, and net fat synthesis.

Hyperglycemia is the most important stimulus for insulin secretion, although an increase in the blood amino acid concentration also stimulates insulin release. Therefore, the absorption of metabolic substrates during a meal represents a powerful regulator of the insulin concentration in the blood. In addition, insulin secretion is inhibited by sympathetic neural activity and epinephrine, and enhanced by intestinal hormones, including glucose-dependent insulinotropic peptide.

In contrast to insulin secretion, glucagon secretion is increased during the fasted state. Glucagon, which acts primarily on the liver, counters the effects of insulin by stimulating glycogenolysis, gluconeogenesis, and ketone synthesis. Glucagon release is stimulated mainly by hypoglycemia and inhibited by hyperglycemia, although epinephrine and sympathetic neural activity also stimulate its secretion.

Aside from regulating the secretion of insulin and glucagon, epinephrine and the sympathetic nervous system stimulate glycogenolysis by the liver and muscle, gluconeogenesis by the liver, and lipolysis by adipocytes. Hypoglycemia leads to reflex epinephrine secretion and sympathetic neural activity. Although other hormones, such as cortisol and growth hormone, modulate hepatic metabolism, they do not play an important role in the liver's response to a meal.

In addition to the roles that blood glucose and amino acid concentrations play in the hormonal regulation of the metabolic state, the concentration of glucose in the blood of the sinusoids directly modulates hepatic metabolism. As a result of the activity of certain glucose concentration–dependent enzymes in the liver, elevation of the sinusoidal blood glucose concentration stimulates glycogen synthesis and inhibits glycogenolysis. Together, hormones, the autonomic nervous system, and the concentration of metabolic substrates in the blood precisely modulate the hepatic response to a meal.

SUMMARY

Of necessity, this overview of the function of the GI tract and the liver in response to a meal is brief. The details of the function of each organ are provided elsewhere in this textbook. The overview provides the reader with a framework for understanding the regulatory mechanisms and the interdependence of organ functions and control mechanisms required for optimal functioning of the entire process.

CHAPTER 2

John Furness, Nadine Clerc, Fivos Vogalis, and Martin J. Stebbing

THE ENTERIC NERVOUS SYSTEM AND ITS EXTRINSIC CONNECTIONS

The gastrointestinal tract is unique among mammalian organs in that it has extensive intrinsic neural circuits. These circuits form the enteric nervous system, which contains reflex pathways capable of functioning independently of central control, although the central nervous system normally modifies activity within the gut wall. Enteric neurons have essential roles in the control of motility, blood flow, water and electrolyte transport, and acid secretion in the digestive tract. The enteric nervous system is most commonly the medium through which extrinsic neurons control gastrointestinal function.

STRUCTURAL ORGANIZATION OF THE ENTERIC NERVOUS SYSTEM

The enteric nervous system consists of nerve cell bodies and their processes embedded in the wall of the gut. The number of enteric neurons in a human is estimated to be about 100 million, which is about the same number of nerve cells as in the spinal cord. [1], [2] The nerve cell bodies are grouped in small aggregates, the enteric ganglia, which are connected by bundles of nerve cell processes to form two major ganglionated plexuses in the tubular digestive tract: the myenteric plexus, also called the *Auerbach plexus,* and the submucosal plexus, which is often referred to as the *Meissner plexus*.

Locations of the Enteric Ganglia

The myenteric plexus lies between the longitudinal and circular layers of the muscularis externa and forms a continuous network around the circumference of the tubular digestive tract from the upper esophagus to the internal anal sphincter (Fig. 2-1). In the parts of the large intestine where the longitudinal muscle is gathered into teniae, the myenteric plexus is prominent underneath the teniae and is sparser over the rest of the colonic surface.

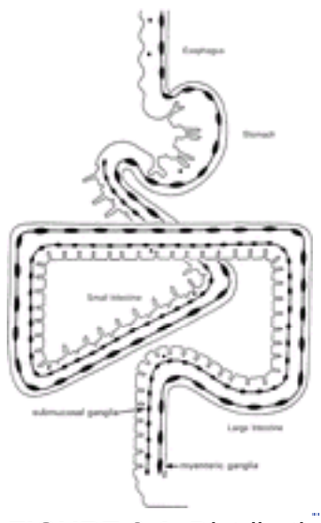

FIGURE 2-1. Distribution of enteric ganglia in the tubular digestive tract. The gastrointestinal tract is depicted in longitudinal section to reveal the myenteric ganglia, which form a continuous plexus from the upper esophagus to the internal anal sphincter, and the submucosal plexus, which is prominent in the small and large intestines. Isolated ganglia occur in the gastric and esophageal submucosa and in the mucosa throughout the digestive tract.

The submucosal plexus of ganglia is significant only in the small and large intestines; extensive networks of linked ganglia are not found in the submucosa of the esophagus and stomach, although isolated ganglia are sometimes encountered in these regions.

Ganglia are occasionally found in the mucosa, specifically in the connective tissue close to the muscularis mucosae. [3] Small ganglia are also found along the extrinsic nerves (i.e., vagus, pelvic, and mesenteric nerves) as they enter the gut. Some of the ganglia associated with the extrinsic nerves are located on the surface of the gut, particularly in the stomach and rectum; these are referred to as *subserosal ganglia*. Enteric ganglia are also present in the gallbladder, biliary ducts, and pancreas.

Nonganglionated Plexuses

A series of nonganglionated plexuses supply effector tissues of the tubular digestive tract: the longitudinal muscle plexus, the circular muscle plexus (and its subdivisions), the plexus of the muscularis mucosae, the mucosal plexus, and the perivascular plexuses (Fig. 2-2). The exception is the striated component of the external musculature of the esophagus, which is found in the upper third of the human esophagus and in a greater proportion of the esophagus in most other species.

The striated muscle cells are innervated at motor endplates, not by a nerve plexus.

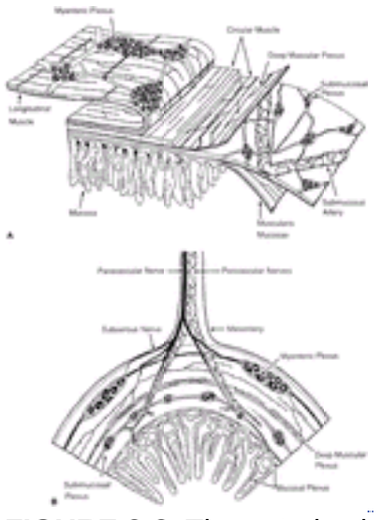

FIGURE 2-2. The enteric plexuses as they are seen (**A**) in whole mounts and (**B**) in transverse section. The drawings depict the small intestine. There are two ganglionated plexuses, the myenteric and the submucosal, in addition to plexuses of nerve fibers in the muscle and the mucosa and around the arterioles. (From ref. [1], with permission.)

The pattern of innervation of the longitudinal muscle differs according to its bulk. In humans, and in other species in which the longitudinal muscle is a thick layer throughout the intestine, the nerve fiber bundles run parallel to the muscle and comprise the longitudinal muscle plexus. In some species, such as the rabbit and the guinea pig, the thickness of the longitudinal muscle of the small intestine is less than about ten muscle cells. In these species, the nerve fiber bundles do not form a plexus within the longitudinal muscle, but rather a tertiary plexus, a component of the myenteric plexus, that lies against the inner surface of the longitudinal muscle (Fig. 2-3). [3], [4] and [5] The processes of individual tertiary plexus neurons ramify extensively on the inner surface of the longitudinal muscle. [6]

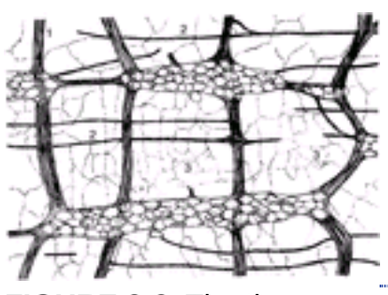

FIGURE 2-3. The three components of the myenteric plexus found in small animals are shown in a drawing of a whole mount from a guinea pig small intestine. Common to all species is the primary component of the plexus (*1*), consisting of the ganglia and internodal strands (interganglionic connectives), and the secondary component (*2*), consisting of nerve strands lying parallel to the circular muscle. The tertiary plexus (*3*) is found only where the longitudinal muscle is thin; in such regions, little or no longitudinal muscle plexus is found within the longitudinal layer (calibration bar = 100 µm). (From ref. [3], with permission.)

The circular muscle plexus is formed by parallel bundles of nerve fibers throughout this muscle layer. In some regions of the gastrointestinal tract, a dense layer of nerve fiber bundles provides additional innervation of the inner part of the circular muscle. The presence of this plexus of nerve fibers and its position in relation to the circular muscle differs among regions. In the small intestine of mammals, including humans, and most other vertebrates, the circular muscle consists of a thick outer layer and a thin inner layer of muscle cells. [7], [8] The dense plexus of nerve fibers located between these two muscle layers in the small intestine is called the *deep muscular plexus*. [9]

The colon of most species lacks an inner specialized layer of circular muscle; a dense layer of nerve fibers, similar to the deep muscular plexus, lies close against the inner surface of the circular muscle, adjacent to connective tissue of the submucosa. A term introduced by Cajal, the *submuscular plexus,* is used to refer to this plexus. [9], [10] and [11] An inner specialized muscle layer has been found in the colon of human and mouse. [12], [13] In the human colon, a deep muscular plexus is found between the two circular muscle layers. The circular layer of the stomach lacks an inner layer of specialized smooth muscle. [10] No dense plexus of nerve fibers near the inner surface of the circular muscle is readily discerned in the stomach of dogs and guinea pigs, although Faussone Pellegrini and colleagues [13] described a submuscular plexus in the human stomach. The circular muscle plexus continues into the circular muscle of the smooth muscle sphincters of the digestive tract without any apparent change in form. The myenteric plexus also continues into the sphincter regions.

The muscularis mucosae throughout the digestive tube consists of outer longitudinal and inner circular layers of smooth muscle innervated by nerve fibers running parallel to the muscle bundles. In the small intestine, muscle bundles extend into the cores of the villi. In the small intestine of small animals, such as mice and rats, the muscularis mucosae is thin and barely discernible in histological sections.

The mucosal plexus is a network of fine nerve fiber bundles that lies beneath the mucosal epithelium. It is sparse in the esophagus but prominent in the stomach, small intestine, colon, and gallbladder. The mucosal plexus in the small intestine is sometimes described as having subglandular, periglandular, and villous components. These components are continuous with one another, although their respective nerve fiber populations differ. [14]

Perivascular plexuses are found around the arteries leading into the gut wall and around the arterioles within the gut. Innervation of veins within the gut wall is sparse or nonexistent, but the mesenteric and hepatic portal veins in most species are innervated. Lymphatic vessels in the gut wall appear to lack innervation.

Myenteric Plexus

The arrangement of an area of the myenteric plexus of the human small intestine is shown in Figure 2-4. The thickness of the ganglia, which are flattened in the plane of the plexus, is usually one to four nerve cells, depending on the state of contraction and the size of the intestine. [15] In any region of the gastrointestinal tract, ganglion size varies widely. In the guinea pig ileum (see Fig. 2-3), ganglia range from a single cell to about 200 nerve cell bodies.

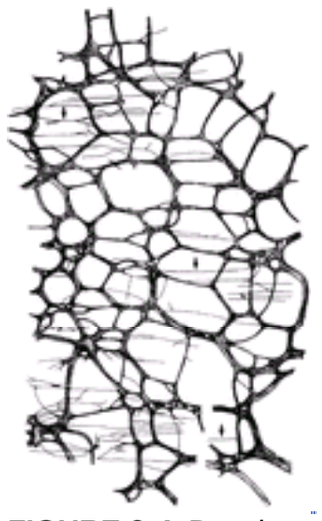

FIGURE 2-4. Drawing of a whole mount of the myenteric plexus of the human small intestine, prepared by Auerbach and published in *Henle's Textbook of Histology* in 1871. Myenteric ganglia, internodal strands, and small nerve trunks of the secondary component of the myenteric plexus (*arrows*) can be seen (calibration bar = 1 mm).

The pattern of ganglia, determined by shape and orientation, differs among regions and species but is often readily identifiable as belonging to a particular part of the intestine. [3], [16] The ganglia are connected to each other by small bands of nerve fibers, known as *internodal strands* or *interganglionic connectives* (see Fig. 2-3 and Fig. 2-4). The meshwork formed by the ganglia and the internodal strands is called the *primary component of the myenteric plexus*. Nerve strands that connect with the primary plexus and run circumferentially constitute the *secondary component of the plexus* (see Fig. 2-3 and Fig. 2-4). [4], [17] Branches from these secondary strands innervate the circular muscle. [18] Nerve fiber bundles (i.e., penetrating fiber bundles) also run through the circular muscle to connect the myenteric plexus with the submucosal and mucosal plexuses. [19]

The major targets for nerve cells in the myenteric plexus are the muscularis externa (which receives most of its innervation from this source), the submucosal ganglia, and other myenteric nerve cells. Myenteric nerve cells also supply the mucosa with nerve fibers, many of which have sensory nerve endings, and they give rise to nerve fibers that project to sympathetic prevertebral ganglia.

Submucosal Plexus

A continuous network of numerous small ganglia is found in the submucosa throughout the small and large intestines. In many species, plexuses of ganglia run in an inner and an outer layer, but some regions in small species have only one layer. [20], [21] The inner and outer plexuses contain different populations of neurons, defined by their morphologic and histochemical characteristics. [22] The electrophysiological properties of the nerve cell populations in the two plexuses also differ. [23] It is assumed that the inner plexus (closer to the mucosa) is mainly concerned with control of fluid movement, and the outer plexus contributes to control of motility of the external muscle. Submucosal ganglia are smaller and less regularly arranged than myenteric ganglia.

The submucosal plexus harbors the cell bodies both of neurons with dual secretomotor/vasodilator function and of neurons that are solely secretomotor. [24], [25] and [26] Some neurons, notably intrinsic primary afferent neurons, project from the submucosa to the myenteric plexus. [27] Other submucosal neurons probably supply the muscularis mucosae of the small and large intestines. [11] Submucosal neurons supply a part of the innervation of the inner circular muscle in some species, including human. [11], [28], [29] and [30] In the stomach, which almost entirely lacks submucosal ganglia, the intrinsic innervation of the mucosa and muscularis mucosae comes from the myenteric plexus.

Ganglia of the Gallbladder, Biliary Ducts, and Pancreas

Because the biliary system and the pancreas develop from diverticula of the small intestine, the ganglia in their walls are part of the enteric nervous system. A plexus of ganglia, similar to the enteric plexuses of the small intestine but differing between species in its relation to tissue layers, is found in the gallbladder, cystic duct, and common bile duct. [3] Numerous nerve fibers are found in the muscle, around blood vessels, and in the mucosa of the biliary tract. Ganglia, connected to each other by small nerve trunks, are scattered through the pancreas, forming a three-dimensional plexus in this solid organ. Nerve fibers are found around the acini and the blood vessels and in the islets. In the gallbladder, the intrinsic neurons control motility and the flux of water and electrolytes. In the pancreas, they appear to be involved in the control of both the endocrine and exocrine components. Nerve fibers connect the plexuses of the biliary system and pancreas with the ganglionated plexuses of the upper small intestine. [31], [32] and [33] These connections are presumed to contribute to coordination between these organs and the gastrointestinal tract.

MICROSCOPIC STRUCTURE OF THE ENTERIC NERVOUS SYSTEM

Shapes of Neurons

The nerve cells of the enteric ganglia can be classified into subgroups according to their shapes. [34], [35], [36] and [37] The first effective classification was by Dogiel, [34] who proposed that the shapes of nerve cells are related to their functions. Dogiel defined three cell shapes: types I, II, and III. The first two are readily recognized in different species and with various staining techniques; the third type is less well defined, but it bears some resemblance to a group later referred to as *filamentous neurons*. Type I neurons are generally flattened in the plane of the ganglia; they have oval cell bodies, prominent flattened (lamellar) dendrites, and a single long axon often characterized by spiny protuberances close to the cell body. Type II neurons have a spheroidal shape and give rise to several axons, usually three to ten, although some type II neurons are pseudounipolar. [35] A few type II neurons have tapering dendrites in addition to several long axonlike processes and are referred to as *dendritic type II cells*. [36], [38]

A variety of other shapes have been described, notably in the pig and guinea pig intestines, which have been studied intensively in recent years. Stach [36] extended Dogiel's classification to include types IV, V, and VI and mini-neurons, based primarily on work in the pig. Type IV neurons may be secretomotor neurons in both the guinea pig and pig. In the guinea pig small intestine, filamentous and small simple neurons (the latter being similar to the mini-neurons in the pig) have been described. [35]

Numbers of Neurons

Counts of nerve cell densities published up to 1985 were tabulated by Furness and Costa. [3] In the myenteric plexus, densities of about 2000 to 20,000 nerve cells per square centimeter were found in a variety of regions and species. In the submucosal plexuses of the small and large intestines, recorded densities range from about 1000 to 5000 nerve cells per square centimeter. Studies emphasize that the accuracy of counts of neurons depends on the methods used and that many published counts are probably underestimates. [2] A thorough study in the guinea pig concluded that there are 6.5 million nerve cells in the myenteric plexus of the small intestine and 7.3 million in the myenteric plexus of the colon. [2]

Ultrastructure

The enteric nervous system consists of a compact arrangement of nerve cell bodies, nerve fiber terminals, bundles of nerve fibers, and neuroglia. Unlike other autonomic ganglia, the enteric ganglia do not contain blood vessels or connective tissue cells, although septa of connective tissue sometimes separate parts of the ganglia in large species, including humans. Nutrients are supplied to the ganglia through the surrounding interstitial fluid. Similarly, hormones or drugs that act on the enteric ganglia are absorbed from the interstitial fluid. It may be significant that the cell bodies of many enteric neurons present large surface areas, devoid of neuroglia, to the extraganglionic space. [39], [40]

Nerve fibers in the enteric plexuses are of two types: fibers of relatively uniform diameter, about 0.2 to 0.5 µm; and fibers that consist of varicosities, usually about 1 to

2 µm in diameter, connected by short intervening segments that measure about 0.2 to 0.5 µm. The nonvaricose axonal segments are nonterminal regions that do not appear to release transmitter, whereas the varicosities are considered to be points of transmitter release. The varicose segments of enteric axons, including those within plexuses and those associated with muscle or mucosal epithelium, are often hundreds of micrometers or several millimeters long. This means that a single axon can contact many nerve cell bodies. The close contacts with nerve cells and their dendrites are of two types: those that have synaptic specializations, consisting of presynaptic accumulations of vesicles and postsynaptic densities; and those in which varicosities containing numerous synaptic vesicles come close to the target neuron, with no intervening glial cell and an absence of postsynaptic density. The latter nonspecialized association is the most common. Most enteric neurons receive both specialized and nonspecialized contacts. [40], [41], [42] and [43]

The nerve fibers that innervate the muscle and epithelium are arranged in bundles in which the individual fibers are partly surrounded by enteric neuroglia. [39] Although there are no obvious postjunctional specializations in which the varicosities come close to muscle cells, such varicosities may make close contacts with muscle cells that are associated with prejunctional specializations, particularly junctional clumping of vesicles. [44]

HISTOCHEMICAL PROFILES AND TRANSMITTER MULTIPLICITY OF ENTERIC NEURONS

The enteric nervous system contains more than 30 substances that affect the activity of neurons, muscle, and epithelial cells—substances that also may be neurotransmitters. [45], [46] and [47] Moreover, individual neurons contain several possible neurotransmitters in addition to other neuron-specific proteins. The combinations of chemical attributes, which are related to the functions of the neurons and their places in nerve circuits, provide a chemical code by which the neurons can be identified. In general, more than one substance contributes to the transmission process, which is therefore described as *plurichemical*. [48]

Co-localized substances do not have equal status as transmitters. [48] One substance (sometimes more) has the major role in transmission; this substance is the primary transmitter. For example, sympathetic vasoconstrictor neurons in many species contain norepinephrine and neuropeptide Y (NPY). The primary transmitter is norepinephrine; NPY has a subsidiary or modifying role. However, the relative contributions of different transmitters can vary between neurons with common functions, depending on the location and the activity of the neurons; the inhibitory muscle motor neurons of the gut are a good example (see section “ Motor Neurons”). Some neurons contain more than one primary transmitter and several subsidiary transmitters or neuromodulators; some classes of enteric neurons have five or more transmitters (Table 2-1).

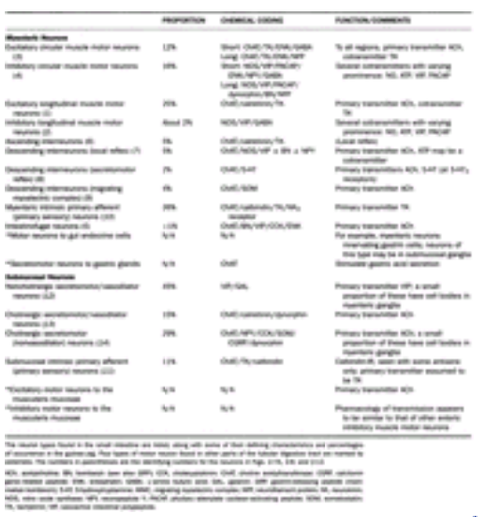

TABLE 2-1 Types of Neurons in the Enteric Nervous System

The chemistries of the subsidiary transmitters of functionally equivalent neurons differ between species. For example, the sympathetic noradrenergic neurons that inhibit intestinal water and electrolyte secretion contain somatostatin in the guinea pig but not in other species, and the noradrenergic neurons that inhibit motility contain NPY in the rat but not in the guinea pig. A broad range of experiments suggest that the primary transmitters are constant between species; many of the observed species differences in neuronal chemistry are probably differences in subsidiary transmitters or neuromodulators. In this chapter, we do not discuss all the substances that may participate in enteric neurotransmission in different species; much of this information is covered in published reviews. [45], [46] and [47]

The immunohistochemical localization of specific combinations of compounds in neurons provides a valuable investigative probe that allows the projections of individual neurons to be determined and their functions to be deduced, even when the roles of the detected chemicals are not known. For example, the inhibitory and excitatory muscle motor neurons in the gastrointestinal tract can be localized by immunoreactivity to vasoactive intestinal polypeptide (VIP) and substance P, respectively.

PHYSIOLOGICAL CHARACTERISTICS OF ENTERIC NEURONS

Electrophysiological Properties of Enteric Neurons

The electrophysiological classification of enteric neurons is confounded because the properties of the neurons differ between regions of the digestive tract, and even in a specific region, properties can vary depending on the circumstances of the experiment. [49], [50] and [51] However, classification is particularly useful when the electrophysiological type can be correlated with the physiological function of the neuron and with its shape and histochemical profile.

In the small intestine of the guinea pig, neurons can be separated into two groups, AH and S, according to their electrophysiological properties (Fig. 2-5). These terms were introduced in 1974, [52] and the classification remains useful, although the reasons for calling them *AH* and *S* are no longer well justified.

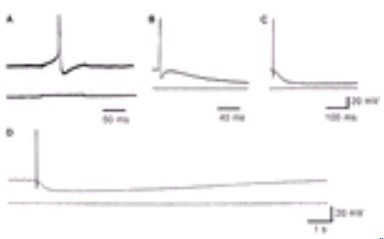

FIGURE 2-5. Action potentials elicited in an S neuron (**A**) and in AH neurons (**B–D**) by intracellular current pulses. The action potential in the S neuron is followed by a brief period of hyperpolarization; the action potentials in the AH neurons are followed by two phases of hyperpolarization (early and late afterhyperpolarizing potentials), one brief (**B**) and the other prolonged (**C,D**). Note the differences in the time scales. (From ref. [52], with permission.)

The S neurons exhibit brief action potentials that are followed by short-duration afterhyperpolarizing potentials (AHPs) lasting 20 to 100 milliseconds. These action potentials are blocked by tetrodotoxin. S neurons have a variety of shapes, which include the Dogiel type I and filamentous morphologies, but never the Dogiel type II morphology. All S neurons have a single axon. They exhibit fast excitatory postsynaptic potentials (EPSPs), and compound fast EPSPs of sufficient amplitude to generate action potentials can be evoked in all S neurons. These EPSPs are referred to as *compound* because they are the summed effects of transmission from

several axons. Slow EPSPs are also recorded from S neurons.

The action potentials of the AH neurons in the guinea pig small intestine are large (i.e., 75 to 110 mV in amplitude) and of longer duration than those of the S neurons, and they have an inflection (hump) on the falling phase. They are normally followed by two separate phases of hyperpolarization (see Fig. 2-5). The early AHP lasts 20 to 100 milliseconds and is similar to the undershoot usually seen in neurons (including S neurons); it is the result of the activation of K^+ channels. The second hyperpolarization, the late AHP, lasts 2 to 25 seconds (see Fig. 2-5); it is the result of the opening of Ca^{2+}-sensitive K^+ channels. [53], [54] and [55] These neurons can generate a soma action potential that is carried by Ca^{2+} and a slow afterhyperpolarization, even when all the voltage-sensitive Na^+ channels are blocked by tetrodotoxin. [52], [56] The Ca^{2+} that enters during the action potential triggers the release of Ca^{2+} from intracellular stores; it is this Ca^{2+} that opens the K^+ channels, which in turn elicit the AHP. [57] In some circumstances, such as during excitation by transmitters or hormones, the prolonged afterhyperpolarization is not apparent. [49] In the guinea pig small intestine, all AH neurons have Dogiel type II morphology. AH neurons in the guinea pig ileum usually do not exhibit fast EPSPs, and when they are recorded, the EPSPs have very small amplitudes. [50], [52], [58] On the other hand, slow EPSPS do occur in AH neurons and can trigger action potentials.

The S and AH nomenclature does not apply, or is less useful, for some other gut regions. For example, in the guinea pig rectum, some neurons that exhibit a prolonged AHP have a single axon and receive fast EPSPs. [59] In the gastric corpus, all myenteric neurons have S characteristics and do not exhibit a prolonged hyperpolarization after the action potential. [60], [61]

Synaptic Transmission in the Enteric Nervous System

Enteric neurons receive fast and slow EPSPs and inhibitory postsynaptic potentials (IPSPs). Transmitter release from terminal axons may be reduced by presynaptic inhibition.

Fast EPSPs are graded in amplitude in relation to the strength of electrical stimulation, and when they are evoked reflexively, individual EPSPs of different amplitudes are observed (see below, Fig. 2-11). Thus, enteric neurons receive multiple fast synaptic inputs. The EPSPs last about 15 to 30 milliseconds. They are associated with an increased membrane conductance, which is attributed primarily to Na^+. Several transmitters contribute to fast EPSPs in S neurons (Fig. 2-6). Acetylcholine (ACh) appears to be one transmitter of fast EPSPs because antagonists of nicotinic cholinergic receptors reduce EPSP amplitude. [52], [62] Some fast EPSPs are in fact completely blocked by nicotinic receptor antagonists, whereas others are reduced only in amplitude, some by as little as 20% (see Fig. 2-6). [63], [64] and [65] In about 60% of neurons with a hexamethonium-resistant fast EPSP, the EPSP after nicotinic block was reduced in amplitude or abolished by PPADS, an antagonist of P_{2X} receptors. [65] This indicates that a purinergic (i.e., adenosine triphosphate [ATP]-mediated) transmission underlies some fast EPSPs. [65], [66] Neurons that use ATP as a transmitter project anally in the myenteric plexus. [65], [66] In about 10% of neurons, a 5-HT_3 receptor antagonist blocks or reduces fast EPSPs that remain in the presence of hexamethonium. [67] Those fast EPSPs that are abolished by hexamethonium are purely cholinergic. However, PPADS and 5-HT_3 receptor antagonists can further reduce responses that have already been reduced by hexamethonium. Thus, at some synapses, ATP and 5-HT could be cotransmitters with ACh. In some S neurons, the three antagonists in combination do not fully block fast EPSPs, which implies the existence of one or more other transmitters of fast EPSPs. Pharmacological and immunohistochemical data suggest glutamate may be a transmitter, acting through AMPA receptors, and that the fast EPSPs seen in a minority of AH neurons may also be mediated by glutamate. [68], [69]

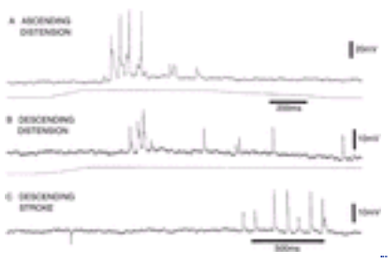

FIGURE 2-11. Intracellular recordings taken from circular muscle motor neurons of the guinea pig small intestine during intestinal reflexes. **A:** The response in an S neuron evoked by a distention of the intestinal wall 25 mm on the anal side of the point of recording. **B:** The response in a different S neuron to distention applied 35 mm on the oral side of the point of recording. **C:** The response of the same neuron illustrated in **B** to mechanical stimulation of the mucosa, without distention, by gentle stroking 35 mm on the oral side of the point of recording. In each case, the stimulus evoked a burst of fast excitatory postsynaptic potentials.

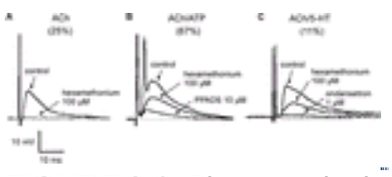

FIGURE 2-6. Pharmacological dissection of fast excitatory postsynaptic potentials (EPSPs) in S neurons of the myenteric plexus of the guinea pig ileum. **A:** A fully cholinergic EPSP is blocked by the nicotinic receptor blocker hexamethonium. **B:** A fast EPSP is partly reduced by hexamethonium. The remaining component is largely blocked by the purinergic P_{2X} receptor antagonist PPADS. **C:** A fast EPSP in which the response remaining after the administration of hexamethonium is blocked by the 5-HT_3 receptor blocker ondansetron. *ACh,* acetylcholine. (From ref. [47], with permission.)

In the guinea pig small intestine, slow EPSPs usually last between 15 and 120 seconds and occur in at least 75% of S-type neurons and in probably all AH neurons. [51], [70] The slow EPSPs evoked by electrical stimulation are likely to be the result of the superimposed actions of several different transmitters, each producing superficially similar synaptic potentials. [70] Electrical stimulation of internodal strands typically evokes cholinergic (via muscarinic receptors) and noncholinergic slow EPSPs in S neurons and in some AH neurons. [71] Other AH neurons exhibit only noncholinergic slow EPSPs. By simultaneously recording from an AH neuron and from an S or another AH neuron in the same ganglion, it has been shown that AH neurons provide slow excitatory synaptic inputs to S neurons and to AH neurons. [72] Other experiments indicate that AH neurons activated by sensory stimuli cause slow EPSPs in AH and S neurons. [51], [73] No evidence suggests that S neurons are a source of slow EPSPs, although adequate research to exclude this possibility has not been carried out.

The nature of the transmitter responsible for the noncholinergic slow EPSPs has been the subject of extensive speculation. [74] Although several substances found within enteric nerve terminals mimic slow EPSPs, including 5-HT, substance P, VIP, and somatostatin, pharmacological and other data indicate that one of the transmitters mediating this response is a tachykinin. [75], [76], [77] and [78] The majority of AH neurons have tachykinin immunoreactivity, but they never contain 5-HT, somatostatin, or VIP. [46]

A combination of membrane changes underlie slow EPSPs: reduction in the K^+ permeability of the neuronal membrane (including inhibition of the gK_{Ca} that is important for the late AHP after an action potential); an increase in Cl^- conductance; and block of a tetraethylammonium-sensitive outward rectifier current. [51], [79], [80] Reducing the permeability of the membrane to K^+ increases the neuronal excitability in two ways. First, it depolarizes the cell membrane, bringing it closer to the threshold potential needed to trigger an action potential. Second, increasing the input resistance of the cell enhances the effect of other currents on the membrane potential, making fast EPSPs more effective.

Inhibition of the outward rectifier current has a profound effect on the excitability state of S neurons; instead of firing briefly in response to depolarization, the neurons can fire tonically and at high rates. [51] Slow EPSPs in AH/Dogiel type II neurons affect neuronal excitability by reducing or abolishing their characteristic slow AHP,

presumably by inhibiting opening of the Ca^{2+}-sensitive K^+ channels. This inhibition facilitates the firing of prolonged, high-frequency trains of action potentials, which is an effect similar to that produced by the inhibition of the outward rectifier current, although through a different mechanism.

An unusual type of slow excitatory transmission, termed *sustained slow postsynaptic excitation* (SSPE), has been described in myenteric AH neurons.[81] Activation of presynaptic axons supplying AH neurons for extended periods (1–30 minutes) at low frequency (1 Hz) gives rise to a slowly developing, sustained increase in the excitability of the neurons associated with depolarization, increased input resistance, and suppression of the late AHP. Successive stimulus trains (duration, 1–4 minutes) elicit successively greater increases in excitability. Increased excitability can last up to 3.5 hours after a stimulus period of 30 minutes. This phenomenon may represent a type of neuronal memory and may be involved in adaptive responses.

IPSPs in myenteric neurons have been reported rarely, and then only in a small proportion of neurons in the guinea pig small intestine.[79,82] It is possible that electrical stimulation of internodal strands with one or more pulses affects both excitatory and inhibitory fibers. The excitatory responses may obscure any IPSPs that are evoked simultaneously. Studies in which enteric reflex pathways are activated by physiological stimuli have also failed to evoke IPSPs in myenteric neurons.[51,73,83,84,85,86] This suggests that any physiological role for this type of synaptic potential may be confined to a small group of myenteric neurons.

Electrophysiological studies of *submucosal* neurons have been performed in preparations from the small intestine, the cecum, and the distal colon of the guinea pig.[87,88,89,90,91] About 90% of all submucosal neurons exhibit fast EPSPs, and a large proportion of these also exhibit slow EPSPs, similar to those observed in myenteric neurons. The fast EPSPs are blocked by hexamethonium and are presumably mediated by ACh acting through nicotinic receptors. The slow EPSPs are probably caused by a reduction in K^+ permeability. Although several substances found within nerve terminals in the submucosal plexus can mimic the slow EPSPs, none has been shown unequivocally to be a transmitter. For example, lesions that cause a complete loss of substance P–containing nerve terminals in the submucosal plexus reduce the number of neurons with slow EPSPs.[92]

Although slow IPSPs are not observed in myenteric neurons, they are commonly seen in submucosal neurons. Stimulation of the internodal strands evokes a substantial IPSP in about 50% of submucosal neurons in the guinea pig small intestine and in as many as 90% of the neurons in the cecum.[87,88,89,90] In contrast, slow IPSPs were not observed in submucosal neurons of the guinea pig distal colon.[91,93] Most submucosal neurons with slow IPSPs also exhibit slow EPSPs, and all have fast EPSPs. In the small intestine, neurons with slow IPSPs contain VIP and are probably noncholinergic secretomotor/vasodilator neurons.[87,92]

The IPSP is caused by a substantial increase in the K^+ permeability of the membrane, which leads to a hyperpolarization of up to 30 mV. Two separate contributions to IPSPs have been identified, adrenergic transmission from the terminals of sympathetic secretomotor inhibitory neurons (see section "Sympathetic Effects on Motility and Secretion") and nonadrenergic transmission from intrinsic neurons.[87,94,95]

Lesion studies reveal that most submucosal neurons receive fast cholinergic input from neurons in the myenteric plexus and from other neurons in the submucosal plexus.[96] The slow EPSPs in many submucosal neurons appear to come from myenteric neurons, but some may come from submucosal neurons.[92,96]

Presynaptic inhibition may also have a role in the enteric nervous system. Sympathetic nerve stimulation reduces the amplitudes of fast EPSPs in both myenteric and submucosal neurons, probably by decreasing the amount of ACh released from the synapses,[97,98] although postsynaptic inhibitory effects may also play a role. It appears that the presynaptic inhibitory effect of the sympathetic neurons is the primary mechanism by which they diminish the contractile activity of the gut.[3] This inhibition is mediated through a-receptors. ACh released from enteric nerve terminals can act presynaptically to regulate the subsequent release of ACh and possibly to modify the release of the transmitters mediating slow EPSPs.[99] Several other putative transmitters contained within enteric nerve terminals (e.g., dynorphin, enkephalin, ?-aminobutyric acid, 5-HT) have been observed in pharmacological experiments to reduce transmitter release in the gastrointestinal tract. No physiological role has yet been established for these latter substances in presynaptic inhibition in the enteric nervous system.

FUNCTIONALLY DEFINED ENTERIC NEURONS

The identification of neurons by function has been derived by combining data from studies of the physiological properties of enteric reflexes, the morphologic identification of those neurons that are present (and could thus fulfill the physiological functions), and the correlation of neurochemical (primarily immunohistochemical) and pharmacological properties of enteric neurons (see Table 2-1). The model species has been the guinea pig. From these data has come a complete definition of the types of neurons in the small intestine,[100] and a thorough, but not yet complete, definition of the neuron types in the colon[101] and the stomach[102,103,104] (Fig. 2-7). Sufficient data are available from other species, notably human, pig, rat, and mouse, to suggest that the data from guinea pig can be extrapolated. The main difference between species is the placement of cell bodies of some neurons; specifically, the cell bodies of motor neurons of the external muscle are present in both the myenteric and submucosal plexuses in human and pig, whereas they are confined to the myenteric plexus in guinea pig, rat, and mouse.

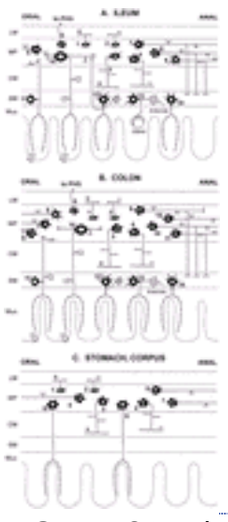

FIGURE 2-7. The types of neurons, as defined by their functions, cell body morphologies, chemistries, and projections, in the ileum (**A**), colon (**B**), and gastric corpus of the guinea pig (**C**). Types 1 through 4 are found in each region; types 5 and 10 through 14 are found in ileum and colon. *1,* Excitatory longitudinal muscle motor neuron; *2,* inhibitory longitudinal muscle motor neuron; *3,* excitatory circular muscle motor neuron; *4,* inhibitory circular muscle motor neuron; *5,* intestinofugal neuron (rare in stomach); *10,* myenteric intrinsic primary afferent neuron (IPAN); *11,* submucosal IPAN; *12,* noncholinergic secretomotor/vasodilator neuron; *13,* cholinergic secretomotor/vasodilator neuron; *14,* cholinergic secretomotor (nonvasodilator) neuron. **In the ileum (A):** *6,* ascending interneuron; *7,* descending interneuron (local reflex); *8,* descending interneuron (secretomotor reflex); *9,* descending interneuron (migrating myoelectric complex). The numbers adjacent to the neurons correspond to the numbers in Table 2-1, which lists all the neuron types according to function and provides data on the percentage of the cell bodies of each type in the myenteric or the submucosal ganglia, in addition to information about their chemistries. **In the colon (B):** *6, 7, 8,* types of ascending interneurons; *9, 15, 16, 17,* types of descending interneurons. **In the corpus of the stomach (C):** *8, 9,* neurons that project from the myenteric plexus to the mucosa; some of these are probably involved in the control of gastric acid secretion. IPANs are not present, and neuron cell bodies in the submucosal layer are rare or absent. *LM,* longitudinal muscle; *MP,* myenteric plexus; *CM,* circular muscle; *SM,* submucosal plexus; *Muc,* mucosa; *PVG,* prevertebral ganglia.

Motor Neurons

Muscle Motor Neurons of the Stomach and Intestines Excitatory neurons innervate the longitudinal and circular smooth muscle and the muscularis mucosae throughout the digestive tract. The primary transmitter of these neurons is ACh, which acts on the muscle through muscarinic receptors.[3] Tachykinins contribute to the excitatory transmission but have a lesser role than ACh, except perhaps in the rat small intestine.[105,106] and[107] The tachykinins in the enteric neurons are substance

P, neurokinin A, neuropeptide K, and neuropeptide-?. Direct experimental evidence has been obtained for the involvement of two of these, substance P and neurokinin A, in neuromuscular transmission. [108] The tachykinin component of excitatory transmission appears to be more prominent at high rates of neuron firing. Immunohistochemical studies and quantitative electron microscopy reveal that ACh and tachykinins are contained in the same excitatory muscle motor neurons. [109], [110] In the guinea pig small intestine, these neurons, and the inhibitory motor neurons, are S neurons by electrophysiological classification. Intrinsic motor neurons that relax the muscle are involved in descending reflexes that facilitate the passage of contents along the bowel and relax regions, such as the stomach, that expand to accommodate and retain their contents. These neurons, called *enteric inhibitory neurons,* release a combination of transmitters that contribute to relaxation in varying degrees, depending on the region and the species. [48], [111], [112], [113] and [114] The neurotransmitters are nitric oxide, ATP, pituitary adenylate cyclase–activating peptide (PACAP), and VIP. VIP and the enzyme nitric oxide synthase are found together in the inhibitory motor neurons. [115] Nitric oxide synthase inhibitors and scavengers of nitric oxide reduce inhibitory transmission in many species, including humans, indicating that nitric oxide is an inhibitory transmitter. [116], [117] However, electrophysiological and pharmacological evidence indicates that at least one other primary transmitter must be involved in the transmission from these neurons. [48] ATP relaxes the muscle, and when the inhibitory neurons are active, increased levels of ATP and its metabolites are detected in perfusates. [118] Suramin, an antagonist of the action of ATP on P_2 purinoceptors in intestinal muscle, can depress transmission from the inhibitory neurons of the guinea pig tenia coli. [119] A contribution of VIP to inhibitory transmission has been demonstrated in some gastrointestinal muscles, but in muscle in other regions, it makes little contribution. [120] Peptide histidine isoleucine (PHI), or its human equivalent, PHM, is derived from the same gene as VIP and has similar effects. Another member of the VIP family, PACAP, also relaxes intestinal muscle and is found in enteric neurons. [121] Immunoneutralization and pharmacological antagonism of the PACAP receptors both indicate that PACAP contributes to enteric inhibitory transmission in some regions. [114], [122] Thus, nitric oxide, VIP or PHI, PACAP, and ATP probably all contribute to the inhibition of transmission to muscle. In most instances, nitric oxide is a primary transmitter, and the contributions of VIP, PACAP, and ATP vary.

Muscle Motor Neurons of the Striated Esophagus The striated muscle of the esophagus is innervated by axons that form motor endplates, but unlike motor endplates elsewhere, individual endplates in the esophagus receive dual innervation, one axon being from a vagal motor neuron with its cell body in the medulla oblongata and the other originating from a cell body in the myenteric plexus. [123], [124] and [125] In the rat, the vagal endings are immunoreactive for calcitonin gene–related peptide (CGRP), and the endings of myenteric origin exhibit nitric oxide synthase immunoreactivity. Double staining with the use of these markers indicates that both fibers make synaptic connections with the muscle, and that the two fiber types are often closely apposed, facilitating presynaptic interaction. [125]

Secretomotor and Secretomotor/Vasodilator Neurons Controlling Fluid Exchange Secretomotor neurons in the small and large intestines and gallbladder enhance water and electrolyte secretion. Some enteric neurons send axons both to the mucosal epithelium, where the effect is to cause water and electrolyte secretion, and to the submucosal arterioles, where they have vasodilator actions (see section “ Enteric Pathways for Secretomotor and Vasodilator Control”). For practical reasons, in most studies of the functions of these neurons, only one outcome of their activity, secretion or vasodilation, has been measured. Nevertheless, if the different experiments are considered together, it can be deduced that some neurons have only a secretomotor role and some a dual secretomotor/vasodilator role (Fig. 2-8). Secretomotor transmission to the mucosa has both cholinergic and noncholinergic components. [126] ACh released from the cholinergic neurons acts on muscarinic receptors on the mucosal epithelium. The primary transmitter of the noncholinergic secretomotor effect is probably VIP. [127] In addition, HCO_3^- secretion in the duodenum and jejunum is augmented by secretomotor neurons. [128] Local vasodilator reflexes can be elicited in the intestines by mechanical or chemical irritation of the mucosa, and substantial evidence indicates that the vasodilator neurons are intrinsic to the intestine and are noncholinergic. [129] Experiments in which single neurons were stimulated, and the resulting changes in the diameter of submucosal blood vessels measured, provide direct evidence for the presence of both submucosal cholinergic and noncholinergic vasodilator neurons. [25], [130] Immunohistochemical studies, combined with denervation, confirm that both intrinsic cholinergic and noncholinergic neurons innervate submucosal arterioles. [131] It is probable that a primary effector of noncholinergic transmission is VIP. [3], [129], [132] In the colon, but not the ileum, the mucosa receives a polarized innervation by descending noncholinergic and ascending cholinergic neurons of the submucosal plexus. [133]

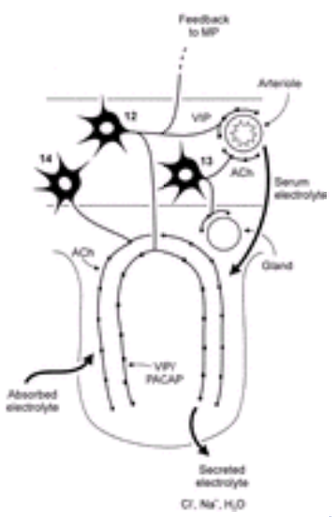

FIGURE 2-8. Neurons with secretomotor and vasodilator actions in the small intestine of the guinea pig. Functional evidence, supported by immunohistochemical and projection data, indicates that secretomotor effects are exerted through motor neurons, some of which are secretomotor/vasodilator and some of which are secretomotor only. The numbers adjacent to the neurons correspond to the numbers in Table 2-1, which lists all the neuron types according to function and provides data on the percentage of the cell bodies of each type in the myenteric or the submucosal ganglia, in addition to information about their chemistries. *ACh,* acetylcholine; *MP,* myenteric plexus, *PACP,* pituitary adenylate cyclase–activating peptide; *VIP,* vasoactive intestinal polypeptide.

Gastric Vasodilator Neurons Gastric acid secretion and blood flow are enhanced when the vagus nerve is stimulated; these effects are reduced by muscarinic antagonists. In most experiments, it is not possible to determine whether vasodilation that is the result of a direct vascular action of cholinergic neurons occurs in addition to a functional hyperemia consequent to the increased secretion. [132] However, Thiefin and colleagues [134] showed that centrally administered thyrotropin-releasing hormone stimulated a vagal pathway in the rat that caused gastric vasodilation after acid secretion was blocked by omeprazole. The increased blood flow in the absence of secretory change was antagonized by atropine. There is also evidence for noncholinergic gastric vasodilator neurons that use VIP as a transmitter. [135]

Gastric Secretomotor Neurons That Stimulate Acid Output Some secretomotor neurons govern gastric acid secretion. These neurons are cholinergic and act on the parietal cells through muscarinic receptors. For a complete description of the roles of these neurons and their relation to the hormonal control of gastric acid secretion, see Chapter 13.

Motor Neurons Innervating Enteric Endocrine Cells A variety of endocrine cells reside in the mucosa of the gastrointestinal tract, and because the mucosa is densely innervated, most of these cells have nerve fibers in close proximity. The best-documented motor neurons innervating the enteric endocrine cells are those controlling the release of gastrin, which is under the influence of vagal and intrinsic gastric pathways. The final neurons in both paths are in the stomach wall. Transmission from the final secretomotor neurons is mediated at least in part by gastrin-releasing peptide. [120] Release from other enteroendocrine cells is also likely to be under neural control. For example, the basal release of motilin is reduced by atropine and by tetrodotoxin and stimulated by muscarinic agonists; these findings suggest that motilin cells receive an excitatory cholinergic input. [136]

Motor Neurons Innervating Lymphoid Tissue (Peyer Patches) Evidence suggests that enteric neurons innervate Peyer patches, [137], [138] and [139] and that receptors for enteric neuron transmitters reside on lymphocytes therein. [140]

Enteric Interneurons

Interneurons have been identified in all gut regions, although their characteristics may vary between regions more than those of other neuron types. For example, the ileum and colon contain the same, or very similar, motor neurons and intrinsic primary afferent neurons, but their complements of interneurons are quite different (see Fig. 2-7).

Within the myenteric plexus, the interneurons form chains of like neurons that run both orad and toward the anus. [140], [141] In the guinea pig small intestine, at least three classes of descending interneurons and one class of ascending interneurons exist. Detailed studies of synaptic connections indicate that the chains formed by two of the types of descending interneurons interconnect. [142] The ascending interneurons appear to be involved in local motility reflexes, as are the descending cholinergic neurons that contain nitric oxide synthase. [26] Another type of descending interneuron, the ACh/somatostatin interneurons, may be linked to the passage of the migrating myoelectric complexes (MMCs). These neurons have a distinctive appearance (filamentous neurons) with numerous branching, tapering, filamentous dendrites [140]; they have very rare connections from intrinsic primary afferent neurons (IPANs). [143], [144] MMCs are waves of excitatory activity that are conducted

aborally along the gut. They are mediated through the intrinsic neural pathways of the small intestine. [145] Interruption of the continuity of the enteric nervous system blocks conduction of the MMC. [146] MMCs begin in the duodenum and travel the full length of the small intestine, but they are not conducted along the colon. It is thus pertinent that the ACh/somatostatin filamentous descending interneurons are found in both the ileum and the duodenum but not in the proximal or distal colon. The third type of descending interneuron, the ACh/5-HT interneuron, is possibly involved in secretomotor reflexes. [26] Interneurons also make connections between the myenteric and submucosal plexuses.

Recordings made during reflexes reveal that some transmission between interneurons is through fast EPSPs. [83] Pharmacological analysis indicates that transmission in the ascending pathway is cholinergic, through nicotinic receptors, whereas descending reflexes are resistant to blockade by the nicotinic antagonist hexamethonium. [75], [111], [147] Pharmacological data reveal that one of the transmitters of descending pathways is ATP, acting at P_{2x} receptors. [148] Nitric oxide, which is probably released from descending interneurons containing nitric oxide synthase, does not appear to be a primary transmitter. It appears to act as a retrograde transmitter, being released from the cell bodies of the interneurons and acting retrogradely on the endings of the terminals of IPANs to reduce transmitter release. [149]

Intrinsic Primary Afferent Neurons

The intrinsic reflex pathways involved in the control of gut movement, blood flow, and secretion are activated through neurons that respond to several stimuli, such as distention, lumenal chemistry, and mechanical stimulation of the mucosa. These intrinsic afferent neurons have now been positively identified as AH neurons with Dogiel type II morphology in the small intestine (see Chapter 3).

About 100 years ago, several investigators showed that enteric motility reflexes could be elicited in segments of intestine that had no neural connections with the central nervous system. [150], [151] and [152] It was therefore assumed that primary afferent neurons were contained in the gut wall. However, it was discovered at about the same time that reflexes, notably cutaneous vasodilator reflexes, could be initiated via axon collaterals even when the axons bearing the collaterals were disconnected from their cell bodies. [153] This led to a controversy about the existence of IPANs—a controversy that has been resolved only in the last decade.

Direct evidence that enteric responses can be initiated by axon reflexes comes from experiments in which reflexes were examined before and after degenerative section of the mesenteric nerve supplying the rat colon. [154] Reflexes initiated by muscle stretch were completely abolished after degenerative section of extrinsic nerves, but reflexes initiated by mechanical stimulation of the mucosa were unaffected. These findings imply that primary afferent fibers for mucosal mechanoreception have cell bodies in the wall of the colon, whereas primary afferent neurons for stretch reflexes in the colon have cell bodies in the dorsal root ganglia. Contrasting results were observed in the guinea pig small intestine. [155] In this case, reflexes initiated by mucosal distortion, and those initiated by radial stretch, were both unaffected by neural isolation of a segment of intestine. Thus, both reflexes depend on IPANs. Similar results have been reported for guinea pig colon. [156]

IPANs have been directly demonstrated by experiments in which activity-dependent changes were used in the labeling, [157], [158] and by intracellular recording. [73], [159] The experiments indicate that the cell bodies of the mucosal mechanoreceptor primary afferent neurons are in the submucosal ganglia, the cell bodies of chemoreceptor afferent neurons are in myenteric ganglia, and that the cell bodies of stretch-responsive primary afferent neurons are also in myenteric ganglia (see Chapter 3). Physiological studies have identified the primary afferent neurons as neurons with AH electrophysiological properties and Dogiel type II morphology in the small intestine of the guinea pig. These findings agree with deductions made from studies of the morphology and projections of Dogiel type II neurons. [19], [160] Neurons with similar morphology, histochemistry, and projections have been found in the guinea pig colon and rat small intestine. [161], [162] and [163] Neurons with Dogiel type II morphology that project to the mucosa, presumed to be IPANs, have been described in the human small intestine. [164] In the pig, Dogiel type II neurons also project to the mucosa and provide terminals in the enteric ganglia [21]; they have some electrophysiological characteristics in common with IPANs in the guinea pig. [165] Unlike their counterparts in the guinea pig and rat, IPANs in the pig are not immunoreactive for calbindin, but they are immunoreactive for CGRP and cholinergic markers; they do not all have such a prominent late AHP as that seen in guinea pig IPANs.

IPANs in the guinea pig are immunoreactive for both tachykinins and choline acetyltransferase. [46], [166] Therefore, they might be expected to transmit using tachykinins and ACh as cotransmitters. They transmit to other IPANs and to S neurons through slow EPSPs [72] that are probably mediated, in part, by tachykinins. [78], [167] Less direct evidence indicates that the AH neurons probably also communicate with other myenteric nerve cells at greater circumferential distances through cholinergic fast EPSPs. [144]

EXTRINSIC CONNECTIONS

Sympathetic Neurons

Norepinephrine is the primary transmitter of the sympathetic postganglionic neurons that supply the gastrointestinal tract. [3] Their cell bodies are in prevertebral and paravertebral ganglia, and their axons run to the gut with the mesenteric nerves. The major roles of these neurons are to regulate blood flow to the gastrointestinal tract, to regulate intestinal fluid and electrolyte secretion to keep it in balance with whole body requirements, and to inhibit gastrointestinal motility (see section "Sympathetic Effects on Motility and Secretion").

Neurons of Vagal and Pelvic Motor Pathways

The vagus nerves contain the axons of neurons whose cell bodies lie within the brainstem. A variety of effects, primarily on the upper gastrointestinal tract, are mediated through these neurons, including control of esophageal peristalsis, relaxation of the proximal stomach, enhancement of gastric peristalsis, stimulation of gastric secretion of acid, promotion of gastrin secretion, stimulation of pancreatic secretion, and modification of gallbladder function. In each case, the vagal neuron does not act directly; it forms synaptic connections with enteric neurons. Vagal efferent neurons also project to the small intestine and proximal colon. It is interesting that Brunner glands in the small intestine appear to be innervated directly by vagal pathways, but not by local intrinsic neurons. [168]

According to the convention used for other cranial autonomic pathways, the vagal neurons of these motor pathways have been called *parasympathetic preganglionic* or *vagal preganglionic neurons*. Reference to vagal input neurons as preganglionic wrongly implies that enteric neurons are relay neurons in parasympathetic pathways. Vagal input neurons are neurons in complex circuits in which enteric reflexes of several types are integrated with signals from the central nervous system and from other parts of the gastrointestinal tract. Most enteric neurons do not receive direct vagal connections. Thus, it is wrong to use the term *parasympathetic* to describe enteric neurons and enteric ganglia.

Transmission from vagal input neurons to enteric neurons is mediated principally by ACh acting on nicotinic receptor; the effects of stimulating vagal motor pathways are blocked or substantially attenuated by drugs that block nicotinic receptors.

The primary gastrointestinal effects of the pelvic nerves are on movement, secretion, and blood flow in the distal colon and rectum. The pathways are analogous to those of the vagus; pelvic efferent neurons with cell bodies in the sacral spinal cord form synapses on enteric neurons at which ACh is an excitatory transmitter acting through nicotinic receptors.

Extrinsic Primary Afferent Neurons

The extrinsic primary afferent neurons are discussed in Chapter 3. These neurons are subdivided into two groups: those with cell bodies in the vagal (nodose) ganglia, and those with cell bodies in the dorsal root ganglia. In general, the vagal afferent pathways carry information about the physiological state of the digestive organs. Impulses conveying pain or discomfort are conducted through the dorsal root ganglion (spinal afferent) pathways.

ENTERIC PATHWAYS FOR MOTILITY CONTROL

The circuits involved in local peristaltic reflexes in the small intestine, and the projections of the component neurons, have been deduced from studies of guinea pig small intestine (Fig. 2-9 and Fig. 2-10; see Fig. 2-7). The general features of these reflex pathways appear to be similar in the guinea pig large intestine and in the

small and large intestines of other species. Less is known about the circuits in the stomach, although propulsive reflexes do occur in this organ. [169] In all species, excitatory and inhibitory motor neurons supply the muscle; the general patterns of small intestine motility are similar (see Chapter 11), and intrinsic reflexes are evoked by the bulk and chemical nature of the lumenal contents.

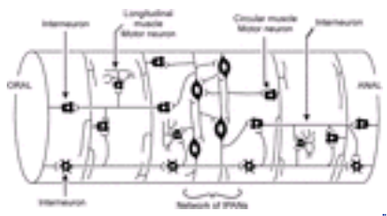

FIGURE 2-9. Pathways for propulsive reflexes in the intestine. A short segment of intestine is represented, on which the first parts of the descending inhibitory and the ascending excitatory reflex pathways are depicted. The patterns in the circuitry for the ascending and descending pathways are similar. Intrinsic primary afferent (sensory) neurons (IPANs) are circumferentially oriented and form self-reinforcing networks. They provide outputs to ascending and descending interneurons and monosynaptic connections to motor neurons. The interneurons form descending and ascending chains and also provide outputs to motor neurons. In the descending pathway, some neurons excite the longitudinal muscle, and some neurons inhibit the circular muscle. Ascending reflex pathways supply inputs to excitatory longitudinal muscle motor neurons and excitatory circular muscle motor neurons. A set of descending interneurons (**bottom part of diagram**) involved in conducting the migrating myoelectric complex receives very little input from IPANs but connects with motor neurons.

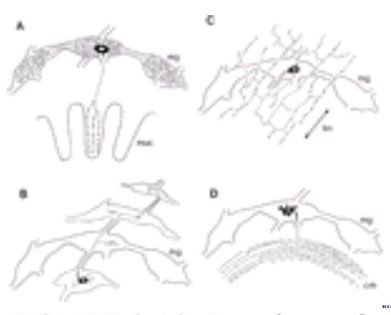

FIGURE 2-10. Drawings of enteric (**A**) intrinsic primary afferent neurons (IPANs), (**B**) interneurons, and motor neurons to (**C**) longitudinal muscle and (lm) (**D**) circular muscle (*cm*). These drawings are derived from studies of the guinea pig small intestine. The morphologies of the IPAN, the interneuron, and the motor neuron innervating longitudinal muscle are determined primarily by filling neurons with intracellular marker dye. The morphology of the motor neuron innervating circular muscle is determined by an evaluation of dye filling, in addition to histochemical and lesion studies. *mg,* myenteric ganglia; *muc,* mucosa.

The movements of the intestine are a result of the contractions and relaxations of the external longitudinal and circular muscles and of the muscularis mucosae. The neural control is superimposed on an underlying rhythm of muscle activity (i.e., slow waves), which occurs at frequencies of about 3 to 12 per minute in humans (see Chapter 6). [170] The major role in forming the pattern of mixing and propulsive movements appears to be taken by the circular layer of the external muscle, areas of which contract (or relax) like an annulus to close or open the lumen partly during both propulsive and mixing movements.

To study enteric muscle motor reflexes, investigators isolate segments of intestine to eliminate the influences of the central nervous system and circulating hormones. This simplifies recording from the muscle and enteric neurons. In these preparations, lumenal distention, or chemical or mechanical stimulation of the mucosa, elicits reflexes whose effects on the circular muscle can be recorded with intracellular microelectrodes. [85], [86], [147], [171], [172] and [173] The major responses of the muscle are depolarizing potentials (i.e., excitation) in the circular layer orad to the site of the stimulus and aborad hyperpolarizing potentials (i.e., inhibition). This polarization of electrical responses is analogous to that of the mechanical events seen when the intestine is distended. Longitudinal muscle motor neurons are also activated by reflex stimuli. [84] The longitudinal muscle contracts at the same time as the circular muscle, although there may be delay between the commencement of contraction in the two layers. [151], [174], [175] Evidence suggests that longitudinal muscle contraction in the colon may in effect pull the intestine over a solid bolus. [175]

Neither the reflex responses to stimulation of the mucosa nor those to distention pass along the gut if the myenteric plexus is cut, but they are unaffected by interruption of the submucosal plexus. [147], [171], [176] Therefore, the reflex pathways excited by mucosal stimulation must pass locally from the sensory receptors in the mucosa to the myenteric plexus. Responses evoked by distention persist if the mucosa is removed, a finding that implies the existence of sensory receptors in the external muscle. [147], [177], [178] These receptors have now been directly demonstrated (see Chapter 3). Mucosal distortion releases 5-HT from enterochromaffin cells in the epithelial lining, [179] which, in turn, activates the endings of the IPANs to initiate peristaltic reflexes. [179], [180] and [181]

In the guinea pig small intestine, IPANs with cell bodies in the myenteric plexus provide extensive varicose networks in the ganglia, primarily close to and surrounding the cell bodies. [19], [38] A minority of the neurons have aborally projecting collateral axons. [182] Ultrastructural studies show that the varicosities of IPAN terminals provide synaptic inputs to the majority of neurons in the myenteric plexus. [183] Electrophysiological studies of the effects of the activation of IPANs through their nerve endings in the mucosa confirm that they communicate with other neurons by means of slow EPSPs, [51], [73] whereas recording at a distance circumferentially implies that some synapses from IPANs cause fast EPSPs. [144] Slow EPSPs are evoked consistently only at rates of electrical stimulation of presynaptic neurons of about 3 Hz or more. In accordance with this finding, the primary afferent neurons fire in response to physiological stimuli in bursts that commonly achieve rates of 10 to 40 Hz. [51], [73]

It is notable that physiological as well as ultrastructural [183] studies indicate that IPANs synapse with other IPANs to form a self-reinforcing network (see Chapter 3). IPANs are numerous, about 500 per millimeter-length of the small intestine. Because the stimuli giving rise to intestinal reflexes (e.g., lumenal chemicals, distention, mucosal distortion) are not spatially confined to submillimeter distances, it can be deduced that reflexes are usually initiated by the more-or-less synchronous activation of a population of several hundred interconnected primary afferent neurons. The summation of the synaptic events caused by the transmissions from the primary afferent neurons results in the nearly simultaneous activation of numerous interneurons and motor neurons. The IPANs in the submucosal plexus project to the myenteric plexus and appear to be directly sensitive to mechanical and chemical stimulation of the mucosa. At least some portion of the reflexes evoked by stimulation of the mucosa is mediated by these neurons.

Enteric reflexes often extend for several centimeters along the intestine from a single point of stimulus, unlike the processes of the majority of IPANs and of motor neurons. This implies that most enteric reflex pathways in the guinea pig include interneurons, which, as previously explained, form interconnecting chains that run along the intestine, and which may individually run for more than a centimeter. [184] The pathway lengths may be greater in other species. Immunohistochemical data indicate that, in the guinea pig small intestine, there is one population of orally directed interneurons, which are cholinergic; and several populations of aborally directed interneurons, many of which are immunoreactive for choline acetyltransferase (see Table 2-1 and Fig. 2-7). Intracellular recordings made from enteric neurons during reflexes evoked by distention and mucosal distortion have generated morphologic data (Fig. 2-11). [83], [84], [85] and [86] Fast EPSPs, which are the output events of interneurons, are seen in neurons at distances of 0.5 to 2.5 cm from the stimuli (see Fig. 2-11). Physiological and structural studies indicate that interneurons make connections with both motor neurons and other interneurons, confirming the pattern of connectivity shown in Figure 2-9. The circuits in Figure 2-9 depict individual neurons, although cohorts of neurons are actually activated. [185]

The projections of motor neurons to the circular muscle have been determined by mapping the responses in the muscle to transmural nerve stimulation in normal pieces of intestine and in pieces in which the nerve paths were lesioned and allowed to degenerate, [186], [187] by microscopic analysis of the effects of nerve lesions, [3] and by the observation of retrograde transport of microcrystals of dye placed on the inner surface of the muscle. [110] Most excitatory and inhibitory motor neurons supplying the circular muscle extend only 1 to 2 mm along the guinea pig intestine, but they run up to half the distance around its circumference, which is about 6 to 8 mm in the guinea pig small intestine (see Fig. 2-10). Thus, the response to reflex activation is spread around the intestine. This finding is consistent with the common

observation that the intestine undergoes annular, not eccentric, contractions or relaxations. The reflex probably involves a summed response to transmission from many motor neurons; Bornstein and colleagues [186], [187] estimated that each smooth muscle cell is influenced by approximately 25 inhibitory motor neurons, and a similar convergence of excitatory influence can be expected. Furthermore, the electrical communication between smooth muscle cells ensures a summation of the effects of the population of motor neurons. Some excitatory motor neurons project in an oral direction for up to 10 mm, and some inhibitory motor neurons project aborad for as much as 30 mm.

In addition to the simple reflex whose neural circuits have now been deduced, the intestine exhibits mixing movements and cyclic changes of activity, collectively called *migrating myoelectric complexes* (MMCs). The MMCs pass along the intestine from the stomach to the terminal ileum. In humans, these cycles last about 90 minutes and are seen between digestive periods. The myoelectric complex is generated by the enteric nervous system. [3] During digestion, the contents of the intestine trigger irregular mixing contractions. The neural pathways depicted in Figure 2-9 presumably provide the building blocks for both the irregular contractile activity and the MMCs, with the irregular contractile activity perhaps representing the superimposition and interaction of simple reflexes. It has been deduced that the descending neuron chains for the MMC are separate from those of local reflexes (see section "Enteric Interneurons" and ref. [144]).

ENTERIC PATHWAYS FOR SECRETOMOTOR AND VASODILATOR CONTROL

Secretomotor and Vasomotor Reflexes Related to Fluid Exchange

Distention, mechanical stimulation of the mucosa, and the application of chemicals to the mucosa cause motility reflexes in the intestine and also evoke secretomotor and vasodilator reflexes. [126], [188], [189], [190] and [191] The secretomotor neurons stimulate the epithelial cells to pump Cl^- into the lumen, which takes with it counter ions, mostly Na^+, and water. It is likely that the same ion channels are responsible for HCO_3^- secretion, the amount secreted being dependent on the lumenal pH. [192] Histochemical studies in the guinea pig small intestine indicate that two of the motor neurons for secretion are also motor neurons for vasodilation (see Fig. 2-8); that is, these secretomotor neurons may cause a physiologically appropriate vasodilation, concomitant with secretion, through collaterals to submucosal arterioles. [131], [193], [194] and [195] Thus, there may not be separate reflexes for secretion and vasodilation, although no evidence suggests a third type of secretomotor neuron projects to the vasculature (see Fig. 2-8). In the small intestine, an important physiological stimulus for secretion appears to be the presence or active uptake of nutrients. Nutrients such as glucose, which are absorbed by a Na^+ cotransporter, draw in Na^+ along with Cl^- and water. At the same time, glucose or its uptake stimulates the enteric secretomotor reflex. [196] Enteric reflexes also cause HCO_3^- secretion in response to duodenal acidification, although other acid-sensitive mechanisms, including a neurally independent stimulation of prostaglandin production, also release HCO_3^-. [128] Secretomotor reflexes can also be initiated pathologically by toxins, such as cholera toxin or enterotoxins, in the lumen.

The enteric secretomotor/vasodilator circuits consist of IPANs with their endings in the mucosa and an integrating circuitry that feeds back to motor neurons with cell bodies in the submucosal ganglia (Fig. 2-12). In some cases, the reflex pathways involve the myenteric ganglia (e.g., cholera toxin–induced secretion [197]), whereas reflexes initiated by mechanical stimulation of the mucosa can be mediated entirely through the submucosal plexus. [126], [189] Pathways from the myenteric plexus also cause vasodilation. [198] There are two types of secretomotor neurons: cholinergic and noncholinergic. The noncholinergic neurons appear to mediate most of the local reflex response, using VIP, or a related peptide, as their primary transmitter. [126], [127], [132] In the guinea pig small intestine, there are two types of cholinergic neurons, those that also contain NPY (and other peptides) and those that contain calretinin. The ACh/calretinin neurons preferentially innervate the glands at the base of the mucosa and have collaterals to submucosal arterioles, whereas the ACh/NPY neurons do not appear to innervate the arterioles. The presence of three classes of secretomotor neurons, two of which also have vasodilator collaterals, may provide a mechanism to balance secretion and vasodilation appropriate to the digestive state (see Fig. 2-8 and Fig. 2-12). The control of secretion in the small intestine contributes to the regulation of whole-body water and electrolyte status. In an equilibrium state, the amount of fluid lost through the kidneys and through respiration and perspiration should be matched by absorption from the alimentary tract. If more fluid is absorbed with nutrients or across the gastric mucosa than is lost, some of the excess can be passed back under the control of secretomotor reflexes. Thus, the source of secreted fluid in the small intestine can be a mixture of serum electrolytes and locally absorbed electrolytes. We postulate that local computation of the need for vasodilation and local absorption to supply electrolytes for secretion determines the relative activation of vasodilator and nonvasodilator secretomotor neurons (see Fig. 2-12).

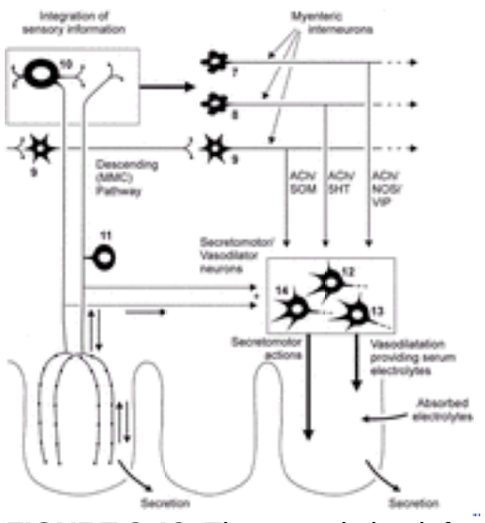

FIGURE 2-12. The neural circuit for secretomotor/vasodilator control in the guinea pig small intestine. Secretomotor responses are mediated both through antidromic action potential invasion of the mucosal endings of intrinsic sensory neurons, and through reflex activation of secretomotor and vasodilator neurons. Fluid absorbed across the mucosa during digestion, and fluid from the vasculature, whose supply is modified by vasodilation, are identified as sources of fluid for secretion. The numbers adjacent to the neurons correspond to the numbers in Table 2-1, which lists all the neuron types according to function and provides data on the percentage of the cell bodies of each type in the myenteric or the submucosal ganglia, in addition to information about their chemistries. *ACh,* acetylcholine; *MMC,* migrating myoelectric complex; *NOS,* nitric oxide synthase; *SOM,* somatostatin; *VIP,* vasoactive intestinal polypeptide.

In addition to reflexes that have secretomotor neurons as their outputs, there is evidence that IPANs may have direct secretomotor effects. The intrinsic sensory neurons are immunoreactive for tachykinins, and their varicose processes are immunoreactive for the vesicular ACh transporter. [166] Thus, their mucosal endings are likely to release ACh and tachykinins, both of which cause secretion. It has been directly shown that action potentials in one process of a sensory neuron traverse the cell body to invade other processes, [199] and the pattern of branching of the neurons indicates that action potentials could be conducted, as an axon reflex, between terminals that branch within the mucosa (see Fig. 2-8). Interestingly, the secretory responses to distention and to mucosal stroking in the guinea pig colon are reduced by tetrodotoxin (which blocks nerve conduction) and by atropine (which blocks the ACh receptors on the epithelium), but not by mecamylamine, an antagonist of cholinergic fast neuroneuronal transmission. [189], [191] The concentration of mecamylamine that was used was shown to block nicotinic receptors in the colon. [191] Moreover, the responses to stroking were not reduced by extrinsic denervation, a finding that indicates they are dependent on the activation of intrinsic neurons. [200] Thus, there is good evidence that ACh released by axon reflex, or by mononeuronal reflexes crossing the IPAN soma, contributes to secretory responses (see Fig. 2-8).

SYMPATHETIC EFFECTS ON MOTILITY AND SECRETION

Sympathetic neurons slow transit along the digestive tract, by constricting the sphincters and by inhibiting the contractile activity of the nonsphincter regions. [201] Inhibition of muscle movement in the nonsphincter parts of the gastrointestinal tract is primarily through actions of the noradrenergic axons in the myenteric ganglia, including the presynaptic inhibition of excitatory transmitter release. The nerve fibers also have direct inhibitory actions on the nonsphincter muscle. In the sphincter regions, the sympathetic neurons contract the muscle. Other sympathetic neurons innervate and inhibit submucosal secretomotor neurons. Another group of noradrenergic sympathetic neurons supply the gastrointestinal vasculature, constricting the arterioles and arteries and the major mesenteric veins. Their physiological

roles, which primarily involve adjustments of the proportion of the cardiac output going to digestive organs, are reviewed elsewhere. [132]

The existence of inhibitory reflexes whose pathways travel to the central nervous system and then back to the intestine through sympathetic ganglia was shown early in the 20th century. [3] Reflexes are conducted from one part of the gastrointestinal tract to another through sympathetic prevertebral ganglia, even when these ganglia are completely isolated from central nervous connections. [202], [203] These enteroenteric reflexes can be studied after the central pathways have been selectively inactivated, or in isolated preparations of intestine with ganglia attached.

Sympathetic enteroenteric inhibitory reflexes that decrease motility are initiated in one part of the gastrointestinal tract; they pass through prevertebral ganglia to other regions and also return to the first region through prevertebral ganglia. The peripheral enteroenteric reflex pathways and their associations with other sympathetic pathways are illustrated in Figure 2-13. Because it is not possible to survey all the evidence for the diagram in this chapter, only major points are discussed. Intestinofugal neurons that synapse in the prevertebral ganglia were demonstrated by intracellular recordings from the ganglia in preparations consisting only of a segment of intestine connected to a ganglion that had been completely removed from the body. [204] Activation of intestinal tension receptors evoked fast EPSPs in many nerve cells in the prevertebral ganglia. [204], [205] and [206] The EPSPs were blocked by the application of nicotinic antagonists to the ganglia, suggesting that they are cholinergic. This conclusion has been consolidated by the observation that all intestinofugal neurons are immunoreactive for choline acetyltransferase. [207] There is also a component of slow excitatory transmission from the intestinofugal neurons, which is a result of the release of a cotransmitter, possibly VIP. [202] Evidence that intestinofugal neurons are second-order neurons that nevertheless may also be directly activated by stretch is summarized in Chapter 3. The cell bodies of the intestinofugal neurons were observed in the myenteric ganglia after the injection of dye transported retrogradely into prevertebral ganglia. [208], [209], [210] and [211]

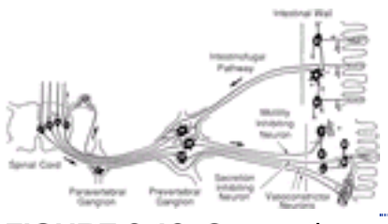

FIGURE 2-13. Connections of sympathetic pathways that affect intestinal motility, fluid exchange, and blood flow. Intestinofugal neurons, which have cell bodies in the wall of the intestine, are probably directly activated by sensory stimuli and indirectly activated by other enteric neurons. The intestinofugal neurons make excitatory synaptic connections with the cell bodies of motility-inhibiting and secretomotor-inhibiting neurons in the prevertebral ganglia. They do not connect with vasoconstrictor neurons.

Sympathetic motility-inhibiting neurons probably have little or no activity in undisturbed humans or animals. [3], [212] The enteroenteric inhibitory reflexes appear to have a protective role for the gastrointestinal tract. [3] For example, in the case of enterogastric reflexes, the slowing of gastric emptying protects the duodenal mucosa from acid and osmotic stress. Enteroenteric inhibitory reflexes affecting other parts of the intestine can be initiated by the distention of any region. Most studies have dealt with reflexes affecting the stomach and intestine, but similar reflex pathways affect the biliary system. [213] Inhibition of the stomach can also be caused by acidity or hypertonicity in the lumen of the upper small intestine. The reflexes that pass through the central nervous system are commonly evoked by noxious stimuli or by pain of visceral origin. For example, biliary colic, abdominal injury, and irritation within the abdominal cavity caused by chemicals or infection activate sympathetic reflexes that inhibit gut motility.

The net movement of water and electrolytes between the gut lumen and body fluid compartments is regulated to maintain overall fluid homeostasis. This is accomplished by sympathetic pathways that can override the enteric secretomotor reflexes (see Fig. 2-13). Axons arising from the sympathetic secretomotor-inhibiting neurons in prevertebral ganglia innervate secretomotor neurons, in which they elicit inhibitory synaptic potentials (see section “Synaptic Transmission in the Enteric Nervous System”). Persuasive evidence indicates that in day-to-day circumstances, the intrinsic secretomotor reflex activity is inhibited by tonic activity of the sympathetic secretomotor inhibitory pathways. Cutting the sympathetic pathways releases the brake on the enteric secretomotor reflex and results in what Bernard, in 1859, called *paralytic secretion*. [214] The level of activity of the sympathetic secretomotor inhibitory neurons responds to measures of whole-body water content and electrolyte status; thus, sympathetic activity is increased and water and electrolyte secretion is reduced in response to hemorrhagic hypotension, unloading of the baroreceptors, or reduction in right atrial pressure. [215], [216], [217] and [218] HCO_3^- secretion is also inhibited by sympathetic nerves. [219]

SUMMARY

Neural control of the gastrointestinal tract is hierarchical and somewhat complex. The neurons influence several aspects of digestive tract function, prominent among these being motility, secretion, and blood flow. At the organ level, control is exerted through local intramural reflexes whose component neurons are within the enteric nervous system. Regions of the gastrointestinal tract are linked through long intramural and extrinsic pathways; these include vagovagal reflexes and sympathetic enteroenteric reflexes. At the next hierarchical level, the gastrointestinal tract is controlled by activity in pathways originating in the central nervous system.

CHAPTER 3

John B. Furness, Martin J. Stebbing, and Nadine Clerc

SENSORY NEURONS OF THE GASTROINTESTINAL TRACT

The sensory system of the gastrointestinal tract is complex. Detection of the state of the gastrointestinal tract involves three systems of sensors: primary afferent neurons, enteroendocrine cells, and immune cells (Fig. 3-1). Each of these detecting systems is more extensive than those of other organs. [1] About 20% of neurons in the enteric nervous system, which contains on the order of 10^8 neurons, are sensory, and more than 50,000 axons reaching the gut through the vagus and splanchnic nerves also are sensory. The gastroenteropancreatic endocrine system contains thousands of enteroendocrine cells, many of which react to their local environment, and from which more than 20 identified hormones are released. The gut immune system senses immunogens and contains 70% to 80% of the body's immune cells.

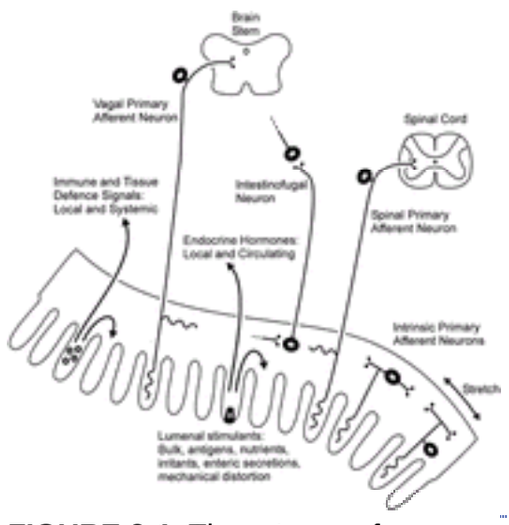

FIGURE 3-1. Three types of sensory signals originate from the gastrointestinal tract. Endocrine messages take the form of hormones released from cells in the mucosal epithelium. The hormones enter the circulation and can act at remote sites, but they also can act locally, on nerve endings, on the epithelium, and possibly on cells of the immune system. Immune messages are conveyed by circulating lymphocytes, which are activated if antigens are presented to them from the lumen or if the mucosal epithelium is breached, from their local tissue environment. Neural messages are conveyed by neurons whose sensitive endings are in the lamina propria, beneath the mucosal epithelium, in the muscle, and in enteric ganglia. Some neurons have cell bodies in the gut wall (IPANs and intestinofugal neurons), and others are in extrinsic ganglia (extrinsic primary afferent neurons; see Fig. 3-2).

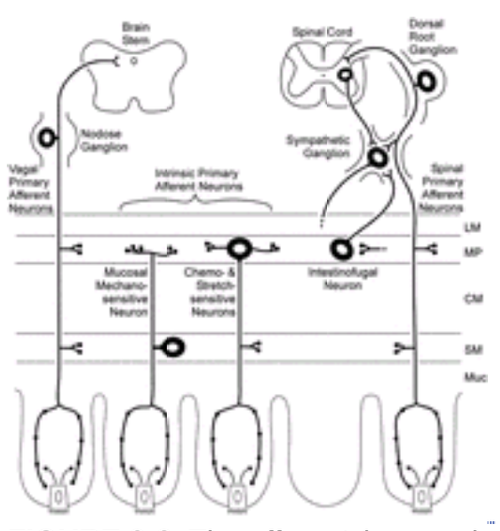

FIGURE 3-2. The afferent (sensory) neurons of the digestive tract. Three classes of *intrinsic* primary afferent neuron (IPAN) have been identified: tension-sensitive neurons with cell bodies in myenteric ganglia, chemosensitive neurons with myenteric cell bodies and processes that detect changes in lumenal chemistry, and mucosal mechanosensitive neurons with submucosal cell bodies and processes that detect mechanical distortion of the mucosa. The enteric afferent neurons are known to be modality selective; each also responds to other stimuli. *Extrinsic* afferent neurons have cell bodies in dorsal root ganglia (spinal afferent neurons) and vagal (nodose and jugular) ganglia. They can be subdivided into several classes (see text). Spinal afferent neurons supply collateral branches in prevertebral ganglia. Intestinofugal neurons are part of the afferent limbs of enteroenteric reflex pathways. Nerve endings in the mucosa can be activated by hormones released from enteroendocrine cells. *LM,* longitudinal muscle; *MP,* myenteric plexus; *CM,* circular muscle; *SM,* submucosa; *Muc,* mucosa.

The neurons that detect the states of tissues are known as *primary afferent neurons, primary* because they are the first neurons in reflex pathways, and *afferent* because they run toward reflex control centers. Three broad classes of afferent neurons are associated with the gut: intrinsic primary afferent neurons (IPANs), which have cell bodies, processes, and synaptic connections in the gut wall; extrinsic primary afferent neurons, which have cell bodies in vagal and dorsal root (spinal)

ganglia; and intestinofugal neurons, which have cell bodies in the gut but send processes to neurons outside the gut wall (Fig. 3-2). The monitoring and control of the digestive system by neurons is hierarchical. The gut contains an extensive collection of neurons—the enteric nervous system—within its walls (see Chapter 2). This intrinsic nervous system is capable of generating appropriate reflex responses to the contents of the intestinal lumen; for example, local reflexes generate mixing movements of the muscle, local changes in blood flow, and secretion of water and electrolytes. The enteric nervous system also participates in reflexes between organs—between the duodenum and stomach, for example, to regulate gastric emptying. Furthermore, the digestive organs send signals to the central nervous system: afferent signals for reflexes that act on the digestive system, signals that mediate coordination with other body systems, and signals that relate to sensations including discomfort, nausea, pain, and satiety.

INTRINSIC PRIMARY AFFERENT NEURONS

IPANs in the small intestine have been studied extensively, and those in the colon, to a limited extent. It is not clear whether neurons with the same function exist in the stomach. If they do, the morphology and cell physiology of most gastric IPANs are different from those of IPANs in the small intestine and colon. IPANs react to at least three types of stimuli: chemical changes in the intestinal lumen, distention of the intestine (even in the absence of the mucosa), and mechanical distortion of the mucosa.

Properties of IPANs

The IPANs identified to date are multiaxonal, with one or more axons that lead to and branch in the lamina propria of the mucosa, just beneath the absorptive epithelium, and axons that enter the myenteric ganglia and supply terminals around several types of nerve cells, including other IPANs, interneurons, and motor neurons. They have a distinctive shape known as *Dogiel type II morphology*. In addition, these neurons have distinct electrophysiological properties. They have broad action potentials that are carried by both Na^{+} and Ca^{2+} currents and are followed by early and late afterhyperpolarizing potentials (AHPs). Moreover, these neurons, unlike all other enteric neurons (at least in the guinea pig small intestine), do not receive prominent fast excitatory postsynaptic potentials (EPSPs). In other regions and species, fast EPSPs are more readily recorded from presumed IPANs. However, they do receive synaptic inputs through which slow excitation is mediated. This is unusual because neither spinal nor vagal afferent neurons receive synapses at their cell bodies. [2] Thus, IPANs differ from extrinsic sensory neurons in that their excitabilities can be modified by synapses at the cell body.

The electrophysiological properties of IPANs are influenced by the recording conditions. If the background synaptic transmission is suppressed, IPANs exhibit the late AHP that identifies them as AH neurons in the terminology of Hirst and colleagues, [3] but when IPANs are acted on by neurotransmitters or hormones, the late AHP can be suppressed or obliterated. [4], [5]

Two inward currents underlie the action potential in the soma of the IPAN, a tetrodotoxin (TTX)-sensitive Na^{+} current (gNa_V) and a TTX-insensitive Ca^{2+} current (gCa_V). [6], [7] In the presence of TTX, the Ca^{2+} current is still sufficient for action potential generation in the soma, but active conduction of action potentials in the processes of the Dogiel type II cells is blocked. The calcium channels are primarily N-type. There is also evidence of a TTX-resistant gNa_V, [8] but its physiological significance is not yet known.

The early AHP is continuous with the falling phase of the action potential and lasts about 50 to 100 milliseconds. The currents of the early AHP have been investigated in some detail. [9] This is a post-spike hyperpolarization similar to that observed in neurons of many types, in the central nervous system and in autonomic ganglia. The major part of the current is formed by the opening of large conductance (BK) channels. [10]

The late AHP, which is characteristic of Dogiel type II neurons when they are in their basal state, has an onset latency of about 70 milliseconds following a single action potential and can last from about 2 up to about 30 seconds. [3], [11] Two conductances increase during the late AHP: an outward Ca^{2+}-dependent K^{+} conductance, gK_{Ca} (an intermediate conductance, IK channel [10]), which exists in all Dogiel type II neurons, and an inwardly rectifying (i.e., depolarizing) cation conductance, g(K,Na), which generates the I_H current and exists in about 80% of these neurons. [12]

Chemosensitive IPANs

Intracellular records taken from nerve cell bodies in the guinea pig small intestine have identified a class of intrinsic neuron that responds to the application of chemicals, such as inorganic acid and short-chain fatty acids at neutral pH, to the lumenal surface of the mucosa of the small intestine. [13], [14] Activation of submucosal and myenteric neurons by the application of glucose to the mucosa also has been reported. [15]

IPANs may indirectly detect changes in the chemical content of the gut lumen via the release of hormones from enteroendocrine cells. Indirect action is inferred because the mucosal epithelium separates the nerve endings from the lumenal environment. Substantial evidence suggests that 5-HT, a potent IPAN stimulant, acts as an intermediate in enteric reflexes. [16], [17] and [18] 5-HT is released when the mucosa is mechanically stimulated to elicit motility reflexes, and the reflex responses are antagonized by drugs that block 5-HT receptors. [16], [17] and [18] Furthermore, mechanical stimulation of the mucosa induces c-Fos expression in IPANs in submucosal ganglia, and this induction is blocked by 5-HT receptor antagonists. [19] Other hormones in gut endocrine cells, such as cholecystokinin (CCK) and motilin, are released by nutrients and act on neurons; however, their roles as reflex intermediaries are untested.

Stretch-sensitive IPANs

IPANs also respond to tension in the muscle and to direct distortion of their processes. [20], [21] The mechanism through which these neurons are activated has been deduced (Fig. -3). The neurons respond phasically at the beginning of a stretch or when their processes are directly deformed. [21] During maintained stretch, the muscle contracts more or less rhythmically, and IPANs continue to be activated. [20] The rate of discharge is proportional to the degree of distention. However, the discharge of action potentials is abolished if the muscle contraction is prevented by muscle relaxants, indicating that active tension in the muscle contributes to the excitation of the tension-sensitive IPANs (see Fig. 3-3). The involvement of the muscle is interesting because it has long been known that intestinal muscle cells are directly sensitive to stretch and respond to it by contracting. [22] This reaction of the smooth muscle may be integral to the response of IPANs during sustained stretch. The neurons themselves possess mechanosensitive ion channels, and when the processes of the neurons are distorted, they discharge action potentials. [21], [23]

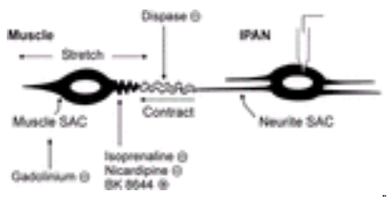

FIGURE 3-3. Mechanism of activation of stretch-sensitive intrinsic primary afferent neurons (IPANs). Stretch opens stretch-activated channels (SACs) in the muscle membrane, which results in muscle contraction. If the muscle SACs are blocked by gadolinium, or if contraction is prevented by isoprenaline or nicardipine, stretch-induced excitation of IPANs ceases. On the other hand, causing the muscle to contract by opening L-type Ca^{2+} channels with BK 8644 activates IPANs. The muscle pulls on IPAN processes through connective tissue, which can be weakened by dispase, preventing IPAN activation in response to stretch. The distortion of IPAN processes opens gadolinium-insensitive SACs, resulting in depolarization and action potential initiation.

Interestingly, the IPANs are inhibited if their cell bodies are distorted, or if a small area of their surface membrane is stretched. [21] This occurs through the opening of BK-type K^{+} channels on the cell soma, which appear to be directly stretch-sensitive. Myenteric nerve cell bodies are distorted by muscle movement, [24] and it is possible that sufficient pressure in the wall of the intestine may inhibit IPANs as part of a protective mechanism that limits the strength of reflex contraction of the

intestine.

Mucosal Mechanoreceptors

Functional evidence for IPANs with cell bodies in submucosal ganglia comes from experiments that have localized the activity-dependent induction of c-Fos and the activity-dependent uptake of styryl dyes. c-Fos immunoreactivity was detected in submucosal nerve cells after mucosal distortion by puffs of nitrogen gas ejected from a pipette. [19] Styryl dyes, which are taken up by active neuron endings and transported back to the cell bodies, also have been used to identify IPANs that are mucosal mechanoreceptors. [15] The results suggest that cell bodies of mucosal mechanoreceptors are in submucosal ganglia and project to the myenteric plexus (see Fig. 3-2). The activation of mucosal mechanoreceptors is likely to be partly indirect, through the release of 5-HT from enterochromaffin cells in the mucosa. [25]

Distention stimuli can activate both mucosal mechanoreceptors and distention-sensitive neurons (myenteric IPANs), explaining why both myenteric and submucosal neurons are revealed after distention. [15] The presence of stretch-sensitive neuron cell bodies in the submucosal ganglia, as well as in myenteric ganglia, has not yet been determined.

Possible Polymodal Nature of IPANs

It appears that intrinsic afferent neurons may be modality preferring, rather than modality specific. For example, primary afferent neurons in myenteric ganglia that respond to chemicals applied to the mucosa can also respond to mechanical stimulation of the mucosa, [14], [26] whereas under some circumstances, mechanical stimulation excites only neurons with cell bodies in submucosal ganglia. [15]

In the guinea pig small intestine, all myenteric neurons with the IPAN morphology project to the mucosa. [27], [28] It is impossible to say whether all these IPANs respond to chemical stimulation from the lumen because to record from them part of the mucosa must be removed. [14] About 50% of the neurons responded to electrical stimulation of the remaining intact mucosa. Thus, it is possible that only 50% of IPANs had intact mucosally projecting axons in the test regions. Of the neurons that responded to focal electrical stimulation of the mucosal surface, 60% responded to chemicals (acid, base, or fatty acid) applied to the mucosa. [14] Thus, at least 60% of myenteric IPANs are chemoreceptive. This may be an underestimate of this population because it is not possible to be certain that the appropriate chemical stimulus reached each nerve ending. In tissue that was stretched to excite stretch-activated IPANs with cell bodies in the myenteric plexus, about 80% of neurons responded to a 40% increase in intestinal circumference. [20] About 70% of these stretch-sensitive neurons responded directly. Thus, the data indicate that some IPANs are activated by more than one sensory stimulus.

Assemblies of IPANs

Physiological studies, [29] as well as ultrastructural studies, [30] indicate that IPANs synapse with other IPANs, thus forming a self-reinforcing network. [14], [31] The neurons are very frequent, about 500 per millimeter length of small intestine. Furthermore, they overlap considerably in their receptive fields; retrograde tracing indicates that each villus is supplied by the axons of 65 IPANs (on average) with cell bodies in the myenteric ganglia. [28] Because the stimuli that give rise to intestinal reflexes (i.e., lumenal chemicals, distention, mucosal distortion) are not spatially confined to submillimeter distances, it can be deduced that reflexes usually are initiated by the more or less synchronous activation of a population of several hundred interconnected primary afferent neurons.

Roles of IPANs

Intrinsic reflexes that affect motility, water and electrolyte secretion, and blood flow all occur in the small intestine. (For details of the reflex circuits, see Chapter 2.) Each of these reflexes is evoked by similar stimuli, although it is not known whether the same, different, or overlapping populations of IPANs contribute to motility, secretomotor, and vasomotor reflexes.

Muscle motor reflexes have been studied as stereotypical responses of the circular muscle; that is, excitation oral and relaxation aboral can be evoked by distention of the muscle (effected without distorting the mucosa), by the application of chemicals to the mucosal surface, and by distortion of the mucosa. [32], [33] and [34] These reflexes occur after the degeneration of extrinsic afferent nerve endings and are therefore the consequences of IPAN activation by sensory stimuli (see Chapter 2).

Secretomotor reflexes are initiated physiologically by chemical or mechanical interaction of lumenal contents with the mucosa, or pathologically by toxins, such as cholera toxin or enterotoxins, in the lumen. [35], [36] Enteric reflexes also cause HCO_3^- secretion in response to duodenal acidification. [37] The enteric secretomotor circuits consist of IPANs with their endings in the mucosa and nerve circuits that pass through the myenteric and submucosal plexuses and feed back to secretomotor neurons with cell bodies in the submucosal ganglia. [35], [36], [38], [39] The secretomotor neurons stimulate the epithelial cells to pump Cl^- ions, which are accompanied by water, into the lumen.

Local vasodilator reflexes in the small intestine are caused by mechanical or chemical irritation of the mucosa, and substantial evidence indicates that the vasodilator neurons are intrinsic to the intestine and transmission from them is predominantly noncholinergic. [40], [41] It is presumed that the first neurons in these reflexes are the IPANs, but this has not been directly shown. In fact, of the reflexes in the intestine, the vasomotor reflexes are the least studied. The same motor neurons have axons that branch to supply both the secretory epithelium and arterioles; thus, some secretomotor and vasodilator reflexes may share the same final neurons (see Chapter 2). This makes physiological sense because the secreted water and electrolyte come indirectly from the vasculature.

The roles of IPANs are to signal changes in the state of the intestine that are the consequences of the presence and nature of its contents. The information is conveyed to other neurons of the enteric nervous system that integrate the information and cause appropriate changes in mixing and propulsive activity, in water and electrolyte transport, and in local blood flow.

EXTRINSIC PRIMARY AFFERENT NEURONS

Extrinsic primary afferent neurons have cell bodies in the nodose and jugular ganglia, from which axons follow vagal pathways to innervate the gut (vagal primary afferent neurons), or in dorsal root ganglia (spinal primary afferent neurons). The fibers of spinal primary afferent neurons in the thoracic and lumbar regions pass through the sympathetic ganglia to reach the gut via the splanchnic and mesenteric nerves. Some fibers originating from thoracic dorsal root ganglia join the vagus nerve, either through the stellate ganglion or directly via small connecting nerves in the thorax. Conversely, many axons of vagal afferent neurons supplying the small intestine are in the celiac branch of the vagus and join with spinal afferent fibers in the mesenteric nerves as they run to the gut. The axons of spinal primary afferent neurons with cell bodies in the sacral ganglia follow the pelvic nerves to reach the colon and rectum.

The types of information carried to the central nervous system by extrinsic afferent neurons are summarized in Table 3-1. Very broadly, the afferent information can be divided into *that which reaches conscious sensation,* such as sensations of gastric or intestinal fullness, warmth, various types of pain (cramp, colicky pain, sharp pain), discomfort, nausea, hunger, and satiety, and *that which is not perceived,* such as the chemical nature of the contents of the intestines and the mechanical activity of the gut during normal digestion, which initiate responses such as gastric acid secretion, pancreatic secretion, and gastric and intestinal motor activity.

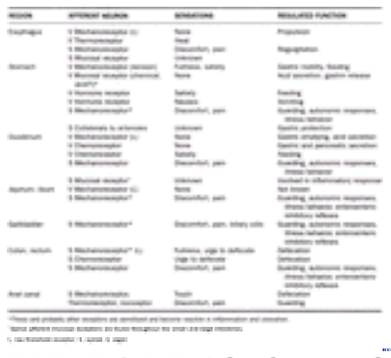

TABLE 3-1 Extrinsic Vagal and Spinal Gastrointestinal Afferent Neurons: Simplified Classification of Neurons, Sensations, and Regulated Functions

The level of specificity and detail of the afferent information that reaches the central nervous system is not known. The central nervous system may be informed of the general state of the digestive organs by the summation of afferent signals. This is suggested by the substantial sizes of the receptive fields of the afferent neurons.[42] It is also suggested by the responses of the organs—for example, acid or enzyme secretion, gallbladder contraction, or gastric relaxation, none of which appear to be finely graded. Moreover, hormones such as CCK that diffuse locally and via the bloodstream act on many afferent nerve endings. Consciously perceived sensations that are conducted by extrinsic primary afferent neurons also are generalized and usually difficult to locate to any particular abdominal organ. Satiety is indirectly perceived; for example, we feel sated after a meal, but the feeling of satiety is not directed to a particular organ.

Conscious perception of the state of the gastrointestinal tract is subject to psychosensory modulation.[43],[44] and[45] Perception is enhanced when attention is paid to the gut and is diminished with inattention. Sensation also is diminished when a painless somatic stimulus is simultaneously applied.[43] A classification of extrinsic primary afferent neurons by the stimuli to which they respond, by the sensations to which they give rise, and by the functions they regulate appears in Table 3-1.

Structural Studies

Large numbers of peripheral axons of extrinsic primary afferent neurons enter the gut. In animals such as cat and rabbit, the abdominal vagus contains about 20,000 to 30,000 primary afferent nerve fibers; the human abdominal vagus contains about 40,000 to 50,000.[46] Spinal afferent fibers also are plentiful; in the greater splanchnic nerve of the cat, there are about 3000 to 4000; in the lumbar splanchnic nerves, about 4000 to 5000; and in the pelvic nerves, about 3500.[46] Almost all the afferent fibers entering the gut are unmyelinated and soon become mixed with the processes of enteric neurons, from which they are indistinguishable by normal light and electron microscopy, with the exception of the intraganglionic laminar endings.

Three types of vagal afferent endings have been identified, mostly by anterograde tracing studies: intramuscular arrays,[47],[48] branching varicose axon endings that innervate the mucosa,[49],[50] and intraganglionic laminar endings (IGLEs).

An intramuscular array consists of an axon that supplies branches, sometimes ten or more, several millimeters long and running parallel to the longitudinal or circular muscle. They are most numerous in the stomach but are found throughout the gastrointestinal tract, from the smooth muscle part of the esophagus to the distal colon, where they are relatively rare.[51] The morphology of intramuscular arrays suggests that they are in-parallel length receptors, even though most physiological evidence suggests that vagal mechanoreceptors in the stomach are tension receptors.[52]

IGLEs were illustrated in 1929 by Lawrentjew,[53] who showed, by their degeneration after vagal nerve section, that they are of vagal origin. Subsequently, their afferent nature was demonstrated when they were found to degenerate after extirpation of nodose ganglion cells, but not after section of the vagus nerve central to the nodose ganglion.[54] The IGLE consists of numerous lamellae, generally about 2 to 5 μm across, that interconnect with each other and form a discontinuous covering of myenteric neurons. In the rat stomach, about six neurons are covered by each IGLE.[47] Experiments have confirmed that IGLEs are mechanoreceptors.[55] IGLEs are very common in the esophageal, gastric, and duodenal myenteric ganglia, and occur at lesser densities in the rest of the digestive tract. In rat, they have been reported to occur at a density of 6.3/mm ^{2} in the gastric corpus, 3.3/mm ^{2} in the duodenum, 0.6/mm ^{2} in the jejunum and ileum, and 0.2/mm ^{2} in the distal colon.[51] The proportion of ganglia innervated also decreases along the digestive tract. After labeling by left vagal ganglion injection, IGLEs were found to supply 88% of ganglia in the esophagus and 31% in the corpus; the proportion decreased to 1% in the distal colon.[56],[57]

The mucosal vagal afferent endings consist of branching varicose fibers that come close up against the mucosal epithelium, and, in the esophagus, may enter the epithelium.[49],[50],[58],[59] Morphologically, these fibers seem indistinguishable from the motor fibers and intrinsic afferent endings that supply the epithelium.

Less attention has been devoted to determining the distributions of spinal afferent neurons with the use of neuronal tracers. In some species, however, a high proportion of spinal afferent neurons contain neuropeptides, particularly tachykinins and calcitonin gene–related peptide (CGRP).[60] Where spinal nerve endings containing these peptides can be distinguished from nerve fibers of intrinsic origin, the peptides have proved to be useful markers. The axons of spinal afferent neurons provide a sparse network of varicose axons in the myenteric ganglia of the esophagus,[61] stomach[60],[62] and small intestine.[63] They are prominent around arterioles in the gut wall,[60],[61],[64],[65] and they also branch within the lamina propria of the mucosa throughout the gastrointestinal tract. Rare fibers are found in the muscle layers.[60],[62],[66] In the cat esophagus, they penetrate deep into the squamous epithelium.[61]

Functional Subtypes Identified by Location of Afferent Endings

Extrinsic primary afferents have been classified as mucosal receptors, muscle receptors, and serosal receptors on the basis of electrophysiological studies of the response patterns to various mechanical and chemical stimuli. Location also discriminates receptors; whether a location is superficial (in the mucosa or the serosa) or deep (in the muscle or myenteric ganglia) can be determined by testing the effect of removing or anesthetizing the mucosa or serosa. Electrophysiological studies, with the use of single-unit recording, imply that most vagal primary afferent fibers innervate the mucosa and muscle layers, whereas the spinal afferent fibers innervate the muscle layers and serosa, but not the mucosa.[67],[68] and[69] However, morphologic data show that the axons of spinal primary afferent neurons innervate the mucosa of the esophagus, stomach, and intestines. These may have nonmechanoreceptor functions.

Muscle Receptors Muscle receptors, found throughout the gastrointestinal tract, are sensitive to variations in muscle tension.[46] Increased discharge when the muscle contracts (i.e., when tension is increased but length is decreased) implies that that they are tension receptors.[70] A carefully controlled study of vagal mechanoreceptor discharge over a range of different gastric volumes and wall tensions confirmed the original designation of these afferents as tension receptors.[71] Muscle receptors exhibit a dynamic response that adapts slowly. Most vagal mechanoreceptors that innervate the gastric muscle fire at low frequency, even when the stomach is empty. Thresholds for their activation vary, but all are in the normal (i.e., nonpathological) range of pressures.[72],[73] Spinal afferent neurons include low- and high-threshold muscle receptors and silent nociceptors.[74],[75] and[76] Silent nociceptors are neurons whose endings are not activated by mechanical forces, except when the tissue they innervate is injured or inflamed. It has been persuasively argued that the term “silent nociceptor” is likely to be a misnomer for most fibers so identified because these fibers, unresponsive to intense mechanical stimuli, may be responsive to other (untested) stimuli; furthermore, not all mechanically insensitive neurons are nociceptors.[77] High-threshold muscle receptors of spinal primary afferent neurons that are sensitive to ischemia are likely to be nociceptors.[74],[75] Spinal mechanoreceptive afferent neurons are generally polymodal. Afferent neurons that respond to colonic distention also respond to bile salts, inflammatory mediators (a mixture of bradykinin, prostaglandin, 5-HT, and histamine), and temperature.[78] These neurons may in fact be mucosal receptors or have collaterals in the mucosa.

Mucosal Receptors Mucosal receptors are found all along the gut. They respond vigorously to mucosal deformation but are likely to be polymodal—that is, able to respond to two or more stimuli, including mechanical deformation (stroking), lumenal chemicals (acid or nutrients), heat or cold, and in some cases increased lumenal osmolarity.[46],[79],[80],[81],[82] and[83] In contrast, feline studies suggest that some mucosal receptors in the esophagus and stomach are selective for temperature,[84] and that others in the small intestine are selective for nutrients, such as amino acids[85] and lipids.[86] This apparent selectivity, however, may have been a consequence of the narrow range of stimuli being tested.[46],[69] A study of sheep demonstrated that duodenal mucosal endings that respond to amino acids are also mechanoreceptors.[81] Nerve fiber recording did not reveal mucosal receptors sensitive to carbohydrates in rat,[87] rabbit,[88] or ferret[83] small intestine. Nevertheless, infusions of glucose, maltose, and mannose into the duodenum evoke reflex responses in rat stomach and pancreas via the activation of vagal afferents,[89],[90]

implying that carbohydrate-sensitive endings are indeed present. Both slow and rapid adaptation to mucosal mechanical stimuli are encountered. [46], [81] Responses to lumenal chemicals generally are slowly adapting. [85], [86] Although present in the stomach and esophagus, thermal receptors appear to be absent from the duodenum. [81]

Serosal Receptors Serosal receptors seem to be activated by high-threshold mechanical stimuli, such as bowel movement, distention, and squeezing, although gentle probing, light squeezing, or puffs of air also elicit responses. [46] Serosal receptors are also sensitive to ischemia. The serosa is continuous with the mesentery and the parietal peritoneum, where receptors with similar properties reside.

Indirect Activation of Mucosal Receptors by Enteroendocrine Cell Products

The stimulatory effects of nutrients on mucosal afferent endings in the small intestine are indirect, which is in accord with the separation of lumenal chemicals from mucosal nerve endings by the intestinal epithelium. The alternative method of activation, directly after passage across the mucosa, probably also occurs (e.g., diffusion of inorganic acid). CCK and 5-HT, which are released in the mucosa, activate the mucosal receptors but not the muscle receptors of vagal primary afferent neurons. [83], [91], [92], [93] and [94] A physiological role for CCK released from enteroendocrine cells and acting on vagal afferent endings has been demonstrated; the activation of vagal primary afferent neuron endings by lipid or protein in the duodenum is blocked by CCK_1 receptor antagonists. [95], [96] 5-HT appears to be an intermediate for the excitation of vagal primary afferent neurons by intralumenal hyperosmotic or hypoosmotic solution in the duodenum and to high concentrations (>275 mM) of the monosaccharides glucose and mannose. [90] Increased discharge of vagal afferent neurons caused by these agents was blocked by the intravenous infusion of the $5\text{-HT}_{3/4}$ antagonist tropisetron, and by the 5-HT_3 antagonist granisetron. In contrast, activation of afferent fibers by duodenal distention was not affected. The intraduodenal chemical stimuli did not elevate plasma 5-HT, implying that the site of action of 5-HT was in the mucosa near its points of release. The activation of afferents mediating vagovagal pancreatic reflexes depends on the release of both CCK and 5-HT from enteroendocrine cells. [97]

Lumenal fat is a stimulus for reflexes from the distal to more proximal ileum, the ileal brake. [98] Release of peptide YY from mucosal enteroendocrine cells of the mid nd distal small intestine and colon leads to slowing of small intestinal transit. Although the neural pathway of this effect is not known, it appears to be a neural reflex. [99]

Efferent Effects of Primary Afferent Neurons

Ultrastructural studies show that afferent fibers contain numerous synaptic vesicles, similar to the endings of unmyelinated motor neurons or interneurons. [58], [100] The axolemma of these fibers is sometimes naked, which suggests that neurotransmitters released by afferent fibers have good access to effector cells. Myenteric neurons are a target because frequent appositions of naked fibers arising from spinal primary afferent neurons occur on the cell bodies. [100] The afferent nerve endings contain bioactive peptides, including CGRP and tachykinins. [60], [63]

Several pharmacological and physiological studies have revealed muscle contraction in response to antidromic stimulation of spinal afferent nerve fibers, [101], [102] and one study has implicated axon reflexes in initiation of the peristaltic reflex (see Chapter 2). Neuropeptides released from primary afferent nerve endings cause vasodilation [103], [104] and [105] and stimulate myenteric neurons [106] and mast cells. [107]

The effects of antidromic release of transmitter from afferent nerve endings on gastric and duodenal motility are most likely of trivial physiological importance. [108] By contrast, vasodilation caused by transmitter released from the peripheral processes of afferent neurons has an important role in mucosal protection (see section "Tissue Protection"). There is also evidence that transmitter released from the mucosal sensory endings of IPANs contributes to the regulation of fluid secretion. [109]

Roles of Extrinsic Primary Afferent Neurons

Extrinsic primary afferent neurons signal to the central nervous system information necessary to regulate organs and behaviors that are beyond the immediate local territories of the afferent endings. The signals that reach the central nervous system convey information about several qualities of the gastrointestinal tract, including the state of distention, the presence of chemicals in the lumen (e.g., nutrients, irritants, and toxins), and the presence of tissue injury and inflammation. The signals can be decoded and interpreted consciously as satiety, pain, or hunger. They can also be used to direct digestive functions automatically; for example, esophageal propulsion, gastric relaxation in response to a meal, and gastric acid secretion may all be controlled through the vagus, defecation via the pelvic nerves, and the control of water and electrolyte transport and blood flow in relation to the relative needs of all organs via sympathetic motor pathways.

Pain and Discomfort For a long period, there was considerable doubt regarding whether the gastrointestinal tract was innervated by pain fibers because clearly injurious insults to the stomach, small intestine, and most of the large intestine are not perceived. [46] On the other hand, there is conscious sensation from the esophagus (e.g., hot food or drink) and from the anal canal. Pain from the abdomen is diffuse, and its origin from a particular organ or site usually is not obvious to the patient. It is no longer uncertain that the gastrointestinal tract is an origin of pain. This pain is evoked by excessive distention (i.e., intralumenal pressure =30 mm Hg) and is exacerbated by inflammation. [110] In humans, excessive distention of the stomach, gallbladder, small intestine, colon, or rectum causes pain that is not felt after bilateral section of the splanchnic (spinal afferent) nerves that carry sensations of pain or discomfort from the abdominal viscera. [111], [112] The quality of the sensation from the digestive tract changes with the intensity of distention, from feelings of fullness to discomfort to pain. [46] Pain signals are believed to be mediated through the activation of high-threshold mechanoreceptors and, in pathological conditions, through afferent fibers that are unresponsive to pressures above the pain threshold in nonpathological conditions (e.g., unresponsive to a lumenal pressure of 70 mm Hg). These unresponsive neurons (silent nociceptors) become mechanosensitive when tissue is inflamed, or when they are exposed to inflammatory mediators. [76] At moderate pressures, low-threshold mechanosensitive afferent neurons are activated to cause reflexes that are unnoticed by a subject without inflammation or other gut pathology. Greater distention activates higher threshold mechanoreceptors and evokes feelings of fullness. Further distention can lead to discomfort and pain. Painful sensations are more likely, and occur at lower thresholds, if the gut is inflamed or if a functional bowel disorder exists, such as irritable bowel syndrome (IBS). This is because the nerve endings in inflamed tissues and in tissue affected by IBS are sensitized. In general, low-threshold primary afferent endings are vagal in origin, and high-threshold nerve endings are of spinal origin. However, some spinal primary afferent neurons are activated by low-threshold mechanical stimuli. [74], [113], [114] Visceral pain is accompanied by somatic and general autonomic reactions, including hunching, abdominal contraction, elevated heart rate, and increased blood pressure. In humans, the intensity of these reactions is directly related to the degree of pain (Fig. 3-4). The somatic and autonomic accompaniments to pain persist when pain itself is prevented by anesthesia. Because they are indications of a stimulus that would normally come to conscious attention, the somatic and autonomic responses observed in a subject under general anesthesia have been called *pseudoaffective responses*. [115] Animal studies confirm that pain is conducted from the intestine through spinal afferent pathways. The neurons are rendered unresponsive by pretreatment with capsaicin, which initially stimulates then desensitizes the endings of primary afferent neurons.

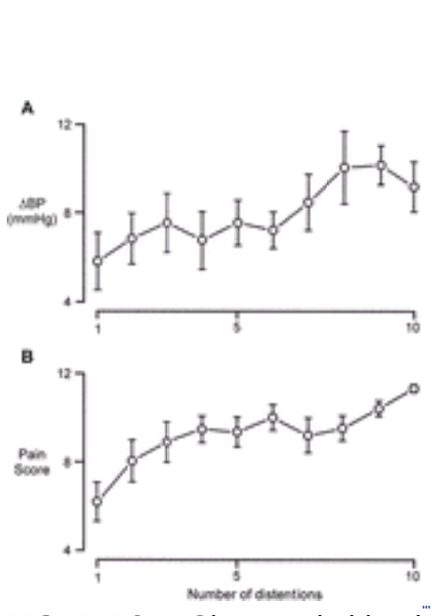

FIGURE 3-4. Changes in blood pressure and psychometric measure of pain perception in human volunteers subjected to inflation of an intrarectal balloon. Successive inflations of the balloon cause more pronounced increases in blood pressure and increased discomfort or pain. (From Ness TJ, Metcalf AM, Gebhart GF. A psychophysiological study in humans using phasic colonic distension as a noxious visceral stimulus. Pain 1990;43:377–386, with permission.)

Chronic changes in the sensitivity of the intestine are observed in IBS. There is a decreased pain threshold to distention of the intestine and exaggerated pseudoaffective responses. [116], [117] and [118] Patients with IBS can feel motility changes that are almost always undetected by healthy individuals. Moreover, contractions within the normal range of amplitude sometimes cause pain in patients with IBS. [119], [120] These and other observations imply a long-lasting increase in the sensitivity of spinal primary afferent mechanisms in IBS.

Nausea The activation of vagal afferent fibers contributes to the nausea and vomiting induced by a number of agents, notably chemotherapy agents, such as cisplatin. In animal models, retching or bursts of synchronous activity in respiratory motor neurons have been used to indicate that nausea or vomiting activity has been elicited. In ferrets, retching and emesis induced by cisplatin or cyclophosphamide were abolished by combined subdiaphragmatic vagotomy and splanchnic nerve section, and were substantially reduced by 5-HT $_3$ receptor antagonists. [121] However, 5-HT $_3$ receptor antagonists did not block retching caused by electrical stimulation of the central end of the severed vagus, leading to the hypothesis that the relevant 5-HT receptors are located peripherally, possibly on the endings of vagal afferent neurons. [122] Subsequent demonstration of 5-HT release by nauseants led to the hypothesis that toxins that induce nausea and vomiting do so by provoking the release of 5-HT from enterochromaffin cells in the proximal small intestine. [123] The 5-HT then stimulates vagal afferent nerve endings, which take signals to the rather loosely defined medullary vomiting centers, including the area postrema and nucleus tractus solitarius. Consistent with the animal studies, 5-HT $_3$ receptor antagonists are effective in reducing chemotherapy-induced and postoperative nausea and vomiting in humans. [124], [125]

Satiety The ingestion of food is dependent on feelings of hunger and satiety, as well as on social and cultural influences. The physiological control center for eating is in the hypothalamus and is influenced by circulating hormones (e.g., leptin), olfactory and taste receptors, and afferent nerve signals conducted from the digestive system to the central nervous system through the vagus nerves. The vagal signals for satiety relate to the volume of food in the stomach, and to the chemical nature of the food products in the duodenum. An animal whose food is diverted by an esophageal cannula and never reaches the stomach provides a model for investigating control through vagal afferents. Studies in such sham-fed animals indicate that gastric distention has a satiating effect, and that the inhibition of eating caused by distention is lost after vagus nerve section. [126], [127] Studies in which the movement of gastric contents is prevented and the composition of the contents is varied indicate that gastric volume, not the nutrients present, is signaled by the vagus. [128], [129] Once the food has entered the duodenum, its nutrient content becomes a factor in influencing satiety. Thus, fat in the duodenum releases CCK from enteroendocrine cells; the CCK, through CCK $_1$ receptors, activates vagal endings and feeding is reduced. [130] CCK acts on mechanoreceptive tension receptors, presumably muscle receptors, as well as on mucosal chemosensitive receptors. [80], [131] Other peptides of gut origin may have roles in determining satiety, possibly through actions on the vagus. These include bombesin, glucagon-like peptide, and ghrelin. [130], [132]

Vagovagal Reflexes Stimuli resulting from the ingestion of food, and the presence of food in the stomach and upper intestine, activate vagovagal reflexes that regulate the activity of the stomach itself and of the pancreas and gallbladder. These reflexes use afferent neurons that end in the nucleus tractus solitarius of the medulla oblongata, integrating circuits within the brainstem, and outputs through vagal efferent neurons that form synapses in enteric ganglia, from which neural connections are made with final effectors (smooth muscle or glands). Vagal afferent endings in the esophagus that are stimulated by swallowing cause a reflex relaxation of the proximal stomach, which is called *receptive relaxation* (i.e., a relaxation in advance of the arrival of the food bolus). [133] The arrival of food in the stomach triggers another reflex through the vagus, the vagovagal accommodation reflex, which involves relaxation of the proximal stomach as well as acid secretion and increased contractile activity in the antrum. [134], [135] A duodenal phase of vagovagal gastric relaxation is triggered by CCK, which is released in response to nutrients, particularly fat, in the lumen of the duodenum. [96], [136] CCK acts on the peripheral ends of primary afferent neurons in the mucosa, relaxing the stomach and thus slowing gastric emptying. The presumed function of this reflex is to allow time for the assimilation of nutrients in the small intestine. Pancreatic function is also influenced by vagovagal reflexes. Nutrients in the upper intestine and stroking of the intestinal mucosa increase pancreatic secretion. This effect is reduced by treatment with capsaicin, or by blocking efferent transmission in the pancreas with atropine. [137], [138] Distention of the body of the stomach, but not the antrum, also increases pancreatic enzyme secretion, again through a vagovagal reflex. [139] Vagovagal reflexes also contribute to the conversion of intestinal motility from the fasted to the fed pattern. [140]

Reflexes Mediated through Spinal Primary Afferent Neurons In addition to conveying pain and discomfort, spinal afferent neurons are involved in the reflex control of the gut, especially the large intestine. The nonnociceptive spinal afferents of the terminal bowel that are concerned with visceral reflexes are analogous to the vagal afferents involved in visceral reflexes. [141] Colonic spinal afferents participate in the control of fecal continence and defecation. Thus, injuries to the pelvic nerves, which carry many of the spinal primary afferent fibers from the descending colon and anal canal, cause derangements of defecation. [142] Defecation reflexes are initiated by rectal distention and chemical or mechanical irritation of the rectoanal mucosa, implying that both muscle tension receptors and mucosal spinal afferent nerve fibers are involved in these reflexes. [143] The section “Intestinofugal Neurons” discusses enteroenteric inhibitory reflexes that pass through prevertebral ganglia without entering the central nervous system. There also are intestinointestinal reflexes in which spinal afferent neurons form the afferent arm and sympathetic pathways are the efferent pathway. [144] These pathways can be activated by distention and also by irritation within the abdominal cavity, such as handling of the intestine, or by infection of the abdominal cavity. It has been suggested that the reflex inhibition of motility through these spinal afferent pathways and through the prevertebral ganglia may facilitate each other because synaptic excitation converges on the noradrenergic neurons in the prevertebral ganglia. [145]

Tissue Protection Neurotransmitters released from the peripheral ends of extrinsic primary afferent neurons may effectively restrict the deleterious consequences of tissue damage. [146] In the stomach, compromising sensory neuron function by pretreating animals with capsaicin aggravates mucosal damage caused by acid, ethanol, nonsteroidal antiinflammatory agents, and other chemicals. [147], [148], [149] and [150] Capsaicin alone is not injurious; in fact, the short-term effect of capsaicin is protective. There is compelling evidence that capsaicin induces the release of the sensory neurotransmitter CGRP from spinal afferent nerve endings, a transmitter that has a major role in protecting the mucosa. [146] Thus, blocking CGRP receptors, or reducing the effectiveness of CGRP by immunoneutralization, compromises gastric protection. [151], [152] The preexperimental application of capsaicin to the spinal afferent pathways, but not to the vagus nerves, blocked the CGRP-dependent hyperemic response to the acute application of capsaicin, indicating that gastric protection is dependent on the integrity of spinal afferent neurons. [153] Because the protection is reduced by the application of the nerve conduction blocker TTX to the stomach, axon reflexes are likely to be involved (i.e., action potential invasion of collateral branches of activated nerve endings). [150] Tachykinins are often co-localized in the gastric spinal afferent neurons, and data indicate that tachykinins, released from the spinal primary afferent endings and acting through NK $_2$ receptors, contribute to gastric protection. [154] The protective mechanism involves vasodilation and increased mucosal blood flow. CGRP and tachykinins cause vasodilation by releasing nitric oxide from vascular endothelial cells, and thus, inhibition of nitric oxide synthase increases gastric damage. [155] Transmitter release from afferent endings in the colon also reduces the severity of damage consequent on inflammation, at least in the acute phase. [156]

INTESTINOFUGAL NEURONS

Intestinofugal neurons are an unusual type of neuron. Their cell bodies are in the gut wall, and their processes run toward the central nervous system and orm synapses in prevertebral sympathetic ganglia. Their presence was deduced by Kuntz and Saccomanno in the 1930s, [157] who found that distention of one region of the gastrointestinal tract inhibits motility in other regions and that these enteroenteric inhibitory reflexes persist after connections with the central nervous system are severed, provided that the integrity of the connections with prevertebral sympathetic ganglia is maintained. Methods to study these reflexes in vitro were developed in the early 1970s, [158] and since that time, the organization of the pathways has been studied in considerable detail. [145] The location of the cell bodies of intestinofugal neurons in the myenteric ganglia of rats and guinea pigs was determined by injecting retrogradely transported dye into prevertebral ganglia. [159], [160], [161] and [162] In pig, some intestinofugal neurons have cell bodies in submucosal ganglia. [163] Intestinofugal neurons are most numerous in the large intestine; in the small intestine, they increase in number distally, and they are rare in the stomach. The axons of intestinofugal neurons form excitatory synapses with the cell bodies of sympathetic neurons in prevertebral ganglia. The axons of the sympathetic neurons project back to the gut. All intestinofugal neurons have the same primary transmitter, acetylcholine. [145], [164], [165]

Roles of Intestinofugal Neurons

The roles of intestinofugal neurons have been analyzed almost exclusively in relation to motility control, although these neurons also innervate sympathetic neurons that inhibit water and electrolyte secretion in the intestine (see Chapter 2). The intestinofugal neurons that affect motility are in the afferent limbs of enteroenteric inhibitory reflexes. These reflexes appear to act primarily on sites in the gastrointestinal tract that are proximal to the sites from which they are initiated. [145] Thus, the reflexes are one of the mechanisms by which more distal parts of the intestine regulate the proximal regions from which they receive products of digestion. The enteroenteric inhibitory reflexes appear to have a protective role in the gastrointestinal tract. For example, enterogastric reflexes slow gastric emptying, thereby protecting the duodenal mucosa from acid and osmotic stress.

OVERVIEW

The gastrointestinal tract can be regarded as a sensory organ. It has three detecting systems: neurons, endocrine cells, and the gut immune system. The neural detection of sensory information is through both intrinsic sensory (primary afferent) neurons and extrinsic sensory neurons. The neural sensory system is responsible for detecting the state of the digestive system. The detected information is used to govern (1) reflexes confined within the gut wall (intrinsic reflexes) that change

motility, blood flow, and transepithelial fluid transfer; (2) extrinsic, but peripheral, reflexes between digestive organs; (3) reflexes through the central nervous system that are not consciously perceived; and (4) conscious sensation, such as satiety, hunger, discomfort, pain, and nausea. Although many of the effects mediated through digestive system afferent neurons have been elegantly dissected, the subtleties of their interactions are still being unraveled. The challenge remains to establish a good linkage between what is known of the responses of individual primary afferent neurons and the integration of the information they provide to yield an output, either a conscious experience or a physiological response.

CHAPTER 4

Laurence J. Miller

GASTROINTESTINAL HORMONES AND RECEPTORS

The gastrointestinal endocrine system represents the largest and most complex endocrine organ in the body. Whereas traditional endocrine organs are composed of a solid mass of hormone-secreting cells that are homogeneous, or at least organized with a defined spatial orientation relative to one another, the sources of the gastrointestinal regulatory molecules are single endocrine cells and peptidergic neurons that are scattered along the length of the digestive tract. They all share the property of producing and secreting polypeptides. Because these hydrophilic molecules cannot cross a lipid bilayer, they must interact with other molecules that span the plasma membrane of target cells, which can activate the intracellular machinery of those cells. These membrane protein targets of gastrointestinal hormone action are called *receptors*. They have specialized domains for ligand recognition that are accessible to the extracellular space, as well as effector domains for molecular interactions or enzymatic activity that are located intracellularly. The diversity and design of the gastrointestinal endocrine system also necessitate broadening the basic concept of classic endocrinology, which requires that a hormone be delivered to its targets by way of the bloodstream. Although the bloodstream delivers some gastrointestinal hormones, the gastrointestinal endocrine system also uses more direct and focused means of transmitter delivery.

The endocrine cells are scattered among the epithelial cells of the mucosal lining of the gut and the ductular elements that enter the gut. They have an open or closed morphology. Endocrine cells with an open morphology can sense the composition of chyme and secretions through processes that extend into the lumen. A closed morphology facilitates sensing of the interstitial environment. [1,2] Peptidergic neurons also exist and are organized into syncytia, which extend between and along layers of the mucosa and into the solid digestive organs. These neurons are classified as extrinsic or intrinsic, depending on the location of their cell bodies. Extrinsic parasympathetic innervation comes from the vagus and pelvic nerves, whereas sympathetic innervation comes from various sympathetic ganglia. The major source of peptidergic nerves is intrinsic to the gut and is affected little by sympathectomy or vagotomy. There are numerous varieties of both the endocrine cells and the peptidergic neurons of the gastrointestinal tract. Each type of cell has a distinct distribution and is able to sense and respond to a unique complex of stimuli, resulting in the synthesis and secretion of a single predominant peptide.

Each hormone or neurotransmitter affects only those target cells possessing appropriate receptors on their surface. Cells that can be regulated include the vast spectrum of epithelia, smooth muscle cells, and neurons residing at all levels of the digestive tract. Responses span the temporal spectrum, from rapid and transient to delayed and prolonged. The former includes effects on behavior or sensation, secretory or absorptive phenomena, motor events, and metabolic events. The more prolonged effects typically involve cellular growth, differentiation, or morphogenesis. The combination of unique stimuli, limited distribution of distinct types of hormone-secreting cells, and exquisite selectivity of target cells and their responses provides almost unlimited opportunities for regulation. This elegant system integrates digestive functions at all levels of the gastrointestinal tract, thereby optimizing the digestion and absorption of nutrients. For all these reasons, the gastrointestinal endocrine system has been referred to as the *brain of the gut*.

ORGANIZATION OF THE GUT ENDOCRINE SYSTEM

The organization of the gastrointestinal endocrine system is the key to its power and flexibility. Acutely regulated gastrointestinal events are dynamic, complex, and interrelated; the ingestion of a meal initiates changes in secretion, absorption, and transit along the gut and in its associated digestive organs, and the net composition of chyme and its rate of delivery vary markedly over time and space. More delayed and prolonged effects on the differentiation and growth of enteric cells are equally important for the optimal digestive responses for an individual's dietary habits and nutritional requirements. Given the diversity in size and composition of ingested meals, the gastrointestinal endocrine system must be capable of highly varied programs of responses, not only to ensure proper assimilation of the nutrients, but also to make eating the pleasurable experience it represents for the vast majority of the population.

The gastrointestinal endocrine system must be responsive both to intralumenal digestive events and to systemic status. The combination of "open" and "closed" endocrine cells and nerves provides sensitivity toward both worlds, recognizing that the general health, nutritional status, and metabolic needs of the organism can modify the optimal nutritional impact of a meal. With each hormone-secreting cell sensitive to its local environment, and with each such cell strategically located, endocrine cells of the same type in two different locations likely secrete their peptides at different times, reflecting the dynamic changes occurring along the length of the gut after a meal. An additional level of control is made possible by the route of delivery and the mode of action of the secreted regulatory peptide. This can be endocrine, autocrine, neurocrine, or paracrine (Fig. 4-1).

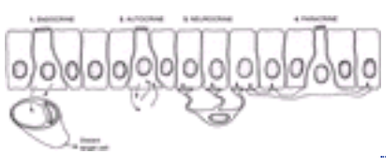

FIGURE 4-1. Modes of delivery of gastrointestinal regulatory peptides from endocrine cells and nerves, illustrating endocrine, autocrine, neurocrine, and paracrine mechanisms.

The term *endocrine* specifically refers to hormonal delivery by way of the bloodstream, providing a mechanism to transport the hormone to distant sites. If this circulation traverses a specialized organ, such as the portal circulation through the liver, the opportunity exists to extract a particular hormone efficiently from the blood, thereby preventing broad systemic distribution. This can differentially affect certain molecular forms of the same hormone. For example, short molecular forms of cholecystokinin (CCK) are extracted in a single pass through the liver, whereas long forms pass through to the systemic circulation. [3] There are also specialized circulatory delivery systems relevant to gastrointestinal peptides, such as those secreted from the pancreatic islets; an islet-acinar portal circulation provides high

concentrations of peptides to the surrounding pancreatic acinar cells. [4]

Autocrine loops are postulated to exist, whereby the peptide synthesized by a cell affects that same cell. This may occur after secretion into the interstitial space, such that back-diffusion allows high local concentrations of peptide to interact with receptors on the plasmalemmal surface of the hormone-secreting cell. Although more difficult to understand from a mechanistic standpoint, it also has been postulated that autocrine effects occur within the cell, independently of hormone secretion. This would require the ability of the peptide, which is within a membrane-bound vesicular compartment, to interact with another molecule playing the role of receptor in an accessible location within the cell. There is no reason why such a molecule must be identical to the receptor molecules we recognize to reside within the plasmalemma with their hormone-binding sites exposed to the extracellular milieu. There has been some indication that molecules, such as guanine nucleotide–binding proteins (G proteins), which are proximal effectors of hormonally stimulated events at the level of the plasmalemma, may also reside on secretory granule membranes. [5], [6]

Neurocrine delivery of peptides usually involves their local release adjacent to a target cell bearing relevant receptors. [7], [8] Neurons are particularly well suited for this mode of delivery because they can have highly specialized long processes that terminate on or adjacent to potential target cells. It is also important to appreciate that this mode of delivery provides a gradient of transmitter concentrations from the point of release. Concentrations may fall off rapidly with distance from this point, limiting action on other receptor-bearing cells in the general area.

Paracrine delivery reflects the identical process originating within an endocrine cell rather than a peptidergic neuron. These cells are also capable of developing specialized processes that allow the secretion of a key transmitter adjacent to its target cell. The first identified example of this was the relationship between somatostatin-secreting cells and gastrin-secreting cells in the gastric antrum. [9]

Once the regulatory peptide is delivered to its target cell, a high level of regulatory diversity is still provided by the specificity of receptors expressed on each cell and by a whole universe of potential signaling and regulatory molecules. A given endocrine cell can further regulate hormone-stimulated events in several different ways: by altering coupling events between receptor and proximal effector, by modifying the complement of molecules intrinsic to each signaling pathway, and by cross talk between the molecules involved in signaling pathways. Each cell also can regulate the receptors it expresses, a phenomenon highly relevant to any understanding of the gastrointestinal endocrine system. This regulation can take the form of modification of the number of receptors on the cell surface, modification of the ability of those receptors to bind ligands or to initiate signaling, movement of receptors into different cellular compartments, and modification of the total cellular complement of receptors by effects on receptor synthesis and degradation. [10], [11] and [12]

A given type of receptor may be present on a wide variety of cells of the body, but the secretion of its hormonal agonist may affect only a small subset of those cells. This may reflect the different limited delivery systems discussed above. It also may reflect a gradient in delivery by diffusion from a point source, with potential target cells also expressing different numbers of receptors on their surfaces. Receptors on distinct cells may be in different states of sensitization or desensitization. A certain type of cell may express a receptor differently at each stage of its life, depending on cell growth, the stage in the cell cycle, and other active metabolic and biochemical processes within the cell.

The gastrointestinal endocrine system represents a system of substantial complexity, which is dynamic and responsive to feedback and cross regulation at the levels of both the hormones and the receptors. It is precisely because of this complexity that the system is so sensitive and has such extraordinary capabilities to keep us well nourished and pleased with our dining experiences.

HISTORY OF GASTROINTESTINAL ENDOCRINOLOGY

Classic endocrinology and gastrointestinal endocrinology were born together in 1902, with the discovery of the first hormone, secretin, by Bayliss and Starling [13] and the recognition that chemical messengers can be carried in the bloodstream. This earliest period in gastrointestinal endocrinology has been termed the *juice-physiology era*. [14] The discovery of gastrin by Edkins followed quickly in 1905. [15] This flourish of activity in the gastrointestinal hormone field was followed by minimal discoveries for many years, while the field of classic endocrinology achieved steady and substantial growth. The solid and homogeneous classic endocrine organs could be studied with relative ease, whereas methods had not yet been developed to gain analogous insights into the scattered diverse gastrointestinal endocrine cells.

Gastrointestinal endocrinology finally achieved its status as a distinct discipline in the chemical era, when a long series of candidate hormones were discovered by means of the techniques of purification and peptide sequencing. The first was gastrin, whose structure was determined in 1964 after it had been extracted from a tumor. [16] Subsequently, the number of recognized potential regulators of digestive function expanded logarithmically. The Gastrointestinal Hormone Laboratory, founded by Mutt and Jorpes at the Karolinska Institutet, [17] was the site of the initial chemical characterization of secretin, CCK, glucose-dependent insulinotropic peptide (GIP), vasoactive intestinal polypeptide (VIP), motilin, gastrin-releasing peptide (GRP), and many other candidate structures.

The next key advance was also methodologic—the development of radioimmunoassay to detect or quantify minute quantities of molecules. Application of this methodology to the quantification of a hormone by Yalow and Berson [18], [19] and its application to CCK [20] initiated the immunologic era of gastrointestinal endocrinology. The usefulness of antibodies was appreciated quickly; these were applied to the localization of hormone-secreting cells by immunohistochemistry and to the quantification of peptide hormones by radioimmunoassay. The usefulness of radiolabeled peptide hormones also was recognized quickly. The radiolabeling of gastrointestinal hormones to highly specific radioactivity made it possible to demonstrate directly the binding of hormones to receptors. The competition-binding technique made it possible to identify receptor subtypes, to define the cellular location of receptors, and to quantify receptor density on a given type of cell.

Since the 1970s, gastrointestinal endocrinology has become increasingly biochemical and molecular. Gastrin led the way into the new era of the molecular biology of peptides. [21] A more biochemical understanding of hormones excited interest in the biochemistry of receptors. During this era of molecular receptorology, [21] receptors increased in status from representing simple sites of hormone binding to being the focus of intense interest. It was critical to understand the structure of receptor molecules before the details of the basis of binding, activation, and regulation became meaningful.

The first insights into the structure of receptors came from affinity labeling approaches, [22], [23] which represented a logical extension of the receptor-binding assay described above. These approaches involved the use of a radiolabeled form of the hormone, as rich a source of receptor as possible, and a chemical method to link the two molecules together covalently. The siting of a photolabile group within the pharmacophoric domain of a hormone has been particularly successful in the covalent labeling of hormone receptors and their domains. [24]

The most exciting and powerful insights in this era have come from cloning the complementary DNA (cDNA) encoding the receptors. If the partial receptor sequence is available, an oligonucleotide probe can be designed. [25], [26] Hybridization screening also can be used to detect a homologous receptor or a known receptor in a new species or tissue. [27] Expression cloning efforts bypass the need for pure receptor and partial receptor sequence. [28] Given the difficulties in purifying what are typically very sparse molecules that are extremely hydrophobic and difficult to work with, this has become a very popular approach to cloning.

Once a receptor cDNA has been cloned and sequenced, a universe of possibilities is revealed. The deduced amino acid sequence provides insights into the receptor class represented. By finding its position in a phylogenetic tree, additional insights can come from analogy with studies of the closest known members of the family. [29] This can take the form of mutagenesis studies that provide insights into structure-function relationships. Chimeric receptors that combine specific regions of two or more receptors can be useful in identifying which domain is important for a given function. [30], [31] Also, truncations and site mutants can help localize such regions. [32] Such receptor constructs can be constructed rapidly and expressed transiently to gain new insights. It is also possible to produce stable cell lines that express such constructs, [33] and to modify the expression of natural or mutagenized hormones and receptors in laboratory animals. A variety of transgenic and null (i.e., knock-out) animals are available to explore the impact of such modifications in an intact animal.

The next era will probably be the era of molecular conformation and molecular interaction. [21] Now that the primary structures of receptors can be catalogued, molecular conformations must be studied, including both resting and active conformations. There will be major interest in the sites and molecular determinants of binding and activation, as well as the use of such insights for the rational design of useful pharmaceuticals. We are already witnessing dramatic advances in drug development resulting from novel strategies of synthesizing and screening vast libraries of potential receptor ligands. [34], [35] These have led to the successful development of numerous nonpeptidyl antagonists, and even nonpeptidyl agonists, for peptide hormone receptors. [36], [37] There is no doubt that for gastrointestinal

endocrinology, the future promises to be even more exciting and successful than the recent past.

HORMONE SECRETORY CELLS

Several cellular sources exist for the synthesis and secretion of gut hormones. As previously noted, these can represent the numerous types of endocrine cells that are isolated and scattered throughout the gut mucosa, as well as the neurons contained within the enteric nervous system. Both cell types share many features: (1) the machinery for peptide biosynthesis and processing, (2) the packaging of products for export into secretory granules and the exocytic secretion of these products, and (3) the specialized processes that may facilitate focused delivery of secretory products. Based on these shared characteristics, similar embryogenesis also has been postulated. This section focuses on each of these features as they relate to the sources of gastrointestinal hormones and neurotransmitters.

In 1968, A.G.E. Pearse [38] introduced the concept of amine precursor uptake and decarboxylation (APUD) and suggested that it is a feature that paraneuronal cells, such as the gastrointestinal endocrine cells, may share with neurons. It can now be concluded that the endocrine cells and enterochromaffin cells of the gastrointestinal tract arise from embryonic endoderm, like the pancreatic islets. [39], [40] All types of intestinal epithelial cells appear to be derived from a single type of pluripotent stem cell precursor. [40], [41], [42] and [43] Gastrointestinal endocrine cells continuously differentiate and follow the highly organized vertical paths of migration along the crypt to the villous axis. These cells have embryological associations and evolutionary relationships similar to those of the endocrine cells of the pancreatic islets. The gastrointestinal hormones gastrin, secretin, and peptide YY are all transiently expressed in fetal islets during development, and the pancreas and duodenum are common sites of gastrin-secreting tumors. [44], [45]

In contrast, the enteric neurons are derived from the neural crest and the neuroectoderm. [8], [46] Some extremely interesting data suggest that the phenotype of cells derived from the neural crest is most dependent on environmental influences in the regions to which they migrate, rather than on the level of the neural axis from which they originate. [46], [47] The complexities of cell types and interactions typical of the enteric nervous system result largely from the mesenchymal substrate that these cells contact. The factors responsible for the development and differentiation of each of the gastrointestinal mucosal endocrine cells are even less well understood.

Despite this apparent difference in their developmental origins, the gastrointestinal endocrine cells and the enteric peptidergic neurons share many biologic and biochemical specializations necessary for polypeptide synthesis, processing, and secretion. Key in this sequence of events is the packaging of the peptide product for export into a secretory granule. The details of this process were clearly defined by Jamieson and Palade, [48], [49], [50], [51] and [52] who studied the pancreatic acinar cell (Fig. 4-2). The identical processes appear to exist in the gastrointestinal endocrine cell.

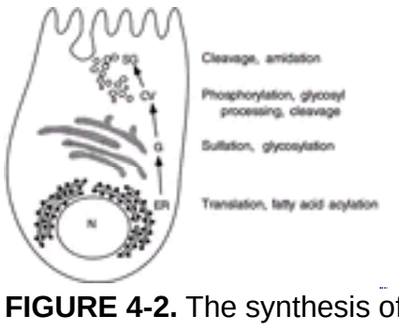

FIGURE 4-2. The synthesis of proteins or peptides for export (i.e., secretion) from polarized epithelial cells follows a highly conserved biosynthetic route. Synthesis begins at the level of the rough endoplasmic reticulum (*ER*) and proceeds through the Golgi apparatus (*G*), condensing vacuoles (*CV*), and secretory granules (*SG*) before exocytosis at the apical pole of the cell.

ENDOCRINE CELL LOCALIZATION AND CHARACTERIZATION

Some gastrointestinal endocrine cells can be recognized by the relatively distinct ultrastructural appearance of their secretory granules [1], [2] (Fig. 4-3). Other gastrointestinal endocrine cells can be tentatively identified not only according to the appearance of their secretory granules but also according to their position along the digestive tract. However, more specific techniques are required to identify most endocrine cells and any of the peptidergic nerves. These techniques are directed toward the polypeptides themselves or to the genes and messenger RNA (mRNA) molecules encoding them (Fig. 4-4). Peptide antisera have been most useful in the immunohistochemical localization of peptides. In situ hybridization has been successfully used to localize relevant hormone mRNA.

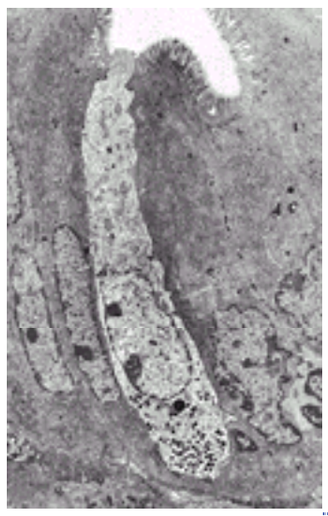

FIGURE 4-3. Electron micrograph of a gastrointestinal endocrine cell in the human jejunum. This cell extends from the lumen to just above the basal membrane and includes the typical electron-dense secretory granules in its basal pole. (From Solcia E, Capella C, Buffa R, et al. Endocrine cells of the digestive system. In: Johnson LR, ed. Physiology of the gastrointestinal tract, 2nd ed. New York: Raven Press, 1987:112, with permission.)

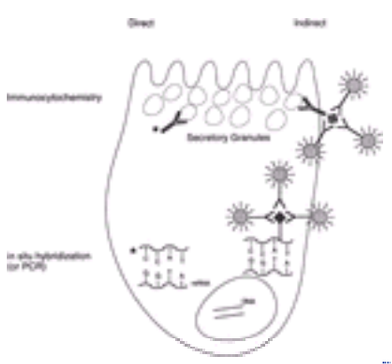

FIGURE 4-4. Methods to identify specific endocrine cells include direct and indirect immunocytochemistry, with antibodies directed toward the hormones themselves, and in situ hybridization (or polymerase chain reaction [PCR]), in which oligonucleotide probes bind to mRNA.

Immunohistochemistry has become a standard technique to localize any antigen in a tissue section to which specific antisera have been raised. With the current understanding of the primary structure of the molecular forms of a given hormone, and of the unique and shared domains within that structure, it is easy to choose a potentially useful antigenic epitope. By conjugating that peptide to a hapten, such as keyhole limpet hemocyanin, a strongly immunogenic antigen can be produced. Most endocrine cells and peptidergic nerves concentrate their peptides in secretory granules in preparation for secretion, providing an ideal concentrated target that has multiple copies for immunolocalization. A potential problem relates to the ability to fix these highly soluble compounds without interfering with the antibody recognition domains. Trials of different fixatives and conditions of fixation may be necessary for an optimal signal.

In situ hybridization is an analogous localization technique based on the specific interaction of an oligonucleotide probe with its complementary sequence within the cell. [53] This most often takes the form of an mRNA molecule. A complementary, single-stranded, antisense riboprobe provides optimal sensitivity and specificity. Here, too, multiple choices exist: fluorescent, colorimetric, or radioactive detection. [54] Limited copy number for a specific mRNA may represent a problem for applying this technique to some hormone genes.

BIOSYNTHESIS AND PROCESSING OF GASTROINTESTINAL HORMONES

The gastrointestinal hormones and neurotransmitters discussed in this chapter are single-chain polypeptides. All are encoded by single-copy genes, containing one or more exons that determine the primary amino acid sequence by a series of nucleotide triplets known as *codons* (Fig. 4-5). For the multiple-exon genes, these coding regions are separated by noncoding introns. While still in the nucleus, the DNA sequences are transcribed by RNA polymerase II to form mRNA. The noncoding regions of the gene, particularly those upstream of the site of the initiation of transcription (i.e., the 5' flanking sequence), often contain *cis*-active regulatory sequences that influence the rate of transcription. Regulation of gene expression typically occurs slowly, over a number of hours, whereas hormone secretion of prepackaged product occurs rapidly, being initiated within seconds of stimulation. During the process of transcription, the sequences complementary to the exons are spliced together while those complementary to the introns are eliminated. Sometimes, there is more than one product of transcription, representing alternatively spliced products in which some potential coding regions are eliminated. This can have substantial functional significance and may occur selectively in a given type of cell or may even be a regulated process occurring only at certain times in that cell. For many hormones, the product of transcription represents a preprohormone, with an amino acid sequence that helps direct the product of translation into the exocytic pathway for export and undergoes additional cleavage and processing before secretion from the hormone-producing cell.

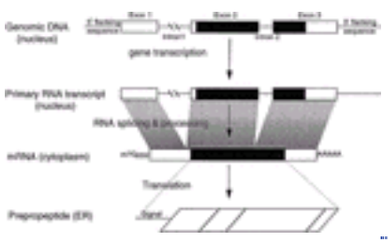

FIGURE 4-5. The gene structure and the molecular biologic events leading to protein synthesis. Posttranscriptional processing events that occur in the nucleus include splicing, capping, and polyadenylation of the RNA to produce mature mRNA. Mature mRNA is transported into the cell cytoplasm, where it directs translation at the surface of the rough endoplasmic reticulum (*ER*).

Several examples exist of alternate processing of a single gene. There may be more than one distinct product within a single gene. Examples of this include the proopiomelanocortin gene, which contains sequences for ß-endorphin, corticotropin, and melanocyte-stimulating hormone, [55] and the proenkephalin gene, which contains five copies of the Met enkephalin sequence and one copy of the Leu enkephalin sequence. [56] VIP, neuromedin A, and peptide histidine isoleucine (PHI) sequences all exist within a single gene. [57] Another phenomenon is the production of distinct gene products by alternate splicing of a single gene, such as that which occurs in the production of calcitonin and calcitonin gene–related peptide. [58] Similarly, alternate splicing of a single gene product may also occur. [59] Several hormone receptors can have a variety of alternately spliced sequences to yield products of different lengths with short deletions or insertions from the predominant species. [60], [61]

The fully spliced mRNA is translocated to the cell cytoplasm, where translation occurs (Fig. 4-6). Translation is the process of producing the polypeptide chain representing the preprohormone that is encoded by the mRNA. Peptide synthesis begins on the ribosome bound to the rough endoplasmic reticulum. Peptides destined for export have a characteristic amino-terminal signal sequence that leads to their segregation within the lumen of the endoplasmic reticulum. [62] As the nascent chain crosses into the lumen of the endoplasmic reticulum, the signal sequence is bound to a signal-recognition particle and cleaved by a signal peptidase to yield the prohormone. Also, posttranslational modifications may begin cotranslationally. For example, sulfation, phosphorylation, glycosylation, and amidation may continue as the peptide moves through the Golgi apparatus and into secretory granules that are at various stages of maturity. The ultrastructural appearance of these secretory granules can be characteristic of a particular type of gastrointestinal endocrine cell. [1] The large secretory granules typify regulated pathways of exocytosis, with constitutive secretory pathways most commonly using much smaller vesicular structures. Glycosylation is a multistep process that occurs through each of these compartments. Tyrosine sulfation seems to occur early in biosynthesis, within the Golgi apparatus. [63]

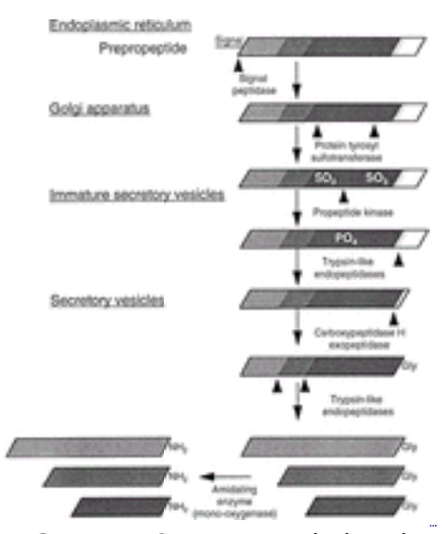

FIGURE 4-6. Posttranslational processing events that occur in distinct cellular compartments in preparation for secretion of a peptide from the cell. These types of reactions are used selectively for different secretory products.

A unique posttranslational processing particularly relevant for peptide hormones is the selective cleavage of the prohormone into fragments of different lengths, with each form possessing biologic activity. [64], [65] Examples of multiple, biologically active forms of a hormone include gastrin and CCK; the multiple forms of these hormones share the carboxyl-terminal sequence critical for activity. Endoproteolytic processing occurs during biosynthesis while the product traverses the late Golgi cisternae and early secretory granule compartments. Dibasic amino acid residues are a common location for such processing. Trypsinlike endopeptidases, such as PC1 and PC2, which are uniquely expressed in endocrine and neuroendocrine cells, have been described to be important in the endoproteolytic processing of

gastrointestinal hormones. [66], [67]

Carboxyl-terminal amidation is a very common posttranslational modification of gastrointestinal hormones. [68], [69], [70] and [71] It occurs in about half of the recognized hormones and peptide neurotransmitters, and was the basis of a discovery strategy used early in the chemical era by Tatemoto and Mutt. [72] A series of enzymatic reactions is necessary to yield an amidated product (1) cleavage at a site of dibasic residues, (2) trimming of the remaining basic residues by carboxypeptidase H, and (3) conversion of the glycine-extended intermediate to the corresponding carboxyl-terminal amide with an a-amidating monooxygenase. These processes occur within the secretory granules themselves.

The processing of gastrin in the antral G cell is an excellent example of these processes. [73] The biologically active region of this peptide that is key for binding to its classic receptor has been carefully isolated to the carboxyl-terminal tetrapeptide-amide of the mature forms of gastrin. [74], [75] The gastrin gene is composed of three exons, with exons 2 and 3 possessing the coding sequences. [76], [77] and [78] The primary mRNA transcript is processed to eliminate approximately 3 kilobases of intron sequence between the first two exons and 130 bases of intron sequence between exons 2 and 3. This is translated to yield preprogastrins of 101 amino acid residues in man and 104 amino acid residues in rat and pig. The signal peptide is then cleaved to yield progastrin, which rapidly undergoes further proteolysis at Arg ^{57,58}, Lys ^{74,75}, and Arg ^{94,95} to yield four fragments. The Arg ^{94,95} cleavage is followed by carboxypeptidase H trimming of carboxyl-terminal basic residues and conversion of the Gly-extended intermediate to the carboxyl-terminal amide. G34 and G17 are the major products of these cleavages. Serine phosphorylation and tyrosine sulfation may also occur. [73], [79] One of the sites of serine phosphorylation is Ser ^{96}, immediately adjacent to the site of cleavage at the dibasic residues, which ultimately results in carboxyl-terminal amidation. Tyrosine sulfation can occur at Tyr ^{87} and Tyr ^{103}. Whether these modifications affect physiological processing remains unclear. [80]

Posttranslational modifications of gastrointestinal hormones are potentially important for their activity. Most of the amidated hormones require modification (i.e., amidation) for recognizable activity. Gastrin exhibits a spectrum of activities, including growth stimulation, which has been attributed to a nonamidated Gly-extended form of the hormone. [81] Presumably, this posttranslational modification is mediated through a receptor that is distinct from the molecule mediating its classic activities. Another key modification is the sulfation of the tyrosine, seven residues from the carboxyl terminus of CCK peptides. [82] This modification is critical, with the desulfated peptide more than 1000-fold less potent. The structurally related gastrin peptides also can exhibit tyrosine sulfation six residues from the carboxyl terminus, but this modification has little or no impact on receptor binding or hormone activity.

HORMONE AND TRANSMITTER MOLECULES

As noted above, all the relevant hormones and neurotransmitters discussed in this chapter represent single-chain polypeptides. They are all hydrophilic and soluble in aqueous media. This property prevents them from traversing the lipid bilayer in the target cell and necessitates the presence of a receptor molecule with which they can interact at the level of the target cell. By first principles, peptides are also flexible. The peptide bonds linking the amino acid residues are stable and strong, broken only by peptidase enzymes under normal biologic conditions. This flexibility enables peptides to sample a large range of potential conformational space, but makes it somewhat difficult to predict the relevant conformation of these molecules as they bind to their targets. Some insights have come from observing the conformationally constrained analogs of some hormones, but such insights are limited. [83]

Dramatic advances in peptide chemistry have permitted the routine synthesis of small peptides. Peptide synthesis can be achieved in solution or by solid phase techniques in which one amino acid residue is added at a time to a growing chain of residues. [84], [85] This technique can be used to produce the natural peptides themselves, or analogs that can provide important primary structure and activity information.

Gastrointestinal hormones can be categorized according to (1) predominant localization in endocrine cells or peptidergic neurons; (2) localization to different levels of the gastrointestinal tract; (3) rapid effects versus more prolonged effects on growth and differentiation; or (4) the presence of structural similarities between the hormones themselves (Table 4-1). A single peptide hormone can be found in endocrine cells and nerves, it can be present at several levels of the gastrointestinal tract, and it can have both acute and chronic growth regulatory effects. This is also true for families of structurally related hormones. A single peptide can interact with and activate more than one type of receptor. Only by appreciating the scope of options for these peptides and their receptors can the complexity and the power of the gastrointestinal endocrine system be understood.

TABLE 4-1 Organization Schemes for Gastrointestinal Hormones, Neuropeptides, and Locally Secreted Growth Factors According to Their Cell of Origin, Anatomical Location, and Structural Similarities

MEASUREMENT OF HORMONES

Hormone concentrations can be quantified by bioassay or by a type of competition-binding assay, such as radioimmunoassay or receptor-binding assay. FONT size=-1>[19], [86] Before the chemical characterization of hormones, concentrations could be determined only in an activity assay. The specificity of an activity assay is unreliable because more than one hormone can produce the same response and because antagonistic agents can influence the net activity. The determination of the chemical identity of many hormones has facilitated the assay of unpurified samples.

Competition-binding assays are based on the competitive inhibition of the specific binding of a radiolabeled form of the hormone to an antibody or receptor. The radiolabeled and natural hormones compete for binding to the antibody or receptor. Radioimmunoassay benefits from the availability of specific antibodies that are easy to handle and store. In contrast, radioreceptor assay depends on the preparation of a receptor that may be difficult to produce and store in an active form.

For all hormone assays, sample collection and handling are critical, and sampling conditions should be reproducible. Samples usually are collected during fasting because hormone concentrations may increase in the postcibal period. Gastrin, CCK, secretin, GIP, and pancreatic polypeptide all increase transiently after a meal, whereas concentrations of most neurotransmitters (e.g., VIP) change minimally. [87] After sample collection, low temperature and protease inhibitors minimize hormone degradation.

Knowledge of hormone concentrations in the circulation can provide important insights. Elevated basal levels may reflect excess secretion or reduced clearance. Excess secretion may develop if hormone-secreting cells proliferate, as occurs in gastrin cell hyperplasia, or if cells have lost their feedback inhibitory mechanisms and secrete constitutively, as occurs in various types of endocrine cell neoplasia. Because polypeptide hormones are cleared by the kidneys, high levels of hormones have been reported to exist in renal failure. [88] In some settings, it may be useful to measure hormone concentrations serially after some type of stimulus, such as the ingestion of a meal or the perfusion of a region of the intestine, to define the timing and characteristics of a normal stimulated response. There are provocative tests

for some endocrine tumors, such as secretin stimulation of gastrin in gastrinoma. [89]

The confirmation of the role of a hormone in a particular physiological process is not simple. Determination of the physiological activity of a particular gut peptide is based on the following criteria: (1) There is a relationship between the appearance of the hormone in the circulation and the physiological event; (2) the physiological effect can be reproduced by infusion of pure or synthetic hormone to achieve the same serum concentration observed under physiological conditions; and (3) the physiological activity can be inhibited by infusion of a specific antibody or receptor antagonist, when available. [90], [91] The circulating concentrations of the hormone that produce the biologic effect should be similar for the natural peptide released physiologically or the synthetic peptide infused into the experimental subject. When multiple molecular forms of a hormone exist, it is important for the infusion to reproduce the forms naturally observed as closely as possible.

Unfortunately, it is more difficult to determine the relevant concentration of gastrointestinal hormones at the level of their receptors. Interstitial concentrations can vary significantly over short distances. There is no good, reproducible method to collect the relevant fluid to measure hormones at their site of action. This is a particular problem for hormones and neurotransmitters released through paracrine or neurocrine mechanisms.

RECEPTORS

Receptor molecules also have a special place in gastrointestinal endocrinology. Hormones and transmitters cannot cross the plasma membrane of target cells to activate intracellular machinery. Therefore, a molecule that spans the lipid bilayer in the target cell plasma membrane, such as a receptor, is required. The receptor molecule has two spatially distinct domains one domain to bind ligands that approach the molecule from the extracellular side of the membrane, and a second to initiate activity cascades within the cell. The cellular response can be triggered by a ligand-induced conformational change that activates an enzymatic activity intrinsic to the receptor. Alternatively, the ligand-induced change in the conformation of the receptor can expose a receptor domain that interacts with an important intracellular molecule, and the interaction initiates the cascade of signaling events typical of that receptor and ligand pair.

With the cDNAs of many receptor proteins now cloned, and their primary structures known, insights into the structural basis of cell activation are being advanced rapidly. Gastrointestinal hormone receptors are grouped into three broad classes according to their membrane topology: (1) the single-transmembrane receptors, (2) receptors with subunits that traverse the membrane multiple times, and (3) the G protein–coupled receptors that traverse the membrane seven times (Fig. 4-7).

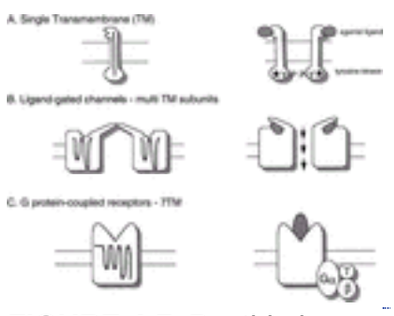

FIGURE 4-7. Peptide hormone receptors can be divided into three groups according to their membrane topology. The basal conformations are shown on the left and activated states on the right. **A:** The single-transmembrane (*TM*) receptors dimerize; some also possess intrinsic tyrosine kinase activity that contributes to the autophosphorylation of the complex. **B:** The ligand-gated complexes undergo a conformational change that opens the channel. **C:** The G protein–coupled receptors become associated with their heterotrimeric G proteins, which then initiate the signaling cascade.

The largest group of single-transmembrane receptors possess intrinsic ligand-triggered enzyme activity. This group includes ligand-triggered protein tyrosine kinases, such as the epithelial growth factor receptor, insulin-like growth factor receptors, platelet-derived growth factor receptor, fibroblast growth factor receptor, and transforming growth factor receptors. [92], [93] and [94] Ligand-triggered membrane guanylate cyclases also exist, such as the receptor for atrial natriuretic peptide. [95] There is also a group of single-transmembrane receptors that do not appear to have any intrinsic enzymatic activity, but rather function by dimerization and initiation of cascades of modular interactions. These include receptors for growth hormone, erythropoietin, prolactin, and several cytokines. [96], [97]

The second group of receptors (ligand-gated channels) have subunits that span the membrane multiple times and associate to form pores or channels. [98] Examples include the nicotinic acetylcholine, GABA $_A$, 5-HT $_3$ (serotonin), glycine, and glutamate receptors. The best characterized is the nicotinic acetylcholine receptor. This complex is composed of five membrane-spanning units (a, a, ß, ?, and d), each having four transmembrane domains, which associate to form a central cation-conducting channel.

The last group is by far the largest group of gastrointestinal hormone receptors and the largest group of receptors in the body—the heptahelical G protein–coupled receptors. [99], [100] and [101] Several thousand of these have been cloned to date, representing 1% to 5% of the genome of different species. They are activated by extraordinarily diverse ligands, ranging from odorants to photons, peptides, and even large glycoproteins and viral particles. There is a somewhat parallel organization of groups of these receptors with structurally similar groups of ligands. [29] These receptors all initiate signaling by coupling with heterotrimeric G proteins. [102], [103] and [104]

The membrane protein tyrosine kinases have extracellular ligand-binding domains and intracellular kinase domains. [92] On activation, these molecules associate into dimers and are autophosphorylated. In addition to the phosphorylation of the receptors themselves, various members of this group phosphorylate and activate phospholipase C, GTPase-activator proteins, and intracellular tyrosine and serine/threonine kinase cascades. These events are closely associated with cell growth, differentiation, and oncogenesis.

The ligand-gated channels are multimers that comprise the same or related subunits and that cross the plasma membrane multiple times. [98] Proteins with four transmembrane domains are the most common subunit structure. The association of these proteins establishes a channel or a water-permeable pore. Ligand binding results in a conformational change, which regulates the size and permeability of the channel.

The heptahelical receptor proteins typically have no intrinsic enzymatic activity. Instead, they signal by associating on their cytosolic face with heterotrimeric G proteins. [102], [103], [104] and [105] These can then regulate a variety of effectors, such as phospholipase C and adenylate cyclase. These receptors have seven segments of approximately 20 to 25 hydrophobic residues representing the putative transmembrane helices (Fig. 4-8). The most highly conserved residues in each family of G protein–coupled receptors are located in these domains. Typically, there are sites of potential N-linked glycosylation in predicted ectodomains. This posttranslational modification likely plays an important role in helping the receptors fold and maintain their solubilities during biosynthesis. There are often serine- and threonine-rich areas in predicted cytosolic domains of these receptors that may be sites for phosphorylation and, thereby, receptor regulation.

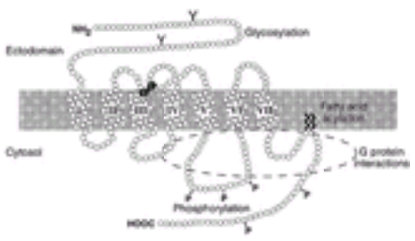

FIGURE 4-8. A prototypical G protein–coupled receptor depicted from the side (**top**) and looking down on the transmembrane helices (**bottom**). Each receptor is predicted to have seven hydrophobic segments traversing the lipid bilayer, with most having sites of N-linked glycosylation in the ectodomain and sites of phosphorylation in cytosolic domains. Also shown is the position of a highly-conserved disulfide bond linking the second and third extracellular loops, and a position of fatty acid acylation that is present in the carboxyl-terminal tail of some of these receptors.

The heterotrimeric G proteins consist of three subunits—a, ß, and ?. [105], [106] The a subunit has intrinsic GTPase activity and is the site of guanine nucleotide binding. The ß and ? subunits remain bound together, binding to the GDP-bound a subunit as a paired unit. There is a cycle of agonist binding to the receptor, association of the GDP-bound G-protein heterotrimer, GTP displacement of GDP, dissociation of the GTP-bound a subunit from the ß? dimer, hydrolysis of the GTP, and reassociation of the GDP-bound a subunit with ß? (Fig. 4-9). Crystal structures have been solved for these G-protein complexes, providing insights into the molecular interactions between receptor and G protein and between G protein and effectors. Early attention was focused on the GTP-bound a subunit as the molecule that interacts with effector proteins to activate them. More recently, it has become clear that the ß? dimer also plays this role for many effector proteins. [107], [108] In mammals, genes for 16 a subunits, 4 ß subunits, and 7 ? subunits have been isolated. [106] The innumerable combination of these various subunits into heterotrimers contributes to the vast diversity of effects and regulatory properties of peptide hormones.

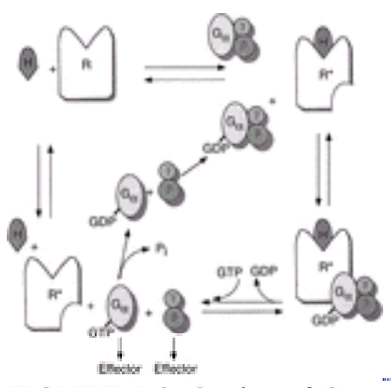

FIGURE 4-9. Cycles of G protein–coupled receptor activation and proximal signaling events at the level of the plasma membrane, which occur in response to agonist occupation. The earliest step is an induced conformational change in the receptor (*asterisk*) that facilitates its association with a G protein. At that point, the G protein is in its GDP-bound trimeric state. The receptor association facilitates GTP exchange for the GDP, which in turn results in the dissociation of the ternary complex and dissociation of the GTP-bound a subunit from the ß? dimer. Both of these can move on to interact with effectors in other compartments within the cell. The a subunit of the G protein has intrinsic GTPase activity that results in the elimination of one of the phosphates and reassociation of the trimeric form of the G protein.

The G protein–coupled receptors relevant to the gastrointestinal hormones fall into two families. Most of the small and carboxyl-terminally amidated peptides, which have focused domains for receptor binding at the carboxyl terminus, are members of the rhodopsin/ß-adrenergic receptor family. The larger peptides with diffuse pharmacophoric domains with amino-terminal determinants of specificity tend to be members of the secretin receptor family [109], [110] (Fig. 4-10). A notable exception is the amino terminal–specific receptor for motilin, which has been cloned and identified as a member of the rhodopsin/ß-adrenergic receptor family. [111] The binding of most agonists acting through this superfamily of receptors is influenced by hydrolysis-resistant analogs of GTP. This property provides an important clue that an action is mediated by this class of receptors.

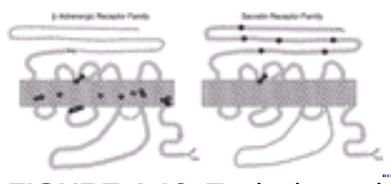

FIGURE 4-10. Typical members of the rhodopsin/ß-adrenergic receptor family and the secretin receptor family of G protein–coupled receptors. The typical signature sequences of the rhodopsin/ß-adrenergic receptor family are not present in the secretin receptor family. Other major differences include a shorter, third intracellular loop and a long amino-terminal tail that includes six highly conserved cysteine residues in the secretin receptor family.

Like the hormones, the gastrointestinal hormone receptors are all the products of single genes. Most do not have signal sequences, and they do not undergo extensive proteolytic processing. Alternate splicing is particularly common in the secretin family of G protein–coupled receptors, in which multiple exons are the rule. [112] The alternatively spliced products can differ substantially in ligand-binding specificity and activation characteristics. [113] The genes encoding the gastrointestinal hormone receptors have been known for less time than those encoding the hormones themselves. As a result, less is known about regulation of the receptor genes. Many receptors undergo substantial posttranslational modifications. Most of the G protein–coupled receptors are glycosylated. This feature helps to establish the appropriate folding and solubilities for biosynthetic transport to the cell surface, and likely helps to protect the receptors from proteolysis. [114], [115] and [116] Palmitoylation of Cys residues within the carboxyl-terminal tail is common in many G protein–coupled receptors. [117], [118], [119] and [120] This modification may bring another loop up to the plasma membrane, and may have a role in regulating access for G-protein coupling. Receptor phosphorylation is another common posttranslational modification, but it occurs predominantly after the mature receptor has been inserted into the plasma membrane. [121], [122] and [123]

Most of the gastrointestinal hormone receptors are present on the cell surface in small to moderate numbers of copies. There are typically fewer than several thousand molecules per cell. In such low numbers and given the very low concentrations of most of the circulating natural ligands, high affinity and specific binding interaction between hormone and receptor are critical. The receptor is an ideal target for regulating the sensitivity of the system. The pharmaceutical industry recognizes this and targets numerous drugs to act at cell surface receptors. Receptors are also a site of substantial endogenous regulation. A shift in the accessibility of the receptor-binding domain to ligand or a reduction in the number of receptors on the cell surface affects the sensitivity of the signaling system.

Receptors are dynamic molecules that have a life cycle in the cell (Fig. 4-11). Most receptors are synthesized at a slow rate, relying on reversible regulatory processes that conserve receptor molecules. The resting cell has a fixed complement of mature receptors on its surface and a small number of molecules in the biosynthetic pathway within the cell. Agonist occupation often initiates many events that can influence the receptor. By definition, agonist occupation of every receptor

initiates signaling processes within the cell. The details of these events vary with the receptor class, family, and even the particular ligand being bound or the cell in which the receptor is expressed. Within many signaling cascades are protein kinases and phosphatases that feed back and act on the receptor itself. For G protein–coupled receptors, this can uncouple the receptor from its proximal G-protein effector. [12] For receptor tyrosine kinases, autophosphorylation is critical. Many receptors undergo internalization processes that remove them from the surface, thus removing the potential for further stimulation. [10], [11] This mechanism protects the cell from damage caused by overstimulation. Some internalized receptors travel to the lysosome and are degraded, whereas others are recycled to the cell surface. For many ligand-occupied receptors, the pair of molecules internalize together and move through the proximal endocytic cascade, in which the endosome becomes acidified and releases the ligand. The ligand can then move independently from its receptor. To be certain of the details of these processes, both ligand and receptor must be studied.

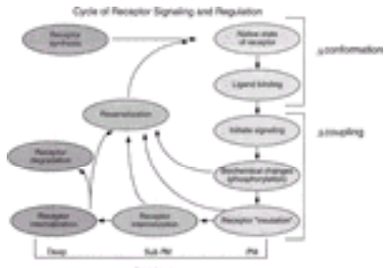

FIGURE 4-11. Events in the life cycle of a receptor in a cell. In the basal state, most of the receptor is usually at the level of the plasma membrane (*PM*). Agonist occupation results in changes in receptor conformation, biochemical modifications, and trafficking through the cell, which impact on accessibility for ligand binding, proximal effector coupling, and signaling events. The cycle is completed by reversal of the biochemical changes and the return of the receptor to the original cellular compartment. Because some receptor is lost to degradation, new synthesis also can replenish the cellular complement of receptor. The details of these cycles differ depending on the ligand, receptor, and cell type.

RECEPTOR CHARACTERIZATION AND QUANTIFICATION

Receptors can be characterized on the basis of their biologic activities or their receptor-binding properties. The availability of analogs of a given hormone that have a spectrum of activities from full agonist to partial agonist to antagonist simplify the characterization of biologic activity. If an activity is mediated by a particular receptor, the receptor antagonist should inhibit it in a competitive manner. Such an activity assay can be used to screen for compounds that are active at a particular receptor. This type of assay is necessary to determine if a new receptor ligand is an agonist or an antagonist.

The binding characteristics of receptors have been the subject of intense investigation. [124] The availability of radiolabeled forms of hormones with highly specific radioactivities that bind normally to their receptors provides a tool to analyze binding. The law of mass action should apply to the binding. Numerous software programs are capable of analyzing the binding data generated from this type of experiment. For such data and analysis to be valid, binding must be performed under conditions in which the concentration of radioligand is below the dissociation constant (K_d) and in which binding is permitted to reach steady state or equilibrium. The method of separating bound and free ligand should be rapid and efficient. The saturability of the binding is a critical feature that focuses on biologically relevant binding of appropriate affinity.

Biochemical characterization of receptors can be performed by affinity labeling. [24], [125], [126] This represents a variant of a receptor-binding study in which the specifically bound radioligand is covalently bound to the receptor molecule and subsequently purified and has provided many important insights into the nature of the receptor molecules. It also represents the only way to study posttranslational modifications of the receptor. By far the most valuable insight into biochemical characterization of receptors has come from cDNA cloning. Several powerful methods provide primary structural information for many gastrointestinal hormone receptors. With the cDNAs of many receptors already cloned, more receptors can be identified by hybridization screens and polymerase chain reaction by using probes designed to recognize domains conserved within families of receptors. Subtypes of receptors and alternatively spliced products can be identified by screening cDNA libraries with probes based on the full-length receptor cDNA. Improved receptor purification techniques facilitate the determination and use of specific sequence information. Expression cloning strategies are powerful and widely applicable to all classes of receptors.

Post-receptor signaling is an independent topic that is discussed in detail in Chapter 15. Such signaling is complicated and may be interdependent. It will undoubtedly become more complex before we understand enough to simplify. The view of signaling as a direct vectorial series of events is overly simplistic. There are numerous points of branching, feedback regulation, and subcellular translocalization at which kinases, phosphatases, lipid metabolites, and many other molecules affect the sensitivity of other molecules and other pathways. The phosphorylation events alone, which are activated by cell stimulation, number in the hundreds or thousands. Themes and rules will develop with increased understanding. It is now clear that many G protein–coupled receptors also stimulate tyrosine phosphorylation events [127] and can influence cell growth and differentiation, as well as the rapidly regulated events normally attributed to such messengers. The tremendous level of cross talk and cross regulation between signaling pathways provides extraordinary opportunity for cell-specific regulation.

HORMONE-SPECIFIC INSIGHTS

Gastrin-Cholecystokinin Family

The gastrin-CCK family of peptides is composed of the various molecular forms of the mammalian polypeptides gastrin and CCK. All share the same carboxyl-terminal pentapeptide-amide (Fig. 4-12). Evolutionary studies of gastrin and CCK suggest a common precursor peptide, with these hormones diverging late in evolution. [128], [129] and [130] Because the biologic information in both is highly localized to relatively small pharmacophoric domains at their carboxyl terminus, various different-length molecular forms of each share these domains. These forms provide an opportunity for differential regulation, clearance, and activity. Both gastrin and CCK have well-established physiological actions.

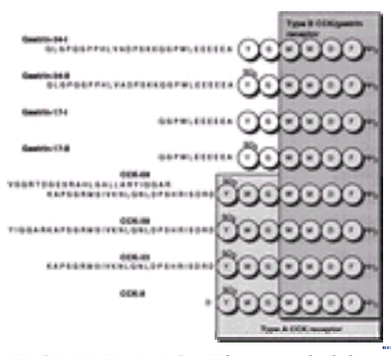

FIGURE 4-12. The variable molecular forms of gastrin and cholecystokinin (*CCK*). All share the same carboxyl-terminal pentapeptide-amide. Shown are the critical domains for recognition by type A CCK receptors and type B CCK/gastrin receptors.

Gastrin The major biologically active forms of gastrin are 17– and 34–amino acid peptides that have a tyrosine residue six residues from the carboxyl terminus, which may (gastrin-17-II, gastrin-34-II) or may not (gastrin-17-I, gastrin-34-I) be sulfated. This posttranslational modification of gastrin appears to have no functional significance, all forms being equally potent and efficacious at traditional gastrin receptors. The critical information in gastrin peptides is in the carboxyl-terminal tetrapeptide-amide, with most extensions and modifications of that domain well tolerated. Gastrin-17 is cleared from the circulation faster (half-life of 7 minutes) than gastrin-34 (half-life of 30 minutes). [78] This results in the situation that most gastrin in the circulation during fasting is gastrin-34, whereas the major form released after

a meal is gastrin-17. The greatest proportion (>95%) of gastrin in the normal circulation is fully processed and contains a carboxyl-terminal phenylalanine-amide. [131] Within some tissues, gastrin can be produced, but not processed, resulting in the presence of nonamidated and carboxyl-extended forms of this peptide. Also, in gastrin-producing neoplasms, processing is often incomplete, resulting in the release of large quantities of nonamidated forms into the peripheral circulation. [131] This has even been proposed as an assay for such neoplasms. [72] The major site of gastrin expression in the adult is open endocrine cells (G cells) in the gastric antrum. Low levels of gastrin are present in the vagus nerve and in pituitary corticotrophs, and transient expression is observed in fetal pancreatic islets and colon. [44], [132] This hormone is found in a number of neoplasms. [133], [134] The highest levels of processed and autonomously secreted gastrin come from islet cell tumors (gastrinomas) in the Zollinger-Ellison syndrome [135] (see Chapter 67). It has also been reported in unprocessed forms in some colon, lung, and ovarian cancers. [133], [134] Excellent radioimmunoassays for gastrin are widely available. Specialized assays for unprocessed forms of this hormone also have been developed. Gastrin secretion from antral G cells is regulated by lumenal, paracrine, endocrine, and neural stimuli. [136] Ingestion of a meal is a strong stimulant of the secretion of this hormone. Small peptides, aromatic amino acids (e.g., phenylalanine and tryptophan), and calcium in a meal are key contributors to its stimulatory effect. Coffee, wine, and beer also have been reported to be stimulants, but the ethanol and caffeine components are not major contributors. Of interest, carbohydrate and fat components of a meal contribute little to the gastrin response. There is an important feedback loop, whereby the major result of gastrin stimulation, acid secretion, results in lowered intragastric pH and reduced G-cell secretion of gastrin (Fig. 4-13). This is mediated by the paracrine effect of somatostatin. The neurocrine mediator GRP stimulates G-cell secretion. Sympathetic innervation and parasympathetic innervation have complex effects. Sham feeding and gastric distention both stimulate gastrin release, and atropine actually enhances this effect.

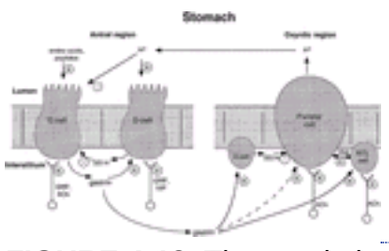

FIGURE 4-13. The regulation of gastric acid secretion by gastrin represents a complex series of interactions and feedback. Some of the key components of this cycle are stimulatory events (+) and inhibitory events (-). Acetylcholine (*ACh*) stimulates the ECL (*enterochromaffin-like*) cell, the parietal cell, and the gastrin-producing G cell. Gastrin-releasing peptide (*GRP*) stimulates both the G cell and the D cell. Gastrin stimulates the D cell, the parietal cell, and also the ECL cell, which then secretes histamine (*Hist*) also to stimulate the parietal cell. Somatostatin (*SS14*) secreted by the D cell inhibits both the G cell and the parietal cell. Acid (H^+) secreted by the parietal cell has regulatory effects as well. *VIP,* vasoactive intestinal polypeptide.

The classic target for gastrin is the gastric parietal cell, which secretes hydrochloric acid. This effect is mediated by a G protein–coupled receptor, which is identical to the most abundant CCK receptor present in the central nervous system (i.e., type B CCK receptor). This receptor is in the rhodopsin/ß-adrenergic receptor family and closely resembles the type A CCK receptor. This is particularly interesting, given the likely shared evolutionary relationship between gastrin and CCK. The receptors also probably evolved from a common precursor, with divergence at some point. It is not yet clear whether the hormones or receptors diverged first, or how the relationship between the molecular basis of binding and activation might compare at these two receptors. Both receptors are coupled with Gq/11. The structural specificity of ligand binding to these two receptors is quite distinct [137], [138] (Table 4-2). The type B CCK/gastrin receptor requires only the carboxyl-terminal tetrapeptide-amide for high-affinity binding and activation. It recognizes all forms of gastrin and CCK almost equally (CCK-8 = gastrin = CCK-8-desulfate = CCK-4). In contrast, the type A CCK receptor has more stringent requirements. At that target, the carboxyl-terminal heptapeptide-amide of CCK is required, with the sulfated tyrosine being critical for high-affinity interaction (CCK-8 >> gastrin = CCK-8-desulfate > CCK-4). Gastrin is recognized poorly, being more than 1000-fold less potent and binding with similarly low affinity.

	APPROXIMATE LIGAND AFFINITIES (nM)	
Ligand	*Type A CCK Receptor*	*Type B CCK/ Gastrin Receptor*
CCK-8	1	2
CCK-8-desulfate	500	10
CCK-4	10,000	10
Gastrin-17	1000	10
L-364,718	1	100
L-365,260	300	2

TABLE 4-2 Specificity of Cholecystokinin (CCK) Receptors

The type B CCK receptor is also expressed on enterochromaffin-like (ECL) cells of the gastric mucosa, on smooth muscle cells at various levels along the gastrointestinal tract, and on diffuse domains of the brain. Experimental antagonists acting at this receptor (L-365,260) have been reported to inhibit gastric acid secretion. [36], [139] However, this result also can be accomplished by a number of other pharmacological routes, such as the use of histamine H_2 receptor antagonists or hydrogen-potassium ATPase inhibitors, which are already in wide clinical use. The most useful application for gastrin receptor antagonists may be for their neuronal effects, which reduce anxiety and panic attacks. [140] As noted, a major physiological effect of gastrin is the stimulation of gastric acid secretion. Of interest, isolated parietal cells respond weakly to gastrin alone. [141], [142] This response is augmented in the presence of histamine or acetylcholine, both of which provide potentiating interactions. Thus, the action of gastrin in vivo to stimulate its receptor on the ECL cell and thereby stimulate histamine release helps provide the optimal background for a brisk acid secretory response. Gastrin also has been shown to stimulate histidine decarboxylase, a key enzyme in histamine synthesis. In addition to its classic acute roles in stimulating acid and histamine secretion, gastrin also appears to function as a growth factor to stimulate mucosal proliferation. [143], [144] and [145] Its role as a growth factor may be unique, with different tissue-specific expression during development and in adult life. During the fetal period, gastrin is expressed in pancreatic islets and in colonic epithelium. Islet expression ends at birth as these cells undergo terminal differentiation. The trophic effect on the gastric oxyntic epithelium has been suggested by the hyperplasia associated with the Zollinger-Ellison syndrome of hypergastrinemia and by the atrophy associated with low levels of gastrin after antrectomy. Chronic high-level gastrin stimulation also has been correlated with enterochromaffin cell hyperplasia. [146] Additionally, in gastrin receptor–deficient mice generated by gene targeting (i.e., receptor knock-out animals), the gastric mucosa was remarkably atrophic, even in the presence of hypergastrinemia. [147] In humans, more than 95% of gastrin peptides normally secreted are fully processed and amidated; the percentage of Gly-extended forms is small. Substantial alterations in gastrin processing have been observed in several pathological states. [148], [149] and [150] These include the increased synthesis that occurs with achlorhydria and with some neoplasms, such as gastrinomas and colonic carcinomas. It has been postulated that Gly-extended gastrins may act as growth factors. [81], [151], [152] and [153] Such forms are several orders of magnitude less potent at stimulating acid secretion, but they may be equipotent or even more potent than processed gastrin in some growth activities. The growth-stimulating actions of Gly-extended gastrin have been reported in the pancreatic tumor cell line AR42J [81], [154] and in Swiss 3T3 cells. [155] Both reports support actions independent of the classic CCK-B receptor. A report of a misspliced form of this receptor as being constitutively active in some colon carcinomas may explain some of these observations. [156] If there is a new and distinct receptor that mediates this activity, it will likely not be structurally related to the type A or type B CCK/gastrin receptors. No reports as of yet demonstrate this action in vivo, and the postulated relationship between gastrin and colon cancer remains unclear.

Cholecystokinin Like gastrin, CCK is found as diverse forms sharing their carboxyl-terminal heptapeptide-amide. Unlike gastrin, which has sulfated and unsulfated forms, all the CCK in the normal circulation is sulfated. This is consistent with the structure-activity relationship described above. Although CCK-8 and possibly CCK-33/39 have previously been thought to be the major forms of this hormone in the circulation, CCK-58 and possibly CCK-83 may be more prominent. [157], [158] It is difficult to measure these very large forms because they are readily cleaved to smaller forms and because little standardized peptide has been available for characterization and validation of assays. A recent report again claims that CCK-33 is the major circulating form. [159] No differential biologic effects of the molecular forms of CCK have been described. Much less is understood about the proteolytic processing of CCK than of gastrin. Although the processing enzymes are likely analogous, the order of cleavages and the mechanisms for tissue-specific processing are not understood. Like gastrin, the various molecular forms are cleared from the circulation at different rates. The small form, CCK-8, has a half-life of only about 1 minute and is cleared almost quantitatively in a single pass through the portal circulation. [3], [160], [161] Larger forms are not cleared by the liver but seem to be metabolized by various capillary beds and by the kidney. CCK is predominantly produced in endocrine I cells scattered throughout the proximal two thirds of the small intestine. [162] It is also found in less abundance in various enteric neurons and in pancreatic islets. [162] CCK-secreting endocrine neoplasms have not been well documented in the literature. The brain contains a large amount of CCK, but the regulation of peptide synthesis and release in the brain is poorly understood. Both protein and fat components of meals stimulate secretion of CCK from I cells; carbohydrates are ineffective. [163] Long-chain triglycerides and fatty acids, both aromatic and aliphatic amino acids (e.g., phenylalanine, tryptophan, valine, and methionine), and small peptides can all stimulate CCK secretion. Measurement of CCK is not as routine as that of gastrin. CCK appears to be present in the circulation in much lower concentrations (basal values < 1 pM CCK versus 100 pM gastrin). Also, because the most common carboxyl-terminal–directed antibodies

can cross-react with both hormones, a selective radioimmunoassay is difficult to establish. A few radioimmunoassays are used in research that incorporate antisera directed against the amino-terminal domain of CCK-8, which are sensitive to the tyrosine-sulfate. [159], [164], [165] The more common assay for CCK uses the ability of the type A CCK receptor to distinguish CCK from gastrin. This is a bioassay in which partially purified peptide is used to stimulate dispersed pancreatic acini to secrete amylase. [166] Feedback regulation also is involved in CCK secretion [167], [168] and [169] (Fig. 4-14). The major targets of this hormone are the rodent pancreatic acinar cells and human pancreatic neurons. When pancreatic exocrine cells are stimulated to release digestive enzymes that make their way into the lumen of the intestine, CCK secretion is reduced. Lumenal administration of a trypsin inhibitor results in increased levels of CCK and increased pancreatic enzyme secretion. Bile acids in the lumen also appear to have a regulatory effect on this feedback phenomenon. [170] Two candidates for representing endogenous CCK-releasing factors have been described. [171], [172] Both have their activities inhibited by trypsin and fulfill the initial expectations of such a mediator, but additional studies will be necessary to define their potential roles in normal physiology.

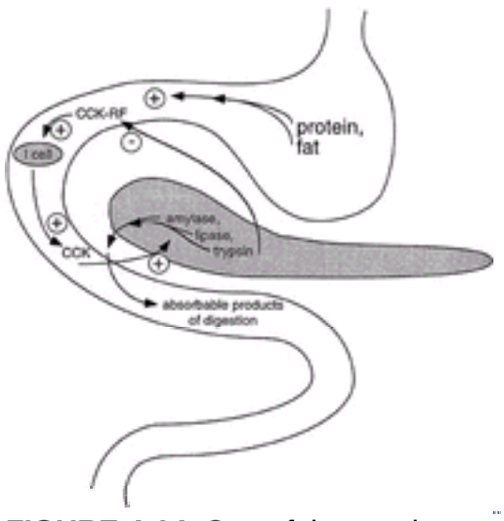

FIGURE 4-14. One of the regulatory cycles for CCK action on the pancreatic acinar cell. Nutrient ingestion results in the release of CCK-releasing factors (*CCK-RF*) into the intestinal lumen. These act on the I cells to secrete CCK, which stimulates pancreatic exocrine secretion. The proteolytic enzymes (particularly trypsin) then degrade the CCK-releasing factors, thereby terminating the cycle.

The type A CCK receptor is structurally similar to the type B CCK/gastrin receptor (50% identical, 66% homologous). [27], [28], [173] It is a member of the rhodopsin/ß-adrenergic receptor family. This receptor has substantial structural specificity, recognizing the carboxyl-terminal heptapeptide-amide of CCK, with a clear requirement for the tyrosine-sulfate, the carboxyl-terminal phenylalanine-amide, the nonoxidized state of the methionine residues, and the residues in almost every position of this peptide. Only the amino terminus is freely available for extension or modification without interference with the binding and biologic activity of CCK. Understanding of the molecular basis of binding the natural agonist peptide to this receptor has improved substantially, with direct evidence of contacts in the extracellular loop and tail domains. [24] Nonpeptidyl antagonists (e.g., L-364,718, lorglumide, PD140548) and even a nonpeptidyl agonist are available for selective action on this receptor. [174], [175] None of these reagents have clinical use. The antagonists induce gallbladder stasis; their use, therefore, is complicated by gallstone formation. The agonist could provide a new mechanism to achieve satiety, but no clinical studies have been reported. CCK is interesting for the diversity of its established physiological and biologic effects. [176] Almost all its actions relate to nutrient homeostasis. Its major digestive effects are to stimulate pancreatic acinar cell secretion of zymogens and to stimulate gallbladder muscularis smooth muscle cell contraction. Both of these events result in the delivery of key ingredients for digestion to the intestinal lumen. It also effects contraction of the pylorus to slow gastric emptying, providing optimal nutrient delivery for digestion. A key neuronal effect of this hormone is to satiate appetite. Less well-established effects include modification of enteric and colonic transit, reduction in acid secretion by its effect as a somatostatin secretagogue, stimulation of secretion of pancreatic polypeptide, and an insulinotropic effect.

Pancreatic Polypeptide Family

The pancreatic polypeptide family includes pancreatic polypeptide (PP), peptide YY (PYY), and neuropeptide Y (NPY). These peptides have extensive homology within their carboxyl-terminal domains, with absolute conservation of an arginine-tyrosine–amide. PYY and NPY have extensive overall homology with each other. These three peptides also have cross recognition of a group of three receptors. Each peptide has a unique distribution and unique functions.

Pancreatic Polypeptide PP was originally identified as a contaminant in preparations of insulin extracted from pancreatic islets. [177] It is a 36–amino acid peptide that is predicted to have a globular shape, resulting from interactions between a polyproline helix and an a helix. [178], [179] Its biologic activity resides in its carboxyl-terminal hexapeptide-amide, with the carboxyl-terminal tyrosine-amide being the critical residue for this activity. It has a short half-life in the circulation (about 7 minutes), with renal clearance apparently most important. PP cells are found in the periphery of pancreatic islets and scattered within the parenchyma of the pancreatic head and uncinate lobe, in contrast to the distribution of glucagon in the pancreatic body and tail. There is a clear PP response to the ingestion of a meal. The response is biphasic; the early increase is neurally mediated and inclusive of cephalic and vagal phases. In many ways, secretion of PP correlates with vagal tone. The nutrients that stimulate gastrin and CCK secretion also stimulate PP secretion. Secretion of this hormone also appears to be stimulated by CCK, gastrin, GRP, neuromedins B and C, and secretin. Although several biologic effects of PP have been proposed, debates continue. [180] This hormone has been thought to inhibit pancreatic exocrine secretion, but antibody neutralization studies have failed to show any effect on pancreatic secretion. A metabolic role as an inhibitor of hepatic glucose production has also been proposed. A series of receptor subtypes that recognize this family of peptides have been confirmed, with the revised nomenclature including the PP1 receptor and NPY receptor subtypes Y1 through Y6. [181], [182] All are structurally related members of the rhodopsin/ß-adrenergic receptor family of the G protein–coupled superfamily of receptors. The PP1 receptor recognizes pancreatic polypeptide better than either of the other family members (PP >> NPY = PYY). Both the Y1 and Y2 receptors recognize PYY and NPY similarly, and much better than PP (PYY = NPY >> PP). There are selective agonists that distinguish between these receptors, with (Leu ^{31}, Pro ^{34})PYY and (Leu ^{31}, Pro ^{34})NPY selective for the Y1 receptor, and carboxyl-terminal fragments (PYY-3-36 and PYY-13-36, NPY-13-36) selective for the Y2 receptor. [183] Much less has been established for the Y4, Y5, and Y6 receptor subtypes. Perhaps the best current use of PP is as a marker for islet cell tumors. Plasma levels have been elevated in a high percentage of islet cell carcinomas and multiple endocrine neoplasia. The percentage of positive values varies with the type of endocrine tumor; VIP-secreting tumors have very high levels, and gastrin-secreting tumors have substantially lower levels.
PYY PYY is also a 36–amino acid peptide. It is found in highest concentrations in enteroendocrine cells in the distal small intestine and colon, [184], [185], [186] and [187] mainly in the basal crypts of L cells. [188], [189] It can act through endocrine mechanisms after release into the bloodstream, or through paracrine mechanisms with specialized basal processes surrounding columnar cells in the vicinity of the endocrine cells. It is released in response to meals. Fat is the major stimulant, but other nutrients (e.g., carbohydrate) and bile acids also stimulate secretion. Neuronal release mechanisms also have been postulated, and in some malabsorptive states, high circulating levels have been observed. GRP also can stimulate its release. Like PP, PYY has a short half-life in the circulation. The actions of PYY are largely inhibitory. [190], [191] It inhibits gastrointestinal motility, pancreatic and gastric secretion, and chloride secretion. It has been given the name *ileal brake* because it helps to establish longer contact times when nutrients reach the distal gut and colon. PYY has also been shown to have trophic effects, but the physiological significance of this action is not yet clear.
NPY NPY is also a 36–amino acid peptide that is structurally homologous with PYY. [192], [193], [194] and [195] It appears to be the neurotransmitter equivalent of PYY, found in the central and peripheral nervous systems. It is one of the most abundant peptides in the brain, along with CCK. [196] It is found in enteric neurons, alone or co-localized with other neuropeptides. [197], [198] and [199] It is especially prominent in sympathetic neurons that innervate blood vessels. Postulated effects of NPY include the stimulation of appetite, alteration of circadian rhythms, and vasoconstriction. [200], [201], [202] and [203] It has many of the same effects as PYY because they both recognize the same receptors, but its physiological role relates mainly to its anatomic distribution.

Tachykinin Family

The tachykinins are a group of biologically active peptides sharing the carboxyl-terminal dipeptide-amide Leu-Met-NH_2. Included in this group are substance P, GRP, the neuromedins, and many mollusk and amphibian peptides (bombesin, physalaemin, eledoisin, kassinin, and phyllomedusin). In this group of transmitters, as in the two groups discussed above, the pharmacophoric domain is predominantly within the carboxyl terminus and well circumscribed. Consistent with this feature, the receptors for this family also are in the rhodopsin/ß-adrenergic receptor family of the G protein–coupled superfamily of receptors.

Substance P (Neurokinin A) Substance P is an 11–amino acid peptide-amide that is widely distributed in the brain, spinal cord, and peripheral and enteric nervous

systems. [204] Its highest concentrations along the digestive tract are in neurons of the esophagus, proximal small intestine, and colon. Substance P stimulates esophageal and intestinal peristalsis and pancreatic secretion, and it inhibits biliary secretion and somatostatin secretion. It likely plays a sensory role along the digestive tract, participating in the afferent limb of various reflexes and possibly mediating pain impulses. In the central nervous system, it probably acts as a neuromodulator.

Gastrin-Releasing Peptide GRP was originally isolated during a search for an analog to the amphibian peptide bombesin. [205], [206] and [207] Like bombesin, GRP stimulates gastrin secretion. It is present in neurons of the stomach, intestine, and colon, as well as in the brain and spinal cord. It also stimulates the release of CCK, motilin, neurotensin, enteroglucagon, insulin, somatostatin, and substance P, and it can stimulate pancreatic acinar cell secretion and gut motility. The release of secretin from S cells is not stimulated by GRP. It also may play a role as an excitatory neurotransmitter, acting on enteric interneurons. Like several of the peptides discussed, GRP appears to have trophic activity. Receptors for this peptide have been described on small cell carcinomas of the lung, where a trophic response may have clinical significance. [208], [209] Several of the neuromedins were isolated during a search for mammalian homologs of the amphibian peptides. Neuromedin C shares its carboxyl-terminal decapeptide-amide with GRP. Neuromedin B is related to ranatensin. Four receptor subtypes are now recognized for this class of ligands. [210] They are currently termed *BB1, BB2, BB3,* and *BB4*. The BB1 receptor recognizes neuromedin B with highest affinity (neuromedin B = bombesin > GRP). The BB2 receptor recognizes GRP best (GRP = bombesin >> neuromedin B). The BB3 receptor has a high degree of homology with the other two but binds both GRP and neuromedin B with low affinities. Its natural ligand has not yet been identified. Its presence has been reported in reproductive organs and lung carcinoma; it may not have a relationship to the gastrointestinal tract. The BB4 receptor was isolated from frog brain and has a unique pharmacological profile—it is highly dependent on the penultimate phenylalanine residue for agonist activity, and it has a unique capability for antagonist recognition. [211]

Somatostatin Family

The two molecular forms of somatostatin are 28 and 14 amino acids in length, with somatostatin-14 representing the carboxyl-terminal domain of somatostatin-28. Both forms of somatostatin contain a critical disulfide bond giving them a cyclic structure [212], [213] and [214] (Fig. 4-15). The amino acid residues 7 through 10 within the short cyclic structure of somatostatin-14 are also critical for activity. Although this hormone was originally identified for its ability to inhibit growth hormone, it is now recognized as having much broader significance.

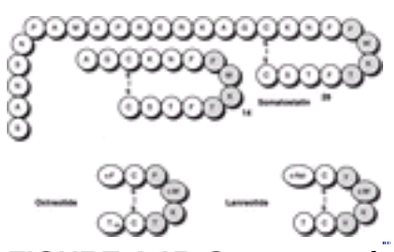

FIGURE 4-15. Structures of somato-statin-14 and somatostatin-28, as well as two prominent synthetic agonist analogs, octreotide and lanreotide, that incorporate unnatural amino acids and terminal blocking groups, prolonging biologic action.

Somatostatin is synthesized and secreted from both neurons and enteroendocrine cells, with the latter (D cells) present as either open or closed. [215], [216] In the stomach, there are highly specialized D cells with characteristic long processes that extend to G cells, parietal cells, and chief cells. [217] These configurations make somatostatin one of the most flexible regulators of the gastrointestinal tract. Its multiple roles as hormone, paracrine transmitter, neurotransmitter, and neuromodulator reflect this flexibility. Along the digestive tract, 90% of somatostatin is present in the mucosa and 10% in the neuromuscular layers. In the stomach, pancreas, and neuromuscular layers of the intestine, somatostatin-14 is the predominant form, whereas both somatostatin-14 and somatostatin-28 are found in the mucosa of the bowel. Somatostatin-14 has a very short half-life of 1 to 3 minutes, whereas somatostatin-28 has a half-life of about 15 minutes. The degradation sites of this hormone are not well defined, but they likely involve capillary beds.

Most of the biologic effects of somatostatin are inhibitory. It inhibits gastric, pancreatic, biliary, and even salivary secretion, in addition to inhibiting the release of a broad variety of gastrointestinal hormones. These include gastrin, CCK, secretin, pancreatic polypeptide, GIP, motilin, glucagon, and insulin. It also inhibits gut motility, but this effect results from the peptide's ability to inhibit cholinergic neurons. Somatostatin decreases splanchnic and portal blood flow.

Somatostatin receptors are in the rhodopsin/ß-adrenergic receptor family of the G protein–coupled superfamily of receptors. There are five recognized receptor subtypes: SSTR1, SSTR2, SSTR3, SSTR4, and SSTR5. [218], [219] and [220] These receptors are structurally homologous, but each couples to distinct G proteins and has a distinct tissue distribution. They are most closely related to the opioid receptors, with which they share about 40% homology. Based on structural similarity, there are two groups of somatostatin receptors: SSTR1 is related to SSTR4, and SSTR2, SSTR3, and SSTR5 are related to each other. SSTR5 is unique among the somatostatin receptors because it has a higher affinity for somatostatin-28 than for somatostatin-14. SSTR1 is found in the stomach and intestine. These receptors most prominently couple to adenylate cyclase; some receptors also activate potassium channels and voltage- and potassium-dependent calcium channels. The somatostatin receptor also may activate a protein tyrosine phosphatase, although the precise molecular mechanism for this is unclear.

An analog of somatostatin that is a long-acting cyclic agonist peptide has become a highly useful clinical reagent. It represents an 8–amino acid cyclic peptide with unnatural residues that make it resistant to proteolysis. It has been used in the treatment of gastrointestinal hormone-secreting tumors, diarrheal disorders, and carcinoid syndrome. [221], [222], [223], [224] and [225]

Motilin Family

Motilin is a 22–amino acid linear peptide that was originally recognized as being secreted into the circulation in a cyclic manner that correlated with increased motor activity along the bowel. It has become one of the most important endogenous prokinetic peptides, and its receptor is recognized as a useful pharmacological target, activated by erythromycin. [226] Despite extensive insight into the structure-activity relationships for the motilin receptor, [227] it has been difficult to isolate and characterize biochemically. This may reflect the substantial interspecific differences in motilin peptides. The most highly conserved sequence resides in the amino-terminal portion of the peptide, and the pharmacophoric domain has been localized to the amino-terminal decapeptide region. [228]

Finally in 1999, with the use of a unique high-throughput screen of compounds that could interact with cloned orphan receptors, the cDNA for the motilin receptor was identified. [111] Sequence analysis showed that it was a member of the rhodopsin/ß-adrenergic receptor family of the G protein–coupled superfamily of receptors, having closest homology to a group of growth hormone secretagogue receptors. One extremely interesting aspect of studying the growth hormone secretagogue receptor was the discovery of ghrelin, an endogenous agonist ligand representing a 28–amino acid peptide that has a high degree of homology with motilin, and that has a unique posttranslational modification of N-octanoylation of the Ser residue in position 3 [229] (Fig. 4-16).

FIGURE 4-16. Alignment of sequences of motilin and ghrelin, members of the motilin family. Ghrelin has a unique posttranslational modification of the serine residue in position 3, representing N-octanoylation.

To date, only a single motilin receptor cDNA has been identified, even though there is pharmacological evidence for more than one pattern of responses to this

hormone. [230] Examination of the molecular basis of these varied responses will likely become an area of active exploration.

Protease-Activated Receptor Family

Proteases, such as trypsin, have traditionally not been thought of as signaling molecules. There is evidence, however, of distinct G protein–coupled receptors in the rhodopsin/ß-adrenergic receptor family of G protein–coupled receptors that are activated by proteolytic cleavage of an amino-terminal peptide sequence. [231] This makes an endogenous peptide ligand at the new amino-terminal end of the receptor accessible for binding to the remainder of the receptor, thus providing a novel molecular mechanism of action. To date, two such receptors have been identified—the thrombin receptor (or protease-activated receptor 1) [232] and the protease-activated receptor 2. [233] A receptor activation mechanism that requires proteolytic cleavage has substantial implications for receptor regulation, particularly for ensuring the inability for resensitization. [234], [235]

These receptors are believed to play roles in the linkage of tissue injury and vascular leakage to cellular responses, such as occurs in hemostasis, inflammation, and angiogenesis. [236] Roles have been postulated for these receptors in the intestine and pancreas as well.

Chemokine Family

The chemokines constitute an extremely large family of ligands and receptors, with biologic activities best described for leukocytes. Although not specific to the gastrointestinal tract, this system has great relevance to it. More than 40 distinct human chemokines have been described and assigned extremely varied original names based on the tissue or cell of origin, the target cell type, the size of the molecule, or the action. A more coherent nomenclature that correlates with the organization of the receptors for these ligands was proposed in 1999. [237] This system classifies chemokines by their structure, based on the number and the spacing of conserved cysteine residues, into four groups: C, CC, CXC, and CX $_3$C. The CC, CXC, and CX $_3$C cytokines have four conserved cysteine residues, with the first two such residues being adjacent to one another, or having one or three other residues between them, respectively. The C cytokines have only two conserved cysteine residues, representing the second and fourth cysteine residues that are present in the other groups of chemokines.

The chemokine receptors are in the G protein–coupled receptor superfamily. They typically recognize more than one chemokine, but these are usually members of a single chemokine family. The receptor nomenclature is based on the ligand specificity, starting with CC or CXC, and followed by R and a number. Of this group, 18 chemokine receptors have been cloned, and these express 25% to 80% sequence identity among themselves.

Another interesting feature of the chemokines and their receptors is the substantial diversity of structure across species, with up to 55% sequence divergence reported. The pressure for the rapidity in evolution of these structures has not been established. Also of note are the nonchemokine ligands for these receptors, which include HIV, in which the chemokine receptor seems to play an important role as a coreceptor for the virus, permitting its entry into the target cell. On tumor cells, these receptors may determine metastatic pattern.

Secretin Family

The secretin family of hormones is characterized by homology that is most evident in the amino-terminal half of moderately large polypeptides (Fig. 4-17). Members of this family with known hormone and receptor sequences include secretin, [25], [238] VIP, [239] pituitary adenylate cyclase–activating peptide (PACAP), GIP, [240] glucagon, glucagon-like peptide-1 (GLP-1), calcitonin, calcitonin gene–related peptide (CGRP), parathyroid hormone, [241] corticotropin-releasing factor (CRF), and growth hormone–releasing factor (GHRF). [242] Some of these are not relevant to the gastrointestinal tract and are not further discussed. It must be recognized, however, that insights from any members of this family may provide important clues relevant to the entire family. Based on the structural homology of hormones, it is expected that the PHI receptor also belongs to this family, although a distinct receptor for this peptide has not yet been cloned.

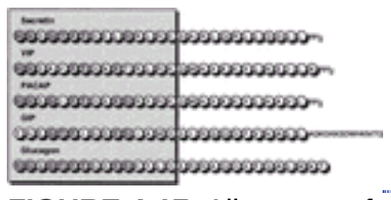

FIGURE 4-17. Alignment of sequences of members of the secretin family. The amino-terminal domain is most critical for agonist action, whereas the pharmacophore extends throughout the entire peptide sequence.

The pharmacophoric domains of these hormones are rather diffuse and spread throughout their primary sequences, usually requiring peptide analogs to span essentially the entire length of the natural hormones for maintenance of biologic activity. In some of these hormones, the amino-terminal residue and a free amino terminus are particularly important. This observation implies the interesting notion that amino-terminally extended precursor molecular forms may not be biologically active. In fact, few of the hormones in the secretin family have more than one molecular form, as is so common for peptide hormones belonging to the rhodopsin/ß-adrenergic receptor family. Some truncated forms of the secretin family hormones have been synthesized and found to continue to bind with high affinity, but these possess markedly reduced biologic activity. Another interesting feature of this family is that its members stimulate dual signaling cascades; low concentrations typically stimulate adenylate cyclase, and higher concentrations stimulate intracellular calcium responses. [243] This also may occur in the rhodopsin/ß-adrenergic receptor family, but it is less common.

Secretin Secretin holds a special place in gastrointestinal endocrinology and in endocrinology generally. Its discovery in 1902 by Bayliss and Starling [13] established the concept of hormones as chemical messengers that travel through the bloodstream to control the function of a target organ. As such, the discovery of secretin gave birth to the whole field of endocrinology. It was therefore the first gastrointestinal hormone, although not the first one to be characterized chemically. Secretin clearly has important physiological functions. Because of its relatively large size and the chemical difficulties encountered in working with this peptide and with its receptor, a detailed molecular understanding of this hormone has been delayed substantially. The recent cloning of cDNAs for members of this receptor family has charged this field with new life and excitement, and it promises to be a fertile area for investigation in the years ahead. Secretin is a 27–amino acid linear peptide with important residues scattered throughout the length of the hormone. [244] It is synthesized in endocrine cells (S cells) that are most abundant in the duodenum and proximal jejunum and present in reduced numbers throughout the distal small intestine. [245] The major stimulus for secretin secretion is unbuffered hydrogen ions as they traverse the duodenum. This stimulus becomes apparent when the duodenal pH decreases to 4 or lower. Secretin secretion also can be stimulated by nutritional acids, such as fatty acids, and by ethanol and components of spicy foods (e.g., 1-phenylpentanol). Bile acids appear to enhance stimulated secretin release. Of interest, the S cell is one of the few enteroendocrine cells that is not responsive to GRP. However, the existence of a secretin-releasing peptide has been postulated. [246] Like most of the peptide hormones, secretin has a short half-life of less than 3 minutes in the circulation. [247] The kidneys appears to be the major site of clearance. The major effect of secretin is the secretion of bicarbonate from biliary and pancreatic ductular epithelium and Brunner glands. [248], [249] and [250] This nicely completes the regulatory cycle, with the acid stimulant of secretin release neutralized by the bicarbonate secreted in response to this hormone. It has been estimated that secretin is responsible for 80% of the bicarbonate response to a meal. In nonhuman species, secretin also has been shown to inhibit gastric secretion and gastric motility, to lower esophageal sphincter tone, and to stimulate insulin release and colonic mucus secretion, but these are likely not physiological actions in humans. [251], [252] Consistent with these observations, the most prominent targets for secretin include ductular epithelial cells in the biliary tree and pancreas, and Brunner gland cells. [248], [249] and [250], [253] Receptors are also believed to be expressed on pancreatic acinar cells of some species, vascular smooth muscle in selected organs, some enteric smooth muscle (particularly in the region of the lower esophageal sphincter), and some enteric mucosal cells. [250], [254], [255], [256] and [257] These targets were initially characterized as having a potent biologic response to secretin, and a lesser response to VIP. Such studies are difficult to interpret because of the cross recognition of many peptides in the family by receptors in the family. Now that the structure of receptors is better understood, the expression of receptors on distinct cells has become easier to identify. The secretin receptor cDNA was initially cloned in 1991 by Ishihara and colleagues. [238] Its structure appeared to have the seven hydrophobic helical transmembrane domains typical of the G protein–coupled receptor superfamily, but other features of the receptor were unique. In fact, the level of homology with previously cloned receptors in the rhodopsin/ß-adrenergic family was only 12%. Subsequent cloning of cDNAs encoding receptors for calcitonin and

parathyroid hormone, [241], [258] which are more similar to secretin receptors, defined a new class of G protein–coupled receptors. The most highly conserved areas are in the transmembrane domains, and a particularly long amino-terminal tail contains six highly conserved cysteine residues that are highly sensitive to reducing and cysteine-reactive reagents. [259] Although the pattern of the disulfide bonds has not been experimentally defined, research supports the existence of three such bonds among these six residues. [260] Another such bond that is likely to be present is the connection between cysteine residues in the first and second extracellular loops, in positions that are conserved throughout the entire superfamily of G protein–coupled receptors. This bond has been characterized for other receptors in the rhodopsin/ß-adrenergic family. [261] Various studies including mutagenesis and photoaffinity labeling have demonstrated the importance of the amino-terminal tail and extracellular loop domains of this receptor for secretin binding and activation. [30], [31], [262], [263] This finding is consistent with the general theme for this superfamily, in which increasingly larger ligands bind to domains moving from the confluence of intramembranous helices to the cellular surface, and ultimately to the extracellular loop and tail domains. Despite having new signature sequences unique to the secretin receptor family, the secretin receptor seems to signal and to be regulated much like the receptors in the rhodopsin/ß-adrenergic family. [264] The secretin receptor is coupled to both Gs and Gq/11. The most potent response to hormonal stimulation is an increase in adenylate cyclase, and less potent is the stimulation of intracellular calcium. [243] The secretin receptor is phosphorylated in response to agonist stimulation, [264] and this phosphorylation interferes with G-protein coupling. Like most G protein–coupled receptors, this receptor is internalized after agonist occupation. [264] The details of the molecular basis of these events are being explored.

VIP VIP is a 28–amino acid linear peptide with close structural homology to secretin. [265] Conformational studies have supported similar structures as well. [266], [267] Unlike the hormone secretin, VIP is exclusively a neurotransmitter. In addition to being present in enteric neurons, VIP is also present in neurons of the brain, spinal cord, lung, urogenital system, and other endocrine organs. VIP has a very short half-life of less than 1 minute in the circulation. Plasma levels accordingly are quite low and unresponsive to the ingestion of a meal. High plasma levels have been reported in the setting of watery diarrhea-hypokalemia-achlorhydria syndrome associated with a VIP-producing endocrine tumor (VIPoma). [268] The VIPoma syndrome provides insight into potential targets and actions of VIP. The normal physiological role of VIP is difficult to determine because of the local actions and absence of reagents with which to dissect its role from those of other related transmitters. Among the potential actions are stimulation of enteric smooth muscle, stimulation of pancreatic exocrine and intestinal secretion, inhibition of gastric acid secretion, and modification of immune function and gastrointestinal blood flow. [269], [270], [271], [272], [273], [274], [275], [276], [277], [278] and [279] The list of tissues and cells containing VIP receptors includes pancreatic acini, pancreatic and biliary ductular epithelial cells, gastric and intestinal epithelial cells, vascular smooth muscle cells, lymphocytes, and a number of epithelial tumors. Direct effects on enteric smooth muscle cells and modulatory effects on interneurons have been demonstrated. VIP is a key candidate for mediating descending relaxation of the peristaltic reflex and relaxation at the lower esophageal sphincter, the internal anal sphincter, and the tenia coli. [280], [281], [282] and [283] Two VIP receptors have been cloned: VIP_1 (or $VPAC_1$) and VIP_2 (or $VPAC_2$) receptors. [239], [284], [285] Both are typical members of the secretin family of G protein–coupled receptors. VIP is also well recognized by the PACAP (or PAC_1) receptor. [113], [286] Both the VIP_1 and VIP_2 receptors have similar structural specificities for VIP, PACAP, and PHI (VIP = PACAP > PHI). Secretin is recognized weakly by the VIP_1 receptor, and not at all by the VIP_2 receptor. The selectivity of the PACAP receptor is quite distinct (PACAP > VIP > PHI). Another interesting feature of the PACAP receptor is prominent alternative splicing, yielding variants that differ in both ligand recognition and intracellular signal transduction pathways. The specific tissue and cellular distribution of these receptors is being characterized. Studies with chimeric constructs incorporating domains of the VIP and secretin receptors have also supported the importance of the amino-terminal domain of these receptors in their selectivity for binding and initiation of active conformations. [30], [31], [287], [288] Such observations indicate the need to understand more about the conformation of the ectodomain of these receptors in an effort to contribute to the rational design of drugs that might act on this important family of receptors.

PACAP PACAP is a 27–amino acid linear peptide that was initially isolated from ovine brain. [289] Unusual for this family of hormones, there is also a second molecular form, PACAP-38, [290] which consists of PACAP with a carboxyl-terminal extension of 11 amino acids. Like many other brain peptides, PACAP is also present in the gastrointestinal tract, [291], [292] in nerve fibers, and in myenteric and submucous ganglia. [292], [293] PACAP-38 is predominant in nonenteric locations (e.g., brain, lung, and testes), whereas PACAP-27 is predominant in the intestine. [294], [295] Like VIP, PACAP is present in the circulation in very low levels, which are unresponsive to the ingestion of a meal. Because of the high degree of homology between PACAP and VIP and the relationship of their receptors, interest has been focused on this neurotransmitter, even though it does not yet have proven physiological functions. Candidate functions include relaxation effects on colonic smooth muscle, stimulation of pancreatic exocrine secretion, and vasodilation. [296], [297] and [298]

GIP GIP was originally called *gastric inhibitory peptide,* until it became clear that inhibition of acid secretion is not a physiological action of this hormone. Instead, its most prominent effect is to stimulate insulin production in a glucose-dependent manner, hence the name *glucose-dependent insulinotropic peptide*. A 42–amino acid linear peptide homologous to secretin and glucagons, [299], [300] GIP is produced in K cells in the proximal intestinal crypts. [301], [302] This peptide hormone is secreted predominantly in response to the ingestion of a meal, with fat the major nutrient stimulant. Both the secretion of GIP and the response of target organs to GIP are affected by cholinergic tone. GIP has a half-life of 18 minutes, which is longer than that of most gastrointestinal peptides. The GIP receptor, like the peptide, is homologous to other members of the secretin receptor family. [240] This is also true for the description of its coupling, signaling, and regulatory events. [303], [304] The main established biologic function for GIP is its role as a stimulant of insulin secretion (incretin). [303] Incretins provided the explanation for the greater insulin responses to nutrients administered orally as opposed to parenterally. [305] There have been many candidates to mediate this action, but GIP and GLP-1 are considered important. For GIP to exert this effect on the cell of the pancreatic islet, the serum glucose level must be above 110 mg/dL, thus providing protection against hypoglycemia. Other metabolic effects of GIP have been described, such as inhibition of hepatic glucose output, inhibition of fat absorption, and inhibition of lipoprotein lipase. The physiological role of GIP in mediating these effects is not clear.

Tyrosine Kinase Receptor Family

The receptors in this family are quite distinct from the G protein–coupled receptors. All are single-transmembrane receptors and all have prominent effects on cell growth (Fig. 4-18). Some also affect cell survival, differentiation, and movement. Many G protein–coupled receptors also appear to mediate effects on cell growth, but they do so through a distinct mechanism. Perturbations of several tyrosine kinase receptors have been associated with tumorigenesis. Activation of G protein–coupled receptors can also stimulate tyrosine phosphorylation events; however, most of the substrates are distinct from those phosphorylated in response to activation of the tyrosine kinase receptor family. [127]

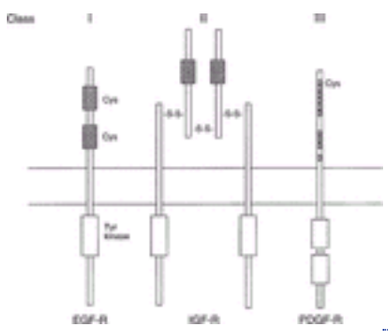

FIGURE 4-18. The three classes of tyrosine kinase receptor molecules. All possess cysteine-rich regions in the ectodomain and tyrosine kinase catalytic domains in the cytoplasm. The classes are dependent on the continuity and spacing of these regions, as well as the subunit structure necessary to achieve a functional unit for the class 2 receptors.

Epithelial Growth Factors Epithelial growth factor (EGF) is a 53–amino acid single-chain polypeptide that contains three intramolecular disulfide bonds. Additional ligands in this family include transforming growth factor-a, amphiregulin, betacellulin, heparin-binding EGF, and the neuregulins. All share the sequence motif CX_7 $CX_{2–3}$ $GXCX_{10–13}$ $CXCX_5$ GXRC. All are produced as single-transmembrane proteins with an amino-terminal proregion, a mature growth factor region ranging in length from 50 to 87 residues, and a relatively short cytosolic domain. Members of the EGF family are active both while anchored to the membrane and after proteolytic processing to release the mature growth factor domain. [92] There are four members of the EGF receptor subfamily, including the EGF receptor encoded by *erb*-b and proteins encoded by *erb*-b2, *erb*-b3, and *erb*-b4. All are single-transmembrane glycoproteins that incorporate two distinct cysteine-rich regions in the ectodomain and a tyrosine kinase catalytic domain and typical sites of potential phosphorylation in cytoplasmic regions. Receptor dimerization or oligomerization is a typical initial step in signaling that is induced by agonist binding. This is followed by cross phosphorylation on tyrosine residues of the receptor and the recruitment of kinase substrates and other signaling proteins. Many of these substrates have Src-homology-2 (SH2) domains. A large number of potential signaling cascades have been described, including the Ras, Raf, and MAP kinase pathways and the JAK/STAT pathways. [306], [307] EGF signaling also includes activation of phosphatidylinositol pathways, with activation of protein kinase C isozymes and increases in intracellular Ca^{2+}. Many gastrointestinal functions can be affected by this family of hormones

and receptors. Included among the most prominent effects are inhibition of gastric acid secretion, protection against injury, and stimulation of intestinal cell growth. There are also putative growth-stimulating and inhibitory effects on a number of gastrointestinal tumors. This provides many interesting possibilities for therapeutic uses of agonists and antagonists acting at these receptors. [308]

Fibroblast Growth Factors Fibroblast growth factors (FGFs) are a group of polypeptides with angiogenic and mitogenic activities that are active in tissue repair and in modulating tissue differentiation. FGFs induce chemotactic activities in fibroblasts and endothelial cells. [94] Nine members of the FGF family have been identified, each with a conserved core sequence of approximately 120 residues and with high affinity for heparin and glycosaminoglycans. FGF1, also known as *acidic fibroblast growth factor,* and FGF2, also known as *basic fibroblast growth factor,* are not efficiently secreted, whereas all other forms possess signal peptides and are secreted. FGF7 is also known as *keratinocyte growth factor (KGF)*. Receptors for the FGFs are monomeric, and like other growth factor receptors, they possess a tyrosine kinase domain. Unlike that of most such receptors, the tyrosine kinase domain of these receptors is discontinuous, with a 14-residue interruption. Also, the FGF receptors have two or three immunoglobulin-like domains within an extracellular domain. At least four distinct genes encode FGFR-1 through FGFR-4. FGFR-1 and FGFR-2 also have multiple alternatively spliced forms. All four types of FGFR can be activated by either the acidic or basic forms of FGF (FGF1 or FGF2). FGF7 (KGF) binds only to the KGFR, which is a distinct splice variant of the FGFR-2. Heparin sulfate proteoglycans on the cell surface also can bind these growth factors, but with low affinity. It has been postulated that this is a site for the collection of the ligand in preparation for binding to its high-affinity receptor. Autophosphorylation of the FGF receptors occurs and is a mechanism for regulation. Tyrosine phosphorylation occurs in response to FGF binding, thereby opening and exposing the kinase domain. Phospholipase C-? can associate with the tyrosine-phosphorylated receptor. Activation also stimulates Shc association with a kinase domain of the receptor, which leads to activation of Grb2/SOS. This in turn leads to the typical series of events activated by other growth factors, such as activation of Raf-1, MAP kinase kinase, and MAP kinase. FGF receptors can form homodimers or heterodimers. The composition of the dimer can determine the details of the signaling initiated. Signaling cascades appear to be quite similar to those described for the EGF receptors. Biologic actions for this group of hormones include prominent effects on angiogenesis, through effects on endothelial cells. Also described are effects on fibroblasts, smooth muscle cells, and various neuronal cells. Like other growth factors, FGFs also have been implicated in tumorigenesis.

Insulin-like Growth Factors Insulin-like growth factors (IGF-1 and IGF-2) are single-chain polypeptides homologous to proinsulin. [93] These hormones were first recognized by the demonstration that the addition of insulin antiserum to neutralize insulin activity failed to inhibit all activities attributed to that hormone. The IGFs are structurally related to insulin, but they bind poorly to traditional insulin receptors. Like insulin, the IGFs have both A and B domains. Unlike insulin, they lack the C domain, which is cleaved in the processing of insulin to achieve its mature two-chain form. IGFs remain a single chain, although they fold to achieve a conformation similar to that of insulin. Like the insulin receptor, the type 1 IGF receptor consists of a heterotetrameric structure with two a subunits and two ß subunits, both of which come from a single gene product. Disulfide bonds link the complex, with the a subunits residing entirely outside the cell and possessing the binding determinants, and the ß subunits spanning the plasma membrane and containing the tyrosine kinase domain intracellularly. As in the insulin receptor, signaling involves tyrosine autophosphorylation, as well as association and phosphorylation of other substrates. In addition to the receptor, there are soluble circulating and interstitial IGF-binding proteins (IGFBPs 1–6). They may affect the volumes of distribution and half-lives of IGF and thereby modify its biologic activities. IGFs affect the growth and differentiation of a variety of tissues.

Toll Receptor Family

All multicellular organisms have innate immunity as a form of host defense against microbes. Infection or infestation leads to early defenses at the levels of phagocytic leukocytes, endothelial cells, and mucosal epithelial cells, with responses mediated by receptors that recognize pathogen-associated molecular patterns, such as the lipopolysaccharide in bacterial cell walls. Activation of such receptors leads to biologic responses that are designed to clear the offending stimulus and to protect the organism. The toll-like receptors are a particularly interesting group of this type of receptor that can recognize and distinguish between various classes of pathogens. [309] They are located on monocytes, macrophages, neutrophils, dendritic cells, intestinal epithelial cells, and endothelial cells. A major signaling target of these receptors is the activation of NF-?B transcription factors, which can affect the expression of various cytokines, adhesion molecules, acute phase proteins, and inducible enzymes.

The toll receptors represent a family of single-transmembrane molecules having multiple copies of leucine-rich repeats in their unique extracellular domain and a cytoplasmic toll/1R (TIR) motif that is related to that found in the interleukin-1 (IL-1) receptor. Because of the latter motif, these receptors signal like the IL-1 receptor. They are thought to dimerize and bind to adapter proteins that initiate signaling. These receptors may represent interesting and possibly productive targets for the treatment of inflammatory and immune-mediated diseases.

HORMONES IN GASTROINTESTINAL DISEASE

As critical as gastrointestinal hormones and their receptors are for the integration and regulation of digestive function in health, their major interest for the clinician is in regard to hormone-secreting tumor syndromes. These syndromes can be dramatic expressions of unregulated overactivity of a particular one of these hormones, without the advantage of the normally active mechanisms for feedback inhibition. Such tumors are typically of the islet cell type, arising in the pancreas, although the duodenum is another common location for gastrinomas. The two most common and dramatic presentations of such tumors, exclusive of the insulinomas and glucagonomas typically seen by the endocrinologist, are gastrin-secreting and VIP-secreting islet cell tumors. [135], [268] Gastrin is produced in the fetal pancreas, but normally it is not produced at all in the adult pancreas. [44] VIP is a normal pancreatic neurotransmitter that is present in very low concentrations under normal circumstances. The syndromes of gastrin overproduction in Zollinger-Ellison syndrome (gastrinoma) and VIP overproduction in the Verner-Morrison syndrome or watery diarrhea-hypokalemia-achlorhydria syndrome (VIPoma) are discussed in detail elsewhere in this book (see Chapter 67 and Chapter 97). Knowledge of the biologic actions of these peptides based on the previous discussion should provide good insight into these clinical syndromes.

The clinical contributions of the gastrointestinal endocrine system to other gastrointestinal diseases is less clear because of the redundancy of the control mechanisms, with more than one hormone and neurotransmitter serving similar functions. Common disturbances of gastrointestinal function, such as irritable bowel syndrome, peptic ulcer disease, gallstone disease, dysmotility states, and even pancreatitis, may be influenced by a diverse menu of hormones and neurotransmitters. Only when the choice of selective pharmacological agonists and antagonists is similarly broad will the roles of these agents be deconvoluted. The reduced clearance of several of these hormones from the circulation in renal insufficiency can be associated with a broad spectrum of results because of the antagonistic effects of elevated peptides. [88], [310] Because nutrient absorption is needed to stimulate the secretion of many gastrointestinal hormones, circulating levels can be influenced markedly by syndromes of maldigestion, such as occurs in pancreatic insufficiency or celiac disease.

Some gastrointestinal peptides and analogs have reached clinical practice. They have numerous diagnostic applications. Pentagastrin is the agent of choice for gastric acid secretory testing. [311] CCK is used for pancreatic function testing, as well as in radiographic studies of gallbladder emptying and pancreatic duct size. [312] Secretin is administered in a provocative test for gastrinoma. [89] Glucagon is used to relax the gastrointestinal smooth muscle activity to facilitate endoscopic, radiologic, and intubation procedures. [313]

In addition to having diagnostic applications, potent agonist analogs of somatostatin are now commonly used as therapeutic agents (see structures of octreotide and lanreotide in Fig. 4-15). A long-acting depot form of lanreotide that can be injected intramuscularly is now available. These ligands have highest affinities for receptor subtypes 2 and 5, with moderate affinity for subtype 3 and very low affinity for subtypes 1 and 4. Somatostatin and its analogs suppress hormone release and hormone action for a number of gastrointestinal peptides. They are being used to treat the diarrhea and flushing of metastatic carcinoid syndrome, the secretory diarrhea of the VIPoma syndrome, the skin lesions of the glucagonoma syndrome, and other refractory diarrheal syndromes and fistulae. [314] Although these agents effectively inhibit acid hypersecretion in gastrinoma, there are better methods for controlling acid secretion, such as hydrogen-potassium ATPase inhibitors and histamine H_2 receptor antagonists. [315], [316] Somatostatin agonists have helped to relieve symptoms, and in rare cases they have induced islet cell tumor regression. They are also being tested for action against other epithelial carcinomas. More selective somatostatin receptor antagonists have been recently developed but are not yet available for clinical use.

Gastrointestinal hormones, such as gastrin-releasing hormone and gastrin, have been implicated as autocrine growth factors in various epithelial malignancies. Antagonists directed toward blocking the action of these peptides may have important clinical applications in the future.

CHAPTER 5

Graham J. Dockray

THE BRAIN-GUT AXIS

The gastrointestinal tract and the central nervous system (CNS) engage each other in two-way communication. The CNS is informed of the state of the gastrointestinal tract by afferent neurons, and is able to control or modulate digestive function though efferent neurons that are part of the autonomic nervous system (Fig. 5-1A). Afferent neurons signal information to the CNS about the chemical environment of the gut lumen, about tension in the gut wall, and about the condition of tissues (e.g., inflammation) (Fig. 5-1B). Efferent neurons determine gastrointestinal responses during the cephalic phase of digestion. They also mediate gastrointestinal responses after reflex stimulation of afferent pathways, activation of somatosensory inputs, and stimulation by higher centers, including, for example, changes in the emotional state.

FIGURE 5-1. Relationships between the brain and the gut. **A:** The gastrointestinal tract down to the midcolon is supplied with efferent and afferent nerve fibers running in the vagal and splanchnic trunks. **B:** Afferent neurons discharge in response to lumenal chemicals, mechanical deformation of their terminal fields, humoral factors, cytokines, and other inflammatory mediators; endocrine cells, mast cells, and cells of the immune system may be influenced by lumenal chemicals. **C:** Efferent neurons in both splanchnic and vagal nerve trunks terminate on myenteric nerve cell bodies from which intrinsic motor neurons influence secretion and motility; sympathetic efferents may also directly supply blood vessels. The response of the enteric motor neurons is also regulated by humoral factors and by other enteric neurons. *CNS,* central nervous system; *gang.,* ganglion.

The major pathways for communication between the brain and gut are the vagal, splanchnic, and sacral nerve trunks; all three contain both afferent and efferent nerve fibers. It has been recognized since the early 20th century that afferent signals associated with the physiological regulation of digestion are typically conveyed by the vagal pathway and painful sensations are conveyed by the splanchnic pathway. [1] Mechanisms that modulate afferent signals have been identified at various levels, including at the peripheral end of afferent fibers and within the CNS, and are a feature in a number of gastrointestinal diseases. [2]

Vagal efferent neurons provide the major parasympathetic route regulating gut function during digestion. Splanchnic efferent neurons constitute the sympathetic outflow to the gut and are activated in stress and adaptation to potentially noxious challenges. The neurons of the enteric ganglia are a major target for both types of efferent pathway (Fig. 5-1C). The motor neurons in these ganglia supply smooth muscle, glandular cells, and blood vessels. The enteric ganglia also function as centers for integration; they communicate with each other, and they receive inputs from intrinsic afferent neurons and from endocrine cells. Ganglion cells act, then, both to modulate and to mediate efferent signals from the CNS. Not surprisingly, the relative importance of information exchange between the alimentary tract and CNS varies between different functions and between different regions of the gut.

DEVELOPMENTAL BIOLOGY OF THE BRAIN-GUT AXIS

The pathway taken by the vagus nerve marks the route by which cells of the neural crest migrate to the gut during development. The molecular mechanisms that determine this migration are now being elucidated. They are of interest because they provide a basis for understanding the developmental biology not just of the brain-gut axis but also of the entire intrinsic nervous system of the gastrointestinal tract. Thus, cells of the vagal neural crest migrate the length of the gut to supply most of the intrinsic innervation, although a small number of cells from the truncal and sacral neural crests also contribute to the colonization of the stomach and distal colon, respectively. Neural crest cells give rise to multiple cell lineages, including neurons, neuroglia, and melanocytes, but not to epithelial enteroendocrine cells as previously thought. [3] The consequences of impaired migration or maturation of neural crest cells are illustrated by Hirschsprung disease, in which a failure of neuronal precursors to colonize the distal part of the colon leads to an aganglionic segment associated with tonic smooth muscle contraction and a dilated proximal segment. Mutations in several genes that regulate neural crest cell survival, migration, and maturation have been identified in people with Hirschsprung disease and in mutant mice with an aganglionic colon.

The development of enteric neural crest cells requires the c- *ret* protooncogene that encodes a receptor tyrosine kinase. The latter forms the transducing component of a signaling pathway activated by glial cell line–derived neurotrophic factor (GDNF). [4], [5] GDNF binds to a second protein, a glycosyl phosphatidylinositol–linked protein, GFRa $_1$, that then activates Ret. [6] Loss-of-function mutations of the c- *ret* gene occur in some cases of Hirschsprung disease. [7], [8] Interestingly, other mutations of this gene are associated with multiple endocrine neoplasia type II. In mice, deletion of either c- *ret* or *GDNF* leads to a failure in the development of the kidney and of neurons throughout the intestine. [9], [10], [11] and [12] The c- *ret* gene is expressed relatively early by neural crest cells, [13] and it is thought that this system is

required for the proliferation and survival of enteric neural precursor cells. A second system known to be required for the maturation of neural crest derivatives involves endothelin-3 (ET-3) and its G protein–linked receptor, the endothelin-B (ET_B) receptor. In some patients with Hirschsprung disease, a missense mutation in the gene encoding the ET_B receptor is associated with impaired Ca^{2+} signaling on stimulation. Similarly, targeted disruption of the ET_B receptor in mice leads to the loss of enteric ganglion cells in the distal colon, but not more proximally. Mice with mutations of the *ET3* gene that prevent the appropriate posttranslational maturation of the ET-3 precursor protein also exhibit impaired development of the enteric nervous system and an aganglionic distal colon. [14] It is thought that the ET-3/ET_B system functions after the c-*ret*/*GDNF* system, [15], [16] and acts to delay neuronal differentiation so that loss of function leads to a failure in the migration of neuronal precursors as a result of premature differentiation. These are not the only control systems determining the maturation of different populations of intrinsic gut neurons. Others include the homeobox gene *Phox2b,* which is required for expression of Ret, and of a second transcription factor, Mash-1, which regulates the expression of a catecholaminergic phenotype in neural crest–derived cells. [17], [18]

METHODS FOR STUDYING THE BRAIN-GUT AXIS

Present knowledge of the organization and function of the brain-gut axis is based on observations based on a wide variety of different experimental techniques. These methods can be loosely grouped into four categories.

1. *Methods directed at the study of organ function.* Methods that measure changes in secretion or motility in the gut after sham feeding, electrical stimulation of nerve trunks, or loss of function after nerve section (e.g., vagotomy) have often provided the first evidence for functional pathways linking the brain and the gut. Similar experiments can often be performed in humans and animals (e.g., barostat measurements of gastric motility). Taken in isolation, however, the results of such studies seldom allow the precise definition of brain-gut interactions because the relative importance of endocrine mediators and nervous reflexes that are extrinsic or intrinsic to the gut is difficult to evaluate in the intact organism. This type of approach can be coupled with the use of drugs to block or activate particular neurotransmitters or types of neurons, but again, interpretation of the data may be impeded by the fact that the same neurochemical mechanisms operate at multiple sites in the gut and the CNS.
2. *Morphologic methods that define the cellular basis of the brain-gut axis.* The nerve pathways linking the brain and the gut can be precisely defined by using tracers that are taken up by nerve cells and transported along axons—for example, fluorescent compounds such as True Blue, and pseudorabies virus, which is transported across synapses and so reveals chains of neurons in a pathway. In addition, the expression of immediate-early gene (e.g., c-*fos*) proteins has been widely used to identify neuronal responses to stimulation, although this technique does not reveal neurons that are inhibited by a particular stimulus. These methods can be coupled with surgical or chemical lesioning of neurons, and with immunocytochemistry for neurochemical characterization of a labeled neuron. Together, such methods provide quantitative information on the organization and neurochemistry of both afferent and efferent pathways, and on CNS pathways. This type of approach is, however, better suited to studies of experimental animals rather than of humans.
3. *Single-unit electrophysiological recording.* The physiological properties of single afferent and efferent nerve fibers, or of CNS neurons, can be studied by electrophysiological recording of their discharge in response to gastrointestinal stimulation. The data obtained allow rigorous analysis of the patterns of signaling, and can provide a formal framework for the description of reflex pathways identified in whole-organism studies or by morphologic methods. Again, however, these methods are more readily applied to animal than human studies.
4. *Methods appropriate for the study of the human brain-gut axis.* A heterogeneous group of methods has been of particular value in human studies. There are disadvantages to each of the techniques listed below, and the combined use of more than one of them therefore offers obvious advantages.
   i. *Evoked potentials.* Before the advent of modern imaging techniques, the activation of human CNS neurons after stimulation (e.g., balloon distention, electrical stimulation) was studied by observing the evoked potentials detected by scalp electrodes. [19], [20] This method is useful for measuring cortical neuronal responses (cortical-evoked potentials) that are relatively superficial in the brain, but it is not useful for studies of the activity of deeper neurons. It can, however, be used for recording responses from spinal neurons, and of the various techniques presently available, it is probably the method of choice for the noninvasive detection of human spinal afferent pathways. The temporal resolution is good (i.e., milliseconds), but the spatial resolution is only 1 to 2 cm.
   ii. *Magnetoencephalography (MEG).* This technique is based on the use of magnetic sensors near the scalp that detect changes in the magnetic field as a consequence of neuronal activity in the underlying part of the brain. The spatial resolution can be 2 to 5 mm, and images can be obtained in milliseconds. Like cortical-evoked potentials, however, MEG can be difficult to use for recording from subcortical regions.
   iii. *Positron emission tomography (PET).* This technique provides a view of neuronal activity as reflected by changes in blood flow. The time lag between changes in neuronal function and blood flow to the relevant region, however, may make it difficult to detect rapid responses. PET allows the identification of brain regions with a resolution of 2 to 8 mm, but the temporal resolution is relatively poor (i.e., 40 seconds). Repeated studies on individuals are difficult because of the risk associated with isotopic exposure and the relatively high cost.
   iv. *Functional magnetic resonance imaging (fMRI).* This imaging technique also detects changes in neuronal activity as reflected by blood flow. The spatial resolution is 2 to 8 mm. Temporal clustering analysis of fMRI data has shown that it is possible to resolve feeding-related changes in hypothalamic function. [21] fMRI is cheaper than PET, and repeated measurements are harmless.
   v. *Transcranial magnetic stimulation (TCMS).* Unlike the other techniques mentioned, this approach does not depend on the detection of neuronal responses; rather, it provides a method to activate specific CNS regions selectively. This is not a new technique, but its introduction to gastroenterology is recent. It can be used repeatedly in humans, and it is useful for the activation of cortical motor regions when coupled with the recording of gut function (e.g., electromyography). [22]
   vi. *Reporting visceral sensations.* Subjects report sensations after stimulation (mechanical, chemical, electrical) of the gut by using visual analog scales or by selecting adjectival descriptors of sensation. This approach is widely used and often valuable when combined with other techniques (e.g., fMRI). [23]

BRAIN-GUT CONNECTIONS

Afferent Neurons

The vagus nerve consists predominantly of afferent nerve fibers. In the rat, between 75% and 90% of vagal fibers are thought to be afferent. [24], [25] Almost all these fibers are unmyelinated or only lightly myelinated, and consequently their conduction velocities are relatively low (0.5 to 5 m/s). The cell bodies of vagal afferent nerve fibers are located in the nodose ganglia, and their central terminals are found in the nucleus of solitary tract (NST). The cell bodies of splanchnic and sacral afferent fibers are found in the dorsal root ganglia, and their central terminals are in the spinal cord. [26]

Different populations of afferent fibers respond to stimuli arising in the mucosa, muscle layers, and serosa. The stimulus in the lumen may be mechanical, thermal, or chemical. In addition, afferent neurons express receptors for various hormones, neurotransmitters, and immunomodulators (see Fig. 5-1B). It is convenient to use the term *afferent* to describe the direction in which information is passed relative to the CNS. However, many visceral afferent neurons (particularly splanchnic ones) synthesize neuropeptides that are transported to terminals both in the CNS and in the periphery, where they are released on nerve stimulation, giving rise to motor (or efferent) functions through an axon reflex. [27], [28]

Some intrinsic gastrointestinal neurons project to the prevertebral ganglia (see Fig. 5-1C). These neurons are therefore distinct from vagal, splanchnic, and sacral afferents, but they function as the afferent arm in some reflexes operating through the sympathetic ganglia. Electrophysiological recording of the discharge of nerve fibers running in the mesenteric nerve bundles detects both extrinsic afferent and intrinsic afferent nerve fibers, and care is required in distinguishing between them.

Organization The vagal afferent supply of the upper gastrointestinal tract is conveyed by the gastric branches of the vagus. More distal regions are innervated by vagal fibers that pass through the celiac–superior mesenteric ganglia and travel with the mesenteric nerve bundles running along blood vessels. There is a loose viscerotopic representation of vagal afferent terminals within the NST. [29], [30] Tracing experiments suggest that within the bowel wall, vagal afferent nerve fibers run in the myenteric plexus, where they form characteristic intraganglionic laminar endings. The innervation of the mucosa is variable. In the intestine, some villi appear to lack an afferent innervation, whereas others exhibit vagal afferent fibers in the lamina propria; afferent fibers do not appear to penetrate the epithelium. [31], [32] Splanchnic afferent nerve fibers enter the spinal cord through the dorsal roots and pass to the gut along blood vessels. They traverse the prevertebral ganglia, where they may supply collateral fibers innervating the ganglion cells, suggesting a direct modulatory role in sympathetic postganglionic discharge (see Fig. 5-1B). In the spinal cord, there are fewer terminals of splanchnic afferent neurons than of somatic afferent neurons. Splanchnic afferents terminate mainly in lamina I of the dorsal horn, although some project to lamina V. [33] The spinal cord neurons that respond to visceral afferent stimulation may also have inputs from somatic afferent nerve fibers. The peripheral terminals of splanchnic afferent nerve fibers can be identified within the gastrointestinal tract with the use of peptide markers such as calcitonin gene–related peptide (CGRP), which is found in fibers in the myenteric plexus, smooth muscle, around submucosal blood vessels, and in the mucosa. [34], [35]
Neurochemistry: Peptide Transmitters Marked neurochemical differences are found among gastrointestinal afferent neurons. About 80% of the spinal afferent neurons serving the rat stomach contain CGRP immunoreactivity, and about 50% contain substance P immunoreactivity. [34], [36] In contrast, fewer than 10% of the vagal

afferent neurons projecting to the gut contain these peptides. The proportion of the spinal afferent neurons associated with substance P or CGRP immunoreactivity is considerably higher in the gastrointestinal tract than in skin or joints. [37] Almost no primary afferent neurons containing somatostatin project to the stomach, however, although dorsal root ganglia neurons containing somatostatin project to the skin and joints. Low doses of the sensory neurotoxin capsaicin selectively stimulate C-fibers, whereas high doses selectively destroy C-fibers, particularly in neonatal animals. [38] Capsaicin-induced lesioning of afferent neurons produces a decrease in the expression of CGRP and substance P and a loss of immunoreactive nerve fibers in the gut. [34], [36] Surgical section of afferent nerve trunks also leads to the decreased expression of CGRP and substance P in primary afferent neurons. Interestingly, this treatment produces an increase in the expression of vasoactive intestinal polypeptide (VIP) and galanin in the afferent neurons. [39] The afferent innervation of the upper gastrointestinal tract does not normally contain VIP, although an exception may be the sacral afferents serving the distal colon of the cat, which reportedly express VIP. [40]

Neurochemistry: Receptors Vagal afferent neurons projecting to subdiaphragmatic structures express cholecystokinin type A receptors (CCK-A). [41] After ligation of the vagal nerve trunk, CCK-A receptors accumulate on the central side of the ligature, indicating transport toward the gut. [41], [42], [43] and [44] Capsaicin inhibits this transport. The data suggest that CCK receptors are expressed by vagal afferent neurons, a conclusion supported by the cloning of CCK-A receptor cDNA from nodose ganglia and the localization by in situ hybridization of CCK-A receptor mRNA to nodose ganglion cell bodies. [44] These neurons also express the putative peptide transmitter cocaine- and amphetamine-regulated transcript (CART). [45] In rabbit nodose ganglion, a common population of cell bodies has been shown to express CCK-A and neuropeptide Y (NPY)–1 and NPY-2 receptors. [46] Vagal afferent neurons also express 5-HT $_3$ receptors; these are probably transported centrally, to the NST, and peripherally, where they are thought to be important in mediating the actions of 5-HT released from intestine. [47]

Efferent Neurons

Organization The cell bodies of parasympathetic preganglionic nerve fibers that run in the vagus nerve are found in the dorsal motor nucleus of the vagus. There is a viscerotopic representation of neurons within the dorsal motor nucleus, and columns of cells corresponding approximately to the branches of the vagal nerve can be identified. [25], [48] The peripheral terminals of vagal efferent fibers have been mapped with the use of tracers such as DiI and PHA-L. [31], [49] Different tracers elicit quantitatively different results, but several conclusions emerge from the available data. Vagal efferent fibers can be shown to supply the gastrointestinal tract as far as the descending colon, but there is a proximal-distal gradient in the relative abundance of these fibers. In the stomach, where the vagal innervation is most dense, virtually all gastric myenteric ganglia are contacted by vagal efferent nerve fibers, but there is little or no supply to the submucosa or mucosa [31], [49] (see Fig. 5-1C). A single vagal efferent fiber may contact many myenteric ganglia. The contacts between preganglionic fibers and ganglion cells exhibit considerable variation; some are clear synaptic-like associations, whereas others are less well defined. The nerve cell bodies of postganglionic sympathetic neurons to the gut are in the prevertebral ganglia, and the preganglionic cell bodies are in the intermediolateral column of the spinal cord. Most of the upper gut receives its innervation from the celiac–superior mesenteric ganglia, and the lower gut from the inferior mesenteric ganglion. The postganglionic fibers run along blood vessels. Enteric ganglion cells are a major target, but so too are submucosal blood vessels (see Fig. 5-1C).

Neurochemistry The predominant phenotype of vagal efferent neurons is cholinergic, although the cell bodies of up to 30% of the neurons of the dorsal motor nucleus projecting to the stomach also appear to express tyrosine hydroxylase and may have a dopaminergic phenotype. [50] Some gastric vagal efferent fibers also contain galanin immunoreactivity, [49] and a population of the motor neurons of the nucleus ambiguus that project to the esophagus contains CGRP immunoreactivity. [51] It has been recognized for several generations that the main synaptic contact between vagal efferent fibers and cells of the myenteric plexus is cholinergic-nicotinic; combined anterograde tracing and immunohistochemistry suggest that gastric myenteric ganglion cells with a vagal input contain 5-HT, VIP, and enkephalin immunoreactivity. [49] The adrenergic phenotype of sympathetic neurons to the gut is well recognized. Many of these neurons also express neuropeptides, however, and the neurons seem to be chemically coded on the basis of their gastrointestinal targets. Thus, neurons of the celiac ganglia that project to submucosal blood vessels in the gut often contain NPY, and those that go to the submucosal plexus contain somatostatin. [52]

CNS Regions and the Digestive Tract

Ascending CNS Pathways Stimulated from the Gut Important early studies of the CNS regions responding to gut stimulation were conducted with cortical-evoked potentials. [19], [20] Subsequently, many groups have made recordings of the activity of identified CNS neurons responding to gastrointestinal stimuli or humoral mediators. [53], [54] and [55] Insight into the organization of CNS regions associated with digestive function has been obtained more recently by means of tracing techniques, the induction of immediate-early gene expression (e.g., c- *fos*), and, in the case of the human brain, the application of PET and fMRI. [19] Major CNS projections from the vagal complex identified by anterograde labeling include those to the paraventricular nucleus, the bed nucleus of the stria terminalis, the central nucleus of the amygdala, as well as those to the parabrachial nuclei and the subthalamus. [31] Many of the same regions are identified by the induction of c-Fos protein in response to nutrients and to the peripheral administration of regulatory peptides. [56], [57], [58] and [59] Noxious stimulation of the spinal afferents (visceral, somatic) increases c-Fos in the spinal cord neurons. [60], [61] Schuligoi and colleagues [62] reported that noxious stimulation of the gastric mucosa with HCl and formalin did not increase the spinal cord expression of c-Fos detected by in situ hybridization, but serosal application of formalin produced a significant increase. Because mucosal stimulation in these experiments increased blood flow, and this response is recognized to be mediated by splanchnic afferent neurons, it seems possible that noxious stimulation of the gastric mucosa may evoke an afferent fiber response of sufficient strength to trigger a local axon reflex but inadequate to recruit spinal nociceptive circuits. In healthy human subjects, PET and fMRI studies have identified responses in the anterior cingulate cortex in response to painful rectal distention. Interestingly, patients with inflammatory bowel disease exhibit differential responses in this region after similar stimulation. [63], [64] The anterior cingulated cortex is probably important more generally in visceral pain. Thus, nonnoxious stimulation of the human esophagus activates the central sulcus, the insular cortex, and the frontal/parietal operculum [65]; noxious stimulation activates the same regions, and also the anterior cingulate cortex and an expanded region of the insular cortex (Fig. 5-2). The CNS regions that respond to visceral stimuli exhibit plasticity; for example, there are prolonged changes in the cortical responses to short-term stimulation of the esophagus. [66] The cellular mechanisms accounting for plasticity and differential responses in disease are still largely unknown.

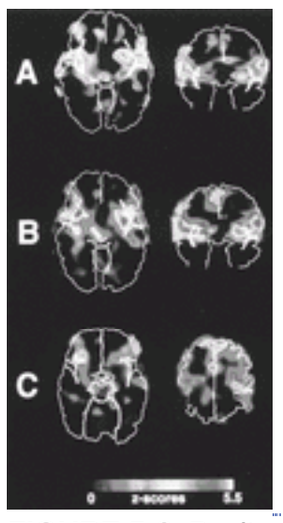

FIGURE 5-2. Positron emission tomography data after esophageal stimulation in humans. Scans of cortical areas activated during definite sensation–no sensation (**A**), pain–no sensation (**B**), and pain–definite sensation (**C**) are shown. **A:** Left and right scans show bilateral activation of the insular and primary somatosensory cortex. **B:** There is greater activation of the insular and primary somatosensory cortex, and some activation of the anterior cingulate gyrus. **C:** The left scan shows activation of the right anterior insular cortex, and the right shows activation of the anterior cingulate cortex. (Adapted from ref. [65], with permission.)

CNS Projections to the Vagal Complex The electrical stimulation of different CNS regions provided convincing early evidence of the role of the CNS in controlling digestive function. [67] Subsequently, retrograde tracing from the vagal complex has revealed the major monosynaptic connections. Thus, the vagal complex receives inputs from the obscure and pallidal raphe nuclei, the paraventricular nucleus, the dorsomedial and lateral areas of the hypothalamus, the central nucleus of the terminal stria, and the insular and medial prefrontal cortexes. [68] In humans, TCMS has been used to examine the cortical control of esophageal function. The relevant area of the cerebral cortex is asymmetric; the greatest esophageal responses were evoked from the right hemisphere in eight of ten subjects and from the left hemisphere in the other two. [69] This asymmetry may explain why the dysphagia that develops after stroke is variable in degree and duration. [22]

SIGNALING FROM GUT TO BRAIN

From the 1950s onward, Paintal, [70], [71] Iggo, [72] and others made electrophysiological recordings of the discharge of single vagal or splanchnic afferent fibers in anesthetized animals. This work has provided the foundation for modern views of visceral afferent nerve function. Individual afferent fibers respond to mechanical deformation of their terminal regions, to the presence of chemical stimulants in the gut lumen, and to humoral agents administered into the circulation. Because visceral afferent nerve fibers may be mechanoreceptors, chemoreceptors, or both, recent classifications of afferent nerve response have been based on the distribution of terminal fields rather than the modality of the receptor. [73], [74]

Mucosal, Muscle, and Serosal Afferents

The responses of vagal afferent nerve fibers to mucosal stimulation, typically in the stomach and proximal small intestine, have been reported by many groups. Less is known about splanchnic afferent responses to mucosal stimulation. [74] All the major macronutrients (i.e., protein, fat, carbohydrate) have been reported to stimulate mucosal afferent nerve fiber discharge. There are also fibers that respond to a variety of nonnutrient chemicals, including acid, alkali, and hypertonic solutions. [74], [75] Many mucosal afferent fibers are multimodal and respond to mechanical as well as chemical stimulation. These fibers, in particular, also respond to light mechanical stimulation, such as brushing or stroking of the mucosa; the responses are rapidly adapting.

The afferent fibers supplying the muscle layers of the gut typically respond to both passive stretch and active contraction, hence the name *in-series tension receptor*. They are characteristically slowly adapting, and if innervating the stomach and proximal small intestine, they have a single receptive field.

The serosal afferent innervation appears to be predominantly spinal in origin. These afferent fibers respond to deformation of the serosa and mesentery, particularly around the bifurcation of blood vessels, thereby conveying information about visceral tension and movement. The receptive fields of these afferent fibers are often punctate.

Mechanoreceptors: Transduction

Sensitivity to mechanical stimulation is a common physiological response and accounts for mechanisms involved in hearing, balance, touch, the regulation of cell volume, and muscle cell responses to stretch. A variety of different cellular mechanisms are now recognized to account for these responses. Many cells have stretch-sensitive ion channels that are gated by changes in membrane tension. The accompanying alterations in membrane potential lead to the propagation of action potentials. Although there is little direct evidence, it is plausible that this type of mechanism is responsible for the sensitivity of muscle and serosal afferent fibers. Balloon distention has been widely used to stimulate mechanoreceptor discharge in visceral afferent fibers.

Afferent fiber populations differ in sensitivity. For example, pelvic afferent fibers responding to distention in the physiological pressure range (<5 mm Hg) are known as *low-threshold fibers*; discharge of these fibers is proportional to distending pressures of up to about 30 mm Hg, which is in the range likely to be perceived as noxious. A separate population of fibers (i.e., high-threshold), however, discharge only in response to high pressures (>30 mm Hg), suggesting a primary function in noxious signaling. [74]

Signals from mucosal afferent fibers that respond to mechanical deformation may be mediated initially by enterochromaffin cells, and many years ago, Bulbring and Lin [76] proposed stimulation of these cells to be the first step in activation of the peristaltic reflex in response to distention of the small intestine. Mechanical deformation at the lumenal surface was postulated to release 5-HT that then stimulated subepithelial nerve fibers. The observation of increased c-Fos immunoreactivity in myenteric neurons after mechanical deformation of guinea pig ileal mucosa, along with evidence of mediation by 5-HT, provides some support for this model. [77]

Chemoreceptors

Transduction The term *chemoreceptor* is used to describe the capacity of afferent nerve fibers to respond to defined chemical agents. Both nonlumenal (neurohumoral) and lumenal chemicals clearly stimulate gastrointestinal afferent nerve fiber discharge. The first humoral stimulants of afferent fibers to be recognized were histamine, 5-HT, and bradykinin. Subsequently, hormones such as CCK were also identified as direct stimulants of visceral afferent nerve fibers. The mechanisms underlying afferent responses to lumenal chemical stimuli are less clear. However, the molecular sensing mechanisms involved in taste perception by the tongue provide a model for understanding what may happen within the gastrointestinal tract. Thus, compounds associated with the taste of salt or acid act by gating of ion channels. [78] Small molecules may therefore penetrate the mucosa to act directly on afferent nerve fibers (e.g., cation channels gated by extracellular H^+). [79] Compounds associated with sweet or bitter tastes are known to act in the tongue through G protein–coupled receptors. [78] a-Gustducin, the GTP-binding subunit of a heterotrimeric G protein, is a putative mediator in these cells. [80] At the cellular and molecular levels, the transduction mechanisms may be similar in the tongue and in the gut, even though taste perception is restricted to the buccal cavity. Consistent with this idea, a-gustducin immunoreactivity has been displayed on the apical membrane of brush cells in the stomach and in the duodenum. These cells are distinct from endocrine cells but are rich in nitric oxide synthase, suggesting that changes in the lumenal environment of the gut trigger the release of nitric oxide, which in turn acts on primary afferent nerve fibers. [81]

Endocrine Cells As Transducers Lumenal stimuli also activate classic enteroendocrine cells, the products of which are putative messengers from the gut to the brain (Fig. 5-3). The mediators include CCK, 5-HT, gastrin, somatostatin, and peptide YY (PYY). CCK is thought to mediate the effects of lumenal protein and fatty acid in the intestine, and 5-HT may mediate the effects of intestinal carbohydrate stimulation. [82] The transduction mechanisms at the apical membrane have, until recently, been uncertain. However, for G cells, it now seems that a G protein–coupled receptor, CaR, responding to both extracellular Ca^{2+} and aromatic amino acids such as L-tryptophan and L-phenylalanine, provides the initial molecular recognition event for multiple lumenal stimuli. [83], [84] After the release of putative endocrine cell mediators, there are two general ways that gut endocrine cell products may signal to the CNS. First, they may penetrate the CNS from the circulation in regions where the blood-brain barrier is absent or leaky; possible examples are pancreatic polypeptide (PP) and ghrelin, which are discussed in subsequent sections. Second, as already noted, primary afferent nerve fibers possess receptors for some of the products of gut endocrine cells (e.g., CCK and 5-HT), which are therefore putative mediators of endocrine-neural signaling pathways. [37] Two schools of thought have emerged regarding how CCK may signal in this way. One line of evidence indicates that CCK stimulates vagal afferent fibers that also function as gastric in-series tension receptors. [85], [86] According to this view, CCK acts by way of the systemic circulation to stimulate vagal afferent fibers serving the gastric musculature. An alternate line of evidence indicates that CCK acts on intestinal mucosal afferent fibers in the subepithelial regions surrounding the CCK-secreting cells. [87], [88] It seems likely that 5-HT released from enterochromaffin cells similarly acts as a paracrine stimulant of local afferent nerve fibers. The pathways have largely been elucidated for rat but probably are similar for humans; for example, lipid-induced depression of gastric motility and sensations of fullness were inhibited by a CCK-A antagonist in healthy human subjects. [89]

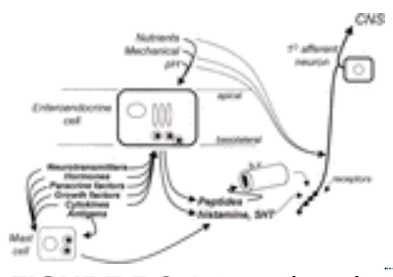

FIGURE 5-3. Interactions between lumenal factors, mast cells, endocrine cells, and primary afferent nerve fibers. The latter may express receptors for endocrine and mast cell secretory products, and may also respond directly to lumenal chemicals that penetrate the mucosa. The discharge of afferent fibers to the smooth muscle may be secondary to passive stretch (distention caused by a meal) or to the contraction of smooth muscle. Peptides released by endocrine cells are thought to act directly on afferent nerve fibers and after transport in the circulation. The receptors expressed by afferent neurons are synthesized in the cell body and may be transported to peripheral terminals. *CNS,* central nervous system; *b.v.,* blood vessel.

Mast Cells and the Extrinsic Innervation of the Gut There is a close relationship between mast cells and substance P–immunoreactive nerve fibers. [90] Mast cell products (i.e., histamine and 5-HT) stimulate the discharge of intestinal afferent fibers, [91] and there is evidence that motor responses to mast cell discharge in vivo are mediated by 5-HT_3 receptors and vagal afferent nerve fibers. [92] In ovalbumin-sensitized rats, antigen challenge increased c-Fos expression in the NST, the lateral parabrachial nucleus, and the paraventricular nucleus. These responses were inhibited by systemic administration of the 5-HT_3 antagonist ondansetron and by

perivagal capsaicin, suggesting a mechanism involving peripheral 5-HT $_3$ receptors and vagal afferent neurons in signaling to the CNS during intestinal anaphylaxis.[93] In addition to the stimulation of afferent fibers by mast cell products, mast cell secretion is stimulated by the activation of vagal efferent fibers (see Fig. 5-3). For example, the administration of a thyrotropin-releasing hormone (TRH) analog that strongly stimulates vagal efferent neurons elicited the release of mast cell markers into the rat intestinal lumen.[94]

Inflammatory Modulation of Afferent Function

Inflammation of the gut wall is a strong stimulant of afferent nerve discharge[95,96] (see Fig. 5-3). Many splanchnic afferent fibers appear normally to be silent; for example, up to 90% of splanchnic afferents to the distal colon are reported to be insensitive to stimulation in the physiological range.[62] Inflammation induced experimentally by the administration of mustard oil, acetic acid, or formaldehyde, however, leads to an increased sensitivity to stimulation.[97] Seemingly silent afferent fibers may play little or no role in the normal physiology of the gastrointestinal tract, but they are important components of the signaling pathway activated by damage or inflammation, and may therefore play a role in gastrointestinal disease states. Activation is likely, in part, to be attributable to the release of cytokines such as interleukin-1ß (IL-1ß), which increase the sensitivity of afferent fibers to stimulation[97] (see Fig. 5-3).

Pain and Visceral Hypersensivity

The noxious stimulation of splanchnic afferent nerve fibers is associated with painful sensations. The sensation of pain may, however, also be evoked by normal or innocuous stimuli, a process sometimes called *hypersensitivity*. It is well recognized that patients with irritable bowel syndrome may report painful sensations in response to distention of the colon at pressures that are not perceived as painful by healthy subjects. The term *allodynia* is used to describe noxious sensations evoked by innocuous stimuli, and the term *hyperalgesia* describes exaggerated responses to noxious stimuli. The mechanisms that account for visceral hypersensitivity have generated considerable interest.[23] These mechanisms are a feature of both inflammatory and noninflammatory conditions (e.g., functional bowel disorders). Changes at any of several different levels in the brain-gut axis may be involved. Thus, in addition to the exaggerated responses of afferent neurons and the recruitment of otherwise “silent” afferent fibers (see previous section), there is also central modulation of afferent stimuli.[2] Perfusion of the lower esophagus with acid increases the sensitivity of the upper esophagus to electrical stimulation, providing direct evidence of central sensitization. Patients with noncardiac chest pain exhibit a marked decrease in their visceral pain threshold.[98] The effects of central sensitization are often relatively long-lasting. For example, irritation of the colon in young rats leads to hypersensitivity in later life despite an absence of apparent pathology in the gut.[99]

The term *wind-up* is sometimes used to describe the increased synaptic transmission at afferent nerve terminals in the spinal cord; this event is thought to involve enhanced transmission by the neurotransmitter glutamate acting at NMDA receptors. In addition, the inhibitory influences on spinal cord cells from nervous pathways that descend in the spinal cord may be altered. Finally, hyperalgesic states clearly are associated with changes in neuronal activation at supraspinal levels, including, for example, the expansion of cortical regions associated with the response to a defined stimulus.[66,96]

EFFERENT FUNCTIONS OF PEPTIDERGIC VISCERAL EFFERENT NEURONS

After the stimulation of visceral afferent nerve fibers, the peptides produced by these neurons are released at both central and peripheral terminals. Peptides released peripherally modulate blood flow, motility, secretion, the discharge of enteric ganglion cells, and a number of functions associated with epithelial protection.[27,28,100] There is now good evidence that noxious agents in the lumen activate splanchnic afferent fibers, which in turn regulate protective or damage-limiting mechanisms within the mucosa, as well as signaling to the CNS (Fig. 5-4). Capsaicin, which is the active ingredient of hot peppers, has been used extensively in studies of primary afferent nerve function.[101] This compound acts on a nonselective cation channel, the vanilloid receptor (VR $_1$), to increase intracellular calcium concentrations.[102] Because the VR $_1$ ion channel is located almost exclusively in primary afferent nerve fibers, capsaicin is a valuable selective stimulant of these neurons. At low doses, capsaicin is excitatory, and at high doses, it produces long-lasting or permanent loss of function.

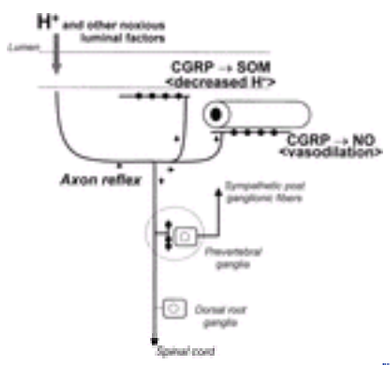

FIGURE 5-4. Axon reflexes in response to noxious chemical stimuli. The latter activate primary afferent neurons that also synthesize neuropeptides (e.g., CGRP) that are transported to their peripheral terminal fields and released by axon reflexes on stimulation. Responses include increased blood flow, probably secondary to stimulation of nitric oxide synthase, and stimulation of somatostatin-producing D cells, which leads to inhibition of acid secretion. *CGRP*, calcitonin gene–related peptide; *SOM,* somatostatin; *NO,* nitric oxide.

Elucidation of the role of peptides released at the peripheral terminals of visceral afferent fibers is complicated for those neuropeptides produced in both afferent and intrinsic neurons (e.g., the tachykinins). However, CGRP-a in the rat stomach has proved to be a valuable model for studies of the relevant mechanisms. CGRP-a is absent from gastric intrinsic neurons and endocrine cells; it is scarce in gastric vagal afferent neurons but abundant in splanchnic afferent nerve fibers. An intact splanchnic afferent innervation mitigates damage of the gastric mucosa inflicted by noxious agents (e.g., ethanol), suggesting that afferent nerve fibers have a protective role.[103] There is good evidence that CGRP-a is a protective mediator in this system. Thus, capsaicin increases the release of CGRP in the perfused rat stomach, and on acute administration, it reduces the lesions produced by ethanol; immunoneutralization of CGRP, or administration of the CGRP antagonist CGRP $_{8–37}$, abolishes capsaicin-induced protection.[100,104,105] The release of CGRP is associated with increased mucosal blood flow mediated by nitric oxide; this hyperemic response is a key part of the protective mechanism (see Fig. 5-4). Multiple other actions of CGRP are likely to be protective, including stimulation of somatostatin secretion and increased somatostatin synthesis at the level of mRNA abundance,[106] which tend to decrease secretagogue-evoked acid secretion.

CNS CONTROL OF THE GUT

The CNS influences all major gastrointestinal functions, including secretion, motility, blood flow, and defense against noxious challenge. A substantial body of literature describes gastrointestinal responses after the administration to defined CNS regions of virtually all the main classic and peptide neurotransmitters, including glutamate, ?-aminobutyric acid, acetylcholine, biogenic amines, corticotropin-releasing factor, opioids, CGRP, CCK, somatostatin, VIP, and neurotensin.[107,108,109] and[110] Both stimulation and inhibition of gastrointestinal motor and secretory responses may be evoked by the same substance in different CNS regions. It is unlikely that all the effects described after the CNS application of neuroactive substances are physiologically relevant. This chapter focuses on the most intensively studied CNS peptide systems regulating gastrointestinal function, particularly those in which the mechanisms and functional significance are clearest. The CNS-peptidergic control of acid secretion has been the subject of several reviews.[109,111]

Thyrotropin-Releasing Hormone

The stimulation of colonic motility and gastric acid secretion in response to the intracisternal administration of TRH was among the first gastrointestinal effects of CNS peptides to be discovered.[112] It is now clear that TRH is a reliable stimulant of a wide range of gastrointestinal responses, including gastric acid and pepsinogen secretion, gastric histamine secretion, gastric mucosal blood flow, gastric motility, and mast cell secretion.[109] In high doses, TRH produces gastric lesions. For the

most part, these effects are mediated by the stimulation of vagal efferent neurons and so are blocked by vagotomy and atropine. They can be mimicked by stable TRH analogs, such as RX77368. There is a rich TRH innervation of the dorsal motor nucleus of the vagus that arises mainly from the obscure and pallidal raphe nuclei. [68] These neurons are also serotonergic. It is likely that the coexisting transmitters, 5-HT and TRH, interact after release. Stimulation of the raphe nuclei, similar to the administration of TRH into the dorsal motor nucleus, increases gastric acid secretion and motility by a vagal cholinergic mechanism. [113], [114] Intracerebroventricular administration of TRH antibodies reduces acid secretion in the pylorus-ligated rat, and immunoneutralization also inhibits the response to raphe nuclei stimulation, providing clear evidence that TRH is an endogenous regulator of the vagal efferent outflow to the upper gastrointestinal tract and may participate in vagovagal reflexes. [113], [115]

Bombesin/Gastrin-Releasing Peptide

Central administration of peptides of the bombesin/gastrin-releasing peptide group can produce effects opposite to those evoked by peripheral administration. In particular, bombesin and gastrin-releasing peptide administered intracisternally inhibit acid secretion, [116] but they generally stimulate it on peripheral administration (reflecting vagal noncholinergic stimulation of the G cell). Retrograde tracing and immunocytochemistry indicate that bombesin-immunoreactive nerve fibers in the dorsal vagal complex originate from cell bodies in the medial parvocellular subdivision of the paraventricular nucleus of the hypothalamus, [117] which provides support for the notion that bombesin-related peptides mediate descending inhibitory effects from the paraventricular nucleus to vagal efferent neurons.

PYY/PP/NPY

The peptides of the PP family (NPY, PYY, and PP itself) influence the brain-gut axis at various levels, almost certainly through a diverse family of receptors (six or more). The different family members vary in their affinity for different, naturally occurring receptors. PP released from endocrine cells of the pancreas is thought to act directly within the vagal complex to stimulate acid secretion and gastric motility. Neurons that are excited by PP have been identified electrophysiologically and characterized as part of a vagovagal circuit activated by antral distention. [118], [119] In contrast, PYY is an inhibitor of acid secretion that is thought to suppress vagal efferent stimuli. Thus, PYY released from the ileum inhibits sham feeding–stimulated acid secretion by a presynaptic effect on the vagal pathway. [120] The complexity of these responses is further illustrated by observations that NPY injected into the paraventricular nucleus inhibited rat gastric acid secretion, but in other hypothalamic regions outside the paraventricular nucleus, it had excitatory effects. [121]

Oxytocin

The intravenous administration of CCK stimulates oxytocin secretion from the posterior pituitary by a mechanism that involves capsaicin-sensitive vagal afferent pathways. [122] Electrophysiological data suggest that oxytocin-secreting neurons of the supraoptic nucleus of the hypothalamus are stimulated by systemic CCK, and by gastric distention, through a vagal mechanism. [123] Intracerebroventricular administration of oxytocin inhibited gastric motility, and an antagonist increased motility, although the antagonist did not influence the response to CCK. [124] Because neurons of the paraventricular nucleus project to the dorsal vagal complex, it seems possible that oxytocin mediates the hypothalamic-vagal pathways regulating digestive function.

VAGOVAGAL REFLEX MECHANISMS

The physiological control of digestion depends on cross talk between the gastrointestinal tract and the brain; the relevant interactions are well illustrated by vagovagal reflexes. Control of pancreatic and gastric secretion, gallbladder contraction, and the motility of stomach and intestine may all include a component that involves a vagovagal reflex. The afferent arm of these reflexes was thought for many years to be triggered by direct mechanical or chemical stimulation of the vagal afferent fibers. It is now clear, however, that local paracrine or hormonal factors also stimulate the afferent arm of vagovagal reflexes; moreover, there may be multiple, interacting inputs to afferent nerve discharge. One of the best-studied examples involves CCK and the reflex regulation of gastric motility and pancreatic secretion. In this context, the primary function of CCK is the regulation of protein and fat digestion in the small intestine. Thus, CCK stimulates the delivery of pancreatic enzymes and bile salts to promote digestion in the intestine; at the same time, it delays further delivery of nutrients to the small intestine by inhibiting gastric emptying and food intake. Taken together, these actions allow matching of the capacity for digestion (enzymes and bile salts) with nutrients already in the small intestine.

Distention of the stomach activates vagovagal reflexes that result in relaxation of the gastric corpus and the stimulation of acid secretion. [125] Gastric relaxation is important early in digestion to accommodate the delivery of food, so that gastric volume increases without an increase in pressure (Fig. 5-5). Electrical stimulation of the vagal nerve trunk generally produces gastric contraction, but relaxation is induced by the same stimulus in the presence of the cholinergic muscarinic antagonist atropine. There are, therefore, a vagal excitatory muscarinic pathway that maintains gastric tone and a vagal inhibitory nonmuscarinic pathway that leads to relaxation of the body of the stomach (and a decrease in intragastric pressure). For some years, VIP was thought to mediate the latter effect, [126] but nitric oxide is also now recognized as a mediator of this response. [127], [128]

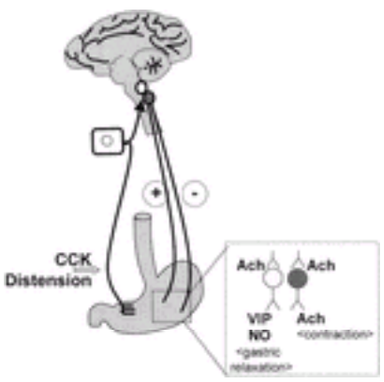

FIGURE 5-5. Vagovagal reflex control of gastric motility. Gastric mechanoreceptors and CCK acting on vagal afferents trigger a vago- vagal reflex that produces inhibition of tone in the gastric corpus. The latter is likely to be secondary both to inhibition of tonically active vagal, cholinergic, excitatory pathways (*shaded*) and to stimulation of vagal inhibitory pathways with VIP and nitric oxide as the final mediators. The reflex is important in receptive relaxation of the stomach early in digestion and in inhibition of gastric emptying (by decreasing the pressure difference between corpus and duodenum) later in digestion. *CCK,* cholecystokinin; *Ach,* acetylcholine; *VIP,* vasoactive intestinal polypeptide.

Neurochemical, electrophysiological, and integrative physiological studies indicate that CCK acts at CCK-A receptors on vagal afferent fibers, which constitute the afferent arm of a vagovagal reflex by which CCK relaxes the gastric corpus [37] (see Fig. 5-5). This response is reduced after capsaicin is topically administered to the vagal nerve trunk, or systemically administered to newborn rats. [129], [130] Lumenal nutrients in the intestine induce CCK release and, like exogenous CCK, relax the gastric corpus by a mechanism sensitive to capsaicin and to CCK-A receptor antagonists. [131], [132] and [133] An important consequence of gastric relaxation in response to CCK is a decrease in the pressure driving the gastric emptying of liquids.

In parallel with the reflex relaxation of the stomach, CCK also appears to activate vagal reflexes leading to the stimulation of pancreatic secretion. It seems that pancreatic acinar cells are controlled both directly by the effects of CCK delivered in the circulation, and indirectly by acetylcholine released from postganglionic parasympathetic neurons as a consequence of CCK-stimulated vagovagal reflexes. [134], [135]

SATIETY MECHANISMS

Food intake is determined by a wide range of influences, including signals from adipose tissue, from the gastrointestinal tract, and arising within the CNS (Fig. 5-6). Together, these mechanisms serve to maintain body weight within narrow limits over long periods in the face of changing metabolic demands. Progress in elucidating the cellular and molecular mechanisms relevant to the control of food intake has been impressive, [136] and it is in part attributable to the study of genetically modified

animals, which has revealed the role of specific transmitters and receptors. [136]

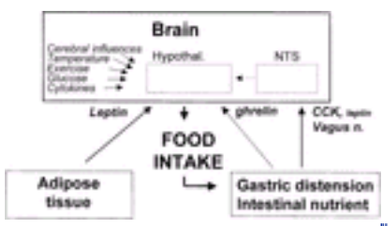

FIGURE 5-6. Schematic representation of the mechanisms controlling food intake. There is inhibition of food intake in the short term (i.e., over the period of a single meal) by gastric distention (which appears not to be nutrient-related) and by the release of CCK from the small intestine (which is related to the fat and protein content of the meal). Both mechanisms result in the activation of vagal pathways terminating in the nucleus of the solitary tract and projecting to the hypothalamus. Feeding inhibits the release of ghrelin from the stomach; ghrelin acts on the hypothalamus to decrease fat utilization. Over the long term, food intake is regulated by leptin released from adipocytes. Among other things, leptin inhibits hypothalamic neuropeptide Y–producing neurons that stimulate food intake. *CCK,* cholecystokinin; *hypothal.*, hypothalamus; *NTS,* nucleus of solitary tract; *vagus n.,* vagus nerve.

Leptin-NPY System

It was thought for many years that fat stores might somehow signal to the CNS to influence food intake (i.e., the lipostatic theory of food intake). The molecular basis for this mechanism has emerged from the characterization of a genetic defect in mice (*ob/ob*)—a homozygous recessive mutation associated with obesity, hyperphagia, decreased locomotion, hypometabolism, diabetes, and infertility. Zhang and colleagues [137] showed by positional cloning that these mice have a mutation in a gene encoding a putative hormone signaling from adipose tissue to the CNS, now known as *leptin*. Subsequently, mutations in the leptin gene were also reported in two obese human subjects. [138] The receptor for leptin is mutated in a different mouse strain (*db/db*) that is also characterized by hyperphagia, hypometabolism, and diabetes. [139] The intracellular signaling pathway activated by the leptin receptor appears to resemble the JAK/STAT pathway. [140] The administration of leptin reduced body weight in *ob/ob* mice and increased energy expenditure. [141], [142] There appear to be important interactions between leptin and several hypothalamic systems. One involves NPY, which is a powerful stimulant of food intake when administered into the ventromedial and paraventricular hypothalamic nuclei. [143]

Leptin secretion reflects the size of the adipose tissue mass, and as leptin reduces NPY synthesis and release, it provides a negative feedback influence on the hypothalamic system that stimulates feeding. [144] Deletion of the NPY gene in *ob/ob* mice partially reverses the phenotype of the latter, providing direct support for the idea that leptin acts through the modulation of NPY release. [145]

The melanocortin-4 (MC-4) receptor is also implicated in the response to leptin. Mice of the agouti strain are hyperphagic and obese, with elevated plasma leptin concentrations; they generate an endogenous peptide antagonist of the MC-4 receptor that, in addition to having CNS effects, blocks the effects of the melanocyte-stimulating hormone on skin melanocytes, giving the animals a yellow color (hence agouti). The intracerebroventricular administration of synthetic MC-4 receptor agonists inhibited feeding in agouti and *ob/ob* mice, and in mice injected with NPY. [146] Moreover, hyperphagia, hyperinsulinemia, and hyperglycemia, similar to that of agouti mice, developed in mice in which the MC-4 receptor had been inactivated. [147] The data suggest multiple signaling systems in the hypothalamus that are activated by leptin. One system is linked to increased feeding and is mediated by NPY; another, which leads to the inhibition of feeding, is linked to melanocyte-stimulating hormone and the MC-4 receptor. However, these are certainly not the only hypothalamic transmitter systems relevant to the control of food intake. Others that are part of this system include catecholamines, 5-HT, glucagon-like peptide I, melanocyte-concentrating hormone, and orexins. [148], [149] and [150]

Gastrointestinal Satiety Signals

The leptin system is thought to provide a mechanism to match energy stores in the body with food intake, and to function as a relatively long-term signaling system. Signals from the gastrointestinal tract that control food intake operate over shorter intervals and limit the size of individual meals, thereby serving to match meal size with the capacity for digestion. Gut hormones are likely to be important regulators of these events, and, as already mentioned, there is considerable support for the idea that CCK may signal to the CNS through vagal afferent fibers. [151], [152] and [153] Thus, exogenous CCK inhibits food intake; this effect is inhibited by abdominal vagotomy, lesioning of the NST, sectioning of vagal afferent rootlets, and the use of capsaicin. [154], [155], [156] and [157] Moreover, the occurrence of missense mutations in the CCK-A receptor in some obese patients provides molecular support for the idea that CCK has a functional role at CCK-A receptors in the control of food intake in humans. [158] It has been suggested that leptin may also act as a gastrointestinal satiety signal. Leptin is produced in gastric chief cells (as well as in adipocytes), and it has been suggested that CCK induces the release of gastric leptin. [159], [160] There appear to be functional leptin receptors on vagal afferent neurons and to be interactions between leptin and CCK in stimulating the discharge of gastric vagal afferent fibers, suggesting a local gastric leptin system that potentiates the satiety effects of CCK. [161]

Physiologically, it is likely that both nutrient and non–nutrient-activated mechanisms contribute to the gastrointestinal control of food intake. One important nonnutritive signal is the volume of the gastric contents. Gastric distention (regardless of nutrient content) inhibits food intake by a vagal mechanoreceptor mechanism. [162], [163] and [164] It seems, however, that there are also interactions between CCK-mediated (nutrient-dependent) mechanisms and gastric volume (non–nutrient-dependent) because there is evidence for potentiation between gastric distention and CCK in the inhibition of food intake. [165] There appears, then, to be synergistic interactions between CCK and leptin, and CCK and nonnutritive stimuli, at the peripheral end of gastric vagal afferent fibers. Further studies are needed to elucidate the CNS projections from the NST to the hypothalamus for nutrient- and non–nutrient-initiated stimuli and to define the ways in which these pathways are integrated with signals from the leptin-adipocyte pathways to control food intake.

In addition to signals from the gut that inhibit food intake, it now appears that there may be other types of gut-brain signals. The peptide ghrelin was discovered as the ligand of orphan receptors that mediate the action of synthetic secretagogues on growth hormone release. [166], [167] Interestingly, ghrelin both releases growth hormone and increases adiposity in rats by decreasing fat utilization. Ghrelin is mainly produced in the stomach; plasma concentrations are increased by fasting and decreased by feeding. [168] It has been suggested that ghrelin signals from the stomach to the hypothalamus to increase metabolic efficiency (see Fig. 5-6).

OVERVIEW

The gastrointestinal tract and brain involve each other in two-way communication. These interactions provide a basis for the gastrointestinal control of CNS responses (e.g., control of food intake) and, conversely, the CNS control of gastrointestinal function (e.g., during the cephalic phase of digestion). More importantly, they provide the capacity for integrating information about the state of the gut contents and inputs from other parts of the body. A direct consequence of these integrative functions is modulation of the signaling between brain and gut during normal digestion. However, the modulation of signaling pathways is also likely to be important clinically, and it may account for the hypersensitivity that is a feature in disease states involving inflammation in the gut, as well as those that do not. The results of a variety of experimental approaches have shown that it is possible to explain in molecular and cellular terms the development of the brain-gut axis and its organization, neurochemistry, and physiology. Impressive progress also is being made in the combined application of CNS imaging techniques and functional studies of the human digestive tract. These approaches should make it possible to define how dysfunction of brain-gut signaling contributes to gastrointestinal disease.

CHAPTER 6

Gabriel M. Makhlouf

SMOOTH MUSCLE OF THE GUT

The main function of smooth muscle of the gut is to mix and propel intralumenal contents, to enable efficient digestion of food, progressive absorption of nutrients, and eventual evacuation of residues. This function is regulated by the intrinsic electrical and mechanical properties of smooth muscle, such as the ability to maintain tone or undergo phasic contraction, and by alterations in these properties in response to hormonal and neural signals, particularly signals emanating from the enteric nervous system. A distinctive feature of physiological regulation in the gut is that stimuli of hormonal release and neural activation arise within the lumen from the mechanical and chemical properties of food and digestive secretions.

STRUCTURE OF SMOOTH MUSCLE

Muscle Layers

Smooth muscle of the gut consists of a thin, outer, longitudinal layer and a thick, densely innervated, circular layer; the layers derive their names from the orientation of the long axis of muscle cells in them. The layers are separated by laminar septa into bundles about 1 mm long that probably act as contractile units. The muscle cells are embedded in a connective tissue matrix, a product of their synthetic and secretory activity consisting mainly of elastic and collagen fibrils. The layers include glial cells, fibroblasts, and a distinctive population of muscle-like cells, the interstitial cells of Cajal.

Muscle Cells: Membranes and Organelles

Single smooth muscle cells are about 400 µm long and 5 µm wide when fully relaxed. They are spindle-shaped and have a high ratio of surface area to volume (1.5 $\mu m^2/\mu m^3$). Their plasma membranes consist of two specialized structures known as *caveolae* and *dense bands.* [1], [2] and [3]

The caveolae, 70 nm wide and 120 nm deep, are basket-shaped invaginations of the membrane that are arranged in clusters (Fig. 6-1). There are about 150,000 caveolae per cell, and they occupy about one third of the outer surface of the cell but constitute a much larger fraction of the surface of the plasma membrane. The bases of caveolae are surrounded by an abundant endoplasmic reticulum, the site of Ca^{2+} storage and release in smooth muscle. The arrangement suggests that caveolae may be functional equivalents of the transverse tubules in striated muscle. Caveolin-1a, caveolin-1ß, and caveolin-3 are the main structural proteins in smooth muscle caveolae. [4], [5] They bind a variety of signaling molecules and are thought to act as scaffolds to facilitate signaling. In smooth muscle, caveolins also bind transiently to agonist-activated a and ß? subunits of G proteins, prevent their reassociation, and induce desensitization of responses mediated by these G proteins. [6]

FIGURE 6-1. Surface organization of three adjacent muscle cells from the circular muscle layer of guinea pig ileum. Clusters of basket-shaped caveolae (*c*) surrounded by endoplasmic reticulum (*er*) are separated from each other by dense bands (*db*) (original magnification ×67,000). (From ref. [1].)

Clusters of caveolae are separated from each other by electron-dense structures, 1 to 2 µm long and 0.2 to 0.4 µm wide, called dense bands, that occupy about one half of the surface of the cell (Fig. 6-2). Dense bands are points of attachment of thin actin filaments; like dense bodies, their counterpart in the cytoplasm, they consist mainly of actinin, a protein that is a major component of the Z-line in striated muscle. Intermediate 10-nm-thick filaments, consisting mainly of desmin in visceral smooth muscle, link dense bands in the membrane to dense bodies in the cytoplasm and transmit the force generated by the contractile apparatus within the

cell to the entire surface of the cell. [7]

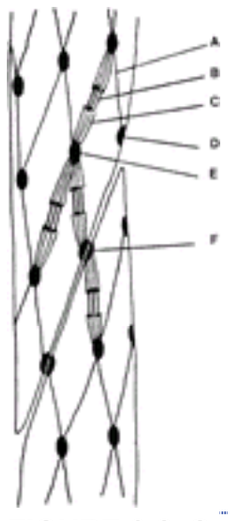

FIGURE 6-2. Organization of the contractile and cytoskeletal apparatus in smooth muscle cells. Thin actin filaments (*C*) emerge from the poles of cytoplasmic dense bodies (*E*) and interdigitate with thick myosin filaments (*B*). Dense bodies (*D*) in the plasma membrane are connected to dense bodies (*E*) in the cytoplasm by intermediate filaments (*A*). When juxtaposed, dense bodies from adjacent cells can form close intermediate junctions (*F*). (Adapted from ref. [7].)

Some dense bands are juxtaposed to dense bands in adjacent cells. At these locations, called *intermediate junctions,* the intercellular space narrows to less than 30 nm and is filled with condensed extracellular matrix (see Fig. 6-2). At other locations, dense bands in one cell are linked by collagen fibrils to dense bands in adjacent cells. Together, intermediate junctions and collagen fibrils anchor adjacent cells to each other, transmit force from one cell to the next, and couple the contractile apparatus of adjacent cells to the rest of the syncytium.

In some regions, patches of the plasma membrane of adjacent cells are closely apposed, and the space between them is reduced to less than 3 nm; the space is bridged by intercellular channels that permit free movement of ions and small molecules. These patches, known as *gap junctions* or *nexuses,* are the most likely sites of electrical coupling between muscle cells. [1], [2] and [3], [7], [8] and [9] Gap junctions permit movement of intracellular regulatory molecules, such as cyclic AMP (cAMP), inositol 1,4,5-triphosphate (IP_3), or Ca^{2+}, and they help to propagate the signal from cell to cell.

Dense bodies and contractile filaments occupy about 80% of the interior of the cell; the remainder is occupied by various organelles, including the nucleus, mitochondria, Golgi apparatus, lysosomes, and rough and smooth endoplasmic reticulum. The last, located immediately beneath and parallel to the plasma membrane, occupies 2% of the cell volume and is the site of Ca^{2+} uptake and release. [10], [11], [12] and [13] It consists of several functional compartments, only one of which is sensitive to IP_3, the membrane-derived messenger responsible for the release of intracellular Ca^{2+} (see Fig. 6-1). [14] The mitochondria, considered a low-affinity, high-capacity storage site, can take up large amounts of Ca^{2+} but only after cell injury, when cytosolic Ca^{2+} increases to more than maximal physiological levels (>1–5 µM). [15]

Contractile Apparatus: Thin and Thick Filaments

Three types of filaments can be differentiated in smooth muscle cells: thin actin filaments (5–7 nm), thick myosin filaments (15 nm), and intermediate desmin filaments (10 nm). Intermediate filaments link dense bodies in the cytoplasm to dense bands on the plasma membrane. Although the arrangement of thin, thick, and intermediate filaments and their attachments to cytoplasmic dense bodies lack the order found in striated muscle, assemblies reminiscent of primitive sarcomeres can be seen.

Thin filaments consist of actin, a ubiquitous, 42-kDa, globular protein (G actin) that polymerizes to form two-stranded helical filaments (F actin) of indeterminate length. [16] Inserted into the grooves of the actin helix is another protein, tropomyosin. Thin filaments have a distinct polarity, and they appear to be inserted into or emerge from the poles of dense bodies and are arranged in bundles that run parallel to the long axis of the cells, with their free ends surrounding and interdigitating with thick myosin filaments (see Fig. 6-2). [1], [2] and [3], [17] The insertion of thin filaments in dense bodies is analogous to that found in Z discs of striated muscle cells; in effect, dense bodies may be viewed as dispersed fragments of Z discs held together and anchored to dense bands of the cell membrane by intermediate filaments.

Thick filaments are aggregates of myosin molecules, a complex 480-kDa protein formed by the association of six different proteins. [16], [17] and [18] These proteins are not covalently linked and can be dissociated from each other into one pair of myosin heavy chains and two pairs of myosin light chains (MLCs) (Fig. 6-3). The heavy chains are coiled around each other to form a rigid, insoluble, helical core or tail. Each strand of the core terminates in a globular head surrounded by two MLCs: a 20-kDa regulatory chain and a 17-kDa essential chain. Each globular head contains a binding site for actin and an actin-activated Mg^{2+}-ATPase.

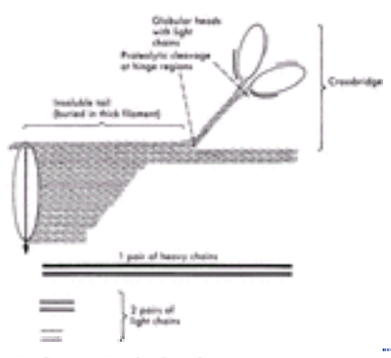

FIGURE 6-3. Component proteins of the myosin molecule. A crossbridge projects laterally from the main segment of the myosin core (i.e., tail). Each crossbridge consists of a pair of myosin heads, each surrounded by a 17-kDa and a 20-kDa myosin light chain and a laterally projecting segment of the myosin core between the two hinge regions. The cores of many myosin molecules form thick filaments with several projecting crossbridges. (Adapted from ref. [7].)

A hinge located at the junction of the globular head and the core enables the head to rotate about the core. Another hinge in the core enables the globular heads to project laterally. The globular heads and the segments of the core between the two hinges are called *crossbridges* because they constitute a link or bridge between thick myosin and thin actin filaments.

Only three to five thick filaments are surrounded by and interdigitate with a much larger number of actin filaments. The ratio of thin to thick filaments is reflected in the relative content of actin and myosin. Visceral smooth muscle contains the same amount of actin as striated muscle (22 versus 28 mg/g of cell) but a lower amount of myosin (20 versus 62 mg/g of cell). [16] Despite the low content of myosin, smooth muscle generates as much force as striated muscle (up to 6 kg/cm^2 of cross-sectional area). [7], [19]

INTERACTION OF CONTRACTILE PROTEINS

The interaction of myosin and actin with hydrolysis of ATP is the fundamental reaction whereby chemical energy is converted into mechanical energy in smooth muscle. The reaction generates force and induces shortening as a result of the sliding of overlapping, interdigitating thin and thick filaments.

Phosphorylation of Myosin Light Chain

An essential step in smooth muscle contraction is phosphorylation of the 20-kd regulatory MLC (MLC $_{20}$) by MLC kinase. [16], [20], [21], [22], [23] and [24] Several steps lead to the activation of this Ca^{2+}-dependent enzyme. An increase in cytosolic free Ca^{2+} occurs when the cell is stimulated. The increase results from the influx of Ca^{2+} into the cytosol through voltage-gated Ca^{2+} channels or from the release of Ca^{2+} into the cytosol from intracellular Ca^{2+} stores. Ca^{2+} sequentially binds to the four binding sites on the regulatory protein calmodulin; the binding of Ca^{2+}-activated calmodulin to MLC kinase forms the active complex Ca^{2+}-calmodulin–MLC kinase. Phosphorylation of MLC $_{20}$ induces a conformational change in the myosin head that greatly enhances the ability of actin to activate myosin–Mg^{2+}-ATPase and to induce the hydrolysis of ATP bound to the myosin head.

Interaction of Myosin and Actin in the Crossbridge Cycle

The interaction of myosin and actin with hydrolysis of ATP occurs in a cycle, the crossbridge cycle, the essential feature of which is a shift in the affinity of myosin for actin. [16] ATP, bound weakly to myosin, is hydrolyzed to ADP and inorganic phosphate (P_i). The products of hydrolysis remain bound to the myosin head, and the energy released is stored in the myosin molecule, which has a high affinity for actin in this state. On the release of ADP and P_i, ATP binds again to myosin, which then reverts to a state of low affinity for actin.

Several models have been proposed to describe how the interaction between phosphorylated myosin heads and actin filaments could generate force, filament movement, and cell shortening. [16], [25] According to one model (Fig. 6-4), the myosin crossbridge (which includes the myosin head, associated MLCs, and a segment of the myosin core) with ATP bound to the myosin head (myosin·ATP) is detached or weakly bound to actin. Hydrolysis of ATP by myosin–Mg^{2+}-ATPase yields a myosin intermediate (myosin·ADP·P_i). Release of P_i from this intermediate is the force-generating step that causes a transition from weak to strong binding of myosin and actin (actin·myosin·ADP) and a change from 90° to 45° in the angle of the myosin head. The change of angle imposes a strain on the crossbridge that is relieved when the actin molecule slides past the crossbridge. In the next step, ADP is released from the myosin head. This step occurs slowly in smooth muscle and limits the velocity of shortening. In smooth muscle, myosin therefore remains bound to actin for a longer period, and it generates more force with less consumption of energy than in striated muscle. After release of ADP, the myosin head is free to rebind ATP (myosin·ATP) and reverts to a 90° angle in which it is weakly bound to the next actin molecule for the start of another cycle.

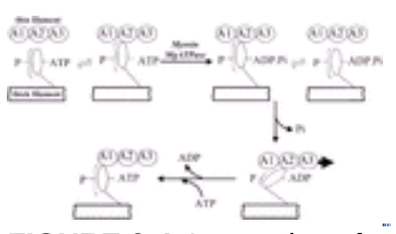

FIGURE 6-4. Interaction of myosin and actin filaments: the crossbridge cycle. At the start of the cycle, the myosin head with ATP bound to it (*myosin·ATP*) is detached or is weakly attached to an actin molecule (*A2*) in the thin filament. Hydrolysis of ATP by the myosin–Mg^{2+}-ATPase yields an intermediate with the products of hydrolysis still bound to it (*myosin·ADP·*P_i); the intermediate is detached or weakly bound to the actin molecule. Release of P_i in the next step causes a transition from weak to strong binding of myosin and actin (*actin·myosin·ADP*) and a change from 90° to 45° in the angle of the myosin head. The strain imposed on the crossbridge by the change of angle is relieved when the actin molecule slides past the crossbridge. ADP is released slowly; the myosin head rebinds ATP (*myosin·ATP*) and reverts to a 90° angle facing the next actin molecule (*A1*) for the start of another cycle. Dephosphorylation of the myosin light chain surrounding a bound myosin head yields a strongly attached, slowly cycling, latch crossbridge. The interaction of only one myosin head in the crossbridge is illustrated. P_i, inorganic phosphate. (Adapted from ref. [16].)

The force generated by crossbridge cycling depends on the number of crossbridges acting in parallel. Because the crossbridges do not cycle in unison, the contraction induced by their concerted action is slow and continuous. Force and shortening velocity depend on the stimulus in smooth muscle; this finding implies that, unlike in striated muscle, the number and cycling rate of activated crossbridges in smooth muscle are regulated.

Crossbridge cycling ceases after the stimulus is withdrawn. Cytosolic Ca^{2+}, MLC kinase activity, and MLC $_{20}$ phosphorylation revert to their resting levels, and the dephosphorylated myosin crossbridges are arrested in a detached state that is characteristic of relaxed muscle. [19], [26]

A different pattern of crossbridge cycling is observed during sustained (i.e., tonic) contraction of smooth muscle. A rapid increase in cytosolic Ca^{2+}, MLC kinase activity, MLC $_{20}$ phosphorylation, and shortening velocity during the initial phase reflects a rapid crossbridge cycling rate; these events precede but are correlated with the increase in muscle tension. [19], [22], [26] Within seconds, despite continued stimulation, cytosolic Ca^{2+} levels and MLC kinase activity decrease to very low levels, whereas MLC $_{20}$ phosphorylation and muscle contraction decrease only slightly (Fig. 6-5). [27] This type of contraction is functionally useful in muscle that is required to maintain the dimensions of a hollow organ against imposed loads with minimal energy consumption. [19]

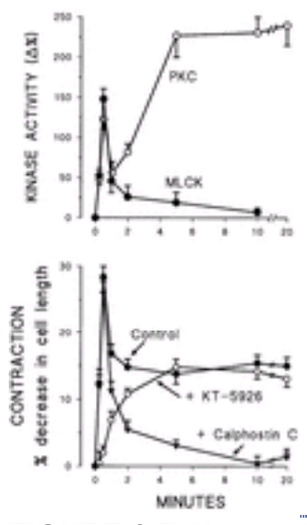

FIGURE 6-5. Upper panel: Time course of activation of protein kinase C (*PKC*) and myosin light-chain kinase (*MLCK*). MLCK activity occurs mainly during the initial phase of contraction. PKC activity is derived from phosphoinositide hydrolysis by PLC-ß during the initial phase and from phosphatidylcholine hydrolysis by phospholipase D during the sustained phase. **Lower panel:** Initial contraction is mediated by Ca^{2+}/calmodulin–dependent activation of MLCK and is inhibited by the MLCK inhibitor, KT-5926; sustained contraction is mediated by PKC and is inhibited by the PKC inhibitor, calphostin C. See details of the pathways in the text and in

Figure 6-6.

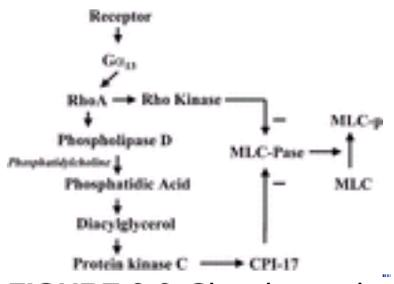

FIGURE 6-6. Signal transduction pathway mediating sustained contraction of smooth muscle. The pathway involves activation of the a subunit of G_{13}, RhoA and its associated kinase, and phospholipase D. Hydrolysis of phosphatidylcholine by phospholipase D generates phosphatidic acid, which is dephosphorylated to diacylglycerol, with resulting activation of protein kinase C. Protein kinase C potently activates CPI-17, an endogenous inhibitor of myosin light chain (*MLC*) phosphatase activity, thereby maintaining MLC phosphorylation (*MLC-p*). A parallel pathway links Rho kinase to the inhibition of MLC phosphatase.

Sustained MLC_{20} phosphorylation and contraction are now known to be Ca^{2+}-independent. MLC_{20} phosphorylation is determined by a signaling pathway that involves sequential activation of the heterotrimeric G protein, G_{13}, and the monomeric G protein, RhoA, followed by activation of Rho kinase, phospholipase D, and one or more isoforms of protein kinase C (PKCe with agonists and PKCa with growth factors), which results in inhibition of MLC phosphatase and maintenance of MLC_{20} phosphorylation and contraction (Fig. 6-6). [28], [29], [30] and [31] An endogenous 17-kd inhibitory protein, CPI-17, that is greatly activated by PKC and inhibits the catalytic subunit of MLC phosphatase, provides the link between PKC activation and MLC phosphatase inhibition. [32], [33]

Unlike tonic contraction, phasic (rhythmic) contraction increases and decreases rapidly in phase with the influx and efflux of Ca^{2+}, driven by rhythmic changes in membrane potential and the opening and closure of voltage-gated ionic channels. A closer correlation prevails during phasic activity among Ca^{2+} levels, MLC kinase activity, MLC_{20} phosphorylation, crossbridge cycling rate, and contraction. Consequently, more energy is required to sustain phasic contraction. Energy is saved, however, because phasic contractile activity usually is maintained in abeyance by a dominant inhibitory neural input.

SIGNAL TRANSDUCTION IN VISCERAL SMOOTH MUSCLE

Source of Activator Calcium

The concentration of Ca^{2+} in the cytosol is the essential determinant of the initial, transient phase of smooth muscle contraction. Two agonist-driven mechanisms lead to an increase in cytosolic Ca^{2+} during contraction. In the first, interaction of a contractile agonist with its receptor on the plasma membrane generates a messenger that causes the release of Ca^{2+} from intracellular stores. In the second, interaction of the contractile agonist with its receptor generates a messenger that induces depolarization of the plasma membrane, which opens voltage-gated Ca^{2+} channels and causes Ca^{2+} influx, followed by Ca^{2+}-induced Ca^{2+} release. The first mechanism occurs in the circular muscle layer, the second in the longitudinal muscle layer. Spontaneous depolarization of the plasma membrane by slow waves or spike potentials can open voltage-gated Ca^{2+} channels in muscle from both layers. By increasing the frequency or amplitude of these depolarizing events, agonists can cause further increase in Ca^{2+} influx through voltage-gated Ca^{2+} channels.

Components of the Transduction Pathway

The transduction of an external signal, such as a neurotransmitter or a hormone, into an internal signal involves sequential activation of three membrane proteins: a receptor and a guanosine triphosphate (GTP)–binding protein (G protein) that couples the receptor to a specific effector enzyme. The effector enzyme acts on membrane-bound or cytoplasmic precursors to generate one or more regulatory signals or second messengers (Fig. 6-7 and Fig. 6-8; see Fig. 6-6).

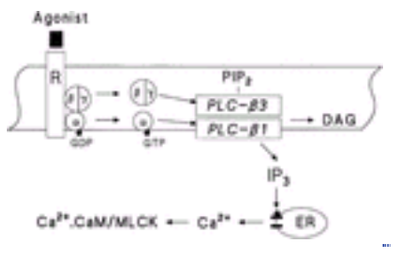

FIGURE 6-7. Signal transduction pathway for Ca^{2+} mobilization in smooth muscle cells of the circular muscle layer during the initial phase of contraction. The sequence involves binding of an agonist to a specific receptor, activation of a transducing G protein and binding of guanosine triphosphate (*GTP*) to its mobile a subunit, and dissociation of the ß? subunits. For receptors that couple to G_q (e.g., CCK-A, muscarinic M_3, 5-HT_2), Ga_q activates phospholipase Cß1 (PLC-ß1); for receptors that couple to G_i, (e.g., muscarinic M_2, adenosine A_1, opioid µ, ?, and d) G_{i}ß? activates PLC-ß3. In circular muscle cells, the immediate substrate hydrolyzed by PLC-ß1 or PLC-ß3 is phosphatidylinositol 4,5-bisphosphate (PIP_2), yielding inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (*DAG*) as second messengers. IP_3 diffuses through the cytosol to interact with IP_3 receptors–Ca^{2+} channels on the membrane of the endoplasmic reticulum (*ER*), causing release of Ca^{2+} into the cytosol. Ca^{2+} binds to calmodulin (*CaM*), and the complex activates MLC kinase (*MLCK*). (See refs. [41] and [55].)

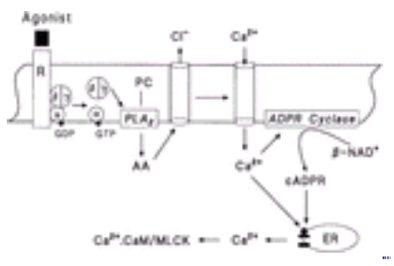

FIGURE 6-8. Signal transduction pathway for Ca^{2+} mobilization in smooth muscle cells of the longitudinal muscle layer during the initial phase of contraction. The sequence involves activation of phospholipase A_2 (PLA_2) by Gß? and hydrolysis of membrane-bound phosphatidylcholine (*PC*) to yield arachidonic acid (*AA*) and lysophosphatidylcholine. Arachidonic acid activates chloride (Cl^-) channels causing Cl^- efflux from the cell, resulting in depolarization of the plasma membrane, opening of voltage-gated Ca^{2+} channels, and Ca^{2+} influx into the cell. The resultant increase in cytosolic Ca^{2+} stimulates Ca^{2+} release (i.e., Ca^{2+}-induced Ca^{2+} release) from endoplasmic Ca^{2+} stores through ryanodine-sensitive receptor–Ca^{2+} channels. In addition, Ca^{2+} activates a membrane-bound ADP–ribosyl cyclase (*ADPR cyclase*) that synthesizes cyclic ADP ribose (*cADPR*) from ß-nicotinamide adenine dinucleotide (ß-NAD^+). cADPR acts as a Ca^{2+}-mobilizing messenger, stimulating Ca^{2+} release by directly activating ryanodine receptor–Ca^{2+} channels and by potentiating Ca^{2+}-induced Ca^{2+} release. (See refs. [57] and [59].)

Receptors consist of external, membrane-spanning, and cytoplasmic domains with features that determine which specific ligand they bind or agonist they recognize and which G protein or membrane enzyme they activate. [34], [35]

G proteins are a large family of closely related proteins that act as signal transducers. [36], [37] Among these are G proteins that stimulate (G_s) or inhibit (G_i and G_o) adenylate cyclase activity and G proteins that stimulate phospholipase C (PLC) activity (G_q). G proteins are heterotrimeric with subunits designated a, ß, and ? in order of decreasing mass. The a subunit (Ga), which serves to differentiate G proteins, contains a single, high-affinity binding site for GTP and possesses GTPase activity; the latter is crucial for terminating the action of G proteins. In the basal state, guanosine diphosphate (GDP) is tightly bound to the a subunit. The binding of a ligand to its receptor enables the ligand-receptor complex to interact with the G protein and stimulate the dissociation of GDP; this opens up a site that is rapidly filled with abundant cytoplasmic GTP. The binding of GTP to the ligand-receptor–G-protein complex causes the following:

1. A decrease in the affinity of the ligand for the receptor and of the receptor for the G protein, thus freeing the receptor for a new cycle of ligand and G-protein binding
2. A decrease in the affinity of the a subunit for the ß? subunit, resulting in the dissociation of a Ga-GTP complex and a ß? dimer that activate different effector enzymes.

The hydrolysis of GTP by the intrinsic GTPase activity of the Ga-GTP complex terminates the activity of the complex; the inactive Ga-GDP complex binds to and inactivates ß? and enables the reassociation of the a, ß, and ? subunits. The slow hydrolysis of GTP is accelerated by two classes of GTPase-activating proteins (GAPs): one class includes effector enzymes such as PLC-ß; the other consists of a group of Ga-GAPs, also known as *regulators of G-protein signaling* (RGS). Certain RGS proteins have been identified that appear to be specific for various a subunits.

G proteins act as transducers that conduct and amplify the external signal and as adapters that allow the same receptor to be coupled to different effector enzymes. The initial focus on a subunits has shifted with the realization that ß? subunits can also activate or inhibit effector enzymes. The involvement of a or ß? subunits depends on the specific receptor activated (see later).

Effector Enzymes and Second Messengers

Several effector enzymes capable of yielding different messengers are involved in the regulation of smooth muscle contraction. They include PLC-ß isoforms, which are activated by the a subunit of G_q or the ß? subunits of G_i and G_o (see Fig. 6-7), phospholipase A_2 (PLA_2), which is activated by G_i (see Fig. 6-8); and phospholipase D, which is activated during the sustained phase of contraction by the a subunit of G_{13} and RhoA (see Fig. 6-6). All can hydrolyze membrane-bound phospholipids. In most cell types, the effector enzyme activated by agonists capable of mobilizing intracellular Ca^{2+} is one of several isoforms of PLC-ß (i.e., PLC-ß1, PLC-ß2, PLC-ß3, and PLC-ß4); the isozymes hydrolyze inositol phospholipids located on the inner leaflet of the plasma membrane. [14], [38], [39], [40], [41] and [42] These phospholipids are products of the sequential phosphorylation of phosphatidylinositol (PI) to phosphatidylinositol monophosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2). The last is the immediate substrate hydrolyzed by PLC-ß.

The hydrolysis of PIP_2 generates two messengers: a water-soluble inositol phosphate, IP_3, which diffuses into the cytosol to activate IP_3 receptor–Ca^{2+} channels located in a compartment of the endoplasmic reticulum; and diacylglycerol, which activates various Ca^{2+}-dependent (e.g., a, ß, ?) and Ca^{2+}-independent (e.g., e) isoforms of PKC and initiates their translocation from the cytosol to the plasma membrane (see Fig. 6-7). [40] IP_3 can be converted by sequential phosphorylation to IP_4, IP_5, or IP_6 or by dephosphorylation to IP_2, IP, and inositol. The metabolic products of the two messengers eventually merge to reconstitute PI. Partial depletion of Ca^{2+} stores by IP_3 triggers Ca^{2+} influx into the cell—a process known as capacitative Ca^{2+} influx—and leads to Ca^{2+} release from adjacent Ca^{2+} stores (i.e., Ca^{2+}-induced Ca^{2+} release). The process is manifested by localized changes in Ca^{2+} concentrations (Ca^{2+} oscillations) that sweep through the cell at intervals of 5 to 60 seconds, and it is most effective in the presence of IP_3. [14], [43] IP_3 and Ca^{2+} can flow rapidly (about 10 µm/s) through gap junctions to neighboring cells, propagating the intracellular signal and providing a means for sustained or oscillatory response of the tissue as a whole.

The IP_3 receptor–Ca^{2+} channel is homologous to the ryanodine receptor–Ca^{2+} channel in skeletal and cardiac muscle. [44], [45] and [46] Both receptor types consist of four subunits surrounding a Ca^{2+} channel; each subunit contains a large N-terminal cytoplasmic domain that includes binding sites for IP_3 and Ca^{2+} and the site for regulatory phosphorylation (i.e., inactivation) by cGMP-dependent protein kinases (PKG and PKA). The cytoplasmic domain appears to bridge the space between the endoplasmic and plasma membranes and is postulated to participate in mediating capacitative Ca^{2+} influx. [47]

The involvement of IP_3 in Ca^{2+} mobilization is confined to circular smooth muscle. In longitudinal smooth muscle, Ca^{2+} mobilization involves PLA_2, which hydrolyzes the membrane phospholipid phosphatidylcholine to yield arachidonic acid and lysophosphatidylcholine (see later).

Mobilization of Calcium in Cells of the Circular Muscle Layer

The transduction pathway initiated by the hydrolysis of PIP_2 is fully expressed in cells from the circular muscle layer of the stomach, intestine, gallbladder, and various sphincters. The various steps in this pathway have been examined in detail in dispersed muscle cells devoid of neural elements. The cellular homogeneity of the suspension makes it possible to characterize receptors and intracellular messengers, such as IP_3, diacylglycerol, cytosolic Ca^{2+}, and cyclic nucleotides, and to determine their coupling to mechanical responses, such as contraction and relaxation. [12], [13], [47], [48], [49], [50] and [51]

The exposure of cells derived from the circular muscle layer to a contractile agonist induces rapid contraction (i.e., cell shortening) accompanied by a transient increase in IP_3, cytosolic Ca^{2+}, and Ca^{2+} release (Fig. 6-9 *A*). [12], [13], [51], [52] and [53] These events are closely correlated, and their magnitudes depend on agonist concentration (Fig. 6-9B). The initial increase in IP_3 and Ca^{2+} is followed by the slow reuptake of Ca^{2+} into the cell (capacitative Ca^{2+} influx). The withdrawal of Ca^{2+} from the medium or the addition of Ca^{2+} channel blockers has no effect on the initial increase in Ca^{2+}, but it blocks Ca^{2+} influx. The pattern of response in muscle cells from the circular muscle layer implies that contractile agonists elicit an initial contraction by means of G-protein–dependent activation of PLC-ß, hydrolysis of membrane-bound PIP_2, and generation of IP_3; the latter diffuses through the cytosol to interact with sarcoplasmic IP_3 receptor–Ca^{2+} channels to induce Ca^{2+} release and a transient increase in Ca^{2+}. Depletion of Ca^{2+} stores triggers capacitative Ca^{2+} influx.

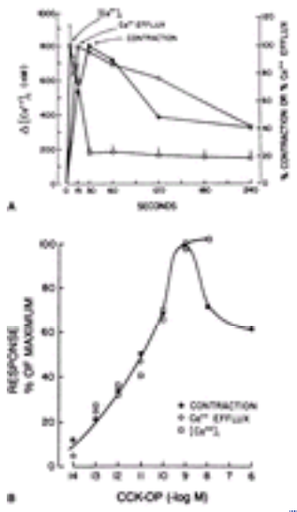

FIGURE 6-9. Time course (**A**) and stoichiometry (**B**) of contraction, cytosolic Ca $^{2+}$ ($[Ca^{2+}]_i$), and Ca $^{2+}$ release from endoplasmic stores, in smooth muscle cells isolated from guinea pig stomach in response to cholecystokinin octapeptide (*CCK-OP*). Similar results are obtained for muscle cells from human stomach and intestine using other agonists. (From ref. [51].)

Studies using a variety of probes confirm this sequence. Direct activation of G proteins by sodium fluoride or GTP?S mimics the effects of receptor-linked agonists, by causing contraction and an increase in IP $_3$ and cytosolic Ca $^{2+}$ levels; the effects of GTP?S, like those of agonists, are abolished by GDPßS. [53], [54] Exogenous IP $_3$ causes contraction (median effective concentration, EC $_{50}$ 0.3 µM), Ca $^{2+}$ release, and an increase in cytosolic Ca $^{2+}$. [13], [53] The responses to IP $_3$, GTP?S, and agonists are inhibited by heparin, which blocks IP $_3$-induced Ca $^{2+}$ release. [53], [54] and [55] In permeabilized muscle cells and in microsomal fractions, IP $_3$, but not other inositol phosphates, binds with high affinity to specific IP $_3$ receptors, and its binding is accompanied by Ca $^{2+}$ release. [55] Although most receptors use G $_q$a and PLC-ß1 to mediate PIP $_2$ hydrolysis, others use G $_{i/o}$ß? and PLC-ß3. Cholecystokinin (CCK) acting through CCK-A receptors, serotonin (5-hydroxytryptamine, 5-HT) through 5-HT $_2$ receptors, and tachykinins through NK $_1$ and NK $_2$ receptors preferentially activate PLC-ß1 through Ga $_q$, whereas somatostatin acting through sst $_3$ receptors, opioid peptides through µ, d, and ? receptors, adenosine through A $_1$receptors, and ATP and uridine triphosphate through P $_{2Y2}$ receptors preferentially activate PLC-ß3 through the ß? subunits of G $_{i1}$, G $_{i2}$, or G $_{i3}$. Acetylcholine acting through muscarinic M $_3$ receptors activates PLC-ß1 through Gaq, and, acting through M $_2$ receptors, it activates PLC-ß3 through the ß? subunits of G $_{i3}$. [53]

Mobilization of Calcium in Cells of the Longitudinal Muscle Layer

The pattern of inositol phospholipid metabolism in longitudinal muscle differs markedly from that in circular muscle. Only a small amount of IP $_3$ is generated in longitudinal muscle, less than 10% of that generated in circular muscle. The preferred substrate is PIP, which yields the inactive IP $_2$ and diacylglycerol. [41], [53], [54], [55], [56] and [57] IP $_3$ does not bind to the endoplasmic and sarcoplasmic membranes of longitudinal muscle cells or cause Ca $^{2+}$ release at maximal concentrations (1 µM); partial Ca $^{2+}$ release is elicited at supramaximal concentrations (10–50 µM).

Contraction and the increase in cytosolic Ca $^{2+}$ induced by agonists in muscle cells from the longitudinal muscle layer are IP $_3$-independent and are abolished in Ca $^{2+}$-free medium or in the presence of Ca $^{2+}$ channel blockers, implying that an initial step involving Ca $^{2+}$ influx is a prerequisite for Ca $^{2+}$ mobilization in these cells. [44], [47], [48] and [49] The initial influx of Ca $^{2+}$ acts as a trigger for Ca $^{2+}$ release from intracellular stores (i.e., Ca $^{2+}$-induced Ca $^{2+}$ release) (see Fig. 6-8). These stores are highly sensitive to Ca $^{2+}$ alone; increments of cytosolic Ca $^{2+}$ in the physiological range (100–500 nM) trigger Ca $^{2+}$ release. In contrast, Ca $^{2+}$ stores in circular muscle develop high sensitivity to Ca $^{2+}$ only in the presence of IP $_3$. Ryanodine, a specific ligand of ryanodine receptor–Ca $^{2+}$ channels in skeletal and cardiac muscle, binds with high affinity to the sarcoplasmic membranes of longitudinal muscle cells and induces Ca $^{2+}$ release (EC $_{50}$ 2 nM) and contraction (EC $_{50}$ 1 nM). [56] The characteristics of ryanodine binding and Ca $^{2+}$ release in longitudinal muscle cells are similar to those in cardiac muscle cells. [44]

The messenger responsible for initiating Ca $^{2+}$ mobilization in longitudinal muscle cells is arachidonic acid, a product of the hydrolysis of phosphatidylcholine by PLA $_2$ (see Fig. 6-8). An initial agonist-induced, G-protein–mediated activation of PLA $_2$ occurs in longitudinal, but not circular, muscle cells. [57] Suppression of PLA $_2$ activity by selective inhibitors abolishes contraction and the increase in cytosolic Ca $^{2+}$ induced by agonists in longitudinal muscle cells. Arachidonic acid in nanomolar concentrations mimics the effect of contractile agonists and causes an increase in cytosolic Ca $^{2+}$ that is abolished by Ca $^{2+}$ channel blockers. The increase in Ca $^{2+}$ reflects arachidonic acid–dependent Ca $^{2+}$ influx followed by Ca $^{2+}$-induced Ca $^{2+}$ release from intracellular stores. Depletion of Ca $^{2+}$ stores attenuates the increase in cytosolic Ca $^{2+}$ by eliminating the component resulting from Ca $^{2+}$-induced Ca $^{2+}$ release; the residual increase in Ca $^{2+}$ reflects the initial step, that is, arachidonic acid–dependent Ca $^{2+}$ influx. Ca $^{2+}$ influx results from activation of Cl $^-$ channels by arachidonic acid, which leads to depolarization of the plasma membrane and opening of voltage-sensitive Ca $^{2+}$ channels (see Fig. 6-8). [58]

The ryanodine receptor–Ca $^{2+}$ channels in longitudinal muscle cells are highly sensitive to cyclic ADP-ribose (cADPR), a product of the hydrolysis of ß-nicotinamide adenine dinucleotide (ß-NAD+) by ADP–ribosyl cyclase, a membrane-bound enzyme present in longitudinal, but not circular, muscle cells (see Fig. 6-8). [59] cADPR formation is stimulated in a concentration-dependent fashion by contractile agonists in longitudinal, but not circular, muscle cells. It binds with high affinity to microsomes (IC $_{50}$ 2 nM), stimulates Ca $^{2+}$ release (EC $_{50}$ 4 nM) by itself, and potentiates Ca $^{2+}$-induced Ca $^{2+}$ release.

In summary, Ca $^{2+}$ mobilization in longitudinal muscle is mediated by an IP $_3$-independent mechanism, initiated by G $_i$-dependent activation of PLA $_2$ and generation of arachidonic acid; the latter activates Cl $^-$ channels and thus causes depolarization of the plasma membrane and opening of voltage-sensitive Ca $^{2+}$ channels. Ca $^{2+}$ influx through these channels induces Ca $^{2+}$ release by activating sarcoplasmic ryanodine receptor–Ca $^{2+}$ channels. Concomitant activation of membrane-bound ADP–ribosyl cyclase generates cADPR, which potentiates Ca $^{2+}$-induced Ca $^{2+}$ release.

Regulation of Cytosolic Calcium at Rest and During Contraction

Resting and agonist-stimulated cytosolic Ca $^{2+}$ concentrations in cells from the longitudinal and circular muscle layers are remarkably similar in various species (e.g., human, guinea pig, rabbit). [13], [53], [54], [55], [56], [57], [58] and [59] Resting levels (70–100 nM) increase two- to threefold during half-maximal contraction and six- to eightfold during maximal contraction. Exposure of permeabilized muscle cells to these concentrations of Ca $^{2+}$ elicits degrees of contraction similar to those elicited by agonists in intact muscle cells.

Smooth muscle cells, like other cells, possess efficient mechanisms to dispose of the Ca $^{2+}$ transients that occur during contraction. In the resting state, the cells maintain low concentrations of Ca $^{2+}$ in the cytosol despite large chemical (e.g., 2 mM Ca $^{2+}$ outside versus 100 nM Ca $^{2+}$ inside the cell) and electrical (e.g., membrane potential of -40 to -80 mV) gradients favoring the movement of Ca $^{2+}$ into the cell. The gradient for Ca $^{2+}$ is maintained because of low permeability of the plasma membrane to Ca $^{2+}$, the presence of efficient Ca $^{2+}$ extrusion mechanisms in the plasma membrane, and a Ca $^{2+}$ uptake mechanism in the endoplasmic reticulum. The Ca $^{2+}$ extrusion mechanisms in the plasma membrane include a calmodulin-dependent Ca $^{2+}$, Mg $^{2+}$-ATPase, which acts as a high-affinity Ca $^{2+}$ pump sustained by ATP hydrolysis that responds to low Ca $^{2+}$ concentrations, similar to those that occur during contraction, and a low-affinity, high-capacity Na $^+$-Ca $^{2+}$ exchanger sustained by the Na $^+$ gradient across the plasma membrane that responds to more drastic changes in cytosolic Ca $^{2+}$ concentrations.

The Ca $^{2+}$ uptake mechanism into the endoplasmic Ca $^{2+}$ stores is also a high-affinity Ca $^{2+}$-ATPase pump, and it participates in dissipating the Ca $^{2+}$ transients

during contraction. However, most of the Ca^{2+} required to replenish endoplasmic Ca^{2+} stores enters the cell from the outside through voltage-gated Ca^{2+} channels in smooth muscle.

Mechanisms of Relaxation by PKA and PKG

Inhibition of initial contraction (i.e., relaxation) results from inhibition of the initial Ca^{2+} transient. Most agents cause relaxation by stimulating the production of cAMP (e.g., ß–adrenergic agonists), cGMP (e.g., nitric oxide [NO]), or both cAMP and cGMP (e.g., vasoactive intestinal polypeptide [VIP] and pituitary adenylate cyclase–activating peptide [PACAP]), leading to the activation of PKA, PKG, or both. [60], [61], [62], [63], [64], [65], [66], [67], [68] and [69] The levels of cAMP and cGMP in gastrointestinal smooth muscle are regulated by the combined activities of cyclases (i.e., membrane-bound adenylate cyclases types V and VI and soluble guanylate cyclase) and phosphodiesterases (PDEs). [70], [71], [72] and [73] Cyclic AMP, which is produced in amounts 10 to 15 times greater than cGMP, is rapidly degraded by cAMP-specific PDE3 and PDE4. [70], [71] Both enzymes are activated by PKA, but only PDE3 is inhibited by cGMP. cGMP is rapidly degraded by cGMP-specific PDE5, which is activated by PKG, and when present, also by PKA. [71], [72] Each protein kinase selectively inhibits the activity of the corresponding synthetic enzyme: PKA inhibits adenylate cyclase, and PKG inhibits soluble guanylate cyclase. [70], [72] Thus, regulatory feedback from the protein kinases inhibits synthesis and accelerates degradation, thereby maintaining levels of cyclic nucleotides within narrow ranges. The interplay of protein kinases, cyclases, and PDEs in the regulation of cyclic nucleotide levels in smooth muscle is depicted in Fig. 6-10.

FIGURE 6-10. Interplay of adenylate and guanylate cyclases with cyclic nucleotide–dependent phosphodiesterases (*PDE*) and protein kinases. Concurrent release of nitric oxide (NO), vasoactive intestinal polypeptide (VIP), and pituitary adenylate cyclase–activating peptide (PACAP) is the physiological norm in gastrointestinal smooth muscle, leading to activation of adenylate cyclase type V/VI (*AC V/VI*) and soluble guanylate cyclase (*sGC*). This leads to concurrent generation of cyclic AMP (cAMP) and cyclic GMP (cGMP) and activation of both cAMP-dependent and cGMP-dependent protein kinases (*PKA* and *PKG*). PKA activates cAMP-specific phosphodiesterase 3 and 4 (*PDE3* and *PDE4*) and inhibits adenylate cyclase activity, thus stimulating degradation and inhibiting further synthesis of cAMP. PKG activates cGMP-specific PDE5 and inhibits soluble guanylate cyclase activity, thus stimulating degradation and inhibiting further synthesis of GMP. PDE5 is further activated by PKA, whereas PDE3 is inhibited by cGMP. Thus, concurrent generation of cAMP and cGMP leads to enhancement of cAMP levels (through inhibition of PDE3 by cGMP) and attenuation of cGMP levels (through activation of PDE5 by PKA). Furthermore, the affinity of cAMP for, and its ability to activate, PKG is greatly enhanced in the presence of cGMP. Because cAMP is present in 10 to 15 times greater abundance than cGMP, it becomes the main activator of PKG. (From ref. [70]. See also ref. [72].)

Although cAMP preferentially activates PKA, it can, at higher concentrations (e.g., with high concentrations of relaxant agonists) also cross-activate PKG (see Fig. 6-10). [68] An increase in both cAMP and cGMP, such as that brought about by corelease of NO, VIP, PACAP, and peptide histidine isoleucine (PHI; *P*eptide with N-terminal *H*istidine and C-terminal *I*soleucine) from the same or adjacent nerve terminals, is the physiological norm during nerve-induced relaxation in the gut. Inhibition of PDE3 by cGMP enhances cAMP levels, whereas activation of PDE5 by PKA and PKG attenuates cGMP levels. Autophosphorylation of PKG by cGMP greatly increases its affinity for the more abundant cAMP. Under these conditions, PKG is activated by both cGMP and cAMP. [73]

Although both PKA and PKG decrease cytosolic Ca^{2+}, they do so by different mechanisms. [53], [66] Common and distinctive cellular targets of PKA and PKG in smooth muscle are depicted in Fig. 6-11. Both protein kinases can inhibit Ca^{2+} mobilization by inhibiting IP_3 formation in circular muscle and arachidonic acid formation in longitudinal muscle. Both also inhibit the activity of membrane Ca^{2+} channels and stimulate the activity of membrane K^+ channels, leading to hyperpolarization of the plasma membrane and interruption of capacitative Ca^{2+} influx into the cell. However, only PKG can phosphorylate the sarcoplasmic/endoplasmic Ca^{2+}/ATPase pump and can accelerate Ca^{2+} reuptake into the stores. [66] Both PKA and PKG can phosphorylate the IP_3 receptor in vitro or in permeabilized smooth muscle cells, but only PKG can phosphorylate the IP_3 receptor in vivo and can thus inhibit IP_3-induced Ca^{2+} release, implying that PKA does not gain access to the IP_3 receptor under physiological conditions. [66], [68], [74] In summary, both PKA and PKG can inhibit the formation of Ca^{2+}-mobilizing messengers, but only PKG can directly inhibit IP_3-induced Ca^{2+} release in circular muscle by phosphorylating the IP_3 receptor–Ca^{2+} channel. PKG likely inhibits Ca^{2+}-induced Ca^{2+} release in longitudinal muscle by phosphorylating the ryanodine receptor–Ca^{2+} channel.

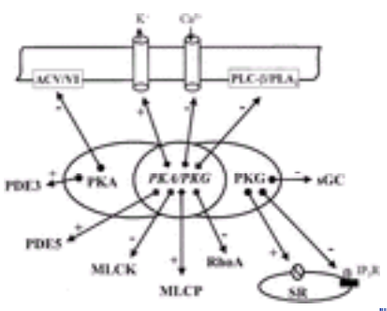

FIGURE 6-11. Distinct and shared cellular targets of cyclic AMP (cAMP)- and cyclic GMP (cGMP)-dependent protein kinases (*PKA* and *PKG*). Only PKA activates cAMP-specific phosphodiesterases 3 and 4 (*PDE3* and *PDE4*) and inhibits adenylate cyclase type V/VI (*ACV/VI*), thus attenuating cAMP levels. Only PKG inhibits soluble guanylate cyclase (*sGC*) activity, stimulates Ca^{2+} uptake into the sarcoplasmic reticulum stores, and inhibits sarcoplasmic Ca^{2+} channels. Other targets are shared by both protein kinases. As shown, either one or both kinases decrease cytosolic Ca^{2+} levels by the following: (*1*) inhibiting the activity of phospholipase C ß (*PLC-ß*) in circular muscle and PLA_2 in longitudinal muscle, thereby diminishing the synthesis of Ca^{2+}-mobilizing messengers; (*2*) inhibiting Ca^{2+} release from sarcoplasmic Ca^{2+} stores (*SR*) by phosphorylating inositol 1,4,5-triphosphate (IP_3) and ryanodine receptors/Ca^{2+} channels; (*3*) stimulating Ca^{2+} uptake into stores by activating the endoplasmic and sarcoplasmic Ca^{2+}-ATPase pump; (*4*) inhibiting the activity of plasmalemmal Ca^{2+} channels; and (*5*) stimulating the activity of plasmalemmal K^+ channels. The resultant hyperpolarization causes further inactivation of plasmalemmal Ca^{2+} channels and suppresses Ca^{2+} influx into the cell. Both PKA and PKG inhibit Ca^{2+}-calmodulin–dependent myosin light chain (MLC) kinase (*MLCK*) activity and stimulate MLC phosphatase (*MLCP*) activity, thereby decreasing MLC phosphorylation during the initial and sustained phases of contraction, and both kinases inhibit RhoA activity, thereby interrupting the pathway that mediates sustained contraction. The net effects of PKA and PKG are to inhibit muscle contraction and to induce relaxation.

In addition to affecting the level of cytosolic Ca^{2+}, PKA and PKG can affect the action of Ca^{2+} by phosphorylating MLC kinase, and thereby decreasing its sensitivity to activation by the Ca^{2+}-calmodulin complex, and by phosphorylating MLC phosphatase, and thus enhancing its activity (see Fig. 6-11). [75], [76] Inhibition of sustained contraction, which as previously noted is Ca^{2+}-independent, can be brought about by phosphorylation of RhoA or phosphorylation of MLC phosphatase through both PKA and PKG. [77], [78]

ELECTRICAL PROPERTIES OF SMOOTH MUSCLE

Resting Membrane Potential

The *resting membrane potential,* defined as the steady-state potential at which the net flow of current (i.e., ions) across the plasma membrane is zero, varies from about -40 to -80 mV in muscle cells of the gut. [79], [80], [81], [82] and [83] Graded differences in resting membrane potential exist between muscle cells in different regions, such as the fundus, corpus, and antrum of the stomach, and between muscle cells located at different depths in the same region, such as cells near the myenteric border and cells near the submucosal border of circular muscle in the antrum or colon.

The membrane potential is largely determined by the activity of the Na^+-K^+ pump (i.e., Na^+, K^+-ATPase), which sets up diffusion gradients for K^+ (162 mM inside versus 5 mM outside) and Na^+ (136 mM outside versus 14 mM inside) across the membrane. The permeability of the membrane to K^+ is much greater than to Na^+, and the flow of K^+ ions down their electrochemical gradient creates a diffusion potential that is the major contributor to the resting membrane potential. K^+ ions flow through passive K^+-selective channels that remain open at rest. [84]

In addition to setting up ionic gradients, the Na^+-K^+ pump is electrogenic, moving three Na^+ ions out of the cell for every two K^+ ions into the cell; the net outward flow of positive charge can contribute up to 30 mV to the resting membrane potential. Variability in the direct contribution of this pump may account for regional differences in resting membrane potential. A Cl^- pump, which maintains low Cl^- concentrations (55 mM) in the cell, can contribute up to 10 mV to the resting membrane potential; its effect is partly offset by the tendency of Cl^- ions to diffuse out of the cell.

Gated Ion-Selective Channels

In addition to passive ion-selective channels, the plasma membrane contains ion-selective channels that can be regulated by membrane potential (i.e., voltage-gated channels) and by various humoral, hormonal, or neural agents (i.e., agonist- or ligand-gated channels). Ligands can activate channels directly and through G proteins in the membrane. Ligands can also activate, inhibit, or modulate voltage-gated channels through second messengers.

Channels in the plasma membrane usually are selective for one ion, such as K^+ or Ca^{2+}, although some allow the passage of more than one ion. The two main types of ion channels involved in the regulation of rhythmic activity of smooth muscle of the gut are selective for K^+ or Ca^{2+}. The properties of Ca^{2+} and K^+ channels were first characterized in amphibian gastric muscle cells [85], [86] and [87] and subsequently in muscle cells from various regions of the mammalian gut. [89], [90], [91] and [92] The flow of ions in single channels can be measured in small patches of plasma membrane. [80], [81], [88], [90] The patches can be electrically isolated by suction into the tip of a micropipette, where they form a tight seal that makes it possible to record current flow in one or only a few channels in the patch. The patches can remain attached to the rest of the plasma membrane or can become fully detached such that the inner (i.e., inside-out patch) or outer (i.e., outside-out patch) surface of the membrane faces the external medium. Each configuration has its advantages. Inside-out patches are useful for examining the role of intracellular messengers; outside-out patches are useful for examining the influence of extracellular ions; and patches in the whole cell configuration are useful for examining the effect of ligands and second messengers.

The use of patches has made it possible to characterize ion channels in terms of their ion selectivity, membrane density, activation and inactivation kinetics, voltage or ligand dependence, and dependence on changes in intracellular Ca^{2+}. The channels are electrically defined by their conductance (i.e., reciprocal of resistance), which is expressed in picosiemens (pS) as the amount of current flowing through the channel in response to an electrical gradient (i.e., current/voltage).

Voltage-Gated Calcium Ion Channels

Voltage-gated Ca^{2+} channels have been identified in muscle cells from the stomach and intestine of several mammals. [92], [93] and [94] The channels carry the inward Ca^{2+} current responsible for the upstroke of the fast action potential. The channels are activated rapidly by depolarization of the plasma membrane to about -40 mV but are inactivated more slowly. Inactivation occurs as a result of Ca^{2+} influx and membrane depolarization. The voltage range of activation (-40 to -10 mV) overlaps with that of inactivation (-60 to 0 mV); at - 40 to -50 mV, some channels remain open and can carry a steady inward Ca^{2+} current. [93], [94] The potential at which such a current may flow is close to resting membrane potential in some muscle cells and usually is attained during the plateau phase of a slow wave.

Voltage-Gated Potassium Ion Channels

Several types of K^+ channels have been identified in gastric and intestinal smooth muscle. [89], [90], [91], [92], [93], [94], [95], [96], [97], [98], [99], [100] and [101] The channels differ in their conductance, ranges of voltage activation, and Ca^{2+} sensitivities. The most widely distributed is a high-conductance (100 pS), Ca^{2+}-activated, voltage-sensitive K^+ channel. [89], [91], [95], [96] and [97] Current through this channel flows outward and can be blocked by barium (Ba^{2+}) and tetraethylammonium. During resting conditions, when cytosolic Ca^{2+} concentrations are low ($<10^{-7}$ M), relatively few channels are open. On stimulation, the increase in cytosolic Ca^{2+} induces activation of large numbers of K^+ channels, which carry an outward current that drives the membrane potential to its resting state (i.e., the K^+ equilibrium potential). A stimulus that acts by inducing membrane depolarization and Ca^{2+} influx is terminated. A second voltage-sensitive K^+ channel with lower conductance (50 pS) has been identified; it opens up on prolonged depolarization, as occurs during the plateau phase of slow waves. [90] Other K^+ channels detected in gastrointestinal smooth muscle include delayed-rectifier, apamin-sensitive, and ATP-sensitive K^+ channels. An apamin-sensitive K^+ channel expressed in some human and guinea pig smooth muscles (chiefly teniae coli) mediates the relaxant effect of PACAP in these tissues. [98]

RHYTHMIC ELECTRICAL ACTIVITY OF SMOOTH MUSCLE

Control of Rhythmic Electrical Activity by Calcium and Potassium Ion Channels

Ca^{2+} channels and Ca^{2+}-activated K^+ channels constitute the electrical apparatus that sustains rhythmicity in smooth muscle. The Ca^{2+} sensitivity of K^+ channels links their activity to that of Ca^{2+} channels and creates the dynamic framework for rhythmic electrical activity. Activation of Ca^{2+} channels induces an inward flow of Ca^{2+} ions that depolarizes the membrane and increases cytosolic Ca^{2+}. Depolarization and an increase in cytosolic Ca^{2+} inactivate the Ca^{2+} channels and activate the K^+ channels, by inducing an outward flow of K^+ ions. Suppression of the inward flow of Ca^{2+} ions and enhancement of the outward flow of K^+ ions restore the resting membrane potential. The speed, amplitude, and duration of these cycles of depolarization and repolarization depend on the relative proportions of Ca^{2+} and K^+ channels, modulation by neural and humoral agents, participation of other voltage-gated channels, and coupling of muscle cells to each other and to pacemaker cells.

Fast Action Potentials

Only *fast action potentials* (i.e., spike potentials) occur in isolated muscle cells, spontaneously or after application of small depolarizing currents; slow waves are not seen. [80], [85], [90], [93] Cell dispersion uncouples muscle cells from pacemaker regions responsible for slow wave activity and from other muscle cells in the syncytium. Small inward currents can cause rapid and complete depolarization of isolated muscle cells, with resulting maximal activation of Ca^{2+} channels and rapid influx of Ca^{2+}. The depolarization and substantial increase in cytosolic Ca^{2+} inactivate the Ca^{2+} channels and induce massive activation of the K^+ channels. The rapid depolarization and repolarization are characteristic of fast action potentials.

Fast action potentials lasting 0.1 to 0.2 seconds can occur in intact muscle. [80], [81], [82] and [83] They occur spontaneously in regions of the gut where the resting membrane potential is more positive than a threshold of -30 mV or can be raised above that threshold by neural stimulation. In other regions, spike potentials occur only after the membrane has been depolarized by slow waves. Whether they occur spontaneously or are superimposed on slow waves, spike potentials are accompanied by muscle contraction. However, they are not essential for contraction, which can also be generated by changes in the amplitude and duration of the plateau potential of slow waves.

Slow Waves

Profile A typical *slow wave* consists of the following sequence: rapid depolarization (i.e., upstroke), partial repolarization, a sustained plateau lasting several seconds, and complete repolarization to the resting membrane potential (Fig. 6-12). [82], [83] In some regions, usually pacemaker regions, the upstroke is preceded by a slow, low-amplitude depolarization (i.e., pacemaker potential) that may trigger the subsequent slow wave.

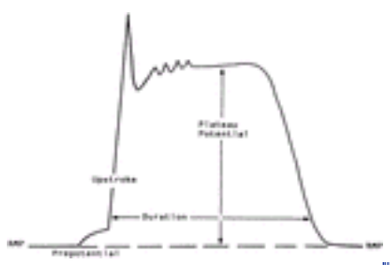

FIGURE 6-12. Profile of a typical slow wave. A slight depolarization (i.e., prepotential) of the resting membrane potential (*RMP*) precedes and may trigger slow waves in some regions. A rapid upstroke is followed by partial repolarization, a plateau potential of variable duration on which may be superimposed small oscillations or spike potentials, and complete repolarization.

The amplitudes, durations, and frequencies of slow waves vary with the location of the muscle. [81] Frequency decreases aborally in human and canine stomach (i.e., 3–5 cycles/min in the corpus to 1.5 cycles/min in the antrum) and intestine (i.e., 12 cycles/min in the duodenum, 7 cycles/min in the ileum, and 5–6 cycles/min in the proximal colon). The frequency gradient is continuous and intrinsic to each region; segments of intestine obtained sequentially along the main axis oscillate at progressively decreasing frequencies. In the canine stomach, the decreasing gradient in frequency is accompanied by an increasing gradient both in the resting membrane potential (i.e., -51 mV in the corpus to -71 mV in the antrum) and in the duration of the plateau potential (i.e., 5 seconds in the corpus to 20 seconds in the antrum). Gradients in resting membrane potential and in the amplitude of plateau potential also occur in the transverse direction, within the thickness of circular muscle. [82] The decrease in the amplitude of the plateau potential in the transverse direction reflects the decay of slow waves with increasing distance from the pacemaker regions at the borders of circular muscle.

Site of Origin Slow waves originate in pacemaker regions located at the myenteric and submucosal borders of circular muscle. [81], [82] and [83] These regions contain a network of cells known as the interstitial cells of Cajal, which act as pacemakers cells capable of initiating rhythmic electrical activity. [102], [103], [104], [105], [106], [107], [108], [109], [110] and [111] The interstitial cells of Cajal are a distinctive population of muscle-like, stellate cells with large nuclei and an abundance of surface caveolae, mitochondria, and rough endoplasmic reticulum. The cells make contact with each other and with muscle cells and nerve terminals. [110] Single interstitial cells isolated from the canine colon appear to be spontaneously active, generating wavelike depolarizations analogous to slow waves. [108], [111] The activity of interstitial cells may not be uniform in all regions, as is evident from the decreasing frequency of slow waves aborally. In some regions (e.g., canine colon), slow waves initiated at the myenteric border differ in configuration and frequency from those initiated at the submucosal border. [102], [105]

Propagation Slow waves originating in the myenteric or submucosal pacemaker regions propagate rapidly around circular muscle and throughout its thickness in the transverse and long axis of the gut. Circumferential propagation is rapid and is facilitated by the peripheral networks of interstitial cells; propagation within the syncytium is facilitated by intramuscular interstitial cells and by the abundance of gap junctions in circular muscle. Slow waves originating in the myenteric pacemaker region of circular muscle also spread to the longitudinal muscle. [104], [105], [112], [113], [114], [115] and [116] After they spread circumferentially, slow waves propagate in oral and aboral directions as discrete rings of excitation capable of eliciting segmental contractions. Propagation in only one direction (i.e., oral or aboral) can occur if the frequency gradient is steep and if the conduction velocity is fast enough to allow slow waves originating in one segment to set the pace of slow waves in another segment [83] or if inhibitory neural input to one segment limits propagation to that segment. [114] Inhibitory neural input to muscle (or pacemaker cells) hyperpolarizes the resting membrane potential and prevents the occurrence of a slow wave, or it decreases the plateau potential and prevents the development of a contraction. Inhibitory neural input reflecting the corelease of NO, VIP, and related neuropeptides appears to predominate normally, masking rhythmic electrical and contractile activity. [114]

Ionic Mechanisms The ionic mechanisms underlying slow wave activity may differ slightly from one region to another. [80], [81], [82] and [83] The rapid upstroke of the slow wave could reflect the inward flow of current through channels of mixed cationic selectivity that are activated at high resting membrane potentials (-60 to -70 mV). Ca^{2+} currents appear to be involved, because the upstroke potential is reduced in the absence of Ca^{2+}. The plateau potential corresponds to the level at which Ca^{2+} channels are activated, and its amplitude reflects the combined activity of voltage-gated Ca^{2+} and K^{+} channels. Ca^{2+}-activated K^{+} channels appear to be the main type of K^{+} channel involved in repolarization of the membrane.

Role in Phasic Contraction The amplitude and duration of the plateau potential determine the magnitude of Ca^{2+} influx through voltage-gated Ca^{2+} channels and can be modulated by excitatory and inhibitory neurotransmitters (Fig. 6-13). Excitatory neurotransmitters, such as acetylcholine or tachykinins, increase the amplitude and duration of the plateau potential and cause a concentration-dependent increase in cytosolic Ca^{2+} and contraction. [104], [117], [118] The increase in Ca^{2+} is accentuated by Ca^{2+} release from Ca^{2+} stores. Spike potentials can be superimposed on plateau potentials and can further augment cytosolic Ca^{2+} concentration and contraction. In some regions, such as the distal antrum and inner lamella of circular muscle in the small intestine, spike potentials appear to be necessary for contraction. [81], [83], [113], [119] Inhibitory neurotransmitters (e.g., NO, VIP, PACAP) decrease the amplitude and duration of the plateau potential or reduce the frequency of spike potentials and prevent the development of contraction associated with a slow wave. These neurotransmitters act predominantly by activating PKA and PKG, which inhibit Ca^{2+} channel activity and stimulate K^{+} channel activity (see Fig. 6-11).

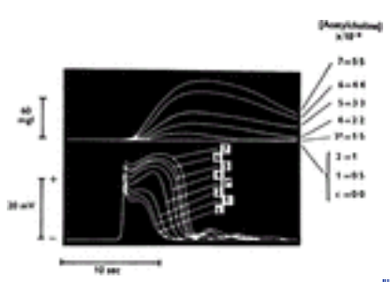

FIGURE 6-13. Relation between the amplitude and duration of the plateau potential (**lower panel**) and the corresponding contraction (**upper panel**) of longitudinal muscle of canine antrum in response to acetylcholine. (From ref. [104].)

Regional Patterns of Contractile Activity

The magnitude of the resting membrane potential, the form, frequency, and site of origin of slow waves, the occurrence and frequency of spike potentials, and the extent of excitatory or inhibitory neural input can be correlated with the neuromuscular function of various regions in the gut. The pattern in humans parallels the pattern observed in dogs.

Stomach The proximal-to-distal gradient in the resting membrane potential of circular smooth muscle in the stomach is depicted in Figure 6-14. The membrane potential in the orad segment or fundus is low, about -50 mV, and lies near or above the threshold for the opening of Ca^{2+} channels and contraction. [81], [120] The segment normally is tonically contracted and is devoid of rhythmic electrical activity. Small changes in stimulatory (i.e., depolarizing) or inhibitory (i.e., hyperpolarizing) neural input can cause further contraction or can induce relaxation of the fundus, features that render this tonic segment suitable for receiving (i.e., receptive relaxation) and discharging (i.e., tonic contraction) a meal into the middle segment or corpus of the stomach. [120]

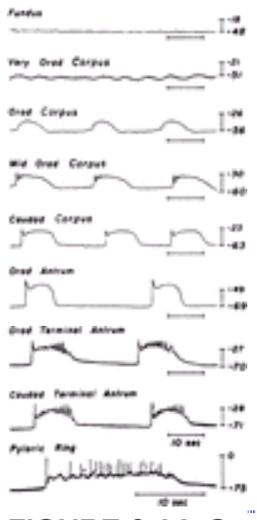

FIGURE 6-14. Gradients in resting membrane potential and profile of slow waves in various regions of the canine stomach recorded with intracellular electrodes. From the proximal to the distal part of the stomach, the resting membrane potential becomes increasingly negative, and the duration of slow waves becomes increasingly longer; potential oscillations and spike potentials are evident in the distal stomach and pylorus. (From ref. [81].)

The corpus is the site of spontaneous pacemaker activity in the stomach and has a higher resting membrane potential. The corpus can undergo both tonic and phasic contraction. Tonic contraction induced by excitatory neurotransmitters is mediated by the release of intracellular Ca^{2+}; the concomitant decrease in the resting membrane potential is not sufficient to activate Ca^{2+} channels and to cause Ca^{2+} influx (Fig. 6-15). [111] Phasic contraction of the corpus is determined by the amplitude and duration of the plateau potential. Small changes in amplitude or duration induced by excitatory neurotransmitters result in substantial changes in the magnitude of phasic contraction.

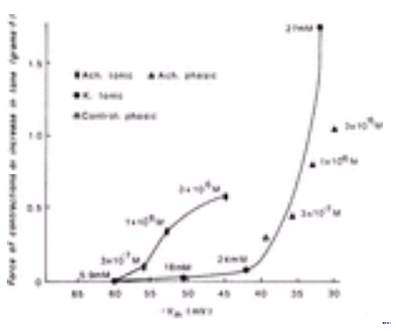

FIGURE 6-15. Comparative effects of acetylcholine (*Ach*) and extracellular K^{+} on membrane potential and contraction in circular muscle from the corpus of the canine stomach. Acetylcholine caused an increase in tonic contraction; the depolarization induced by acetylcholine does not exceed the threshold for opening of Ca^{2+} channels, implying that the source of Ca^{2+} for agonist-induced tonic contraction is intracellular. During slow wave activity, the magnitude of phasic contraction in response to acetylcholine correlates with the amplitude of the plateau potential. Contraction induced by extracellular K^{+} results from depolarization and an influx of Ca^{2+} and coincides with the pattern of phasic contraction induced by acetylcholine. (From ref. [81].)

Intrinsic pacemaker rhythm is highest in the orad corpus (5 cycles/min) and decreases progressively throughout the rest of the corpus, antrum, and pylorus. Slow waves originating in the corpus propagate to and pace antral muscle. Slow waves originating in the distal antrum and pyloric sphincter have prolonged plateau potentials on which spike potentials are usually superimposed. As a whole, the antrum has little tone and is best suited for propagation of slow waves and contractions originating in the corpus. [81], [118], [119] Antral slow waves propagate aborally to the pyloric sphincter, where they pace longitudinal muscle and the outer layer of circular muscle. The slow waves decay before reaching muscle cells in the inner layer of circular muscle; muscle cells in this region are electrically quiescent and may be responsible for the intrinsic tone of the sphincter. Opening of the sphincter is mediated by an inhibitory (i.e., relaxant) neural reflex triggered by distention of the distal antrum; distention occurs when the gastric contents are propelled aborally by phasic or peristaltic contractions originating in the pacemaker region in the corpus of the stomach.

Small Intestine In most mammals, including humans, there is a decreasing gradient in slow wave frequency from the duodenum to the ileum. Slow waves originate in a pacemaker region located at the myenteric border of circular muscle from where they propagate to the bulk of circular muscle and to longitudinal muscle. [111], [112] Removal of a thin layer at the myenteric border of circular muscle abolishes slow waves in longitudinal muscle and in the bulk of circular muscle. Propagation around and in the long axis of the intestine occurs preferentially through circular muscle. The configuration of slow waves in the small intestine is similar to that in the corpus of the stomach and consists of a rapid upstroke followed by a sustained plateau potential. Excitatory and inhibitory neural input influences the amplitude of the plateau potential and the frequency of spike potentials, and determines the occurrence and magnitude of phasic contraction in the intestine. [111], [112]

Colon There is a decreasing gradient in resting membrane potential across circular muscle of the canine colon from -80 mV in muscle cells at the submucosal border to -45 mV in muscle cells at the myenteric border (Fig. 6-16). Rhythmic electrical activity is mediated by two pacemaker regions, one at the myenteric border and the other at the submucosal border. Each pacemaker region generates slow waves with distinctive forms and frequencies that spread passively and summate in the bulk of circular muscle, to yield waves of mixed form. [82], [104], [105], [121]

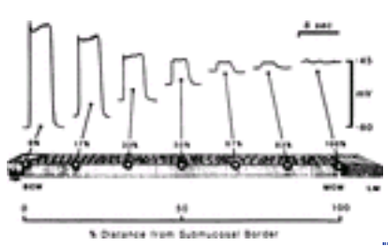

FIGURE 6-16. Records of slow waves obtained at various depths from the submucosal border of circular muscle in canine colon. Two gradients are evident: a decline in the amplitude of the plateau potential from the submucosal (*SCM*) to myenteric (*MCM*) border is matched and offset by a decrease in the resting membrane potential. The plateau potential during slow wave activity attains or exceeds the threshold potential throughout the thickness of circular muscle. Slow waves of a different configuration originate at the myenteric border; as they propagate in circular muscle, they summate with slow waves originating in the submucosal border. (From ref. [106].)

Slow waves originating at the submucosal border have a frequency of five to six cycles per minute, a configuration similar to that found in the small intestine and corpus of the stomach, and a plateau potential lasting 3 to 15 seconds (see Fig. 6-16). [82] The amplitude of the plateau potential decreases as the waves spread toward the myenteric border; the decrease is matched and offset by the decrease in resting membrane potential such that the plateau potential is maintained at about -45 mV, which is close to the threshold for mechanical activity. Slow waves originating at the myenteric border of circular muscle have a frequency of 17 cycles per minute and a sinusoidal configuration. [82], [104], [105], [121] The waves, called *myenteric potential oscillations,* spread to and pace muscle cells in the longitudinal muscle layer. They also spread in circular muscle toward the submucosal border, their amplitude decreasing as a function of distance from the myenteric border. The waves summate with waves originating at the submucosal border; the encounter boosts the plateau potential of waves that originate at the submucosal border and elicits contractions at the rate of six per minute. In longitudinal muscle, myenteric potential oscillations generate fast action potentials. The frequency of these fast transients and of longitudinal muscle contractions is regulated by neural input from the enteric nervous system. Fast action potentials are not generated in circular muscle and only rarely propagate from longitudinal to adjacent circular muscle cells. Excitatory and inhibitory input from neurons of the enteric nervous system is directed at both pacemaker regions, where the density of innervation is highest. [113] Input from these neurons affects slow wave and phasic contractile activity in the same way it does in the small intestine.

Stimulus-Contraction Coupling in Syncytia: Tonic and Phasic Contraction

The signal transduction pathways described in isolated circular and longitudinal muscle cells regulate tonic contraction and relaxation of intact, syncytial muscle.

Small depolarizations caused by hormones or excitatory neurotransmitters are not sufficient to cause tonic contraction, except in some regions of the gut, such as the fundus of the stomach; there the resting membrane potential is close to the mechanical threshold, which is the membrane potential at which Ca^{2+} channels are presumed to open. In circular muscle of the intestine and corpus of the stomach, tonic contraction induced by excitatory neurotransmitters occurs at membrane potentials more negative than the mechanical threshold, implying that the source of Ca^{2+} responsible for tonic contraction in these regions is intracellular (see Fig. 6-15). [111], [112] However, when circular or longitudinal muscle is depolarized by a slow wave, relatively small changes in the plateau potential imposed by the effect of an excitatory neurotransmitter are sufficient to induce Ca^{2+} influx and contraction. The contraction is phasic, coinciding with and determined by the amplitude of the plateau potential; mobilization of intracellular Ca^{2+} by the excitatory neurotransmitter amplifies the phasic contraction.

In some regions, spike potentials superimposed on the plateau potentials produce the requisite depolarization for contraction. Spike potentials are not seen in circular muscle of the colon, [82] the small intestine except for a thin inner lamella, [111] and the corpus of the stomach. [81] In the proximal colon, slow waves emanating from the pacemaker region at the myenteric border of circular muscle elicit spike potentials when they spread to the longitudinal muscle only. Spike generation appears to be more prevalent in longitudinal muscle and may be related to signal transduction pathways and channel characteristics in this muscle.

As previously noted, hormones and inhibitory (i.e., relaxant) neurotransmitters act through PKA or PKG to decrease cytosolic Ca^{2+} and the sensitivity of contractile proteins to Ca^{2+} (see Fig. 6-11). They do so by inhibiting Ca^{2+} release and enhancing sequestration of Ca^{2+} in intracellular stores, [66], [68] a mechanism well suited to the relaxation of tonic contraction, or by hyperpolarizing the plasma membrane and reducing Ca^{2+} influx, a mechanism well suited to the relaxation of phasic contraction (see Fig. 6-11). The hyperpolarization is mediated by inhibitory phosphorylation of voltage-gated Ca^{2+} channels and stimulatory phosphorylation of voltage-gated, Ca^{2+}-dependent K^{+} channels. The hyperpolarization determines the profile or occurrence of slow waves and thus determines the occurrence of phasic contractions. It has traditionally been labeled the *inhibitory junction potential* because it leads to inhibition of phasic electrical and contractile activity.

NEURAL REGULATION OF SMOOTH MUSCLE BY THE MYENTERIC PLEXUS

The intrinsic electrical and mechanical properties of smooth muscle are modulated by neurotransmitters released from neurons of the enteric nervous system, especially neurons of the myenteric plexus. These neurons constitute the final neural pathway regulating smooth muscle activity. Neurons of the submucosal plexus innervate the innermost layers of circular muscle in large species, such as humans and dogs.

Two populations of sensory neurons have been identified. The first, activated by mucosal stimuli, is wholly intrinsic, and the second, activated by muscle stretch and painful stimuli, has neuronal cell bodies in the dorsal root ganglia. Extrinsic neurons of the sympathetic and parasympathetic systems influence smooth muscle indirectly by acting on neurons of the myenteric plexus. Adrenergic and peptidergic neurons in prevertebral and paravertebral ganglia synapse with and inhibit the activity of cholinergic and noncholinergic neurons of the myenteric and submucosal plexuses.

Neuronal Topography

The neural organization of the enteric nervous system is well conserved in mammals and has been extensively studied in guinea pigs, rats, dogs, and humans (see Chapter 2). [122], [123], [124], [125] and [126] Neurons in the myenteric plexus synapse with neurons in the myenteric and submucosal plexuses and paravertebral ganglia and innervate cells in the circular and longitudinal muscle layers. The fibers that make up the deep plexus close to the submucosal border of circular muscle are derived from neurons of the myenteric and submucosal plexuses in large species.

Advances in immunocytochemical and imaging techniques have made it possible to map these neurons and to correlate their morphologic, electrophysiological, and neurochemical properties, specifically their content of neurotransmitters. Neurons of the myenteric plexus fall into two broad categories: about 25% contain VIP or PACAP together with NO synthase (NOS), the enzyme responsible for synthesis of NO in nerve terminals; and about 60% contain acetylcholine, usually together with the tachykinins, substance P, and neurokinin A (NKA). There is virtually no overlap between these categories of neurons. [122], [123], [124], [125], [126], [127] and [128] VIP neurons also contain a homologous peptide, designated PHM (i.e., *P*eptide with N-terminal *H*istidine and C-terminal *M*ethionine) in humans and PHI in animals, which is derived from the same precursor, pro-VIP. Substance P neurons contain NKA, also known as substance K, which is derived from the same precursor, ß-protachykinin. The two main categories of neurons correspond to major roles for acetylcholine and the tachykinins as excitatory neurotransmitters and for VIP, its homologs, and NO as inhibitory neurotransmitters. Excitatory neurotransmitters stimulate Ca^{2+} release, depolarize the plasma membrane (i.e., trigger *excitatory junction potentials*) and induce Ca^{2+} influx, increase muscle tone, and induce phasic contraction. Inhibitory neurotransmitters inhibit Ca^{2+} release, hyperpolarize the plasma membrane (i.e., trigger inhibitory junction potentials) and inhibit Ca^{2+} influx, decrease (i.e., relax) muscle tone, and inhibit electrical slow wave and phasic contractile activity.

Subpopulations of neurons in the two main categories contain one or more of the following: bombesin, also known as gastrin-releasing peptide; neuropeptide Y; the opioid peptides, dynorphin, methionine-enkephalin and their derivatives; and galanin. A few neurons contain ?-aminobutyric acid (GABA), serotonin (<3%), or somatostatin (<5%). Neurons that contain serotonin or somatostatin act mainly as interneurons and influence smooth muscle cells indirectly by means of other neurons.

Peptide and Other Neurotransmitters

Pharmacological Profile Peptide and nonpeptide neurotransmitters are released from axonal varicosities near muscle cells. They diffuse across distances ranging from 20 to 100 nm to interact with receptors on muscle cells or on the same (autoreceptors) or adjacent nerve terminals. The presence of receptors on muscle cells and the possibility of direct action can be determined in isolated muscle cells by measuring the binding of specific radioligands, the release of intracellular messengers (e.g., increase in cytosolic Ca^{2+}, IP_3, or cyclic nucleotides), or the mechanical response of the cell (i.e., contraction or relaxation). [129], [130] Determining the presence of receptors on neurons or their terminals and the possibility of indirect, neurally mediated action of neurotransmitters on muscle cells requires the use of innervated muscle strips; the neurally mediated component of a mechanical response is identified by its sensitivity to blockade by neurotoxins. [129], [130] and [131]
Direct and neurally mediated response. When given exogenously, peptide and nonpeptide neurotransmitters can cause contraction or relaxation of smooth muscle cells directly or indirectly by stimulating or inhibiting the release of other excitatory or inhibitory neurotransmitters. Bombesin and CCK, for example, cause contraction in isolated muscle cells and innervated muscle strips; in the latter, they also elicit release of acetylcholine and substance P. [132], [133], [134] and [135] Their effect in strips is in part neurally mediated and can be partially blocked by the axonal blocker, tetrodotoxin, or by a combination of muscarinic and tachykinin antagonists.
Linkage between VIP/PACAP and NO. VIP, PACAP, PHI, and PHM cause relaxation of isolated muscle cells and muscle strips. [60], [61], [62], [63] and [64], [68], [136], [137] The effects of PHI and its human counterpart, PHM, are mediated by cAMP, whereas the effects of VIP and PACAP are mediated by both cAMP and cGMP. [54], [55], [59] The increase in cGMP is the result of stimulation of NO production in smooth muscle cells by VIP and PACAP (see later). [63], [67], [68] A unique interplay exists between VIP or PACAP and NO in smooth muscle of the gut. NO produced in nerve terminals regulates VIP and PACAP release from the same or adjacent nerve terminals (Fig. 6-17). The release of VIP and PACAP from these terminals regenerates NO in target muscle cells (Fig. 6-18; see Fig. 6-17). [64], [67], [68], [138], [139], [140], [141], [142], [143], [144] and [145]

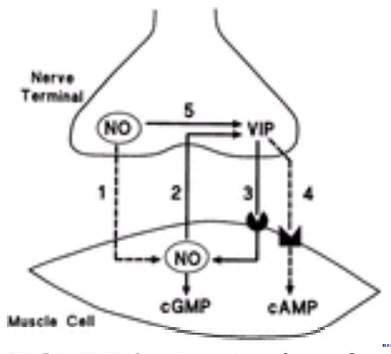

FIGURE 6-17. Interplay of vasoactive intestinal polypeptide (*VIP*) and nitric oxide (*NO*) in the regulation of smooth muscle relaxation. VIP and neuronal NO synthase are often located in the same enteric neurons. NO produced in nerve terminals regulates VIP release (*5*) and diffuses to muscle cells (*1*). VIP released from nerve terminals interacts with one class of natruretic peptide receptors (*NPR-C*) coupled to an endothelial-type NO synthase in muscle cells, leading to the production of

NO and cyclic GMP (*cGMP*) (*3*). NO produced in muscle cells diffuses to nerve terminals, where it facilitates VIP release (*2*). VIP interacts with $VPAC_2$ receptors (previously known as VIP_2/or $PACAP_3$ receptors) coupled to adenylate cyclase to generate cyclic AMP (*cAMP*) (*4*). The amount of NO produced in muscle cells (60% to 80%) is much larger than that produced in nerve terminals (20% to 40%). The linkage between NO production and VIP release and the dual sources of NO explain why NO synthase inhibitors are potent inhibitors of NO production, VIP release, and relaxation and why the VIP antagonist $VIP_{10–28}$ is a potent inhibitor of NO production and relaxation. Oxyhemoglobin neutralizes extracellular NO and blocks only pathways 1 and 2. Identical pathways link the release of pituitary adenylate cyclase-activating peptide (*PACAP*) and NO; PACAP interacts with the same two classes of receptors as VIP.

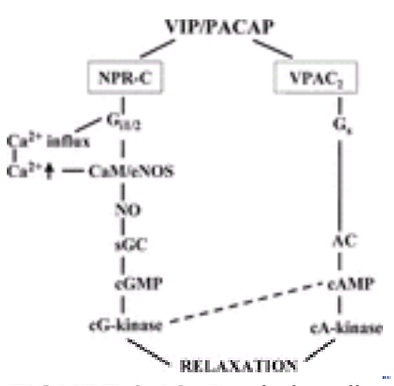

FIGURE 6-18. Dual signaling cascades initiated by the interaction of vasoactive intestinal peptide (*VIP*) and pituitary adenylate cyclase–activating peptide (*PACAP*) with two classes of receptors. VIP and PACAP interact with $VPAC_2$ receptors (previously known as VIP_2 receptors or $PACAP_3$ receptors) coupled by G protein G_s to activation of adenylate cyclase (*AC*), formation of cyclic AMP (*cAMP*), and activation of cAMP-dependent protein kinase (*PKA)*; high agonist concentrations generate higher levels of cAMP that can also cross-activate cyclic GMP (*cGMP*)-dependent protein kinase (*PKG; dotted line*). VIP and PACAP interact with one class of natriuretic peptide receptors (*NPR-C*) coupled by G proteins G_{i1} and G_{i2} to stimulation of Ca^{2+} influx into the cell and activation of a constitutive Ca^{2+}-calmodulin (*CaM*)–dependent isoform of nitric oxide synthase (endothelial type NOS [*eNOS*]). The resultant increase in nitric oxide (*NO*) activates soluble guanylate cyclase (*sGC*), stimulates cGMP formation, and leads to activation of PKG. Both kinases act concurrently to cause relaxation and hyperpolarization of smooth muscle cells. CG-kinase, PKG; cA-kinase, PKA. (Adapted from refs. [67] and [147].)

There is much evidence to support the dual interplay between VIP or PACAP and NO in various regions of the gut in mammalian species (human, dog, opossum, rabbit, guinea pig, rat, and mouse). In isolated myenteric ganglia devoid of muscle cells, the nicotinic agonist, dimethylphenylpiperazinium, stimulates NO production and VIP release; NOS inhibitors abolish both NO production and VIP release, implying a dependence of VIP release on NO production. [138], [139] Exogenous NO causes VIP release from these ganglia, but exogenous VIP has no effect on NO production. [138] Studies in synaptosomal membranes have confirmed that NO donors stimulate VIP release, whereas VIP does not stimulate NO production. [146] In isolated muscle cells devoid of neural elements, VIP and PACAP, but not the homologous peptides, PHI, PHM, or secretin, stimulate NO production. [63], [67], [139], [140] The processes that occur in neurons and muscle cells are reflected in VIP/PACAP release and NO production occurring during nerve stimulation of muscle strips. [63], [67], [139], [141] NOS inhibitors abolish NO production induced by all neural stimuli, and they also abolish VIP release induced by low stimuli and partially inhibit VIP release induced by intense stimuli, indicating that VIP and PACAP release is mediated by NO but can occur independently of it during intense nerve stimulation. [139] The VIP antagonist, $VIP_{10–28}$, which blocks the postjunctional effects of VIP on muscle cells, inhibits NO production by 60% to 80%, indicating that VIP- and PACAP-induced NO production in muscle cells is the major source of NO. [139], [142] The effectiveness of NOS inhibitors in blocking muscle relaxation induced by nerve stimulation led investigators to conclude incorrectly that relaxation was exclusively mediated by NO released from nerve terminals. NOS inhibitors elicit their potent effects by acting at several locations: by suppressing NOS production in nerve terminals, the inhibitors also suppress VIP and PACAP release and thus prevent VIP/PACAP-mediated regeneration of NO in muscle cells. The cellular mechanisms in VIP- and PACAP-induced relaxation involve the interaction of VIP with two distinct receptor types (see Fig. 6-18): $VPAC_2$ receptors (previously known as VIP_2 or $PACAP_3$ receptors), which are coupled through G_s to the activation of adenylate cyclase; and natriuretic peptide receptors type C (NPR-C), which are coupled through G_{i1} and G_{i2} to the activation of NOS in smooth muscle cells. $VPAC_2$ receptors are also recognized by PHI and PHM but with lesser affinity, whereas NPR-C receptors are recognized exclusively by VIP and PACAP, as well as by natriuretic peptides. [67], [143] The distinctive feature of NPR-C is the presence of a truncated 37-amino acid intracellular domain devoid of kinase or guanylate cyclase activity. Site-directed mutagenesis corroborated by studies using peptide fragments derived from the intracellular sequence of NPR-C have identified a 17-amino acid intracellular segment that determines the ability of NPR-C to activate G_{i1} and G_{i2}. [147], [148] and [149] The interaction of VIP and PACAP with NPR-C initiates a signaling cascade involving Ca^{2+} influx that leads to Ca^{2+}-calmodulin–dependent activation of a membrane-bound constitutive NOS, identified by in situ polymerase chain reaction on single muscle cells as endothelial NOS (eNOS) (see Fig. 6-18). [144], [145] The resultant increase in intracellular NO activates soluble guanylate cyclase, and this leads to the generation of cGMP and the activation of PKG. Together, PKA and PKG are responsible for the relaxation of muscle tone. [63], [67], [68] As previously discussed, the two kinases also cause hyperpolarization of the muscle cells, which can prevent the development of phasic contractions in innervated muscle strips. Although the amount of eNOS in muscle cells is small and immunocytochemical detection is difficult, eNOS coupling to G proteins greatly amplifies its effect. In smooth muscle cells of the gut, eNOS is susceptible to inactivation by PKC. [150] A common experimental flaw, whereby the tone of muscle strips is increased using contractile agonists that activate PKC, leads to the suppression of NOS activity in muscle cells and precludes detection of the VIP-NOS linkage in these cells. The mechanisms of action of VIP and PACAP are different in teniae coli, and the receptors for both peptides are distinct from their counterparts in other regions of the gut. Smooth muscle cells in this region are devoid of eNOS. VIP interacts with a specific receptor that does not recognize PACAP. PACAP interacts with a receptor that does not recognize VIP or couple to adenylate cyclase but that couples to the activation of apamin-sensitive K^+ channels. [98], [151]

GABA, somatostatin, and opioid peptides. GABA, acting through $GABA_A$ receptors, causes relaxation in muscle strips but not in isolated muscle cells. The relaxation induced by GABA in muscle strips is accompanied by the release of VIP and NO and can be blocked by VIP antagonists and NOS inhibitors (see Fig. 6-17 and Fig. 6-18). Opioid peptides have an opposite effect. They cause a transient tonic contraction, followed by phasic contractions in previously quiescent muscle strips. The transient tonic contraction is a direct effect of opioid peptides on smooth muscle and is demonstrable in isolated muscle cells. [152] The phasic contractions result from inhibition of the background release of inhibitory neurotransmitters (e.g., VIP, PACAP, and NO) that normally mask phasic contractile activity. [137] Elimination of this background with VIP antibody, VIP antagonists, or NOS inhibitors induces phasic contractions in quiescent muscle strips. Somatostatin stimulates VIP (and probably PACAP) release and NO production indirectly through pathways that inhibit opioid peptide release. The inhibition of opioid peptide release eliminates the restraint exerted by opioid neurons on VIP, PACAP, and GABA neurons, resulting in stimulation of VIP and PACAP release and NO production. The interplay of somatostatin, opioid, and GABA neurons is expressed in the regulation of VIP and PACAP release and NO production during the descending phase of peristalsis (Fig. 6-19).

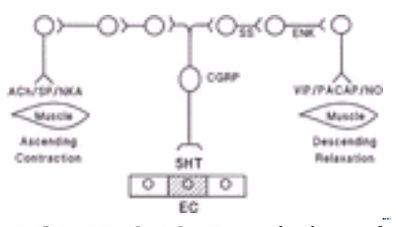

FIGURE 6-19. Regulation of the peristaltic reflex by neurons of the myenteric plexus. The reflex has ascending and descending phases: the descending relaxation and the ascending contraction in circular muscle shown here are accompanied by reciprocal descending contraction and ascending relaxation of longitudinal muscle (*not shown*). The reflex can be triggered by mucosal stimuli and circular muscle stretch. Mucosal stimuli (but not muscle stretch) release serotonin (5-hydroxytryptamine; *5-HT*) from intestinal enterochromaffin (*EC*) cells that acts on 5-HT_4 receptors located on the nerve terminals of intrinsic sensory calcitonin gene–related peptide (*CGRP*)–containing neurons with cell bodies in the wall of the intestine. CGRP acts on modulatory interneurons coupled to (*a*) inhibitory motor neurons that release the relaxant neurotransmitters vasoactive intestinal polypeptide (*VIP*), pituitary adenylate cyclase–activating peptide (*PACAP*), and nitric oxide (*NO*), and (*b*) excitatory motor neurons that release the contractile neurotransmitters acetylcholine (*ACh*), substance P (*SP*), and neurokinin A (*NKA*). The interneurons consist of somatostatin (*ss*) and opioid neurons (enkephalin; *ENK*) connected in series. The increase in somatostatin inhibits the release of opioid peptides, thereby suppressing the inhibitory restraint of opioid neurotransmitters on release of VIP, PACAP, and NO. The reflex triggered by muscle stretch does not involve release of 5-HT; muscle stretch activates extrinsic CGRP-containing sensory neurons with cell bodies in the dorsal root ganglion. These sensory neurons

couple to the same modulatory interneurons and motor neurons. The pathways mediating the reflex are identical in rats and humans.

Physiological Profile The pharmacological profile of actions described in the previous section provides a framework for understanding the regulatory role of neurotransmitters released from neurons of the myenteric plexus. Excitatory motor neurons release one or both types of contractile neurotransmitters: acetylcholine and the tachykinins, substance P and NKA. [153] Inhibitory motor neurons release the relaxant neurotransmitters, VIP with PHI or PHM, PACAP, and NO. Other neurotransmitters modulate the release of excitatory and inhibitory neurotransmitters from motor neurons, as previously noted. Peptides expressed in neurons of the myenteric plexus may be identified as neurotransmitters if they meet the following criteria: [130]

1. Demonstration of peptide synthesis in neurons and presence of the peptide in nerve terminals close to target cells, such as muscle cells, or interstitial cells of Cajal
2. Release of the peptide by physiological stimuli, such as chemically or mechanically induced reflexes
3. Coupling of peptide release to a putative function, as evident from blockade of a physiological response by a specific antiserum or antagonist
4. Mimicry of the response by exogenous application of the peptide, provided the substance does not evoke unrelated pharmacological effects that mask the physiological response.

Several excitatory and inhibitory peptide motor neurotransmitters, such as VIP, PACAP, substance P, and NKA, fulfill these criteria. The example of VIP demonstrates its role as a relaxant motor neurotransmitter (see Fig. 6-18 and Fig. 6-19). VIP and neuronal NOS (nNOS) are colocalized in neurons of the myenteric plexus that innervate mainly circular muscle throughout the gut. [122], [123], [124], [125], [126], [127] and [128] VIP and NO are released concurrently in response to neural stimulation, and their release is accompanied by a proportional increase in relaxation. [136], [137], [139] VIP and its homologs cause relaxation in smooth muscle from all regions of the gut, including the stomach, intestine, gallbladder, and sphincters. [63], [67], [139], [140], [154], [155] The effect of VIP is partially the result of its ability to stimulate NO production in muscle cells (see Fig. 6-18). NO is released from nerve terminals by activation of nNOS and from smooth muscle cells by activation of a VIP/PACAP-dependent eNOS. [139] Neutralization of VIP with specific VIP antiserum, blockade of its effect with selective VIP antagonists, inhibition of VIP release from nerve terminals, and inhibition of its relaxant effect in muscle cells by NOS inhibitors inhibit neurally induced relaxation in all regions of the gut. [64], [139], [142], [154], [155] and [156] Reflex activation of myenteric neurons by physiological stimuli (e.g., stretch or mucosal stimulation) causes VIP and PACAP release, NO production, and muscle relaxation. VIP or PACAP antiserum and VIP/PACAP antagonists inhibit relaxation and NO production by suppressing the effect of VIP and PACAP on muscle relaxation and NO production. NOS inhibitors block NO production in nerve terminals and muscle cells and inhibit NO-dependent VIP and PACAP release, effectively blocking nerve-induced relaxation (see Fig. 6-18 and Fig. 6-19). [139], [141]

Peristaltic Reflex

The peristaltic reflex exemplifies the role of enteric neurons in regulating a physiological motor function (see Fig. 6-19). [142], [156], [157], [158], [159], [160], [161], [162], [163], [164], [165], [166], [167], [168], [169] and [170] The reflex can be evoked by stroking, which stimulates sensory nerve terminals in the mucosa, or by radial stretch, which stimulates sensory nerve terminals in circular muscle. The reflex consists of an orad (or ascending) and a caudad (or descending) component or phase. During the caudad phase, circular muscle relaxes while longitudinal muscle contracts; during the orad phase, circular muscle contracts while longitudinal muscle relaxes. Reciprocal contraction and relaxation of the two muscle layers maintain the dimensions of the segment (see Fig. 6-19). [163] In vitro stimulation of hollow or flat segments of intestine at the orad end to elicit only the caudad (i.e., descending) phase, or at the caudad end to elicit the orad (i.e., ascending) phase, makes it possible to identify the types of neurotransmitter released and their functional coupling to each component of the peristaltic reflex. Compartmented flat-sheet colonic preparations are particularly useful in examining the reflex in humans, which is identical to that observed in rat and guinea pig. Sensory neurotransmitters are released into the central compartment, where stimuli are applied, but not into the peripheral compartments, where orad and caudad mechanical responses are measured. [164], [165] and [166]

Excitatory and Inhibitory Motor Neurons VIP, PACAP, and NO are released during and are responsible for the descending relaxation of circular muscle; VIP or PACAP antiserum, VIP or PACAP antagonists, and NOS inhibitors inhibit the descending relaxation (see Fig. 6-19). [142], [156], [157] Acetylcholine, substance P, and NKA are released during and are responsible for the ascending contraction of circular muscle; contraction is partially inhibited by muscarinic antagonists and is abolished by a combination of muscarinic antagonists and tachykinin antagonists or antibodies (see Fig. 6-19). [157], [158] The pattern illustrates the involvement of the main excitatory and inhibitory motor neurotransmitters of the myenteric plexus in regulating the motor limb of the peristaltic reflex.
Modulatory Interneurons Interneurons of the myenteric plexus participate in the peristaltic reflex by modulating the release of excitatory and inhibitory neurotransmitters from motor neurons. [159], [160], [161] and [162] The release of somatostatin increases during the descending phase, whereas the release of opioid peptides decreases. [160], [161] In the resting state, opioid interneurons exert a continuous restraint on VIP/PACAP/NOS motor neurons. This restraint is eliminated during the descending phase when opioid peptide release is decreased, leading to an increase in VIP, PACAP, and NO release. [159], [160], [161] and [162] Opioid inhibitors applied during the descending phase enhance the release of VIP, PACAP, and NO and increase muscle relaxation; the application of opioid peptides has the reverse effect. The decrease in opioid peptide release, which eliminates opioid restraint on VIP/PACAP/NOS motor neurons, is mediated by the increase in somatostatin during the descending phase. Neutralization of somatostatin with somatostatin antibody increases opioid peptide release and decreases VIP, PACAP, and NO release and muscle relaxation. Exogenous somatostatin has the opposite effect, enhancing VIP, PACAP, and NO release, as well as circular muscle relaxation. [159], [161] The interplay of somatostatin and opioid interneurons that regulates the activity of VIP/PACAP/NOS motor neurons also regulates the activity of VIP/PACAP/NOS interneurons. These interneurons synapse with cholinergic/tachykinin motor neurons that innervate longitudinal muscle. [163] The activation of these interneurons results in contraction of longitudinal muscle during the descending phase concurrently with relaxation of circular muscle. A switch in the activity of somatostatin interneurons during the ascending phase presumably leads to a reverse pattern of circular muscle contraction and longitudinal muscle relaxation, which is characteristic of the ascending phase of the peristaltic reflex. P> **Sensory Neurons Mediating Peristalsis** Two distinct populations of sensory neurons that can be differentially activated and desensitized mediate the peristaltic reflex, which is elicited by muscle stretch and mucosal stimulation. [164], [165] and [166] Muscle stretch activates the intramuscular nerve terminals of extrinsic sensory neurons, which have cell bodies in the dorsal root ganglion and axonal projections to myenteric neurons. Mucosal stimulation activates intrinsic (i.e., enteric) sensory neurons with nerve endings in the mucosa. Activation is initiated by the release of 5-HT from mucosal enterochromaffin cells that acts on 5-HT $_4$ receptors located on sensory nerve terminals and causes the release of the sensory neurotransmitter, calcitonin gene–related peptide (CGRP). [165], [166], [167], [168], [169] and [170] The addition of lumenal 5-HT or selective 5-HT $_4$ agonists induces CGRP release and triggers the peristaltic reflex. Selective 5-HT $_4$ antagonists block CGRP release and the mechanical components of the reflex induced by mucosal stimulation. CGRP antagonists block the ascending and descending phases of the reflex. The release of 5-HT and CGRP and the effects of 5-HT $_4$ agonists, 5-HT $_4$ antagonists, and CGRP antagonists are elicited only in the compartment where stimuli are applied, clearly identifying 5-HT and CGRP as components of the sensory limb of the reflex. Exposure of the intestinal lumen to 5-HT $_4$ agonists initiates peristaltic activity and stimulates propulsion of intralumenal contents. [168], [169] and [170] Addition of opioid d-receptor antagonists suppresses the inhibitory restraint exerted by opioid interneurons on excitatory and inhibitory motor neurons and greatly enhances the propulsive effect of 5-HT $_4$ agonists. [169] The potent synergism between opioid antagonists and 5-HT $_4$ agonists at near-threshold concentrations endows the combination with therapeutic potential. Events corresponding to the two phases of the peristaltic reflex underlie propulsion and the opening and closure of various sphincters, including the lower esophageal, pyloric, choledochal, ileocecal, and internal anal sphincters. [154], [155], [171] In these regions, VIP (and likely PACAP) acting directly and by means of NO appears to be the main neurotransmitter responsible for sphincter relaxation; acetylcholine and probably tachykinins participate in sphincter contraction.

HORMONAL REGULATION OF SMOOTH MUSCLE FUNCTION

Hormonal influences on smooth muscle activity are evident during and in between meals. The example of CCK illustrates the interplay of hormonal and neural influences. After ingestion of a meal, CCK is released into the circulation from the upper small intestine; it causes both direct and cholinergically mediated contraction of muscle cells in the gallbladder and neurally mediated relaxation of muscle cells in the sphincter of Oddi. Relaxation of the sphincter is accompanied by the release of VIP and is blocked by VIP antiserum, VIP antagonists, and NOS inhibitors, implying that CCK causes relaxation by stimulating the release of VIP and NO from intramural neurons. [155]

Motilin illustrates the participation of a hormone in the regulation of smooth muscle activity between meals. In humans and other mammals, cycles of electrical and contractile activity, described in greater detail in Chapter 11, recur at 1.5- to 2-hour intervals between meals. The cycles consist of four distinct phases, collectively known as the *interdigestive myoelectric complex* or *migrating motor complex.* The cycles culminate in phase III, a 5- to 10-minute period of intense phasic contractile activity. Cycles typically begin in the stomach and migrate aborally throughout the small intestine; some cycles appear to begin in the small intestine. Motilin, a peptide released from endocrine cells of the upper small intestine, appears to be responsible for initiating cycles that begin in the stomach. Peaks of motilin coincide with the onset of phase III in the stomach. Neutralization of circulating motilin with motilin antiserum disrupts phase III activity, and infusion of motilin in concentrations that mimic circulating levels induces premature phase III activity. [172], [173] Cycles that begin in the intestine are not controlled by motilin and may be regulated by input

from enteric and extrinsic neurons. The neural and hormonal mechanisms that cause suppression of the cycles on ingestion of a meal are unknown.

HUMORAL REGULATION OF SMOOTH MUSCLE FUNCTION

In addition to neurotransmitters and circulating hormones, humoral agents produced by nonneural cells within the smooth muscle layer influence smooth muscle activity. These include ATP, histamine, serotonin, adenosine, and eicosanoids, such as prostaglandins, thromboxanes, and leukotrienes. Receptors for most of these agents have been identified on smooth muscle cells of the gut.

ATP, whether released as a neurotransmitter or as a metabolic product, interacts with two P_2 receptors on muscle cells. [174] The term P_2 is preferable to purinergic because it recognizes that purine and pyrimidine nucleotides can act as preferential ligands of various receptor subtypes. At low concentrations, ATP interacts with P_{2Y2} receptors coupled by G_q to PLC-ß1 and by G_{i3} to PLC-ß3 and elicits IP_3-dependent Ca^{2+} release and muscle contraction. At higher concentrations, ATP also interacts with ligand-gated P_{2X1} receptors that act as cationic channels and cause depolarization of the plasma membrane and Ca^{2+} influx through voltage-gated Ca^{2+} channels. At high concentrations, ATP also activates K^+ channels; the notion that activation of these channels on release of ATP from inhibitory nerves is responsible for initial hyperpolarization has some proponents.

ATP is rapidly degraded to adenosine, which also interacts with two types of receptors, A_1 and A_2, on smooth muscle cells of the intestine. [175] These receptors are coupled to three signaling pathways. A_2 receptors are coupled by G_sa to the activation of adenylate cyclase, whereas A_1 receptors are coupled by G_{i3}a to the inhibition of adenylate cyclase and by G_{i3}ß? to the activation of PLC-ß3 and IP_3-dependent Ca^{2+} release in circular muscle and to the activation of PLA_2 and Ca^{2+}-induced Ca^{2+} release in longitudinal muscle. [175] The net effect of adenosine is contraction, which is augmented after blockade of A_2 receptors; blockade of A_1 receptors unmasks relaxation.

Two types of receptors for serotonin, 5-HT_2 and 5-HT_4, coexist on smooth muscle cells of the stomach and intestine. The 5-HT_2 receptors mediate contraction through the increase of cytosolic Ca^{2+}, and the 5-HT_4 receptors mediate relaxation through an increase in cAMP. [176] Similarly, two types of receptors for histamine, H_1 and H_2, coexist on smooth muscle cells of the stomach and intestine. H_1 receptors mediate contraction through an increase in Ca^{2+}, and H_2 receptors mediate relaxation through an increase in cAMP. [177] For both 5-HT_2 and histamine H_1 receptors, Ca^{2+} mobilization in circular muscle is mediated by means of PLC-ß1 and IP_3-dependent Ca^{2+} release, while in longitudinal muscle it is mediated by means of PLA_2 and Ca^{2+}-induced Ca^{2+} release. The net effect of 5-HT and histamine is contraction, reflecting the dominant influence of 5-HT_2 and H_1 receptors, respectively. The blockade of 5-HT_4 or H_2 receptors augments the contraction, whereas blockade of 5-HT_2 or H_1 receptors unmasks relaxation.

The influence of histamine, serotonin, adenosine, and various eicosanoids probably is more pronounced when smooth muscle is inflamed. Humoral agents are released from cells that lie in proximity to muscle cells and to myenteric neurons and their terminals. These agents can act directly on muscle cells, or they can act indirectly by stimulating or inhibiting the release of neurotransmitters and thereby influencing physiological responses.

SUMMARY

Smooth muscle of the gut exhibits variable tone on which are superimposed rhythmic contractions, driven by cycles of depolarization and repolarization (slow waves) that originate in pacemaker cells (interstitial cells of Cajal) located mainly at the periphery of circular muscle. Ca^{2+} influx occurs when the depolarization attains a level at which voltage-gated Ca^{2+} channels are activated, triggering a transient contraction superimposed on muscle tone. Release of excitatory neurotransmitters (mainly acetylcholine and the tachykinins, substance P, and NKA) from enteric motor neurons accentuates depolarization and Ca^{2+} influx and initiates Ca^{2+} release, causing an increase in both tone and rhythmic contraction. Release of inhibitory/relaxant neurotransmitters (mainly VIP, PACAP, and NO), enhanced by VIP/PACAP-dependent generation of NO from smooth muscle cells, induces hyperpolarization of the plasma membrane and suppresses rhythmic contractile activity (hence the term *inhibitory*) and attenuates muscle tone (i.e., induces relaxation). In some regions, interstitial cells within the muscle mass may participate in relaying neural input to smooth muscle.

The effects of excitatory and inhibitory neurotransmitters on tone (and, to a lesser extent, on rhythmic contractions) are mediated by G-protein–coupled receptors. Muscle contraction occurs in two phases. The initial phase consists of a transient contraction mediated by Ca^{2+}-calmodulin–dependent activation of MLC kinase and phosphorylation of MLC_{20}. Ca^{2+} mobilization during the initial phase involves G-protein–dependent activation of PLC-ß and stimulation of IP_3-dependent Ca^{2+} release in circular muscle and G-protein–dependent activation of PLA_2 and arachidonic acid–stimulated Ca^{2+} influx, followed by Ca^{2+}- and ADP ribose–induced Ca^{2+} release in longitudinal muscle. The second phase consists of a sustained Ca^{2+}-independent contraction during which MLC_{20} phosphorylation is maintained by PKC- and Rho kinase-dependent inhibition of MLC phosphatase. The pathway that leads to inhibition of MLC phosphatase involves activation of the heterotrimeric protein, G_{13}, the monomeric G protein, RhoA and its associated kinase, phospholipase D, and PKC.

Relaxation is mediated by NO- and VIP/PACAP-dependent stimulation of cAMP and cGMP and activation of both PKA and PKG. cAMP and cGMP levels are maintained within narrow limits by PKA/PKG-dependent feedback mechanisms that activate PDEs and inhibit cyclases. PKA inhibits adenylate cyclase and activates cAMP-specific PDE3 and PDE4 and cGMP-specific PDE5, whereas PKG inhibits soluble guanylate cyclase and activates PDE5. The concurrent stimulation of cGMP enhances cAMP levels by inhibiting PDE3 activity and greatly increases the affinity of cAMP for PKG. Thus, during physiological neural activity when both cyclic nucleotides are present, the more abundant cAMP preferentially activates PKG. Both protein kinases inhibit PLC-ß and PLA_2 activities, but only PKG directly inhibits IP_3-induced Ca^{2+} release. These properties are mainly responsible for the ability of PKA and PKG to inhibit initial contraction. The inhibition of sustained contraction is mediated by the ability of both protein kinases to inhibit RhoA activity and to stimulate MLC phosphatase activity.

The interplay of smooth muscle cells, interstitial cells, and enteric neurons (interneurons, sensory neurons, and excitatory and inhibitory motor neurons) is seen to best advantage in the regulation of the peristaltic reflex. The reflex is triggered by mucosal stimuli produced by the passage of digesta through the intestine, and only exceptionally by distention, which uses an extrinsic sensory pathway. Mucosal stimulation releases 5-HT from enterochromaffin cells; 5-HT acts on 5-HT_4 receptors located on the nerve terminals of intrinsic, sensory CGRP-containing neurons; the information is relayed sequentially through somatostatin and opioid interneurons to the ascending and descending excitatory and inhibitory motor neurons. The ascending limb of the reflex involves the release of acetylcholine and tachykinins from excitatory motor neurons and mediates orad contraction of circular muscle; the descending limb, which mediates caudad relaxation of circular muscle, involves the combined release of VIP, PACAP, and NO from inhibitory motor neurons, accentuated by VIP/PACAP-mediated NO production in muscle cells. A distinct set of VIP/PACAP/NOS interneurons that synapse with tonic cholinergic/tachykinin motor neurons innervating longitudinal muscle mediates reciprocal caudad contraction and orad relaxation of longitudinal muscle. The ability of 5-HT_4 agonists to initiate peristalsis, particularly when combined with opioid antagonists, underlies their therapeutic potential.

CHAPTER 7

Richard S. Blumberg and William F. Stenson

THE IMMUNE SYSTEM AND GASTROINTESTINAL INFLAMMATION

The intestinal epithelial cell surface represents a vast frontier of body surfaces that must be defended by the immune system. The intestinal immune system must defend against the many infectious and toxic assaults that may breach the epithelium and cause intestinal injury. The immune system also must recognize epithelial cell transformation, to which the intestine may be uniquely prone, because toxin exposure and the high proliferation rate of the epithelial cells increase the risk for cytogenetic error and malignant transformation. [1] The intestinal immune system must simultaneously ignore the multitude of commensal organisms and dietary antigens that are not threats to the host.

Because specific immunity is driven by antigen recognition, the components of the immune system that protect the gut are presented with a significant challenge in differentiating foreign or nonself material from self-antigens by responding to the former and ignoring the latter. Except for a few other epithelial surfaces, no other organ system is presented with this combination of problems in such a dramatic fashion. The skin is covered by a horny layer of epithelial cells that effectively excludes most antigens. As a result of constant antigenic exposure, the gut possesses abundant lymphoid cells (i.e., B and T lymphocytes) and myeloid cells (i.e., macrophages, neutrophils, eosinophils, mast cells). The mucosal immune system of the gastrointestinal tract represents one of the largest immunologic compartments in the body. [2]

To deal with this challenge, the gut-associated lymphoid tissue (GALT) has evolved several important modifications of antigen processing, humoral immunity, and cellular immunity to cope with its organ-specific responsibilities. These include flattened epithelial microfold (M) cells that transport antigens, the specialized epithelial cells of the domes overlying lymphoid aggregates that sample lumenal antigens selectively, the immunoglobulin A (IgA) system that helps to exclude and remove foreign antigens, and unique mechanisms of generating local specific secretory immunity in the context of systemic tolerance. [3], [4], [5], [6] and [7] The functional segregation of intestinal from systemic compartments reiterates the separate role of the intestine as a unique lymphoid organ that is linked to other mucosal surfaces, such as those of the lung, breast, and genitourinary tract, to create a common mucosa-associated lymphoid tissue (MALT). [8] Functional linkage of the MALT is accomplished by the regulated traffic of lymphocytes between the affiliated tissues. [9]

Advances in molecular biology have provided important insights into the general operation of the immune system, including the manner in which the immune system processes, presents, and recognizes antigens through the major histocompatibility complex, T-cell receptors, and immunoglobulins; the mechanisms by which the responsive cellular elements are stimulated after antigen contact through accessory molecules, adhesion molecules, and signal transduction; and the manner in which the activated immune cells carry out their functional destiny through the production of cytokines and other humoral factors and through cytolysis. The immune response generated by these events usually is self-limited after the foreign antigen is cleared. Without self-regulation or with persistent uncleared antigen, chronic inflammation results, as in inflammatory bowel disease. [10]

INNATE AND ADAPTIVE IMMUNITY

Two types of immunity normally function along the mucosal surfaces: natural (innate) and acquired (adaptive). Although natural immunity is nonspecific and rapidly mobilized, acquired immunity is specific for antigens on foreign substances and is mobilized slowly over several days or weeks after an initial or primary exposure. In general, specific immunity amplifies the initial protection provided by natural immunity in a focused, antigen-specific manner, in part through the further mobilization of the natural immune components. In the adaptive immune system, lymphocytes interact with antigens through receptors (the T-cell receptor and the B-cell receptor) that are specific for that antigen. When a specific antigen is presented to one of the few lymphocytes with a receptor capable of recognizing it, that lymphocyte undergoes clonal expression. Unlike natural immunity, adaptive immunity is characterized by the acquisition of memory during the course of a specific immune response, which produces a more rapid mobilization of directed, specific immunity in future or secondary antigen encounters.

Natural intestinal immunity has two components: nonimmunologic and immunologic. The mucosal surface of the intestine expresses a variety of nonimmunologic physiochemical barriers to exclude, inactivate, or clear pathogenic substances and organisms. These barriers include gastric acid, digestive enzymes, and other potentially antipathogenic factors, such as bile acids, lysozymes, intestinal mucus, normal peristalsis, indigenous microbial flora, and the epithelial cell itself, whose tight junctions are usually impenetrable when intact. In diseases such as the acquired immune deficiency syndrome (AIDS), defects in one or more of these factors may increase susceptibility to invasive pathogens.

A second class of natural immunity is composed of immunologic factors. [11] These include cellular and soluble elements. Virtually all classes of cells participate in innate immunity, including natural killer (NK) cells, a subclass of T cells called *NK-T cells,* phagocytes, mast cells, and epithelial cells, among others. In response to specific cell surface signals delivered by a variety of receptors, these cells either engulf microorganisms (e.g., phagocytes) or secrete a wide variety of soluble substances. The latter function to remove pathogens (e.g., cryptdins from intestinal epithelial cells), recruit other cell types (e.g., interleukin-8 [IL-8] from intestinal epithelial cells), arm other cell types against microbial invasion (e.g., interferon-? [IFN-?] from NK-T cells), remove cells altered by infection or malignancy (e.g., granzymes and perforins from natural killer cells), or modify specific immune responses (e.g., IL-4 from NK-T cells). Many of these responses are initiated by interactions between specific components of microbes and either soluble or cell surface receptors on host cells (pattern recognition receptors) that recognize characteristic microbial structures, such as the recognition of bacterial lipopolysaccharide by toll receptors (Table 7-1). In contrast to the adaptive immune system, in which there are many thousands of distinct T-cell and B-cell receptors, there are relatively few (several hundred) receptors in the innate immune system. The innate immune system receptors recognize a few highly conserved molecules that exist in large groups of microorganisms and are termed *pathogen-associated molecular patterns*. These microbial molecules, which include lipopolysaccharides, peptidoglycans, and lipoteichoic acids, share certain attributes: (1) None of them are

expressed by the host, (2) they are required for microbe survival, and (3) they are shared by a broad group of pathogens. The receptors of the innate immune system are expressed on antigen-presenting cells, which include monocytes, macrophages, dendritic cells and B cells; some are also expressed on intestinal epithelial cells. The receptors of the innate immune system—pattern recognition receptors—include toll-like receptors, which recognize lipopolysaccharides, and macrophage mannose receptors, which recognizes carbohydrates with large numbers of mannose units, characteristic of microorganisms. Pattern recognition receptors are expressed uniformly on large numbers of cells of a given class. For example, all macrophages express the same mannose receptor, in contrast to the acquired immune system, in which different T cells express thousands of different T-cell receptors. Recognition of bacterial products by pattern recognition receptors results in prompt intracellular signaling events and a biologic response. For example, recognition of lipopolysaccharide by toll-like receptors results in the activation of nuclear factor-?B (NF-?B) and, as a consequence, the induction of a wide variety of inflammatory- and immune-response genes. This prompt biologic response in the innate immune system occurs over a few hours, in contrast to the much slower response in the acquired immune system, which involves clonal expression of relevant lymphocytes over several days. The innate immune system, therefore, is much better situated than the acquired immune system to deal with acute infections caused by pathogens new to the host.

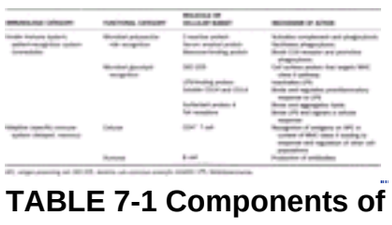

TABLE 7-1 Components of Innate and Adaptive Immune Responses

Specific immunity also has two components: humoral and cellular. Humoral immunity is represented by antibodies derived from B lymphocytes and defends against extracellular events. Cellular immunity is derived from T lymphocytes and provides protection from deleterious intracellular events that are not amenable to the effects of antibodies.

Both types of specific immunity possess several properties that differentiate them from nonspecific immunity. First, to respond to the wide variety of potential antigens to which humans may be exposed during a lifetime, a large number of clonally distinct lymphocytes specific for particular determinants or epitopes on a molecule are maintained. The molecular basis for this clonotypic specificity is determined by a cell surface receptor (i.e., immunoglobulin for B cells and T-cell receptor for T cells) that is unique to each cell or clone. Second, each cell or clone expressing its unique or clonotypic receptor is selected to differentiate a self-antigen from a nonself or foreign antigen. This process, which is primarily the result of positive selection (i.e., selection of good receptors) and negative selection (i.e., deletion of bad receptors) of B cells in the bone marrow and T cells in thymus during lymphocyte development, results in the production of an army of lymphocytes that are tolerant or nonresponsive to self. [12], [13] and [14]

In the absence of tolerance, inappropriate recognition of self may occur, resulting in autoimmunity. The intestine, liver, and peritoneum participate in the extrathymic pathways of T- and B-cell development, and self-reactive lymphocytes that escape from the normal selection processes may reside within these organs. [14], [15] The fact that intestinal autoimmunity is not commonly observed suggests that peripheral mechanisms in the intestine prevent the activation of potentially pathogenic clones (see section “ Autoimmunity and Oral Unresponsiveness”).

The specific immune system generates memory during the course of the immune response that results in the expansion of long-lived cells, representing the progeny of the original responsive antigen-specific B-cell or T-cell clones. After reexposure to the original offending antigen, the adaptive immune system responds more rapidly, is quantifiably larger, and becomes more specific. In the case of B cells, for example, immunoglobulins are generated that bind more avidly to their antigen.

COMPONENTS OF THE IMMUNE SYSTEM

T Lymphocytes

T lymphocytes play a crucial role in immune effector function and regulation by recognizing and eliminating infectious agents and tumors and by orchestrating a coordinated immune defense through their regulatory effects on other cell populations. Lymphoid progenitors destined to be T cells arise from pluripotent stem cells in the bone marrow and migrate to the thymus. Within the thymus, maturation and education about self-antigens occur, leading to the production of self-tolerant T cells that migrate to and populate the secondary lymphoid organs, including the spleen, lymph nodes, and tonsils. The intestine contains secondary lymphoid aggregates in the form of Peyer patches (see section “ Peyer Patches and Lymphoblast Homing”).

Unlike B cells, which recognize determinants on whole soluble antigens, most T cells recognize processed nominal antigens or peptide fragments from the whole antigen in association with components of the major histocompatibility complex (MHC) on the surface of an antigen-presenting cell. [16] The antigen-specific or clonotypic receptor on the cell surface of T cells that is responsible for the recognition of antigen in the context of an MHC molecule is the T-cell receptor. The T-cell receptor consists of immunoglobulin-like, heterodimeric glycoproteins, called *aß* and *?d heterodimers*. [16], [17] Rarely, the T-cell receptor exists on the cell surface as a ßß homodimer. Most mature T lymphocytes in the peripheral blood and intestine express the aß heterodimer, and the others express the ?d receptor. Transfection experiments and, more recently, x-ray crystallography have proved that the aß heterodimer achieves recognition of a peptide in association with an MHC molecule. [18] The mechanism of recognition of the ?d T-cell receptor is not as clearly defined. [19] However, T cells bearing a ?d T-cell receptor have been shown to recognize a variety of target cell structures, including classic and nonclassic MHC class I molecules (e.g., recognition of MHC class I chain-related gene A [*MICA*] by ?d T cells in the human intestinal epithelium serves to remove impaired epithelial cells), extracts of mycobacteria, heat shock proteins, viral glycoproteins, and small nonpeptide phosphorylated molecules.

The protein structures of the T-cell receptor a, ß, ? and d chains, as deduced from their complementary DNAs, consist of a leader peptide, a long amino-terminal extracellular domain, a transmembrane region, and a short cytoplasmic tail. [20] These protein segments are organized into variable (V), joining (J), constant (C), and, for the ß and d chains, diversity (D) regions. Like immunoglobulins, these structural regions are each encoded by distant gene segments on chromosome 14 (e.g., T-cell receptor a and d) and chromosome 7 (e.g., T-cell receptor ß and ?) that recombine during T-cell development in the thymus (Fig. 7-1). In the case of the T-cell receptor ß chain, for example, there are approximately 60 different V gene segments, organized into 24 different V-region families, 2 D-region segments, 13 J-region segments, and 2 C-region segments. The sequential recombination of a D-region gene to a J-region gene and a V-region gene to a D-region gene, with looping out and deletion of the intervening genomic sequences, results in a functional transcriptional unit that is transcribed, spliced appropriately, and translated. These genetic recombination events are orchestrated by protein products of the recombination-activating genes (RAGs). In the absence of functional RAG proteins, T- and B-cell development does not occur.

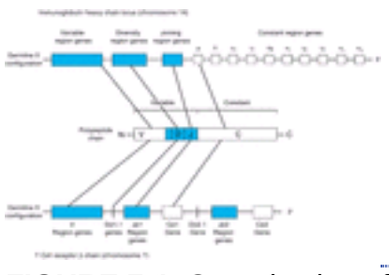

FIGURE 7-1. Organization of the immunoglobulin heavy chain locus on chromosome 14 and the T-cell receptor ß-chain locus on chromosome 7. In both, distant clusters of gene segments encoding variable (*V*), diversity (*D*), joining (*J*), and constant (*C*) regions recombine during T-cell development in the thymus and B-cell development in the bone marrow to create a functional transcriptional unit that is translated into a polypeptide chain. The polypeptide chain contains a variable region

that is involved in antigen binding (i.e., soluble antigens for B cells and peptide fragments in the context of an MHC component for T cells), and a constant region that is involved in anchoring the immunoglobulin or T-cell receptor protein to the plasma membrane as an integral membrane protein. Alternative immunoglobulin transcripts are expressed that encode a secreted form of the molecule in which the constant region domain (i.e., Fc portion) of the protein possesses an effector function (e.g., complement fixation, opsonization, antibody-dependent cell-mediated cytotoxicity, immediate hypersensitivity). Most of the variable region is concentrated at the junction of VDJ regions (*shaded areas*), which are involved in antigen (e.g., immunoglobulin) and peptide/MHC (e.g., T-cell receptor) binding. In the case of the T-cell receptor, more amino-terminal sequences in the variable region are primarily involved in interactions with the MHC protein outside the peptide-binding pocket.

To allow for the multitude of potential antigenic interactions, diversity of the T-cell receptor is accomplished by several mechanisms: the existence of multiple V-, D-, and J-region genes; recombination of the D region in multiple reading frames; addition of nucleotides not included in the germ-line configuration at the V-D and D-J junctions by activity of terminal deoxynucleotidyl transferase (non–germ-line or N-region additions); and different combinations of either the T-cell receptor a and ß or ? and d chains. [21] As a result, most of the variability of the T-cell receptor is concentrated at the V-D-J junction or complementarity-determining region 3 (CDR3) part of the receptor. This hypervariable region of the T-cell receptor, or NDN region, represents the clonotypic determinant of the receptor, with sequences in the more amino-terminal region of the T-cell receptor (CDR1 and CDR2 regions) more involved in MHC interactions. The average length of the CDR3 region of the T-cell receptor a and ß chains is about ten amino acids. The longer length of the T-cell receptor ?- and d-chain CDR3 regions (20+ amino acids) is consistent with the hypothesis that counterligands for these receptors may be recognized in a manner that is more similar to that of immunoglobulins. Simultaneous crystallization of the T-cell receptor aß heterodimer and MHC class I molecule has shown that the CDR3 region of the T-cell receptor is the major contact site for antigenic peptide. [18]

Intimately associated with the aß or ?d T-cell receptor in a noncovalent fashion on the cell surface are at least four proteins of the cluster of differentiation 3 (CD3) complex: ?, d, e, and ?. The CD3 complex likely has a stoichiometry that consists of two e and ? chains and one ? and d chain. Although invariant and not contributing to the antigen specificity of the T-cell receptor, the CD3 proteins are members of the immunoglobulin supergene family. The CD3 proteins are involved in the assembly and transport of the T-cell receptor to the cell surface and in signal transduction after the T-cell receptor binds antigen in the context of MHC. The T-cell receptor and CD3 complex together play the central role in cognate or antigen-specific interactions with an antigen-presenting cell.

Several molecules play important roles in noncognate or antigen-nonspecific interactions between a T cell and an antigen-presenting cell. T cells are segregated into distinct functional subtypes by the expression of combinations of these molecules as defined by the CD antigens. T cells can be broadly divided into two categories: cells that express CD4 and cells that express CD8. Cells that express the CD4 molecule, a 60-kd glycoprotein, help coordinate immune responses and recognize antigenic peptides in the context of class II MHC molecules. Most cells that express CD8, a 32-kd heterodimeric glycoprotein, have the aß heterodimer, and a minority have an aa homodimer. The CD8-positive ($CD8^+$) T cells recognize antigenic peptides in the context of class I MHC molecules, whereupon they elicit cytolysis or secrete cytokines that influence immune response networks. [22] The antigen-independent conjugate formation between CD8 and class I MHC and between CD4 and class II MHC determinants provides a stabilizing environment for the ternary interactions between the T-cell receptor and its target antigenic peptide and MHC complex. Through interactions with other intracellular ligands, such as the nonreceptor lck protein tyrosine kinase, the CD4 and CD8 molecules play an essential role in signal transduction in addition to their noncognate cell surface binding activities. [23]

In addition to CD4–MHC class II and CD8–MHC class I determinants, other important T-cell and antigen-presenting cell interactions play a role in modulating adhesion and signal transduction. T-cell activation requires two events. First, the T cell must adhere to the local connective tissue matrix and antigen-presenting cell, which stabilizes subsequent intercellular interactions and may provide intracellular signals for subsequent events. Second, the T cell must appropriately receive two distinct intracellular signals from cell surface molecules: an antigen-specific signal (signal 1) through the T-cell receptor and CD3 complex (i.e., cognate signal) and an antigen-independent signal (signal 2) through an accessory molecule on the T cell (i.e., noncognate or costimulatory signal) that is delivered by its ligand counterpart on an antigen-presenting cell. [24] Delivery of these two signals provides the appropriate impulse for activation.

In response to the composite of cognate and noncognate cell surface interactions, a signal is transmitted intracellularly, resulting in a cascade of early biochemical and later nuclear events that lead to the expression of new cell surface antigens important to further intercellular interactions, cell growth, and the functional expression of the cell. The signal transduction pathways initiated by T-cell receptor–CD3 complex ligation and binding of the CD4 and CD8 coreceptor are highly complex and include activation of tyrosine kinases (lck, fyn, ZAP70), leading to activation of phospholipase C?1, ras, and phosphatidylinositol 3-kinase, leading in turn to mitogen-activated protein kinase (MAPK) and protein kinase C activation and calcium mobilization. Subsequent activation of cytosolic and translocated nuclear factors, such as nuclear factor of activated T cells (NFAT), initiate new gene transcription, such as IL-2 production. [23]

In the absence of the costimulation provided by a second signal, clonal anergy (i.e., tolerance) to the antigen or apoptosis (i.e., cell death) may occur. [25] The requirement for two signals is probably fundamental to antigen-specific events and presumably plays an important role in extrathymic mechanisms of avoiding autoimmunity. Costimulation is most important to activating naive (virgin) T cells and less so to previously activated T cells, which may depend more on cytokine signals (e.g., from IL-15). [26] Some of the accessory molecular interactions between a T cell and an antigen-presenting cell are summarized in Table 7-2. In particular, the signal delivered to several CD28-related molecules on the T cells by several CD80/CD86-related molecules on the antigen-presenting cell may be critical for T-cell activation. [27], [28] A molecule homologous to CD28, CTLA-4, is expressed on activated T cells and uses CD80 and CD86 as its ligands. CTLA-4 may function to provide a corollary down-regulatory signal to T cells on binding CD86. Blockade of the CD28-CD80/CD86 pathway with recombinant decoy molecules resembling CD28 suppresses cellular activation. [28]

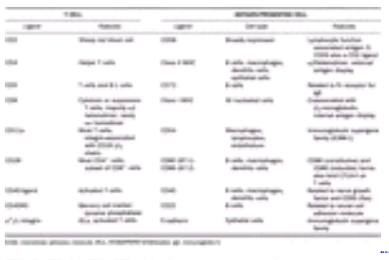

TABLE 7-2 Ligand Interactions Between T Cells and Antigen-Presenting Cells

Major Histocompatibility Complex and Antigen Presentation

The strict dichotomy between CD4- and CD8-bearing T cells in terms of their recognition of antigens in the context of class II and class I MHC, respectively, has important functional implications. An understanding of the molecular basis of antigen processing is essential to appreciate these effects.

The human MHC is also known as the *human leukocyte antigen (HLA) complex*. The MHC or HLA products and the genes that encode them are subdivided into three classes. The MHC class I and class II glycoproteins are involved in antigen presentation to T cells. The three main MHC class I genes are designated *HLA-A, HLA-B,* and *HLA-C;* the three main MHC class II genes are designated *HLA-DP, HLA-DQ,* and *HLA-DR*. The class III MHC genes encode for a variety of functionally distinct proteins (e.g., complement components, heat shock proteins, and tumor necrosis factors).

The genes for the MHC class I and II molecules and several genes that are involved in antigen processing, such as the proteosome-like genes and transporter genes, are encoded in the MHC locus on the short arm of human chromosome 6. Each MHC class I protein is expressed on the cell surface as a dimer composed of two noncovalently linked polypeptide chains: a 43-kd integral membrane glycoprotein called the *heavy* or *a chain,* encoded by the *HLA-A, HLA-B,* and *HLA-C* genes, and an associated non–MHC-encoded, nonglycosylated 12-kd protein called *ß2-microglobulin*.

The a or heavy chain of the MHC class I molecule consists of three extracellular folded domains, a_1, a_2, and a_3, that are each encoded by separate exons and share structural homology with immunoglobulins. The a_1 and a_2 domains of the *HLA-A, HLA-B,* and *HLA-C* genes are highly polymorphic, adjacent, and roughly parallel to one another. Based on the defined crystal structure of an HLA-A2 molecule, the two domains form a groove consisting of a series of ß-pleated sheets

bounded by two a helices that bind a peptide of relatively strict length (nine amino acids). [29], [30] The degree of observed variability within the a_1 and a_2 domains suggests that antigenic peptides reside in the groove, and that exposed surfaces of the a helices interact with the V region of the T-cell receptor. Because each person carries six different HLA-A, HLA-B, and HLA-C alleles and each allelic gene product is capable of binding a variety of different peptides, the peptide-carrying capacity of the endowed class I MHC is theoretically enormous; the estimate is about 50 HLA-A, 97 HLA-B, and 34 HLA-C alleles in the human population. [31]

Certain molecules encoded within the HLA class I region, such as HLA-E, HLA-F, HLA-G, and Hfe, and the MHC class I chain-related gene A (*MICA*), are unique in the absence of extensive polymorphism within their a_1 and a_2 domains. These nonpolymorphic molecules may be involved in immunologic recognition or other unique functions. [32] For example, leader peptides from HLA-G are presented by HLA-E to inhibitory receptors on natural killer cells. [33] Distinct alleles of Hfe have been linked to the pathogenesis of hemochromatosis. [34] These molecules are considered to be nonclassic MHC class I or MHC class Ib molecules. Some MHC class Ib molecules (e.g., CD1 and the neonatal Fc receptor for IgG) are encoded by genes outside the MHC locus on chromosome 6. The CD1 molecules appear to present lipid antigens to T cells. [35]

Class II molecules are nondisulfide-linked heterodimeric glycoproteins consisting of a 32- to 34-kd a chain and a 29- to 32-kd ß chain that are encoded by different genes in the MHC class II genetic locus. Significant allelic variation exists for the *DRß* (126 alleles), *DPß* (60 alleles), and *DQß* (26 alleles) genes, in contrast to the *DRa* (2 alleles), *DPa* (8 alleles), and *DQa* (15 alleles) genes. [31] The extracellular portion of a class II molecule consists of two domains, approximately 90 amino acid residues long, called a_1-a_2 and $ß_1$-$ß_2$, respectively. Similar to the class I MHC, x-ray crystallographic studies of HLA-DR1 show that the a_1 and $ß_1$ domains of an MHC class II molecule form a peptide-binding pocket with somewhat less stringency in peptide length (15–18 amino acids) than MHC class I–associated peptides. [36] The class II MHC is highly polymorphic, with the polymorphic residues concentrated in the membrane-distal a_1 and $ß_1$ domains, which are involved in peptide binding. The three-dimensional structure revealed by x-ray crystallography shows that each MHC class II molecule naturally exists as a dimer similar to immunoglobulin. Multimeric receptor forms are also possible for other molecules involved in cognate recognition (e.g., MHC class I, T-cell receptor) and probably increase the avidity of the reaction with the apposing cell.

Although extensive structural similarities exist between class I and class II MHC molecules, the origin of the derived peptide differs substantially. MHC class I peptides usually are derived from intracellular proteins, and MHC class II peptides usually are derived from the extracellular milieu. Distinct cellular compartments and trafficking pathways determine the source of antigenic peptides for the two classes of MHC molecules. MHC class I molecules primarily bind cytoplasmic proteins (e.g., viral proteins in infected cells) that are degraded into peptides by a large cytoplasmic proteolytic complex derived from at least two genes in the HLA class II region that code for low-molecular-mass polypeptides 2 and 7. These peptide fragments are transported into the endoplasmic reticulum by an endoplasmic reticulum membrane–associated heterodimer that is derived from the gene products of the MHC class II–associated genes, transporter-associated protein 1 (TAP1) and TAP2. In the endoplasmic reticulum, the transported peptides bind to the MHC class I groove or binding pocket. On loading with peptide, $ß_2$-microglobulin associates with the MHC class I heavy chain, and a stable conformation is assumed that allows cell surface transport of the MHC class I peptide complex. [37]

Class II MHC molecules bind peptides derived from exogenous proteins that have been internalized by means of antigen-presenting cells in a coated pit into the endocytic pathway, where antigen degradation generates functional peptides. Intersection of the endocytic pathway with class II MHC molecules derived from the trans–Golgi network results in binding of the exogenous peptide to the peptide-binding groove of the class II proteins and the release of the invariant or ? chain, which stabilizes class II molecules before peptide binding. Before release of the MHC class II–associated invariant chain, the ? chain is proteolytically degraded to a smaller fragment, CLIP, which remains associated with MHC class II until exchange with exogenous peptide occurs. The exchange is facilitated by a nonpolymorphic product of the MHC class II locus, HLA-DM, which is restricted to an intracellular location within a specialized MHC class II compartment related to lysosomes. The resulting peptide-protein complex is then translocated to and expressed on the cell surface. [37] The antigen-processing machinery associated with the CD1-related molecules (CD1a-d) for presentation of glycolipids overlaps with and is highly homologous to the MHC class II pathway and is considered to be a third pathway of antigen presentation. [35]

At any given time, cells display a summary of their internal antigenic exposure through class I molecules and their external antigenic exposure through class II MHC molecules. Under normal circumstances, self-proteins are displayed, leading to a state of tolerant inactivity. Under abnormal circumstances, deleterious intracellular events lead to the display of MHC class I molecules bound with foreign peptides, the activation of $CD8^+$ T cells, and the generation of cytolytic T cells. Similarly, extracellular exposures to foreign substances result in the cell surface display of class II MHC molecules bound with foreign peptides, leading to the activation of $CD4^+$ T cells, the induction of B cells through helper T-cell activity, and immunoglobulin production.

The CD8–MHC class I pathway is propelled by internal cellular events. Because virtually all nucleated cells express MHC class I molecules, essentially all cells can act as antigen-presenting cells for $CD8^+$ T cells, providing important protection against harmful intracellular processes such as viral infection and neoplasia. The CD4–MHC class II pathway is responsive to external cellular events, but the relative restriction of constitutive MHC class II expression and antigen-presenting capacity to B cells, macrophages, dendritic cells, venular endothelial cells, and probably intestinal epithelial cells of the small intestine and colon during inflammation limits the possibilities and consequences of activating $CD4^+$ T cells. Moreover, the restricted expression of accessory molecules essential to T-cell activation, such as CD80 and CD86, also imposes strict limitations on antigen-initiated T-cell activation.

Immunoglobulins

When expressed on the surfaces of B lymphocytes, immunoglobulin molecules serve as clonotypic receptors, comparable to the T-cell receptor on T cells. [38] After binding their cognate antigens, the surface immunoglobulins initiate a cascade of events that may activate the B cell, prompt clonal proliferation, and generate plasma cells. The immunoglobulins that are secreted as a result of this activation function as antibodies, traveling throughout tissue fluids to detect and bind to the antigenic molecules that first triggered their production.

Each B cell expresses a unique immunoglobulin molecule that contains hypervariable regions conferring its antigenic specificity or idiotype. The secreted antibodies consist of two identical light chains of about 24 to 28 kd, each linked by disulfide bridges to two identical heavy chains of about 55 to 70 kd that are linked by disulfide bridges to each other. Each chain consists of repeating homologous globular domains, called *immunoglobulin domains,* in tandem. [17]

There are two immunoglobulin light chain types (? and ?) and five immunoglobulin heavy chain isotypes (?, µ, a, e, and d). There are two isotypes of IgA (IgA1 and IgA2) and four isotypes of IgG (IgG1, IgG2, IgG3, and IgG4), which are determined by the C-region gene segment (see Fig. 7-1). Alleles, or allotypes, of these isotypes also exist. Although the biologic function of the antibody (e.g., complement fixation) is determined by the Fc portion of the isotype, the antigen specificity of the antibody is determined by the amino terminus of the heavy and light chains, which are encoded by the V-, D-, and J-region gene segments—the idiotypic region of immunoglobulins. The polymorphism of the V region is further concentrated into three hypervariable stretches, called *complementarity-determining regions (CDR1–3),* the tertiary structure of which complements that of the bound antigen and plays an important role in antigen binding. Four protein segments intervene between the three CDR regions. These four segments are relatively nonpolymorphic and are called *framework regions (Fr1–4)*.

The diversity of immunoglobulins for interaction with the wide variety of environmental antigens is accomplished by mechanisms similar to those described for the T-cell receptor. Unlike T-cell receptors, immunoglobulins also increase diversity by somatic mutation of the variable gene sequence after recombination of immunoglobulin gene segments has taken place, which accounts for the avidity maturation of immunoglobulins during secondary antigen encounters. Most avidity maturation generated by somatic mechanisms involves the CDR1–3 regions and, less commonly, the Fr1–4 regions.

B Lymphocytes

B lymphocytes are the progeny of hematopoietic stem cells in bone marrow and fetal liver. Pre–B cells express cytoplasmic IgM heavy chain and, in the absence of cell surface IgM, are antigen-independent. Further antigen-independent maturation within the bone marrow leads to the development of antigen-responsive, membrane IgM- and IgD-positive B cells expressing the same V region or idiotype. The membrane IgM on mature B cells is noncovalently associated with a disulfide-linked heterodimer, consisting of Ig-a and Ig-ß transmembrane glycoproteins, that participates in IgM cell surface transport and signal transduction after antigen binding. [39] Similar to the CD3 complex association with the T-cell receptor, Ig-a and Ig-ß probably link the surface immunoglobulin with cytoplasmic protein kinases, which become functionally activated after antigen binding.

Like T cells, B-cell subsets can be identified on the basis of phenotypic markers other than membrane immunoglobulin. CD5, a T-cell marker, is expressed by 5% to

10% of B-lineage cells. These CD5 $^{+}$ B cells, or B-1 cells, are capable of autoantibody production and may mature outside the bone marrow within the peritoneal cavity, based on studies in mouse models. [14] Within the privileged space of the peritoneum, these cells are not likely to encounter their antigen and be activated to produce antibody. Their expansion in autoimmune disease suggests that under certain circumstances they may be activated to express autoantibody. Most B cells do not express CD5; they are known as *B-2* or *common B cells*. Other B-cell molecules of potential significance include CD19, CD20, and CD40. These molecules are expressed by all human B cells and are involved in B-cell activation, proliferation, and, for CD40, isotype switching. [40] CD40 binds to CD40-ligand on an activated T cell and functions as an important costimulatory molecule. [41]

Outside the bone marrow in the periphery, the stimulation of mature B cells by an appropriate soluble antigen results in the clonal expansion of the responding B cell and the generation of a secreted form of the membrane-bound immunoglobulin using the same idiotype and, therefore, the same antigen specificity. Some of the clonally expanded B cells differentiate into memory cells; antigen-unstimulated B cells have a relatively short half-life. After further modulation by antigen-specific T cells, B cells switch the isotype form associated with the antigen-specific V region (usually to isotypes of IgG in the periphery and IgA in the GALT) and differentiate into plasma cells, which secrete extremely high levels of immunoglobulin. These stages of B-cell development depend on specific cytokines released by antigen-specific T cells, the most important of which are likely to be transforming growth factor-ß (TGF-ß), IL-4, IL-5, and IL-6.

Natural Killer Cells

Natural killer cells, which comprise about 10% of the peripheral blood lymphocytes, express neither membrane immunoglobulin nor the T-cell receptor–CD3 complex. [42] They were originally considered to be neither B cells nor T cells and were referred to as *null cells*. They may express some T-cell differentiation antigens, such as CD2 and CD8 (as an aa homodimer), and myelomonocyte differentiation antigens, such as CD11b, CD11c, CD14, and CD15. These large, granular lymphocytes characteristically express CD56, which is homologous to neural cell adhesion molecule, and sometimes express CD16, a low-affinity receptor for the Fc portion of IgG. CD16 is often associated with the CD3-? homodimer found in the T-cell receptor–CD3 complex.

Natural killer cells are a major component of the natural immune system. They elicit cell-mediated cytotoxicity, which plays an important role in resistance to intracellular pathogens and in the elimination of tumor cells. Although natural killer activity is a component of natural immunity, it can be modulated by T-cell–derived cytokines, such as IL-2. In turn, natural killer cells represent an important source of cytokines, such as IFN-?.

Natural killer cells are stimulated to elicit cytotoxic activity by one of two mechanisms: through binding of a target cell opsonized by IgG by means of CD16 on the natural killer cell (i.e., antibody-dependent cell-mediated cytotoxicity) or through the recognition of target cells that lack HLA-A, -B, or -C expression. Because many viruses and tumors, including intestinal cancers, down-regulate HLA-A, -B, or -C expression to evade adaptive immune responses involving classic MHC class I molecules, this mechanism of recognition is extremely important. Natural killer cells express cell surface receptors for specific HLA alleles, which, when engaged by HLA proteins, inhibit killer cell function. These killer-inhibitory receptors (KIRs) include molecules such as NKB1 (p70 KIR), which binds HLA-Bw4, and p58.1 KIR, which binds HLA-Cw4. In the absence of these inhibitory signals by MHC class I molecules, killer-activating receptors (KARs) such as p50 KAR stimulate natural killer cell activity by inducing the release of proteins such as granzyme and perforin, which kill the target cell.

Myelomonocytic Cells

Cells of the myelomonocytic lineage include monocytes and their progeny (macrophages and dendritic cells) and polymorphonuclear leukocytes (neutrophils, eosinophils, and basophils). They evolve from a common myeloid progenitor cell in the bone marrow in response to cytokines, including several interleukins (e.g., IL-1, IL-3, and IL-6) and the macrophage and granulocyte colony-stimulating factors (e.g., G-CSF, GM-CSF, M-CSF).

Monocytes, mononuclear phagocytes that mature into macrophages when residing within tissues, and dendritic cells play central roles in natural immunity through their phagocytic function and inflammatory cytokine secretion, and in specific immunity through their ability to endocytose, process, and present foreign antigens to T cells. [43] Monocytes within the peripheral blood almost uniformly express the CD14 marker (see Table 7-1) and shed this molecule within tissues such as the lamina propria of the intestine, which they enter during an inflammatory response, such as occurs in inflammatory bowel disease. These recruited monocytes evolve into tissue macrophages that have active phagocytic functions. The phagocytic function of macrophages is aided by their expression of receptors for the Fc portion of immunoglobulins and complement components (C3b) that coat foreign antigens. These phagocytic functions are important not only for eradicating invading microorganisms but also as the essential first step in initiating antigen processing and presentation for MHC class II pathways, which is a prerequisite for activating CD4 $^{+}$ T cells that orchestrate further immune responses. Macrophages promote inflammation by secreting IL-12 and IL-18, which drive CD4 $^{+}$ T cells to secrete IFN-? that in turn activates the phagocytic and antigen presentation functions of the macrophage.

Dendritic cells are the most potent antigen-presenting cells. The GALT, both organized (Peyer patches) and nonorganized (lamina propria and epithelium), contains dendritic cells. [44] Within tertiary lymphoid tissues such as the lamina propria, dendritic cells are considered to be immature; they exhibit active phagocytic functions but poor antigen presentation functions. On migration to regional lymph nodes, such as the Peyer patches and mesenteric lymph nodes, dendritic cells mature and up-regulate their antigen presentation functions through the expression of important costimulatory molecules, such as CD80 and CD86. A characteristic feature of dendritic cells is their heterogeneity, which likely correlates with specific immunologic functions. In the mouse, three subsets of dendritic cells, defined by CD11c expression, have been identified that express either CD11b (myeloid), CD8 (lymphoid), or neither marker (double-negative). Although the function of the double-negative subset remains unknown, the myeloid and lymphoid subsets appear to be responsible for inducing differentiation of naive T cells into Th2/Th3 and Th1 subsets, respectively.

Nonimmune Parenchymal Cells

A variety of parenchymal cells, which are not considered immune cells per se, exhibit important immunologic functions, thus creating an immunophysiological network. These cell types do not likely function to initiate specific immune responses through the education of naive lymphocytes but function to integrate and enhance ongoing immune responses and contribute to immunopathology in disease states. [45] These cell types include intestinal epithelial cells (see section “ Epithelial Cells” under “Gastrointestinal Inflammation”), mesenchymal cells (e.g., fibroblasts), smooth muscle cells, and endothelial cells. Fibroblasts, through the expression of cell surface molecules, connective tissue components, and cytokines, regulate local lymphocyte survival and function and contribute to TGF-ß–mediated fibrosis associated with chronic inflammation. Smooth muscle cells can present antigens in an MHC class II–restricted fashion in the context of inflammation and respond to inflammatory cytokines such as IL-4 with alterations in intestinal motility, which may play a role in increasing peristalsis, an attribute important in eradicating lumenal pathogens. Endothelial cells play a key role in regulating tissue inflammation by both directing the recruitment of leukocytes and myeloid cells (see section “ Adhesion Molecules and Cell Trafficking”) and secreting a variety of soluble mediators that enhance inflammation.

Cytokines

Cytokines are an ever-expanding group of protein hormones secreted by a variety of cell types—including immune cells (e.g., lymphocytes, macrophages) and nonimmune cells (e.g., endothelium, epithelium, fibroblasts, smooth muscle)— that have autocrine, paracrine, and endocrine functions (Table 7-3). The effect of each cytokine depends on the cytokine receptor expression of target cells, which depends on the cell’s differentiation state and previous cytokine exposure, reflecting the networks that exist between cytokine action. The pleiotropism of cytokine action creates significant repetition within these networks.

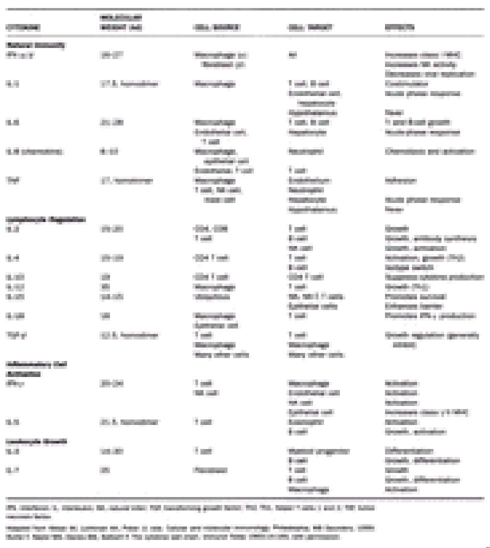

TABLE 7-3 Cytokines

Although a given cell type can secrete a variety of different cytokines and significant redundancy exists in their actions, some patterns allow functional classification of the cytokines and the cells that produce them (Fig. 7-2). Helper T (Th) cells that have been persistently stimulated can be divided into Th1 cells, which predominantly secrete IL-2 and IFN-?, a profile that supports the early events of T-cell and B-cell development (IgG1 production) and cell-mediated immunity (delayed-type hypersensitivity); Th2 cells, which predominantly secrete IL-4, IL-5, IL-6, IL-10, and IL-13, a profile associated with humoral immunity (IgG4 and IgE production); Th3 cells, which predominantly secrete TGF-ß, a profile associated with suppression; and T-regulatory (Tr1) cells, which predominantly secrete IL-10, a profile also associated with suppression. [46] Consistent with these phenotypes, T cells often are considered either effector (Th1, Th2) or regulatory (Th3, Tr1) cells. $CD4^{+}$ cells, which express CD25, the IL-2 receptor a chain ($CD4^{+}CD25^{+}$ cells), may be a particularly important T-regulatory cell capable of secreting IL-10 and TGF-ß, responsible for preventing autoimmune gastritis and inflammatory bowel disease. [47] Th0 cells exhibit a secretory pattern of cytokines that includes those associated with Th1 and Th2 patterns and also represents newly stimulated T cells. [48], [49] Th0 cells are driven to become either Th1 cells by IL-12, which stimulates the transcription factor T-bet, or Th2 cells by IL-4, which stimulates the transcription factor GATA-3. [50] Although there has been considerable interest in defining T-cell clones in this manner, most T-cell clones are not so easily defined. In addition, because many cell types secrete several cytokines, it is probably best to ascribe combinations of cytokines as type 1 and type 2 when identifying patterns of cytokine production so as not to overemphasize the source of the cytokine. These issues are important owing to the increased evidence that certain idiopathic diseases, such as inflammatory bowel disease, and inappropriate immune responses to certain infectious pathogens may be associated with distinct cytokine profiles. CD8-bearing T cells may also preferentially secrete combinations of cytokines that fall into either a type 1 or type 2 pattern. One possible classification of cytokine activity is provided by their association with natural immunity, regulation of lymphocyte function, activation of inflammatory cells, and regulation of leukocyte growth (see Table 7-3).

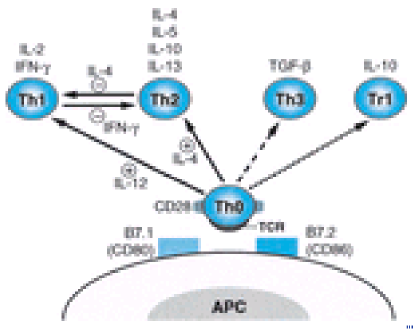

FIGURE 7-2. Helper T-cell differentiation. After the uptake and processing of the antigen, a professional antigen-presenting cell (*APC*), such as a macrophage or dendritic cell, provides two signals to a naive helper T cell (*Th0*); signal 1 is provided by presentation of the nominal peptide of the antigen in the context of an MHC class II molecule to the T-cell receptor on the T cell (*TCR*), and signal 2, the costimulatory signal, is provided by either CD80 or CD86 to CD28 on the T cell. In the presence of IL-12, the Th0 differentiates to a Th1 phenotype, and in the presence of IL-4, the Th0 differentiates to a Th2 phenotype. The Th0 cell can also differentiate to a Th3 or T-regulatory 1 (Tr1) phenotype, although the differentiating signals are unknown. *IL*, interleukin; *TGF-ß*, transforming growth factor-ß; *IFN-?*, interferon-?.

The redundancy in cytokine effects probably is related to similarities between cytokine receptors and their associated signal transduction pathways, which can be grouped into four varieties. [51] The hematopoietic cytokine receptor (R) family includes IL-2Rß, IL-2R?, IL-3R, IL-5R, IL-6R, IL-7R, IL-9R, GM-CSFR, G-CSFR, LIF-R, and gp130R. A common feature of these receptors is that they function as multimers with each other and other nonhematopoietic cytokine receptor family members, such as IL-2aR or IL-15aR. The interferon receptor family includes the receptors for type I interferons (IFN-a and IFN-ß) and type II interferon (IFN-?), which share extracellular fibronectin-like domains with the hematopoietic cytokine receptors. The tumor necrosis factor receptors (TNFR) consist of two types: p55 (TNFR1) and p75 (TNFR2). They are homologous to CD95 (Fas antigen), CD40, CD27, and nerve growth factor receptor and are involved in either proliferation or programmed cell death (apoptosis). [25] The receptors for chemokines (either C-C or C-X-C) are seven-membrane–spanning G-protein–linked receptors that are coupled to cell activation through calcium mobilization. The signal transduction pathways that transfer cell surface information to the intracellular milieu for the other cytokine receptors include the JAK/STAT and sphingomyelinase-ceramide pathways. The interferon receptor family and some members of the hematopoietic receptor family (including IL-3, IL-4, IL-6, and GM-CSF) bind and activate the Janus kinases (JAK), which are protein tyrosine kinases that phosphorylate various signal transducers and activators of transcription (STAT) factors that bind and transactivate DNA elements such as IFN-stimulated response elements (ISRE). The TNF receptor family and IL-1R activate sphingomyelinases that induce the release of ceramide as a second messenger from sphingomyelin, thus coupling cell surface receptor events to cellular responses.

CELLULAR INTERACTIONS IN THE IMMUNE SYSTEM

Although lipid and polysaccharide antigens may activate mature B cells to produce immunoglobulins, primarily of the IgM class, B-cell responses to protein antigens require the help of T cells. In the latter process, two requisite events occur. First, the binding of the protein antigen to B cells through membrane immunoglobulin activates the B cell, making it receptive to other signals delivered by T cells. Second, the protein antigen that is bound to membrane immunoglobulin is internalized through coated pits into the endocytic pathway, leading to peptide loading of the class II MHC molecule that the B cell constitutively expresses. Peptide fragments derived from the antigen complementary to the idiotype of membrane immunoglobulin of the B-cell clone are presented to antigen-specific $CD4^{+}$ T cells (Th1- and Th2-type cells). The close intercellular contact required for this B-cell and T-cell interaction makes available the cytokines expressed by helper T cells. The cytokines function as the necessary second signals to B cells for prompting immunoglobulin isotype switching and secretion. The T cell similarly requires and receives complementary signals from the B cell that are a prerequisite for its activation.

The generation of effective cell-mediated immune responses requires the cooperation of cell populations. Delayed hypersensitivity is a T cell–mediated reaction at the site of a perceived foreign substance, as is observed during the course of skin testing with antigens such as purified protein derivative and *Candida* antigen. It is a clinically important immune response to invasive intracellular organisms and to tumors. It is characterized pathologically by granulomas formed by the aggregation of monocytes or macrophages. Foreign antigen, taken up by resident class II molecule–bearing antigen-presenting cells, such as dendritic cells and macrophages, is presented as peptide fragments to antigen-specific $CD4^{+}$ T cells (predominantly Th1 cells). Antigen binding results in T-cell activation, causing the clonal expansion of the antigen-responsive T cells, cytokine secretion by the T cells, and monocyte recruitment. Primarily through the activity of IFN-?, recruited monocytes differentiate into activated macrophages that express higher levels of MHC class II molecules on the cell surface, secrete inflammatory mediators, kill microorganisms and tumor cells, and secrete additional proinflammatory cytokines.

The effective generation of $CD8^{+}$ T cells directed at infected or transformed target cells expressing foreign peptides in the context of class I MHC molecules requires the cooperation of $CD4^{+}$ T cells. The $CD4^{+}$ T cells, which are responsive to peptide fragments derived from internalized antigens, secrete cytokines (e.g., IL-2, IL-4,

IFN-?) that provide the requisite costimulation for CD8 $^{+}$ T-cell differentiation into cytotoxic T cells from precursors normally present at low concentrations in the peripheral blood. Cytolysis of the foreign antigen-bearing target cells is effected by perforin, a membrane pore–forming protein, and granzyme, a cytolysin, stored in preformed granules. CD4 $^{+}$ T cells can also function as cytolytic effectors, primarily through the expression of Fas ligand (CD95 ligand, or CD95L). CD95L is induced on T cells early after T-cell receptor/CD3 complex–mediated activation of T cells. CD95L-bearing cells induce CD95-bearing (or Fas-bearing) cells. Because CD95 is widely expressed, including expression in cells of the lymphoid lineage, the CD95L-CD95 pathway also represents a major mechanism of down-regulating immune responses.

This overview of the immune system is necessarily brief. For more in-depth discussions of these and other topics, the reader is referred to several excellent texts. [52], [53] and [54]

GUT-ASSOCIATED LYMPHOID TISSUE

The cellular elements of the GALT are organized into functional compartments that are anatomically contained within the lamina propria and epithelium. The lamina propria is composed of an organized compartment, including Peyer patches and follicle-associated epithelium, and a nonorganized compartment that is loosely distributed throughout the lamina propria. Peyer patches, which are unencapsulated lymphoid nodules, constitute an afferent limb of the GALT that recognizes antigens through the specialized sampling mechanism of the M cell contained within the follicle-associated epithelium. Detection of substances that move across the small bowel epithelium results in the education and dissemination of B and T lymphoblasts to other tissues linked to the MALT, such as the lungs, breast, and genitourinary tract, and the loosely affiliated compartment of the lamina propria. The lamina propria represents an efferent or effector limb of the GALT, which is populated by lymphoid cellular effectors, such as B cells, plasma cells, T cells, and natural killer cells, and by mononuclear and polymorphonuclear phagocytes and mast cells. The immune compartment within the epithelium consists of a resident population of T cells, the intraepithelial lymphocytes. Evidence from rodent models indicates that dendritic cells found adjacent to the intestinal epithelium may also obtain local antigens and migrate to regional lymph nodes (mesenteric lymph nodes), where immune responses are initiated. [55]

Peyer Patches and Lymphoblast Homing

The follicle-associated epithelium contains M cells, which are derived directly from undifferentiated, immature epithelial stem cells in the crypts that surround the organized lymphoid follicles called *Peyer patches* (Fig. 7-3). The evolution of M cells may be influenced by subjacent B cells within the lamina propria. The morphologic feature that differentiates M cells from absorptive epithelial cells is fewer, shorter, and wider microvilli. M cells cover the lymphoid follicles in the gastrointestinal tract and provide a site for the selective sampling of intralumenal antigens. [3], [56] Clusters of M cells transport particulate molecules such as horseradish peroxidase and ferritin through a transcellular vesicular pathway into the underlying lymphoid tissues of the Peyer patches. Various microorganisms initiate an immune response through this pathway and, in certain circumstances, use the pathway to invade tissues. The mechanism is unknown, but it may involve specific carbohydrate interactions because M cells absorb certain lectins. Among the many infectious agents known to undergo endocytosis and transport by M cells are the human immunodeficiency virus, reoviruses, *Vibrio cholerae,* and species of mycobacteria.

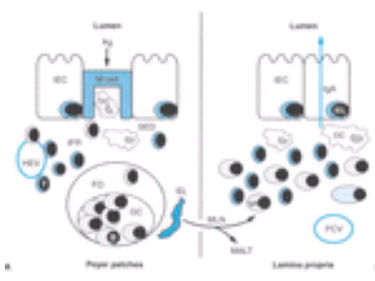

FIGURE 7-3. Antigen processing and lymphocyte trafficking in the gut-associated lymphoid tissue (GALT). **A:** Peyer patches (afferent or inductive limb of GALT). Antigen (Ag) is transported across M cells into a subepithelial pocket containing naive B and T cells in close proximity to professional antigen-presenting cells, such as macrophages and dendritic cells. The antigen-presenting cells engulf, process, and present the antigens, leading lymphocytes to recognize the lumenal antigen. The activated T- and B-cell blasts emigrate from the Peyer patches via regional lymphatics into the mesenteric lymph nodes (MLNs). **B:** Lamina propria and epithelium (efferent or effector limb of GALT). The T- and B-cell blasts migrate through the MLNs and from there enter the thoracic duct and subsequently home to other tissues associated with the mucosa-associated lymphoid tissue (MALT) and back to the loosely affiliated lamina propria and epithelium as intraepithelial lymphocytes (IELs) after emigration through the postcapillary venules (PCVs) of the lamina propria. The B cells differentiate into plasma cells, where they secrete predominantly immunoglobulin A (IgA) and, to a lesser extent, IgG. See text for details. *IEC*, intestinal epithelial cell; *HEV*, high endothelial venule; *IFR*, interfollicular region; *SED*, subepithelial dome; *FO*, lymphoid follicle; *GC*, germinal center; *EL*, efferent lymph.

The antigens and microorganisms transported ablumenally by the M cell come into contact with lymphocytes, macrophages, and dendritic cells that have migrated into the lymphoid aggregates or Peyer patches below the M cells (see Fig. 7-3). Some of these mononuclear cells enter an intercellular space or central hollow that indents the M cell. [56] Naive B and T lymphocytes that have never encountered their cognate antigen express a combination of cell surface receptors that directs them to emigrate into lymphoid aggregates such as Peyer patches associated with follicle-associated epithelium. [57] This emigration occurs through interactions between cell surface receptors on the naive lymphocytes and their counterligands on specialized endothelium, the high endothelial venules present within the organized lymphoid structures. M cells transport selected antigens from the intestinal lumen to facilitate macrophage (and dendritic cell) processing and antigen presentation to the naive lymphocytes in the intestinal lymphoid follicles. A specific mucosal immune response is initiated by these interactions. This interaction may preferentially direct naive T cells to either a Th2, Th3, or Tr1 phenotype over a Th1 phenotype. Such an outcome is likely a consequence of the properties of the dendritic cells within the Peyer patches and plays an important role in generating mucosal tolerance. During infection or pathological conditions, such as inflammatory bowel disease, a Th1 bias may occur relative to Th3 or Tr1. The observation of lysosomal organelles containing MHC class II components in M cells confirms that, under certain circumstances, M cells also may serve as primary antigen-presenting cells. [58]

Activated lymphocytes from intestinal lymphoid follicles begin a maturational journey in which they leave the intestinal tract and migrate into afferent lymphatics that drain into mesenteric lymph nodes. [59], [60] During this process, the lymphocytes mature into T and B lymphoblasts enriched in IgA-bearing B cells. The B lymphocytes become surface IgA-bearing lymphoblasts after being promoted to switch their immunoglobulin isotype by regulatory (i.e., “switch”) T cells within Peyer patches. [6], [7], [61] Switch T cells control isotype switching and B-cell clonal expansion by secreting cytokines (e.g., IL-2, IL-4, IL-5, IL-6, IL-10, and TGF-ß). Lymphocytes then enter the efferent lymphatics of the mesenteric lymph nodes and pass through the thoracic duct into the peripheral blood. These lymphocytes subsequently reenter the loosely affiliated lamina propria through interactions with flat endothelial cells of the postcapillary venules. After homing to mucosal sites, B lymphoblasts mature into IgA-secreting plasma cells under the control of antigen-activated T lymphocytes that have completed a similar maturational journey. Lymphoblasts that have homed to the gastrointestinal mucosa and have matured into effector cells provide protective immunity within the lamina propria.

Lymphoblasts recirculate or home to the sites of the original antigenic stimulation and to other mucosal secretory sites. After antigenic stimulation in the gastrointestinal tract, IgA lymphoblasts circulate to the mucosal secretory sites of the breast, lung, and eye, where antigen-specific antibodies are secreted. [59], [62] A breast-feeding mother can passively transfer secretory IgA in the breast milk to her nursing child. The transferred breast milk secretory IgA protects the infant against bacteria or viruses found within the mother’s gastrointestinal tract, supporting the importance of the common mucosal immune system. [6] Homing of stimulated lymphoblasts to mucosal secretory sites allows the secretion into lung, breast, and eye fluids of protective antibodies directed against antigens recognized within the gastrointestinal lumen. The intestinal immune system thus has components that allow selective antigen sampling and subsequent induction of immune responses that provide protection for the gastrointestinal tract and other mucosal surfaces.

The selective interaction between lymphocyte-specific proteins and counterligands on endothelial cells in specific organs regulates the distribution of lymphoid effector cells to the intestine and other mucosal secretory sites. Antigenic stimulation and chronic inflammation result in a rapid increase in the number of endothelial venules. The number and adhesiveness of endothelial venules increases because of enhanced differentiation and stimulated proliferation. [63], [64] and [65] Cytokines, including IL-1, IFN-?, and TNF-a, increase lymphoblast adherence to endothelial cells, trigger the development of endothelial cell differentiation markers, and

enhance the expression of endothelial adhesion molecules. The increased expression of adhesion molecules on endothelial cells stimulates an increase in the influx of antigen-specific, sensitized lymphocytes into areas of chronic inflammation or areas where cell-mediated host defense processes are needed. Endothelial venules are closely associated with dense, lymphocytic infiltrates, particularly if the mononuclear cell–mediated processes are persistent. [63], [64]

Nonorganized Lamina Propria

The efferent, or effector, compartment of the lamina propria consists of T cells, B cells, plasma cells, natural killer cells, phagocytic cells, and mast cells. About 60% of the lymphoid cells are T cells. $CD4^+$ and $CD8^+$ T cells occur in a ratio of about 2:1, which approximates their concentrations in peripheral blood. [65], [66] Virtually all T cells within the lamina propria express the aß T-cell receptor. Closer examination of aß T-cell receptor usage shows some skewing, with an overabundance of certain receptors, suggesting the expansion of some T-cell clones. [65] The CD45 isoform expression confirms that these cells are memory cells, indicating previous encounters with antigens, presumably in the Peyer patches (see Table 7-2). [66] The $CD4^+$ cells in the lamina propria exert a helper-inducer function for immunoglobulin production, a major function of lamina propria T cells. [67], [68] Consistent with this, in response to antigen, lamina propria lymphocytes (LPLs) respond primarily with cytokine production rather than proliferation. [67] Most $CD8^+$ LPLs as well as a significant proportion of $CD4^+$ LPLs express a unique $ß_7$-integrin associated with a novel a chain, a ^{E}, which plays a role in intestinal epithelial cell binding. [69], [70] The population of $CD8^+$ LPLs probably contains precursors, such as TCR-aß $^+$, $CD8^+$, a $^E ß_7^+$ ($HML\text{-}1^+$), and $CD45RO^+$ T cells, in transit to the epithelium.

A set of lymphocytes in the intestine are cytotoxic effector precursor cells that can participate in host mucosal defense mechanisms when needed, without continuously causing damage to the surrounding tissue when not needed. Functional precursor natural killer cells and cytotoxic T lymphocytes can be enriched from isolated lamina propria mononuclear cells. LPLs can be induced to mediate cell-mediated cytotoxicity by incubation with IL-2, IFN, lectins, and monoclonal antibodies directed against the T-cell receptor, typical of antigen-primed effectors and consistent with their CD45RO phenotype. [71], [72], [73], [74], [75], [76] and [77] Although cytotoxic effectors are present, the intestinal LPLs generally are poor mediators of cell-mediated cytotoxicity in a variety of systems, including spontaneous cell-mediated cytotoxicity, antibody-dependent cellular cytotoxicity, and cell-mediated cytolysis. [71], [72]

Most mucosal T lymphocytes are also $CD95L^+$ and $CD69^+$ and exhibit elevated levels of cytoplasmic Ca^{2+}, consistent with an activated phenotype. [78] Controlled activation of the intestinal immune system may be important in regulating effector cell function. This includes cytotoxic function that may be directed at the lymphocytes themselves for the purposes of down-regulating immune responses. [79] In this way, the gut can remain in a state of physiological inflammation, poised for intervention when necessary but maintaining a general tone of restraint. Humoral extracts from the healthy lamina propria, containing humoral substances of unknown origin, are capable of suppressing the activation of peripheral nonintestinal lymphoid populations, which may account for the low level of responses to proliferative signals delivered by the T-cell receptor–CD3 complex. [80]

About 40% of the lymphoid cells in the lamina propria are B cells derived primarily from precursors in Peyer patches. [81], [82] These B cells and their progeny plasma cells are predominantly focused on IgA synthesis and focused to a lesser extent on IgM, IgG, and IgE synthesis. Lamina propria B cells are induced to differentiate terminally into IgA-secreting cells by IFN-?, IL-4, IL-5, IL-6, and IL-10. [4], [7], [62], [83], [84], [85], [86], [87], [88] and [89] IL-4 and IL-5 activate resting B cells and induce the division and growth of activated B cells. IL-6 is critical for the terminal differentiation of IgA plasma cells, resulting in the secretion of large amounts of IgA. The sequence of cytokine-mediated events that regulates B-cell growth, differentiation, and development toward IgA production involves both Th1 (IFN-?) and Th2 (IL-4, IL-5, IL-6, IL-10), indicating the importance of this antibody to mucosal protection. In diseases such as inflammatory bowel disease, the numbers of lamina propria B cells and plasma cells, which produce IgG, are markedly increased. [10]

Immunoglobulin Secretion

A major protective immune mechanism for the intestinal tract is the synthesis and secretion of dimeric IgA. The intestine contains more than 70% of the immunoglobulin-producing cells in the body. [2], [90] Although IgG and IgM antibodies are also produced by lamina propria B cells within the normal intestine, the predominant antibody synthesized and secreted is IgA. Evidence suggests that IgE and even IgG also may be important secretory immunoglobulins (Fig. 7-4). [90], [91] and [92]

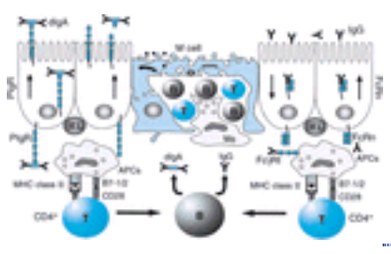

FIGURE 7-4. Immunoglobulin transport across intestinal epithelial cells. The interaction between professional antigen-presenting cells (APCs) and $CD4^+$ T cells in the lamina propria induces local B cells to secrete predominantly immunoglobulin A (IgA) and IgM and, to a lesser extent, IgG, except in inflammatory conditions such as inflammatory bowel disease, in which significant amounts of IgG are produced. IgA is secreted from the B cell as a dimer in association with J chain (dIgA). This polymeric IgA and IgM (which is pentameric) is taken up by the polymeric immunoglobulin receptor (pIgR) along the basal surface of the intestinal epithelial cell. The pIgR then transports the dimeric IgA and IgM across the cell in a transcytotic pathway to the apical cell surface. At the apical cell surface, cell surface proteases cleave the pIgR, releasing the polymeric IgA and IgM in association with secretory component, a proteolytic fragment of the pIgR. In a similar manner, the neonatal receptor for IgG (*FcRn*) transports local IgG transcellularly in a transcytotic pathway. However, in contrast to the pathway associated with the pIgR, the FcRn pathway is bidirectional and not associated with cleavage of the FcRn.

There are two IgA subclasses: IgA1 and IgA2. In serum, less than 15% of the IgA is IgA2, but in external secretions, as much as 50% of IgA is IgA2. [93] One possible explanation for the preferential production of IgA2 in intestinal secretions is the observation that IgA1 is easily cleaved by proteases produced by bacteria, but IgA2 is more resistant to cleavage and may survive longer in the intestinal lumen. [94] Plasma cells produce IgA in monomeric form or as a dimeric structure in which two IgA monomers are joined by a polypeptide called *J chain*. J chain is also produced within the plasma cell. [95] J chain produces polymerization of IgA and IgM. By subsequent interaction with another polypeptide on the basal surface of the epithelial cell, called *polymeric immunoglobulin receptor* (pIgR), J chain participates in the transport of polymeric IgA and IgM molecules across the intestinal epithelial cell into the lumen. [90], [96], [97]

pIgR, produced by epithelial cells, is a membrane receptor that exhibits selective binding to polymeric immunoglobulins such as IgA and IgM, which contain J chain. [95], [98], [99], [100], [101], [102], [103] and [104] pIgR is synthesized in the rough endoplasmic reticulum of the epithelial cell, glycosylated in the Golgi complex, and directed to the basolateral cell surface by a sorting signal in the cytoplasmic tail. [101], [102] After the initial interaction between polymeric IgA and the pIgR, the entire IgA-pIgR complex undergoes endocytosis into the basal side of the epithelial cell. The IgA-pIgR complex is then transported to the apical surface of the epithelial cell in endocytic vesicles that fuse with the apical membrane and subsequently release a portion of the pIgR, secretory component, as an intact secretory IgA molecule into the intestinal lumen.

Secretory component remains bound to polymeric IgA after its release into the external secretions, although it can also be found by itself in mucosal secretions as a secreted glycoprotein not bound to polymeric immunoglobulins. [95], [98], [99], [100], [101], [102], [103] and [104] Secretory component may prevent proteolytic degradation of the secretory IgA molecule and may stabilize the structure of the polymeric IgA complex, protecting the secretory IgA that is secreted into a hostile environment containing numerous proteolytic enzymes, bacteria, and other substances that could otherwise rapidly degrade it.

IgA is also translocated across the hepatocyte or bile duct epithelium into the bile. [105], [106] IgA in the bile is carried into the duodenum. Important interspecies differences have been observed; IgA and secretory component are major components of the bile of the rat and rabbit, whereas the bile of sheep, dogs, and humans

contains much smaller amounts of IgA. These differences in IgA translocation into bile appear to be related to the presence of pIgR on hepatocytes in rats and rabbits, resulting in highly efficient movement of IgA into the bile, but pIgR is expressed only on biliary epithelium in humans, resulting in less efficient IgA translocation. The presence of secretory IgA in bile provides passive immunity and protection for the biliary tract and the proximal parts of the small bowel. A second implication of the hepatobiliary secretion of IgA is that complexes of IgA and antigen can be transported into the bile from the circulation. Hepatic removal of IgA-antigen complexes may protect against harmful absorbed substances, including dietary antigens and bacterial products.

The major function of secretory IgA in host defense is protection against bacteria, viruses, and lumenal antigens. [2], [4], [59] Secretory IgA inhibits the adherence of bacteria to epithelial cells and prevents their effective colonization and multiplication. Secretory IgA neutralizes bacterial toxins and prevents their action on intestinal epithelial cells. The major antiviral properties of IgA are neutralization of viral activity and passive protective immunity. Secretory IgA also blocks the absorption of antigens from the gut and may be particularly important in disease states in which the mucosal barrier is broken. IgA also is able to neutralize intracellular pathogens within a cell that possesses a transcytotic pathway for IgA. [107] The intersection of endocytic compartments containing pathogens and secretory IgA leads to neutralization of the foreign substances and their excretion after transport to the apical surface.

IgA does not activate complement and does not enhance cell-mediated opsonization or destruction of infectious organisms or antigens. In this lack of complement activation, IgA sharply contrasts with other immunoglobulins, such as IgG, which can also be secreted by B cells in the intestine and initiate important complement-mediated and cell-mediated protective events within the intestine.

Transcellular pathways for IgE and IgG transport also exist in epithelial cells. The activities of CD23 (FceR1, or IgE receptor), whose expression in epithelial cells is regulated by IL-4, appear to direct IgE vectorially from the lumen into the tissues. [108] Such a pathway may be very important to intestinal allergic responses. High concentrations of IgE in the lumen during parasitic infestations suggest an alternate pathway of IgE transport from the tissues into the lumen. However, the molecular basis for this pathway is unknown.

Transcytosis of IgG also occurs across intact epithelial barriers during adult life in rodents and humans. [109], [110] This process is mediated by the MHC class I–related molecule FcRn (neonatal Fc receptor for IgG). In contrast to the pathway related to the pIgR, the FcRn-mediated pathway is bidirectional (apical to basal and basal to apical) and is not associated with proteolytic cleavage of the transporting receptor such that multiple rounds of transport are possible. The FcRn binds to the Fc portion of IgG at acidic pH (pH 6.0), the pH of endosomes, and releases IgG at neutral pH (pH 7.4), the pH of the interstitium. Such a pathway may endow the epithelium with a means to monitor the antigens within the lumen without disrupting the epithelial barrier.

Intraepithelial Lymphocytes

The epithelium of the human intestine contains a unique population of lymphoid cells, the intraepithelial lymphocytes (IELs), that reside between intestinal epithelial cells along their basolateral surface. [111] A few IELs are $CD4^+$ T cells, but most IELs express the CD8 aß heterodimer, the CD45RO isoform, and the aß T-cell receptor, indicating that they are memory cells driven by MHC class I or class I–like molecules. [112], [113] Between 5% and 30% of these T cells, especially in the colon, express the ?d T-cell receptor. [114] Virtually all the ?d T cells in the human intestine reside within the epithelium, suggesting that they are responsive to specific chemotactic factors or antigens within this location. [115] More than 95% of IELs express the unique $a^E ß_7$-integrin, HML-1, which, in view of its role in epithelial cell binding, probably plays an important role in the epithelial cell tropism of these cells. [69], [116] The $a^E ß_7$-integrin binds E-cadherin, an immunoglobulin supergene family member, on the basolateral surface of the intestinal epithelial cell. [73] In the presence of TGF-ß, presumably secreted by local intestinal epithelial cells, high levels of this integrin are expressed somewhat reciprocally to the $a^L ß_2$-integrin lymphocyte-function associated antigen-1 (LFA-1; i.e., CD11a/CD18), a $ß_2$-integrin commonly expressed by peripheral blood lymphocytes. [69], [116]

Despite their contiguity to the gut lumen, potential exposure to a variety of antigens, and the expectation that these cells express a diverse, polyclonal array of aß and ?d T-cell receptors, IELs within the small and large intestine are oligoclonal and express a small number of aß and ?d T-cell receptors based on an analysis of CDR3 regions. [65], [117], [118] A limited variety of T-cell clones are, in fact, widely disseminated throughout the intestinal epithelium. [119] With a CD45RO phenotype, [120] these cells are memory cells that recognize an extremely limited number of antigens, not the multitude of lumenal antigens. The abundant expression of CD8 further indicates that these cells recognize these putative antigens in the context of an MHC class I or class I–like molecule such as CD1 or the MHC class I chain–related gene A gene product. [34], [121], [122] The CD8 expression of IELs suggests that they function biologically as cytolytic effectors as a consequence of antigenic recognition. IELs exhibit a high level of cytolytic activity in a variety of in vitro systems, especially after activation, [123] and likely in disease states in vivo. IELs in situ, however, do not express granzyme, perforin, or CD94L. [124] This suggests that their major biologic function in health is the secretion of cytokines (e.g., IFN-? and keratinocyte growth factor), which regulate epithelial cell function and possibly responses to lumenal antigens. [125] ?d IELs, for example, may play a role in regulating responses to orally delivered antigens. [126] On activation, IELs may acquire cytolytic machinery that can contribute to epithelial cell death through apoptosis. Their cytolytic capabilities, large number, and extremely limited T-cell receptor repertoire together indicate that IELs are a regionally specific population of cells involved in immunosurveillance against abnormal epithelial cells based on the recognition of a limited number of proteins not normally expressed on the cell surface of intestinal epithelial cells. IELs may be the first line of defense against deleterious epithelial events. Their numbers are markedly increased in intestinal graft versus host disease, gluten-sensitive enteropathy, and protozoal infections of the epithelium, such as those caused by *Cryptosporidium* and *Isospora* species.

Human IELs and the $CD8^+$ T cells within the lamina propria share many phenotypic characteristics, but their origin is unclear. Studies of murine systems suggest the existence of two IEL populations: thymus-dependent (i.e., selected in the thymus) and thymus-independent (i.e., selected in the intestine) lymphocytes. [127] A feature of thymus-independent mouse IELs is the expression of CD8 as an aa homodimer rather than the more common aß heterodimer and the expression RAG transcripts. Considering the rarity of this form of CD8 in normal human adult intestine, the extrapolation from the mouse models to humans remains uncertain. Nonetheless, mouse models of rotavirus and reovirus infections indicate that TCR-$aß^+$, $CD8^+$, MHC class I–restricted, virally specific cytotoxic effectors can be found within the epithelium that are probably derived from cytotoxic T-cell precursors in the Peyer patches. [128], [129] These results, taken together with those of other studies showing that most IELs are restricted by classic MHC class I molecules, [130] suggest that IELs are likely to be the clonally expanded progeny of MHC class I–restricted cytolytic effector cells.

AUTOIMMUNITY AND ORAL UNRESPONSIVENESS

Autoimmunity

Despite the processes of negative and positive selection that occur within the thymus for T cells and within the bone marrow for B cells, healthy persons maintain low numbers of autoreactive T-cell and B-cell clones. Rather than a failure of immunologic selection within the central immunologic compartments, the existence of these autoreactive clones may represent the need for B-cell and T-cell clones that recognize dominant microbe-derived peptides to which a person may be exposed—peptides that resemble or mimic peptides derived from normal self-antigens. [131]

The intestine also may be a site of thymus-independent T-cell maturation. [128] The evidence remains unclear for humans, but mice have a pathway of T-cell development in which the intestinal epithelial cell may play a central role in T-cell selection. Studies of mouse models suggest that the selection pathways operating in the intestine may not involve classic MHC class I or II molecules. [15]

The normal host must therefore maintain active peripheral mechanisms within tissues, including the intestine, to prevent potential autoreactive clones from becoming autoimmune clones that participate in immune-mediated diseases. This presumably is accomplished by suppressor T-cell networks, the effects of immunosuppressive cytokines (e.g., TGF-ß, IL-10), the negative feedback effects of antibodies on B cells, the presentation of antigenic peptides to the T-cell receptor in the absence of an appropriate costimulatory signal, and the existence of anti-idiotype networks (i.e., antibodies that bind to the antigen-binding site of an antibody and block its function). [132] The end result of these potential mechanisms is active suppression, clonal anergy, or clonal deletion through apoptosis.

Because the gastrointestinal tract must continuously mount immune responses against bacteria, viruses, and other antigens, molecular mimicry or immune dysregulation leading to the activation of self-reactive T cells and the development of autoimmune diseases in genetically predisposed hosts is possible. These mechanisms are indirectly supported by several mouse gene knock-out models. In mice made deficient in the genes for IL-10, TGF-ß, IL-2, IL-2R, MHC class II molecules, and TCR-a, an inflammatory bowel disease–like process develops that includes the production of autoantibodies. [133], [134], [135], [136] and [137] This suggests that

the loss of crucial control mechanisms may allow the release of autoreactive clones that are triggered by microbial antigens because bacterial colonization may be essential for the development of the disease process in these animals. Autoimmunity appears to be relevant in the development of chronic inflammatory disorders of the gastrointestinal tract. Autoimmune responses to tissue transglutaminase stimulated by gliadin in genetically susceptible individuals who express particular MHC class I molecules may be an essential feature of celiac sprue. [138] In autoimmune gastritis, inappropriate cellular responses to the H^+,K^+-ATPase in association with excess Th1 cytokine production are observed. [139]

After the autoreactive T-cell clones have been activated, a variety of effector mechanisms can be brought into play. Cytokines can destroy host cells directly and activate other cell types to mediate tissue damage. Cytokines such as IFN-? enhance MHC class II expression on cells such as epithelial cells, leading to increased presentation of autoantigens or lumenal antigens, which may result in other potential molecular mimicry events. T-cell regulation of B cells through cytokines may lead to the generation of IgG autoantibodies, which, through activation of complement, may lead to the production of chemotactic factors and an increasing influx of various cell types, including macrophages, granulocytes, and eosinophils. In models of chronic idiopathic intestinal inflammation, an imbalance of cytokines is common; for example, in a situation of excessive production of type 1 cytokines relative to type 2 cytokines, inhibition of the type 1 cytokines mitigates the inflammation.

Oral Tolerance

Because the gastrointestinal tract contains many antigens, including dietary proteins, that can lead to cross-reactivity and activation of self-reactive T cells, an important function of the gastrointestinal immune system is the generation of a state of tolerance to mucosal antigens. The gastrointestinal tract exhibits a fascinating example of specific tolerance to orally ingested antigens, called *oral tolerance*. [140], [141], [142] and [143]

The oral administration of antigens can lead to systemic antigen-specific unresponsiveness, which results in the lack of specific T-cell and B-cell responsiveness to those antigens. Concurrently, local specific secretory immunity can develop, resulting in lymphoblasts capable of IgA production. [143] This dichotomy between mucosal and systemic compartments appears to reflect a solution to the need for excluding the specific antigen during future encounters and avoiding inappropriate systemic responsiveness. The ability of antigens in the gastrointestinal tract to induce a state of functional anergy is precise. The state of unresponsiveness or anergy holds only for the specific antigen that was presented orally to the gastrointestinal tract and depends on the nature of the antigen. Not surprisingly, the gastrointestinal tract possesses mechanisms to protect against mounting adverse immunologic reactions. If this were not the case, numerous bacterial and viral antigens and food components could lead to frequent cross-reactive immunologic stimulatory events and result in intestinal autoimmune disorders, and many food substances could give rise to diverse and uncontrollable food-induced allergic reactions.

In model systems, the induction of oral tolerance depends on the type of antigen, the amount of antigen, the frequency of antigen sensitization, the type and genetic background of the animal being studied, the age of the animal, and the particular immune response being evaluated. [140], [141] and [142] Two mechanisms of tolerance have been hypothesized: T-cell suppression and clonal anergy. The application of low doses of antigen to the intestine appears to induce the development, within Peyer patches and mesenteric lymph nodes, of $CD4^+$ T cells capable of secreting TGF-ß (Th3) and $CD4^+$ T cells with a Th2 cytokine profile, capable of secreting IL-4 and IL-10. [141] These cell types migrate to a variety of lymphoid and nonlymphoid tissues, where they inhibit the generation of antigen-specific effector cells. High doses of a tolerogen appear to induce the clonal anergy or apoptosis of antigen-specific Th1 cells. [142] The administration of high doses of antigen may lead to systemic leakage of the antigen, causing inappropriate antigen presentation in the periphery by antigen-presenting cells that lack the necessary costimulatory second signal.

The successful induction of oral tolerance may help prevent the initiation of autoimmune diseases. Mice prone to the development of autoimmune disease exhibit defects in the induction of oral tolerance. The complex regulatory processes operating in the mucosal immune system facilitate the development of a local protective mucosal immune response against pathogenic organisms and prevent the development of adverse systemic autoimmune reactions to the same antigens. Although oral tolerance creates an impediment to vaccination, certain mucosal adjuvants, such as cholera toxin, can reverse oral tolerance. [144]

Oral tolerance is used to advantage in treating several autoimmune diseases. In murine models, feeding myelin basic protein, collagen type II, S antigen (i.e., retinal autoantigen), porcine insulin, and class II MHC peptides suppresses experimental allergic encephalitis, collagen- or adjuvant-induced arthritis, experimental allergic uveitis, diabetes mellitus, and organ transplant rejection, respectively. [145], [146], [147] and [148] This approach is being tested in the treatment of systemic human diseases and inflammatory conditions of the intestine itself. [148]

GASTROINTESTINAL INFLAMMATION

The process of inflammation consists of the activation of neutrophils and monocytes and the effects of that activation on endothelial cells, epithelial cells, and other cell types. Inflammation is a prominent component of a number of important gastrointestinal diseases, including gastroesophageal reflux disease, pancreatitis, peptic ulcer disease, *Helicobacter pylori* gastritis, inflammatory bowel disease, and various enteric infections.

The immune response and the inflammatory response are entwined. From one point of view, the inflammatory response is an effector mechanism for the immune response. For example, when a bacterial infection activates the immune system, antibodies that are specific to the invading bacteria are produced and bind to the bacteria, and neutrophils that express antibody receptors on their surface efficiently phagocytose the antibody-coated bacteria. In this example, a portion of the inflammatory response—that is, phagocytosis by neutrophils—acts as an effector mechanism for the humoral component of the immune response. From another point of view, the inflammatory response is a damage control mechanism that is invoked only if the immune response breaks down or is overwhelmed. In most instances, immune processes eliminate foreign antigens without the development of clinically apparent inflammation. The histology of the normal small intestine and colon demonstrates immune activation and a low-grade inflammatory response, which result from the stimulation of lamina propria immune cells by lumenal antigens. In health, this limited immune activation and low-grade inflammation are clinically silent. The development of clinically apparent inflammation suggests that the immune system has been overwhelmed by a large antigen load, by an antigen in a location inaccessible to the immune response (e.g., osteomyelitis), or by an antigen that is resistant to the immune response (e.g., tuberculosis). Some chronic inflammatory diseases, such as inflammatory bowel disease, may result from dysregulation of the immune response, resulting in an inappropriately prolonged and inappropriately amplified immune activation. [149]

Inflammation also can be viewed as a component of the larger process of wound healing [150] (Fig. 7-5). After injury, blood clotting and fibrinolysis are followed by the infiltration of inflammatory cells. Surviving epithelial cells migrate to cover the epithelial defect induced by injury. This process overlaps with the influx of inflammatory cells. The migration of inflammatory cells and the repair of the epithelium are regulated by the same cytokines and mediators. Events that affect inflammation also affect epithelial healing, and events that affect epithelial healing affect inflammation.

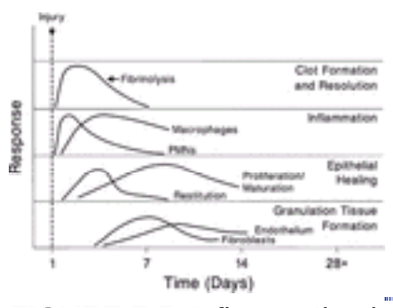

FIGURE 7-5. Inflammation is a component of the larger process of wound healing. Each curve represents the relative intensity of the biologic activity or the concentration of the biochemical or structural component with a time course beginning with injury on day 1. The earliest events are clot formation and resolution. At about the same time that clot forms, neutrophils begin to enter the injured area. Soon after neutrophil migration begins, monocytes enter the area of injury and differentiate into macrophages. Epithelial cells from the edge of the wound rapidly migrate to restore the integrity of the epithelial layer. Full epithelial healing requires the proliferation of additional epithelial cells. Later stages of wound healing include the proliferation of fibroblasts and neovascularization.

Various initiating agents, including aspirin, ethanol, and radiation, result in gastrointestinal inflammation, but the evolutionary pressures that formed the inflammatory

response were not the pressures of aspirin, ethanol, and radiation, but rather those of infectious agents. Our ancestors were exposed to contaminated food and water and poor sanitation, which resulted in viral, bacterial, and parasitic gastrointestinal tract infections. The inflammatory response evolved to deal with these infections. Many of the inflammatory diseases of the gastrointestinal tract today reflect the activation of defense mechanisms that evolved in response to infectious agents but have been adapted (or maladapted) to defense against noninfectious insults. A corollary to this observation is that if the inflammatory response defends against infectious agents, then therapeutic attempts to diminish the inflammatory response may impair the host's ability to respond to infection.

The immune response in the GALT differs in many respects from the systemic immune response. In contrast, gastrointestinal inflammation is similar to inflammation in other organ systems. The inflammatory cells, the cytokines, and the mediators that respond to shigellosis are similar to those that respond to pneumococcal pneumonia. One distinguishing feature of gastrointestinal inflammation is the enormous antigen load in the intestinal lumen. No other organ is faced with foreign antigens in such abundance. This antigen load, particularly the bacterial component, is the stimulus for the chronic low-grade inflammatory response in the healthy gastrointestinal tract. The differences between the histology of the gastrointestinal tract of germ-free rodents and that of conventional rodents are striking. [151] The expected difference is fewer lymphocytes and macrophages in the germ-free animals; the Peyer patches are smaller with fewer germinal centers, and plasma cells are absent. The nonimmune cells also exhibit differences. In germ-free animals, the villi are thinner and the crypts shallower. Epithelial proliferation is diminished, and the time required for epithelial cells to migrate from the crypt to the villus tip is doubled. It is not known what portion of these differences represents the direct effects of bacteria on epithelial cells and what portion represents indirect effects mediated through immune cells.

The epithelium is essential to the control and regulation of the inflammatory response in the gastrointestinal tract. The intact epithelium acts as a barrier, preventing the immune cells in the lamina propria from being overwhelmed by the antigens in the lumen. Breaks in the epithelial monolayer result in a clinically apparent inflammatory response. Epithelial breaks expose lamina propria immune cells to the several hundred species of bacteria that flourish in the human colon. The diversity of antigenic stimuli triggers nonspecific inflammatory responses. In diseases marked by breaks in the epithelial barrier, the immune or inflammatory response to the initiating agent may be difficult to distinguish in the midst of the response to the normal intestinal flora that invade through the epithelial breaks.

Gastrointestinal inflammation is remarkable in that diverse initiating events, such as infections, ischemia, radiation, and chemical toxins, all induce inflammatory responses that are clinically, endoscopically, and histologically similar. The colonoscopic and histological appearances of ulcerative colitis, radiation proctitis, shigellosis, and ischemic colitis are similar. The commonality of the inflammatory responses is explained partly by the similarity between the proinflammatory cytokines, the patterns of leukocyte migration, and the inflammatory mediators induced by these initiating events (Fig. 7-6). Moreover, in each of these diseases, the inflammatory response is largely directed against normal colonic flora that has activated the immune cells of the lamina propria as a result of the loss of epithelial integrity.

FIGURE 7-6. The intestine has a stereotyped inflammatory response to injury. One of the remarkable features of intestinal inflammation is that a wide variety of initiating events—including infection, ischemia, radiation, and chemical toxins—can induce intestinal inflammatory responses that are remarkably similar histologically, endoscopically, and clinically. The reason for the commonality of the inflammatory responses induced by diverse initiating events is that the proinflammatory cytokines, patterns of leukocyte migration, and mediators of inflammation induced are all largely similar.

Gastrointestinal inflammation is distinguished also by the organ-level physiological response, primarily increased motility and secretion. [152], [153] and [154] The gastrointestinal tract responds to enteric infections by attempting to wash out the offending microbes with increased electrolyte and water secretion and increased motility. Increased secretion and motility result in cramps and diarrhea, which are prominent clinical features of enteric infections. The increases in secretion and motility are mediated by the inflammatory response. Because the inflammatory response in the gastrointestinal tract is stereotyped irrespective of the initiating event, increased secretion and motility (and the resultant cramps and diarrhea) are also part of the clinical picture in those inflammatory diseases (e.g., radiation enteritis and inflammatory bowel disease) in which there are no pathogenic organisms to wash out.

ADHESION MOLECULES AND CELL TRAFFICKING

A healthy gastrointestinal tract contains many neutrophils, macrophages, and lymphocytes. Most of these cells are found in the lamina propria, the space between the epithelium and the muscularis mucosae. These three cell types arise from the bone marrow, but their life histories are different.

Neutrophils differentiate in the bone marrow before entering the peripheral blood. Leaving the peripheral circulation, they enter the gastrointestinal tissues by binding to adhesion molecules expressed on the endothelium of postcapillary venules. After only 1 or 2 days in the gastrointestinal tract, neutrophils pass between epithelial cells into the intestinal lumen, where they die and are expelled in the stool. Although neutrophils differentiate in the bone marrow, they are primed and activated in the lamina propria. [155] Priming enhances the ability of neutrophils to produce reactive oxygen species, and activation induces the production of reactive oxygen species. Neutrophil priming and activation are mediated by interaction with particulate stimuli (e.g., bacteria) or by stimulation with soluble factors, such as cytokines, inflammatory mediators, and bacterial products (e.g., endotoxin). Neutrophils are incapable of proliferation; the increase in the number of neutrophils in the lamina propria in inflammatory states reflects increased trafficking out of the bloodstream and into the gastrointestinal tissues.

Gastrointestinal macrophages are derived from circulating monocytes produced in the bone marrow. [156], [157] The large increase in the macrophage numbers in clinically apparent inflammation reflects the increased migration of monocytes out of the bloodstream and into the lamina propria rather than proliferation of the resident macrophages. Monocytes enter the circulation and, like neutrophils, bind to adhesion molecules expressed on endothelial cells in the postcapillary venules of the intestine. After binding to these adhesion molecules, monocytes pass between endothelial cells and enter the gastrointestinal tissue.

After entering the lamina propria, the monocyte begins to differentiate into a mature macrophage. As the monocyte differentiates, it can acquire capacities for phagocytosis, proliferation, and bacterial killing. Macrophage differentiation is controlled by cytokines and other soluble factors present in the lamina propria; different combinations of cytokines and mediators result in macrophages with different phenotypes. Macrophage phenotypes are characterized by their surface receptors; these surface receptors determine the stimuli to which the macrophage can respond. No detailed surveys exist of the life span of macrophages in the gastrointestinal tract, but as a group their stay is far longer than that of neutrophils.

For the most part, neutrophil and monocyte trafficking in the gastrointestinal tract is similar to that in other organ systems. The mechanisms of leukocyte trafficking in various organs are qualitatively similar, but the number of leukocytes passing through the gastrointestinal tract greatly exceeds that in other organs. The gastrointestinal tract has a large surface area; as a result, even the modest degree of inflammation seen in the healthy small intestine and colon represents the trafficking of a substantial number of monocytes and neutrophils. In diffuse inflammatory diseases of the gastrointestinal tract, such as ulcerative colitis, the trafficking of leukocytes through the inflamed mucosa expands to the point that most leukocytes produced in the bone marrow travel through the gastrointestinal mucosa into the lumen. [158]

The migration of neutrophils and monocytes from the peripheral circulation into the lamina propria of the gastrointestinal tract is mediated by the expression of adhesion molecules on vascular endothelial cells and on the leukocytes themselves [159], [160] (Fig. 7-7). Adhesion molecules play an important role in many biologic processes—not only in interactions between inflammatory cells and vascular endothelium but also in interactions between different inflammatory cell types, between inflammatory and noninflammatory cells, and in the binding of cells to the extracellular matrix. [161] The adhesion molecules that participate in the binding of inflammatory cells to vascular endothelium fall into three groups: selectins, ß $_2$-integrins, and the immunoglobulin superfamily of adhesion molecules (Table 7-4).

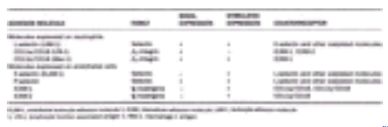

TABLE 7-4 Adhesion Molecules Involved in Neutrophil Binding to Endothelial Cells

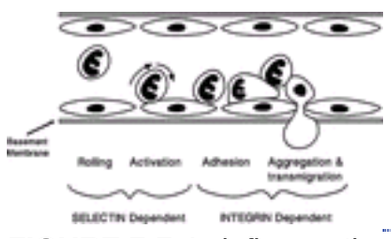

FIGURE 7-7. In inflammation, neutrophils bind to the vascular endothelium through cellular adhesion molecules. Cytokines and inflammatory mediators induce the expression of adhesion molecules on neutrophils and endothelial cells. The initial interactions are mediated by selectins. The weak bonds formed by selectins cause the neutrophils to slow down and roll along the endothelial surface. Later, stronger bonds are formed between the integrins on the surface of the neutrophils and adhesion molecules on the endothelial cells. These stronger bonds firmly attach the neutrophil to the endothelium; after attaching to the endothelial cells, the neutrophils migrate between them.

As inflammation is initiated, leukocytes and endothelial cells express selectins. The three members of the selectin family are L-selectin (leukocyte adhesion molecule-1 [LAM-1]), E-selectin (endothelial leukocyte adhesion molecule-1 [ELAM-1]), and P-selectin. [162], [163] The natural ligands for all three selectins are sialylated Lewis X oligosaccharides, which are found on almost all cell types. Among the molecules with sialylated Lewis X moieties are the selectins themselves, so that L-selectin on neutrophils can bind to E-selectin or P-selectin on endothelial cells.

L-selectin is expressed on lymphocytes, monocytes, and neutrophils; it mediates their adherence to endothelial cells. L-selectin expression is stimulated by inflammatory cytokines (e.g., IL-1 and TNF-a), mediators of inflammation (i.e., leukotriene B $_4$ [LTB $_4$]), and lipopolysaccharide. E-selectin is found only on stimulated endothelial cells, where it promotes leukocyte adherence. It is expressed in response to cytokine stimulation (e.g., IL-1, TNF-a, and IFN-?). P-selectin is expressed on platelets and is involved in thrombosis. It is also expressed on endothelial cells and is involved in leukocyte adhesion. In contrast to E-selectin, which is expressed only in response to stimulation, P-selectin is constitutively expressed on endothelial cells, at least in some organs. Proinflammatory cytokines, histamine, and lipopolysaccharide induce P-selectin expression, but different organs have different levels of sensitivity. Lipopolysaccharide induces endothelial expression of P-selectin and E-selectin, whereas histamine induces P-selectin but not E-selectin. [164]

Selectin bonds are responsible for leukocyte rolling. The selectin bonds that form between leukocytes and endothelial cells are weak; the weakness of these bonds allows leukocytes to roll along the surface of the endothelium by making and breaking selectin-mediated bonds (see Fig. 7-7). Rolling reduces leukocyte velocity before the formation of stronger adhesion bonds that fully immobilize leukocytes on the surface of the endothelium. These stronger bonds are formed between ß $_2$-integrins expressed on the surface of the leukocytes and intercellular adhesion molecules (ICAMs)-1 and -2, members of the immunoglobulin superfamily of adhesion molecules, which are expressed on endothelial cells.

The integrins form a large group of adhesion molecules. [165] Each integrin is a heterodimer that consists of noncovalently associated a and ß subunits. Integrins are divided into subfamilies based on common ß subunits; the ß $_1$ and ß $_2$ subfamilies are the most important in inflammation. ß $_1$-Integins are involved in lymphocyte trafficking. ß $_2$-Integrins are involved in the adhesion of monocytes and neutrophils to endothelial cells. One ß $_2$-integrin, CD11a/CD18 (LFA-1), binds to both ICAM-1 and ICAM-2 on endothelial cells. Another ß $_2$-integrin, CD11b/CD18 (macrophage-1 antigen [Mac-1]), binds only to ICAM-1. CD11a/CD18 is expressed on neutrophils in the basal state, and its expression is not enhanced by cytokines or inflammatory mediators. In contrast, the expression of CD11b/CD18 on leukocytes is induced by products of bacteria (e.g., *N*-formyl-methionyl leucyl phenylalanine [fMLP]) and inflammatory cells (e.g., TNF-a, IL-1, IL-8, LTB $_4$, and platelet-activating factor [PAF]) (Fig. 7-8).

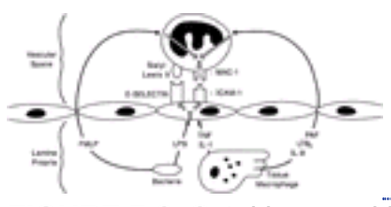

FIGURE 7-8. Cytokines and inflammatory mediators induce leukocytes and endothelial cells to express adhesion molecules. The expression of adhesion molecules on leukocytes (e.g., MAC-1) and endothelial cells (e.g., E-SELECTIN, ICAM-1) is induced by various agents found in inflammatory processes. Among these agents are bacterial products, including fMLP and lipopolysaccharide. Also important in the expression of adhesion molecules are cytokines (TNF, IL-1, IL-8) and lipid mediators of inflammation (LTB $_4$, PAF) produced by tissue macrophages and other inflammatory cells. Other cytokines (e.g., TGF-ß, IFN-?) also are involved in the expression of adhesion molecules. *PAF*, platelet-activating factor; *LTB $_4$* , leukotriene B $_4$; *FMLP*, *N*-formyl-methionyl leucyl phenylalanine.

The third group of molecules important in the binding of leukocytes to endothelial cells is the immunoglobulin superfamily of adhesion molecules. The most prominent members of this family, ICAM-1 and ICAM-2, [159] are expressed on endothelial cells in the basal state; ICAM-2 is expressed at higher levels than ICAM-1. The expression of ICAM-2 is not increased by cytokine stimulation, whereas ICAM-1 expression is enhanced by IL-1, TNF-a, and IFN-?. Thus, the relative importance of ICAM-1 increases in inflammation. ICAM-1 binds both CD11a/CD18 and CD11b/CD18, whereas ICAM-2 binds only CD11a/CD18.

Enhanced expression of adhesion molecules occurs in human diseases marked by gastrointestinal inflammation and in animal models of inflammation. In inflamed colonic mucosa, the expression of ICAM-1, E-selectin, and P-selectin is up-regulated in the vascular endothelium. [166], [167] and [168] Quantitative immunohistochemistry reveals increased numbers of E-selectin–positive vessels in inflamed areas of a colon affected by ulcerative colitis in comparison with the healthy colon. [169]

The role of adhesion molecules in the pathogenesis of intestinal inflammation was carefully addressed in a study of indomethacin-induced enteritis in the rat. [170] Indomethacin treatment results in mucosal ulceration and granulocyte infiltration in the rat intestine and a corresponding inflammatory response in the mesentery characterized by an increase in the number of adherent and extravascular leukocytes and a reduction in leukocyte rolling velocity. The role of adhesion molecules was assessed by the coadministration of indomethacin and monoclonal antibodies directed against P-selectin, E-selectin, or CD11b/CD18. The indomethacin-induced leukocyte–epithelial cell adhesion in mesenteric venules was reduced with coadministration of monoclonal antibodies against CD11b/CD18 or E-selectin but not by the monoclonal antibody against P-selectin. This study suggests that both CD11b/CD18 (expressed on neutrophils) and E-selectin (expressed on endothelial cells) contribute to neutrophil accumulation.

After neutrophils attach firmly to the endothelium, they migrate between the endothelial cells into the extravascular space. On neutrophils, L-selectin (LAM-1) and CD11b/CD18 are expressed consecutively—that is, the expression of CD11b/CD18 increases as LAM-1 is shed. Immunohistochemistry of inflamed tissue demonstrates that some intravascular neutrophils are LAM-1 positive and others are CD11b/CD18 positive, but extravascular neutrophils are all CD11b/CD18 positive and LAM-1 negative, [171] suggesting that both LAM-1 and CD11b/CD18 are important in the adhesion of neutrophils to endothelial cells but that only CD11b/CD18 is important in the subsequent neutrophil migration into the extravascular space.

The final step in leukocyte trafficking in intestinal inflammation is the passage of leukocytes between epithelial cells and out into the lumen. [172], [173] Leukocytes that have passed into the lumen can be found in the stool; indeed, the presence of fecal leukocytes signifies inflammation of the gastrointestinal tract. Adhesion molecules, including ICAM-1, are expressed on epithelial cells in the presence of inflammation, and neutrophil chemotactic factors have been identified in the colonic lumen.

Adhesion molecules are possible therapeutic targets in gastrointestinal inflammation. Antibodies to adhesion molecules, both neutrophil adhesion molecules and endothelial adhesion molecules, have been used to block leukocyte trafficking. Monoclonal antibodies directed against ICAM-1 prevent the passage of neutrophils between endothelial cells. [174] A set of experiments in which antibodies against different components of the ß $_2$-integrins were used defined their role in the migration of neutrophils between endothelial cells. [175], [176] Antibodies against CD18 inhibited neutrophil migration, and antibodies against CD11a or CD11b also inhibited migration. Therefore, the binding of both CD11a/CD18 and CD11b/CD18 to ICAM-1 appears to be important in the migration of neutrophils between endothelial cells. In contrast, antibodies to L-selectin did not inhibit neutrophil migration, which is consistent with the finding that extravascular neutrophils are CD11b/CD18 positive but L-selectin negative. Protein synthesis can be blocked by administering the appropriate antisense mRNA, which will bind to the sense mRNA and prevent translation. Antisense mRNA for ICAM-1 was given intravenously to a small group of patients with steroid-treated Crohn disease in an attempt to improve their clinical status by diminishing leukocyte trafficking. A better clinical outcome was observed in the patients receiving ICAM-1 antisense mRNA than in those receiving placebo. [177]

Lymphocyte trafficking shares some similarity with neutrophil and monocyte trafficking, but the differences are substantial. Lymphocyte trafficking is mediated by the expression of receptors and counterreceptors on lymphocytes and endothelial cells. The interaction of lymphocytes with endothelial cells (like the interaction of leukocytes with endothelial cells) involves three families of cell surface proteins: integrins, selectins, and immunoglobulin-like adhesion receptors. Lymphocytes destined for the intestine display some integrins (e.g., CD11a/CD18) that are also expressed on leukocytes, but they also express lymphocyte-specific integrins, including a ^{4}ß $_7$, an integrin expressed in CD4 and CD8 gut trophic lymphocytes, and a ^{E}ß $_7$, which is expressed on almost all intraepithelial lymphocytes and 40% of lamina propria lymphocytes. [178], [179] and [180]

The a ^{4}ß $_7$-integrin binds to MAdCAM-1, a member of the immunoglobulin superfamily that is selectively expressed on the high endothelial venules of mucosal lymphoid organs. [70] Thus, the migration of selected lymphocyte populations to the intestine is directed by the selective expression of a ^{4}ß $_7$ on these lymphocytes and the selective expression of MAdCAM-1 on certain endothelial populations.

The a ^{4}ß $_7$-integrin binds to E-cadherin on the basolateral surface of endothelial cells. This interaction directs the migration of intraepithelial lymphocytes to the epithelium after they leave the vascular space. [69], [116]

Selectins play a role in the interaction of lymphocytes with the endothelium, just as they do with leukocytes and the endothelium. By nature of the lectin-binding domain, all selectins bind fucosylated lactosamine structures, related to the sialylated Lewis X (sLe ^{X}) blood group antigens. The sLe ^{X} blood group antigens decorate molecules such as MadCAM-1, making them counterligands for L-selectin–bearing lymphocytes. E-selectin plays a role in the adhesion of a subpopulation of memory lymphocytes, neutrophils, and monocytes, and the concentration of E-selectin is increased in inflammatory lesions of the intestine. [181]

Regulated expression of these molecules controls the migration of naive lymphocytes into Peyer patches through high endothelial venules and the subsequent homing of activated memory lymphocytes into the effector compartments of the loosely affiliated lamina propria. Naive T lymphocytes that migrate into Peyer patches in search of an antigen encounter are CD3 $^+$, CD45RA $^+$, L-selectin $^+$, and a ^{4}ß $_7$ ^{Lo}; however, antigen-activated T lymphocytes that migrate into lamina propria are CD3 $^+$, CD45RO $^+$, L-selectin $^-$, and a ^{4}ß $_7$ ^{Hi}. Similarly, naive B cells with a phenotype of surface IgD $^+$, CD20 $^+$, L-selectin $^+$, and a ^{4}ß $_7$ ^{Lo}, and memory B cells with a phenotype of surface IgD $^-$, CD20 $^+$, L-selectin $^-$, and a ^{4}ß $_7$ ^{Hi} are preferentially observed in Peyer patches and lamina propria, respectively. [182]

LEUKOCYTE CHEMOTAXIS AND ACTIVATION

After the neutrophil has adhered to the endothelium and passed between the endothelial cells, it must migrate to the site of bacterial invasion or other injury, a process called *chemotaxis*. After entering the affected tissue, the neutrophil must acquire the ability to produce reactive oxygen species in maximal amounts. [183] The process of enhancing the capacity of the neutrophil for producing reactive oxygen species is called *priming,* and the stimulation of their production is called *activation*.

A chemoattractant is a molecule that stimulates the migration of neutrophils, monocytes, eosinophils, and other cells. Chemotaxis is the migration of a cell in the direction of the higher concentration of a chemoattractant. [184] Chemotactic agents act by binding to specific receptors on the leukocyte plasma membrane; binding of a ligand to its receptor results in intracellular signaling events, reorganization of the cytoskeleton, and movement of the leukocyte. Among the agents that induce neutrophil chemotaxis are fMLP, IL-8, the complement component C5a, PAF, and LTB $_4$; each chemotactic agent has a separate receptor on the neutrophil plasma membrane. The direction of neutrophil migration after the binding of a chemoattractant to its receptor is determined by the location of the receptor on the neutrophil plasma membrane. Receptors are distributed over the surface of the cells, and migration occurs in the direction of the receptor where ligand binding has occurred. Monocytes and eosinophils also are capable of chemotaxis, but they respond to a different range of agents.

Study of the chemotactic agents that affect neutrophils (e.g., fMLP, IL-8, C5a, PAF, and LTB $_4$) reveals ties between neutrophil chemotaxis and bacterial infection. The agents that induce neutrophil chemotaxis suggest that the inflammatory response developed to deal with bacterial infections. fMLP is a tripeptide derived from *Escherichia coli* and other bacteria [185]; binding of fMLP to its receptor results in neutrophil migration toward the bacteria. IL-8 is produced by a variety of cell types, including intestinal epithelial cells and activated monocytes. Intestinal epithelial cells produce IL-8 when infected with invasive bacterial species such as *Salmonella.* [186] IL-8 serves as an early warning system for host events by triggering the influx of neutrophils to sites of bacterial invasion in the intestine. C5a production is part of the immune response to bacterial invasion. [187] The binding of immunoglobulins to invading bacteria results in complement activation and the production of C5a, which attracts neutrophils to the site of the antibody-coated bacteria. PAF and LTB $_4$ are secondary amplification agents for the inflammatory response. Phagocytosis of invading bacteria activates neutrophils and macrophages, resulting in the production of PAF and LTB $_4$, which in turn induce the migration of other neutrophils and macrophages to the site of bacterial invasion. [188] Thus, each of the neutrophil chemoattractant receptors can be related, directly or indirectly, to neutrophil migration to sites of bacterial invasion. The multiplicity of mechanisms stimulating neutrophil migration toward sites of bacterial infection suggests the evolutionary importance of this response.

The adhesion of neutrophils and monocytes to endothelial cells and their migration to the site of inflammation are two highly integrated components of the inflammatory response. The regulation of these events is coordinated by cytokines and inflammatory mediators. A single biologic event, such as the phagocytosis of bacteria by a macrophage, results in the production of agents (e.g., IL-1) that induce the expression of adhesion molecules but not neutrophil chemotaxis, and other agents (e.g., IL-8 and LTB $_4$) that induce the expression of adhesion molecules and neutrophil chemotaxis. Some soluble mediators, such as eosinophil chemotactic factor, are chemotactic for only one cell type, whereas others act on multiple cell types; for example, LTB $_4$ and PAF are chemotactic for both monocytes and neutrophils. The mediators that induce the expression of adhesion molecules and leukocyte chemotaxis constitute a complex and highly redundant network. In chronic inflammatory diseases, multiple agents that induce leukocyte adhesion and chemotaxis act in parallel (Fig. 7-9). The redundancy in the network suggests that therapeutic agents aimed at one specific element in this complex network may not be successful in blocking the inflammatory response.

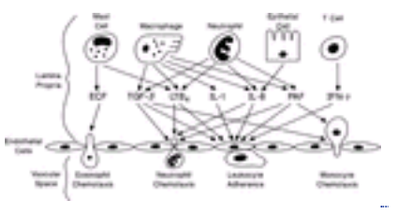

FIGURE 7-9. Chemotactic factors are part of a complex and redundant network. In the intestine, multiple cell types in the epithelium and lamina propria are capable of producing factors that promote the expression of adhesion molecules on leukocytes and endothelial cells or the chemotaxis of leukocytes. These factors include eosinophil chemotactic factor (ECF), transforming growth factor-ß (TGF-ß), leukotriene B_4 (LTB_4), IL-1, IL-8, platelet-activating factor (PAF), and interferon-? (IFN-?). Some inflammatory cells, especially macrophages and neutrophils, produce several of these chemotactic and adherence factors. Some factors act specifically on one cell type, whereas others act on multiple cell types. Some factors affect the expression of adhesion molecules and chemotaxis, whereas others affect only the expression of adhesion molecules.

The complexity of the network of chemotactic agents raises the question of whether all these factors operate in every gastrointestinal inflammatory event or whether some factors are prominent in certain inflammatory events but not in others. The question remains to be answered. The composition of the inflammatory infiltrate may yield some insight. For example, a large number of eosinophils suggests the presence of eosinophil chemotactic factors. In most inflammatory states, it is likely that more than one chemotactic factor is operative and that different factors are more or less prominent as the inflammatory response develops. In response to infectious agents, neutrophil infiltration typically occurs within a few hours and monocyte infiltration occurs later, suggesting that factors promoting neutrophil chemotaxis appear earlier in the development of inflammation than those promoting monocyte chemotaxis.

Circulating neutrophils are not capable of producing reactive oxygen species in maximal amounts. After entering the tissue, neutrophils are primed by IL-1, TNF-a, granulocyte-macrophage colony-stimulating factor (GM-CSF), or lipopolysaccharide, which enhance their ability to make reactive oxygen species. Neutrophils also can be primed by exposure to the extracellular matrix. Exposure to C5a, LTB_4, or fMLP can activate the neutrophil respiratory burst with the production of superoxide, singlet oxygen, and hydroxyl radical. More typically, activation of the respiratory burst in neutrophils is the result of the phagocytosis of bacteria. Neutrophils kill phagocytosed bacteria with reactive oxygen species generated intracellularly within the phagosome. [189] Although the generation of reactive oxygen species serves the useful purpose of killing bacteria, considerable evidence indicates that reactive oxygen species produced by neutrophils contribute to the tissue destruction seen in acute and chronic inflammatory diseases of the gastrointestinal tract, including inflammatory bowel disease. [190]

fMLP is a molecule of particular interest in considering neutrophil chemotaxis and activation in the gut. [185] *E coli* and other bacteria found in normal colons produce a series of formulated oligopeptides, of which fMLP is the prototype. These formulated oligopeptides bind to fMLP receptors on neutrophils and macrophages. The intact epithelial monolayer acts as a barrier to the passage of fMLP, preventing the activation of lamina propria neutrophils by fMLP. Diseases marked by defects in the epithelial monolayer result in the exposure of lamina propria neutrophils to fMLP and the recruitment of additional neutrophils to the area of epithelial damage. fMLP can cross the epithelial monolayer by paracellular pathways, [191] but in health, the epithelial monolayer usually blocks its passage. Increased paracellular permeability caused by drugs, disease states, or genetic disposition can enhance the passage of fMLP across the monolayer and thus enhance neutrophil recruitment. fMLP suppositories have been used to induce neutrophil migration into the colon in animal models of colitis, demonstrating that even in health, the colonic epithelial monolayer is not totally impermeable to fMLP.

Study of the neutrophil fMLP receptors has demonstrated how receptor-ligand interactions also regulate other neutrophil functional activities. Neutrophils have two classes of fMLP receptors: high-affinity receptors and low-affinity receptors. Binding of fMLP to the high-affinity receptor results in chemotaxis; binding to the low-affinity receptor activates the respiratory burst and other neutrophil functions involved in bacterial killing, suggesting a mechanism, mediated by high-affinity fMLP receptors, by which neutrophil migration is induced by low concentrations of a bacterial product at a considerable distance from the bacteria. As the neutrophils migrate toward the bacteria, the concentration of fMLP increases and low-affinity receptors are activated. Binding of fMLP to low-affinity receptors initiates a series of events, particularly activation of the enzymes required for producing reactive oxygen species that prepare the neutrophils for bacterial killing. The interaction of the chemotactic and neutrophil-activating components of fMLP activity was demonstrated by a study in which an fMLP solution was infused into the rat colon. This infusion induced neutrophil infiltration, increased blood flow, and increased endothelial and epithelial permeability. [185] The increase in epithelial permeability was reduced by administering antioxidants and by depleting neutrophils. The ability of antioxidants to block the effects of fMLP on permeability suggests that these effects are mediated by activation of the respiratory burst in neutrophils.

There are disease-specific chemotactic agents. Gastritis caused by *H pylori* is associated with the infiltration of neutrophils into the gastric mucosa. A neutrophil chemotactic agent secreted by *H pylori* has been cloned. [192] Whether this chemotactic factor binds to a previously described receptor for another chemotactic factor or to a novel receptor has not been established. The contribution of this *H pylori*–associated chemotactic factor to the total infiltration of neutrophils in *H pylori*–infected gastritis is not known.

Neutrophil migration has been studied more extensively in ulcerative colitis than in other gastrointestinal diseases. [193] Mucosa affected by ulcerative colitis has high levels of two major chemotactic factors, IL-8 and LTB_4. [194] IL-8 production by both macrophages and epithelial cells is induced by IL-1 and TNF-a, proinflammatory cytokines measured at increased levels in ulcerative colitis. LTB_4 is produced primarily by activated neutrophils, and the mucosa affected by ulcerative colitis is heavily infiltrated with activated neutrophils. The identity of the major neutrophil chemotactic factor in ulcerative colitis was pursued by placing homogenized colonic mucosa from human surgical resections in Boyden chambers and measuring neutrophil chemotaxis. [193] Homogenized mucosa from resections of tissue affected by ulcerative colitis induced a level of neutrophil chemotaxis that was several times that seen with normal mucosa. Most neutrophil chemotactic activity was lipid extractable. Administration of a specific antibody against LTB_4 neutralized about 60% of the total chemotactic activity and nearly all the lipid-extractable chemotactic activity. The data were interpreted to suggest that LTB_4 is the dominant, but not sole, neutrophil chemotactic factor in the mucosa affected by ulcerative colitis. Inhibitors of 5-lipoxygenase, the key enzyme in the synthesis of LTB_4, are effective in the treatment of animal models of colitis, such as acetic acid–or trinitrobenzenesulfonic acid–induced colitis. These animal studies support the hypothesis that LTB_4 is a major chemoattractant in ulcerative colitis and that the pharmacological modulation of LTB_4 levels may diminish neutrophil recruitment and inflammation; however, trials of an inhibitor of 5-lipoxygenase and an inhibitor of 5-lipoxygenase–activating protein (FLAP) in patients with acute ulcerative colitis did not demonstrate a significant difference in the clinical response between the treated and placebo groups. [195] LTB_4 levels were measured in rectal dialysates before and after treatment with the FLAP inhibitor. Pretreatment levels of LTB_4 in dialysates of patients with ulcerative colitis were several times the levels measured in healthy persons. A single dose of the FLAP inhibitor reduced levels of LTB_4 in dialysates by more than 95% for longer than 24 hours, achieving the biochemical goal of reducing LTB_4 levels without inducing a clinical response. Despite success in animal models, leukotriene synthesis inhibitors probably failed to treat ulcerative colitis in humans because inflammation had been present for weeks to months, whereas in the animal model trials, inflammation had been present for hours to days. The prolonged course of inflammation in ulcerative colitis may have allowed time for the development of a more complex and redundant network of chemotactic agents.

LIPID MEDIATORS OF INFLAMMATION

Prostaglandins, leukotrienes, and PAF are referred to collectively as *lipid mediators of inflammation*. In many circumstances, they are produced by the same cell types in response to similar stimuli. Phagocytosis in macrophages results in the production of prostaglandin E_2 (PGE_2), LTB_4, and PAF. Although the lipid mediators are structurally distinct, they have a number of overlapping biologic effects. PGE_2, LTB_4, and PAF enhance vascular permeability; LTB_4 and PAF activate neutrophils.

Prostaglandins and leukotrienes are the products of arachidonic acid metabolism and are referred to as *eicosanoids*. [196], [197] and [198] Prostaglandins are produced through the cyclooxygenase pathway, whereas leukotrienes are produced through the 5-lipoxygenase pathway (Fig. 7-10). Two distinct cyclooxygenases are involved in prostaglandin synthesis. COX-1 is a constitutive enzyme found in most mammalian cell types. In the gastrointestinal tract, COX-1 is expressed in lamina propria mononuclear cells, fibroblasts, muscle cells, epithelial cells, and vascular endothelial cells. The expression of COX-2 is induced by IL-1, TNF-a, and other proinflammatory cytokines. COX-2 expression can be induced in macrophages, fibroblasts, epithelial cells, and other cell types.

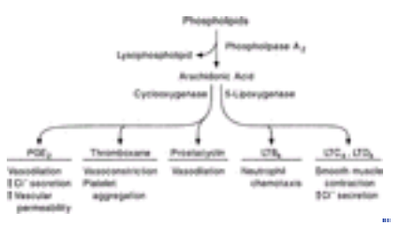

FIGURE 7-10. Arachidonic acid is metabolized to many proinflammatory products. Intracellular levels of arachidonic acid are quite low. The major rate-limiting step in the production of arachidonic acid metabolites is the release of arachidonic acid from phospholipids by the activation of phospholipase A_2. Most agents that induce the synthesis of arachidonic acid metabolites do so by activating phospholipase A_2. There are two major pathways for arachidonic acid metabolism: the cyclooxygenase pathway and a series of lipoxygenase pathways (5-, 12-, and 15-lipoxygenase); 5-lipoxygenase is the most prominent. Essentially all mammalian cells contain cyclooxygenase. The particular mixture of cyclooxygenase metabolites produced by a given cell is a function of the downstream enzymes (e.g., thromboxane synthase and prostacyclin synthase).

Under most circumstances, the rate-limiting step in the synthesis of prostaglandins is the availability of arachidonic acid. Cells have almost no free arachidonic acid; the activation of phospholipases (particularly phospholipase A_2) makes arachidonate available by releasing it from membrane phospholipids. A wide variety of stimuli can activate phospholipase A_2, resulting in the release of arachidonate. Phagocytosis in macrophages activates phospholipase A_2, as do receptor-mediated events, such as the binding of bradykinin to its receptor. Phospholipase activation typically results in the rapid release of arachidonate and the production of prostaglandins within a few seconds to 1 or 2 minutes. Prostaglandin synthesis also can be regulated by the infiltration of prostaglandin-producing cells into the gastrointestinal tract. The large increase in prostaglandin levels in inflammatory bowel disease may reflect the trafficking of prostaglandin-producing monocytes and macrophages into the lamina propria. A third mechanism for the regulation of prostaglandin production is the promotion of COX-1 and COX-2 synthesis. COX-2 synthesis can be induced by proinflammatory cytokines (e.g., IL-1, TNF-a) and phorbol esters. The induction of COX-2 expression occurs over a few hours; thus, the regulation of prostaglandin production by the induction of COX-2 occurs over a longer time frame than the regulation of prostaglandin production by phospholipase activation. Among the products of arachidonic acid metabolism through the COX pathway are PGE_2, thromboxane A_2, and prostacyclin. PGE_2 is made by macrophages, epithelial cells, and fibroblasts. Its biologic effects include vasodilation, increased epithelial Cl^- secretion, increased vascular permeability, and increased intestinal motility. PGE_2 also plays an important role in wound repair; in the face of injury, PGE_2 promotes epithelial cell proliferation. Thromboxane is produced primarily by platelets and results in vasoconstriction and platelet aggregation. Prostacyclin is produced by a number of cell types, including vascular endothelial cells. It is a potent vasodilator.

In the healthy gastrointestinal tract, COX-1 is present in abundance, but COX-2 is not expressed. [199] COX-2 expression has been identified in two animal models of gastrointestinal inflammation: acetic acid–induced gastric ulcers in the mouse and trinitrobenzenesulfonic acid–induced colitis in the rat. [200] The administration of selective COX-2 inhibitors in each of these models resulted in inhibition of spontaneous healing. These studies demonstrate that prostaglandins are involved in wound healing and suggest that the induction of COX-2 synthesis in gastrointestinal injury plays a role in enhancing wound healing. Prostaglandins play a role in down-regulating the immune response in the intestine. [201] A population of intestinal stromal cells constitutively express COX-2; these cells produce PGE_2, which is responsible for shutting down the immune response. [202]

Leukotrienes are made through the 5-lipoxygenase pathway. The cellular distribution of 5-lipoxygenase is much more limited than that of COX-1 and COX-2. LTB_4, a potent neutrophil chemotactic agent, is made in neutrophils, macrophages, and mast cells. The peptidyl leukotrienes (LTC_4, LTD_4, and LTE_4) are made in macrophages, mast cells, and eosinophils. They increase vascular permeability and induce vasoconstriction and smooth muscle contraction, and they may induce epithelial Cl^- secretion.

Inflamed mucosa from patients with ulcerative colitis and Crohn disease contains markedly elevated levels of PGE_2 and LTB_4. [203] Analysis of neutrophil chemotaxis in ulcerative colitis demonstrated LTB_4 to be the major neutrophil chemotactic factor; however, 5-lipoxygenase inhibitors, used as single therapeutic agents, have not been found to be effective in placebo-controlled trials in ulcerative colitis. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandin production through COX-1 and COX-2. In many inflammatory diseases, NSAIDs diminish inflammation and relieve clinical symptoms, but in ulcerative colitis, NSAIDs exacerbate clinical activity. Elevated PGE_2 levels in ulcerative colitis are associated with enhanced COX-2 expression. Immunohistochemical studies demonstrated COX-2 expression in epithelial cells from inflamed tissue affected by ulcerative colitis. [204]

PAF is a phosphatidylcholine with an ether-linked alcohol fatty acid at the first carbon and an acyl-linked acetyl group at the second carbon. [205] There are no intracellular stores of PAF, and its synthesis is initiated by the remodeling of phosphatidylcholine through the activation of phospholipase A_2. PAF is made by neutrophils, macrophages, mast cells, and eosinophils, and it is often produced in parallel with prostaglandins and leukotrienes. The biologic effects of PAF include enhanced vascular permeability, vasoconstriction, platelet aggregation, neutrophil chemotaxis, smooth muscle contraction, and epithelial Cl^- secretion. Many of these biologic effects overlap with those of prostaglandins and leukotrienes. PAF is rapidly degraded to the inactive metabolite lyso-PAF by the enzyme acetylhydrolase. Acetylhydrolase has both intracellular and secreted forms. Intestinal epithelial cells secrete acetylhydrolase, which may be an important mechanism for the defense of the gastrointestinal tract against PAF. [206] Necrotizing enterocolitis is an often fatal disorder seen in premature infants; PAF may be an important mediator in its pathogenesis. An animal model of necrotizing enterocolitis was created by injecting PAF into the superior mesenteric artery of a rat. [207] Ischemia and necrosis in the small intestine resulted, a clinical picture similar to necrotizing enterocolitis in humans.

NITRIC OXIDE

Nitric oxide (NO) is a small, biologically active compound formed when nitric oxide synthase (NOS) oxidizes the guanidino nitrogen of arginine. The biologic effects of NO include actions as a vasodilator, a neurotransmitter, and an important component of the inflammatory response. [208], [209]

The three distinct isoforms of NOS differ in their cofactor requirements, tissue distribution, transcriptional regulation, and posttranslational modification. Type 1 NOS (NOS-1) is found in neural tissue. The nitric oxide produced by NOS-1 is the principal nonadrenergic noncholinergic (NANC) neurotransmitter in the gastrointestinal tract. NOS-1 is found in enteric nerves in the myenteric plexus [210] and circular muscular and is present in neurons containing vasoactive intestinal polypeptide (VIP). NO produced through NOS-1 participates in the control of peristalsis and sphincter function in the gut. Excess production of NO through NOS-1 may contribute to disorders of bowel motility, including ileus.

Type 3 NOS (NOS-3) is found in vascular endothelial cells. NO produced by endothelial cells relaxes vascular smooth muscle cells and dilates the vasculature. Inhibition of NOS-3 in vivo causes an increase in blood pressure; hypertension is the major side effect of nonspecific NOS inhibitors. The effects of NOS-3 inhibition on blood flow are organ specific. In rats, administration of L-NMMA, an NOS inhibitor, increases vascular resistance in the stomach, pancreas, and mesenteric bed but not in the colon or small intestine. [211] NOS-1 and NOS-3 synthesize nitric oxide in relatively small quantities; the physiological effects of nitric oxide as a vasodilator and a neurotransmitter occur at quite low concentrations. NOS-1 and NOS-3 are calcium/calmodulin-dependent enzymes.

In contrast to NOS-1 and NOS-3, which are constitutive, type 2 NOS (iNOS) is inducible by proinflammatory cytokines (e.g., IL-1, TNF-a, IFN-?) and by bacterial lipopolysaccharide. NOS-2 is also called *inducible NOS (iNOS)*. NOS-1 and NOS-3 form NO in picomole concentrations, whereas iNOS forms NO in nanomole concentrations. iNOS produces nitric oxide in quantities that greatly exceed those required for its physiological functions as a vasodilator or neurotransmitter. In macrophages, the large quantity of NO produced by iNOS is used in killing bacteria and tumor cells. [212] NO works in conjunction with reactive oxygen species (e.g., hydroxyl radical, superoxide, and hydrogen peroxide) generated within phagosomes to kill phagocytosed bacteria.

iNOS is induced in intestinal epithelial cells in inflammatory states. It is induced in epithelial cells in vitro by IL-1, TNF-a, IFN-?, and lipopolysaccharide [213]; in vivo administration of endotoxin to rats induces the expression of iNOS in enterocytes. [214], [215] Infection of IFN-?–primed intestinal epithelial cells with *Salmonella* induces iNOS expression. [216] Immunohistochemical studies have revealed induction of iNOS in colonic epithelial cells from areas of inflammation in surgical resections from patients with Crohn disease, with ulcerative colitis, and with diverticulitis. [217] iNOS was not seen in epithelial cells from healthy colon or in epithelial cells from uninvolved areas of surgical resections. Elevated levels of the proinflammatory cytokines IL-1 and TNF-a in the mucosa of patients with Crohn disease and ulcerative colitis may explain the expression of iNOS by epithelial cells in these diseases.

The functional role of epithelial cell–produced NO in mucosal inflammation is not clear. NO produced by epithelial cells dilates mucosal blood vessels; increased circulation acts to wash away noxious products of inflammation. Some evidence indicates that NO may help to maintain the integrity of the epithelial barrier and the normally low permeability of the enterocyte monolayer to macromolecule transit. In studies of ischemia-reperfusion in the cat intestine, inhibition of NO synthesis resulted in marked increases in microvascular permeability and intestinal epithelial permeability. [208] Some question exists as to whether the net effect of NO generated by iNOS is to enhance or diminish gastrointestinal damage in inflammatory states. Most evidence suggests that NO, especially at low to moderate levels of production, is protective; there is some evidence that NO at high levels may promote gastrointestinal damage. Administration of endotoxin to rats induces the

expression of iNOS in the intestine and promotes gastrointestinal injury. Pretreatment of rats with an NOS inhibitor before the administration of endotoxin preserves the viability of enterocytes and diminishes the inflammatory response. [208] Moreover, the gastrointestinal injury associated with the lumenal administration of trinitrobenzenesulfonic acid is prevented by the administration of NOS inhibitors (e.g., L-NAME and aminoguanidine). In contrast to the detrimental effects of high levels of NO on mucosal integrity, low levels may enhance mucosal integrity. In the rat stomach, coadministration of indomethacin and the NOS inhibitor L-NMMA induces gastric mucosal injury. [218]

EPITHELIAL CELLS

Epithelial cells interact with the inflammatory response at several levels. The secretion of electrolytes and water by epithelial cells is an important part of the gastrointestinal response to inflammation. The interaction of inflammation and epithelial cell electrolyte and water secretion has been studied by assessing the effects of individual inflammatory mediators on electrolyte and water secretion, or by identifying the mediators that regulate electrolyte and water secretion in specific inflammatory states. Histamine, PGE_2, serotonin (5-hydroxytryptamine, 5-HT), and LTB_4 are just a few of the inflammatory mediators that induce epithelial cell Cl^- secretion (Fig. 7-11). Neural mechanisms also affect epithelial cell Cl^- secretion directly or indirectly through inflammatory cells. The neurotransmitter acetylcholine induces Cl^- secretion in epithelial cells directly. [219] Neuropeptides such as substance P, VIP, and NPY induce mast cell activation, resulting in the release of histamine and 5-HT, and thus activate epithelial cell Cl^- secretion. [220] Cl^- secretion is accompanied by Na^+ secretion and, consequently, by the passage of water across the epithelium into the intestinal lumen. Diarrhea is the clinical manifestation of the enhanced enterocyte Cl^- secretion induced by these mediators. These same inflammatory mediators induce the secretion of mucus by goblet cells in the gastrointestinal tract. Diarrhea protects the host from infectious agents and their toxins by speeding their passage through the gastrointestinal tract and out of the organism. Mucus secretion protects the host from infectious agents in the gastrointestinal tract by preventing the binding of the infectious agents and their toxins to epithelial cells.

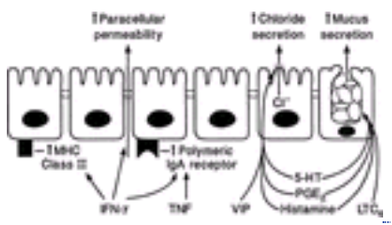

FIGURE 7-11. Intestinal epithelial cells respond to cytokines and inflammatory mediators. *5-HT,* 5-hydroxytryptamine, or serotonin; *IFN-?*, interferon-?; *LTC_4,* leukotriene C_4; *PGE_2,* prostaglandin E_2; *VIP,* vasoactive intestinal polypeptide.

The interaction of inflammation and epithelial electrolyte and water secretion has also been studied by identifying the inflammatory mediators that regulate electrolyte and water secretion in specific inflammatory conditions. One relatively simple animal model of intestinal inflammation is the sensitization of rats to egg albumin followed by antigenic challenge. In this model, antigenic challenge results in increased Cl^- secretion and increased paracellular permeability. [221] The increase in paracellular permeability was demonstrated by the increase in the uptake of ^{51}Cr-EDTA from the intestinal lumen after antigen challenge of previously sensitized rats. The relative contribution of various inflammatory mediators to the increase in Cl^- secretion seen in this model was tested with a series of blocking agents. Ketanserin (an antagonist of 5-HT), diphenhydramine (a histamine H_1 antagonist), and piroxicam (a COX inhibitor) inhibited egg albumin–induced Cl^- secretion by 30%, 42%, and 52%, respectively. The combination of piroxicam and diphenhydramine inhibited the secretory response by 82%. These data suggest that even in this simple model, more than one inflammatory mediator contributes to the increase in Cl^- secretion, and the mediators involved indicate that more than one cell type produces mediators. Histamine and 5-HT are products of mast cell activation. PGE_2, the prostaglandin most likely involved in Cl^- secretion, is produced by fibroblasts or by the epithelial cells themselves. In a similar study, challenge of *Trichinella*-immunized rats with *Trichinella* larvae resulted in increased intestinal fluid secretion. [222] Treatment of the rats with the combination of indomethacin, a COX inhibitor, and diphenhydramine ablated the increase in the fluid secretion induced by exposure to *Trichinella.* In the *Trichinella* model, increased fluid secretion is caused by a combination of prostaglandins and histamine, whereas in the egg albumin model, increased secretion results from a combination of prostaglandins, histamine, and 5-HT.

The epithelium also interacts with the inflammatory response in its function as a barrier. The epithelium separates lumenal antigens from lamina propria inflammatory cells, thus preventing activation of the inflammatory cells by lumenal agents. The effectiveness of the epithelium as a barrier is influenced by the junctions between the epithelial cells. [223], [224] The tighter these junctions, the more effective the epithelium is as a barrier to the passage of noxious agents. The junctions between epithelial cells are fairly loose in the proximal intestine and become progressively tighter in the distal small intestine and colon. Epithelial permeability usually is assessed by measuring the flux of tracer molecules either from the bloodstream into the intestinal lumen or from the intestinal lumen into the bloodstream. One commonly used probe is ^{51}Cr-EDTA. This compound is placed in the intestinal lumen, the animal is challenged, and then the recovery of ^{51}Cr-EDTA in the blood is assessed. Epithelial permeability is affected by inflammatory events. IFN-?, a cytokine produced during intestinal inflammation, increases paracellular permeability by opening the tight junctions between epithelial cells. [225] Increased paracellular permeability has been described in Crohn disease and in several animal models of gastrointestinal inflammation. [226]

Absorptive intestinal epithelial cells can also function as antigen-presenting cells. [227], [228], [229] and [230] Epithelial cells of the small intestine constitutively express MHC class II molecules, possibly as a consequence of the intraepithelial lymphocyte secretion of IFN-?. [231] Colonic epithelial cells do not normally express measurable levels of MHC class II molecules, except in the setting of inflammation, presumably in response to local cytokine production. [232] In vitro studies of intestinal epithelial cell function show that they take up, process, and present soluble antigens to $CD4^+$ T cells in the context of MHC class II molecules. [233] Although soluble antigens can be taken up apically and basolaterally, MHC class II molecules primarily segregate in the basolateral region, where antigen presentation to antigen-specific, MHC class II–restricted T cells occurs. There is evidence that under normal conditions, intestinal epithelial cells take up, process, and present soluble antigens from the lumen in vivo. The implication of these studies is that intestinal epithelial cells may augment or modify afferent pathways that normally result from antigenic events within Peyer patches. Despite in vitro evidence for functional class II MHC expression, intestinal epithelial cells seem to engage and stimulate preferentially $CD8^+$ cells that exhibit suppressor activity—an activity that may contribute to the suppressor tone of the intestine. [228], [229]

One consequence of many forms of intestinal injury is the development of breaks in the epithelial barrier. These breaks are seen in infectious disease, in inflammatory bowel disease, in celiac disease, and in injury caused by radiation and chemotherapeutic agents. There is an orchestrated response to these breaks, beginning with the rapid migration of epithelial cells shouldering the wound to cover the defect. Epithelial cells elongate and thus cover broad areas of denuded mucosal surface.

INFLAMMATION AND EPITHELIAL CELL GENE EXPRESSION

In the presence of inflammation, epithelial cells express a series of genes that are not expressed in the absence of inflammation. Among these are genes for COX-2, [204], [234] iNOS, [216], [217] and IL-8. [186] As previously discussed, an immunohistochemical study of human colon revealed expression of iNOS in epithelial cells from areas of inflammation in ulcerative colitis, Crohn disease, and diverticulitis, but not in epithelial cells from uninflamed areas of the same surgical resections. [217] In parallel studies of the cellular distribution of iNOS and COX-2 in ulcerative colitis resections, these proteins were expressed in exactly the same populations of epithelial cells in areas of inflammation. [204] This colocalization suggests a common regulatory mechanism for the expression of these genes.

Intestinal epithelial cell lines infected with *Salmonella* species and other invasive bacteria express IL-8 and COX-2, whereas uninfected cells or cells infected with noninvasive bacteria do not. [186], [234] Intestinal epithelial cell lines in culture were infected with *Salmonella dublin* and then stained for COX-2 expression and for intracellular *Salmonella*. The *Salmonella*-infected cells expressed COX-2, as did a few contiguous epithelial cells. In contrast, cells that were not infected themselves or were not adjacent to infected cells did not express COX-2. The expression of COX-2 in cells adjacent to an infected cell raises the possibility of a paracrine effect mediated by a soluble factor. *Salmonella* infection also induced epithelial cell COX-2 expression in human intestinal xenografts transplanted into mice with severe combined immunodeficiency disease (SCID), which demonstrates that infection from *Salmonella* induces COX-2 expression in normal intestinal epithelial cells as well

as in transformed epithelial cell lines. Infection of the colonic epithelial cell line HT-29 with *Salmonella* resulted in the expression of COX-2 and, as a consequence, a 50-fold increase in the production of PGE_2, a potent stimulus for Cl^- secretion in epithelial cells. Supernatants from *Salmonella*-infected epithelial cell lines increased Cl^- secretion by polarized intestinal epithelial cells mounted in an Ussing chamber. The demonstration that the PGE_2 in conditioned media from *Salmonella*-infected epithelial cells in culture can induce Cl^- secretion in vitro suggests that the diarrhea affecting humans infected with *Salmonella* may be the result of PGE_2 produced by COX-2 in *Salmonella*-infected epithelial cells. One of the protective responses to infection with enteric pathogens is an increase in electrolyte and water secretion to wash the pathogens out of the gastrointestinal tract. This study proposes that one mechanism for this protective response is the induction of epithelial cell COX-2 expression, which results in increased prostaglandin production and, thus, increased Cl^- secretion.

The genes for IL-8, iNOS, and COX-2 each have an NF-?B site in their promoters. NF-?B is an important transcription factor in the regulation of the synthesis of numerous inflammation-related proteins (e.g., TNF-a, IL-1, ICAM-1, E-selectin, IL-8, iNOS, and COX-2.) [235] NF-?B is a heterodimer that consists of p50 and p65 subunits. In unstimulated cells, NF-?B is bound to I?B-a, which is found in the cytoplasm. When cells are stimulated, I?B-a is phosphorylated and degraded, and NF-?B is released. The release of NF-?B from I?B-a allows NF-?B to enter the nucleus, where it binds to the promoter regions of target genes. NF-?B is activated by proinflammatory cytokines (e.g., TNF-a and IL-1), oxidants, phorbol esters, PAF, and lipopolysaccharide. Some of these agents (e.g., IL-1, TNF-a) are likely to be present in inflammatory states. The importance of NF-?B in the response to infection is demonstrated by the finding that mice lacking the p50 subunit of NF-?B are unable to clear *Listeria* species and other organisms effectively. [236]

Activation of NF-?B results in the parallel stimulation of a number of important genes involved in the inflammatory response. It is this parallel stimulation that probably accounts for the coexpression of iNOS and COX-2 in the same population of epithelial cells in ulcerative colitis. The presence of NF-?B response elements in the genes for E-selectin, ICAM, IL-8, and TNF-a allows for the coordinated expression of a series of proteins involved in the adhesion of neutrophils to epithelial cells, the migration of neutrophils from the vascular space into gastrointestinal tissue, and the activation of those neutrophils. IL-1, TNF-a, and NF-?B are involved in a cycle of activation that results in amplification of the inflammatory response. IL-1 and TNF-a both activate NF-?B; in turn, the synthesis of IL-1 and TNF-a is promoted by the binding of NF-?B to response elements in their promoters. This positive regulatory cycle amplifies and perpetuates the inflammatory response. Although NF-?B has received the most attention, other transcription factors are involved in the regulation of genes associated with inflammation. NF-IL6 sites are presented in the promoters of several of these genes. Preliminary studies suggest that NF-IL6 may be as important as NF-?B in the regulation of these genes. [237]

MAST CELLS

Mast cells are inflammatory cells with large granules containing preformed mediators of inflammation (e.g., histamine and 5-HT). [238] In response to stimulation, mast cells release these granules and produce newly formed non-granule–associated mediators (e.g., NO, PGD_2, PAF, and leukotrienes). In the healthy gastrointestinal tract, mast cells are found in the lamina propria, submucosa, and muscle layers and on the serosal surface. [238] More numerous and activated mast cells have been observed in the gastrointestinal mucosa of patients with helminthic infections, ulcerative colitis, Crohn disease, gastritis, and celiac sprue.

In rodents, the two distinct subpopulations of mast cells are connective tissue mast cells and mucosal mast cells. The connective tissue mast cells, such as those found in the rat peritoneum, have granules that contain 5-HT, heparin, and large amounts of histamine. They are capable of making PAF, NO, PGE_2, TNF-a, IL-1, IL-3, IL-4, IL-6, IL-10, and IFN-?. In contrast, rat mucosal mast cells have granules that contain 5-HT and small amounts of histamine. They are capable of making PAF, NO, PGE_2, leukotrienes, and TNF-a. Connective tissue mast cells and mucosal mast cells arise from a common progenitor cell. There appear to be two subpopulations of mast cells in humans, but the distinctions are not as clear as they are in rodents.

Mast cells can be activated by a variety of factors, but IgE-dependent antigen activation is the most common. Antigen-specific IgE binds to receptors on the surface of the mast cell through its Fc component. Exposure of the mast cell to an appropriate antigen results in cross-linking of the IgE molecules, which in turn results in activation of the mast cell. IgE-mediated mast cell activation is an effective defense mechanism against intestinal worms and other parasites. Parasite antigens cross-link IgE molecules on intestinal mast cells. Mast cell activation releases substances that promote intestinal motility and increase electrolyte and water secretion. Histamine, PGD_2, and peptidyl leukotrienes are released by activated mast cells; all enhance epithelial cell Cl^- secretion and promote intestinal motility. These physiological responses allow the infected host to wash the parasites out of the digestive tract. IgE-mediated mast cell activation is also important in allergic disorders. Pollen cross-links IgE molecules on mast cells in the nasal mucosa, causing allergic rhinitis. Food antigens activate mast cells in the gastrointestinal tract by similar mechanisms. There would appear to be no evolutionary advantage to being able to mount an allergic response to food antigens, but there would be an evolutionary advantage to being able to mount a response to gut parasites that would clear them from the gastrointestinal tract. It may be that food allergies represent the maladaptation of an inflammatory response designed to deal with intestinal parasites.

In addition to IgE-dependent antigen activation, mast cells also can be activated by the calcium ionophore A23187 and by the complement components C3a and C5a. Some subpopulations can be activated by substance P; substance P activation is of particular interest in that substance P is a neurotransmitter that can be released by neural activation in the gastrointestinal tract. Mast cell activation by substance P would provide a mechanism for the induction of intestinal inflammation by neural activation. There are both anatomic and functional interactions between mast cells and the enteric nervous system. In the rat, infection with the intestinal nematode *Nippostrongylus brasiliensis* results in mast cell hyperplasia. Immunohistochemical studies reveal that most of these mast cells are juxtaposed to enteric nerves. There are bidirectional interactions between nerves and mast cells. Neurotransmitters, particularly substance P, cause mast cell degranulation, and mast cells in turn release VIP, which can act as a neurotransmitter.

Mast cell activation plays an important role in various allergic reactions. Exposure to an antigen results in B-cell activation and the production of antigen-specific IgE, which binds to specific receptors on mast cells. Reexposure to the sensitizing antigen results in IgE cross-linking and mast cell activation. Earlier in this chapter, we described the results of studies in which sensitized rats were challenged with albumin; Cl^- secretion increased, as did paracellular permeability. A role for mast cell activation in this process was demonstrated by the finding that Cl^- secretion in response to egg albumin can be significantly diminished by the coadministration of diphenhydramine, an antagonist of the histamine H_1 receptor. [221] Mast cells are the dominant source of histamine in the gastrointestinal tract.

Additional evidence that mast cells are involved in the mediation of enhanced Cl^- secretion after antigen exposure comes from studies with the mast cell–deficient mouse (W-W^V). Antigen challenge in sensitized W-W^V mice results in a 70% decrease in Cl^- secretion in comparison with antigen challenge in wild-type littermates. [239] These data suggest that at least in this model, mast cell–derived histamine is an important mediator of epithelial cell Cl^- secretion. The Cl^- secretion measured in the mast cell–deficient mice (30% of that in the wild-type mice) could be inhibited with NSAIDs, suggesting that the prostaglandins that induce Cl^- secretion are not of mast cell origin.

MOTILITY

The musculature of the gastrointestinal tract is at one level an effector mechanism for the inflammatory response. One mechanism for eliminating pathogenic organisms is to enhance motility and push the offending organisms out of the gut. The cramps and diarrhea that accompany intestinal inflammation are in part the products of inflammation-induced alterations in gastrointestinal motility.

Altered motility has been documented both in animal models of inflammation and in chronic inflammatory diseases in humans. The intrarectal administration of acetic acid in the cat results in a biphasic change in motility in the sigmoid colon. [240] Three days after the administration of acetic acid, spontaneous motility in the colon decreases. This period corresponds to the peak of acute inflammation. Motility returns to normal within a week; later, as the inflammation continues to resolve, motility is increased over normal. In conditions marked by chronic inflammation, changes in motility are more complex. Active ulcerative colitis in humans is associated with diminished sigmoid activity, which returns to normal as the colitis goes into remission. In healthy subjects, there is a reflex increase in colonic motility after meals; in patients with ulcerative colitis, this reflex increase in motility is decreased. [241]

The changes in motility associated with inflammation do not require inflammation in the muscle itself. Superficial mucosal inflammation can result in dysmotility in the underlying muscle, even though the muscle is histologically normal. [242] Moreover, inflammation in one part of the gastrointestinal tract can result in dysmotility in remote parts; for example, colitis can be associated with gastric dysmotility.

Motility of the gastrointestinal tract is affected by inflammation at several levels; mediators of inflammation affect smooth muscle contraction by direct interaction with

the muscle cell, inflammatory cytokines affect the growth of smooth muscle, and inflammation affects muscle contraction indirectly through effects on the neural and hormonal elements that regulate smooth muscle contraction.

Some mediators of inflammation, including prostaglandins, PAF, leukotrienes, and serotonin, act directly on smooth muscle cells. The effects of mediators on muscle contraction can be specific to a species, a region of the gastrointestinal tract, or a muscle type. For example, PGE_2 contracts colonic longitudinal muscle but relaxes colonic circular muscle. A few studies have attempted to define which inflammatory mediators contribute to the altered motility seen in specific inflammatory conditions. Oral challenge of ovalbumin-sensitized rats results in a disruption of the normal migrating motor complex. [243] This effect can be reduced by treating the rats with an antagonist of the 5-HT_1 and 5-HT_2 receptors. These findings suggest a role for 5-HT in the dysmotility associated with anaphylaxis.

Inflammatory cytokines affect smooth muscle growth and regulate enzymes involved in stricture formation. [244] Chronic inflammation is associated with stricture formation. In Crohn disease, smooth muscle hypertrophy is found in the muscularis mucosae. [245] Smooth muscle hypertrophy also is seen in the intestines of rodents infected with *Trichinella spiralis* and *N brasiliensis*. The mechanism of this inflammation-associated smooth muscle hypertrophy is not clearly understood; however, the proinflammatory cytokine IL-1, which is present in abundance in acute and chronic inflammation, is mitogenic for smooth muscle cells. IL-1 activates collagenase and inhibits collagen synthesis in human intestinal smooth muscle cells. [246]

Inflammation influences smooth muscle function through its effects on the enteric nervous system and hormones. Crohn disease is associated with structural abnormalities of enteric nerves and smooth muscle even in unaffected areas of the gastrointestinal tract, [247] which may explain the findings of dysmotility in parts of the gastrointestinal tract remote from the site of inflammation. Intestinal inflammation also has been associated with changes in the levels of neuropeptides. Substance P levels are increased in ulcerative colitis. [248] Substance P may play a role in the increased sensibility of the rectum to distention in patients who have ulcerative colitis. [249] In an animal model of ileitis, inflammation increased the noncholinergic excitation induced by substance P. [250]

NO levels increase in inflammatory bowel disease and in animal models of inflammation. NO is thought to be the major inhibitory neurotransmitter in the intestine. Immunohistochemical studies suggest that in human inflammatory bowel disease, most of the inducible NO synthesis is expressed in epithelial cells. Whether NO produced in epithelial cells can influence contractions in the muscularis propria is not clear.

The interaction between the immune system and smooth muscle cells is bidirectional. Cytokines affect smooth muscle function, and smooth muscle cells can produce cytokines. In vitro incubation of rat intestinal smooth muscle cells with IL-1 results in the production of IL-6. The functional importance of in vivo cytokine production of smooth muscle cells is not clear.

CHAPTER 8

James Madara and James M. Anderson

EPITHELIA: BIOLOGIC PRINCIPLES OF ORGANIZATION

All cavities within the alimentary tract, from the small ducts and acini of the pancreas to the gastric lumen, are lined by sheets of polarized epithelial cells. A common feature of all epithelia is their ability to create selective barriers and to accomplish vectorial transport. These properties are based on the structural polarity of individual cells, their mechanisms of cell-cell and cell-substrate interaction, and their higher-order organization with other cell types. This chapter reviews both the origins of cell polarity and cell interactions and examines how these interactions underlie the structural organization of the gut wall and the biology of gut epithelial barriers. Some aspects of epithelial transport are discussed to emphasize the associations among epithelial transport, barrier function, and structure, but more detailed reviews of active transport processes across specific epithelia are found in Chapter 13, Chapter 14, Chapter 15 and Chapter 16.

ORGANIZATION OF THE GUT WALL

Figure 8-1 depicts the relation of the epithelial layer to other components of the gut wall. Four principal layers exist: mucosa, submucosa, muscularis propria, and serosa or adventitia. The mucosa consists of the epithelium, an underlying layer of loose connective tissue carrying nerves and vessels (i.e., lamina propria), and a thin layer of smooth muscle (i.e., muscularis mucosae). The mucosa also contains an array of lymphocytes, mast cells, macrophages, and, in disease states, polymorphonuclear leukocytes, all of which may be capable of modulating epithelial function.

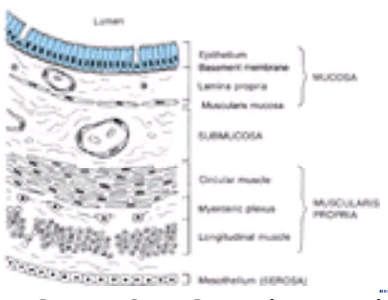

FIGURE 8-1. Generic organization of the gut wall.

An underlying layer of fibroconnective tissue called the *submucosa,* which contains nerves, vessels, and lymphatics, supports the mucosa. The submucosa rests on the muscularis propria, which is composed of two or three layers and is home to the myenteric plexus (see Chap. 2). In most instances, organs are encased by a delicate layer of fibrofatty tissue that supports a continuous layer of mesothelial cells called the *serosa.* Where no serosa exists, as in the esophagus, the fibrofatty tissues of surrounding structures interlace intimately with the external portion of the muscularis propria. These organs are said to have an adventitial, rather than a serosal, encasement.

Grasp biopsies retrieved endoscopically usually go no deeper than the muscularis mucosae, although thin wisps of submucosal tissues occasionally may be seen. Suction biopsies more consistently penetrate the submucosa, although only the most superficial portion of the submucosa is obtained. Deeper portions of the wall appear in endoscopic samples by accident, such as in an aggressive snare of a sessile mucosal lesion.

Organ-specific specializations in epithelial structure exist. Most of the gastrointestinal tract is lined by a simple columnar epithelium (Fig. 8-2; see Fig. 8-1). In contrast, the mouth and esophagus are lined by a nonkeratinizing squamous epithelium that is capable of withstanding the mechanical stress of swallowing but plays no role in transepithelial transport. Hepatocytes are unique, because the apical (canalicular) surface is organized not at one end but as a 3-μm band circumscribing the cell. The liver also lacks extensive subepithelial layers, and capillaries are separated from hepatocytes by only a rudimentary basement membrane in the space of Disse. The folding of epithelial layers also exhibits significant interorgan variation, such as the cuplike acinar organization of the exocrine pancreas and the deep extensions of the epithelium into the lamina propria of Brunner glands in the duodenum. Certain central features, however, are maintained in all epithelial tissues.

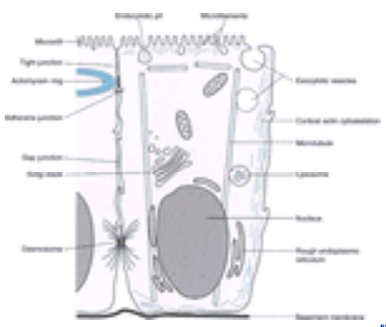

FIGURE 8-2. Generic organization of a gut epithelial cell.

ORGANIZATION OF EPITHELIAL CELLS AND SHEETS

To function properly as a barrier, epithelial cells must assemble into a multicellular sheet (see Fig. 8-1 and Fig. 8-2). Requirements for this higher organization include the following: mechanisms to generate individual cell polarity, cell-cell adhesion, and formation of cell-cell junctions; stabilization of cell shape by the cytoskeleton; and stabilizing interactions with the basement membrane.

Generation of Cell Polarity

A hallmark of epithelial cells is structural and functional polarity. Within each cell, the organelles and components of the secretory and endocytic pathways have specific spatial relationships (Fig. 8-3; see Fig. 8-2). These are largely maintained by attachment to cytoskeletal elements formed by filaments of actin and tubulin. Both microfilaments and microtubules are structurally polarized, with so-called plus and minus ends, and the cell uses this polarity to establish and maintain subcellular asymmetry. The plasma membrane is separated into apical and basolateral domains, and within these there exist microdomains that organize protein complexes of receptors, transporters, signal transduction proteins, and cell junctions. [1] Two examples make obvious the functional requirement for polarity: the sodium (Na^+)-dependent solute transporters must be positioned on the apical cell membrane to accomplish nutrient uptake from the gut lumen; and zymogen granules must be secreted onto the apical pole of the pancreatic acinar cell to reach the duodenum (see Fig. 8-3). Failure of zymogen granule targeting results in intracellular activation of proteases and pancreatitis. [2] The polarized distribution of surface components is maintained by protein sorting by the intracellular secretory machinery, by selective retention at the plasma membrane, and by the intramembrane fence function of the tight junction (see Fig. 8-3).

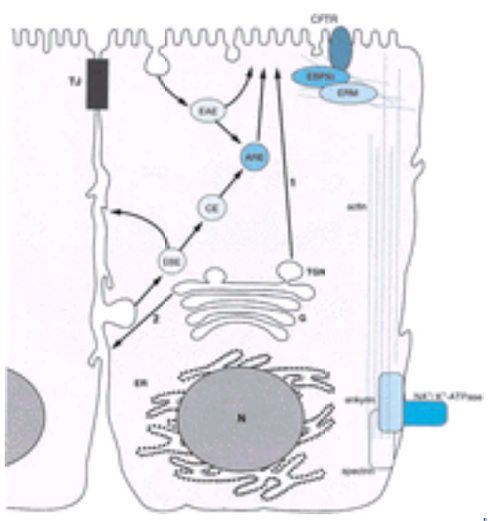

FIGURE 8-3. Three mechanisms for generating epithelial cell polarity. **First:** Membrane and secretory proteins synthesized in the endoplasmic reticulum (ER) pass through the Golgi apparatus (G) and are initially sorted in the trans-Golgi network (TGN). Some proteins are delivered directly to the apical (1) or basolateral (2) surface. Others (e.g., poly-IgA receptor) are delivered to the basal surface and are transcytosed to the apical surface through early basolateral endosome vesicles (EBE). Many receptors are recycled on their respective membranes through early apical endosomes (EAE) or EBE. Crossover between the apical and basal compartments and maintaining fidelity of each can occur through apical recyling endosomes (ARE) and common endosomes (CE). **Second:** Once inserted, many proteins are anchored to the cortical actin cytoskeleton;for example, the Na^+,K^+-ATPase is bound through spectrin and ankyrin; cystic fibrosis transmembrane conductance regulator (CFTR) is bound through EBP50 (ezrin-radixin-moesin family of proteins [ERM]–binding phosphoprotein of 50 kd) and ezrin. **Third:** Tight junctions (TJ) create a barrier to diffusion of components between the membrane domains.

Extracellular Cues Induce Cell Polarity

The spatial cues that induce initial cell asymmetry, and maintain it, arise from contact with the extracellular matrix and with other cells. Important receptors include the large protein families of integrins, heparan sulfate proteoglycans (e.g., syndecan), and others. [3], [4] These respond to ligation of matrix components such as collagens, fibronectin, and laminin by inducing initial polarity of the cytoskeleton, organelles, and intracellular vesicular compartments. These cues also alter or maintain differentiation by controlling gene transcription.

A key transducer of extracellular cues in gastrointestinal epithelia is the cell-cell adhesion molecule, cadherin. The epithelial form, E-cadherin, is a 120-kd calcium (Ca^{2+})-dependent homotypic adhesion molecule found in all epithelial cell types of the gastrointestinal tract (Table 8-1; see Fig. 8-2). [5] In many cell types, E-cadherin is focused at the adherens junction where, through the cytoplasmic linker proteins, a-actinin, and a- and ß-catenin, it is coupled to a perijunctional ring of actin filaments (see Fig. 8-2 and Table 8-1). E-cadherin is also capable of heterotypic adhesion to a $E ß_7$ integrin on intraepithelial lymphocytes. [6] Many experiments support the idea that cell-cell adhesion mediated by cadherin triggers a cascade of cellular events that induces polarity. In addition, cadherin influences gene transcription and inhibits cell motility. [7] This explains why loss of cadherin is strongly correlated with acquisition of an invasive phenotype for many human gastrointestinal neoplasms. Another link to cell proliferation occurs through ß-catenin, which, when not bound to cadherin, functions as pro-growth transcription activator. The activity of cytosolic ß-catenin normally is down-regulated by the adenomatous polyposis coli (APC) gene, thus explaining why mutations in *APC* lead to enhanced ß-catenin activity and growth of adenomas in the colon and demonstrating the functional connections among cell adhesion, polarity, growth, and tumor invasion. [8], [9] Likewise, altered expressions of other cell-cell and cell-matrix molecules are either primary or secondary causes of neoplastic transformation in the gastrointestinal tract, again because of their inductive role in maintaining polarity and the differentiated phenotype.

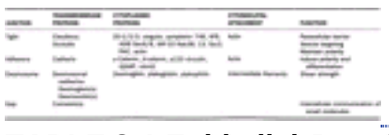

TABLE 8-1 Epithelial Junctions: Molecular Components and Function

Polarized Delivery of Proteins to the Cell Surface

Plasma membrane proteins pass through a series of distinct vesicular compartments as they are sorted to either the apical or basolateral surface. They share a common site of synthesis on ribosomes bound to the rough endoplasmic reticulum, undergo posttranslational modification in the Golgi apparatus (e.g., glycosylation), and are first sorted into distinct vesicles in the trans-Golgi network (see Fig. 8-3). From this point, the patterns of vesicle sorting are specific to different cell types. In hepatocytes, all membrane proteins are first delivered to the basolateral surface; subsequently, the apically destined proteins are “transcytosed” to the canalicular surface. [10] An easily rationalized example of this type of sorting is offered by the poly-immunoglobulin A (IgA) receptor, which picks up IgA from the serum on the basal surface and is then transcytosed and released as secretory component into the bile. [10] Why the apical transporters and channels first traffic through the basal membrane in hepatocytes remains unclear.

Intestinal epithelial cells appear to use a combination of both indirect (transcytosis) and direct sorting for delivery of polarized membrane proteins. [11] In addition, all cell types have active pools of vesicle compartments that recycle proteins on either the apical or basolateral surfaces, called, respectively, *early apical or basolateral*

recycling endosomes (see Fig. 8-3). These are used by receptors cyclically to internalize compounds such as low-density lipoprotein (LDL) and transferrin after being reinserted back onto the correct surface. Proteins in these early endosome compartments can also cross among trafficking pathways in at last two compartments located deeper in the cell, called the *common endosome* and the *apical recycling endosome.* For example, the poly-IgA receptor is transcytosed from the basal to the apical surface through early basal endosomes and the common and apical recycling endosomes. Degradation of proteins from both surfaces is accompanied by sorting early endosomes to a common late endosome and into lysosomes. The polarized sorting of lipid is discussed in Chapter 18.

Signals must exist for sorting proteins among different compartments and for keeping the various compartments biochemically distinct. Emerging themes for maintaining specificity are the presence of distinct members of the Rab family of small guanosine triphosphate (GTP)-binding G proteins on each vesicle type and the presence of different adaptor proteins coating the surface of each compartment. The specificity for recognizing and fusing with the proper surface domain is based on distinct members of the syntaxin, SNAP, and Rab protein families in the vesicles and plasma membrane; these mechanisms are similar to those responsible for synaptic vesicle cycling in neurons, [12] where they are better understood. Although in general these mechanisms remain poorly understood in gastrointestinal epithelia, two excellent examples are the machinery used by zymogen granules for recognition and fusion with the acinar cell membrane [13] and that used for the fusion of membranes containing hydrogen, potassium-adenosine triphosphatase (H^+,K^+-ATPase) with the apical surface of the parietal cell in the stomach. [14]

Initial sorting of proteins to either apical or basolateral surfaces is based on signals within the proteins themselves. Apical sorting signals usually are located in the extracellular or transmembrane domains. These signals can be specific carbohydrate moieties added, like a Zip code, while the protein passes through the Golgi apparatus. [15] Addition of the lipid glycosylphosatidylinositol (GPI), such as found on alkaline phosphatase, also creates an apical targeting signal. The lipid portion of the GPI anchor partitions into cholesterol-rich lipid microdomains, called *rafts,* that somehow are sorted to the apical surface. [16] At present, three types of basolateral sorting signals are recognized:

1. The so-called tyrosine-based motif exemplified by the LDL receptor (tyrosine-X-X-[hydrophobic residue])
2. The di-leucine sequence found on the immunoglobulin Fc receptor
3. A variety of unique motifs.

The sorting machinery that reads these signals is based on a large and diverse family of heterotetrameric adapter proteins (AP1, 2, 3, and 4). For example, the µ1B subunit of AP1 binds the LDL tyrosine motif, and this interaction is required for basolateral delivery of the receptor. [17] How the AP complexes themselves attain specific subcellular locations remains unknown.

Stabilization at the Membrane Surface

Once proteins are delivered to the correct plasma membrane domain, they can be retained through interaction with a cortical network of actin-based cytoskeletal proteins (see Fig. 8-3). For example, the Na^+,K^+-ATPase is stabilized on the basolateral membrane domain by attachment to the cytoskeleton through ankyrin and spectrin. [18] More recent is the recognition that many transmembrane proteins are linked through their extreme C-terminals to so-called PDZ domains within cortical cytoskeletal proteins. PDZ domains bind in a sequence-specific manner to the C-terminal three to seven amino acids of transmembrane proteins. Proteins with PDZ domains typically contain many additional protein-binding motifs that serve to cluster other components involved in regulating a specific channel or receptor signaling pathway. A good example is provided by cystic fibrosis transmembrane regulator (CFTR), which apart from its chloride (Cl^-)-secretory function also regulates electrolyte absorption by influencing the activity of the epithelial Na^+ channel in absorptive epithelial cells such as in the colon. The tail of CFTR is bound to a PDZ domain in a protein called EBP50 (ERM-binding phosphoprotein of 50 kd), which links it to the cortical actin cytoskeleton through an ERM (ezrin-radixin-moesin) protein (see Fig 8-3) and several signaling proteins including protein kinase A, which directly regulates the epithelial Na^+ channel. [19] There is growing interest in the study of cortical cytoskeletal coordination and scaffolding of epithelial cell signaling in the gastrointestinal tract. [1]

Stabilization of Cell Shape by the Cytoskeleton

The cytoskeleton is considered here in the context of the villus absorptive cell of the small intestine, a cell type that has become an important model for studies of cytoskeletal structure and function in nonmuscle cells. Interorgan differences in cytoskeletal organization largely represent variations on a single theme.

Stabilization of epithelial cell structure requires support for the apex of the cell, which confronts the turbulent environment of the gut lumen. Alimentary tract epithelia, except for esophageal squamous epithelia, display microvillus projections on the apical surface. Microvilli are particularly well formed in absorptive cells. A bundle of 20 to 30 microfilaments composed of F-actin resides in the core of these microvilli. [20]

Individual microfilaments are cross-linked to each other by filamentous structures consisting of filamin, a 68-kd actin-bundling protein (with two actin-binding domains that permit tight actin filament bundling), and villin, a 95-kd protein that can bundle or sever F-actin microfilaments, depending on intracellular Ca^{2+} concentrations. Villin knock-out mice demonstrate impaired intestinal epithelial wound healing that appears to result from the inability of microvilli to break down, which is a requirement for the transition from the epithelial to mesenchymal phenotype during wound closure. [21] The microfilament core is linked laterally to the microvillus plasma membrane by a member of the myosin family (myosin 1A). The membrane-myosin-actin link determines the length of the microvillus. The microvillus actin-bundle rootlets jut into the apical pole of the cell and associate with a terminal web of structural proteins. The density of this terminal web is most marked in cell types that do not have substantial exocytosis of secretory vesicles. Fine filaments, composed of type II myosin, link adjacent rootlets. A heteromeric spectrin-like molecule (i.e., TW260/240) also resides at this location and may be important in linking actin filaments and plasma membranes and in assisting in the stabilization of the cell surface.

Columnar epithelial cells display circumferential belts of actin and myosin II around their apices (see Fig. 8-2) that can contract in the presence of micromolar concentrations of Ca^{2+} and millimolar concentrations of ATP. [20] This actomyosin belt has been referred to as the *contractile ring.* The tension exerted by this ring on cell-cell contacts may modulate the barrier function of epithelia (discussed later in this chapter). A cortex of cytoskeletal elements, including actin and numerous cross-linking molecules, also wraps the basolateral pole on the epithelial cell. This cortex plays a crucial role in establishing apical-basolateral polarity, cell junctions, and transmembrane signaling [18] (see Fig. 8-2).

Cables composed of aggregates of 10-nm intermediate filaments course through the cells and function as support cables for structural buttressing. Such tonofilament cables associate with plasma membranes at sites where specialized cell-cell junctions, called *desmosomes,* reside (see Fig. 8-2). The role of desmosome and intermediate filaments in the gastrointestinal tract is highlighted by hepatocyte fragility in mice genetically altered to express a mutant form of keratin-18. These mice also have an increased susceptibility to the hepatotoxins acetaminophen and griseofulvin. [22]

The 25-nm-diameter microtubules, composed of tubulin, create a polarized array throughout the cell. Two large families of microtubule-dependent motor proteins exist, the kinesins and dyneins, which move in the opposite direction on polarized microtubule arrays. Most organelles and all the intracellular sorting compartments are attached to the microtubule network through adaptor proteins and use the motor proteins for trafficking and to maintain their proper subcellular localization. For example, if microtubules are disrupted, intestinal epithelial cells misdirect the apical membrane protein aminopeptidase to the basolateral domain

Intercellular Junctions

Other than the squamous epithelium of the esophagus and perhaps a few enteroendocrine cells, all other alimentary epithelia share a set of distinct intercellular junctions (see Fig. 8-2 and Table 8-1). These include, from the apical direction, the tight and adherens junctions, which form continuous circumferential contacts, and below these, desmosomes and gap junctions, which form macular or spot contacts. Together they seal the paracellular space, provide communication among cells, and stabilize the epithelial monolayer.

In thin sections viewed under the electron microscope, tight junctions appear as 100- to 300-nm-deep zones where adjacent cells closely abut (Fig. 8-4A). Series of punctate fusions or “kisses” between these plasma membranes form a sealing barrier. These fusion sites are arrayed in a linear anastomosing fashion around the cell and correspond to the netlike series of grooves or strands seen in replicated fracture faces of epithelial cells (Fig. 8-4B). The strands are formed by members of the claudin family of tetraspan adhesion molecules, which make contact in the intercellular space to create a selective diffusion barrier. Occludin, a 60-kd transmembrane protein whose function remains unknown, is also found in the strands of some tight junctions. In the intestine, occludin also is expressed diffusely along the entire

lateral cell membrane. Research has shown that occludin knock-out mice are viable. [23]

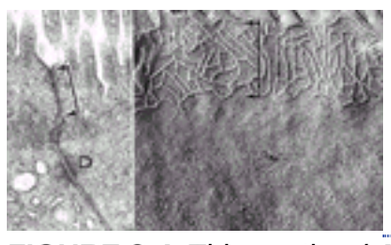

FIGURE 8-4. Thin section (**A**) and freeze fracture electron micrographic appearance (**B**) of the tight junction of an intestinal absorptive cell. In thin sections, the tight junction is a zone of close apposition between the lateral membranes of adjacent cells. By freeze fracture, the strands represent membrane fusion sites within the tight junction zone. Members of the claudin family of transmembrane proteins form the strands.

The cytoplasmic face of tight junctions contains a large number of proteins that fall into different functional categories. Some link the barrier-forming proteins to the actin cytoskeleton, others play a role in creating cell polarity, some form a specialized zone for vesicle targeting, and still others influence gene transcription (see Table 8-1). Many reviews of this complex structure are available. [24], [25] Of special interest is the direct physical link of the claudins to the perijunctional ring of actin and myosin through a PDZ protein called ZO-1, [26] which may play a role in cytoplasmic control of the paracellular barrier. The tight junction barrier is dynamic, and there are many other intracellular and extracellular signals that regulate barrier function under physiological and pathological conditions. [24], [27]

The squamous epithelium of the esophagus is somewhat peculiar. Unlike other alimentary epithelia, the epithelium lining the esophagus is multilayered (i.e., stratified). Data suggest that most layers are relatively devoid of tight junctions, and, where tight junctions do exist, they are discontinuous rather than circumferential. The intercellular barrier appears to be created by secreting sheets of a lipidlike material. [28]

Directly below the tight junction lies a zone, the adherens (or intermediate) junction, in which the lateral membranes of adjacent cells lie parallel to each other and adhere by means of E-cadherin–based interactions (see Fig. 8-2). At this site, the previously mentioned perijunctional contractile ring of actin and myosin resides and attaches to E-cadherin through a-actinin, vinculin, and a- and ß-catenin. [9] Directly below the adherens junctions are desmosomes (see Fig. 8-2 and Table 8-1). Distant relatives of the cadherin family, called *desmogleins* and *desmocollins,* form cell contacts at desmosomes. [29] In contrast to E-cadherin, these transmembrane glycoproteins have evolved different cytoplasmic sequences allowing them to associate with intermediate filaments rather than with actin microfilaments. Consequently, they anchor the cytokeratin-based cytoskeleton between neighboring cells and provide resistance to mechanical shear.

To varying degrees, all epithelial cells of the gastrointestinal tract express gap junctions. Here, the cytoplasm of adjacent cells is in physical continuity through transmembrane channels formed by members of the connexin protein family. Six connexins assemble on each membrane to form a channel and, by adhering across the paracellular space, create a lumen isolated from the extracellular space. Signaling molecules up to about 1500 d (e.g., Ca^{++}, inositol triphosphate) and small nucleotides can diffuse freely between cells and coordinate physiological responses. [30] There are numerous connexin genes in humans, and each shows organ-specific diversity and allows for organ-specific regulation of communication. Gap junctions coordinate epithelial function by allowing sheets of cells to behave as syncytia, for example, coordinating exocytosis of zymogen granules from the pancreas. [13] Gap junction communication in the liver, working through intracellular Ca^{++} waves, modifies bile secretion in response to glucagon and vasopressin. [31] Gap junctions are down-regulated in gastrointestinal cancer, probably reflecting the indifference to extracellular control that is characteristic of the undifferentiated phenotype. [32]

Basement Membranes

The basement membrane was introduced previously as a source of signals for inducing epithelial cell polarity. It also serves an important structural and supportive role. All alimentary epithelia reside on a basement membrane that measures 20 to 40 nm deep; consists of a faintly fibrillar network; and rests on an underlying, complex extracellular matrix. Although the basement membrane in the alimentary tract is incompletely characterized, it appears to be similar to basement membranes found elsewhere. [33] The major elements of the basement membrane include laminin, heparan sulfate proteoglycan, and type IV collagen; minor but possibly important constituents such as thrombospondin and entactin also exist.

Laminin, a 850-kd glycoprotein, consists of an assembly of three chains: a straight A chain and two B chains, which helically wrap a portion of the A chain and flare off at an acute angle. This arrangement imparts a cross shape on rotary-shadowed images of this molecule. Laminin exhibits specific binding sites for type IV collagen, heparan sulfate proteoglycan, cell surface laminin receptors, and entactin. [33] In similar fashion, many matrix components display binding sites for several additional components, thus adding to the complexity of interactions between the epithelial cell and its surrounding environment.

The major proteoglycan of the basement membane is heparan sulfate proteoglycan. Proteoglycans consist of long chains of glycosaminoglycans (e.g., heparan sulfate glycosaminoglycans) linked to a protein core. The structure of these massive molecules (i.e., molecular weight in excess of 10^{6}) is often likened to a test-tube brush, with the bristles representing the glycosaminoglycan extension. Proteoglycans probably organize water within the basement membrane. They hydrate this environment through their capacity to bind water, and they may be able to impart solute-sieving characteristics under conditions of bulk water flow.

Type IV collagen originates as a triple-stranded helical molecule, which, unlike other collagens, does not have its propeptides sheared from it after deposition in the extracellular space. Partially as a result of this, collagen IV does not cross-link into dense fibrils, as many other collagen species do; instead, it assumes a loose, netlike structure by associating with other collagen IV molecules. This meshlike structure of collagen IV may provide the basic structure to the basement membrane.

In addition to the specific components of the basement membrane mentioned previously, other key elements are present in the remainder of the extracellular matrix. For example, the adhesive glycoprotein fibronectin exists in soluble plasma and cell surface forms, and it is found in a highly insoluble fibrillar form in the extracellular matrix. Fibronectin has binding sites for heparan sulfate proteoglycan, collagens, and epithelial cell surface receptors and serves as one link between the cell surface and the matrix underlying the basement membrane.

Basement membrane components can exert significant effects on epithelia, including effects on proliferation, adhesion, migration, differentiation, and perhaps even barrier function. [33], [34] In the intestine, type IV collagen is produced primarily by mesenchymal components, heparan sulfate proteoglycan by epithelial cells, and laminin by mesenchymal and epithelial cells. Many components of basement membranes have multiple binding sites. For example, laminin can bind type IV collagen and heparan sulfate proteoglycan, but it also has a cell binding site.

Basement membrane components bind to a family of epithelial cell surface molecules called *integrins,* which bind to the actin cytoskeleton within the cell by way of linking proteins. Through such associations, structural elements within the cell are able to connect with, and potentially be influenced by, events occurring within the basement membrane and even deeper in the extracellular matrix.

EPITHELIAL BARRIERS

This section addresses the question of how intralumenal threats are restricted to the lumen by the epithelial barrier (Fig. 8-5). At various sites in the alimentary tract reside such threats as H^{+}, chemotactic peptides, undigested potentially antigenic proteins, and bacteria. It is not surprising that the epithelial barrier consists of numerous components; some are site specific and some are universal. To discuss these barriers, we arbitrarily divide them into two major categories: those that are extrinsic to the epithelium (although in some instances produced by the epithelium) and those provided by the physical presence of the epithelium, which we arbitrarily categorize as intrinsic barriers.

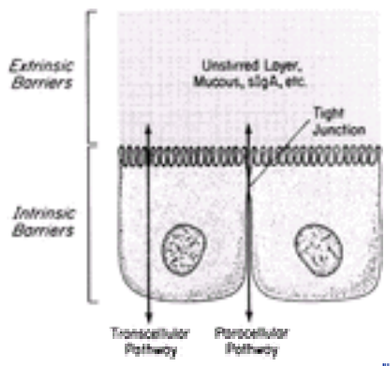

FIGURE 8-5. Gut epithelial barriers.

Extrinsic Barriers

Extrinsic barriers confront the microenvironment overlying the epithelia.

Mucus All alimentary epithelia are coated with a layer of mucus, which protects against bacteria and surface shear. Most surfaces, including those of the stomach, the intestine, the biliary and pancreatic ducts, and the gallbladder, contain specialized cell types that synthesize, package, and secrete mucin. In the esophagus, however, mucin is derived primarily from small glands that lie under the epithelium and connect to the lumen by way of delicate ducts. Although the precise chemical nature of mucus varies throughout the alimentary tract, the various mucin molecules share common features. They are viscous, polydispersed glycoproteins (250–20,000 kd) composed of about 80% carbohydrate by mass. At least eight human mucin-producing genes (*MUC* genes) have been identified. *MUC2* is the predominant form in intestinal and colonic surfaces; [35] its level is altered in inflammatory bowel disease and cancer. Mucin can act as a barrier by behaving as a viscous hydrated gel that undoubtedly attenuates shear forces that the epithelium otherwise would experience from particulates; these are driven down the alimentary tract by propulsive force. In addition, carbohydrate groups on the mucin molecules have the potential for binding to bacterial surfaces and inhibiting surface colonization. In some instances, mucin carbohydrates specifically replicate epithelial carbohydrate binding sites to which bacteria can attach, presumably preventing colonization in a more specific fashion. Given their extensive glycosylation, mucins can cross-link several bacteria and therefore serve to aggregate bacteria. Such aggregation presumably aids in bacterial clearance by intestinal propulsive activity. The protective effects of mucin are highlighted further by the finding that exposure of epithelial surfaces to threats such as bacterial toxins and noxious chemicals often results in a reflexive secretory release of mucins. The expression of mucin genes in goblet cells and mucin secretion respond to intestinal microbes and host-derived inflammatory mediators [36] and are altered by infections, such as *Helicobacter pylori* in the stomach. [37] It has been observed that the diffusion coefficients of hydrophilic molecules are substantially lower in mucin than in free solution. Some researchers have suggested that this alteration would diminish contact between the epithelial surface and lumenal threats such as H^+. Given the depth of the mucin layer and the duration that lumenal contents are in contact with the epithelium, however, small lumenal molecules probably have sufficient time to equilibrate within the mucous gel.

Unstirred Layer Because of the propulsive movements of the alimentary tract, the lumen can be rather turbulent. A body of evidence suggests that this turbulence or convective force does not extend to the epithelial surface. [38] The view is that the apical microenvironment of epithelial cells is still (i.e., unstirred); moving toward the lumen, however, greater degrees of convection are achieved. Estimates of the depth of the unstirred layer range from 300 to 800 µm. The physiological significance of this layer has not been fully determined. [39] Consideration of the unstirred layer is important to investigators bent on achieving accurate kinetic data for epithelial transport systems; if surface convection is absent, transport must depend on the diffusive movement of molecules toward the epithelial surface. If uptake of the molecule by the epithelial transport system is faster than the diffusion to the epithelial surface, however, the concentration of the molecule at the epithelial surface will not be equivalent to the concentration of the molecule in the center of the lumen. To measure the kinetics of uptake of various molecules by epithelial cells, this confounding issue of unstirred layers must be confronted. Such considerations are particularly important when evaluating uptake of molecules such as lipids; these have permeability coefficients that are several orders of magnitude less in water than across lipid membranes. These considerations led to the unproven and perhaps erroneous conclusion that the unstirred layer plays a substantial role in physiological barrier function. First, as with mucus, the exposure of lumenal content to the epithelial surface often is long enough to permit substantial diffusive equilibration. Second, in absorptive epithelia, net inward water flow normally occurs after initiation of absorption, and this would establish inward convective movement at the epithelial surface. Third, experimental measurements of unstirred layers may be artifactual overestimates when they are determined in anesthetized animals. [40] For example, in the conscious rat, the unstirred layer of the small intestine is 100 µm or less, but this value increases dramatically with anesthesia, either alone or with laparotomy, to 200 and 600 µm, respectively. Although consideration of unstirred layers continues to be important to the investigator studying transport kinetics, it is less certain that this phenomenon contributes substantially to epithelial barrier function.

Secretory IgA The epithelial surfaces in the alimentary tract for the most part are bathed by secretory IgA. Secretory IgA is produced as a dimer in the subepithelial space by plasma cells, transported by transcytosis across epithelial cells by he poly-Ig receptor, and released into the lumen as a consequence of proteolytic clipping of the receptor as it reaches the apical membrane. Secretory IgA, by binding to lumenal threats such as pathogenic bacteria or important antigens such as cholera toxin, acts as a barrier to antigens. Although of extreme importance in host defense, this barrier is highly specific and dependent on antigenic sensitization. Secretory IgA binding to the surfaces of pathogens may not only impede pathogen-epithelial interactions over most of the epithelial surface, but may also actually enhance pathogen-epithelial interactions at selected sites such as the M cells, a cell type responsible for the afferent limb of intestinal immunity. [41]

Secreted HCO_3^- All the extrinsic barriers previously discussed exist throughout the alimentary tract; however, other extrinsic barriers have regional variation. A case in point is the net bicarbonate (HCO_3^-) secretion by epithelial surfaces that interface with acidic lumenal compartments: the stomach and the duodenum. Several microelectrode studies have shown that, whereas the pH of the gastric lumen may be 2 to 3, the pH at the surface of epithelial cells is at or near 7. [39] Initially, retarded diffusion of H^+ because of mucus and unstirred layers was thought to be the basis of this observation. As discussed, however, such explanations were inadequate given the time over which diffusive equilibration of H^+ within such barriers could occur. It has since been recognized that gastric surface foveolar cells and duodenal villus absorptive cells secrete HCO_3^- across the apical membrane and potentially assist in creating a microenvironment of neutral pH. This secretory process is an example of a highly specific and regionally localized extrinsic epithelial barrier.

Hydrophobic Layer If a researcher takes an epithelial surface such as that of the stomach or small intestine, blots the surface with absorbent material, places a drop of water on it, and carefully measures the angle at which the drop of water intersects the surface, a reasonable estimate of surface hydrophobicity can be obtained. [42] This highly imaginative yet beautifully simple approach has been used by investigators to demonstrate that at least some alimentary epithelial surfaces are coated with a hydrophobic barrier extrinsic to the epithelial cells. For example, a perfectly wetted surface would have a contact angle for water of 0°, and an extremely nonwetable surface would have a contact angle of 108°. Because the contact angle for aqueous solution on mammalian gastric mucosa is about 80°, it has been concluded that this is a nonwetable, hydrophobic surface. A hydrophobic layer provides a physical barrier to ions in aqueous solution. Questions remain about the chemical nature of hydrophobic barriers and the extent to which they are induced by the methods used to demonstrate them. Acceptance of this potentially important barrier and its distribution throughout the alimentary tract must await further developments in the field.

Antimicrobial Peptides Gut epithelial cells produce and secrete peptides with antimicrobial functions. Several classes of peptides have been isolated from humans, including members of the defensin, cathelicidin, and histatin families. Paneth cells at the base of the crypts in the small intestine and ascending colon produce several defensin peptides, termed cryptdins. [43] There are more than 20 defensins, and they are released specifically in response to bacteria, and not fungi or parasites. Some defensins not only exert direct antibacterial activity but also orchestrate a protective host response by signaling to immune cells and by stimulating apical Cl^- and water secretion to flush the lumen. [44] Paneth cells also release certain enzymes with antimicrobial activity, including lysozyme and type II phospholipase A_2.

Intrinsic Barriers

Extrinsic barriers differ in their relative contribution to different regions of the gastrointestinal tract. In contrast, the universal intrinsic barrier in all tissues is formed by the continuous sheet of epithelial cells that creates a separation of lumenal compounds from the subepithelial fluids.

Classically, discussions of the barrier function of epithelia consider the two pathways available to passive permeation: the transcellular pathway and the paracellular pathway (see Fig. 8-5). The exact physical site where solutes cross the epithelial cell layer was a topic of considerable controversy beginning in the mid 1800s. It seemed implausible that charged ions could traverse a lipid surface, until it was recognized in the 1960s that proteins insert into and form channels across the bilayer. Likewise, the paracellular space was thought to be impermeable and unregulated; a misconception perpetuated well into the 20th century owing to the static

appearance of intercellular contacts seen in early electron micrographs (note the use of the inappropriate term “tight” junction). Eventually, our present understanding of the transcellular and paracellular pathways emerged, along with appreciation that both are physiologically regulated and vary widely in different tissues. [45] We follow this division in our discussion of passive transepithelial movement of hydrophilic solutes. The principles guiding the movement of water and hydrophobic molecules across the epithelium are distinct from those governing the movement of hydrophilic molecules, however. Hydrophobic compounds can cross epithelial cells directly by virtue of their solubility in the lipid bilayer of the plasma membrane. Physiologically, the most important transepithelial movement of hydrophobic compounds occurs during fat absorption (see Chap. 18). Water permeation is complex and is reviewed separately.

Transcellular Pathway The transcellular pathway is highly restrictive to passive flow of hydrophilic solutes. To diffuse passively across a cell, an ion or other hydrophilic solute must interact with three barriers in series: the apical membrane, the cytosol, and the basolateral membrane (see Fig. 8-5). The lipid bilayers of the apical and basolateral membranes severely restrict permeation of hydrophilic solutes and tend to preserve transmembrane electrochemical gradients. For example, the resistance to passive ion flow across model lipid bilayers ranges from 10^{6} to 10^{9} Ohm·cm^{2}. [46] Similarly, as determined in osmotic experiments using such model membranes, the reflection coefficients for NaCl, glucose, and sucrose approximate 1 (i.e., low permeability). [46] Biologic membranes (i.e., lipid bilayers plus integral membrane proteins) also have resistances that restrict passive ion flow, usually in the range of 10^{3} to 10^{4} Ohm·cm^{2}. Such resistance is substantial considering that intact alimentary epithelia range in resistance from about 5×10^{1} to 5×10^{3} Ohm·cm^{2} (Table 8-2).

SITE	Ohm·cm^2

TABLE 8-2 Examples of Transepithelial Electrical Resistance Along the Alimentary Tract of Mammals

The ability of a lipid membrane to retard passive flow of hydrophilic solutes allows epithelial cells to maintain cytosolic ion concentrations far different from those in the interstitial space (e.g., Na^{+} < 40 mmol/L, K^{+} > 100 mmol/L, Ca^{2+} in the nanomolar range). As indicated by these data and as would seem ideal, the major component of ion movement across biologic membranes appears to be mediated by integral membrane proteins such as transporters, pumps, and channels (see Chap. 14). In the absence of specific transport pathways, intact biologic membranes can be considered virtually impermeable to hydrophilic solutes 0.5 nm or larger. In contrast to hydrophilic solutes, hydrophobic molecules readily permeate the lipid bilayer. For example, saturated fatty acids are calculated to exhibit astounding permeability coefficients across jejunal epithelial cell microvillus membranes: 10^{6} to 10^{7} cm/s compared with 10^{-5} to 10^{-6}cm/s in aqueous solution. The remaining barrier, other than the two plasma membranes, to restrict transcellular passive permeation is the cytosol. Because the cytosol has the characteristics of a hydrated gel, the resistance afforded by this cellular compartment is likely to be only marginally greater than that of free solution. It is possible to conclude that plasma membranes are the key barriers that restrict the passive movement of hydrophilic solutes across cells. In the 1960s, the observation that various small hydrophilic solutes could passively leak across gut epithelia led to the conclusion that small transepithelial pores were scattered through this epithelium. It was mistakenly assumed, however, that molecules could not permeate intercellular junctions, and the language used to describe the location of these pores in the early literature incorrectly implies that the pores are transcellular.

Paracellular Pathway The paracellular pathway is a major pathway for passive solute permeation. Although plasma membranes tend toward high resistance, alimentary epithelia, with the exception of the esophageal epithelium, have low net resistance (50–100 Ohm·cm^{2}), meaning they are relatively leaky (see Table 8-2). It follows that the remaining pathway, the paracellular pathway, must be largely responsible for such leaks in these epithelia. [47] The paracellular pathway consists of the apical intercellular tight junction and the underlying paracellular space. Under most conditions, tight junctions are the rate-limiting barrier restricting passive movement of hydrophilic solutes through the paracellular space. However, collapse of the subjunctional paracellular space may contribute to paracellular resistance in leaky epithelia, such as occurs in the gallbladder and small intestine. In the resting physiological state, tight junctions may leak small quantities of molecules the size of monosaccharides and disaccharides (i.e., fluxes on the order of 10^{-2}–10^{-4} mol/L · cm^{-2} · h^{-1}), or up to a physical cutoff of about 15Å in hydrodynamic radius. Such leakiness is physiologically regulated and, under some conditions, greatly increased. [27] As noted, the electrical resistance and even ion selectivity of tight junctions vary throughout the gastrointestinal tract. After the highly selective properties of transcellular transport have generated specific ion and solute gradients, the net composition on either side can be modified further by selective back-diffusion through the tight junction. Transcellular gradients in the leaky epithelia of the gallbladder, liver, and small intestine are quickly dissipated by paracellular movement of water and counter ions, and this explains the isosmotic nature of secretions in these tissues. In contrast, in tighter epithelia such as in the colon, tight junctions can maintain the ion gradients required for net movement of water out of the lumen. The selective and variable properties of tight junctions appear to be based on the differential expression of a family of transmembrane proteins called *claudins.* There are at least 20 members of this barrier-forming protein family in humans. Of the few that have been studied, each has a unique distribution within gastrointestinal epithelia, [48] for example, showing gradients along the crypt-villus axis or along the hepatic lobule. When expressed in cultured epithelial models, some claudins induce an increase and others a decrease in paracellular electrical resistance, and one claudin (claudin-4) has been shown to decrease the permeability of Na^{+} relative to Cl^{-}. [49] The expression of claudin-1 has been shown in cultured intestinal epithelial cells to be regulated by proinflammatory cytokines. [50] Human mutations in two nonintestinal claudins lead to epithelial diseases. Together, these early studies suggest there will soon be major insights into the molecular basis for defining and regulating paracellular transport in normal tissues and in disease.

Water Movement Across the Epithelial Barrier

Despite the obvious importance of fluid transport across gastrointestinal epithelia, controversy remains about the relative importance of the transcellular versus paracellular routes. One route for transcellular water movement is through transmembrane channels created by members of the aquaporin (AQP) protein family. These small (30-kd) integral membrane proteins are well studied in tissues specialized for regulated water transport, such as the collecting duct of the kidney. However, their relative contribution to the large movements of water in the gastrointestinal tract remains unresolved. At present, seven AQP water channel proteins have been described in gastrointestinal epithelia, including AQP1 in intrahepatic cholangiocytes, AQP3 and AQP4 in colonic surface epithelium, AQP4 in gastric parietal cells, AQP5 in salivary gland, AQP7 in small intestine, AQP8 in liver, pancreas, and colon, and AQP9 in liver. Indirect evidence for a role in water transport comes from the phenotype of mice with genetic deletions of AQP1 and AQP4 that show defects in dietary fat processing and colonic fluid absorption, respectively. [51]

A second route for transcellular water movement is across the lipid membranes. Movement of water is much less restricted than movement of hydrophilic solutes. [46] For example, the water diffusional permeability coefficient of model lipid bilayers is in the range of 2×10^{-5} to 2×10^{-2} per second, depending on the details of membrane composition. This range is the approximate range of water permeabilities in biologic membranes. How water permeates a biologic membrane in the absence of a specific channel is uncertain; however, given the equality of the diffusional and osmotic permeability coefficients for water moving across lipid bilayers, it appears that water movement occurs as independent diffusional movement of individual molecules rather than as cooperative laminar flow. One picture that emerges from such studies and that satisfies many of the observed features of water movement across membranes is that water diffuses across the nonpolar portion of the outer membrane leaflet, dissolves in the central polar portion of the membrane in proportion to its molar fraction in the outer aqueous phase, and moves by diffusion across the inner leaflet, assuming an inwardly directed gradient favoring water movement.

Because hydrophilic solutes the size of water can permeate tight junctions, water movement can occur across epithelia by the paracellular route. Although there is agreement that water crosses by the transcellular and paracellular routes, the relative partitioning of water flow between these two pathways is controversial. It has been estimated that about 50% of the water absorption that occurs during stimulated intestinal absorption is paracellular. [52] Data from other epithelia show that interepithelial differences in hydraulic conductivity, a measure of force-induced water flow, correlate reasonably well with paracellular resistance. Similarly, correlations between hydraulic water permeability (determined at hydrostatic pressures that do not move water transcellularly: 24.4 cm H_2O) and transepithelial voltage gradients, an indirect measure of junctional permeability, correlate inversely and well over a wide variety of epithelia. [53]

In aggregate, these observations suggest that the paracellular pathway is a major route for water flow across epithelia when such flow is driven by hydrostatic or osmotic pressures. In other specialized epithelia, such as that of the urinary bladder, most water uptake appears to be transcellular, through aquaporins, not paracellular. A basic consideration in such experiments is whether diffusional or convective movement is being measured. This issue is crucial because diffusional water movement varies with the square of the pore radius (r^{2}), and convective or force-associated water movement varies with the fourth power of the pore radius (r^{4}) as predicted by the Kedem-Katchalsky equation. [54] Although paracellular pathways may contribute little to diffusional water movement, they are important in convective water flow. Moreover, convective water flow secondary to osmotic pressures generated by nutrient or ion transport or by countercurrent vascular flow in the lamina propria is probably the more physiologically significant type of transepithelial water movement in the alimentary tract. Despite the characterization of

aquaporins and tight junction proteins, the basic issue of the route of water flow across gut epithelia remains surprisingly open.

EPITHELIAL HOMEOSTASIS AND RESPONSES TO DISEASE AND INJURY

Inductive Effects of Commensal Bacteria

Bacteria normally colonize the entire human gastrointestinal tract, with the highest concentration and number of species (>400) in the colon. [55], [56] Destructive interactions occur between the epithelium and numerous well characterized pathogenic species such as *Salmonella, Shigella,* and *Clostridium difficile* (see Chap. 88). In contrast, normal function of the gut actually is highly dependent on the resident commensal bacteria species. Such probiotic effects take several forms, including competing with pathogens for attachment to the epithelial surface, release of antimicrobial compounds, or synthesis of fatty acid metabolites that are toxic to the pathogenic species. Studies in germ-free mice demonstrate that normal development of immune cell lineages in the bone marrow and the lamina propria and local humoral defense depend on the presence of the commensal bacteria in the gut. [57], [58] Inductive effects on epithelial cell gene transcription have also been observed. For example, introducing a commensal *Bacteroides* species in germ-free mice extensively alters the transcription profile toward gene products that enhance nutrient uptake and metabolism. [59]

Although the molecular mechanisms remain poorly understood, reports of the probiotic effects of commensal bacteria appear in the clinical literature. For example, administration of *Lactobacillus acidophilus* reduces diarrhea in patients undergoing pelvic radiotherapy, possibly by reducing radiation damage or accelerating healing of the intestinal epithelium. [60] Similarly, ingestion of a mixture of commensal anaerobes prevents recurrent epithelial infections typically observed in patients with ileal pouch–anal anastomosis for ulcerative colitis. [61] The probiotic and pathogenic effects of bacteria on the intestinal epithelium are reviewed in detail in Chapter 25, Chapter 74, and Chapter 88.

Forms of Epithelial Injury Without Enhanced Permeation of Epithelial Monolayers

Epithelial injury is most readily apparent when gaps within the epithelium such as erosions or ulcerations are present; however, because the gut has remarkable ability for repair, there exist numerous forms of injury that do not result in a functionally significant defect. Futhermore, the life span of individual epithelial cells is influenced by physiological events, such as exposure to pancreatic proteases. Thus, one should view epithelial injury as spanning a spectrum that includes normal physiological challenges.

Gut epithelial turnover occurs, on average, once each week by a process of proliferation, migration, apoptosis, and sloughing. For example, gastric surface cells arise from the proliferative zone called the *gastric pit,* migrate to the surface as they become differentiated foveolar cells, and ultimately slough into the lumen. By removing physiological agents from the lumen, the half-life of epithelial cells often can be lengthened. Integral membrane proteins of the cell surface also turn over, displaying half-lives shorter than those of epithelial cells; however, a protein-depleted cell surface does not ultimately result, because these lost or damaged components are replaced constantly by individual epithelial cells. Undoubtedly, turnover of lipids in the membrane also occurs, but documentation is difficult because of the proclivity of membrane lipids to exchange side chains under the influence of membrane phospholipases. Components of individual epithelial cells turn over at rates that can be altered by normal physiological events, and these events also can modulate the life span of the cell. Thus, in its most subtle form, epithelial injury could be viewed as alteration in surface (or cytoplasmic) constituents without change in actual cell number.

A dramatic type of physiological gastrointestinal epithelial injury, limited to the membrane, has been documented. [62], [63] Because of the physical trauma accompanying events such as gut motility, the apical plasma membrane of epithelial cells can transiently break down. In such instances, macromolecular tracers present in the lumen leak into and label the cytoplasm of these cells. These tracers do not appear to leak across the basolateral membrane, and no evidence has been found to suggest that such sites may be foci of transepithelial macromolecular leaks. Because these labeled cells subsequently remain in the epithelium and retain normal appearances for 48 hours, it appears that such transient defects in apical membrane permeability are rapidly repaired. Experiments using cultured epithelial cells have similarly shown that, when scraped or trypsinized, plasma membranes can undergo a cycle of transient breakdown and rapid repair. Transient plasma membrane breakdown and subsequent rapid repair may be considered a second variety of physiological injury.

Subtle forms of epithelial injury also can lead to a diminished life span of individual absorptive cells. Because epithelial monolayers may extrude single damaged cells without loss of the epithelial barrier (even transiently), such events can occur while barrier function remains intact. [64] Dramatic remodeling of the intercellular junctions and extrusion of the apoptotic cell accomplish this without creating a break in the barrier. Such a mechanism is required, considering that about 10% of the proliferating cells in the intestinal crypt undergo apoptosis daily. [65]

Confluent Epithelium and Tight Junction Permeation

Diseases exist in which the epithelium remains confluent, but tight junction permeation is enhanced to inert solutes that are the size of disaccharides and larger. One example is celiac sprue. [66] At least some of the protein-losing gastropathies may fall into this category as well, and it has been suggested that patients with Crohn disease may exhibit a primary defect in tight junction permeability, [67] and that permeability increases before clinical manifestation of a flare in disease severity.

The suggestion that disease states could affect tight junction barrier function arose from various studies indicating that this crucial barrier is physiologically regulated. As described in Chapter 14, active transepithelial transport of nutrients such as glucose occurs across the villus absorptive cells. It appears that the presence of glucose within the lumen results in structural deformation of villus absorptive cell tight junctions and enhanced permeability of junctions to molecules the size of amino acids and glucose and perhaps to substantially larger molecules. The initial triggering event is activation of the Na^+-glucose cotransporter. Mild cytoplasmic alkalinization and subsequent activation of the Na^+/H^+-exchanger occur next. Activation of myosin light-chain kinase, phosphorylation of myosin light chain, and contraction of the perijunctional ring are downstream events. [68] The steps between apical and distal events in this pathway remain unknown. As active transcellular absorption of Na^+ and water proceeds, a transepithelial osmotic gradient of Na^+ and glucose is thought to develop, which drives water movement inward across the tight junction. Because such altered tight junctions have abnormally low reflection coefficients for nutrient-sized molecules, substantial paracellular nutrient uptake by way of solvent drag follows. Demonstration of glucose-induced absorption of undegradable octapeptides (e.g., D-amino acid–substituted) also suggests that this pathway can be used to deliver bulk quantities of stabilized bioactive peptides as oral pharmaceuticals.

If correct, this theory would explain why the intestine continues to absorb increasing amounts of nutrients from the lumen as lumenal nutrient concentrations rise far above the concentration at which the Na^+-glucose cotransporter is saturated. [69] Most important, this phenomenon highlights how transcellular active transport events can be intertwined intimately with paracellular barrier function and shows the plasticity that tight junction barrier function exhibits even in physiological states. In a variety of nonalimentary epithelia, classic intracellular mediators such as Ca^{2+}, cyclic adenosine monophosphate (cAMP), and protein kinase C and inflammatory mediators also can affect tight junction structure or permeability. [27] Such modulation of tight junction permeability may underlie the abnormal epithelial permeability encountered in diseased, confluent epithelia.

Modulation of Epithelia by Subepithelial Elements

Gut epithelial function may be modulated by a host of local factors derived from nonepithelial sources. Specific examples of such influences are provided in detail in chapters dealing with specific epithelia. In this chapter, the point is made that such events may occur throughout the alimentary tract in the physiological state and that subepithelial-epithelial interactions may be altered in states of enhanced epithelial permeation.

Before dealing with the effects of enhanced permeation on these subepithelial-epithelial interactions, the following are examples of such interactions in health. Alimentary epithelia rest on a structurally complex lamina propria, which, as shown in Figure 8-6, contains many candidate elements that could influence epithelial transport events or barrier function. Nerves, microvascular myofibroblasts, and a host of immune cells—including mast cells, macrophages, and lymphocytes—are within micrometers of epithelial cells. The factors derived from such elements may affect epithelial function profoundly. [70] Studies of these factors are performed largely by modulating one subepithelial component or by adding one agent known to be produced by subepithelial components to an in vitro epithelial sheet. Although data derived from these studies provide a framework for understanding how subepithelial elements influence epithelia, the net effects of orchestrated subepithelial events on epithelial function may not be understood clearly for some time.

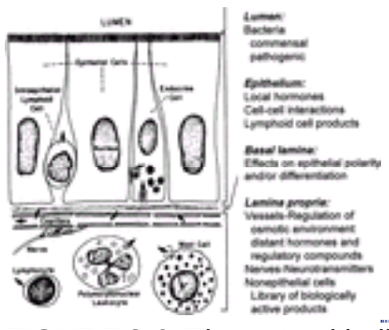

FIGURE 8-6. The gut epithelium is in proximity to lumenal, vascular, neural, and immune factors that substantially influence epithelial function.

Various examples of the dramatic influence of subepithelial signals on epithelial function now exist. For example, the lymphocyte-derived chemokine, interferon-?, induces cultured epithelial cells to down-regulate surface expression of various transporters and elicits surface expression of molecules with immune accessory function. [34] In nature, such cytokine-elicited *phenotype switch* of epithelia is undoubtedly complex, given the additive, negative, or synergistic interactions that can result from the concurrent presence of more than one cytokine.

Neurons of the enteric nervous system also produce a host of bioactive compounds, including peptides (e.g., vasoactive intestinal polypeptide, somatostatin, and cholecystokinin), catecholamines, and acetylcholine. [71] Moreover, termini from these nerves project to subepithelial positions, often within 1 µm of epithelial cells. The compounds produced by neurons influence epithelial functions ranging from acid secretion by gastric parietal cells to ion absorption by intestinal absorptive cells. Other examples of subepithelial influences on epithelial function include histamine, a product of mucosal mast cells, which produces a range of effects (e.g., induction of gastric acid secretion, intestinal Cl ¯ secretion) on alimentary epithelia. Mucosal mast cell activation in disease states in response to enhanced epithelial permeability must be considered another important modulator of epithelial function that may arise locally.

It is likely that enhanced epithelial permeation in disease states substantially modifies epithelial interactions with subepithelial elements and further modifies epithelial function. For example, polymorphonuclear leukocytes (PMNs) migrate across the gut epithelium and collect in gastric pits or intestinal crypts. Indeed, this histological event defines active inflammation in many alimentary inflammatory states. When crossing the epithelium, PMNs squeeze through intercellular tight junctions (Fig. 8-7), and they induce a reversible increase in per- meability. [72] Polarized interactions involving PMNs also can influence epithelial function differentially. For example, PMNs interacting with the apical membranes of cryptlike epithelial cells can elicit electrogenic Cl ¯ secretion as a result of paracrine release of 5'-AMP by PMNs, surface conversion of this signal by CD73 on the apical membrane of epithelial cells, and binding of the resulting adenosine signal to the apical A2b adenosine receptor.

FIGURE 8-7. In an in vitro model of gut epithelial acute inflammation, neutrophils squeeze through an intercellular tight junction and induce only a small increase in junctional permeability. Mediators released from cells of the immune system or other subepithelial cells, such as fibroblasts, also are likely to influence epithelial transport and barrier function, even without direct epithelial cell–immune cell contact, such as that seen here. (From Nash S, Stafford J, Madara JL. Effects of polymorphonuclear leukocyte transmigration on the barrier function of cultured intestinal epithelial monolayers. J Clin Invest 1987;80:1104, with permission.)

It is now clear that not only do subepithelial signals influence epithelial characteristics, but also epithelia can regulate subepithelial events. For example, in response to the detection of apical pathogens such as *Salmonella typhimurium,* epithelial cells release many cytokines that orchestrate transepithelial migration of PMNs. [73]

Healing of Epithelial Wounds

When epithelial proliferation no longer keeps up with accelerated epithelial loss resulting from injury, a defect in the epithelial barrier ensues. Erosions or ulcers develop that also destroy the underlying lamina propria and muscularis mucosae. To evaluate this situation in terms of the concepts reviewed in this chapter, such an injury may be viewed as a dramatic focal expansion of the paracellular pathway associated with loss of the rate-limiting barrier to paracellular flow: the intercellular tight junction. Thus, in open epithelial wounds, the surface area exposed to unrestricted permeation by noxious lumenal solutes in orders of magnitude is greater than if two viable cells are separated at the tight junction by 1 or 2 µm. Governed by Fick's first law of diffusional permeation (P_D), the rate of P_D directly relates to the surface area of the pore (wound), and this finding provides qualitative grounds for the intuitive realization that small breaks encompassing several cell widths expose subepithelial tissues to huge pulses of lumenal solutes. As a result, transepithelial leaks of paracellular tracer molecules, such as polyethylene glycol-400, can increase by more than 200% in patients with erosive intestinal disease, even though the eroded surface may represent a minute percentage of the net intestinal surface area. [67]

Once wounded, epithelia often respond by enhanced proliferation in an effort to replenish cells in the eroded area. An increased fraction of progenitor cells is stimulated to move through the S, G_2, and M phases of the cell cycle. Because the S phase of the cell cycle alone is 6 to 12 hours long, however, the benefit of this proliferative response is not recognized for many hours. Although the stimuli for enhanced proliferation in gut epithelia are not precisely known, various classic growth factors (e.g., epidermal growth factor) may participate in such responses (see Chap. 4 for a detailed description of peptide-elicited mucosal growth). Stimulated production of new epithelial cells requires a minimum of several hours to increase the rate of epithelial cell renewal. In the short term, reepithelialization of small wounds occurs by the remarkable process known as *restitution,* [34] characterized by the rapid spreading of epithelial cells shouldering the wound. By converting from a tall columnar to a spread and somewhat flattened phenotype, these cells produce a maximal footprint on the basement membrane and in so doing attenuate the diameter of the wound. Because an entire collar of cells spreads and surrounds the wound, the wound closes in the time frame of cytoskeletal motility events (i.e., minutes) rather than of cell cycle events (i.e., hours).

Signals involved in the stimulation of restitution are beginning to be understood. Several growth factors (e.g., epidermal growth factor, fibroblast growth factor, and hepatocyte growth factor) enhance restitution by increasing the number of motile, spreading epithelial cells. [34] Several such factors signal through a common transforming growth factor-ß1 (TGF-ß1)–dependent pathway. In fact, TGF-ß1 itself may be released from the epithelial cytoplasm in the process of injury. Other factors that promote healing by stimulating restitution (and perhaps replication) include peptides secreted by epithelia known as trefoil factors. Mice in which the gene encoding intestinal trefoil factor was disrupted experienced difficulty in healing injured mucosa. [74] These various factors use different mechanisms to promote

restitution. Some peptides may stimulate epithelial spreading and motility, and others may do so through a shared TGF-ß1–dependent pathway; still others (e.g., trefoil peptides) may promote the viscosity of the overlying mucous gel, thus potentially protecting the underlying restituting epithelia. [75]

The precise signal transduction pathways and targeted molecular events influenced by restitution-enhancing factors are not well understood currently but undoubtedly include cytoskeletal events and cell-matrix interactions. Roles for laminin isoform a6 and integrin laminin receptors a3ß1 and a6ß4 in the restitution of model intestinal epithelia have been defined. [76]

Nonmatrix elements in the lamina propria also may influence epithelial resealing after injury. In a model of focal intestinal epithelial denudation, restitution is aided by myofibroblast-mediated contraction of the lamina propria. This contractile event effectively diminishes the size of the defect to be reepithelialized.

During the early 1980s, a phenomenon called *cytoprotection* was popularized. Certain compounds (e.g., prostaglandins) that were in concentration too low to influence epithelial proliferation appeared to promote epithelial resealing of open wounds; however, cell injury in these early studies was judged largely by gross inspection of epithelial surfaces. Subsequent microscopic studies revealed that surface epithelial cells often were injured equally in control and cytoprotected mucosae. [77] A major difference between control and cytoprotected groups appeared to be vascular. Cytoprotection prevented extravasation of red blood cells from subepithelial vessels. It is also clear that cytoprotection reduced the depth of mucosal necrosis in some models, which ultimately may have clinical importance.

Integration of Barrier Function, Repair, and Epithelial-Immunological Cell Interactions

The defense of the mucosa against its harsh lumenal environment consists of the integration of the concepts and principles defined in this chapter. The epithelial barrier retards passive movement of molecules across it and is itself continuously repaired by rapid epithelial renewal, restitution, and other mechanisms. Moreover, resident intraepithelial lymphocytes and lamina propria lymphocytes and macrophages, along with the M cell and IgA secretory immune system, interface with this epithelial barrier.

The gut epithelial barrier, which restricts passive permeation, is complex and dynamic. Maintenance of this barrier in health depends on the integrity of cellular plasma membranes and tight junctions and the elaboration of epithelial secretory products such as HCO_3^-. Focal denudation of this barrier results in permeation by a host of threatening lumenal compounds, including antigens, proteases, H^+, and factors chemotactic for inflammatory cells. By initiating inflammation and acting on subepithelial tissues, such factors can further influence epithelial transport and barrier function. Repair of epithelial injury is also complex, and restitution and enhanced epithelial cell proliferation are likely to play major roles. Future studies should be directed toward examining the molecular mechanisms by which such barriers are maintained and repaired.

CHAPTER 9

Piero Biancani, Karen M. Harnett, and Jose Behar

ESOPHAGEAL MOTOR FUNCTION

The esophagus is responsible for transporting food from the mouth to the stomach and for preventing retrograde movement of esophageal or gastric contents, movement that may result in reflux of gastric secretions or regurgitation of food. It is a hollow tube closed at both ends by the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES). Its lumen is lined with squamous mucosa, containing longitudinally oriented muscle fibers and connected to the muscularis propria by a loose network of connective tissue fibers of the submucosa. The muscularis propria consists of an inner circular muscle layer with fibers oriented along the circumference of the tube and an outer longitudinal layer with fibers oriented along its axis.

The pharynx and proximal esophagus contain striated muscle controlled entirely by the swallowing center, located in the brainstem, through the vagus nerves. The control mechanisms for the lower two thirds of the esophagus, which contains smooth muscle, are quite different from the striated muscle portion. In the smooth muscle portion of the esophagus, peristalsis is controlled primarily by intrinsic neural networks located between the longitudinal and circular muscle layers (i.e., the Auerbach plexus) and in the submucosa (i.e., the Meissner plexus) and is only modulated by central mechanisms in the swallowing center. Myogenic factors, however, may also play a role in peristalsis.

Deglutition, which is the normal stimulus that initiates pharyngoesophageal motor activity and results in propulsion of the bolus from the pharynx to the stomach, is divided into buccopharyngeal and esophageal phases. Because of the high speed of contraction in the pharynx, deglutition has been studied by cinefluoroscopy, manometry, and combinations of both methods. The slower esophageal contractions have been studied mainly by manometry.

In humans and most mammals, the esophagus propels its contents in a caudad direction, but it behaves only as a passive conduit when orad transport occurs. Esophageal function is complicated by the fact that the airways and digestive tract cross in the pharynx, and their respective contents must be kept separate; this requires precise control and coordination of swallowing and respiration, controlled by the rich innervation of pharyngeal muscles.

Initiation of swallowing is voluntary, but continuation is mediated reflexly by sensory neurons with input to the swallowing center. In the buccopharyngeal phase, the bolus is gathered on the tongue in preparation for swallowing and is confined to the oral cavity by apposition of the soft palate to the posterior portion of the tongue. The voluntary portion of swallowing consists of closing the mouth and pressing the tip of the tongue against the palate while a progressive wave of contraction travels through the body of the tongue, which squeezes the bolus toward the pharynx. Then follows a series of involuntary events, consisting of transient suppression of respiration, during which the bolus slides to the base of the tongue and is pushed by the tongue toward the oropharynx, which is elevated and forced open. The posterior thrust of the tongue propels the bolus into the pharynx. The descending wave of pharyngeal peristalsis begins and continues through the open UES. A rapid series of events occurs in the pharynx: closure of the velopharyngeus to prevent reflux into the nose, closure of the larynx to prevent aspiration, pharyngeal peristalsis to clear the bolus out of the pharynx, and displacement of the larynx upward and forward to move out of the path of the bolus and to force open the cricopharyngeal region and the UES.

Relaxation of the UES occurs immediately, almost simultaneously with the initiation of swallowing, and has a brief duration. In the esophageal phase, the bolus is forcefully injected into the esophagus through the opened UES. A primary peristaltic wave is initiated in the pharynx and continues into the upper portion of the cervical esophagus. As the bolus enters into the body of the esophagus in upright subjects, it descends by gravity and is propelled by peristalsis. The relative contribution of gravity and peristalsis depends on bolus consistency. In the upright position, liquids travel faster by gravity than the peristaltic contraction that follows the swallow. Liquids travel fast enough to impact on the closed LES.

After the peristaltic wave reaches the liquid bolus, the LES is opened, and the bolus is pushed through the sphincter. Occasionally, small amounts of fluid may remain in the distal esophagus, behind the peristaltic wave, necessitating a second contraction unrelated to swallowing and triggered by local esophageal distention (i.e., secondary peristalsis), to clear the esophagus completely. Solid boluses are propelled by peristalsis even in the upright position, but their movement is helped by gravity. Progression of the bolus does not outstrip peristalsis; the bolus and the peristaltic wave move through the esophagus at the same speed. The bolus, propelled by the peristaltic contraction, forces the opening of the relaxed LES.

Because gastric contents are damaging to the esophageal squamous epithelium, esophageal function must be designed so one-way flow of nutrients occurs, preventing reflux, except for occasional events such as vomiting or belching. The presence of tonic contraction in the UES and LES prevents or minimizes gastroesophageal reflux or esophagopharyngeal regurgitation. If gastroesophageal reflux occurs, however, the refluxed material is cleared by secondary peristalsis triggered by localized distention of the esophagus.

INNERVATION

Esophageal peristalsis and sphincter function are controlled by the autonomic nervous system, with contributions from the parasympathetic, sympathetic, and enteric divisions.

Parasympathetic Nervous System

The central control of esophageal and LES function arises from preganglionic parasympathetic neurons originating in the dorsal vagal complex located in the dorsomedial hindbrain medulla [1], [2], [3] and [4] (Fig. 9-1). The dorsal vagal complex comprises two nuclei, the *nucleus tractus solitarius* (NTS), which receives the sensory input from the viscera, and the *dorsal motor nucleus of the vagus* (DMV), which contains the preganglionic motor output to the viscera. [5] The NTS comprises subdivisions that include the central (NTScen), intermediate (NTSint), and interstitial (NTSis) subnuclei.

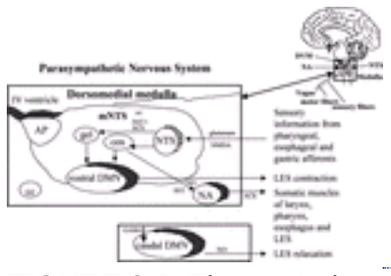

FIGURE 9-1. The central control of esophageal and lower esophageal sphincter (*LES*) function arises from preganglionic parasympathetic neurons originating in the dorsal vagal complex located in the dorsomedial hindbrain medulla (*upper right corner*). A summary diagram of the dorsomedial medulla oblongata is shown on the *left.* The dorsal vagal complex comprises two nuclei: the nucleus tractus solitarius (*NTS*), which receives the sensory input from the viscera, and the dorsal motor nucleus of the vagus (*DMV*), which contains the preganglionic motor output to the viscera. The neurocircuitry controlling swallowing begins with sensory afferents from the esophagus projecting to the NTS and terminating on premotor neurons in the subnucleus centralis (*cen*). Cell bodies from the subnucleus centralis project directly to somatic motor neurons within the nucleus ambiguus (*NA*) that control the buccopharyngeal pattern generator for swallowing. This provides a direct transfer of information coming into the NTS from peripheral sensory endings in the esophagus to the motor neurons in the NA that innervate the muscles involved in deglutition. Relaxation of the LES is controlled by long-loop neural feedback involving the vagus nerve and the DMV. Excitatory and inhibitory control of LES pressure is mediated by vagal efferent neurons located in two distinct sites in the DMV. Excitatory neurons located in the rostral DMV produce LES contraction, and inhibitory neurons in the caudal DMV produce LES relaxation. The neurotransmitters involved in the vagal control of the LES include the neurotransmitters in the subnucleus centralis and medial subnuclei of the NTS (*mNTS*) that mediate afferent integration of swallowing and LES function and the neurotransmitters that control vagal efferent outflow from the DMV to the LES. L-Glutamate is a primary afferent neurotransmitter released in the NTS from esophageal afferents. Control of vagal preganglionic neurons may involve the inhibitory neurotransmitter ?-aminobutyric acid (*GABA*). Most preganglionic neurons in the DMV are cholinergic. Nitrergic neurons form a separate population from the cholinergic neurons in the DMV and peripherally released NO mediates LES and gastric relaxation. *ACh,* acetylcholine; *a1,* a1 adrenergic receptors; *AP,* area postrema; *cc,* central canal; gel, subnucleus gelatinosus; *NMDA, N*-methyl-D-aspartate; *NO,* nitric oxide; *5HT2,* serotonin; *SST,* somatostatin. (Adapted from ref. [59].)

Sensory neurons from the entire esophagus run in the vagus nerve. In the lower esophagus, they are also found in the splanchnic and thoracic sympathetic nerves. The cell bodies of the vagal fibers reside in the nodose ganglion, and those of the sympathetic fibers are found in the vertebral ganglion of the thoracolumbar region. Sensory neurons within the nodose ganglion contain the neurotransmitters glutamate, d-aminobutyric acid (GABA), catecholamines, serotonin, acetylcholine (ACh); and the neuropeptides substance P, vasoactive intestinal polypeptide (VIP), neurokinin A, calcitonin gene–related peptide (CGRP), galanin, enkephalin, somatostatin, cholecystokinin (CCK), neuropeptide Y, and nitric oxide (NO). [6], [7], [8], [9] and [10] These afferent fibers innervate the serosa (adventitia), the longitudinal and circular muscle, and the mucosa of the esophagus. Afferents innervating the muscle are sensitive to distention and chemicals, and afferents innervating the mucosa are sensitive to light touch, pH, and chemicals such as hypertonic saline, sodium hydroxide, serotonin, bradykinin, and prostaglandins. [11]

The DMV innervates the smooth muscle of the LES [12], [13] and stomach. [14], [15] The motor innervation of the striated muscle of the pharynx, esophagus, and LES includes somatic nerves with cell bodies located in the nucleus retrofacialis and the rostral portion of the nucleus ambiguus. These nerves end at the motor endplate of the striated muscle fibers. The transmitter released by these neurons is ACh, acting through nicotinic cholinergic receptors in the endplate of the striated muscle fibers. [16] The somatic motor nerves supplying the pharyngeal muscles, including the UES, accompany the vagus and branch out into the pharyngeal nerve at the level of the nodose ganglion. Most nerves supplying esophageal striated muscle originate from the vagus in the upper cervical region, but some also arise from the recurrent laryngeal nerve. All these somatic nerve fibers are unmyelinated in their terminal portions. [17], [18]

The neurocircuitry controlling swallowing begins with sensory afferents from the esophagus projecting to the NTS and terminating on premotor neurons in the NTScen [5], [19] (see Fig. 9-1). Cell bodies from the NTScen project directly to somatic motor neurons within the nucleus ambiguus [19] that control the buccopharyngeal pattern generator for swallowing, [20], [21] thereby providing a direct transfer of information coming into the NTS from peripheral sensory endings in the esophagus to the motor neurons in the nucleus ambiguus that innervate the muscles involved in deglutition. Sequential, peristaltic contraction of the esophagus is coordinated by the brainstem–pattern generator circuit involving the NTS and is modulated by vagal afferents. The swallowing central pattern generator is an interneuronal network of premotor neurons that organizes the sequential activity of the motor neurons active during swallowing. Two neuroanatomically distinct subnetworks of premotor neurons are involved in the buccopharyngeal and esophageal phases of swallowing. [19], [22], [23] and [24] Palatal, pharyngeal, and laryngeal afferents overlap and terminate in the NTSint and NTSis. [25] In contrast, esophageal afferents terminate in the NTScen and do not overlap in their distribution with palatal, pharyngeal, and laryngeal afferents. [25] Motor neurons projecting to the pharynx and larynx are located in the semicompact and loose formation of the nucleus ambiguus, and esophageal motor neurons reside in the compact formation of the nucleus ambiguus. Although distinct neuroanatomic circuits control the buccopharyngeal and esophageal phases of swallowing, neuropharmacological data suggest that a central mechanism coordinates the phases without peripheral feedback. [26], [27], [28] and [29] Using Barth PRV, an attenuated vaccine strain of swine a-herpesvirus, a subpopulation of esophageal premotor neurons were found to project to pharyngeal and buccopharyngeal premotor neurons in the NTSint and NTSis, providing a synaptic link within the NTS for the central coordination of the two deglutitive phases. [30], [31]

Esophageal peristaltic contraction depends on cholinergic (muscarinic) excitation and NO-mediated inhibition. [32] NO may be involved in the central reflex control of esophageal peristalsis. [33] NO synthase, the NO-producing enzyme, is present in premotor neurons of the NTScen that innervate esophageal motor neurons in the nucleus ambiguus. Nicotinamide adenine dinucleotide phosphate (NADPH)-diaphorase staining of both the somata and terminals of esophageal premotor neurons suggests that NO is involved in neurotransmission in the NTScen and at the site of synaptic contact between esophageal premotor neurons and motor neurons in the nucleus ambiguus. [34] In addition to NO, esophageal premotor neurons of the NTS are tonically inhibited by GABAergic neurons through GABA receptors. The expression of $GABA_{Aa1}$ mRNA subunit within esophageal premotor neurons of the NTS supports a $GABA_{Aa1}$ role for GABA in the brainstem circuit that controls esophageal peristalsis. [35]

Relaxation of the LES is controlled by *long-loop neural feedback* involving the vagus nerve. [5] The integration center of vagal control of LES relaxation is the DMV of the dorsal vagal complex. The vagal motor neurons innervating the LES are clustered within two distinct populations in the DMV, one rostral and one caudal to the obex. The *obex* is an anatomic landmark that marks the opening of the central canal into the fourth ventricle. Studies indicate that excitatory and inhibitory control of LES pressure may be mediated by vagal efferent neurons located in these two distinct sites in the DMV. Excitatory neurons arise from the area rostral to the obex, and inhibitory neurons are located caudal to the obex. [4] Stimulation of rostral neurons by microinjection of the excitatory neurotransmitter L-glutamic acid, increases LES pressure, whereas stimulation of caudal neurons decreases LES pressure. The axons of these efferent neurons are carried in the vagus nerves. The axons branch into the esophageal plexus surrounding the body of the esophagus and enter the esophagus at various levels. They travel within the esophageal body for some distance before synapsing on postganglionic neurons in the enteric esophageal plexuses. These data suggest that both peripheral ascending and central descending inputs related to esophageal function are integrated in the NTS, leading to activation of separate opulations of excitatory and inhibitory preganglionic neurons in the DMV. The contribution of vagal inhibitory and excitatory neurons modulates basal LES pressure, as well as the frequency, amplitude, and duration of spontaneous and swallow-induced LES relaxations. The demonstration of reduced gastric motility and tone after balloon distention of the rat thoracic esophagus supported this view. [36] Esophageal distention resulted in activation of neurons in the solitary tract, pars centralis, the recipient of esophageal afferent projections from the vagus nerve. Activation of the NTS by balloon distention resulted in excitation of lateral and caudal neurons in the DMV and inhibition of medial and rostral DMV neurons.

The neurotransmitters involved in the vagal control of the LES include the neurotransmitters in the NTScen and medial subnuclei of the NTS that mediate afferent integration of swallowing and LES function and the neurotransmitters that control vagal efferent outflow from the DMV to the LES. L-Glutamate (or a closely related substance) is a primary afferent neurotransmitter released in the NTS from esophageal afferents. [5], [37] Microinjection of L-glutamate or NMDA agonists into the NTScen induces swallowing, whereas NMDA antagonist injection inhibits the esophageal component of swallowing. [38], [39] Expression of NMDA receptors within the brainstem circuit that controls esophageal swallowing has been reported. [40] These data suggest that excitatory amino acid release in the NTS in response to gastric distention or pharyngeal stimulation may induce swallowing. Pharyngeal and esophageal components of peristalsis can be stimulated by the microinjection of ACh, [20] serotonin agonists, [41] and a-adrenergic agonists [42] into the NTS. Binding sites for CCK (A and B subtypes) and dopamine (D_2 subtype) have been identified in the NTS. [43] Somatostatin and NO synthase are present in neurons projecting to the laryngeal and pharyngeal motor neurons of the nucleus ambiguus, suggesting that a relay between sensory information and the activation of swallowing is nitrergic [44] and somatostatinergic. [33]

Direct neurotransmitter control of vagal preganglionic neurons may involve the inhibitory neurotransmitter GABA (see Fig. 9-1). [5] Most preganglionic neurons in the

DMV are cholinergic (Fig. 9-2). In addition, catecholaminergic and nitrergic abdominal vagal preganglionic neurons exist in the DMV. The catecholamines are colocalized with ACh in the DMV neurons; however, it is unclear whether the catecholamines contribute to the central control of LES pressure. In contrast, nitrergic neurons form a separate population from the cholinergic neurons in the DMV, and peripherally released NO mediates LES [45], [46] and gastric relaxation. [47], [48], [49], [50], [51], [52] and [53] The nonadrenergic noncholinergic (NANC) inhibitory control of relaxation involves cholinergic preganglionic nerves that innervate NANC myenteric postganglionic neurons (see Fig. 9-2). In addition, NO synthase is present in preganglionic neurons in the DMV that innervate the gastrointestinal tract, [54], [55] and [56] providing a novel pathway in parallel to the more traditional view of vagal NANC inhibition. [5] NO synthase–containing preganglionic neurons are concentrated in two populations in the DMV, one caudal and the other rostral to the obex. Because L-glutamate stimulation of caudal DMV neurons causes LES relaxation, [4] it is possible that the nitrergic preganglionic neurons in the caudal DMV mediate LES relaxation. Hornby and Abrahams [5] reported that stimulation of nitrergic preganglionic vagal motor neurons produces gastric relaxation. Gastric relaxation was stimulated by microinjection of substance P into the nucleus raphes obscurus, a hindbrain nucleus with functional connections to the dorsal vagal complex. [57], [58] With this model, they showed that centrally evoked relaxation depends on simultaneous inhibition of cholinergic tone and activation of NO and VIP pathways. [59] These studies demonstrate a role of preganglionic vagal cholinergic tone and NO release in gastric relaxation. The mechanism for centrally mediated vagal cholinergic and NANC control of LES relaxation is unknown; however, the neurocircuitry for the control of intragastric and LES pressure may be similar because the LES relaxation associated with deglutition is combined with gastric adaptive relaxation to accommodate the bolus of food.

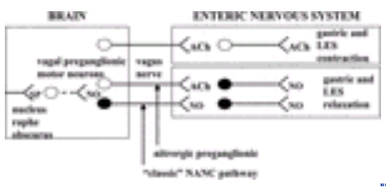

FIGURE 9-2. The “classic” nonadrenergic noncholinergic (*NANC*) inhibitory control of lower esophageal sphincter (*LES*) and gastric relaxation consists of cholinergic preganglionic nerves that innervate NANC myenteric postganglionic neurons. Nitric oxide (*NO*) synthase, however, also is present in preganglionic neurons in the DMV that innervate the gastrointestinal tract and provide a novel pathway in parallel to the more traditional view of vagal NANC inhibition. Microinjection of substance P (*SP*) into the nucleus raphes obscurus stimulates the dorsal vagal complex and produces vagally mediated gastric relaxation. *Solid lines* represent monosynaptic pathways; the *dashed line* represents polysynaptic pathways. (Adapted from ref. [5].)

Sympathetic Nervous System

The cells that give rise to the preganglionic sympathetic fibers innervating the pharynx, esophagus, and LES originate in the intermediolateral columns of the spinal cord (segments T1–T10) (Fig. 9-3), and their preganglionic fibers enter the cervical, thoracic, and possibly celiac ganglia. [60] Most preganglionic fibers pass through the greater splanchnic nerves, terminate in the celiac ganglia, and then synapse with postganglionic neurons. [3], [61] Most postganglionic axons originate in the celiac ganglia or reach the esophagus by way of perivascular fibers. Most postganglionic axons synapse in the myenteric or in the submucosal plexus, and few innervate the smooth muscle directly. [16], [61]

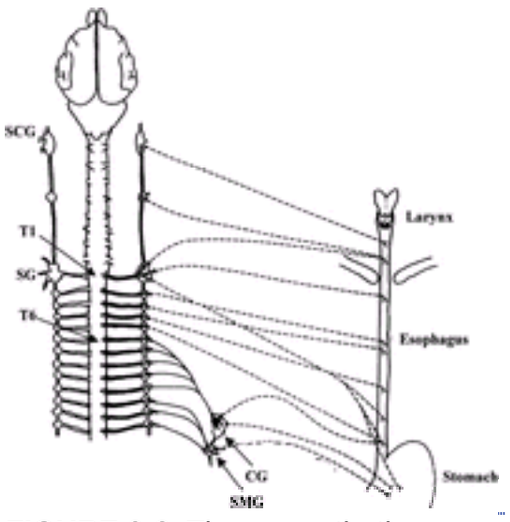

FIGURE 9-3. The sympathetic nervous system. The cells that give rise to the preganglionic sympathetic fibers innervating the pharynx, esophagus, and lower esophageal sphincter originate in the intermediolateral columns of the spinal cord (segments T1–T10). Their preganglionic fibers enter the cervical, thoracic, and celiac ganglia. Most preganglionic fibers pass through the greater splanchnic nerves and terminate in the celiac ganglia, where they synapse with postganglionic neurons. Most postganglionic axons originate in the celiac ganglia or reach the esophagus by way of perivascular fibers, and most postganglionic axons synapse in the myenteric or in the submucosal plexus. A few innervate the smooth muscle directly. *CG,* celiac ganglion; *SCG,* superior cervical ganglion; *SG,* stellate ganglion; *SMG,* superior mesenteric ganglion; *T1,* first thoracic spinal cord segment; *T6,* sixth thoracic spinal cord segment. (Adapted from ref. [60].)

Enteric Nervous System

The esophagus has a rich network of intrinsic neurons in the submucosa (i.e., the Meissner plexus) and between the circular and longitudinal muscle layers (i.e., the Auerbach plexus). The enteric neural network receives instruction from and sends signals to the central nervous system by way of the vagi, the adrenergic ganglia in the thoracic sympathetic chain, and the celiac ganglia. This network of enteric neurons is capable of producing secondary peristalsis in the smooth muscle portion even when the esophagus is separated from the central nervous system and is isolated in an organ bath. [62]

At the turn of the 20th century, Bayliss and Starling [63], [64] and [65] described descending relaxation in the intestine that persisted when the intestine was extrinsically denervated by resecting vagal and mesenteric fibers. Langley and Magnus [66] reported that this reflex was maintained in vitro in the absence of any extrinsic innervation. Based on this evidence, the intrinsic neurons were thought to constitute a separate enteric division of the autonomic nervous system. It has become apparent that this enteric network is composed of a variety of neural cells containing numerous neuropeptides that also are found in the brain. Peptides present in esophageal and LES neurons include the following: VIP; neuropeptide Y, which is often present in neurons containing VIP or catecholamines; CGRP; substance P, which is often present with enkephalins and galanin; and pituitary adenylate cyclase–activating peptide (PACAP), which is often present with VIP. [6], [7], [34], [67], [68], [69], [70], [71], [72], [73] and [74]

In addition to the neuropeptides, NO-releasing nerves regulate esophageal and LES smooth muscle function. [75] Stimulation of intrinsic esophageal nerves releases NO from the LES. [76] NO synthase colocalizes with such neuropeptides as VIP, CGRP, and galanin and rarely with neuropeptide Y and substance P, [77] a finding suggesting that the nerves responsible for peristalsis in the esophagus may act by releasing NO along with other inhibitory neuropeptides, such as CGRP, galanin, and VIP, but not excitatory substances, such as neuropeptide Y and substance P. [75], [77]

PHARYNX AND OROPHARYNX

Initiation of swallowing is voluntary, but its continuation is mediated reflexly by sensory neurons with input to the swallowing center located in the brainstem. The

tongue is the major participant in the oral phase. It contributes to the formation, containment, and propulsion of the bolus; it adapts to bolus size and creates a larger propulsive chamber with increasing bolus sizes. During deglutition, the tongue exhibits a pattern of surface motion suggesting a lingual propulsive activity that appears as a wave along the central groove of the tongue. Propulsion is accomplished with the tip of the tongue pressing against the palate, with its lateral aspects sealing against the alveolar ridges and pharyngeal walls, and with the central groove of the tongue exhibiting appropriate motions to push the bolus toward the pharynx. This process is followed by a transient suppression of respiration while the bolus slides over the base of the tongue into the pharynx. [78]

Pharyngeal Anatomy

The pharynx, connecting the nose and mouth on the proximal end to the esophagus and trachea on the distal end, is responsible for separating food and air as they pass through this area (Fig. 9-4). The necessary fine motor control is reflected by the complexity of this structure. An excellent representation of pharyngeal muscles and deglutition sequence is shown in the article by F. H. Netter, [79] found in the Ciba Collection of Medical Illustrations.

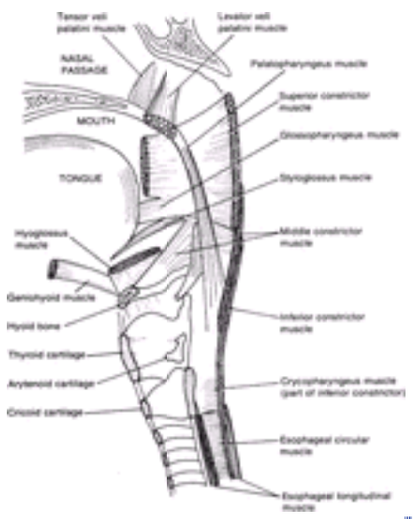

FIGURE 9-4. The pharynx, connecting the nose and mouth on the proximal end to the esophagus and trachea on the distal end, is responsible for separating food and air as they pass through this area. This process requires fine motor control and is reflected by the complexity of this structure. The pharynx consists of several distinct muscle groups, and in its lower portion, it is supported anteriorly by arytenoid, cuneiform, corniculate, and cricoid cartilages. Traditionally, the pharynx has been divided into the nasopharynx, the oropharynx, and the hypopharynx. The nasopharynx, extending from the base of the skull behind the soft palate to the distal edge of the soft palate, is not part of the alimentary tract. Muscles in the nasopharynx, such as the tensor veli palatini, levator veli palatini, and others, contribute to elevating the soft palate and closing the nasopharyngeal passage during swallowing, to prevent bolus entry into the nasal passage. The oropharynx extends from the soft palate above to the base of the tongue and the level of the hyoid bone below and contains the upper border of the epiglottis, called the valleculae. In this area, the respiratory and gastrointestinal tracts cross. Muscles in the oropharynx are responsible for bolus propulsion (e.g., middle constrictor) and for elevation (e.g., palatopharyngeus) and forward displacement (e.g., geniohyoid) of the pharynx. The hypopharynx extends from the valleculae at the base of the tongue to the lower border of the cricoid cartilage and contains the inferior constrictor muscle and the upper esophageal sphincter. (Adapted from ref. [79].)

The pharynx is a hollow cylinder, 12 to 14 cm long, extending from the base of the skull to the lower border of the cricoid cartilage and bordering posteriorly on the cervical spine. It consists of several muscle groups and in its lower portion is supported anteriorly by the arytenoid, cuneiform, corniculate, and cricoid cartilages.

Traditionally, the pharynx has been divided into three segments: nasopharynx, oropharynx, and hypopharynx. The nasopharynx extends from the base of the skull, behind the soft palate, to the distal edge of the soft palate and is not part of the alimentary tract; however, muscles located in the nasopharynx contribute to elevating the soft palate and closing the nasopharyngeal passage during swallowing, thus preventing bolus entry into the nasal passage. The mechanism of nasopharyngeal closure during belching and swallowing is different. During swallowing, nasopharyngeal closure consists of palatal elevation and adduction of the superior pharyngeal muscle, whereas during belching, only palatal elevation occurs. [80] The oropharynx extends from the soft palate above to the base of the tongue and the level of the hyoid bone below, and it contains the upper border of the epiglottis, called the *valleculae.* In this area, the respiratory and gastrointestinal tracts cross. The hypopharynx extends from the valleculae at the base of the tongue to the lower border of the cricoid cartilage and contains the UES.

The muscle groups participating in deglutition are those of the soft palate, pharyngeal isthmus, tongue, and hyoid bone—pharyngeal constrictors and muscles that elevate and displace the pharynx in a forward direction (Fig. 9-5). They may be classified as extrinsic muscles, which are responsible for altering the shape of the pharynx and closing the airways, and intrinsic muscles, which are responsible for collapsing the lumen of the pharynx and propelling the bolus.

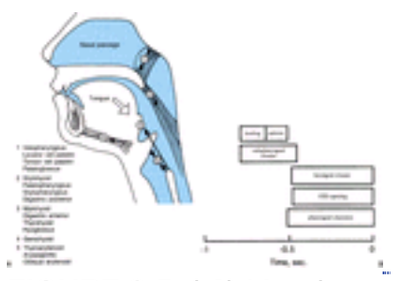

FIGURE 9-5. (**A**) Muscle groups participating in deglutition may be classified as extrinsic muscles, which are responsible for altering the shape of the pharynx and closing the airways, and intrinsic muscles, which are responsible for collapsing the lumen of the pharynx and propelling the bolus. The extrinsic muscles, including the levator veli palatini, tensor veli palatini, and palatoglossus, are located in the nasopharynx; they raise and tense the soft palate and uvula and close the nasal passage, to prevent pressure generated in the mouth from being dissipated through the nose. The stylohyoid, palatopharyngeus, stylopharyngeus, digastric posterior, and other muscles located posteriorly cause elevation, and the geniohyoid, mylohyoid, digastric anterior, thyrohyoid, and other muscles located anteriorly cause forward displacement of the larynx and pharynx and contribute to opening the upper esophageal sphincter (*UES*). The thyroarytenoid, aryepiglottic, and oblique arytenoid muscles and others close the larynx to prevent food from entering the trachea. (**B**) During swallowing, a rapid series of events occurs: closure of the velopharyngeus to prevent reflux into the nose; closure of the larynx to prevent aspiration; pharyngeal peristalsis to clear the bolus out of the pharynx; laryngeal upward and forward displacement to move the larynx out of the path of the bolus and to force open the cricopharyngeal region; and opening of the UES. The *graph* depicts the temporal sequence of some of the events occurring during swallowing of a 1-mL liquid bolus. Time zero represents the end of the swallow, determined by the occurrence of UES closure. Velopharyngeal closure occurs as the bolus is gathered on the tongue (i.e., loading) and propelled forward (i.e., pulsion). Laryngeal closure and UES opening occur later, during the phase of pharyngeal clearance. (Adapted from ref. [78].)

The extrinsic muscles, including the levator veli palatini, tensor veli palatini, palatoglossus, and others, are located in the nasopharynx; with the palatopharyngeus, they raise and tense the soft palate and uvula and close the nasal passage, thus preventing pressure generated in the mouth from being dissipated through the nose. When selective paralysis of these muscles occurs, as in poliomyelitis, the bolus sometimes is pushed into the nasopharynx. [81] The stylohyoid, styloglossus, palatopharyngeus, stylopharyngeus, digastric posterior, and other muscles located posteriorly cause elevation, and the geniohyoid, mylohyoid, digastric anterior, thyrohyoid, and other muscles located anteriorly cause forward displacement of the larynx and pharynx and contribute to opening the UES. Activation of these groups of muscles causes negative pressure to develop in the hypopharynx.

During the pharyngeal phase of swallowing, the area located ahead of the bolus exhibits an incrementally decreasing pressure caudally, which may facilitate bolus

transport and may contribute to airway protection. [82] The combination of the negative pressure in front of the bolus and the positive pressure caused by the tongue, palate, and proximal pharynx behind the bolus imparts a powerful propulsive movement, resulting in high-speed injection of the bolus into the esophagus. [83], [84] When swallowing occurs, the thyroarytenoid, aryepiglottic, oblique arytenoid, and other muscles close the larynx, thus preventing food from entering the trachea.

The intrinsic pharyngeal muscles are the superior, middle, and inferior pharyngeal constrictors (see Fig. 9-4). These muscles overlap like tiles on a roof and insert into a collagenous sheet, called the *buccopharyngeal aponeurosis.* In the upper pharynx, this structure is attached to the prevertebral fascia by a median raphe; distally, the constrictors are vertically mobile in relation to the prevertebral fascia and allow considerable axial movement during swallowing. [85]

The inferior pharyngeal constrictor has two anatomic components: the thyropharyngeus, which extends posteriorly from the thyroid cartilages and overlaps the middle constrictor, and the cricopharyngeus. The cricopharyngeus consists of a horizontal muscle loop surrounding the esophageal inlet, constituting part of the UES, and an oblique component on its posterior and proximal portion that attaches to the median raphe. This arrangement creates a thin, triangular area in the posterior aspect of the hypopharynx, called the *Killian triangle.* This area is structurally weak and susceptible to failure, producing outpouching of the mucosa through the muscular layer, called a *Zenker diverticulum.* [86] The term *cricopharyngeus muscle* commonly refers to the horizontal portion of the cricopharyngeus. The UES consists of the horizontal cricopharyngeus muscle and portions of the inferior constrictor. The sphincter is part of the pharynx. Some evidence suggests that muscles of the proximal esophagus do not contribute to UES function. [84], [85], [86], [87] and [88]

Pharyngeal Function and Control

Mastication of food, mixing it with saliva, and forming a bolus of a size and consistency appropriate for swallowing occur in the mouth under voluntary control. The deglutitive functions of the tongue include bolus containment, volume accommodation, and bolus propulsion. The tongue's graded actions are capable of accommodating boluses of different volumes and are responsible for increasing intrabolus pressure for vigorous bolus expulsion. [78] Tongue propulsive force and the clearing pressure during the swallow modulate bolus viscosity. The anterior two thirds of the tongue shows both greater force development and greater modulation than the tongue base. [89] Based on evidence obtained from simultaneous pressure measurements and cinefluorography, it has been suggested that the driving pressure produced by the tongue and the negative pressure generated in the pharyngoesophageal segment contribute significantly to the driving force of the bolus. When these components are absent or reduced in patients with tongue impairment or who have undergone laryngectomy, the transit of a food bolus is impaired. [83]

The presence of a bolus in the oropharynx activates a variety of receptors located at the base of the tongue, tonsils, soft palate, uvula, posterior pharyngeal wall, and larynx. [16], [90], [91] The afferents carrying the input to the swallowing center are thought to run in the maxillary branch of the trigeminal nerve, the glossopharyngeal nerve, and the superior laryngeal branch of the vagus nerve. [92], [93] The pharyngo-UES contractile reflex is activated by pharyngeal mucosal mechanoreceptors whose afferent limb is the glossopharyngeal nerve and whose efferent limb is the pharyngoesophageal branch of the vagus nerve. [94] The initial response to injection of water into the pharynx is inhibitory, and it can block ongoing primary and secondary peristalsis in the esophageal body. [95] Continuation of deglutition in the pharynx and striated esophagus is under involuntary reflex control by motor nuclei in the swallowing center. The swallowing center that controls the deglutition reflex is located in or near the NTS in the brainstem. [16], [96], [97]

Afferent mucosal receptors, sensitive to pressure and taste, are present through the pharynx and larynx. The epiglottal edge appears to be the most sensitive trigger zone for swallowing. [98] Afferent receptors activate glossopharyngeal and vagal fibers that innervate the swallowing center. Central recognition of the incoming sensory stimulus is thought to be accomplished by a pattern recognition system in the brainstem that identifies the stimulus as appropriate for swallowing and generates the required neuromuscular response. [97], [99] The swallowing center then initiates a pattern of excitation and inhibition of medullary motor neurons; it interacts with other brainstem centers and coordinates cessation of breathing, initiation of swallowing, opening of the UES, and peristalsis in the striated portion of the esophagus. [90], [100], [101]

Sensory loss in the oropharyngeal isthmus, pharynx, or larynx that may be caused by local anesthesia often is associated with impairment of swallow or aspiration, suggesting that proper coordination of swallowing and respiration may depend in part on the appropriate input from receptors located in the pharynx or larynx. [102], [103] The sensory afferents are connected to motor nuclei in the brainstem by interneurons. Discrete motor input is distributed to all muscle groups in the pharynx, larynx, and soft palate through motor fibers in the glossopharyngeal and vagus nerves, except for the tensor veli palatini, which is innervated by the trigeminal nerve. The axons of the motor neurons to the pharyngeal muscles run through the vagi into the superior pharyngeal nerves, arising from the vagi at the level of the nodose ganglion. These nerve fibers form the pharyngeal plexus and control the pharyngeal muscles, including the cricopharyngeus and the upper portion of the esophagus.

Videofluoroscopic analysis of the pharyngeal phase of swallowing reveals rapid succession or almost simultaneous occurrence of multiple component actions: laryngeal closure that results from elevation of the larynx; nasopharyngeal closure that results from the elevation of the soft palate; UES opening associated with sphincter relaxation and traction of the anterior wall resulting from laryngeal elevation and contraction of the suprahyoid and infrahyoid muscles; bolus propulsion accomplished by the actions of the tongue; pharyngeal clearance that results from the longitudinal shortening and elevation of the larynx; and transverse contractions, which are aborally propagated and responsible for the emptying of any residue. Compromising any of these components can cause dysphagia. [104]

Longitudinal contractions, observed early in the swallow, are caused by contraction of the stylopharyngeus muscle, which changes the conformation of the pharynx and transforms it from a respiratory to a deglutitive organ. They approximate the UES to the base of the tongue. Transverse contractions occur late in the swallow and are aborally propagated as the bolus tail travels the length of the pharynx. This peristaltic action is performed entirely by the posterior wall of the pharynx because the anterior wall is composed of cartilaginous structures that are devoid of any electromyographic activity. The speed of this highly complex function varies with the volume of the bolus. It is progressively slower with increasing bolus volumes. Only the duration and amplitude of contraction of the pharyngeal constrictors associated with pharyngeal clearance remain constant regardless of bolus size. [105]

The oropharyngeal swallow accommodates a range of bolus volumes. Volume accommodation is accomplished by augmenting and prolonging reconfiguration from a respiratory to deglutitive pathway. [106] When bolus volume is increased, more time is allocated for reconfiguration, that is, sustained laryngeal elevation and hyoid excursion. In terms of bolus expulsion volume, accommodation is accomplished within the same period by using increased vigor of expulsion. [105]

The descending wave of pharyngeal peristalsis begins and continues through the open UES. Within 1 to 2 seconds, the velopharyngeus closes to prevent reflux into the nose, the larynx closes to prevent aspiration, pharyngeal peristalsis clears the bolus out of the pharynx, and the larynx is displaced upward and forward to move it out of the path of the bolus and to force open both the cricopharyngeal region and the UES. [107]

UPPER ESOPHAGEAL SPHINCTER

Functionally, the UES is defined as a high-pressure zone, 2 to 4 cm wide, separating the pharynx from the body of the esophagus. It is composed of both opening and closing muscles. The opening muscles include the thyrohyoid and the geniohyoid, and the closing muscles include the cricopharyngeus, thyropharyngeus, and those of the cervical esophagus. The relative contribution of each muscle to the opening and closing of the UES varies with the physiological state. Although the cricopharyngeus may be the primary muscle of the UES, it cannot account for all the observed functions of the UES. [108] There is some uncertainty about the muscles responsible for maintaining the high pressure, because the width of the horizontal cricopharyngeus accounts for only 1 to 1.5 cm of the UES. It appears, however, that the UES high-pressure zone encompasses the cartilaginous hypopharynx, including the cricoid cartilage anteriorly and the cricopharyngeus and other components of the inferior pharyngeal constrictor. [16], [79], [109], [110] Data obtained from animal studies show good correlation between intralumenal pressure and electromyographic activity in the cricopharyngeus and inferior pharyngeal constrictor. [87]

The UES or pharyngoesophageal segment maintains closure of the proximal end of the esophagus, [111] and it constitutes an additional barrier to refluxed materials entering the pharynx (Fig. 9-6). It also prevents air from entering the esophagus, because intraesophageal pressure during inspiration is lower than pharyngeal pressure. In humans, the UES exhibits an asymmetric pressure profile longitudinally and radially. [112], [113], [114], [115] and [116] Peak pressure is highest in the pharyngoesophageal segment, lower in the inferior constrictor area, and lowest at the level of the tongue base. [116] Radial asymmetry is considerable in the UES, with the highest pressures occurring in an anteroposterior direction and peak pressures occurring at slightly different locations in the anterior and posterior directions. In the anterior direction, the peak pressure occurs 1 cm distal to the upper border of the high-pressure zone, and in the posterior direction, it occurs 2 cm distal to the upper border of the high-pressure zone. [115] The asymmetry disappears in patients who have undergone laryngectomy, suggesting that this feature may be caused by squeezing of the esophagus against the laryngeal cartilages forming the anterior wall of the sphincter. [115] The asymmetry also may result from different mechanical

constraints at different levels of the pharynx, or it may be a reflection of the neural control of swallowing in the brainstem. [116]

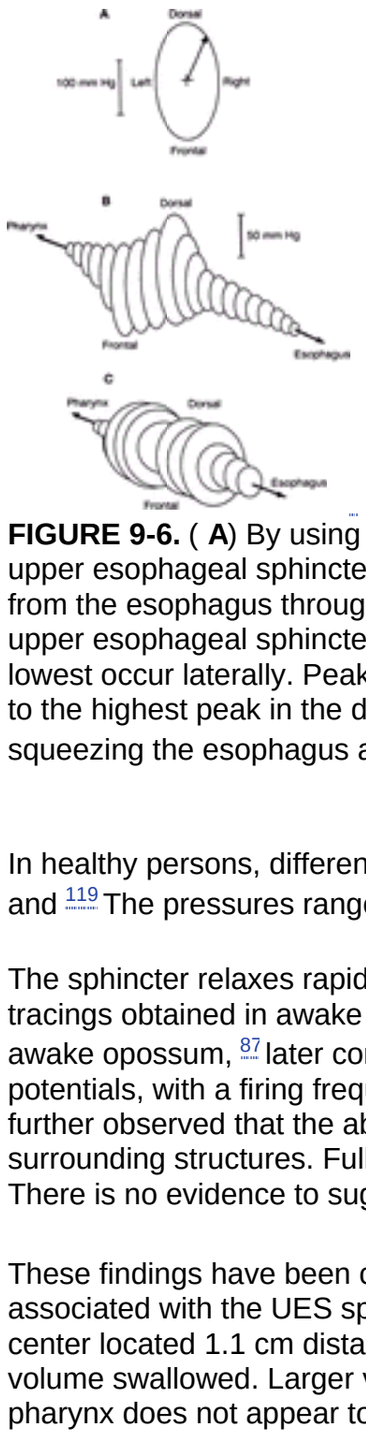

FIGURE 9-6. (**A**) By using multiple pressure sensors oriented in different directions, it is possible to measure pressure as a function of the radial orientation within the upper esophageal sphincter. In this sphincter, pressure is highest in the frontal and dorsal directions and is lowest in the lateral directions. (**B**) As the probe is moved from the esophagus through the sphincter and into the pharynx, a three-dimensional representation of the sphincter's pressure profile is obtained. In humans, the upper esophageal sphincter exhibits an asymmetric pressure profile longitudinally and radially. The highest pressures occur in an anteroposterior direction, and the lowest occur laterally. Peak pressures occur at slightly different locations in the anterior and posterior directions. The highest peak in the frontal direction occurs orad to the highest peak in the dorsal direction. (**C**) The asymmetry disappears in patients who have undergone laryngectomy, suggesting that it may be caused by squeezing the esophagus against the laryngeal cartilages, thus forming the anterior wall of the sphincter. (Adapted from ref. [115].)

In healthy persons, different resting pressures have been recorded by different investigators and by the same investigators using different techniques. [111], [115], [117], [118] and [119] The pressures range between 40 and 100 mm Hg, with pressures in the lateral orientations as low as 30% of the pressures in anterior or posterior orientations.

The sphincter relaxes rapidly and exhibits significant longitudinal excursions during swallowing that cause considerable confusion in the interpretation of pressure tracings obtained in awake persons. In experimental animals, anesthesia affects the spike potentials associated with contraction of striated muscles. Studies of the awake opossum, [87] later confirmed in studies of the cat, [120] showed that the cricopharyngeus and the inferior pharyngeal constrictor exhibit continuous electrical spike potentials, with a firing frequency proportional to the resting tone present in the sphincter and relaxation occurring after abolition of the spike potential. The studies further observed that the abolition of spike potentials reduced resting tone only by half, because some passive pressure was present as a result of the elasticity of the surrounding structures. Full relaxation occurred on contraction of the geniohyoid muscle, which caused forward displacement of the larynx and forced open the UES. There is no evidence to suggest that esophageal fibers distal to the cricopharyngeus are involved in maintenance of sphincter closure.

These findings have been confirmed in humans using a combination of videofluoroscopy and appropriate intralumenal manometry. [121] The high-pressure zone associated with the UES spanned about 3 cm, but the width of the high-pressure zone with pressure greater than 25% of peak pressure averaged 1.6 cm, with its center located 1.1 cm distal to the vocal cords. On swallowing, the UES moved orad 2 to 3 cm, with the extent of movement and opening size dependent on the volume swallowed. Larger volumes are accommodated by greater axial excursions, wider openings, and prolonged opening intervals. Peristaltic velocity in the pharynx does not appear to be affected by bolus volume.

Deglutition evokes an almost immediate UES relaxation, which briefly precedes pharyngeal contractions and, within 2 seconds, relaxes the LES. LES relaxation is observed as the peristaltic contraction appears within the middle third of the esophagus. [122] The UES relaxes briefly (<1 second) and fully to the level of pharyngeal or atmospheric pressures.

Neural input to the UES is required for maintenance of high resting pressure and for precise coordination of relaxation with swallowing. In the opossum, sphincter tone is mediated through neural fibers in the vagal trunks that originate in the nucleus ambiguus of the medulla. [123] Vagal transection abolishes activity in the cricopharyngeus and inferior pharyngeal constrictor muscles. [87] These muscles normally exhibit continuous spike activity, which is abolished by curare. Tone alters with changing firing frequency, indicating that motor neuron activity is responsible for maintenance of tonic muscle activity. Cessation of firing causes relaxation. Swallowing is further facilitated by forward displacement of the pharynx, which forces the sphincter to open. [87]

Resting tension in the UES is influenced by breathing, because it increases during inspiration when thoracic and esophageal resting pressures decrease. [124], [125] The change in pressure cannot be the result of transmission of pressure from the body of the esophagus but probably results from reflex neural activity. In the opossum, this increase in resting pressure is associated with increased spike activity in the cricopharyngeus and persists until stage 3 anesthesia, at which point, activity of UES muscles is reduced or abolished. [87] UES pressure is reduced during sleep and increases in persons under acute emotional stress. [124], [126]

Intrabolus pressure is an important determinant of UES opening in the healthy oropharynx. The healthy UES has residual opening capacity that can be demonstrated by altering body posture. These findings were confirmed in humans by using a combination of videoradiography and intralumenal manometry. Hypopharyngeal intrabolus pressure increases significantly in the horizontal compared with the upright position, resulting in increased maximal sphincter diameters during bolus flow, shorter duration of sphincter opening, and increased transsphincteric flow. [127]

Distention with small air-filled balloons or injection of water or acid into the body of the esophagus causes an increase in UES pressure. [128] The increase is greater when the bolus is closer to the UES and is greater for acid than for water or saline in healthy persons. [129] In infants with gastroesophageal reflux, the response to acid perfusion is not different from that of healthy age-matched controls, but in patients with esophagopharyngeal regurgitation, neither saline nor acid causes a significant increase in UES pressure. [130], [131]

Increased UES pressure, in response to reflux, [132] has been observed in patients with esophagitis and in healthy volunteers. Mechanisms responsible for this reflex were examined in the dog. [133] In this species, UES pressure increases in response to acid perfusion and to balloon distention of the proximal esophagus. The response to acid increases with decreasing pH and with proximity of the distending balloon to the UES. The response to intraesophageal acid perfusion at all levels within the esophagus is abolished by bilateral blockade of the vagosympathetic trunks. The response to balloon distention of the distal esophagus is abolished, but the response to distention of the proximal esophagus is only reduced. These data suggest that the afferent pathways for the response to acid are found exclusively in the vagosympathetic trunks, presumably arising from branches of the recurrent laryngeal nerves. Responses induced by distention, at least in the proximal esophagus, may partially depend on another pathway.

Injection of air into the body of the esophagus or distention by large balloons relaxes the UES. [134] The relaxation facilitates expulsion of the air bolus by belching. The afferent mechanisms mediating discrimination between distention by fluid, which causes contraction, or by air, which causes relaxation, are unknown. It is possible that the spatial pattern and rapidity of esophageal distention may provide discrimination in the response to fluid or air. [134] When refluxed contents reach the upper esophagus, the UES prevents further retrograde movement. [135] During deep sleep, however, the UES pressure decreases, possibly resulting in a reduced ability to prevent reflux at a time when the risk of reflux is higher. [124]

UES relaxation occurs during deglutition, belching, or vomiting. Relaxation during swallowing has two components. The first is inhibition of neural input arising from motor neurons in the brainstem and resulting in cessation of spike activity in the muscles of the UES. [87], [136], [137] The second is forceful opening of the UES, resulting from elevation and forward displacement of the larynx by muscles of the oropharynx. The styloglossus, stylohyoid, palatopharyngeus, stylopharyngeus, digastric

posterior, and other muscles located on the posterior aspect of the pharynx presumably contribute to elevation, and the geniohyoid, mylohyoid, digastric anterior, thyrohyoid, and other muscles located anteriorly contribute to forward displacement. Inhibition of tonic muscle activity by itself is not sufficient to cause relaxation, and forceful opening of the sphincter is required to abolish resting pressure.

Pharyngeal peristalsis may force the bolus through the sphincter even in the absence of forceful opening; conversely, displacement of the larynx may force the UES open, even in the absence of cricopharyngeal inhibition. Impairment of relaxation or opening of the sphincter may affect the smooth coordination of swallowing. Impairment of cricopharyngeal relaxation results in a prominent bar across the cricopharyngeal region (i.e., cricopharyngeal achalasia), and paralysis of the suprahyoid pharyngeal muscles may cause paralytic achalasia of the UES. [16]

ESOPHAGUS

Esophageal Anatomy

The body of the esophagus is about 18 to 25 cm long, extending from the inferior border of the UES to the upper border of the LES. The length of the esophagus correlates with body height and usually is longer in men than in women. It has a longitudinally oriented muscle layer in the muscularis mucosae and two muscle layers in the muscularis propria, with the inner one oriented along the circumference (i.e., circular layer) and the outer one along the axis (i.e., longitudinal layer).

Although the muscle in the muscularis mucosae is longitudinally oriented and smooth throughout the whole length of the esophagus, the muscularis propria is composed of striated muscle in the most proximal portion. Esophageal striated muscle has histological characteristics different from those of other striated muscles. These differences include the type of motor innervation and endplates, arrangement of the muscle fibers, fiber diameter, and type of myosin adenosine triphosphatase. [17], [138], [139] and [140]

It is generally accepted that the junctional area between the striated and smooth muscle occurs in the middle third of the esophagus. Data suggest that, on average, the proximal 4.1 cm of the circular and 5.1 cm of the longitudinal layers are entirely striated muscle. The point at which the circular layer is about half smooth and half striated muscle occurs 4.7 cm distal to the cricopharyngeus. [141] A 4- to 8-cm transition area (i.e., middle third of the esophagus) has various proportions of striated and smooth muscle; the distal 10 to 14 cm consist exclusively of smooth muscle whose fibers are oriented in a circular or an elliptical direction. [142] This distribution is typical of the human esophagus, but there are considerable species differences in the relative proportions of striated and smooth muscle. A distribution similar to that in humans occurs in other primates, cats, and opossums. The pig esophagus is predominantly striated muscle, with a short smooth muscle portion. In dogs and sheep, the esophagus is entirely striated. In some species, such as the rat, the striated muscle portion includes the LES. [143] Knowledge of the muscle composition of the esophagus is crucial for the interpretation of physiological and pathophysiological data.

Esophageal Function

Cinefluoroscopic studies of barium swallows have demonstrated that as an ingested bolus enters the body of the esophagus (Fig. 9-7), it travels by gravity or peristaltic propulsion, depending on its consistency. Liquids travel by gravity if the subject is upright. Liquids fall fast enough (within 2 seconds) to find the LES closed, causing distention of the distal esophagus and creating the radiological appearance of the phrenic ampulla. After the peristaltic contraction reaches the liquid bolus, it pushes it through the relaxed LES. When the subject is supine, the column of barium travels just ahead of the peristaltic wave. Small amounts of fluid may remain in the distal esophagus after the peristaltic wave.

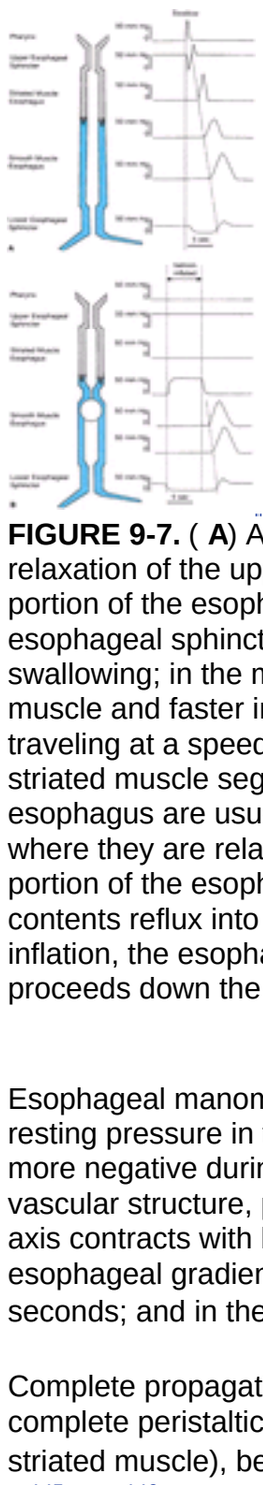

FIGURE 9-7. (**A**) At rest, the normal esophagus is quiescent, without any spontaneous contractions, and the sphincters are tonically contracted. Swallows trigger relaxation of the upper and lower esophageal sphincters and give rise to a peristaltic contraction traveling smoothly through the striated and then the smooth muscle portion of the esophagus. Each location along the esophageal axis contracts with a latency that increases gradually from the upper esophagus to the lower esophageal sphincter. The latencies are site dependent and reproducible. In the upper third of the esophagus, contraction occurs within 1 to 2 seconds after swallowing; in the middle third, within 3 to 5 seconds; and in the lower third, between 5 and 8 seconds. The velocity of the peristaltic wave is slower in the striated muscle and faster in the smooth muscle segments of the esophagus. Contractions reach the smooth muscle segment within 2 seconds after the onset of the swallow, traveling at a speed of about 3 cm per second; in the smooth muscle segment, the velocity of propagation may be as fast as 5 cm per second. The contractions in the striated muscle segment are shorter (1–2 seconds), and in the smooth muscle segment, they are longer (4–7 seconds). Contractions in the distal one third of the esophagus are usually stronger (50–150 mm Hg) than those in the upper third (40–120 mm Hg), and both are stronger than those in the middle third (20–80 mm Hg), where they are relatively weak, probably occurring at the transition between the striated and the smooth muscle. (**B**) A similar sequence occurs in the smooth muscle portion of the esophagus during secondary peristalsis, which happens when a bolus remains in the esophagus after ineffective primary peristalsis or when gastric contents reflux into the esophagus. Secondary peristalsis is thought to be caused by distention and can be demonstrated by inflating a balloon in the esophagus. On inflation, the esophagus contracts proximal to and relaxes distal to the balloon, including the lower esophageal sphincter. When the balloon is deflated, peristalsis proceeds down the esophagus.

Esophageal manometry shows that the normal esophagus at rest is quiescent without any spontaneous contractions, but the sphincters are tonically contracted. The resting pressure in the esophagus is an approximate reflection of thoracic negative pleural pressures. These pressures vary with the respiratory cycle and become more negative during inspiration. Occasionally, a 1- to 3-cm-long high-pressure zone is present in the middle esophagus, resulting from extrinsic compression by a vascular structure, possibly the aorta. Swallows trigger peristaltic contractions traveling along the entire length of the esophagus. Each location along the esophageal axis contracts with latency that increases gradually from the upper esophagus to the LES. The latencies are site dependent and reproducible, constituting the esophageal gradient. In the upper third of the esophagus, contraction occurs within 1 to 2 seconds after swallowing; in the middle third, it occurs within 3 to 5 seconds; and in the lower third, it occurs between 5 and 8 seconds. [144]

Complete propagation of the peristaltic contraction takes place after a swallow if a second swallow does not occur within at least 5 seconds after the first one. The complete peristaltic sequence is inhibited if a second swallow occurs within 5 seconds or less; a contraction may appear in the upper third of the esophagus (i.e., striated muscle), because it may occur before the second swallow is taken, but the peristaltic sequence is always inhibited in the lower two thirds of the esophagus. [144], [145] and [146] After repeated swallows at short intervals, no contractions are observed in the entire esophagus until after the last swallow, which is followed by a high-amplitude contraction. The inhibition of peristalsis by repeated swallows has been called *deglutitive inhibition.* Deglutitive inhibition maintains esophageal atony during guzzling, (i.e., taking repeated swallows at very short intervals). The second swallow affects the motor response to the first; the first swallow may also impair the response to the second if the two swallows are taken at short intervals. [147] Weak swallows may not evoke a full esophageal response; they may induce LES relaxation without esophageal contractions. [148] Occasionally, even in healthy persons, deglutition may induce simultaneous contractions within a 5- to 10-cm segment.

The velocity of the peristaltic wave is slower in the striated muscle and faster in the smooth muscle segments of the esophagus. Contractions reach the smooth muscle segment within 2 seconds after the onset of the swallow, traveling at a speed of about 3 cm per second. In the smooth muscle segment, the velocity of propagation may be as fast as 5 cm per second.

Motility studies indicate that the size and viscosity of an ingested bolus affect the speed and force of the esophageal contractions. Increasing the size of the bolus slows its velocity and increases the force of the contractions. Increased viscosity also increases the force of contraction and decreases the speed of peristalsis. [149], [150] Peristalsis also is affected by the temperature of the bolus; warm boluses increase its velocity, and cold boluses reduce it. [151]

Each contraction is preceded by a slight fall in pressure, probably related to alterations in the respiratory pattern during swallowing. [152] Pressures then rise rapidly, usually peaking within 1 to 2 seconds from the onset of the contraction. Normal esophageal contractions have spikelike configurations, particularly in the striated muscle segment of the esophagus (i.e., upper third), but occasionally they may be biphasic. The configuration of the pressure wave may depend on whether the ingested bolus is liquid or solid, but it usually exhibits an initial hump or plateau before rising rapidly. The initial pressure change may reflect the pressure created in the esophagus by the presence of the bolus, preceding the peristaltic wave. Dry swallows reveal that the contractions in the striated muscle segment are shorter (1–2 seconds) than in the smooth muscle segment (4–7 seconds). Contractions in the distal one third of the esophagus are usually stronger (50–150 mm Hg) than those in the upper third (40–123 mm Hg), and both are stronger than those in the middle third (20–80 mm Hg), where they are relatively weak, perhaps because of the transition between striated and smooth muscle. The force of the contractions can vary from segment to segment and even from swallow to swallow. [153]

Segmental peristaltic contractions may occur to prevent the injurious effect of reflux by clearing the esophagus of any refluxed contents. This response is similar to secondary peristalsis, which occurs as result of distention by food, gas, and acid. It is not clear whether local esophageal distention is always necessary to trigger esophageal clearing, because acid alone may evoke peristaltic contractions. [154] In addition, acid increases the perception of esophageal distention. [155]

Control of Esophageal Striated Muscle

Esophageal electromyographic responses can be evoked by stimulation of either the right or left hemisphere, with the largest amplitude responses obtained anterior to those of the thenar eminence, indicating that the esophagus may be represented on either the anterior aspect of the motor cortex or on the premotor cortex. These studies suggest that esophageal motor function shows bilateral cortical representation with consistent interhemispheric asymmetry. [156]

Contraction of esophageal striated muscle depends entirely on neural input arising from neurons located in the nucleus ambiguus and is centrally organized by sequential discharge of motor neurons controlling progressively distal segments in the body of the esophagus (Fig. 9-8). [1], [2], [157] Motor fibers course along the vagus and separate in the upper portion of the neck. These cholinergic fibers release ACh and stimulate nicotinic cholinergic receptors on the motor endplates of the striated muscle fibers. Bilateral vagotomy high in the neck, above the origin of the pharyngoesophageal fibers, completely abolishes peristalsis in this portion of the esophagus, but peristalsis in the smooth muscle portion can still be initiated by local distention. [16] Unilateral vagotomy has no effect, and transection of the striated muscle segment does not affect the normal progression of the peristaltic contractions evoked by swallowing. Peristalsis in the striated muscle portion of the esophagus does not depend on the continuity of esophageal plexuses but is under central nervous control. [158], [159]

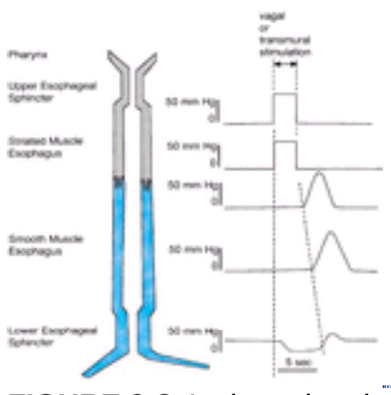

FIGURE 9-8. In the striated muscle portion of the esophagus, peristalsis is controlled directly by the central nervous system, and sequencing of peristalsis occurs in the swallowing center. Motor neurons are activated sequentially, first those innervating the proximal striated esophagus and then those activating the more distal portion of the striated muscle. In the opossum, after division of the vagus at the cervical level, stimulation of the distal end, which activates simultaneously all vagal fibers, produces simultaneous contraction of the striated esophagus and relaxation of the lower esophageal sphincter. At the end of the stimulus, peristalsis occurs in the smooth muscle esophagus. This suggests that, although peristalsis in the striated esophagus is under central nervous system control, local mechanisms are responsible for peristalsis in the smooth muscle portion. Even in the smooth muscle portion, central input may regulate peristalsis. Two types of vagal fibers may participate in smooth muscle peristalsis. Short-latency fibers, firing within 1 second of swallowing, coincide with the onset of inhibition in the esophagus and lower esophageal sphincter and may stimulate neurons that release inhibitory neurotransmitters. Long-latency fibers, discharging their impulses within 1 to 5 seconds, may coincide with the onset of contraction at various locations in the esophagus. These fibers may activate motor neurons to release excitatory neurotransmitters. It is possible that, on swallowing, the central nervous system mediates initial inhibition throughout the esophagus by way of a nonsequential mechanism activating short-latency fibers that results in hyperpolarization in the esophagus and relaxation of the lower esophageal sphincter. As hyperpolarization ends, sequential excitatory input through the long-latency fibers causes sequential contraction and peristalsis in the smooth muscle esophagus.

Other types of esophageal responses in the striated muscle portion also appear to depend on central control, including secondary peristalsis, the inhibition evoked by frequent swallows, and reversed peristalsis in ruminants. [160] Extrinsic denervation or bilateral cervical vagotomy eliminates the esophageal contractions evoked by esophageal distention in this segment. Frequent swallows taken at short intervals abolish the response of the striated muscle of the esophagus until the last swallow occurs. [146] Because the striated muscle is under direct central control, swallow-induced inhibition probably originates in the swallowing center.

The strength of contraction in the striated muscle may be modulated by a variety of sensory inputs, including bolus volume and temperature. [151], [161], [162] An increase in volume augments the force and duration of the contractions while slowing the velocity of propagation. Warm boluses increase the force, and cold boluses decrease the force of the contractions. These effects may depend on afferent input to the central nervous system with subsequent modulation of vagal control of the striated esophageal fibers. [163]

Control of Esophageal Smooth Muscle

Control of peristalsis in the smooth muscle segment of the esophagus (see Fig. 9-8) is influenced by sequencing of motor neurons in the swallowing center, resulting in progressive stimulation of intramural cholinergic neurons. [164] Central sequencing alone, however, cannot account for the occurrence of sequential peristaltic contractions in response to stimulation of the decentralized efferent vagus at the cervical level. [165] Long latencies in response to field stimulation have been observed, even in vitro in muscle strips taken from the distal esophagus, when compared with strips from the proximal esophagus, which exhibit shorter latencies. [166]

Control of peristalsis also may arise from peripheral mechanisms located in the intramural plexuses, because stimulation of decentralized vagal efferent nerves evokes peristalsis that is similar to the peristaltic wave produced by swallowing. [165], [167] Nerve conduction studies indicate that neural stimuli initiated by swallowing propagate with a speed of 5 to 6 cm per second and therefore reach the intramural neurons of the entire length of the esophagus at about the same time, but the timing of the contractions reveals an aboral increment in latency of contraction during peristalsis. [168] In vitro distal esophageal strips exhibit longer latencies than proximal strips. [166], [169] Esophageal transection at the level of the smooth muscle segment markedly affects the propagation of the peristaltic wave below the level of the transection, but transection of the striated esophagus does not affect the orderly transmission of peristalsis across the cut, suggesting that the integrity of the

intramural mechanisms is essential for the normal progression of peristalsis in the smooth but not in the striated esophagus. [159]

Peripheral control is illustrated also by distention of the esophageal smooth muscle segment after extrinsic denervation. [62], [170] Peristalsis induced by balloon distention always is propagated in the caudad direction after extrinsic denervation with cervical vagotomy and even in the isolated esophagus mounted in an organ bath. Esophageal peristalsis evoked by balloon distention is similar to that caused by swallowing, with a similar sequence of inhibition or hyperpolarization during distention followed by a latency period and contraction or depolarization after balloon deflation. Repeated stimulation of the decentralized efferent vagal fibers at short intervals inhibits the esophageal responses, with contraction occurring only after the last stimulus. [171] This experimental model mimics deglutitive inhibition and suggests that the mechanism responsible resides in the intramural neurons.

Primary peristaltic waves in this segment are affected by the presence of a bolus and by central mechanisms. The bolus modifies the speed, duration, and force of the contractions. [172] Central mechanisms are also capable of modulating the occurrence and features of esophageal contractions, including the polarity of peristalsis, as occurs under some pathophysiological conditions. Changing the parameters of vagal stimulation can induce peristaltic or antiperistaltic sequences at different speeds of propagation. [165]

The preganglionic fibers that mediate this control branch out from the thoracic vagus nerve, to form a plexus around the esophagus, and then enter into the esophageal wall, where they travel a few centimeters before synapsing with the myenteric neurons. [173], [174] They arise from the dorsal motor nucleus and may synapse to the intramural neurons. [2], [3] During swallowing, central regulation may be mediated by two types of vagal fibers. Short-latency fibers firing within 1 second may stimulate neurons that release inhibitory neurotransmitters, and long-latency fibers discharging their impulses within 1 to 5 seconds may activate motor neurons to release excitatory neurotransmitters. [175], [176]

Central mechanisms also control the contractions of the longitudinal muscle layer. Swallowing induces peristaltic sequences with gradual activation from orad to caudad segments and a correspondent progressive increase in latencies. [177] Unlike the responses observed in the circular muscle layer, stimulation of decentralized vagal efferent fibers causes simultaneous contractions in the longitudinal muscle layer. [165] In the human esophagus, both circular and longitudinal muscle contractions occur as propagating segments during peristalsis, with the longitudinal muscle contraction leading the circular muscle contraction. Propulsive force occurs during proximal circular and distal longitudinal muscle contraction. [89]

Esophageal peristalsis is characterized by a gradient, with increasing latency of contractions along the length of the esophagus. The latent period is the interval between the swallow or electrical stimulus and the onset of contraction at a given site in the esophagus. In humans, it is 2 seconds in the proximal smooth muscle esophagus and 5 to 7 seconds just above the LES. [144] The nature of the latency gradient is controversial, but it can be changed by varying the parameters of vagal stimulation or by pharmacological manipulation of the esophageal contractions, suggesting that latency may result from the interaction between the initial inhibition and subsequent excitation of esophageal smooth muscle. [165] The muscarinic cholinergic antagonist atropine increases the latency of contraction, and the acetylcholinesterase inhibitor physostigmine decreases it. [176], [178]

The data support the view that peristalsis is largely determined by neurally dependent esophageal gradients, because the esophageal response to low-frequency electrical stimuli is tetrodotoxin sensitive and is aborally transmitted no matter where in the esophagus the stimulus is applied. [165]

Preganglionic vagal fibers synapse with intramural excitatory neurons through activation of nicotinic receptors. The nicotinic ganglionic inhibitor hexamethonium blocks cervical vagal stimulation. [167] The nature of the postganglionic intramural neurons varies with the animal species studied. It has been suggested that these neurons are exclusively inhibitory, using NANC transmitters. Stimulation of these neurons results in an initial inhibition, followed by a rebound contraction after cessation of the stimulus. [179] Studies in the opossum and cat suggest that the inhibition occurring during the stimulus and the “off” contraction occurring at the end of the stimulus are mediated by separate transmitters, if not by different neurons, although considerable species-related differences occur.

Swallowing causes a single contraction at each level of the esophagus after a given latency. Brief stimulations (1 second) of the efferent vagal fibers or of circular muscle strips also evoke a single contraction with a given latency [178]; however, the esophageal response induced by prolonged stimulation (5–20 seconds) is dissociated into an “on” contraction that occurs during the stimulus and an “off” contraction after the end of the stimulus. Because the act of swallowing is brief, it is conceivable that the on and off responses represent dissociations of one or more excitatory neurons during artificially prolonged stimulation. The on responses are not seen at lower stimulus frequencies, which are thought to be more representative of physiological events. [178] It is unclear how the results of these experimental studies may relate to the esophageal response evoked by deglutition.

In the opossum, cholinergic and NANC excitatory neurons are responsible for the off response; proximal segments are controlled primarily by cholinergic fibers, and distal segments are controlled by noncholinergic motor neurons. [178] In the cat esophagus, the off response seems to be entirely under cholinergic control. The contractions induced by field stimulation in vitro or by vagal stimulation are blocked by atropine. [144], [179], [180] Because atropine decreases the amplitude of pressure generated by swallowing and the force developed in vitro by esophageal muscle in response to electrical (i.e., neural) stimulation, [181], [182] and [183] cholinergic fibers also contribute to the human esophageal contractions.

The intramural neural pathway that mediates the descending peristaltic reflex induced by balloon distention in the opossum involves long descending neurons that depend on NO as a final mediator. [184] NO is produced from L-arginine by the enzyme NO synthase, which is present in myenteric neurons. [185], [186] NO synthase is reversibly inhibited by some analogs of L-arginine, including *N*-nitro-L-arginine methyl ester and *N*-nitro-L-arginine. NO synthase inhibitors decrease the latency and amplitude of off contractions in the in vitro esophageal circular muscle [187] and in the in vivo esophagus in response to swallowing. [45], [188] *N*-nitro-L-arginine dose dependently reduces the propagation time of contraction in the distal esophagus. [189] In vivo, this effect is more pronounced in the distal esophagus, where latency is longer. NO synthase inhibitors reduce the latency gradient so contraction in response to swallowing occurs almost simultaneously in the smooth muscle portion of the esophagus. In vivo infusion of recombinant human hemoglobin (rHb1.1), which inactivates NO by binding with it, interferes with esophageal peristalsis, LES relaxation, and precipitates esophageal spasm. [190], [191] and [192] These studies suggest that endogenous NO may mediate the coordinated latency between swallowing and progressive contraction along the esophageal body that is responsible for peristalsis. [45], [190], [191], [193], [194]

The hypothesis that esophageal smooth muscle response may result from more than one neurotransmitter is supported by the finding that it is possible to dissociate esophageal inhibition and esophageal excitation by using selective antagonists. The initial inhibition may be partially mediated by VIP-containing neurons, which are present in the body of the esophagus. [195] Esophageal muscle strips tonically contracted with bethanecol relax during field stimulation; this neurally mediated (i.e., tetrodotoxin-sensitive) relaxation is partially blocked by VIP antiserum without affecting the force and duration of the off contractions, which are blocked by atropine. [144] In addition, NO colocalizes with such neuropeptides as VIP, CGRP, and galanin, but it shows little colocalization with neuropeptide Y and substance P, suggesting that the nerves responsible for peristalsis in the esophagus may act by releasing NO along with other inhibitory neuropeptides, but not excitatory substances, such as neuropeptide Y and substance P. [75], [77]

Esophageal muscle is relaxed at rest and contracts in response to vagal or field stimulation with a brief and forceful contraction. In the cat, this contraction is mediated by M_2 muscarinic receptors [196] linked to a pertussis toxin–sensitive guanosine triphosphate (GTP)-binding protein of the G_{i3} type and results in the activation of at least three phospholipases acting on membrane phospholipids. Phosphatidylcholine-specific phospholipase C and phospholipase D hydrolyze phosphatidylcholine to produce diacylglycerol without the production of inositol phosphates. [197], [198] A cytosolic phospholipase A_2 (PLA_2) [199], [200], [201] and [202] is also activated, resulting in the production of arachidonic acid. [203] Activation of these phospholipases requires the presence of Ca^{2+}, which is provided by the influx of extracellular Ca^{2+} through voltage-dependent channels, [204] possibly augmented by the release of Ca^{2+} from intracellular stores. [205], [206] Once diacylglycerol is produced, the Ca^{2+}-independent protein kinase C (PKC_e) is activated and contraction proceeds through a calmodulin-independent pathway that may not be directly regulated by activation of myosin light chain kinase. [207], [208] and [209] Arachidonic acid, produced by PLA_2, which is also Ca^{2+}-dependent, potentiates the diacylglycerol-induced activation of PKC and contributes to the initiation of PKC activity and ultimately to the strength of contraction (Fig. 9-9). [203]

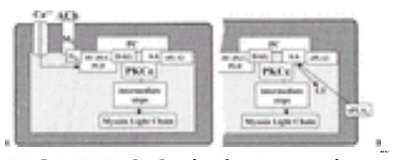

FIGURE 9-9. (**A**) Normal esophagus. Contraction of esophageal circular muscle in response to maximally effective doses of the cholinergic neurotransmitter acetylcholine (*ACh*) is mediated through muscarinic M_2 receptors linked to pertussis toxin–sensitive G proteins of the G_{i3} type. It results in activation of at least three phospholipases acting on the membrane phospholipid phosphatidylcholine (*PC*). Phosphatidylcholine-specific phospholipase C (*PC-PLC*) and phospholipase D (*PLD*) hydrolyze PC to produce diacylglycerol (*DAG*) without production of inositol phosphates. A 100-kd cytosolic phospholipase A_2 (*cPLA* $_2$) is also activated, resulting in the production of arachidonic acid (*AA*). Activation of these phospholipases requires the presence of Ca^{2+}, which may be provided by the influx of extracellular Ca^{2+} through voltage-dependent channels or by release from Ca^{2+} stores. AA produced by PLA_2 potentiates the DAG-induced activation of protein kinase C (*PKCe*), contributing equally to the initiation of PKC activity and to the strength of contraction. (**B**) Esophagitis. The roles of PLA_2 and AA and its metabolites are altered by the inflammatory responses associated with the induction of experimental esophagitis by repeated esophageal acid perfusion. In normal esophageal circular muscle, AA, produced by a $cPLA_2$, directly contributes to ACh-induced contraction by potentiating DAG-induced activation of PKC, and AA metabolites such as prostaglandins and leukotrienes (*LTs*) do not play a major role in contraction. After the induction of acute experimental esophagitis, the amplitude of response to ACh in cells or muscle strips of esophageal muscle is not altered greatly, but contraction is mediated in part by a low-molecular-weight (14-kd) secreted PLA_2 ($sPLA_2$). $sPLA_2$ and $cPLA_2$ differ in several respects, including molecular weight, substrate specificity, and localization within an organism. In addition, after esophagitis, AA is metabolized to LTs; because resting levels of LTs are greater than in normal circular esophageal muscle, LT levels increase in response to ACh, and ACh-induced contraction is reduced by LT antagonists. In animals with esophagitis, LTs contribute to contraction by activating LT-selective membrane receptors and by potentiating the DAG-induced activation of PKC.

K^+ channels play a role in maintaining the membrane resting potential. Some K^+ channels are active at or near the resting membrane potential and may participate in maintaining membrane polarization. [210], [211] Others are activated at more positive potentials as the membrane is depolarized and may contribute to ending depolarization and restoring the resting membrane potential. K^+ channels in many tissues are targets for modulation by inhibitory as well as excitatory factors. [212], [213] Agents that cause relaxation of esophageal muscle activate K^+ currents and contribute to hyperpolarization. For example, NO activates a K^+ current in the opossum esophagus, contributing to inhibitory junction potentials, [214], [215] and K^+ channels are activated by cyclic AMP (cAMP)-dependent pathways. [216] In addition, K^+ currents are targets for suppression by excitatory pathways. Cholinergic excitation suppresses spontaneous outward K^+ currents in esophageal muscle, [217] and it inhibits some cloned smooth muscle K^+ currents. [218]

Chloride ($C1^-$) channels may play a role in inducing depolarization. [219], [220] It has been suggested that agonist receptor binding and G-protein activation induces arachidonic acid formation by activation of a cytosolic PLA_2. Arachidonic acid in turn causes opening of $C1^-$ channels and efflux of $C1^-$ from the cell, resulting in depolarization, opening of voltage-sensitive Ca^{2+} channels and Ca^{2+} influx into the cell. Ca^{2+}-influx stimulates the production of cyclic adenosine diphosphate–ribose, which acts directly on ryanodine-sensitive Ca^{2+} channels in the endoplasmic reticulum and causes Ca^{2+} release. [221] $C1^-$ channels are another site of action for NO, which inhibits $C1^-$ efflux. [220]

The roles of PLA_2 and arachidonic acid and its metabolites are altered by the inflammatory responses associated with experimental esophagitis [222] induced by repeated esophageal acid perfusion. [223] In normal esophageal circular muscle, arachidonic acid produced by a 100-kd cytosolic PLA_2 contributes to ACh-induced contraction by potentiating diacylglycerol-induced activation of PKC; arachidonic acid metabolites such as prostaglandins and leukotrienes do not play a major role in contraction. [203] After induction of acute experimental esophagitis, the amplitude of response to ACh in cells or muscle strips of esophageal muscle [224] is not greatly altered, but contraction is mediated in part by a low-molecular-weight (14-kd) secreted PLA_2 ($sPLA_2$). [222] $sPLA_2$ and cytosolic PLA_2 are different in several respects, including molecular weight, substrate specificity, and localization within an organism. [225], [226] After induction of esophagitis, arachidonic acid is metabolized to leukotrienes, as demonstrated by the following observations: resting levels of leukotrienes are greater than in normal circular esophageal muscle, leukotriene levels increase in response to ACh, and ACh-induced contraction is reduced by leukotriene antagonists. In animals with esophagitis, leukotrienes contribute to contraction by activating leukotriene-selective membrane receptors [227] and by potentiating the diacylglycerol-induced activation of PKC (see Fig. 9-9).

LOWER ESOPHAGEAL SPHINCTER

Anatomy

An anatomic sphincter distinct from the body of the esophagus is found in human autopsies and consists of an asymmetric, thickened, ringlike structure that angles obliquely upward from the lesser to the greater gastric curvature. The length of the thickened area along the lesser curvature is about 2.5 cm and about 3 cm along the greater curvature. The LES proper is composed of complete muscle rings. Distally, the rings are split into two segments: one straddles the greater curvature and is parallel to the sling fibers of the stomach, and the other consists of short clasps straddling the lesser curvature and connecting at an angle to the sling fibers. [228] The squamocolumnar junction is present within this structure. In similar studies on the esophagogastric junction of cats, a clear correlation was found between the manometrically defined high-pressure zone and the thicker segment of circular muscle, with the squamocolumnar junction slightly distal to the high-pressure point. [229] The thickness of the circular muscle increases from the esophagus toward the LES, peaks at the in vivo high-pressure zone, and then decreases toward the stomach.

Electron microscopic studies reveal that the sarcolemma of the LES muscle has more evaginations than that of the esophageal muscle. [230], [231] It is unclear whether this morphologic feature has functional significance or whether it results from the tonically contracted state of the muscle. More abundant mitochondria and a more developed endoplasmic reticulum also differentiate the LES muscle from the circular muscle of the esophageal body. [231]

Basal Pressure

At rest, the LES is tonically contracted. The contraction is maintained by muscular mechanisms, even in the absence of neural input, [232], [233] and [234] and it creates an effective barrier consisting of a 3- to 5-cm-long high-pressure zone that effectively separates the esophagus from the stomach. The skeletal muscle crural diaphragm appears to contribute to the pressure barrier. [235] The pressure in the high-pressure zone ranges from 12 to 30 mm Hg above gastric pressures and exhibits radial and axial asymmetry, which may be attributed in part to extrinsic compression by the crural diaphragm. [236] The highest pressures are usually at the point of respiratory reversal, where the esophagus crosses the diaphragm. [237] This point separates the thoracic esophagus, where pressures decrease with inspiration, from the abdominal esophagus, where pressures increase with inspiration because the descending diaphragm compresses the abdominal contents.

LES pressures are affected by respiratory excursions and may be augmented by diaphragmatic contraction. [238], [239] Mid- or end-expiratory pressures are an indication of LES strength. The end-expiratory pressure is a result of the tonic activity of the smooth muscles of the LES. The pressure at the esophagogastric junction increases during inspiration, owing to the effect of the crural diaphragm. There is a reflex contraction of the LES during periods of increased intra-abdominal pressure, and the crural diaphragm contributes to this reflex. [235], [240] The end-expiratory pressure in the resting state is caused by the contraction of the LES, whereas the additional increase in pressure during inspiration is caused by the crural diaphragm. [238], [241] These two sphincters seem to relax simultaneously during swallowing, belching, and vomiting. [242] Gastroesophageal reflux secondary to transient LES relaxation is also accompanied by the simultaneous relaxation of the LES and the crural diaphragm. [240], [243], [244]

Extrinsic support of the LES by the crural diaphragm may be important, and loss of this support through development of hiatus hernia may contribute to LES dysfunction. The diaphragmatic and LES smooth muscle components normally supplement each other to maintain competence in static conditions and during dynamic stresses associated with increased intra-abdominal pressure or swallowing. These sphincteric components also interact with each other pathophysiologically. Hiatus hernia reduces LES pressure and alters the dynamic responsiveness of the LES by spatially separating pressure components derived from the intrinsic LES and the extrinsic compression of the esophagus within the hiatal canal. In patients with hiatus hernia, the esophagogastric junction high-pressure zone has two discrete segments, one proximal to the squamocolumnar junction and one distal, attributable to the extrinsic compression within the hiatal canal. Inspiration and abdominal

compression augments pressure mainly in the distal segment. [236], [245]

LES smooth muscle exhibits spontaneous tone and myoelectric activity that is characterized by continuous spike-burst activity with or without short phasic contractions. [112], [246] Spikes occur at a frequency of 15 to 40 per minute and may be associated with minicontractions, 5 to 15 mm Hg in amplitude. Partial relaxation of the LES is accompanied by complete cessation of electrical activity, and there is substantial residual LES tension that is not accompanied by any detectable electrical activity. Phasic contractions and electric spike activity become prominent after the administration of bethanecol or during phases II and III of the migrating myoelectric complex. [247] Phase III of the migrating myoelectric complex begins in the LES, lasts for about 15 minutes, and is characterized mostly by an increase in short phasic contractions. [247] The control mechanisms have not been established completely, but they appear to be under vagal control and are associated with a rise in circulating levels of the peptide motilin. Feeding, barbiturates, and cholinergic antagonists abolish electrical activity and associated contractions.

The composition of a meal also affects LES pressure; it is lower after a fatty meal and higher after a protein meal. [248] In the anesthetized cat, distal esophageal acidification causes an increase in LES pressure. [249] The physiological role of this response is unclear; it may be designed to tighten the sphincter to prevent further gastroesophageal reflux.

Gastrointestinal hormones or regulatory peptides may affect in vivo LES pressure, but it is difficult clearly to demonstrate a physiological role for many of them because of the lack of selective antagonists and because, when infused at concentrations similar to the circulating levels, many have little effect on the LES. The pharmacological effects of these hormones and endogenous compounds are well established, including some of their mechanisms of action. Gastrin causes LES contraction by direct muscle action. [167], [250] Other hormones, such as motilin, bombesin, pancreatic polypeptide, galanin, and substance P, cause LES contraction when used in pharmacological doses. [251], [252], [253], [254] and [255] In contrast, secretin, CCK, glucagon, gastric inhibitory peptide, VIP, peptide histidine isoleucine (PHI), CGRP, and neurotensin decrease LES pressures, although significant species differences occur. [256], [257], [258], [259], [260], [261], [262], [263] and [264] For instance, CCK causes LES relaxation in humans and in cats and causes LES contraction in the opossum. [257], [263], [264] It causes relaxation by stimulating the intramural NANC inhibitory neurons and causes contraction by direct muscle action. [263], [264] Glucagon relaxes the human LES, probably by direct action, but it contracts the cat LES by releasing catecholamines from the adrenal medulla. [256]

Some experiments suggest a physiological role for selected hormones. Intravenous infusion of neurotensin in humans at or below the serum levels obtained postprandially causes a dose-dependent decrease in pressures and may involve a cholinergic pathway. [265] Neurotensin levels increase after intragastric infusion of fat, and neurotensin antibodies reduce the decrease in LES pressure induced by fat infusion, suggesting that neurotensin may participate in this pathway. [266] Increases in the circulating levels of pancreatic polypeptide correlate with a rise in LES pressures after a protein meal and are abolished by duodenal exclusion from the meal. [253] Somatostatin has no effect on basal LES pressures but blocks the postprandial rise in LES pressures. [267] These observations suggest that a meal-induced rise in LES pressures is mediated by hormonal mechanisms, and it is known that somatostatin inhibits hormonal release. [268], [269] Gastroduodenal hormones may play a physiological role in regulating LES pressures during the digestion of certain foodstuffs (e.g., fatty meals, chocolate, alcohol, coffee) and during changes in gastroduodenal pH (e.g., acid or alkaline solutions), which may decrease or increase LES pressures in humans. [270], [271]

Basal LES pressures in vivo or basal circular muscle tension in vitro are maintained even in the absence of neural input. [232], [234], [272], [273] Bilateral cervical vagotomy and denervation with the neural poison tetrodotoxin do not eliminate in vivo LES tension in most animal species; in the opossum, LES pressures do not change at all. [234] In vivo experiments, however, usually are performed in anesthetized animals. General anesthesia depresses LES pressure in the baboon, suggesting that the neural input may be reduced or abolished in some in vivo experiments. [274] Some evidence indicates the presence of a neural contribution to the genesis or modulation of LES pressures in several animal species. Atropine reduces LES pressures in conscious humans and dogs, but similar doses of atropine do not affect LES pressures in conscious opossums and monkeys or in anesthetized opossums and cats. [178], [234], [272], [274], [275] and [276] Atropine has no effect on the tone of human LES smooth muscle strips, [277] a finding suggesting that cholinergic modulation of LES pressure may be of central origin. The precise contribution of cholinergic input to LES pressure is difficult to estimate because resting pressures may be modulated by excitatory and inhibitory influences. A decrease in tonic excitatory cholinergic input may enhance the tonic inhibitory effect. In the dog, however, LES pressures clearly are dependent on vagal tonic activity. [278], [279] In the cat, some adrenergic input contributes to LES pressure, and sympathetic nerves also mediate a reflex contraction. [272] The a-adrenergic blocking agent phentolamine decreases LES pressures by 25%, and a similar reduction is seen after tetrodotoxin administration. [272] Some of the controversies surrounding the significance of neural input in the genesis or modulation of LES pressures may reflect species differences.

The LES circular muscle is a major determinant of LES tone, although the relative neurogenic contribution may vary with the animal species. Functionally, this muscle is distinguished by the ability to maintain sustained tonic contraction in vivo and in vitro, even after the removal of neurogenic contributions by the administration of high doses of tetrodotoxin. [232], [233] and [234] Functional differences in esophageal and LES muscle may be related in part to the presence of different contractile proteins in the two types of muscle. [280] Maintenance of tone also may be related to the sustained activity of a pancreatic-like PLA_2 (Fig. 9-10). [281], [282]

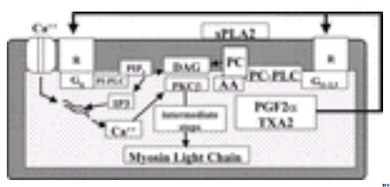

FIGURE 9-10. Resting lower esophageal sphincter (LES) tone is associated with the spontaneous activity of phosphatidylinositol-specific phospholipase C (*PI-PLC*) and phosphatidylcholine-specific phospholipase C (*PC-PLC*) resulting in the production of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (*DAG*) and the activation of a Ca^{2+}-sensitive protein kinase Cß (*PKCß*). A low-molecular-weight (14-kd) secreted, pancreatic-like (group I) phospholipase A_2 (*sPLA* $_2$) may play a role in resting LES tone by producing arachidonic acid (*AA*), which is then metabolized to prostaglandin F_2a (*PGF* $_2a$) and thromboxane A_2 (*TXA* $_2$). PGF_2a and TXA_2 are membrane permeable and bind to specific G-protein–linked receptors, to cause activation of PI-PLC and PC-PLC, producing second messengers and contraction. G_q, $G_{i1-2,3}$, G proteins; PIP_2, phosphatidylinositol biphosphate; *R,* receptor.

The PLA_2 enzymes comprise a growing family of enzymes that catalyze the hydrolysis of glycerolphospholipids at the *sn*-2 position, producing free fatty acids and lysophos- pholipids. [283], [284] and [285] These enzymes regulate phospholipid-acyl turnover for membrane repair or for the production of arachidonic acid. Specific cellular processes, including the regulation of PKC and phospholipase C-? and the modulation of Ca^{2+} transients, are controlled by arachidonic acid. This fatty acid is also the precursor to biologically active lipids including prostaglandins, leukotrienes, thromboxanes, and platelet activation factor.

The presence of an immunoreactive group I–like $sPLA_2$ in the human LES circular muscle layer has been demonstrated by Western blot analysis, [281] but the precise amino acid sequence of this enzyme remains to be determined. $sPLA_2$ may mediate LES tone through the production of arachidonic acid and its metabolites, such as prostaglandins F_2a and thromboxanes A_2/B_2, which are present in LES circular muscle. Selective group I $sPLA_2$ inhibitors and cyclooxygenase inhibitors reduce the basal tone of in vitro LES muscle strips and $sPLA_2$-induced contraction of isolated LES cells from cats and humans. [281], [282] These arachidonic acid metabolites maintain activation of G proteins such as G_{i3}, $G_{i1/2}$, and G_q. G_{i3} and G_q are coupled to phosphatidylinositol-specific phospholipase C and phosphatidylcholine-dependent phospholipase C. [196], [286] Low-level activities of these phospholipases produce threshold levels of the second messengers diacylglycerol and inositol 1,4,5-trisphosphate (IP_3). IP_3 and diacylglycerol, produced at submaximal levels, act synergistically; their interaction is dependent on Ca^{2+} release and is mediated through the sensitive PKCß, to maintain a PKCß-dependent basal tone. [208], [287], [288]

In contrast to spontaneous tone, contraction induced by maximally effective doses of the cholinergic neurotransmitter ACh is mediated through muscarinic M_3 receptors, linked to pertussis–toxin insensitive GTP-binding proteins of the G_q-G_{11} type. They activate phospholipase C, producing IP_3 and diacylglycerol. IP_3

causes the release of intracellular Ca $^{2+}$ and the formation of a Ca $^{2+}$-calmodulin complex, resulting in activation of myosin light-chain kinase and contraction through a calmodulin-dependent pathway (Fig. 9-11A). [287]

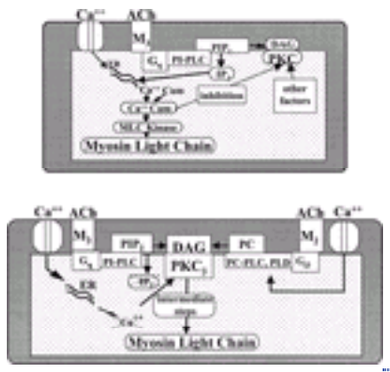

FIGURE 9-11. (**A**) Contraction of lower esophageal sphincter (LES) circular muscle in response to maximally effective doses of the cholinergic neurotransmitter acetylcholine (*ACh*) is mediated through muscarinic M $_3$ receptors, linked to pertussis toxin–insensitive G proteins of the G $_q$–G $_{11}$ type. They activate phospholipase C (*PLC*), which hydrolyzes phosphatidylinositol bisphosphate (*PIP* $_2$), producing inositol 1,4,5-triphosphate (*IP* $_3$) and diacylglycerol (*DAG*). *IP* $_3$ causes the release of intracellular Ca $^{2+}$ in levels sufficient to form a Ca $^{2+}$-calmodulin (*Ca* $^{++}$*Cam*) complex. The Ca $^{2+}$-calmodulin complex activates myosin light-chain (*MLC*) kinase, resulting in contraction by means of a calmodulin-dependent pathway. In addition, activated calmodulin may inhibit protein kinase C (*PKC*), eliminating any PKC-dependent contributions. (**B**) In a model of acute experimental esophagitis (*AE*) in the cat, resting in vivo LES pressure, spontaneous in vitro tone, levels of IP $_3$, and releasable intracellular Ca $^{2+}$ stores were reduced. Because the release of Ca $^{2+}$ from intracellular stores is reduced in AE, the available Ca $^{2+}$ may be insufficient to activate calmodulin; and thus, a PKC-dependent pathway may be unmasked that otherwise would be suppressed by calmodulin activation. After AE, the contribution of M $_3$ receptors, G $_{q/11}$, and phosphatidylinositol-specific PLC (*PI-PLC*) is reduced. M $_2$ receptors, G $_{i3}$-type G proteins, and phosphatidylcholine-dependent PLC and phospholipase D (*PC-PLC, PLD*) are activated and produce diacylglycerol, which, in turn, causes contraction through a PKC-dependent pathway. These changes in the functional signal transduction pathway are mimicked in normal LES muscle by acute depletion of intracellular Ca $^{2+}$ stores by thapsigargin and may therefore be related to the impaired release of Ca $^{2+}$ from intracellular stores, which arises from both impaired production of IP $_3$ and depletion of releasable Ca $^{2+}$ stores subsequent to induction of AE. *ER,* endoplasmic reticulum.

Therefore, unlike LES tone, which is associated with submaximal phospholipase C activity and activation of a PKCß-dependent pathway, maximal cholinergic stimulation activates a calmodulin-dependent pathway. The mechanisms responsible for a switch from a PKC-dependent to a calmodulin-dependent pathway are not entirely clear. They may result from the different Ca $^{2+}$ requirements of calmodulin and PKC. Lower Ca $^{2+}$ levels are required for PKC activation than for calmodulin activation. [286], [287], [289] For instance, relatively low (180 nmol/L) cytosolic Ca $^{2+}$ levels can support contraction induced by the PKC agonist diacylglycerol but not by calmodulin, which requires Ca $^{2+}$ levels approaching 1 µmol/L. [287] In addition, when Ca $^{2+}$ levels are elevated sufficiently to activate calmodulin, calmodulin may inhibit PKC. [290], [291] and [292] Thus, it is possible that at Ca $^{2+}$ levels insufficient to activate calmodulin, contraction will be PKC dependent. In contrast, at Ca $^{2+}$ levels sufficient to fully activate calmodulin, the contraction will be calmodulin dependent, and PKC activity will be inhibited.

These observations may be of some help in understanding the following changes reported in a model of acute experimental esophagitis in the cat. Repeated perfusion of the esophageal lumen with 0.1 N hydrochloric acid for 3 to 4 days cause a reduction in resting in vivo LES pressure, [293] spontaneous in vitro tone, levels of 1,4,5-IP $_3$, and releasable intracellular Ca $^{2+}$ stores. [223], [224], [289] Acute experimental esophagitis also causes a shift in the intracellular pathway mediating the response to a maximally effective dose of ACh from a calmodulin-dependent to a PKC-dependent pathway. [286] After acute experimental esophagitis, contraction induced by a maximally effective dose of ACh is mediated through M $_2$ muscarinic receptors, linked to G $_{i3}$-type G proteins, which activate phosphatidylcholine-dependent phospholipase C and phospholipase D to produce diacylglycerol. Diacylglycerol causes contraction through a PKC-dependent pathway (Fig. 9-11B). These changes in the functional signal transduction pathway are mimicked in normal LES muscle by acute depletion of intracellular Ca $^{2+}$ stores by thapsigargin. [286] Therefore, they are related to the impaired release of Ca $^{2+}$ from intracellular stores. This impairment arises from both impaired production of IP $_3$ [224] and depletion of releasable Ca $^{2+}$ stores [289] subsequent to the induction of acute experimental esophagitis. Because the release of Ca $^{2+}$ from intracellular stores is reduced in acute experimental esophagitis, the available Ca $^{2+}$ may be insufficient to activate calmodulin; thus, a PKC-dependent pathway is unmasked that would otherwise be suppressed by calmodulin activation. Depletion of releasable Ca $^{2+}$ by inflammation secondary to acute experimental esophagitis may be the central event from which all other observed changes follow.

The significance of these subchronic changes in the cat to the understanding of esophagitis in humans, in whom gastroesophageal reflux disease is likely to develop over a longer period, remains to be established. In a chronic model of esophagitis obtained by performing a myotomy of LES circular muscle, we find similar, if less accentuated, endoscopic, histological, and functional changes 6 months after surgery. [294] Metaplasia was present in some specimens 10 months after myotomy. [295] In addition, in the chronic model, the suppression of hydrochloric acid secretion, either after the onset of mild chronic esophagitis or at the time of myotomy, reverses or prevents the changes in smooth muscle signal transduction, presumably by inhibiting or preventing the injury caused by reflux. [294]

Relaxation

Transient Relaxation At times, particularly after meals, reflux of gastric contents may occur as a result of transient relaxations of the LES (TLESRs) [243] unrelated to swallowing or secondary peristalsis. [154], [296], [297] and [298] TLESRs occur in healthy persons, but they are more frequent in patients with gastroesophageal reflux disease. [154], [298] In healthy persons, TLESRs are most likely associated with expulsion of air from the stomach, [299], [300] whereas in patients, higher percentages of TLSERs are associated with reflux. [301], [302] In patients, TLESRs are the most common mechanism of reflux, accounting for the largest proportion of reflux episodes. [297], [298] The proportion of reflux episodes related to TLESRs, however, is greater in patients without endoscopic evidence of reflux esophagitis, in whom reflux occurs almost exclusively because of TLESRs, and it decreases with increasing severity of the disease. In patients who have severe esophagitis, the prevalence of reduced LES basal pressures probably plays a greater role in facilitating TLESR-unrelated reflux. [297], [303] Vagal pathways and the hindbrain control the occurrence and pattern of TLESRs, [304] although many aspects of these mechanisms are not well understood. [243], [305] TLESRs occur more frequently in the postprandial state when the stomach accommodates the meal by a receptive relaxation of the fundus; the resultant distention relaxes the LES, perhaps to facilitate belching. TLESRs may represent a silent belch. [299], [300] As the pH of gastric contents decreases, the probability of TLESRs increases. [306] In addition, pharyngeal stimulation, (e.g., by intubation), [307] which by itself may induce LES relaxation, increases TLESR frequency. [308], [309], [310], [311] and [312] Weak swallows also may evoke LES relaxations, without triggering an esophageal response in humans, [148], [311] or in the opossum, in which isolated and transient LES relaxations are also triggered by weak electrical stimulation of the vagus. [313] The latter non–swallow-associated relaxations, however, do not involve inhibition of the crural diaphragm, as occurs with swallow-induced relaxation [240] or TLESRs, nor do they involve the esophageal common cavity and acid reflux, and therefore, they may not be representative of proper TLESRs. [311] TLESRs triggered by gastric distention may use NO and CCK as neurotransmitters, because they are increased by intravenous CCK and are blocked by NO synthase inhibitors [314] and by CCK-A antagonists. [315], [316], [317] and [318] The frequency of TLESRs increases during intravenous infusions of CCK and after fatty meals. [319], [320] CCK infusion and fatty meals cause a rise in circulating CCK levels; the associated increase in TLESRs is mediated through CCK-A receptors, because CCK-A antagonists inhibit the increase in TLESRs. Muscarinic receptors may be involved in TLESRs, because TLESRs are also antagonized by atropine. [312], [321], [322], [323] and [324] GABA agonists, such as baclofen, inhibit TLESRs, [304], [325], [326] and [327] possibly by acting on receptors located in the DMV. [5], [328] It is thought that afferents located in the subdiaphragmatic vagus, particularly in its ventral branch, [14], [25], [243] initiate the non–swallow-induced relaxations that occur during belching, TLESRs, gastroesophageal reflux, and vomiting. [329] The afferent and efferent neural pathways responsible for swallow- and non–swallow-induced relaxations have been compared in the mouse. [329] The efferent limb of both swallow-associated and non–swallow-associated relaxations lies in the preganglionic vagal inhibitory pathway to the postganglionic nitrergic neurons in the LES. [315] Both relaxations can be blocked by bilateral cervical vagotomy, cervical vagal cooling, or chemical blockers of

neuronal NO synthase. [243], [330], [331] The afferent arms of these two types of relaxation, however, differ from one another. The afferent arm of the swallow-induced relaxation lies in the pharyngeal and superior laryngeal nerves, and the central neural circuit for the swallowing reflex is in the medullary subnuclei. [23], [26], [27], [101] Electrophysiological and tracer studies in the rat and larger animal species and c-*fos* expression in the mouse have further localized the brainstem circuit of the swallowing reflex to include interneurons in interstitial, intermediate, and central subnuclei, and motor neurons in the nucleus ambiguus and in the DMV. [332], [333] and [334] Non–swallow-induced relaxations, in contrast, are initiated through gastric afferents in the subdiaphragmatic vagus and activate neurons in the medial, dorsomedial, and commissural solitary subnuclei and motor neurons in the caudal part of the DMV. [329]

Swallow-Induced Relaxation The passage of an ingested bolus is expedited by LES relaxation and by the force of peristaltic contractions. Within the first 2 seconds after swallowing, LES resistance to bolus transit is caused by resting LES pressures. As the LES relaxes, it is passively forced open by the bolus that has been propelled by the peristaltic wave. Although accurate measurements are difficult because of motion artifacts resulting from longitudinal esophageal movement during swallowing, it is estimated that the LES relaxes fully. LES relaxation occurs within 2 seconds of deglutition, at a time when the peristaltic wave appears in the middle esophagus, at the beginning of the smooth muscle segment. Within 1 second, LES pressures fall to equal those of the stomach or esophagus, depending on the location of the pressure sensor within the LES. When ingested boluses reach the LES, it is relaxed but closed. The bolus forces the LES open by its own weight or with the aid of the peristaltic contraction. Deglutition induces an initial inhibition of the entire smooth muscle of the esophagus, and LES relaxation is part of this inhibitory response. After 5 to 7 seconds, the LES recovers its initial pressure and then undergoes an aftercontraction, which probably represents the end of the peristaltic pressure wave as it reaches the distal end of the esophagus. [149] Circular muscle strips obtained from the LES proper exhibit relaxation only, but more proximal strips reveal relaxation followed by an after-contraction, perhaps because of the presence of mixed LES and esophageal muscle fibers. [229] The inhibitory innervation that mediates LES relaxation on swallowing or as a result of gastroesophageal distention has been studied extensively. [179], [335], [336] LES relaxation induced by swallowing is mediated by the vagus nerve, which synapses with intramural inhibitory neurons. Electrical stimulation of decentralized efferent vagal fibers in vivo and field stimulation of LES muscle strips in vitro cause full relaxation, with concomitant circular muscle hyperpolarization. [112], [337] The vagus nerve uses ACh as a ganglionic transmitter acting through nicotinic and muscarinic receptors, because transmission is blocked by a combination of hexamethonium (i.e., nicotinic blocker) and atropine (i.e., muscarinic blocker). LES relaxation can be triggered by distention from both sides of the esophagogastric junction. [338] This relaxation induced by esophageal distention is volume dependent; it is brief during inflation with small volumes but persists during inflation with large volumes. [339], [340] The relaxation is unaffected by cervical vagotomy and therefore is mediated by intramural neurons. The intramural neurons of these reflexes use NANC inhibitory neurotransmitters, and relaxation is not affected by adrenergic or cholinergic blockers. It is only antagonized by tetrodotoxin, which denervates smooth muscle without affecting its contractile function. [341] Convincing evidence supports a role for NO as a neurotransmitter responsible for LES relaxation. NO is produced by NO synthase from the amino acid L-arginine. Three isoforms of NO synthase derived from three different genes have been identified: neuronal (type I), inducible (type II), and endothelial (type III). Inducible NO synthase is not present under physiological conditions; it is induced during inflammation and tissue injury. Neuronal and endothelial forms of NO synthase are constitutively present and play a role under physiological conditions. Neuronal NO synthase is a soluble cytosolic enzyme present primarily in nerves and is the source of NO that is involved in neurotransmission, whereas endothelial NO synthase is particulate and membrane bound and is present mainly in endothelial cells and smooth muscle cells. [342] Endothelial NO synthase produces NO that is involved in producing endothelial-dependent relaxing factor, [343] and it has been proposed to play a role in neuromuscular transmission. [344] The enzyme NO synthase has been identified in neurons of the myenteric plexus and has been found to be colocalized with VIP, which may be a second inhibitory neurotransmitter in the LES as well as in the esophageal body. NO is released on neural stimulation in the esophagus, LES, and stomach. [76], [185], [345], [346] and [347] In the LES, NO has a marked inhibitory effect. Many studies performed in vitro and in vivo have shown that inhibition of NO synthesis by NO synthase inhibitors results in blockade of neurally mediated LES relaxation, and NO-induced LES relaxation is associated with an increase in cyclic guanosine monophosphate (cGMP), as occurs during neural stimulation. [45], [187], [310], [348], [349], [350] and [351] Conclusive evidence that neuronal NO synthase plays a role in LES relaxation has been obtained by comparing wild-type and genetically engineered, neuronal NO synthase–deficient mice. LES ring preparations developed spontaneous tone in all animals. In wild-type mice, electrical field stimulation produced frequency-dependent relaxation, which was abolished by the NO synthase inhibitor *N*(omega)-nitro-L-arginine methyl ester, whereas in neuronal NO synthase–deficient mice, the relaxation was absent. [352] Evidence has been presented in support of VIP as one of the neurotransmitters of these neurons. VIP-containing neurons have been demonstrated in the submucosal plexus by immunofluorescent methods. [68], [71], [353], [354] VIP relaxes the LES in vivo and in vitro by direct muscle action. [256], [355], [356] Electrical stimulation of in vitro LES muscle strips relaxes the LES and releases VIP in the muscle bath, and VIP antiserum partially reduces the LES relaxation induced by VIP and evoked by vagal or field stimulation. [356], [357] There is some evidence that PHI in the cat and, to a lesser extent, CGRP in the opossum also may participate as inhibitory neurotransmitters. [358], [359] Like VIP, PHI and CGRP relax the LES fully or in part by a direct action on the muscle. [358], [359] and [360] PHI is of some interest because it is derived from the same precursor as VIP and coexists with VIP in the same neurons. [361] PACAP-27– and PACAP-38–immunoreactive nerve structures have also been found in the cat and the human LES, with an abundance in the circular smooth muscle layer. PACAP-27 immunoreactivity often was colocalized with VIP immunoreactivity. [74] PACAP, however, has a less potent relaxant action than VIP, and its functional importance remains to be established. It is thought that VIP released from nerve terminals acts on neural terminals to release NO and on gastric muscle cells to stimulate production of NO by the muscle. [344], [362], [363], [364] and [365] These observations have been confirmed in part by studies of mutant, NO synthase–deficient mice, which suggest that VIP is a prejunctional neurotransmitter that causes NO release by activating a "neuronal" NO synthase. [366] The finding of a small amount of NO synthase in intestinal muscle has provided further confirmation. [367] The notion that multiple neurotransmitters may interact to produce LES relaxation may resolve inconsistencies and discrepancies that follow from the assumption that any one neurotransmitter is the only one responsible for LES relaxation. Reports of the colocalization of NO synthase, VIP, PACAP, CGRP, and galanin in the myenteric neurons of the distal esophagus support this concept. [46], [368], [369] Several investigations suggest that carbon monoxide also may contribute to LES relaxation. Carbon monoxide is generated by heme oxygenase isoenzymes in the degradation of heme- containing molecules. In the LES and other sphincters, heme oxygenase is present in neuronal and nonneuronal cells, and it is colocalized with VIP and NO synthase in myenteric neurons. [370] Similar to NO, carbon monoxide reduces spontaneous LES tone by increasing cGMP but not cAMP levels. Carbon monoxide may contribute to VIP-, PHI-, and PACAP-induced relaxations, because inhibition of the carbon monoxide–producing enzyme heme oxygenase causes a rightward shift for the relaxation responses to these peptides. [371] Anatomic evidence for the presence of a carbon monoxide–producing enzyme is strong, [371], [372], [373] and [374] whereas functional evidence is considerably weaker. Certain metalloporphyrins, which are inhibitors of heme oxygenase and have been widely used as pharmacological tools to establish a messenger role for carbon monoxide, also are associated with a large range of nonspecific effects. [375] For example, zinc protoporphyrin attenuates LES relaxation induced by VIP and other adenylate cyclase–mediated smooth muscle relaxants (e.g., isoproterenol). [376], [377] In summary, the esophagus functions as an active neuromuscular conduit that produces primary peristaltic contractions to transport a bolus from the pharynx to the stomach. Prevention of retrograde reflux of gastric contents is accomplished by maintaining tonically contracted LES and UES and by the clearance function of secondary peristalsis. Primary peristalsis is initiated by swallowing, which is voluntary. Its continuation is mediated reflexly by sensory neurons with input to the swallowing center located in the brainstem. The swallowing center initiates a pattern of excitation and inhibition of medullary motor neurons; interacts with other brainstem centers; and coordinates cessation of breathing, initiation of swallowing, opening of the UES, and peristalsis in the striated portion of the esophagus. Peristalsis in the smooth muscle segment of the esophagus depends on peripheral mechanisms in the intramural plexuses, which evoke peristalsis by activating inhibitory and cholinergic excitatory intramural neurons, but it also can be influenced by the sequencing of motor neurons in the swallowing center, resulting in progressive stimulation of intramural cholinergic neurons. The interplay between these inhibitory and excitatory neurons produces propulsive contractions that travel the entire length of the esophagus and LES relaxation. Whereas UES tone is dependent primarily on continued vagal input, specialized myogenic mechanisms contribute to the maintenance of LES tone.

CHAPTER 10

William L. Hasler

PHYSIOLOGY OF GASTRIC MOTILITY AND GASTRIC EMPTYING

Motor activity of the stomach serves distinct roles under fasting and fed conditions. Interdigestive patterns clear the stomach of undigested debris and sloughed epithelial cells. After eating, the stomach accommodates the ingested bolus, which is then ground and dispersed into fine particles that are delivered to the duodenum at a controlled rate. The stomach can be divided into three functional regions: the proximal stomach (cardia, fundus, and proximal body), the distal stomach (distal body and antrum), and the pylorus. Coordinated actions of these regions with feedback control from the small intestine regulate the emptying of gastric contents. Gastric motor activity is controlled by myogenic properties, extrinsic and intrinsic innervation, circulating hormones, and external influences from the central nervous system.

SMOOTH MUSCLE CHARACTERISTICS OF THE STOMACH

The complex anatomic orientation of the gastric smooth muscle layers serves the needs of regulating nutrient dispersion and emptying. Located below the serosa, the longitudinal muscle layer is prominent in the distal stomach and is mostly continuous with the duodenal longitudinal layer, although some fibers terminate in the pylorus. The circular muscle layer, located below the longitudinal layer, is prominent in all gastric regions. The gastric circular layer is electrically isolated from its duodenal counterpart by a connective tissue septum at the pylorus. The innermost and least complete muscle layer, the oblique layer, is present on the lesser curvature near the cardia and is continuous with the gastroesophageal junction. Specialized pyloric smooth muscle is composed of two circumferential loops that coalesce over the lesser curvature. The pylorus is mainly circular smooth muscle, but it is reinforced by antral longitudinal muscle fibers and by connective tissue from the mucosa and smooth muscle.

INNERVATION OF THE STOMACH

Gastric smooth muscle is innervated by extrinsic nerves that relay information to and from the extragastrointestinal ganglia, the spinal cord, and the central nervous system, and by intrinsic nerves in the gastric wall. The extrinsic supply is provided by the vagus and splanchnic nerves, which contain both efferent and afferent fibers. The major intrinsic innervation projects from the myenteric plexus at the interface between the longitudinal and circular layers. The submucous plexus along the lumenal aspect of the circular layer may play a minor role in some reflex activities.

Efferent Extrinsic Innervation

Only a few vagal fibers provide efferent modulatory input to the gastric myenteric plexus. [1] However, immunohistochemical measurement of myenteric c-*fos* expression in rats indicates a widespread functional efferent vagal innervation of the enteric nervous system. [2] The vagus contains three groups of efferent fibers: preganglionic parasympathetic cholinergic nerves, which supply excitatory enteric neurons; preganglionic cholinergic nerves, which supply inhibitory enteric neurons; and sympathetic fibers from the superior cervical and stellate ganglia. [3] Cell bodies of most efferent vagal fibers reside in the dorsal motor nucleus of the vagus. [4] Stimulation of efferent vagal cholinergic neurons activates nicotinic receptors within enteric ganglia and increases gastric motor activity. Most efferent fibers exhibit a low threshold to electrical stimulation. Some efferent fibers that exhibit a high threshold to electrical stimulation inhibit motor activity through the release of nitric oxide (NO) and vasoactive intestinal polypeptide (VIP). [5], [6]

Sympathetic innervation from splanchnic nerves originates from neuronal cell bodies in the prevertebral celiac ganglia. Preganglionic cholinergic neurons project from the inferomedial spinal cord to the prevertebral ganglia, where they synapse through nicotinic receptors. Postganglionic noradrenergic neurons project to the enteric ganglia through the splanchnic nerves and generally inhibit excitatory myenteric transmission. [7] Smaller numbers of sympathetic fibers project to the smooth muscle, where they also have inhibitory motor effects.

Afferent Extrinsic Innervation

Afferent fibers outnumber efferent fibers by tenfold in the vagus and by threefold in the splanchnic nerves. Vagal afferents terminate in the nucleus tractus solitarius and area postrema. [8] Nucleus tractus solitarius neurons project to the dorsal motor nucleus of the vagus and nucleus ambiguus and to higher cerebral centers. [9] Sensory information from the stomach is also transmitted to the dorsal horn of the spinal cord through the splanchnic nerves, from where second-order neurons project centrally.

The stomach is richly supplied with sensory fibers (Fig. 10-1). Free mucosal nerve endings respond to stroking or to chemical stimuli such as hydrochloric acid. [10] Smooth muscle stretch receptors or mechanoreceptors are activated during passive distention or active contractions or if they are exposed to extreme temperatures. [11], [12] Two types of mechanoreceptors are evident. Intramuscular arrays serve as stretch receptors to mediate tonic activities, whereas intraganglionic laminar endings integrate tension and neuronal activity into propagative motor programs such as peristalsis and emptying. [13] Neurons in the nucleus tractus solitarius and the dorsal motor nucleus of the vagus are activated by gastric distention, indicating vagal transmission of sensory information from gastric mechanoreceptor activation. [14] Mesenteric and serosal receptors respond to tension on the viscera and forceful contractions and may mediate perception of visceral pain. In many gut regions, nociceptive sensory input is carried by the splanchnic nerves. Afferent pathways that mediate extended neural reflexes may be vagovagal, vagosplanchnic, or splanchnosplanchnic, and they are further modified by central nervous system input.

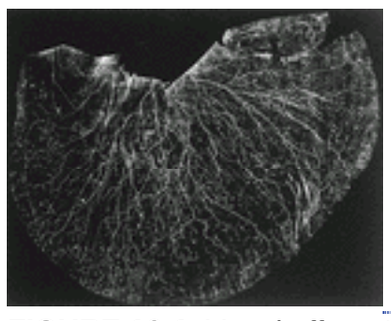

FIGURE 10-1. Vagal afferent innervation of the stomach. The fiber bundles enter from the lower esophageal sphincter (**top**) and radiate to the greater curvature. In the antrum (**upper right**), the gastric branch of the vagus courses across the pylorus to innervate the proximal duodenum. (From ref. [13].)

Intrinsic Innervation of the Stomach

The enteric nervous system possesses the components needed for complete reflex activities, including afferent neurons, interneurons, and motor neurons, and it can initiate many physiological motor patterns in the absence of extrinsic input. Myenteric neurons contain numerous neurotransmitters. Excitatory neurons containing acetylcholine and tachykinins (i.e., substance P and neurokinin A) project to circular muscle. Inhibitory motor neurons containing NO and VIP project aborally and mediate the relaxation phase of peristalsis. [15], [16] The actions of NO are mediated by stimulation of cyclic guanosine monophosphate–dependent kinase, whereas VIP acts through cyclic adenosine monophosphate generation. [17] Serotonin serves a modulatory role in enteric neurotransmission. In some species, excitatory ascending pathways are activated by serotonin (5-hydroxytryptomine, 5-HT) acting on 5-HT $_3$ receptors, whereas by occupying 5-HT $_{1P}$ receptors, serotonin can produce descending inhibition. [18] Other relevant modulators include norepinephrine, endogenous opioids, adenosine triphosphate, peptide histidine isoleucine, ?-aminobutyric acid, neuropeptide Y, gastrin-releasing peptide (GRP), and histamine. [16], [19], [20], [21] and [22]

Both stimulatory and inhibitory neurons in the myenteric plexus interact with the interstitial cells of Cajal in the circular muscle of the proximal gut. [23] Interstitial cells of Cajal are histologically distinct from neurons and smooth muscle cells. In mutant animals deficient in intramuscular interstitial cells, cholinergic excitatory and nitrergic inhibitory functions are impaired, indicating an important physiological role for interstitial cells of Cajal in gastric neurotransmission. [23]

REGIONAL MOTOR PATTERNS IN THE STOMACH AND DUODENUM

Proximal Stomach

The proximal stomach serves to accommodate and store ingested food, to regulate intragastric pressure, and to propel chyme into the distal stomach in a tonic fashion. To accomplish these tasks, the proximal stomach possesses distinct myogenic and neural characteristics.

Electrical Activity The resting membrane potential decreases from -48 mV in the fundus to -71 mV in the antrum. The electrical threshold for gastric contraction is -50 mV. Thus, under basal conditions, the fundus is in a state of continual partial contraction or tone, which is modulated by neural or hormonal input. Minor depolarizations or hyperpolarizations in membrane potential produce significant increases or decreases in tone, respectively. In contrast to the distal stomach, the proximal stomach does not exhibit rhythmic fluctuations in membrane potential.
Contractile Activity The proximal stomach exhibits two distinct contractile patterns. Slow, sustained contractions up to 6 minutes in duration constitute 80% of proximal gastric motor activity and determine the basal intragastric pressure. [24] Superimposed on these slow tonic changes are more rapid phasic contractions up to 30 seconds in duration. Regulation of proximal gastric motility allows the maintenance of a stable intragastric pressure in response to ingested volumes in excess of 1 liter. [25] In dogs, intragastric pressure initially drops after eating and then increases above basal levels 30 to 90 minutes postprandially. [26] In humans, intragastric pressure decreases from 12.9 to 9.8 mm Hg in the first 30 minutes after eating; tone does not return to basal levels until all solids have emptied from the stomach. [27], [28] Maintenance of gastric pressure is controlled by two proximal gastric reflexes: receptive relaxation and gastric accommodation. Receptive relaxation is the reduction in proximal gastric tone that occurs with the act of swallowing. Transfer of the swallowed bolus into the stomach is not required to activate receptive relaxation; the reflex occurs with a dry swallow or mechanical stimulation of the pharynx or esophagus. [29] Gastric accommodation, the relaxation of the proximal stomach in response to gastric distention, is mediated by stimulation of gastric mechanoreceptors and does not require pharyngeal or esophageal stimulation. [29], [30] Because of the accommodation reflex, 80% of fluid placed in the stomach is retained in the fundus and proximal body. Receptive relaxation and accommodation are mediated by vagovagal reflex arcs through the nucleus tractus solitarius. [31]
Neurohumoral Control of Motility Extrinsic innervation exerts an important regulatory influence on proximal gastric tone. Vagal cooling reduces proximal gastric motor activity and demonstrates basal vagally mediated tone. [32] Truncal or proximal gastric vagotomy produces decreased gastric distensibility and increased intragastric pressure after bolus ingestion. [33], [34] Electrical activation of low-threshold vagal fibers increases fundus tone, whereas stimulation of high-threshold fibers relaxes the proximal stomach. [6], [35] Sympathetic nerves also modulate proximal gastric activity. Splanchnicectomy augments the increase in intragastric pressure evoked by vagal activation. [36] Several mediators modify motor activity in the fundus. NO is a major physiological mediator of proximal gastric relaxation. The nitrergic agent nitroglycerin relaxes the proximal stomach, whereas administration of NO synthase inhibitors increases fundic tone, an effect blocked by vagal cooling or atropine; this finding indicates that NO acts presynaptically on vagal cholinergic efferent nerves. [37] Receptive relaxation is postulated to result from VIP release by fundic nerves. [6], [29] Agents that relax the proximal stomach or enhance fundic compliance include cholecystokinin (CCK), secretin, VIP, gastrin, somatostatin, dopamine, GRP, glucagon, bombesin, and the a $_2$-adrenergic receptor agonist clonidine, whereas motilin and thyrotropin-releasing hormone (TRH) increase fundic pressure. [38], [39] and [40] Secretin relaxes the stomach by activating vagal afferent pathways originating in the gastroduodenal mucosa. [41] Pentagastrin-evoked relaxation is mimicked by histamine and is abolished by acid-suppressing agents, suggesting mediation by a mechanism involving gastric secretion.
Reflex Modulation of Motility Neurohumoral mechanisms participate in the reflex control of proximal gastric motility by other regions of the gut. Duodenal balloon inflation reduces fundic tone through vagal and splanchnic nonadrenergic, noncholinergic pathways. [42] Vagal application of the sensory neurotoxin capsaicin attenuates the decrease in fundic pressure after duodenal distention at low inflation volumes. Capsaicin treatment of the celiac and superior mesenteric ganglia reduces the response to all volumes of balloon inflation, indicating activation of vagal sensory pathways by low levels of distention and activation of splanchnic nerve pathways by more intense stimuli. [43] Other enterogastric reflexes, such as the inhibition of proximal gastric activity by duodenal protein or lipid perfusion, are variably mediated by vagal nonadrenergic, noncholinergic pathways possibly involving NO. [42], [44] Enterogastric reflexes are not strictly localized to the duodenum. Colonic distention also inhibits proximal gastric motor function. As part of the ileal brake, ileal perfusion of glucose reduces fundic tone. [26] CCK is postulated to inhibit proximal gastric tone during duodenal perfusion of lipids or certain amino acids such as L-tryptophan. Capsaicin inhibits the reduction in intragastric pressure evoked by CCK, indicating participation by afferent pathways. [45] Fundic relaxations in response to duodenal acid exposure are mediated by multiple pathways. At low hydrochloric acid perfusion rates, relaxation is mediated by endogenous secretin, which acts on vagal afferent pathways. [46] Higher acid loads induce CCK release and have direct action on afferent nerve pathways.

Distal Stomach

The distal stomach exhibits electrical and contractile properties distinct from those of the proximal stomach that serve to grind and triturate solid food and to regulate gastric emptying of solid and, to a lesser extent, liquid meals.

Rhythmic Electrical Activity The distal stomach exhibits a more negative membrane potential than the proximal stomach. Superimposed on the resting membrane potential is a rhythmic depolarization, known as the *slow wave,* consisting of an initial rapid depolarization followed by a more prolonged plateau potential (Fig. 10-2). A site along the greater curvature in the proximal gastric body exhibits the highest oscillatory frequency (3 cycles/min [cpm] in humans) and acts as the dominant pacemaker to entrain the rest of the stomach. [47] The cells of origin of pacemaker activity are believed to reside in the interface between the longitudinal and circular muscle layers. Interstitial cells of Cajal exhibit rhythmic depolarizations in the small intestine and colon and are thought to generate slow wave activity in these organs. Interstitial cells of Cajal are prominent in the myenteric region of the gastric antrum and corpus and may serve a similar pacemaker role in the stomach. [48] Although the slow wave is a myogenic characteristic, altered neural input can destabilize slow wave rhythmicity. Acute vagotomy induces slow wave disorganization with generation of ectopic antral pacemakers. [49]

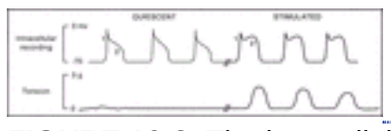

FIGURE 10-2. The intracellular electrical activity of distal gastric smooth muscle and the resultant contractile response are displayed under quiescent conditions and after stimulation with a contractile agonist. In the unstimulated state, distal gastric smooth muscle exhibits rhythmic electrical activity with an initial upstroke (*1*), followed by a plateau potential (*2*). Because the amplitude of this electrical depolarization does not reach a critical threshold, no contraction occurs. With stimulation, the plateau is prolonged and enhanced, so a threshold depolarization is achieved, resulting in phasic contractions in the distal stomach. (Adapted from Kim CH. Electrical activity of the stomach: clinical applications. Mayo Clin Proc 1986;61:205.)

Slow waves are propagated distally through the smooth muscle. Unlike the heart, the stomach has no specialized electrical conduction pathways. Conduction is faster circumferentially than along the longitudinal axis; therefore, the slow wave propagates in well-defined rings of depolarization. [50] Slow wave propagation is slightly faster along the greater curvature, such that myoelectric activity from the greater and lesser curves reach the pylorus simultaneously. The propagation velocity increases from 0.5 cm per second in the gastric body to 4 cm per second in the distal antrum. Slow waves do not propagate proximally into the fundus because of its less negative resting membrane potential and other properties that limit its excitability. Gastric myoelectric rhythmicity matures late in fetal and postnatal development. The percentage of time that normal 3 cpm slow wave activity is demonstrable increases from 37% in preterm infants to 66% 6 months after birth. [51] Anatomic correlates of these observations indicate that neuronal networks within the enteric nervous system are immature at birth, and connections between the interstitial cells of Cajal and smooth muscle cells are poorly coupled. [52]

Contractile Activity Under quiescent conditions, the gastric slow wave is of insufficient amplitude to evoke significant contractions. Although the initial rapid depolarization of the slow wave may induce trivial pressure waves, the plateau potential remains more negative than the contractile threshold. Contractile agonists increase the duration and amplitude of the plateau potential (see Fig. 10-2) and, in some cases, induce action potentials (+100 ms) that are intense depolarizations superimposed on the plateau potential. [53] These events provide the depolarization needed to exceed the contractile threshold. In contrast, relaxing agents reduce the plateau potential amplitude or duration or prevent the stimulatory effects of contractile agonists, although VIP inhibits motor activity without altering slow wave morphology, suggesting the involvement of other mechanisms. [54] Because the contractile threshold is exceeded only during each plateau potential, the slow wave determines the maximal distal gastric contractile frequency (3 cpm in humans). Phasic antral contractions may exceed 100 mm Hg, migrating with the propagating slow wave as a ring and increasing in amplitude and velocity as the slow wave approaches the distal antrum. Because of neurohormonal input, not all ring contractions traverse the entire distal stomach. Some contractions subside before reaching the pylorus, whereas others initiate in the distal antrum. The distal stomach exhibits distinct phasic motor patterns under fasting and postprandial conditions. The fasting *migrating motor complex* (MMC) is a stereotypical pattern that clears the stomach of undigested debris. Loss of the MMC in certain disease states may promote gastric bezoar formation. After eating, the MMC is replaced by a *fed contractile pattern* of variable intensity and duration that grinds and triturates the ingested nutrients.

Migrating motor complex. The MMC clears the stomach and intestine of undigested food particles, mucus, and sloughed epithelial cells during fasting and has been termed the gastrointestinal housekeeper. The MMC consists of three phases with a combined duration of 84 to 112 minutes (Fig. 10-3). [55] Phase I is a period of relative motor quiescence, representing 40% to 60% of the cycle. High-amplitude contractions are not observed during phase I, but diminutive pressure waves of +9 mm Hg in amplitude can occur in phase with the slow wave. [56] Phase II, comprising 20% to 30% of the cycle, exhibits increasing but irregular contractions. Phase III is a 5- to 10-minute period of intense, rhythmic, lumenally occlusive contractions that begin in the gastric body and propagate unimpeded to the pylorus. The frequency of contractions during phase III approaches that of the slow wave. [55] Of the phase III complexes, 71% begin in the stomach, whereas 18% originate in the proximal duodenum, and 10% and 1% start in the distal duodenum and proximal jejunum, respectively. [57] Phase IV, a brief period of transitional motor activity from phase III to phase I, has been described. MMC cycling exhibits diurnal variation, with fewer complexes occurring during sleep (0.25/h) than wakefulness (0.64/h). [58] Phase I is prolonged during sleep, whereas phase II is shortened. The MMC is established early in life, although some infants exhibit an immature pattern of isolated pressure waves alternating with clustered phasic contractions. [59] MMC activity is not impaired in the elderly. [60] MMC cycles are more frequent and phase III complexes are shorter in women than in men. [58]

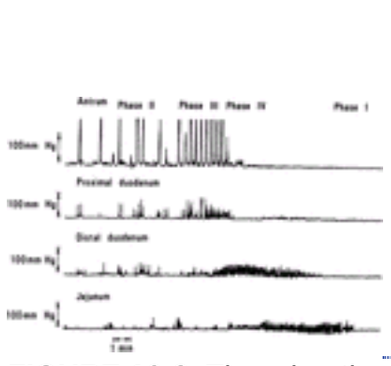

FIGURE 10-3. The migrating motor complex from a healthy human consists of four phases: phase I, a period of motor quiescence; phase II, a period of irregular contractile activity; phase III, a brief complex of intense rhythmic contractions that propagate from the distal stomach into the small intestine; and phase IV, a transitional phase back to the quiescence of phase I. (From Rees WDW, Malagelada JR, Miller LJ, Go VLW. Human interdigestive and postprandial gastrointestinal hormone patterns. Dig Dis Sci 1982;27:321.)

The propulsive characteristics of interdigestive gastric motor activity vary depending on the MMC phase. Phase III contractions are highly propagative. [55] In contrast, phase II motor activity exhibits little coordination from one gastric recording site to the next and is believed to represent a period in which fasting gastric contents are mixed. Emptying of inert liquids and endogenous secretions is more rapid during phase III than in phases I and II. [61]

Fed motor pattern. The fed motor pattern is induced 5 to 10 minutes after eating and persists as long as food remains in the stomach. Intermittent phasic contractions of irregular amplitude similar to those of phase II of the MMC comprise the fed pattern (Fig. 10-4). As with phase II, half of the slow wave cycles are associated with contractions. Fluoroscopic studies of postprandial motor activity demonstrate antral contractions that propel the ingested material distally, only to be retropelled back into the proximal stomach, thus serving to mix and grind the food. [62] Ultrasonographic investigations indicate that this distal gastric motor function shortens the gastric length and alters the configuration of the stomach. [63] Furthermore, interaction of fed gastric contractions with the incisura facilitates the breaking up of solid gastric contents.

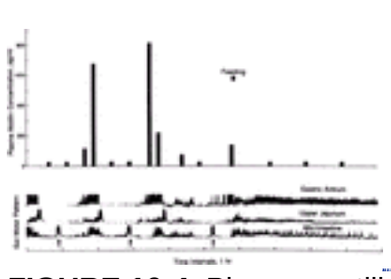

FIGURE 10-4. Plasma motilin levels during fasting and the fed state from a representative canine experiment. Fasting motor activity shows regular cycling of the migrating motor complex. Each antral phase III complex is accompanied by a significant increase in motilin concentration. After a meal, the motor pattern changes to one of irregular but continuous phasic contractions for the duration of time that food remains in the stomach. The fed motor pattern is associated with suppression of plasma motilin levels. (Adapted from ref. [82].)

Postprandial contractile amplitudes depend on the consistency and composition of the ingested material. Antral contractions evoked by eating particulate nutrients are more intense than those induced by an equivalent homogenized meal. [64] The duration of the fed period is proportional to the number of calories consumed, with fats inducing a more prolonged response than proteins or carbohydrates. [65] As little as 17 g of fat may induce a prolonged fed pattern. Nutrients are not strictly necessary to evoke the fed pattern. Sham feeding evokes transient increases in antral contractility and delays the onset of the next phase III. This phenomenon is blocked by the CCK antagonist loxiglumide, suggesting mediation by endogenous CCK. [66] Physical factors modify the characteristics of the fed pattern. The presence of plastic spheres in saline induces stronger antral contractions than a similar amount of saline alone. Increasing the viscosity with polycarbophil, a gel-forming compound, reduces antral contractile amplitudes but prolongs the fed pattern for several hours. [67] More than 50% of individuals fed continuously through an intragastric catheter revert to a fasting pattern, indicating that nutrient inhibition of interdigestive motor activity is self-limited. [68] Intravenous nutrient administration disrupts normal fasting gastric motor activity; this indicates that the systemic effects of a meal may contribute to selected components of the fed motor response. Intravenous amino acid

solutions reduce phase II duration and suppress antral phase III activity. [69]

Neurohumoral Control of Motility Neural pathways are important physiological regulators of distal gastric motor activity. Efferent vagal stimulation of low-threshold fibers evokes antral contractions that are sensitive to atropine, indicating cholinergic mediation. In contrast, stimulation of high-threshold fibers decreases antral motor activity, most likely through release of VIP, and this reduces the sensitivity of gastric smooth muscle to calcium. [6], [70] In dogs, NO synthase inhibitors increase antral contractions, whereas NO precursors decrease motor activity, indicating a physiological relaxant role for NO. [71] Administration of the phosphodiesterase inhibitor sildenafil inhibits antral motor activity by enhancing the action of endogenous NO. [72] Infusion of NO synthase inhibitors evokes MMC-like contractions in fed rats, whereas the NO donor sodium nitroprusside induces complexes similar to the fed pattern, suggesting that NO may be the final mediator controlling fasting and postprandial motility in some species. [73] Hormones and neurotransmitters can modify distal gastric electromechanical function. CCK, bombesin, substance P, and some opiates increase antral contractions, but the physiological relevance of these effects is unknown. [74] Conversely, secretin, somatostatin, glucagon, GRP, TRH, neurotensin, calcitonin, peptide YY, prostaglandin E_2, the a_1-adrenergic receptor agonist phenylephrine, and the a_2-adrenergic receptor agonist clonidine inhibit antral motor activity. [75] Some compounds have dual effects; for example, the 5-HT_3 receptor agonist m-chlorophenylbiguanide increases antral motility under fasting conditions but reduces the amplitude of postprandial antral contractions. [76]

Neurohumoral regulation of the MMC and fed motor pattern. Neurohumoral control of the gastric MMC is complex and incompletely understood. Phase III persists after sectioning of the vagus and splanchnic nerves. Autotransplantation of the stomach or the entire gut with denervation of all extrinsic input does not interrupt spontaneous phase III events in the excluded gastric segment, suggesting that intact extrinsic innervation to the stomach is not needed for phase III initiation. [77], [78] Nevertheless, vagal recordings show increased efferent firing during antral phase III, suggesting participation of vagal pathways. Additionally, vagal cooling abolishes antral phase III patterns; this finding indicates that fasting gastric motor function can be modulated by the vagus. [79] The inhibition of phase III by vagal cooling is not reversed by the a- and ß-adrenergic receptor antagonists phentolamine and propranolol, showing that unopposed adrenergic activity is not responsible for the phenomenon. [80] In contrast to its effects on phase III activity, bilateral vagotomy decreases or abolishes gastric phase II, suggesting that the different MMC phases are regulated by distinct pathways. [81] Many lines of evidence suggest the presence of a hormonal mediator of gastric phase III activity. Initiation of antral phase III correlates temporally with elevations in motilin, a hormone localized to duodenal mucosal cells (see Fig. 10-4). [82], [83] Premature antral phase III is inducible by motilin infusion in dogs and humans. Infusion of motilin antibodies, which suppress circulating motilin levels, abolishes gastric phase III in dogs for several hours. [84] Resection of the duodenum (and presumably most motilin-secreting tissue) eliminates antral phase III in dogs. [85], [86] Motilin stimulates antral phase III in part through cholinergic pathways, because atropine reduces its contractile effects. [87] Duodenal phase III activity, however, can persist in the presence of atropine, indicating control by noncholinergic mechanisms. Depletion of endogenous serotonin by *p*-chlorophenylalanine suppresses spontaneous and motilin-induced gastric phase III, suggesting involvement of serotonergic pathways. [88] Motilin also releases NO. [89] NO synthase inhibitors increase MMC frequency and shorten the duration of phase I in humans; this indicates modulation of MMC activity by endogenous NO pathways. [90] Similarly, in dogs, inhibition of NO synthesis induces premature antral phase III. [91] These effects are associated with increased motilin levels during inhibition of NO synthesis and indicate regulation of motilin release by endogenous NO pathways (Fig. 10-5). [91] The physiological stimulus for motilin release is unknown, although motilin levels increase after vagal stimulation. Extrinsic denervation of the upper gut, however, does not interrupt motilin cycling. [78] Evidence suggests that there is plasticity in the neural regulation of the gastric MMC. In dogs who underwent resection of the pylorus, duodenum, and upper jejunum, MMC cycling resumed 1 to 4 months postoperatively. Reemergence of the MMC was independent of motilin cycling, but it relied on vagal cholinergic and adrenergic efferent pathways. [92]

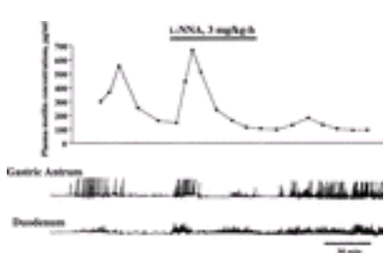

FIGURE 10-5. Effects of nitric oxide (*NO*) synthase inhibition with $N^?$-nitro-L-arginine (*L-NNA*) on gastroduodenal motility and plasma motilin release in a fasted dog. L-NNA induced premature phase III contractions in the antrum and duodenum with an associated increase in plasma motilin levels. (From ref. [91].)

Motilin receptors are present on antral smooth muscle and on nerves within the stomach wall. Receptor subtypes in these regions may be distinct, suggesting possible differential roles in regulating upper gut motor function. [93] The existence of two or more motilin receptor subtypes is supported by neurotransmitter binding studies that show different affinities for two motilin receptor agonists in membranes from neural and muscular tissues of the stomach. [93] Other factors modulate gastric MMC activity. The opioid receptor antagonist naloxone prolongs MMC cycling from 103 to 219 minutes and delays plasma motilin peaking, suggesting that endogenous opiates may regulate motilin release. [94] Naloxone does not prevent phase III evoked by exogenous motilin; this finding confirms that motilin does not act through opiate-dependent pathways. The histamine H_2 receptor antagonist famotidine shortens the MMC cycle length, and this also suggests a modulatory role for endogenous histamine. [95] Pancreatic polypeptide cycles in phase with gastric phase III; however, exogenous pancreatic polypeptide does not induce premature phase III activity. Furthermore, pancreatic resection, which removes pancreatic polypeptide–secreting cells, does not alter the antral MMC. [96] Motilin releases pancreatic polypeptide through vagal cholinergic pathways, indicating that motilin may regulate physiological functioning of this hormone. [97] Secretory activities of the upper gut may influence gastric MMC activity. Fasting pancreaticobiliary and secretory immunoglobulin A output cycle in phase with the MMC, and increases in biliary secretion correlate with motilin release. [98], [99] Additional peaks of pancreatic secretion occur during fasting that are independent of antral phase III and motilin cycling. [100] Duodenal bile acid perfusion suppresses antral contractions, suggesting that endogenous bile release does not mediate the gastric phase III. Antral phase III complexes do not develop when the duodenal pH is less than 7.0 regardless of the plasma motilin level. [101] Furthermore, duodenal hydrochloric acid perfusion abolishes the gastric phase III; this indicates that duodenal alkalinization is a prerequisite for MMC cycling. Gastric acidification to pH 1.0 inhibits spontaneous and motilin-induced gastric phase III through a vagovagal reflex. [102] Patients with chronic pancreatic insufficiency exhibit MMC cycles of shorter duration, indicating an interrelation between antroduodenal and pancreatic function. [103] Neurohumoral factors control postprandial gastric motor function, although the specific mediators of the fed pattern are unknown. Distention of the proximal stomach produces irregular phasic contractions mimicking the fed pattern in the proximal intestine, indicating a possible role for gastric mechanoreceptor-activated pathways. [104] Infusion of a meal into an extrinsically denervated, autotransplanted loop of small intestine interrupts antral MMC activity; this indicates that external innervation is not needed for induction of the fed pattern. [105] However, as with the MMC, extrinsic neural activity can modulate postprandial motor function. Bilateral vagotomy increases the threshold for inducing the fed pattern and shortens its duration. [81] Autotransplantation of the entire gut increases the number of calories needed to abolish MMC activity and induce the fed pattern. [106] Finally, vagal cooling converts the fed pattern to intermittent phase III activity. [107] When blood from a fed animal is perfused into an isolated stomach preparation, motor complexes similar to the fed pattern are generated, suggesting the presence of an unknown circulating mediator. [108] Many candidates for the humoral inducer of the fed pattern have been proposed, but none are proven. Plasma gastrin rises after eating. Physiological infusions of gastrin increase the amplitude and frequency of antral contractions in association with increases in the percentage of slow waves that reach a contractile threshold. [109] These effects, however, are too greatly delayed and are too short in duration for gastrin to represent the major mediator of the fed pattern.

Reflex Modulation of Motility As with the proximal stomach, distal gastric motor activity is subject to reflex modulation from other gut regions. In ferrets, distention of an excluded fundus pouch evokes antral contractions through a vagal cholinergic pathway. [110] A vagal fundoantral reflex is also observed on distention of the human and the canine proximal stomach. [33], [35], [49] During fasting, proximal gastric distention disrupts MMC cycling, suggesting that the fundoantral reflex may regulate physiological induction of the fed pattern to stimulate mixing when the fundus is distended by an ingested bolus. [111] Circumferential myotomy of the midstomach promotes increased antral motor activity after meal ingestion, suggesting that intrinsic connections within the gastric wall mediate a tonic inhibition on the antrum by the fundus. [112] The distal stomach also responds to feedback from extragastric sites. Administration of saline or water to the larynx and epiglottis inhibits antral motor activity in anesthetized rats. [113] Rectal distention reduces antral motor activity and induces slow wave instability. [114] Duodenal distention inhibits antral motor activity, a reflex partly blocked by vagotomy or splanchnicectomy and abolished by both. [42] In contrast, duodenal distention–evoked inhibition of antral motor activity is unaffected by duodenal transection, excluding a prominent role for intrinsic neural pathways in this reflex. Intraduodenal perfusion of lipids, proteins, or hydrochloric acid reduces spontaneous antral contractions—effects that are reduced but not abolished by vagotomy. [115] In rats, duodenal perfusion of glucose and amino acids increase vagal afferent firing. [116] A role for afferent neurons is suggested by studies of capsaicin, which, when applied to the vagus nerves, partially reverses the inhibitory effects of protein, glucose, and trypsin inhibitor on distal gastric motor activity. [117] Intraduodenal lipids reduce motor activity in the denervated stomach and autotransplanted gastric pouches, indicating regulation by hormonal pathways. [118] The ability of the CCK antagonist L364,718 to reverse the inhibitory effects of intraduodenal protein on gastric motility in rats suggests that CCK may mediate enteroantral reflex activity in that species through action on CCK-A receptors. [117] The inhibitory effects of the different nutrient classes are dependent on the chemical nature of the nutrient that is perfused. Protein or amino acid perfusates containing

L-tryptophan potently inhibit antral motility. [115] Long-chain triglycerides are more effective inhibitors of distal gastric contractions than short- or medium-chain lipids. [119]

Pylorus

The pylorus serves as a sieve to regulate outflow of intralumenal contents from the stomach. To fulfill this role, the pylorus possesses unique smooth muscle and neural properties that distinguish it from the surrounding structures. Because of its thickness and the density of connective tissue it possesses, the pylorus acts as a mechanical stricture to the passage of large particles. The sphincteric properties of the pylorus are aided by a redundant, highly folded mucosa that narrows the lumenal diameter. The nerve density in pyloric circular muscle is three to five times greater than that in the adjacent antral circular layer, a feature indicating that regulation of pyloric motor activity is different from the surrounding regions. [120] The sensory nerve supply projecting from the pylorus to brainstem vagal nuclei is greater than from the duodenum, suggesting regional differences in extrinsic afferent innervation. [121] Increased numbers of neurons containing VIP, substance P, enkephalins, neuropeptide Y, and galanin are present in the pylorus as compared with the antrum and duodenum. [120], [122]

Electrical Activity The pylorus exhibits histological characteristics suggesting that its electrical characteristics are different from those of the distal stomach. The density of gap junctions interconnecting pyloric smooth muscle cells is less than in the antrum. [120] Prominent interstitial cells of Cajal interact with pyloric myocytes and may act as pacemaker cells in the pylorus. [123] The pyloric slow wave is entrained to the same frequency as in the distal stomach (3 cpm), but most antropyloric slow waves are not propagated into the duodenum, because of the thick, fibrous septum. In contrast, some spike potentials can cross the pyloric region in patches and may form the basis for gastroduodenal coordination. [124]

Contractile Activity The pylorus is a barrier to gastric emptying that is modulated by internal and external influences. In dogs, the pylorus has a resting pressure of 10 mm Hg and exhibits spontaneous contractions. [123] In humans, resistance to flow also is provided by tonic and phasic pyloric motor activity, although the presence of basal pressure is not reliably demonstrable. In humans, pyloric smooth muscle relaxes during electrical stimulation, indicating a predominance of inhibitory neural input, whereas in the dog, electrical stimulation produces pyloric contraction. [125] The ability of the neural toxin tetrodotoxin to enhance phasic pyloric contractions indicates that this motor activity is an inherent property of the smooth muscle. [125] The pylorus exhibits characteristic motor patterns under fasting and fed conditions. During phase III of the MMC, the pylorus is open, and fasting gastric contents exit into the duodenum. After eating, the pylorus exhibits a complex motor response of prolonged periods of closure interrupted by brief intervals during which antral contents pass into the intestine. [126] In general, pyloric contractions are synchronized with fed antral activity. However, some foods, such as milk, evoke isolated pyloric contractions with antral inhibition before induction of a fed antral pattern. Large particles do not traverse the pylorus during the fed state, indicative of enhanced sieving after meal ingestion. [127] The role of the pylorus as a sieve is illustrated by imaging of antropyloroduodenal motility after a meal. On cinefluoroscopy, a minor ring contraction in the gastric body is followed 2 to 3 seconds later by an intense contractile ring that obliterates the lumen. The minor ring contraction induces pyloric closure as the larger contraction approaches the midantrum. The intense contractile ring further propagates into the distal antrum, propelling trapped food against the occluded pylorus and producing grinding and mixing. This is followed by retropulsion of the mixed bolus into the proximal stomach as the major contractile wave reaches the pylorus. Because the pylorus is closed by the initial minor ring contraction, all gastric emptying occurs early in the cycle before the major contraction reaches the midantrum. The relative timing of the two waves is dependent on the latent period between the initial rapid depolarization of the slow wave, which induces the minor contraction, and the peak of the plateau potential, which is responsible for the major contraction. Because this is a myogenic phenomenon, the timing of the two contractile rings is not dependent on neural, hormonal, or meal-related factors. [128] Ultrasonographic studies show that most transpyloric flow occurs during periods of prolonged pyloric opening not associated with occlusive antral or duodenal contractions with the formation of a common antropyloroduodenal chamber. [129] Furthermore, bursts of duodenogastric reflux are demonstrable before pyloric closure, suggesting that duodenal mixing and retropulsion occur. [129], [130] It is hypothesized that shear forces induced by the sudden change in velocity of the intragastric contents and the squeezing action by the antral walls disperse large particles into smaller ones that subsequently are delivered to the duodenum. Resection of the pylorus does not prevent postprandial sieving and trituration, suggesting that other gastroduodenal regions also possess these capabilities. [131] Resection of both the antrum and pylorus results in loss of this function, with passage of larger, undispersed particles.

Neurohumoral Control of Motility Neurohumoral regulation of pylorus motor function is distinct from that of the duodenum and distal stomach. Electrical vagal stimulation produces pyloric contraction at low frequencies, and relaxation with increases in transpyloric flow at high frequencies, suggesting the presence of both excitatory and inhibitory vagal pathways. [123], [132] That vagally mediated pyloric contractions are blocked by naloxone indicates mediation by opioid pathways. This finding correlates with the documentation of large numbers of enkephalin-containing fibers in pyloric smooth muscle and pyloric branches of the vagus. [133] Electrical stimulation of the splanchnic nerves evokes pyloric contraction. Pyloric motor activity also is influenced by ascending and descending intrinsic neural pathways. Electrical stimulation of duodenal muscle induces pyloric contractions, whereas antral muscle depolarization relaxes the pylorus. Administration of NO donors blunts basal pyloric pressure waves, reduces the pyloric motor response to intraduodenal lipids, and enhances transpyloric flow after eating, confirming the ability of nitrergic mediators to reduce pyloric motor activity. [134], [135] NO synthase inhibitors block the inhibition of pyloric motility evoked by vagal stimulation, antral depolarization, or electric field stimulation of the pylorus and reduce transpyloric flow; these findings suggest that NO is a common mediator of pyloric relaxation (Fig. 10-6). [136], [137] NO may act in concert with purinergic nerves to mediate pyloric relaxation, as suggested by the observation that combined administration of NO synthase inhibitors and P_{2X} purinoceptor antagonists more potently inhibit electrically induced pyloric relaxations than NO synthase inhibitors alone. [138] Several agents have potent effects on pyloric motor activity. VIP, peptide histidine-isoleucine, galanin, prostaglandin E_1, and serotonin relax the pylorus, whereas CCK, secretin, and histamine produce pyloric contraction. [133], [139], [140] Although CCK has a limited role in enteropyloric reflex activity, the finding that the CCK antagonist L364,718 reduces pyloric motility after a meal suggests that CCK plays some role in the postprandial state. [141]

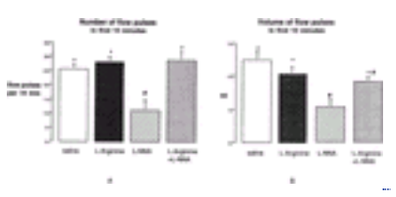

FIGURE 10-6. Effects of nitric oxide (*NO*) synthase inhibition on transpyloric flow. The NO synthase inhibitor $N^{?}$-nitro-L-arginine (*L-NNA*) decreases both the number and volume of flow pulses across the pylorus; this indicates that NO is a physiological relaxant in that region. The NO precursor L-arginine reverses the effects of L-NNA. *, $P < 0.05$ cf L-NNA; #, $P < 0.05$ cf saline. (From ref. [137].)

Reflex Modulation of Motility Pyloric motor activity is modified stimulation of the small intestine. Duodenal perfusion of lipids, amino acids, glucose, hypertonic saline, or hydrochloric acid produces pyloric closure and decreases transpyloric flow. [25] Ileal triglyceride perfusion evokes isolated pyloric contractions. [142] Ileal delivery of short-chain fatty acids increases pyloric tone and reduces the stroke volume of transpyloric fluid pulses. [143] Combined cinefluoroscopy and manometry recordings demonstrate that the pylorus is closed 98.5% of the time that pyloric tone exceeds 4 mm Hg. [144] Induction of isolated pyloric contractions is associated with inhibition of liquid gastric emptying. [142], [145] Pathways that mediate reflex stimulation of pyloric motor activity are dependent on the stimulus. Isolated pyloric contractions evoked by duodenal hydrochloric acid are antagonized by atropine and the ganglionic blocker hexamethonium but are not blocked by vagotomy, indicating mediation by nonvagal cholinergic pathways. [146] Similarly, the response to intraduodenal glucose is blocked by atropine. The ability of the topical anesthetic lidocaine (Xylocaine) to prevent acid-induced pyloric contraction is evidence of a role of mucosal receptors in initiating this enteropyloric reflex. [146] The 5-HT_3 receptor antagonist zacopride reduces pyloric motor responses to intraduodenal hydrochloric acid, indicating that serotonergic nerves also play a role. Although atropine reduces the pyloric response to intraduodenal lipids, it is postulated that hormones such as CCK also modulate the pyloric motor response. However, other studies suggest that CCK plays a limited role in enteropyloric reflex activity under physiological conditions. Mediation by opioid pathways is suggested by the ability of naloxone to block pyloric contractions induced by intraduodenal amino acids. [147] The inability of naloxone to block lipid-evoked pyloric contractility is evidence of differential regulation of pyloric motility by different nutrient classes. [148]

Duodenum and Small Intestine

The small intestine modulates gastric emptying and plays a pivotal role in regulating gastric and pyloric motor activity. The duodenum possesses an electrical pacemaker distinct from that of the stomach, with a frequency of 11 to 12 cpm. Some electrical activity from the stomach propagates across the pylorus, despite the presence of the fibrous septum, and is responsible for intermittent antroduodenal coordination with one gastric slow wave cycling in phase with every three to four duodenal slow waves. This promotes propagation of some antral pressure waves into the duodenum, most commonly during phase II. [149], [150] Because of the higher duodenal slow wave frequency, additional duodenal contractions interspersed between these coordinated antroduodenal waves are generated. The inability of the neural toxin tetrodotoxin to prevent antroduodenal coordination indicates that electrical propagation is carried by pyloric longitudinal muscle fibers and not by neural

pathways. [151]

The duodenum exhibits other contractile patterns as well. After eating, isolated duodenal contractions segment and mix food particles with pancreaticobiliary secretions. Intraduodenal lipid or bile perfusion decreases intestinal flow, an effect associated with increases in duodenal diameter with fewer contractions and reductions in propagation distances. [152], [153] In contrast, hydrochloric acid and hyperosmolar solutions retard duodenal propagation by inducing tonic duodenal lumenal occlusions. [152] Duodenal myotomy reduces the evoked duodenal contractions with enhancement of lumenal propulsion. [154] Under some conditions, strong retroperistaltic contractions in the duodenum propel intestinal contents orally and induce duodenogastric reflux. Studies demonstrating retrograde duodenal motor activity during late phase III of the MMC imply the presence of a retroperistaltic pump that may regulate fasting duodenal pH. [155] Duodenogastric retropropulsion of bile in the refluxate is minimized by phase III–associated closure of the sphincter of Oddi. [156] After eating, 40% to 50% of the pressure waves in the initial 5 to 6 cm of the duodenum are retrograde and may contribute to controlling gastric emptying. [157]

Just as stimulation of the small intestine modulates gastric contractile function, gastric perturbations can alter intestinal motor patterns. Gastric distention delays intestinal transit, a phenomenon known as the *gastroenteric reflex.* [25] This reflex is unaffected by vagotomy but is reduced by small intestinal denervation and by severing connections from the celiac plexus. [25], [158] The abilities of L-arginine applied to celiac ganglion neurons to enhance the reflex and NO synthase inhibitors to block the reflex indicate mediation by celiac plexus NO release. [159] The gastroileal reflex, the increase in ileal propulsion after eating, is abolished by intestinal transection, indicating mediation by intrinsic nerves. [160] Decreases in pressure at the ileocecal junction are reported in response to nutrient ingestion. [161]

GASTRIC EMPTYING

The coordinated actions of the distinct regions of the stomach with feedback from the small intestine regulate emptying of gastric contents into the duodenum. Intragastric contents are categorized as liquids, digestible solids, fats, and indigestible solids because of the differential handling of each by the stomach.

Gastric Emptying of Liquids

Kinetics of Emptying of Inert Liquids Gastric emptying of inert liquids such as water or isotonic saline follows a single exponential curve, termed *first-order kinetics,* with a time to 50% emptying of 8 to 18 minutes. The volume of liquid emptied into the duodenum in a given time is a constant fraction of the volume that remains in the stomach. [162] Thus, a 300-mL saline bolus will empty at a rate twice as fast as a 150-mL load. Studies in preterm infants indicate that mature patterns of liquid emptying develop by the 32nd gestational week; before then, liquid emptying is variably delayed. [163], [164] Some investigations suggest that liquid emptying is slower in women than in men. [165] Nutrient-containing liquids are emptied more slowly in elderly persons (mean age, 73 years) than in young controls. [166]

Factors that Modify Liquid Emptying The nutritional properties of an ingested liquid modify the speed at which it exits the stomach. Consequently, carbohydrate-, protein-, or fat-containing liquids can be digested and absorbed completely before they reach the distal small intestine. [167] Feedback from the small intestine delays gastric emptying of liquid nutrients because of alteration of the first-order kinetic pattern. Gastric emptying of nutrient liquids exhibits an initial rapid phase lasting 5 to 30 minutes, followed by a slower phase in which the nutrient is emptied at a constant rate for up to 120 minutes. [168] Because of the linearity of liquid nutrient emptying, a 300-mL liquid meal of 11% glucose empties at the same rate as a 150-mL liquid 11% glucose meal. [169] Liquids with high caloric density empty more slowly than foods with fewer calories per unit volume (Fig. 10-7). [169], [170] and [171] Liquid nutrient emptying is controlled to a rate that delivers about 200 kcal per hour into the duodenum by modulating the duration of the rapid emptying phase, regardless of whether calories are in the form of fats, proteins, or carbohydrates. [172] Thus, 0.25 M glucose empties four times as fast as 1 M glucose. The concentrated glucose solution shortens the rapid emptying phase so that the slower linear phase delays its exit from the stomach, while the dilute solution prolongs the rapid emptying phase to enhance duodenal delivery. Caloric control of liquid emptying is operative within a limited range of concentrations. A 1 M glucose solution maximally inhibits liquid emptying. Concentrations greater than 1 M empty from the stomach faster than 200 kcal per hour. [170] Similarly, duodenal caloric delivery of milk protein solutions of high caloric density is greater during the early phase of liquid emptying than for less concentrated protein hydrolysates. [171]

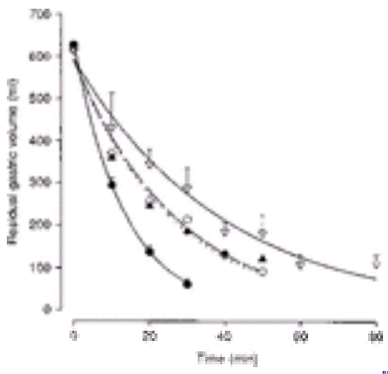

FIGURE 10-7. Gastric emptying profiles of different nutrient liquids. Glucose (*filled circles*) emptied the fastest, whereas liquids with higher caloric density such as milk protein (*open triangles*), pea peptide hydrolysate (*open circles*), and whey peptide hydrolysate (*filled triangles*) emptied much more slowly. (From ref. [171] .)

Other nutrient characteristics regulate liquid emptying as well. Osmolarity is an independent factor in the regulation of liquid emptying. Carbohydrates and most amino acids modulate duodenal delivery, in part, by action on intestinal osmoreceptors. Emptying of glucose solutions is slower than emptying of isocaloric, hypotonic glucose polymer solutions. [173] Vagal osmoreceptor-activated pathways mediate this response, although a dependence on intact celiac ganglia also has been reported. [174] Fructose is a less potent inhibitor of gastric emptying than glucose or xylose, suggesting the participation of other factors as well. [175] L-Tryptophan is considered separately from other amino acids in that it delays liquid emptying in isotonic solutions; this suggests the presence of specific intestinal L-tryptophan receptors. [176] Isocaloric starch, disaccharide, and monosaccharide solutions are equipotent at delaying liquid emptying, as are isocaloric protein and amino acid solutions, suggesting that the digestive products of carbohydrate and protein hydrolysis are the major regulators of duodenal delivery of nutrients. [177] This theory is supported by the report that liquid emptying is not inhibited by a nonhydrolyzable sucrose polyester compound. [178] Fatty acids, rather than triglycerides, mediate emptying of liquid lipid solutions, because triglycerides do not inhibit emptying in exocrine pancreatic insufficiency. [179] Medium-chain fatty acids of 12 to 14 carbons are more potent than longer- or shorter-chain fatty acids. [180] A requirement for endogenous bile is suggested by the observation that biliary diversion prevents the inhibitory effect of fat on gastric emptying. [179] The mechanism by which nutrients slow liquid emptying is unknown, although the effects of protein meals are blocked by antibodies to VIP. [174]

Finally, some studies suggest that the composition of meals ingested previously can modify liquid nutrient emptying. In rats fed a high-protein diet for 3 weeks, gastric emptying of liquid peptones is faster than in animals fed diets lower in protein content (Fig. 10-8). [181]

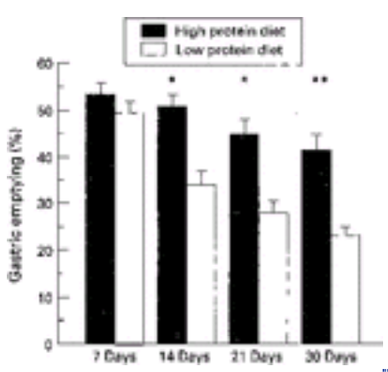

FIGURE 10-8. Gastric emptying of a peptone meal in rats fed a high- or low-protein diet for 7, 14, 21, and 30 days. Long-term ingestion of high-protein meals leads to accelerated emptying of peptone meals. (From ref. [181] .)

Noncaloric physicochemical factors modulate rates of liquid gastric emptying. Emptying of glucose solutions is faster during filling of the stomach than when measured

after meal completion and is dependent on the volume delivered rather than on the rate of gastric filling. [182] Titratable acid delivery to the duodenum is constant regardless of the pH or lipid solubility of acids in the stomach. [183] Large quantities of a weak acid are more potent inhibitors of liquid emptying than trivial amounts of a strong acid such as hydrochloric acid. The mechanism of the inhibitory effects of acid on liquid emptying is not completely understood. Secretin is released on duodenal acid exposure; however, the rapidity of the reflex response to duodenal acidification is more consistent with neural mediation. [184] The actions of intraduodenal hydrochloric acid on liquid emptying require an intact pylorus, suggesting that acid-evoked tonic and phasic pyloric activities are important. [174] Increases in viscosity slow the rate of liquid emptying. [67], [185] Gravity has minimal effects on liquid emptying of carbohydrate or acid solutions, although saline empties slightly faster in a person who is upright than in one who is supine. [186] When a nutrient liquid such as soup is ingested as part of a mixed meal, assuming a supine position may prolong emptying by 50%. [187] Maintaining an upright posture after drinking a nonnutritive liquid produces more long antroduodenal pressure waves and isolated pyloric contractions than does maintaining a left lateral decubitus position. [188] Investigations suggest that liquid emptying is modified by postabsorptive factors. In healthy humans, liquid emptying is slowed by 38% during intravenous hyperalimentation. [189] When half of the amino acids are replaced with branched-chain amino acids, this delay in emptying is attenuated, suggesting that different parenteral nutrients may have distinct effects. Similarly, patients receiving intravenous fat emulsions exhibit delays in gastric emptying.

Roles of Different Physiological Regions in the Control of Liquid Emptying Liquid gastric emptying traditionally has been considered to be controlled by tonic motor activity in the proximal stomach, but investigations have delineated important roles for other regions. If the proximal stomach is extrinsically denervated or resected or if fundoplication is performed, intragastric pressure rises after eating and liquid emptying is accelerated as a consequence of impaired receptive relaxation and accommodation. [64], [190] Receptive relaxation is an important modulator of liquid emptying. Liquid meals delivered to the stomach through orogastric tubes empty faster than swallowed boluses of the same liquid. [191] It has been postulated that the fundus generates a pressure gradient from the stomach to the duodenum that serves to expel liquids from the stomach. However, questions about this model have been raised. Diabetic patients with normal fundus tone commonly exhibit delayed liquid emptying. [192] Furthermore, a pressure gradient between the fundus and duodenum has never been demonstrated. When the pressure in the proximal stomach is maintained 2 cm H_2O lower than that of the duodenum, liquid emptying is unimpaired. [25] These findings suggest that regions other than the proximal stomach play important roles in the emptying of liquids. It is hypothesized that the distal stomach acts as a pump to facilitate liquid emptying. [44], [193] Although antral contractions are not required for liquid emptying, the degree of antral pressure wave activity correlates with expulsion of liquids into the duodenum. [67], [194], [195] Furthermore, when antral contractions are induced by vagal electrical stimulation, liquid emptying is enhanced. In pigs, emptying of nonnutrient liquids occurs in association with non–lumen-occluding gastric corpus contractions that become occlusive in the distal antrum and pylorus, thereby producing discrete flow pulses into the duodenum. [196] Rapid magnetic resonance imaging demonstrates antral contractions of greater amplitude during emptying of nutrients of low caloric density (e.g., 10% dextrose) compared with emptying of more concentrated solutions (e.g., 25% dextrose), indicative of differential regulation of liquid nutrient emptying by action on the distal stomach. [193] If the proximal stomach is surgically excluded, coordinated antropyloric pressure waves generate fluid flow pulses that preserve normal liquid emptying. [197] Antral motor activity also can delay liquid emptying. If the antrum is resected, the initial phase of liquid emptying is accelerated, suggesting that the distal stomach has an inhibitory role during the first several minutes after liquid intake. [198] Furthermore, the antral lumenal diameter is less after ingestion of a liquid nutrient than after ingestion of an inert liquid; this finding indicates that a calorie-containing fluid may be retained by motor properties of the distal stomach. [199] The pylorus plays a crucial role in the emptying of certain liquids. Early studies failed to document an effect of stent placement across the pylorus on the rate of liquid emptying. [200] More recent studies show acceleration of the initial rapid phase of liquid emptying with pyloric stenting without any affect on the subsequent slower linear phase. [201] This finding correlates with observations that pyloroplasty or pyloric myotomy enhance early liquid emptying and with the demonstration that pyloroplasty enhances emptying after highly selective vagotomy. [25], [131], [198], [202] Pyloroplasty also abolishes the resistance to transpyloric flow evoked by hydrochloric acid or lipids. [25] If the duodenum is transected, liquid nutrients do not induce isolated pyloric contractions and are emptied at an accelerated pace, suggesting an important role for stimulated pyloric motility in the control of liquid delivery into the duodenum. [203] Duodenal motor activity also regulates liquid emptying. The absence of duodenal motor activity is associated with accelerated emptying, whereas the presence of continuous duodenal contractile activity correlates with delayed liquid gastric emptying. [128] Enhanced liquid emptying is also noted after circular myotomy of the duodenal wall. [154]

Gastric Emptying of Digestible Solids

Kinetics and Flow Patterns in Solid Emptying The delivery of digestible solid residue to the duodenum is slower than for liquids, with a time to 50% emptying of about 2 hours. [191] The emptying of solids exhibits an initial lag phase, which persists up to 1 hour, during which time little or none of the ingested food leaves the stomach. [204], [205] Cinefluoroscopy demonstrates extensive mixing and retropulsion during the lag phase, during which the food is dispersed into fine particles. The lag phase is followed by a linear emptying phase, during which time the dispersed particles are slowly delivered to the duodenum. [204], [205] This linear phase, which lasts 1 or more hours until the stomach is nearly empty, exhibits *zero-order kinetics;* in other words, lumenal contents leave the stomach at a constant rate that is independent of the volume remaining in the stomach. [206] Solid phase emptying terminates in a third phase of very slow transit of the last remaining particulate gastric contents. [204], [205] In general, solid emptying is slower in premenopausal women than in age-matched men regardless of the phase of the menstrual cycle (Fig. 10-9). [165], [207] This delay in women stems from a slower linear emptying rate, without differences in the lag period. [207], [208] and [209] In rats, oophorectomy accelerates emptying, indicating a physiological inhibitory role for hormonal factors. [210] Finally, studies show that the rate of solid emptying correlates positively with body mass index. [211]

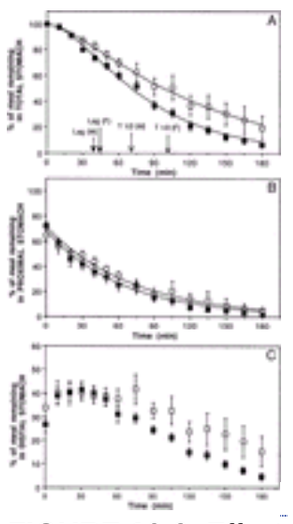

FIGURE 10-9. Effects of gender on solid phase gastric emptying in humans. Women (*open squares*) have delayed emptying compared with men (*filled squares*) as a consequence of a slower linear emptying phase (**A**). In contrast, there is little effect on the initial lag phase of solid emptying. In this study, there were no differences in proximal gastric retention of a solid meal (**B**); however, women exhibited prolonged distal gastric retention compared with men (**C**). (From ref. [207].)

Several theories have been proposed to explain the differential handling of solids and liquids by the stomach. The J shape of the stomach may promote selective retention of solids. [149] In this model, the liquid fractions of a meal are expelled through the pylorus by coordinated gastric motor activity, whereas the particulate components settle because of the effects of gravity. Other investigators suggest that solid particles empty more slowly because of basic fluid mechanics. In these theories, smaller particles are carried in the center of the fluid stream and are expelled with the liquid phase. In contrast, larger particles are propelled in the periphery of the fluid column, which moves more slowly than the center and does not reach the distal antrum until after pyloric closure. This produces retropulsion of larger particles until they can be reduced in size. In this model, contact of the particles with the antral walls is not required; rather, the shearing forces from sudden changes in fluid direction are sufficient to disperse the solids.

Factors that Modify Emptying of Digestible Solids Solid meals exhibit nutritional and physical properties that modify the rate at which they are delivered to the intestine. Radiolabeled eggs or noodles are passed into the duodenum faster than an equicaloric meal of 10-mm cubes of radiolabeled liver. [204], [205] Similarly, when eggs are fed as homogenized preparations, or as 2.5- or 5-mm cubes, the homogenized eggs empty most rapidly, whereas the 5 mm cubes are emptied most slowly. [212] These differences are caused by modulation of the initial lag phase. Larger particles prolong the lag phase, whereas evenly dispersed suspensions have relatively short lag phases. After completion of the initial lag period, a homogenized meal empties at the same linear rate as an unhomogenized one. In humans and dogs, solids are delivered to the duodenum as finely dispersed suspensions of particles less than 1 mm in diameter. [213] After the ingestion of solid chicken pieces, the mean diameter of recovered solid particles is 0.05 mm, and 95% are less than 0.5 mm in diameter. If homogenized food with a mean particle size less than 0.25 mm is consumed, the initial lag phase is nearly abolished. [204] Increasing the viscosity of a solid meal impairs the ability of the stomach to discriminate between large and small particles and leads to duodenal delivery of larger particles. The effects of posture on solid emptying are controversial—some studies show no effect and others

show delay, primarily by inhibiting the linear emptying phase. [187], [214] The caloric content and character of the solid food regulate the rate of solid emptying. Addition of fats, triglycerides, or carbohydrates such as glucose, fructose, or xylose to a solid meal delays its emptying, presumably by prolonging the lag phase. [215], [216] In contrast, if a low-calorie substance such as lettuce is added to a solid meal to enhance its volume but not its nutritive value, solid emptying is accelerated. [217] The quantity of liquid consumed with the solid meal alters the rate of duodenal delivery of solid nutrients. In a mixed solid-liquid meal, the liquids are emptied more rapidly than the solids, suggesting that the stomach is capable of distinguishing the two phases when solids and liquids are presented simultaneously. [218] Furthermore, the presence of liquid in the stomach prolongs the lag phase of solid emptying. [219] In fact, liquid consumption 90 to 180 minutes after a solid meal can blunt antral contractions and can induce a second lag phase of solid phase gastric emptying. [219], [220]

Roles of Different Physiological Regions in the Control of Solid Emptying Solid emptying results from the combined action of the pylorus and distal stomach. In humans who have undergone vagotomy and pyloroplasty, there is no increase in particle sizes delivered to the duodenum. [221] /SUP>Similarly, pyloric resection in dogs does not change particle sizes, indicating that the pylorus is not solely responsible for the controlled delivery of fine suspensions to the intestine. [131], [213] The rate of solid emptying is dependent on the magnitude of antral motor activity. [64] Humans who have undergone vagotomy and antrectomy deliver 30% of the solid meal residue to the duodenum as particles larger than 1 mm in diameter. [221] In these persons, solid phase emptying exhibits an early acceleration with loss of the lag phase. Similarly, in dogs, when the distal 3 cm of antrum and the pylorus are resected, 30% of the particles emptied by the stomach are larger than 1 mm in diameter. [131], [213] Control of particle size is regulated by coordinated antropyloric motor activity. These findings have important nutritional consequences. In dogs ingesting carbon 14 (^{14}C)-labeled fat within a chicken liver meal, 85% of the radiolabel is absorbed before reaching the midintestine. [222] If vagotomy and antrectomy are performed, only 43% of the radiolabel is absorbed after reaching the same site, suggesting that excision of the distal stomach can induce nutrient malabsorption. The roles of the proximal stomach and small intestine in controlling solid emptying are less thoroughly explored. As stated previously, 30% of particles delivered to the duodenum after a solid meal are larger than 1 mm in diameter after antrectomy with or without pylorectomy. Thus, 70% of food material is expelled as fine particles, suggesting that the proximal stomach has some capacity to disperse solid nutrients. [131], [213], [221] The ability of fats to slow solid emptying after antrectomy indicates that intestinal feedback persists in the absence of the distal stomach. [216]

Gastric Emptying of Fats

High-fat foods are handled differently by the stomach, and their emptying patterns are distinct from those of other liquids and solids. Many fats are solid or semisolid before ingestion. After consumption, they are warmed to body temperature and are converted to a liquid phase, which is emptied more slowly than nonlipid liquids. Emptying of fats exhibits an initial lag period, although solid and liquid lipids are handled separately. [223] Solid fats empty at a rate similar to that of liquid lipids in the first hour but are evacuated more slowly thereafter. [224] During the initial lag period, magnetic resonance imaging demonstrates marked increases in to-and-fro movements in the antrum that most likely enhance fat emulsification. [225]

The reasons for delayed emptying of fats are multifactorial. Fats have specific gravities less than 1 g/cm ^{3} and float on top of aqueous liquids in the stomach. [226] In contrast, nonlipid solids have specific gravities greater than 1.2 g/cm ^{3} and settle in dependent fashion. Fats are delivered to the duodenum at the same rate as low-density spheres; this reinforces the importance of specific gravity as a determinant of gastric emptying. Because of poor aqueous solubility, fats coalesce into large globules and fail to disperse into fine particles. Also because of their poor solubility, lipids adhere to solid food particles and thus are retained in the stomach until solid emptying proceeds. [223] Fats potently activate inhibitory enterogastric reflex pathways that further delay emptying. The products of lipid digestion appear to be more important for regulating emptying of fats, because patients with pancreatic exocrine insufficiency exhibit faster emptying of lipids than do healthy persons. [227] Studies in dogs and humans show that inhibition of lipolysis by orlistat accelerates gastric emptying of lipids, supporting this hypothesis. [228], [229]

Gastric Emptying of Indigestible Solids

Indigestible solids, the nonnutritive fibrous residue from a meal, are evacuated from the stomach in a fashion most dependent on particle size. Indigestible spheres smaller than 1 mm in diameter pass into the intestine during the fed period, often faster than solid nutrients. [230] Larger spheres pass more slowly, usually after an initial lag period, with spheres up to 3 mm in diameter passing with the calorie-containing solid meal components. [231], [232] Particles as large as 7 mm do not empty with solid food at all and are retained until the fed motor pattern terminates and gastric phase III activity resumes. The main characteristic that distinguishes phase III from the fed pattern is the presence of an open pylorus during fasting that permits intestinal delivery of large particles. In some reports, undigested materials as large as 2 cm in diameter can pass into the intestine during fasting. From a clinical perspective, particle size is relevant to the design of encapsulated medications. Drug absorption from 0.7-mm pellets is faster than absorption from 3.6-mm pellets, which are delivered to the intestine only with reinitiation of fasting motor activity. [233]

Other physical factors participate in the emptying of indigestible solids. Specific gravity is an independent determinant, with spheres denser than 2.0 g/cm ^{3} or less dense 0.5 g/cm ^{3} emptying more slowly than spheres with a density of 1.0 g/cm ^{3}. [230], [234] Viscosity of gastric contents plays a role in emptying of indigestible spheres. The addition of guar gum to increase viscosity accelerates emptying of 3.2-mm spheres. [235] Compressibility of the gastric compound is important, with soft indigestibles emptying faster than hard ones. [236]

Mediation of emptying of indigestible solids by the distal stomach has been demonstrated in canine models. Distal antrectomy accelerates emptying of indigestible spheres, although excision of the fundus has no effect. [237] Interruption of vagal innervation of the proximal stomach does not modify emptying of indigestible spheres, whereas distal gastric vagotomy delays their passage into the duodenum.

Differential Intragastric Distribution of Solids and Liquids

The differential emptying patterns for solids and liquids provide evidence that the stomach sequesters certain meal components, whereas others are processed for duodenal delivery. Fluoroscopy demonstrates retention of large pieces of ingested food in the fundus, although fine particles are mixed in the antrum. Quantitative scintigraphy shows constant levels of radioactivity in the antrum after a solid meal with progressive decreases in fundic activity, indicating that solids are stored proximally and are delivered to the distal stomach at constant rates for trituration. Studies of distribution of radiolabeled solids such as liver, chopped beef, or egg cubes indicate that the initial lag phase of solid emptying is characterized by antral filling to a maximal level of radioactivity that remains constant during the linear emptying phase while more proximal activity decreases. [212], [238]

Ingested liquids also are retained in the proximal stomach to maintain a constant volume in the distal stomach. [218], [239] Addition of lipid substances such as margarine to ingested liquids promotes redistribution into the fundus with associated delays in emptying. [240] The caloric content of a consumed liquid regulates proximal gastric storage. The antral diameter is greater after a nonnutritive meal than after ingestion of caloric liquids, and fundic retention is less. When liquids and solids are consumed together, the solid fraction is retained in the proximal stomach, whereas the liquid portion is delivered to the antrum. [241] If liquids are replaced by carbonated water, the proximal stomach initially retains a greater proportion of the solid meal, suggesting that gaseous distention of the stomach also modifies intragastric distribution. [242] The size of the solid meal influences the rate of liquid emptying. A large solid meal retards the transfer of liquid from the proximal stomach to the antrum and delays the delivery of liquid to the duodenum. [243]

Indigestible solids are distributed separately from digestible solids. When liver is ingested along with 2.4-mm-diameter plastic spheres, the liver is retained within the fundus, whereas the spheres are transported to the distal stomach, where they remain until the late postprandial period.

External Regulation of Gastric Emptying

There is extensive modulation of gastric emptying by external influences. Feedback inhibition of emptying by intestinal factors is crucial to regulating duodenal caloric delivery. Additional control is provided by extrinsic and intrinsic nerves and from hormones and neurotransmitters. Finally, gastric motor function is subject to modulation by central nervous system factors.

Feedback Inhibition from Distant Sites Feedback from the small intestine is a major regulator of gastric emptying. Duodenal pH receptors are postulated to mediate inhibition of gastric emptying evoked by duodenal acidification. [244] Duodenal perfusion of nutrients such as amino acids nearly abolishes solid emptying and also reduces liquid emptying. [245] If a duodenal fistula is placed to divert nutrients away from intestinal mucosal receptors, liquid emptying exhibits first-order kinetics, in contrast to the curvilinear pattern seen with an intact enterogastric reflex. Intestinal nutrient perfusion modifies solid emptying by altering the duration of the lag phase. Duodenal amino acid perfusion enhances the sieving properties of the stomach and pylorus and increases the percentage of particles less than 1 mm in diameter delivered to the duodenum from 66% to 82%. [245] Many agents act on intestinal osmoreceptors to increase duodenal outflow resistance and to delay emptying. [246] Inhibition of gastric emptying by lipids appears to require the intralumenal presence of component fatty acids, because intestinal perfusion of nonhydrolyzable fats does not inhibit gastric emptying. [178] Duodenal lipid-evoked inhibition of gastric emptying may also require the generation of chylomicrons, because administration of surfactants that prevent chylomicron formation abolishes this enterogastric reflex (Fig. 10-10). [247]

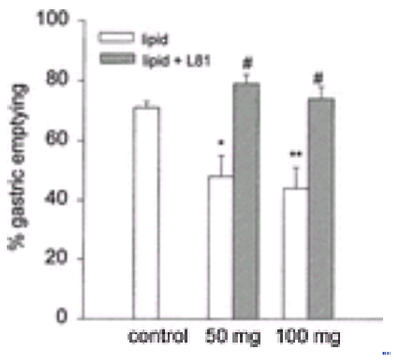

FIGURE 10-10. Effects of Pluronic L-81, a detergent that inhibits chylomicron formation, on the retarding of gastric emptying by duodenal lipid perfusion. Lipid perfusion significantly delays gastric emptying in rats. This inhibition is prevented by treatment with two doses of L-81, indicating that the effects of lipid are mediated by generation of chylomicrons. (From ref. 247.)

The degree of inhibition of gastric emptying by intestinal feedback depends on the length of intestine exposed to the stimulus. Osmoreceptors mediating hypertonic saline–evoked inhibition of emptying are located only in the duodenum, whereas acids, lipids, and glucose have inhibitory effects on longer segments of small intestine. 184, 248 Maximal inhibition of liquid emptying is seen with exposure of the proximal 150 cm of small intestine to acid, glucose, or oleic acid. 169, 249 However, perfusion of only the proximal 15 cm of duodenum with hydrochloric acid or oleic acid, but not glucose or lactic acid, delays delivery of liquids into the intestine. 250 Capsaicin-sensitive afferent nerves mediate enterogastric feedback regulation of gastric emptying in response to some stimuli. Intestinal capsaicin perfusion abolishes the inhibition of emptying induced by intestinal hydrochloric acid, but it reduces the inhibition evoked by duodenal glucose or lipid by only 59% and 42%, respectively. 251 Similarly, vagal capsaicin attenuates lipid-induced inhibition of gastric emptying by 57%. 252 Capsaicin also prevents the inhibitory effects of mechanical stimuli such as duodenal balloon inflation on gastric emptying of saline. 253 Regions other than the proximal small intestine regulate gastric emptying. Nonpainful rectal balloon inflation slows emptying of solids. High-fat soups delay gastric emptying more when ingested orally than when given by intragastric infusion, indicating modulation by orosensory stimulation. 254 Gastric emptying of solids is potently inhibited by glucose or oleic acid perfusion of the ileum, in a phenomenon known as the *ileal brake*. 255 The involvement of opiate pathways is suggested by studies showing blockade of the ileal brake by naloxone. 256 Certain lipids are capable of activating the ileal brake (i.e., petroselinic, oleic, myristoleic, erucic, linoleic, and linolenic acids, corn oil, lecithin, and deoxycholic acid), whereas others cannot (e.g., taurocholic acid). 257

Neurohumoral Modulation

Role of extrinsic and intrinsic innervation in control of gastric emptying. Intact extrinsic innervation is essential for normal gastric emptying of solids and liquids. Thoracic spinal cord transection acutely delays emptying of nutrient liquids. 258 Truncal or proximal vagotomy produces rapid duodenal delivery of liquids. 237, 259 The addition of pyloroplasty enhances the rapid liquid emptying after vagotomy. 202 This rapid emptying is more pronounced when the person is erect than when the person is supine, indicating that the vagus controls postural effects on gastric motor function under normal conditions. 260 In contrast, truncal vagotomy retards overall emptying of digestible and indigestible solids and can lead to bezoar formation in some patients, although the earliest phase of solid emptying may be accelerated. 260, 261 Proximal vagotomy has little effect on solid phase emptying. 259 The intrinsic innervation of the distal stomach also regulates liquid emptying. If the antrum is transected 2 cm proximal to the pylorus and is then reanastomosed, transpyloric flow pulse volumes are reduced and gastric emptying is retarded. 262 This operation does not modify the inhibition of gastric emptying, the inhibition of antral contractions, or the stimulation of pyloric motor activity evoked by duodenal glucose, indicating that intrinsic gastric pathways are not involved in enterogastric reflex activities. However, the demonstration that duodenal transection in pigs impairs nutrient-evoked delay of gastric emptying indicates that intrinsic duodenal neurons participate in enterogastric reflex inhibition. 203

Roles of specific neurohumoral transmitters in control of gastric emptying. Many hormones and neurotransmitters modify gastric emptying, but their physiological relevance is largely unknown. The role of NO in modulating emptying appears to be species dependent. In humans, NO donors delay gastric emptying, whereas NO synthase inhibitors have accelerating properties. 134, 263 In rodent models, NO synthase inhibitors delay gastric emptying by modulating intestinal feedback control. 264 The delay in emptying that occurs with NO synthase inhibition in rodents is associated with increased pyloric and duodenal contractions; therefore, NO may facilitate gastric emptying by inhibiting obstructing pyloroduodenal motor activity. 265 Opiates of different receptor subclasses have inhibitory and excitatory effects on gastric emptying through naloxone-sensitive and naloxone-insensitive pathways. 266 The ability of naloxone to accelerate gastric emptying indicates an inhibitory role for endogenous opioid pathways in controlling gastric emptying. Emptying delays induced by meperidine are reversed by the a-adrenergic receptor antagonist phentolamine, suggesting mediation by adrenergic pathways. 267 Modulation of emptying by serotonergic pathways likely depends on the receptor subtype that is activated. 5-HT $_3$ receptor antagonists and 5-HT $_1$ agonists, such as sumatriptan, delay gastric emptying; this action indicates inhibitory effects of 5-HT $_3$ pathways and excitatory actions of 5-HT receptors. 268, 269 The enhancement of emptying by the histamine (H $_2$) antagonist nizatidine suggests that endogenous histamine may serve as a physiological inhibitor of gastric emptying. 270 Studies demonstrating acceleration of emptying after administering antibodies to secretin suggest that secretin may modulate intestinal nutrient delivery. 271 Blockade of GRP receptors delays emptying of solids, and this also indicates a physiological role for GRP. 272 Antibodies to calcitonin gene–related peptide (CGRP) prevent the inhibition of gastric emptying by intestinal hydrochloric acid or hypertonic saline, suggesting participation of CGRP pathways in enterogastric reflex inhibition. 273 Agents that delay gastric emptying include gastrin, secretin, somatostatin, neurotensin, peptide YY, enteroglucagon, oxyntomodulin, prostaglandin E $_1$ and E $_2$, neuromedin B, amylin, glucagon-like peptide I, epidermal growth factor, transforming growth factor a, and interleukin-1 ß. 38, 109, 274, 275, 276, 277 and 278

Role of cholecystokinin in emptying of nutrient meals. CCK, released by duodenal lipids or proteins, has been extensively investigated as a physiological regulator of gastric emptying; however, its specific role remains incompletely defined. Physiological CCK infusions inhibit liquid emptying and stimulate antral motor activity, whereas higher doses increase pyloric contractions. 74, 279 CCK infusions that mimic the postprandial state produce fundic relaxation and increase proximal gastric compliance. 280 The inhibitory response of the stomach to CCK exhibits plasticity depending on prior dietary exposure. Oleate-induced inhibition of gastric emptying is attenuated in rats fed a high-fat diet. 281 In the same model, exogenous CCK administration less potently inhibits gastric emptying, indicating a loss of sensitivity to the peptide (Fig. 10-11). The physiological significance of these different effects is uncertain, and their mediation is poorly characterized. Antrectomy, in combination with pyloroplasty, inhibits the effects of physiological CCK infusions on gastric emptying. Surgical resection of the fundus prevents CCK inhibition of emptying in some studies but has no effect in others. 282 However, serosal application of the myenteric denervating agent benzalkonium chloride does not prevent the inhibition of gastric emptying by CCK, suggesting that antral neurons are not involved. 283

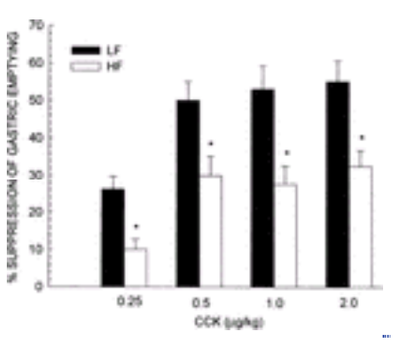

FIGURE 10-11. Gastric emptying of saline is inhibited by cholecystokinin (*CCK*) in rats fed a low-fat (*LF, dark bar*) and high-fat (*HF, white bar*) diet. For rats fed a low-fat diet, CCK inhibits gastric emptying in dose-related fashion. This inhibitory effect on emptying is blunted by the long-term ingestion of a high-fat diet. (From ref. 281.)

Although not universally accepted, the weight of evidence is leaning toward an intrinsic role for CCK in the inhibition of gastric emptying, based on investigations using selective CCK receptor antagonists. The CCK antagonist loxiglumide usually accelerates emptying of mixed meals, glucose, lipids, and radiopaque markers, although some studies have reported no enhancement. 284, 285, 286 and 287 Enhancement of distal gastric contractions by loxiglumide has been observed, indicating that CCK may regulate gastric emptying by inhibiting antral motor function. 288 Similarly, the potent CCK antagonists L364,718, devazepide, and linitript accelerate gastric emptying in some investigations but not others (Fig. 10-12). 141, 289, 290, 291, 292 and 293 One study using L364,718 demonstrated blockade of the enterogastric inhibition of gastric emptying by duodenal maltose perfusion. 294 The ability of devazepide to blunt the retardation of emptying evoked by a peptone meal decreased as the caloric density increased, indicating the involvement of CCK-independent factors with greater nutrient loads. 295

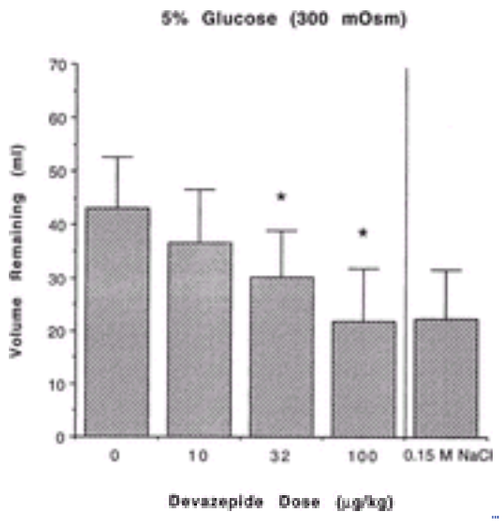

FIGURE 10-12. Volume of a glucose test meal remaining in the stomach 10 minutes after several doses of the cholecystokinin receptor antagonist devazepide. Devazepide produces a dose-dependent acceleration of gastric emptying, with the highest dose producing emptying rates comparable to those of a nonnutritive saline load. (From ref. 289.)

CCK effects on gastric emptying likely are mediated by action on vagal afferents, because perivagal capsaicin abolishes the delay in emptying evoked by CCK. 45 In rats, intraarterial or intraperitoneal CCK increases firing in gastric vagal mechanoreceptor afferents. 296 The ability of devazepide to block the increase in firing rates of gastric vagal afferents evoked by CCK indicates mediation by CCK-A receptors. 297 In another study, CCK amplified vagal afferent discharges induced by duodenal nutrients, indicating an integrative response. 298 Some investigations suggest the additional involvement of splanchnic pathways. 279 Devazepide attenuates the inhibition of gastric emptying evoked by duodenal lipids. 252 However, that there is no additive effect of devazepide and vagal capsaicin on preventing the inhibitory effects of lipids suggests that CCK acts solely on vagal afferent CCK-A receptors in this model. The actions of CCK on gastric emptying are mediated by the release of secondary transmitters that then act on selected gastric sites. Studies in cats show that CCK-evoked catecholamine release from splanchnic efferent nerves produces excitatory and inhibitory effects on gastric muscle through action on a_2- and ß-adrenergic receptors, respectively. 299 In rats, serotonin (i.e., 5-$HT_{2A/2C}$) receptors are postulated to mediate the inhibitory effects on gastric emptying of endogenous CCK released by intestinal lipid perfusion. 300

Central Nervous System Modulation Central nervous system input is a crucial regulator of gastric motor function. Noxious noise modifies fasting gastric contractions in dogs, and mental stress prolongs MMC cycling in humans. 301 Physical restraint of rats replaces the MMC with irregular, continuous phasic contractions. The fed motor pattern is affected by acoustic stress and by immersion of the hand in cold water. 302 Cold stress induces isolated pyloric contractions, inhibits antral contractions, stimulates duodenal phase III, and prolongs liquid emptying. 303, 304 Experimentally induced vertigo, noise stress, restraint stress, cold pain, and ischemic pain all delay gastric emptying. 302, 305 In humans, gastric motor activity is increased during anger and is decreased during fear and depression. Multiple neurohumoral pathways participate in these stress responses, as demonstrated by the associated release of norepinephrine and endorphins and by their blockade after truncal vagotomy or with antagonism of adrenergic or opioid receptors. 306, 307 Corticotropin-releasing factor (CRF) has been extensively investigated as a prominent mediator of stress effects on gastric motor function. Infusion of CRF into the brain or spinal cord delays gastric emptying through a vagal cholinergic pathway. 308, 309 Some stressors evoke intracerebral CRF release. The peripheral effects of many stressors are inhibited by prior administration of CRF receptor antagonists, suggestive of a physiological role for this peptide. 309, 310 and 311 The ability of the selective CRF_2 ligand urocortin to disrupt gastric motility when given intracerebroventricularly and the failure of CRF_1 receptor antagonists to block the effects of CRF or urocortin suggest that the CRF_2 receptor mediates the central responses to CRF. 312, 313 Centrally administered CRF antagonists reverse intracisternal interleukin-$1_ß$–evoked delays in gastric emptying, indicating a possible physiological interaction of inflammatory mediators with central CRF pathways. 314 The ability of a somatostatin analog infused into the fourth ventricle to block the effects of CRF on gastric emptying is suggestive of mediation by endogenous somatostatin pathways. 315 Central neural NO pathways can modulate physiological fasting gastric motor activity. Inhibition of central NO synthase suppresses gastric and duodenal phase III but has no effect on jejunal cycling or on solid emptying; these findings indicate differential central regulation of proximal and distal motor function and on fasting and fed contractile patterns (Fig. 10-13). 316 Central administration of NO synthase inhibitors increases tonic and phasic pyloric motor activity. 317 The ability of truncal vagotomy to block this effect indicates mediation by vagal pathways. The inability of the ganglionic blocker hexamethonium to prevent the gastric relaxation evoked by NO synthase inhibition implies that nonnicotinic pathways participate in this response. 318 The presence of NO synthase activity in the dorsal vagal complex of the brainstem implies a role for NO in the afferent regulation of gastric motor function. 319

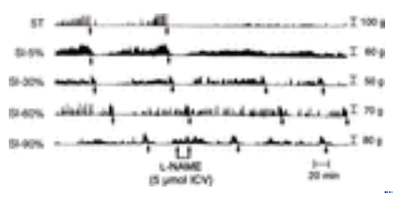

FIGURE 10-13. Effects of intracerebroventricular (*ICV*) injection of the nitric oxide (*NO*) synthase inhibitor *N* G-nitro-L-arginine methyl ester (*L-NAME*) on gastroduodenal motor activity are shown. Central L-NAME inhibited phase III activity in the stomach (*ST*) and duodenum but not in the distal small intestine (*SI*). (From ref. 316.)

Other central nervous system neurotransmitters modulate gastric motor function as well. Central TRH administration increases gastric motor activity by action on vagal pathways. 320, 321 The excitatory effects of TRH are abolished by intracisternal injection of TRH mRNA antisense oligonucleotides, which block the function of TRH. 322 TRH antibodies also block stimulation of gastric contractions evoked by central injection of glutamate, and TRH receptor 1 antisense oligonucleotides block the delay in gastric emptying evoked by cold stress, suggesting that TRH may represent a physiological activator of gastric motility in response to varied central nervous system stimuli. 323, 324 Oxytocin infusion into the dorsal motor nucleus of the vagus reduces gastric motor activity, whereas central administration of an oxytocin antagonist increases fasting gastric activity. 325 Oxytocin receptor antagonists also prevent the inhibition of gastric motor activity evoked by electrical stimulation of the paraventricular nucleus of the hypothalamus, suggesting a possible physiological role for oxytocin as a central inhibitor of gastric motor activity. Central adrenomedullin infusion inhibits gastric emptying through action on adrenal-dependent, CRF- independent, ß-adrenergic pathways. 326 Central administration of CCK, opiates, bombesin, tachykinins, atrial natriuretic factor, ?-aminobutyric acid, calcitonin, CGRP, substance P, or peptide YY inhibits gastric emptying or motility, in many instances through vagal pathways. 308, 320, 327, 328 Conversely, pituitary adenylate cyclase–activating polypeptide-38, pancreatic polypeptide, serotonin, and glutamate increase gastric motor activity when they are administered into selected brainstem nuclei. 329, 330 An important role for the brain-stomach axis is the regulation of food intake. The effects of centrally acting agents on gastric motor function may play pivotal roles in controlling appetite. CCK acting on CCK-A receptors in the gut suppresses food intake through activation of vagal pathways projecting to the nucleus tractus solitarius, lateral parabrachial nucleus, amygdala, and higher sites. 331 Rats lacking CCK-A receptors develop obesity, indicating the importance of CCK as a satiety hormone. 331 When given peripherally, urocortin decreases food intake in lean and obese mice in association with delays in gastric emptying. 332 Leptin is a hormone secreted by adipose tissue and gastric mucosa that plays a prominent role in the control of food intake. 333 When injected into the cerebral ventricles, leptin inhibits gastric emptying through leptin receptors on cholinergic neurons in the dorsal motor nucleus of the vagus. 334, 335 Leptin applied to the stomach activates a subpopulation of vagal afferent neurons that also respond to CCK. 333 When given together, leptin and CCK have an additive effect on vagal discharges (Fig. 10-14). These findings suggest that leptin may modulate the effects of CCK to regulate food intake. Conversely, ghrelin, a peptide secreted by the stomach, was shown to decrease gastric vagal afferent activity and to increase gastric motor activity in rats. 336 Furthermore, ghrelin may act through Y-1 receptors for neuropeptide Y expressed in the arcuate nucleus to increase food intake and to decrease energy use. 336 Ghrelin levels are suppressed by leptin, suggesting that this gastric peptide may act downstream from leptin to control appetite.

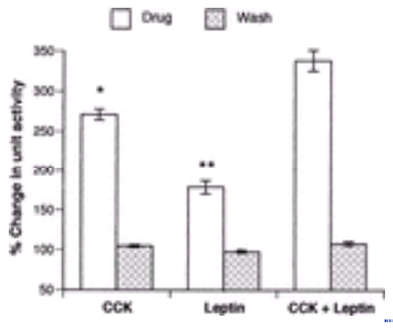

FIGURE 10-14. Effects of cholecystokinin (*CCK*) and leptin on firing of nucleus tractus solitarius neurons receiving gastric vagal afferent input. Both CCK and leptin produce increases in afferent vagal firing; when given together, their effects are subadditive. (From ref. 333.)

CHAPTER 11

William L. Hasler

MOTILITY OF THE SMALL INTESTINE AND COLON

The motor activities of the small intestine and colon are characterized by contractile patterns that serve the requirements of each organ. The small intestine processes and absorbs nutrients for distribution to the rest of the body, whereas the colon extracts water, digests some meal residue, and processes feces for expulsion. Two basic motor patterns, mixing and propulsion, subserve these functions. In the small intestine, triturated food from the stomach is mixed with bile and pancreatic enzymes for digestion and is propelled aborally. During fasting, mixing and propulsion clear the small intestine of undigested solids and sloughed enterocytes. In the colon, prominent mixing patterns afford time for the slow process of fecal desiccation, and less organized propulsion patterns result in slow transit.

Two sphincters in the lower gut regulate transit within and expulsion from the gut lumen. The ileocecal junction prevents reflux of feces from the cecum to the ileum, but its role in modulating delivery of ileal contents to the colon is less clear. The internal and external anal sphincters in concert with pelvic floor muscles control evacuation of solid waste from the body until it is socially convenient. In addition, sphincteric functionality has been attributed to the rectosigmoid junction. [1] Anatomic analyses of this region show a mucosal “rosette” nearly 3 cm in length associated with a narrowed contractile segment that halts fecal transit from the sigmoid colon to the rectum. [2]

Motility of the small intestine, colon, and sphincteric regions is controlled by myogenic characteristics, extrinsic and intrinsic nerves, and circulating hormones. External influences from meals, during sleep, with central nervous system activation, or from immune factors modulate this contractile function, as do effects of intralumenal stimuli.

ANATOMIC CONSIDERATIONS

The small intestine is about 600 cm long, including the duodenum, and the jejunum (40% of the length), and the ileum (60%). Its wall has two regions of muscle tissue, the muscularis externa and the muscularis mucosa. The muscularis externa consists of an outer longitudinal layer and an inner circular layer, oriented at 90° angles to each other. The circular layer is subdivided into inner and outer layers. The muscularis externa is the major effector of mixing and propulsion, whereas the role of the muscularis mucosa is poorly understood. Circular muscle thickening is observed at the ileocecal junction.

The structure of the colon is very different from that of the small intestine. The ileocecal junction attaches to the cecum, a sac-like structure that likely serves a storage function. The ascending, transverse, and descending regions possess a circumferential circular muscle layer with three overlying longitudinal muscle strips, the teniae coli, 120° apart. Haustra are produced by circular and longitudinal muscle contractions that narrow the lumen and shorten the length of the colon. The longitudinal muscle envelops the circumference of the rectosigmoid colon. The rectum exhibits transverse folds (usually two to three) extending beyond the midline of the rectal lumen that contain mucosa as well and circular and longitudinal muscle. [3] These structures provide a shelving function to retard fecal passage.

The anus is a specialized region with both smooth and striated muscle. The internal anal sphincter is a thickened projection of the rectal circular smooth muscle. Rectal longitudinal fibers fan out at the anal verge, pass through the sphincter muscles, and insert in the perianal subcutaneous tissue. The external anal sphincter, a striated structure, is composed of three muscles: the deep external sphincter, the superficial external sphincter, and the subcutaneous external sphincter. The levator ani muscles (puborectalis, pubococcygeus, and iliococcygeus) form a sling to surround the distal rectum and maintain continence when they are contracted.

SMALL INTESTINAL AND COLONIC SMOOTH MUSCLE

Cellular and Electrical Characteristics

Small intestinal and colonic muscle cells are spindle shaped and uninucleate. In contrast to skeletal muscle, there are no specialized regions for neuronal interaction. These cells are electrically active with resting membrane potentials of -40 to -80 mV that are maintained by Na^+,K^+-ATPase activity, and they exhibit spontaneous contractions activated by stretch. Small intestinal myoelectric activity exhibits ubiquitous membrane potential fluctuations of 3 to 15 mV oscillating at 11 to 12 cycles per minute (cpm) in the duodenum and at lower frequencies in distal regions. Extracellular recordings of this slow wave activity show sinusoidal patterns or rapid biphasic deflections from zero potential. Intracellular recordings demonstrate rapid depolarizations followed by partial repolarizations to prolonged plateau phases of depolarization. The slow wave cycle terminates with full repolarization to the resting membrane potential. In vivo slow wave activity also is present in the colon and cycles in two frequency ranges, from 2 to 6 cpm and from 9 to 13 cpm. [4] Colonic slow waves mediate short duration contractions (SDCs). In addition, rapid electrical oscillations at frequencies of 25 to 40 cpm, termed *myenteric potential oscillations,* regulate long-duration colonic contractions. [5], [6] Excised human colon circular muscle strips exhibit spontaneous slow waves of 12 mV in amplitude, 9.4 seconds in duration, and at frequencies of 2 to 4 cpm. [7] Near the myenteric edge of these strips, rapid membrane potential fluctuations at a frequency of 18 cpm are observed.

Smooth Muscle Contraction

In the small intestine, phasic contractions are controlled by the slow wave, although tonic contractions lasting 10 seconds to 8 minutes have been recorded from the circular muscle. [8] In most instances, the slow wave produces insufficient membrane depolarization to initiate contraction. Neurohumoral stimuli or exogenous administration of excitatory agonists evoke motor activity by increasing the duration and amplitude of the slow wave plateau potential or by inducing spike potentials of brief duration (10–100 ms) but high amplitude (50 mV) in phase with the slow wave. Spike potentials generated in isolated longitudinal and circular muscle propagate only a few millimeters. Intestinal relaxation results from removal of a contractile stimulus or application of an active relaxant agent that acts to inhibit spike potentials,

to reduce plateau potential amplitude or duration, or to induce membrane hyperpolarization.

Myoelectric regulation of colonic motor function is more complicated. In colonic circular muscle, contractile activity is generated from the summation of slow wave activity generated along the submucosal border and myenteric potential oscillations generated along the myenteric border. [6] This summed activity is responsible for the complex waveforms observed in colonic recordings. Contractile agonists evoke colonic contractions by increasing myenteric potential oscillation amplitude, enhancing slow wave plateau potential duration and amplitude, or generating spike potentials. [9] Relaxant agents inhibit myenteric potential oscillations, reduce slow wave activity, or evoke membrane hyperpolarization.

Interstitial Cells of Cajal as Generators of the Slow Wave

The interstitial cells of Cajal (ICCs) are believed to be responsible for generation of the slow wave. ICCs with pacemaker properties are localized to the interface of the circular and longitudinal muscle in the small intestine and along the submucosal surface of the circular layer of the colon. A second population of ICCs in the colon is present at the interface of the circular and longitudinal layers and may underlie the generation of myenteric potential oscillations. [6] ICCs are uninucleate with thin cytoplasms and numerous mitochondria indicative of high metabolic activity, as well as abundant surface caveolae with prominent endoplasmic reticula inferring active ion transport. ICCs are distinct from neurons, glia, fibroblasts, and myocytes. [10] In humans, their greatest density is in the transverse colon, which is postulated to represent the physiological pacemaker site. [11]

Substantial evidence points to ICCs as generators of spontaneous electrical rhythmicity. In cat intestine, rhythmic oscillations are generated only by tissue containing ICCs. [12] In colonic circular muscle, slow waves are maximal in amplitude at the submucosal border and become weaker in the myenteric region, indicating the importance of submucosal ICCs. Intracellular recordings from ICCs in canine colon show cyclic oscillations 37 mV higher than the resting membrane potential at 4.6 cpm. [13] Similarly, ICCs from mouse small intestine exhibit a frequency of 14 cpm with a mean amplitude of 13 mV. [14] Cyclic fluctuations in intracellular calcium underlie this electrical rhythmicity. [15] ICC-generated slow waves are reduced by the removal of extracellular calcium but are insensitive to L-type calcium channel blockers. [14] Rhythmicity in cultured ICCs is dependent on calcium release from intracellular stores. [16], [17] Selective injury to ICCs by administration of methylene blue plus intense illumination disrupts the slow wave and provides evidence of the pacemaker capabilities of these cells. [18]

Intrauterine ICC maturation requires signaling by the c-Kit tyrosine kinase receptor. [19] In human fetal small intestine, c-Kit immunoreactivity is demonstrable at a gestational age of 13 weeks. [20] A continuous layer of ICCs forms from week 17 to birth. Staining for c-Kit and smooth muscle myosin heavy chain, investigators have suggested that ICCs and longitudinal muscle cells may share a common mesenchymal progenitor cell. [21] Down-regulated in cells destined to become muscle cells, c-Kit is up-regulated in cells that become ICCs. [22] ICCs mature normally in glial cell line–derived neurotrophic factor knock-out mice that exhibit no enteric neurons, indicating that the enteric plexuses are not required for ICC development. [23] Studies measuring c-Kit expression provide the most convincing support for ICCs as physiological regulators of the slow wave. Mice with mutations in the kit gene lack ICCs and exhibit impaired peristalsis. [24], [25] In animals with mutations in the steel factor, the ligand for c-Kit, ICCs are absent in the small intestinal myenteric plexus, and slow wave cycling is not detected (Fig. 11-1). [19] Finally, in neonatal mice, administration of neutralizing monoclonal antibodies to c-Kit abolishes small intestinal rhythmicity and reduces the number of ICCs, which then assume the appearance of smooth muscle cells. [26], [27]

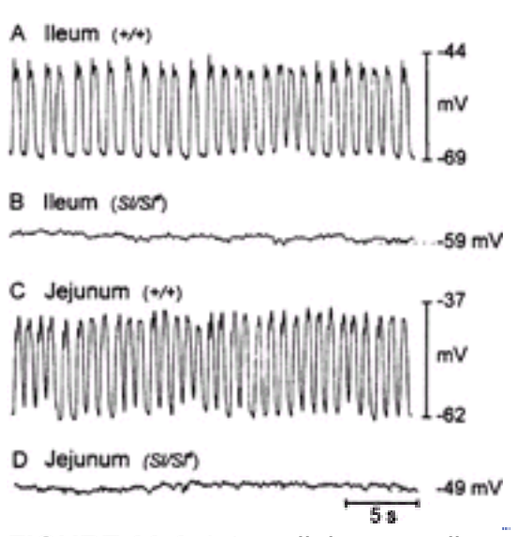

FIGURE 11-1. Intracellular recordings from circular smooth muscle cells from mouse small intestine. In tissue from wild-type mice (+/+), typical slow wave activity is prominent both in the ileum (**A**) and jejunum (**C**). In contrast, steel mutants (*Sl/Sl* ^{d}) which lack the ligand for c-Kit, exhibit no evidence of spontaneous slow waves in either the ileum (**B**) or jejunum (**D**). (From ref. [19].)

Coupling of Small Intestinal and Colonic Contractions

Migration of small intestinal myoelectric and motor activity is regulated by intrinsic electrical coupling properties. Intestinal slow wave propagation requires continuity of both muscle layers. After excision of a 1-mm band of circular muscle, longitudinal slow wave propagation is limited to distances of 3 to 6 mm. [28] Removal of more than 5 mm of longitudinal muscle abolishes slow wave propagation, whereas excision of shorter bands permits inefficient propagation. Significant coupling exists between longitudinal and circular muscle cells in the small intestine. In the circular layer, gap junctions or nexuses provide low-resistance pathways for electrical conduction and for passage of low-molecular-weight second messenger compounds. Close coupling also is observed in the longitudinal layer, which possesses few or no nexuses. In this layer, other structures such as peg-and-socket junctions may mediate intercellular communication. [29] Interconnecting bridges between the circular and longitudinal layers may provide low-resistance coupling across the myenteric region. Furthermore, ICCs are extensively innervated and form close electrical contacts with smooth muscle cells from both layers. Research suggests that gap junctions may not be needed for the pacemaking function of ICCs; rather, ICC coupling may use a syncytium of circular muscle cells. [30] In the deep muscular plexus of the circular layer, specialized ICCs form close junctions with smooth muscle cells as well as nitric oxide (NO) synthase–like and substance P–like immunoreactive axonal varicosities; these findings suggest that ICCs may provide a pathway for nerve-muscle communication. [31], [32] Furthermore, ICCs express M_2 and M_3 muscarinic receptors, NK_1 and NK_3 neurokinin receptors, VIP_1 vasoactive intestinal polypeptide receptors, and stem cell factor, indications of modulation by neuronal pathways. [33]

Because small intestinal smooth muscle coupling is close, cells with the highest slow wave frequency entrain adjacent cells in a phenomenon termed *phase lock.* In humans, the dominant pacemaker extends from the pylorus to the ligament of Treitz. Slow wave propagation is faster in the longitudinal axis (7–10 cm/s) than in the transverse axis (1 cm/s). [34] Uncoupling of slow wave synchrony develops over the long distances encountered in the small intestine and is more pronounced in the ileum than in the duodenum. [35] The human intestinal slow wave frequency decreases from 11 to 12 cpm in the duodenum to 7 to 8 cpm in the distal ileum. In most species, the decrease in frequency from the duodenum to the ileum occurs in stepwise fashion, producing alternating frequency plateaus and regions of variable frequency. Frequency plateaus are prominent more proximally but are often undetectable in the ileum. [35] Consequently, there are expansive regions of myoelectric coupling in the upper gut that promote long distance contractile propagation, whereas uncoordinated ileal slow waves limit the migration distance. In addition to regional variations in frequency, slow wave propagation velocities decrease by up to 50% from the duodenum to the distal ileum. These phenomena are advantageous for efficient digestion. Proximally, nutrients are propelled over a large mucosal surface area for rapid digestion and absorption, whereas distally, retarded propulsion permits absorption of slowly digested and absorbed substances such as fats and bile.

In the colon, slow wave migration requires continuity of the submucosal aspect of the circular muscle. [36] The slow wave is considerably less well entrained across different colonic regions compared with small intestinal myoelectric complexes because of a lesser degree of intercellular electrical coupling. Colonic slow wave frequencies and propagation velocities are highly variable, in part because of a marked reduction in circular muscle nexus density as compared with the small

intestine. [37] Unlike in the small intestine, there is no decrement in slow wave frequency from the ascending colon to the rectum. Colonic slow wave propagation is faster circumferentially (1.6 cm/s) than longitudinally (1–5 mm/s), providing myoelectric coordination of slow propagating segmenting ring contractions. [38], [39]

In addition to regulating peristalsis, slow wave activity generated by the ICCs controls the nonpropagative mixing activities of the gut. Mixing movements within the longitudinal layer are the consequence of spontaneous calcium waves generated by pacemaker sites that spread in all directions and that terminate by collision with calcium waves from other pacing sites (Fig. 11-2). [40]

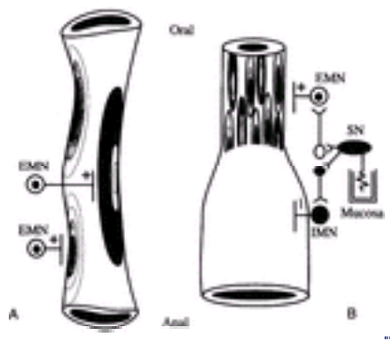

FIGURE 11-2. Neural mechanisms underlying mixing (**A**) and peristalsis (**B**). Mixing is regulated by pacing sites that propagate over large regions evoking localized shortening. Peristalsis results from activation of polarized nerve pathways that induce propagation orad to and suppress propagation caudad to the stimulus. *EMN,* excitatory motor neuron; *IMN,* inhibitory motor neuron; *SN,* sensory neuron located in the mucosa. (From ref. [40].)

Relative Functions of Longitudinal and Circular Muscle

The distinct functions of longitudinal and circular muscle in the small intestine are poorly understood. The circular layer is believed to mediate both mixing and propulsion, because lumenal occlusion and displacement of gut contents require contraction of this layer. The most basic small intestinal contractile pattern, segmentation, results from reciprocal inhibition and disinhibition of adjacent circular muscle. Although longitudinal muscle likely does not have potent propulsive capabilities, contraction of this layer theoretically could shorten the gut and accelerate transit. Longitudinal contraction also can increase lumenal diameter to facilitate movement of large boluses. The timing of contractions in the two layers is controversial; some investigations have observed concurrent motor activity, and others have reported 90° to 270° phase lags between circular and longitudinal contractions. [41], [42] In guinea pig ileum, independent contractions of the two layers are noted at low intralumenal pressures, whereas simultaneous contractions occur at higher pressures. [43] Spatiotemporal mapping has shown the contraction of the longitudinal layer immediately preceding and during the propulsive period of circular muscle contraction. [44] However, when the circular contraction occluded the lumen, longitudinal lengthening occurred.

Less is known about the functions and timing of circular and longitudinal muscle in the colon. Circular muscle contractions are lumenally occlusive, whereas those of the longitudinal layer may shorten the colon. Longitudinal contraction was recorded preceding circular contraction in one study, although other investigators observed similar electrical responses of the two layers during contraction. [45] A model of peristalsis has demonstrated synchronous contraction orally and relaxation aborally of the longitudinal and circular layers in response to a lumenal stimulus. [46]

INNERVATION OF THE SMALL INTESTINE AND COLON

Gut smooth muscle is innervated by extrinsic nerves relaying information to and from the extraintestinal ganglia, the spinal cord, and the central nervous system and by intrinsic nerves within the intestinal wall. The vagus and splanchnic nerves supply the small intestine, ileocecal junction, and proximal colon, whereas the pelvic nerves provide input to the colon and internal anal sphincter. Transcranial magnetic stimulation reveals bilateral cerebral motor cortex representation in the innervation of the anus and rectum. [47] The external anal sphincter and pelvic floor muscles receive sacral spinal input from the pudendal nerves. [48] The myenteric plexus provides the major intrinsic innervation to the small intestine and colon, although the submucous plexus may play a minor role in some reflexes. The number of intrinsic neurons greatly exceeds the number of vagal, pelvic, or splanchnic fibers. The human enteric nervous system contains 10 to 100 million neurons versus 2,000 efferent fibers in the vagus; thus, most motor activities are directed by intrinsic nerves, whereas extrinsic innervation provides a modulatory function.

Extrinsic Innervation

Efferent Neural Pathways Efferent extrinsic fibers are carried in parasympathetic and sympathetic tracts. Most efferent fibers terminate in the myenteric plexus and form connections with enteric ganglia, although some sympathetic axons terminate directly on sphincteric smooth muscle. The vagus nerves contain three groups of efferent fibers: preganglionic parasympathetic excitatory cholinergic nerves to the enteric plexuses, preganglionic inhibitory cholinergic nerves to the myenteric plexus, and sympathetic fibers from the cervical ganglia. Efferent vagal cholinergic neurons activate nicotinic receptors within enteric ganglia with excitation of motor activity. In general, these fibers exhibit a low threshold to electrical stimulation. The cell bodies of these efferent nerves reside in the brainstem vagal dorsal motor nucleus. Those fibers exhibiting high thresholds to electrical stimulation are inhibitory to motor activity via release of VIP and NO. The efferent vagal supply is maximal in the upper gut, although anterograde tracing studies from the rat dorsal motor nucleus confirm vagal innervation to much of the colon. [49] In ferrets, cooling the vagus nerves, thereby inducing temporary vagotomy, abolishes phasic motility in the proximal colon, whereas vagal stimulation evokes proximal colonic contractions. [50] Pelvic nerve fibers arise from cell bodies in the sacral spinal cord and enter the colon at the rectosigmoid junction. From there, they travel in shunt fascicles to innervate the myenteric plexus. Unlike enteric nerves, shunt fascicles have a perineurium, myelinated fibers, and their own blood supply. Pelvic nerve stimulation evokes generalized colonic contractions of the circular and longitudinal muscle layers and accelerates colonic transit. [45], [51] Sympathetic splanchnic innervation is different from vagal parasympathetic innervation in that neuronal cell bodies reside outside the gut in the prevertebral ganglia (i.e., the celiac, and superior and inferior mesenteric ganglia). Preganglionic cholinergic neurons project from the spinal cord to the prevertebral ganglia. Noradrenergic postganglionic neurons then project to the enteric ganglia. Such sympathetic innervation generally inhibits excitatory cholinergic transmission in the myenteric plexus of both the small intestine and colon. [45], [51] The functional significance of these pathways is exemplified by the long inhibitory intestinal reflexes that decrease motility through neural arcs involving the prevertebral ganglia. Conversely, ablation of the prevertebral ganglia has little effect on colonic transit. Numerous neurotransmitters participate in extrinsic neural control of small intestinal and colonic motor function. Peptidergic fibers containing somatostatin, substance P, cholecystokinin (CCK), neuropeptide Y (NPY), enkephalins, and other transmitters are present in the vagus and splanchnic nerves.

Afferent Neural Pathways Afferent fibers outnumber efferent fibers by tenfold in the vagus and by almost threefold in the splanchnic nerves. Vagal afferent fibers terminate in the brainstem nucleus solitarius. Neurons in the nucleus solitarius project to the vagal dorsal motor nucleus and the nucleus ambiguus. Sensory information from the small intestine and colon is transmitted to the dorsal horn of the spinal cord by the splanchnic nerves. From there, second-order neurons project to the brainstem and cerebral cortex. The anus is innervated by sensory fibers that project through the pudendal nerve. The small intestine and colon are richly supplied with sensory fibers. Free mucosal nerve endings respond to stroking or to chemical stimuli such as hydrochloric acid. Mucosal receptors in the anal canal are sensitive to mechanical stimuli, temperature, and electrical current. [52] Thermoreceptor exposure in the small intestine activates perceptual responses and reflex motor responses in the stomach. [53] Mechanoreceptors are activated by passive distention or during active contractions. Pelvic nerve afferent fibers from the colon respond to distention, heat, and bile salts, indicating the polymodal nature of the receptors. [54] That excision of the mucosa, submucosa, and the inner circular muscle does not abolish responses to stretch localizes mechanoreceptors to the outer muscle layers or the myenteric plexus. [55] Mesenteric and serosal receptors respond to tension or to forceful contraction and may mediate visceral pain perception. Intrinsic afferent neurons that mediate local neural reflexes project within the enteric plexuses. Afferent pathways that mediate extended reflexes involve vagal, pelvic, and splanchnic nerves and may be modulated by cerebral input. Afferent information involving perception of nonnoxious stimulation may be transmitted via vagal, pelvic, or splanchnic pathways, whereas nociceptive input is believed to be carried mainly by the splanchnic nerves. Significant interaction between motor and sensory function is evidenced by studies using dual magnetic stimulation of the cerebral motor cortex, in which cortical transmission to the anus was facilitated by prior electrical stimulation of the lumbosacral root or pudendal nerve. [56] Plasticity of sensory nerve activity is shown by experiments that demonstrate reductions in ileal vagal afferent sensitivity with prior exposure of the distal ileum to short-chain fatty acids. [57]

Intrinsic Innervation

The density of myenteric neurons ranges from 3,700 to 12,170 cells/cm [2] in the cat small intestine, approximating that of the spinal cord. [58] In humans, an additional deep muscular plexus innervates the interface of the inner and outer circular muscle layers of the small intestine and colon and receives input from the myenteric plexus. The submucous plexus provides less than 1% of the axons to smooth muscle and projects instead to the mucosa, where it likely mediates secretory and absorptive activities. [59] In the colons of some species, the outer layer of the submucous plexus provides important input to the circular muscles and ICCs. [60], [61]

The enteric nervous system possesses the elements for complete reflex activities, including afferent neurons, interneurons, and motor neurons, and thus can mediate physiological motor patterns in the absence of extrinsic input. Myenteric ganglia resemble the central nervous system in that only neurons and glial cells are present. In the absence of blood vessels and connective tissue cells, neuronal nourishment diffuses from the interstitial fluid. Neurotransmitters released from axonal varicosities diffuse 20 to 100 nm to specific receptors on muscle cells or neurons. In the small intestine, motor neurons typically project 1 to 2 mm longitudinally, although some fibers extend for 30 mm. Excitatory fibers run cephalad, whereas inhibitory fibers project in a caudad direction. Reflex projection of 100 cm or more implies extensive interneuronal connections. [62] Most myenteric neurons project to other myenteric neurons and to the circular muscle; fewer supply the submucous ganglia. The less well supplied longitudinal muscle receives fibers primarily from excitatory motor neurons with little inhibitory input.

Eighty percent to 90% of myenteric neurons contain either tachykinins (40%–45%) or VIP (40%–45%), with no overlap between the two groups. Tachykinin neurons containing substance P, neurokinin A, and acetylcholine mediate most of the excitatory functions of intestinal smooth muscle. [63] In rat intestinal longitudinal muscle, neural stimulation evokes contractions that are incompletely blocked by atropine. [64] The atropine-resistant fraction is abolished by tachykinin receptor antagonists. The inhibitory supply to the small intestine and colon is provided by NO- and VIP-containing myenteric neurons. [65] Inhibitors of NO synthesis block ileal relaxations evoked by electrical depolarization, serotonin (5-HT), ATP, and ?-aminobutyric acid (GABA). [66] Furthermore, inhibition of NO synthase evokes duodenal contractions in rats, indicating tonic inhibition by NO pathways. [67] Similarly, antagonists or antisera to VIP prevent neurally mediated relaxation. [68], [69] A related transmitter, pituitary adenylate cyclase–activating peptide (PACAP), also may act as a physiological relaxant in some regions through activation of PACAP $_{1}$/VIP receptors. [70] NO synthase, the enzyme responsible for NO generation, colocalizes with VIP in colonic neurons, suggesting that the two transmitters perform interrelated functions. [71] In some models, VIP evokes NO-dependent relaxations through an intermediate transmitter, such as GABA acting on GABA $_{A}$ receptors. [72] Some VIP neurons contain NPY, calcitonin gene–related peptide (CGRP), gastrin-releasing peptide (GRP), and galanin. ATP is an important inhibitory neurotransmitter for some gut activities. In rat colon, nearly all ATP-containing myenteric neurons exhibit NO synthetic capabilities. [73] In rat anus, the relaxant response to ATP is reduced by a combination of an NO synthase inhibitor, tubocurarine and apamin, indicating partial NO pathway participation in purinergic innervation. [74] Finally, tachykinin pathways may interact with nitrergic function in some stimulated states, such as lumenal distention. In guinea pig small intestine, NK $_{1}$ receptor activation, mediated by NO release, evokes both stimulatory and inhibitory effects on distention-evoked contractions. [75]

Intrinsic neurons distinct from tachykinin-, NO-, and VIP-containing cells likely function as interneurons to modulate gut motor activity. Opioid neurons regulate both excitatory and inhibitory transmission. Enkephalinergic neurons project orally to both muscle layers, whereas neurons containing GRP and NPY project in an aboral direction. [76] Orphanin FQ immunoreactivity is expressed in excitatory neurons projecting to both muscle layers and to a few interneurons. [77] Neurons containing substance P and CGRP may mediate sensory function in the colon. [78] Colon smooth muscle from mice with a knock-out of the dopamine transporter exhibits impaired contractions to electrical stimulation, indicating a physiological role for endogenous dopamine. [79] Endogenous cannabinoid pathways may inhibit small intestinal motility by acting on CB $_{1}$ receptors. [80]

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL MOTOR PATTERNS UNDER BASAL FASTING CONDITIONS

Small Intestine

During fasting, the small intestine exhibits a prominent cyclic motor pattern, the migrating motor complex (MMC). Other patterns that occur less frequently and with less regularity also play important roles in small intestinal transit, in both health and illness.

Migrating Motor Complex

Physiological characteristics. The MMC is an organized fasting pattern termed the *intestinal housekeeper* that propels undigested food residue and sloughed enterocytes from the proximal gut. [81] The rapid development of small intestinal bacterial overgrowth in rats given morphine to disrupt MMC cycling shows the importance of this motor pattern (Fig. 11-3). [82] The electrical correlate of the MMC is the migrating myoelectric complex. [83] The MMC consists of four phases lasting 84 to 112 minutes (Fig. 11-4). Phase I is a period of motor quiescence lasting 40% to 60% of the cycle length. Phase II, occupying 20% to 30% of the cycle, exhibits irregular phasic contractions involving about half of the slow wave cycles. The duodenal cross-sectional area is greater during phase II than phase I, possibly to accommodate pancreaticobiliary secretions. [84] Phase III is a 5- to 10-minute period of lumenally occlusive, rhythmic contractions, most of which propagate aborally. Some duodenal phase III contractions propagate in an orad direction, however, indicative of a physiological retroperistaltic pump. [85] This retroperistaltic activity is associated with duodenogastric reflux of bicarbonate and immunoglobulin A, which have been proposed to reconstitute the antral mucosal barrier during fasting. [86] The maximal phase III contractile frequency is determined by the slow wave frequency (11–12 cpm in the duodenum, 7–8 cpm in the ileum). Phase III complexes propagate more slowly (4–6 cm/min) than the slow wave because of a loss of slow wave phase locking and shortening of frequency plateaus. [87] Nevertheless, individual phase III contractions propagate over longer distances than phase II contractions. [88] The length of intestine in a given phase III complex decreases from 40 to 60 cm in the duodenum to 5 to 10 cm in the ileum. Phase IV is a transition period of irregular contractions between phase III and phase I.

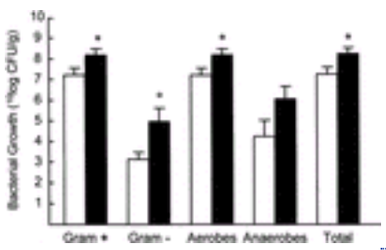

FIGURE 11-3. Growth of different bacteria in the duodenum of rats is shown after administration of placebo (*open bars*) or morphine (*black bars*) to disrupt migrating motor complex (*MMC*) cycling. Morphine led to increases in total bacteria as well as both gram-positive and gram-negative aerobes. (From ref. [82].)

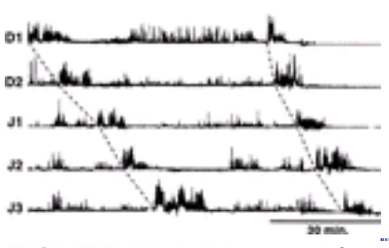

FIGURE 11-4. Manometric recordings of the different phases of the human migrating motor complex (MMC) cycle from the duodenum (D1, 2. to the jejunum (J1, 2, 3). The *dashed lines* show propagation of the leading edge of two phase III complexes. (From ref. [90].)

Although typically present during fasting in healthy persons, MMCs exhibit variability in several parameters. However, sequential manometric recordings in the same patients demonstrate that intraindividual MMC characteristics are very reproducible. [89] In nearly all healthy subjects, at least one phase III develops during 6 hours of fasting. [90] Seventy-one percent of phase III complexes originate in the stomach, with 28% beginning in the duodenum and 1% in the proximal jejunum. [91] The fraction

of MMC complexes that originate in the stomach or duodenum linearly correlates with the duration of fasting. [92] Furthermore, MMC cycle duration is nearly twice as long when the previous phase III complex originated in the stomach versus the duodenum. [93] One half of MMCs propagate beyond the midjejunum, and only 10% reach the distal ileum. Infants born at term exhibit physiological phase III activity, albeit with an increased number of nonpropagated clusters; preterm babies, however, often exhibit low-amplitude, disorganized clustered contractions of short duration without recognizable phase III activity. [94] There are no qualitative differences in MMC characteristics between young (18–39 y) and old (40–69 y) persons, although phase III propagation velocity may decrease in persons older than 80 years. [95]

Neural regulation. Neural regulation of the intestinal MMC involves extrinsic and intrinsic input. Extrinsic innervation from the vagus and splanchnic nerves serves a modulatory function. Bilateral truncal vagotomy, removal of the superior and inferior mesenteric ganglia, total sympathectomy, and complete extrinsic denervation of the small intestine do not prevent MMC cycling, although cycle duration and regularity may be altered. [96], [97] and [98] Bilateral vagotomy increases cycle duration, whereas section of the extrinsic nerves to the jejunum and ileum decreases the MMC cycle length, reduces the percentage of phase III complexes that propagate to the ileum, and disrupts coordination of duodenal and jejunal phase III activity. [96], [99] Vagal cooling in dogs has no effect on intestinal phase III, but it shortens intestinal phase II activity, an effect suggesting a vagally mediated pathway for maintenance of phase II activity and a vagally independent pathway for phase III. [100] Enteric ganglia coordinate small intestinal MMC propagation. Isolated denervated intestinal segments exhibit spontaneous phase III activity that propagates aborally; however, cycling in the excluded segment is out of phase with the main segment, suggesting that continuity of the enteric nervous system synchronizes cycling from one intestinal region to the next. [101] Likewise, intestinal transection into many segments with subsequent end-to-end reanastomosis promotes independent phase III activity in each segment. [102] In this model, neuronal growth across the anastomosis is noted at 28 days, and coordinated cycling resumes at 45 days, features indicative of regeneration of enteric nerve connections. [102], [103] If a segment of colon is interposed between the small intestinal segments or if end-to-side or side-to-side intestinal anastomoses are performed, coordination does not resume; this shows a requirement for continuity of small intestinal–type enteric nerves. [104] In guinea pigs, longitudinal myomectomy with circumferential interruption of myenteric ganglia blocks propagation of 50% to 60% of phase III complexes, whereas complete transection with reanastomosis blocks more than 80% of complexes, indicating an important role for the myenteric plexus in MMC continuity. [103] Other investigators have demonstrated disruption but not abolition of MMC cycling with serosal application of benzalkonium hydrochloride, which selectively destroys myenteric ganglia, suggesting that the deep muscular plexus and submucous plexus have some role in maintaining the MMC. [105] Cholinergic and noncholinergic pathways participate in MMC contractions. In dogs, intravenous administration of atropine, the ganglionic blocker hexamethonium and the neural toxin tetrodotoxin eliminate MMC cycling. [106] Close intraarterial injection of these agents prevents MMC propagation distal to the site of infusion. [107] Adrenergic receptor antagonists disrupt but do not abolish MMC cycling. NO synthase inhibitors evoke premature MMC activity, then more rapid cycling, indicating that endogenous NO may be a physiological inhibitor of fasting motor function. [108], [109] Conversely, the NO donor sodium nitroprusside disrupts MMC activity in rats and induces a postprandial-like pattern. [110] Similarly, the phosphodiesterase inhibitor sildenafil, which prevents cyclic GMP degradation after NO stimulation, disrupts MMC cycling. [111] Selective VIP receptor antagonists block the disruptive effects of NO donors, indicating that NO may mediate its actions through VIP release. [112] After small intestinal transection and reanastomosis in guinea pigs, immunoreactivities for VIP, GRP, and somatostatin are decreased distal to the anastomosis. [103] Recovery of MMC cycling is associated with recovery of these peptides and nerve regrowth, suggesting that peptidergic nerves within the myenteric plexus may contribute to coordinated MMC activity. Endogenous 5-HT has been promoted as a physiological modulator of the intestinal MMC. 5-HT increases the frequency of intestinal contractions, shortens the MMC cycle length, accelerates propagation patterns, and converts mixing patterns to propulsive ones. [113], [114] In rats, ablation of myenteric 5-HT neurons with 5,6- and 5,7-dihydroxytryptamine prolongs MMC periodicity and decreases propagation velocities. [115] Finally, 5-HT $_3$ receptor antagonists inhibit phase III activity or prolong cycle length. [116], [117] Other neural factors may modulate intestinal MMC activity. Morphine induces premature intestinal phase III activity, whereas the μ-opioid receptor antagonist naloxone prolongs MMC periodicity from 103 to 219 minutes. [102], [118] Consequently, opioid peptides may be intermediaries in generating intestinal phase III activity and may function in recovery of phase III cycling after a meal. Neurokinin A and substance P increase phase II activity in the human small intestine, suggesting that tachykinins may selectively regulate that phase of the MMC. [119]

Hormonal mediation. Induction of phase III in the stomach and proximal small intestine results from release of the hormone motilin from the duodenal mucosa. [120] Motilin receptors are expressed in human duodenal and colonic enteric neurons. [121] The motilin receptor is G-protein coupled and is 52% identical to the receptor for growth hormone secretagogues. Motilin also is localized to the hippocampus, thalamus, hypothalamus, amygdala, cerebellum, and vagus in animal models; however, its physiological function in these sites is uncertain. [122], [123], [124] and [125] Antral phase III complexes temporally correlate with plasma motilin elevations in healthy humans, and premature antral phase III activity is inducible by motilin infusion. [126] Motilin-evoked phase III is identical in duration, amplitude, and propagation velocity to spontaneous complexes. [127] In dogs, gastroduodenal phase III, abolished for several hours after infusion of motilin antisera, is replaced by irregular phasic contractions. [128] Likewise, duodenal excision with removal of motilin-secreting tissue alters fasting antroduodenal motility in dogs. [129] The motilin-dependence of MMC cycling exhibits neural plasticity. After duodenectomy, dogs exhibit a recovery of gastroduodenal MMC-like activity 1 to 4 months postoperatively that is vagally mediated and dependent on cholinergic and adrenergic efferent pathways. [130] The physiological stimulus for motilin cycling is not known. Cyclic motilin fluctuations are blocked by atropine and hexamethonium, suggesting regulation by cholinergic pathways. [131] Motilin release is evoked by vagal stimulation, cholinergic agonists, opioid agents, and duodenal pH changes, but the roles of these stimuli in the regulation of motilin release are unclear. [131], [132] and [133] Similarly, NO synthase inhibitors evoke phase III–like antroduodenal complexes with associated increases in plasma motilin. [134] There are differences in the motilin-dependence of phase III complexes in the proximal and distal small intestine. Ectopic complexes originating distal to the ligament of Treitz often are unassociated with plasma motilin elevations. [135] Furthermore, the effects of motilin antisera on distal jejunal and ileal phase III complexes are minimal. [102], [128] Similarly, ectopic phase III complexes form in the jejunum and ileum after resection of duodenal motilin-producing tissues. [129] These findings suggest that “programming” of phase III activity in the medial and distal intestine is a motilin-independent phenomenon that is entrained by the actions of motilin on the antrum and duodenum. The only peptides other than motilin known to cycle in phase with the MMC are somatostatin and pancreatic polypeptide; however, it is unlikely that either is a mediator of the complex. [136], [137] Somatostatin evokes intestinal phase III complexes every 20 to 30 inutes, but the complexes are not physiological because gastric motor activity is suppressed. [136] Furthermore, somatostatin-evoked complexes do not exhibit a phase II–like pattern of irregular contractions, and they delay rather than accelerate transit. It is conceivable that somatostatin may play a role in motilin-independent cycling in the distal intestine. Plasma levels of pancreatic polypeptide, a peptide produced by the pancreas, also peak just before phase III. [138] Furthermore, pancreatic polypeptide is released by exogenous motilin administration through vagal, cholinergic pathways involving 5-HT $_3$ receptors. [139] However, pancreatic autotransplantation has no effect on intestinal phase III cycling despite its disruption of pancreatic polypeptide fluctuations. [140] In addition, pancreatic polypeptide infusion to levels mimicking those during phase III has no effect on fasting intestinal motility. [141] The importance of other hormones in regulating MMC activity is speculative. Glucagon-like peptide 1 (GLP-1) prolongs MMC cycle duration with slowing of transit through activation of NO-dependent pathways. [142] Ileal resections reduce phase I duration, shorten the MMC cycle, and induce intestinal clusters, suggesting modulatory roles for peptides specifically released by the distal small intestine. [143]

Other associated cyclic phenomena. The intestinal MMC cycles in phase with motor activity of the gallbladder and sphincter of Oddi as well as with several secretory functions. Gastric acid and pepsin production and intestinal fluid secretion increase before duodenal phase III. [144] Similarly, the release of bicarbonate, bile acids, bilirubin, pancreatic enzymes, and lumenal secretory immunoglobulin A peaks just before or during phase III. [138], [145] Qualitatively, this relationship persists at night; however, there is a relative reduction in motor activity with preservation of exocrine output providing evidence for differential circadian rhythms for motility and enzyme release (Fig. 11-5). [146] Furthermore, duodenectomy and diseases such as chronic pancreatitis disrupt the synchrony of MMC activity and pancreatic exocrine cycling, suggesting differential regulation of the two phenomena. [129], [147]

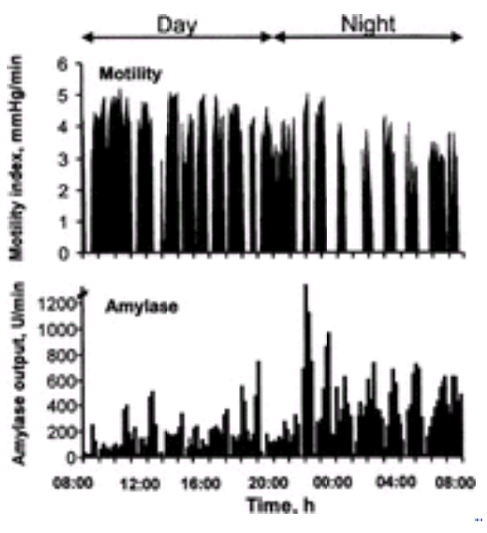

FIGURE 11-5. Circadian cycling of jejunal motility (**top**) and amylase output (**bottom**). Pancreatic secretion exhibits a close correlation with motor cycling, however differential regulation is shown by the observation that enzyme output increases at night while contractile activity is unchanged. (From ref. [146].)

These secretory activities may modulate the induction of MMC cycling. Motilin is released into the circulation after exposure of duodenal mucosa to bile. [148] Furthermore, experimental bile duct occlusion or diversion of bile away from the duodenum disrupts motilin cycling with the loss of duodenal phase III and induction of ectopic jejunoileal complexes. [149] Bile flow restoration and exogenous bile acid perfusion reverse these effects. [150] Despite this information, other studies dispute the role of bile in MMC generation. [151] Peak pancreatic secretion has been observed both in phase and out of phase with phase III cycling. [152] Phase III–independent secretory peaks occurred in subjects with longer MMC cycle lengths.

Giant Migrating Complexes Intense contractile waves that propagate aborally for long distances in the intestine are observed in experimental animals during hypoxia, anemia, and gangrene, after laparotomy, and after death. This phenomenon has been given many names including peristaltic rush, prolonged propagated contractions, migrating action potential complexes, power contractions, and giant migrating contractions (GMCs). Small intestinal GMCs are two to three times greater in amplitude and four to five times longer in duration than individual phasic contractions, and they propagate at 1 cm per second. [153], [154] The duration of an intestinal GMC generally is longer than that of a single slow wave, indicating dissociation of the slow wave regulation of phasic contractile activity. [153] During a GMC, myoelectric measurements record intense bursts of spike potentials lasting 4 to 16 seconds that obscure the slow wave. [154] GMCs typically begin in the jejunum or ileum during fasting and migrate to the ileocecal junction. They are intensely propulsive of ileal contents, in contrast to phase III. [153] Nearly half of the GMCs are associated with propagating sequences in the cecum, indicating a coordinated evacuation mechanism in the distal gut (Fig. 11-6). [155] Consequently, intestinal GMCs are postulated to clear debris from the ileum and to prevent coloileal reflux. Intestinal GMCs, rare in health (0.03/h), are induced by noxious stimuli such as intravenous morphine, intragastric vinegar, ileal perfusion of feces or short-chain fatty acids, ionizing radiation, and infection with *Vibrio cholerae, Clostridium perfringens, Clostridium difficile,* noninvasive *Escherichia coli, Shigella* organisms, and *Trichinella spiralis*. [154] Induction of GMCs is associated with decreases in ileal pH, suggesting that coloileal reflux may be a physiological stimulant of this motor pattern. [156] Diarrhea, fecal urgency, and abdominal discomfort temporally correlate with GMCs during ileal inflammation, a correlation suggesting a role in symptom induction. In enteropathogenic *E coli* infection, GMCs present before the onset of diarrhea, confirming that they are not merely a response to the diarrheal state. [157] Propagation of small intestinal GMC activity is controlled by enteric neural pathways, whereas extrinsic nerves regulate inhibition of motor activity orad to the complex. [158] Research suggests that neurokinin (NK_3) receptors on presynaptic neurons may mediate GMCs in the small intestine. [159]

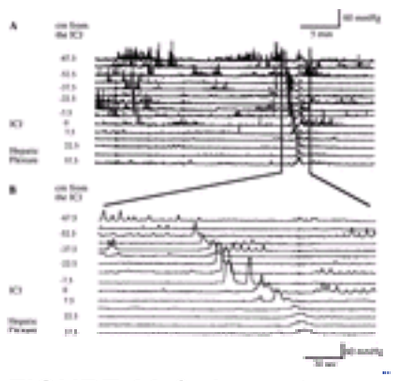

FIGURE 11-6. A spontaneous giant migrating contraction (GMC) originating in the ileum is shown propagating across the ileocecal junction (ICJ) into the proximal colon. (From ref. [155].)

Other Aborally Migrating Patterns Intensely propulsive contractions also occur in clusters termed migrating clustered contractions, discrete clustered contractions (DCCs), or the minute rhythm. [153], [160] DCCs occur while fasting and after eating and consist of 3 to 10 contractions preceded and followed by 1 minute of motor quiescence (Fig. 11-7). DCCs migrate at 5 to 10 cm per minute over distances of 2 to 40 cm and are proposed, along with GMCs, to be a physiological means of emptying the ileum. [153], [160] Unlike GMCs, DCCs rarely extend into the proximal colon. [155] In some studies, increased DCCs are observed in irritable bowel syndrome, intestinal pseudoobstruction, and partial small bowel obstruction. [161]

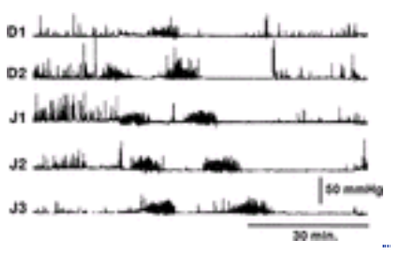

FIGURE 11-7. Discrete clustered contractions (DCCs) occurring in human duodenum (D1, 2) and jejunum (J1, 2, 3). (From ref. [90].)

An extremely propagative pattern, called the *rapidly migrating contraction,* migrates 200 cm at more than 30 cm per second. [162] In contrast to intestinal GMCs, rapidly migrating contractions occur predominantly in the proximal small intestine and are associated with disruption or loss of slow wave activity.

Retrograde Peristaltic Contractions After administration of emetic agents, complexes migrate orally from the medial small intestine to the duodenum before vomiting. These retrograde peristaltic contractions (RPCs) exhibit periods of motor inhibition immediately before and after the complex that are followed by several phasic contractions and then a second inhibitory period. [163] Vagotomy abolishes the entire phenomenon, whereas atropine prevents only the RPC itself. Although most often associated with retching or vomiting, RPCs do occur in their absence. Conversely, retching and vomiting can occur in the absence of RPCs. The purported function of RPCs is to evacuate intestinal contents into the stomach so that they may be expelled during emesis. RPCs exhibit contractile amplitudes 1.3 to 1.8 times greater than normal intestinal contractions with durations 2 to 4 times longer and rapid migrations (8–10 cm/s) over distances greater than 100 cm. [164] RPCs are preceded by slow wave obliteration before generation of electrical bursts that migrate orally. [165] Investigations in dogs involving autotransplantation of small intestinal segments in dogs indicate that retrograde motor activity is controlled by extrinsic neural pathways. [166]

Colon

The movement of colonic contents in humans is regulated by the concerted actions of several distinct motor patterns and their corresponding myoelectric complexes. Additional organized motor complexes are described in some species.

Short and Long Duration Contractions SDCs are stationary pressure waves that mix fecal material to effect water extraction. The myoelectric phenomena underlying SDCs are short spike bursts that occur in phase with colonic slow wave activity. SDCs persist for a mean of 8 seconds, occur at frequencies of 4 to 6 cpm in dogs and 2 to 13 cpm in humans, and are recorded from in vitro circular muscle preparations, suggesting that this is their site of generation. [167], [168] Long duration contractions (LDCs) may be stationary, or they may propagate for short distances in either direction, thus promoting both mixing and local propulsion of feces. In the ascending and transverse colon, many LDCs migrate orally, whereas in the more distal colon, LDCs typically migrate in an aboral direction. [169] The myoelectric correlates of LDCs, long spike bursts, are action potentials generated by myenteric potential oscillations. In contrast to short spike bursts, long spike bursts do not occur in synchrony with colonic slow waves. Although long spike bursts oscillate at 25 to 40 cpm, a single, tetanic LDC usually persists for the length of the electrical complex because of limitations on the rates of relaxation of colonic smooth muscle. LDCs persist for 20 to 60 seconds and are recorded from in vitro longitudinal muscle preparations, suggesting the presence of myoelectric control from a different site than for SDCs. [167], [168], [170] Compared with SDCs, LDCs are of greater amplitude. [171] In general, most LDCs occur during the day, with increased frequency after eating and after awakening. [172]

Giant Migrating Contractions Colonic GMCs, also termed *high-amplitude propagated contractions,* propagate aborally over extended distances and evoke mass movements of feces. [173] The myoelectric correlates of colonic GMCs are migrating, long spike bursts, which are believed to be generated from myenteric potential oscillations. The importance of this motor pattern in fecal expulsion is shown by studies in dogs in which prominent colonic GMCs precede the need to defecate. [173] In ambulatory manometric studies of unprepared colons in healthy humans, propagating pressure waves of high amplitude (>105 mm Hg) and prolonged duration (>14 s) were observed to occur about 10 times daily, most prominently after awakening, after eating, or in association with defecation (Fig. 11-8). [174] Such patterns may

originate as early as 1 hour before stool expulsion. [175] In general, the time interval to defecation correlates negatively with the amplitude of the contractile complex. Most sequences in humans originate in the cecum. [176] Ninety percent of GMCs associated with defecation in dogs are accompanied by propagation to the rectum and relaxation of the internal anal sphincter. [177] In human scintigraphic studies, oleic acid infusion into the cecum produces rapid tracer shifts from the ascending colon to the splenic flexure and descending colon that temporally correlate with the induction of colonic GMCs. [178] Colonic GMCs are evoked by distention and are increased during experimental diarrhea caused by laxatives, abdominal radiation, intracolonic acetic acid, and intravenous cisapride and may thus be partially responsible for the increased defecation frequency and impaired fluid absorption that occur with diarrhea. [179] Orphanin FQ accelerates colonic transit in rats by inducing GMCs. [180] Experimental colonic inflammation enhances the stimulation of colonic GMCs by substance P, suggesting the involvement of neuropeptide mechanisms in producing inflammatory diarrhea. [181] Colonic GMCs evoked by intracolonic glycerol are reduced by lidocaine, hexamethonium, and atropine, indicating mediation by mucosally activated cholinergic pathways. [182] Investigations indicate that colonic GMCs may be mediated by activation of NK_1 receptors on smooth muscle cells. [159]

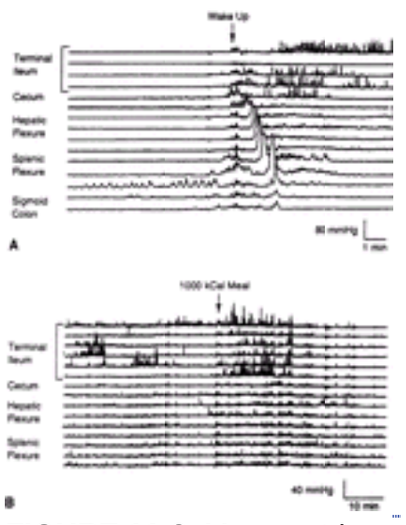

FIGURE 11-8. Manometric recordings of human colonic contractions after awakening and meal ingestion. During sleep, colonic motor activity is minimal. After awakening, colonic contractions increase, and a colonic giant migrating contraction (*GMC*) is observed to propagate from the cecum to the sigmoid colon (**A**). Ingestion of a 1,000-kcal meal evokes increased contractile activity at all levels of the colon (**B**). (From ref. [176] .)

Rectal Motor Complexes Specialized motor patterns may facilitate the storage function of the rectum. Ambulatory manometric studies demonstrate rectal motor complexes that occur about 16 times per day with average durations of 5 to 15 minutes (Fig. 11-9). [183] Motor complexes occur more commonly in the distal rectum compared with the proximal rectum. Contractile complexes consist of two to three contractions per minute, with a mean amplitude of 58 mm Hg. Such rectal motor activity occurs during the day and nocturnally and is not related to meal ingestion; however, most rectal events temporally occur in relation to contractions more proximally in the colon. [184] For the most part, rectal motor complexes do not propagate either in an orad or aboral direction, although some studies support their association with motor events more proximally in the colon. [176] Anal relaxations are not observed during rectal motor complexes, consistent with a role in maintenance of fecal continence. [185]

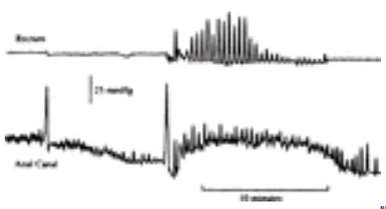

FIGURE 11-9. A rectal motor complex and the associated anal manometric recording. This rectal complex exhibits a duration of about 10 minutes and is associated with an increase in anal tone. (From ref. [185] .)

Migrating Motor Complexes Organized patterns known as MMCs are observed in some species but not in humans. The myoelectric correlates, migrating myoelectric complexes, cycle every 40 to 50 minutes in dogs. Colonic MMCs propagate over more than half the length of the colon with a duration of 30 to 120 seconds. [186] There is no coordination of colonic MMC activity with the small intestinal MMC.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL MODULATORS OF SMALL INTESTINAL AND COLONIC MOTILITY

Motor patterns of the small intestine and colon under fasting conditions can be modified by external stimulation. Additional intralumenal stimuli also may modulate lower gut function.

External Stimuli

Responses to Meal Ingestion

Small intestinal fed motor pattern

Physiological characteristics. After a meal, the MMC is replaced by a fed pattern of intermittent phasic contractions of varying amplitude, occurring throughout the small intestine and peaking 10 to 20 minutes after eating. [187] The number of isolated pressure waves during the fed period is greater than during a comparable phase II period. [188] The myoelectric correlate consists of random bursts of spike potentials in phase with the slow wave. [189] The fed pattern serves to mix and propel intestinal contents. Forty-four percent of fed contractions do not propagate. Of contractions that do, 90% migrate less than 30 cm and 66% migrate less than 9 cm. In the proximal duodenum, 40% to 50% of fed contractions are retrograde. [190] This duodenogastric propulsion may modulate gastric emptying. However, most pressure waves propagate in an antegrade direction for distances of 1.5 to 4.5 cm in the distal duodenum during duodenal lipid perfusion. [191] The small intestinal fed pattern, which persists throughout life, has been recorded in preterm infants. [192] Other motor patterns are seen after meal ingestion. A transitional motor pattern observed immediately after meal ingestion is characterized by highly propagative contractile clusters that expose extended regions of mucosa to nutrients. [193] Intense individual migrating contractions occurring postprandially have amplitudes twice those of normal fed phasic contractions and durations equal to two slow wave cycles. [88] Postprandial ileal contractions, once thought to be weaker than those in the duodenum, have been shown in dogs to have increased contractile amplitudes. [194] Intense pressure waves at frequencies of 19 to 24 cpm have been observed in the terminal ileum and appear to develop 1 to 4 hours after eating when chyme reaches the colon. [195] Myoelectric recordings from dogs show that this activity is accompanied by spike bursts similar to myenteric potential oscillations in the colon. Finally, a delayed tonic relaxation of the ileum is induced by local exposure to bile acids and triglycerides not absorbed in the proximal intestine. [196] The duration of the fed motor pattern is dependent on the caloric content and qualitative aspects of the meal. [197] In dogs, a mixed 450-kcal meal induces a fed pattern lasting longer than 3 hours. The threshold for inducing the fed state in humans is not known, although a 345-kcal meal disrupts MMC cycling for more than 90 minutes. [198] Peanut oil, consisting mostly of 18-carbon triglycerides, induces fed contractions for longer periods (>8 hours) than equicaloric sucrose or milk protein meals. [199] In humans, a 400-kcal meal with 9% fat disrupts MMC activity for 294±21 minutes, whereas a meal with 50% fat prolongs the fed period to 410±42 minutes. [200] Long-chain triglycerides convert the MMC to a postprandial pattern, whereas medium-chain triglycerides in equicaloric amounts have no effect. [201] The addition of guar to a glucose drink prolongs the duration of the fed pattern. [202] Intravenous amino acids shorten the cycle length of the MMC but do not induce a fed motor pattern, indicating that participation of the gut lumen is requisite. [203]

Neural regulation. Extrinsic innervation of the small intestine plays an important role in inducing the fed pattern. In dogs, the sight or smell of food disrupts MMC cycling, suggesting that cephalic phase initiates the fed pattern. In humans, sham feeding disrupts duodenal phase III but does not evoke fed contractions. [204] Bilateral vagotomy, splanchnicectomy, mesenteric ganglionectomy, and total extrinsic denervation do not prevent induction of the fed state, but bilateral vagotomy shortens its duration and increases the latency from the time of eating to the onset of fed contractions. [96], [101] Complete denervation reduces the number of propagated fed contractions, the mean distance of propagation, and the rate of intestinal transit. Jejunoileal autotransplantation, which produces extrinsic denervation, increases the number of calories needed to abolish MMC cycling and to initiate the fed pattern. [205] Finally, vagal cooling during the early postprandial period converts the fed pattern

to intermittent phase III activity. [100] These findings indicate modulation of the fed state by extrinsic neural pathways. Intrinsic innervation also modulates propulsion during the fed period. Intestinal transection and reanastomosis in dogs decrease the frequency and amplitude of fed contractions with decreased propagation. [206] In the absence of continuity of the enteric nervous system, the extrinsic nerves alone are sufficient to suppress fasting motility in excluded intestinal regions. If nutrients are perfused into an isolated, but extrinsically innervated intestinal loop, the MMC is disrupted in the unconnected main portion of the intestine. [207] As with the MMC, atropine and hexamethonium abolish fed motor and spike potential activity, emphasizing the importance of cholinergic innervation. [208] Infusion of an NO synthase inhibitor shortens the duration of the fed pattern, suggesting that endogenous NO pathways are physiological regulators of postprandial function. [108]

Hormonal mediation. Despite much investigation, the role of CCK as a mediator of the fed state remains unproven. CCK levels increase five- to tenfold after eating but do not persist for the duration of the fed state. CCK and its analogs increase intestinal motility, although the motor pattern exhibits nonphysiological characteristics such as prominent retrograde contractions and a preferential stimulation of proximal intestine contractions. [209] CCK inhibits MMC activity but does not prevent motilin cycling. [209] In rats, duodenal perfusion of trypsin inhibitor releases endogenous CCK, which acts on vagal afferent CCK-B receptors to stimulate a central CCK-A receptor pathway to disrupt MMC cycling. [210] Intravenous CCK-B receptor blockade and central administration of a CCK-A receptor antagonist prevent the disruption of MMC activity in response to nutrients in rats. [211] In dogs, the CCK receptor antagonists loxiglumide and MK-329 reduce but do not prevent the fed response or the interruption of MMC cycling after eating. [212] Thus, the role of CCK in mediating the fed response may be species dependent. Other compounds inhibit the MMC and induce complexes similar to the fed pattern, including gastrin, insulin, glucagon, neurotensin, neuromedin-N, enkephalins, and prostaglandin E_2. [96] As with CCK, gastrin does not reproduce the fed pattern, but it does stimulate proximal intestinal motility. Gastrin release also does not persist for the duration of the fed period. [209] Peanut oil, which induces a fed pattern, does not evoke gastrin or insulin release. [213] Conversely, glucose increases insulin levels but does not induce a fed pattern. Indomethacin infusion induces a fed pattern in dogs, but prostaglandin E_2 also disrupts MMC cycling. [214] Neurotensin has been proposed as a mediator of fed motility based on its ability to convert the fasting to a fed pattern along the entire small intestine in rats and humans. [215] In rats, neurotensin antagonists also reduce the duration of the fed pattern. [216] Although motilin is important in initiating fasting activity, it plays no role in the fed state. After eating, motilin levels decrease drastically. If exogenous motilin is given during the fed state, no phase III activity develops. [127] In addition, motilin antisera generate motor patterns similar to those seen in the fed state, suggesting that suppression of motilin release may be necessary for induction of the fed state. [128]

Reversion to the fasting motor pattern. The mechanism for reversion to MMC cycling after completion of the fed pattern is poorly understood. The first MMC after eating begins distal to the duodenum, implying that factors required to initiate normal complexes are not yet operational. [199], [217] There is a strong correlation between initiation of duodenal phase III and completion of gastric emptying. [218] However, in dogs, continuous intraduodenal perfusion of nutrients induces the fed motor pattern for only a finite time, after which the fasting pattern returns, indicating that the presence of intestinal nutrients does not prevent resumption of fasting motor activity. In humans, continuous duodenal feedings produce persistence of the fed pattern for at least 6 hours, whereas phase III activity resumes 4 hours after initiation of intragastric feedings, indicating differential inhibitory effects of the two regions on MMC cycling. [219]

Gastrocolonic response. As in the small intestine, eating produces simultaneous increases in motor activity throughout the colon (see Fig. 11-8). [220] The sigmoid colon exhibits a greater phasic response than the transverse colon. [221] The effect of eating on regional tone is less certain; some studies report greater responses in the transverse colon, and others report larger increases more distally. [221], [222] Myoelectric recordings in humans show increases in propagative and stationary long spike bursts that peak 15 minutes after eating. In some instances, mass fecal movements with defecation may occur during the gastrocolonic response. Prolonged manometric studies in dogs show disruption of the colonic MMC for 582 minutes after eating. [223] Although the fat content of a meal was thought to relate to the magnitude of the gastrocolonic response, studies show no difference in the response to low- and high-fat meals. [224] Mediators of the gastrocolonic response are incompletely defined. The response is abolished by the anticholinergic agent clidinium, indicating mediation by cholinergic pathways. [225] In humans, the 5-HT_3 receptor antagonist ondansetron blunts the tonic response to eating. [226] The human gastrocolonic response consists of a mechanoreceptor component activated by gastric distention and a chemoreceptor component stimulated by intestinal nutrients. [227] Both the mechanoreceptor and chemoreceptor components are partially mediated by 5-HT_3 pathways (Fig. 11-10). [228] Neurotensin receptor antagonists suppress the early fed response in the rat distal colon and block the late response in the proximal colon. [216] In one investigation, spinal cord section did not abolish the gastrocolonic response, but a second study in dogs showed that paraaortic and presacral denervation reduced the colonic response to intragastric lipids, suggesting modulation by the pelvic plexus. [229] Postprandially released transmitters such as CCK and gastrin evoke increases in colonic motor and myoelectric activity in some models; however, a human study showed no increase in colonic motor activity or transit during CCK administration at doses that stimulate pancreatic enzyme secretion and gallbladder contraction. [230] Furthermore, a study in dogs reported that CCK increased phasic colon contractions but decreased tone, whereas meals provoked increases in both. [231] However, also in dogs, the CCK receptor antagonist loxiglumide was shown to blunt the increase in colonic motor activity in response to eating, suggesting possible species-dependent effects. [232] Similar studies in rats using selective antagonists have shown potential roles for both CCK-A and CCK-B receptor mediation of the gastrocolonic response.

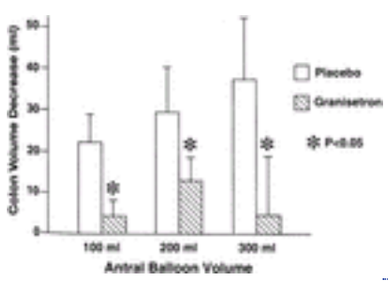

FIGURE 11-10. As a model of the mechanoreceptor component of the gastrocolonic response, inflation of an antral balloon leads to decreases in volume of a colonic recording balloon indicative of increased tone. This tonic contraction is blunted by granisetron, showing mediation by 5-HT_3 pathways. (From ref. [228].)

Motility during Sleep Small intestinal motor patterns exhibit subtle differences during wakefulness and sleep. MMC complexes migrate 2.5 times faster during the day but exhibit higher contractile amplitudes at night. [198] MMC periodicity and phase II duration are shorter during sleep, whereas phase I duration is prolonged. [233] The summed motility index during wakefulness exceeds that during sleep. Prolonged manometric recordings show no correlation of the sleep stage with MMC cycling and no synchrony of rapid eye movement sleep with intestinal phase III. [234] In contrast to fasting activity, fed patterns in humans who fall asleep soon after eating are not different from complexes recorded while people are awake. [235] Colonic motility also exhibits qualitative changes during sleep. Propagating contractions are infrequent during sleep but increase after awakening (see Fig. 11-8). [220] Awakening evokes a threefold increase in motility, including high-amplitude events in isolated segments as well as propagated complexes across long stretches of colon. [174], [236] Nocturnal suppression of colonic motility correlates with the depth of sleep and with the elimination of all propagated contractions during slow wave sleep. Conversely, during rapid eye movement sleep, colonic contraction frequencies increase to levels observed during stage 2 sleep. [237]

Central Nervous System Modulation The central nervous system has pronounced modulatory effects on small intestinal and colonic function. Intestinal phase III is reduced by depression and by acoustic and mental stress (mental arithmetic, video games, driving in rush hour traffic). [238] Phase II and DCCs also are suppressed by stress, whereas acoustic stress prolongs the fed pattern in dogs. [239] MMC disruption depends on the nature of the stressor and the time of day it is administered. Abrupt nighttime awakening does not modify the MMC, despite the subjects' perception that the nocturnal stressor is more noxious than daytime stressors. [238] Stress-induced effects on intestinal motility usually are associated with delayed transit. The colon also is susceptible to stress. Studies using stressful interviews note increases in rectal motor activity and erythema when unpleasant topics are broached. [240] In rats, conditioned fear increases colonic spike bursts. Different forms of stress elicit distinct effects on colonic motility; psychological stress induces propagated contractions, and physical stress evokes simultaneous contractions (Fig. 11-11). [241] Different regions may respond differently to stress. Tail shock in rats suppresses proximal colonic motility by reducing LDCs but increases fecal output from the distal colon. [242] A complex neurohumoral response is associated with stress. Prolongation of the intestinal fed pattern with acoustic stress is associated with gastrin, pancreatic polypeptide, and somatostatin release. [239] The delay in intestinal transit evoked by cold water immersion of the forearm is attenuated by ß-adrenergic receptor blockade. [243]

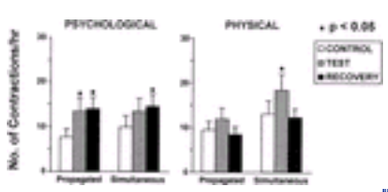

FIGURE 11-11. Effects of different stresses on colonic motor function. Psychological stress evokes predominantly propagated contractions during the stressor, whereas physical stress stimulates simultaneous contractions. (From ref. [241].)

Several compounds administered centrally can modify intestinal and colonic motor patterns. Inhibition of NO synthase in the brain suppresses duodenal phase III in dogs through vagal pathways. [244] Intracerebroventricular (ICV) infusion of NO synthase inhibitors suppresses colonic activity, whereas peripheral administration increases colonic contractions. [245] Destruction of hypothalamic and locus ceruleus adrenergic pathways with 6-hydroxydopamine lengthens MMC periodicity. [246] ICV CCK in-creases and ICV somatostatin decreases MMC cycle duration. [238] ICV calcitonin, CGRP, neurotensin, and opioids evoke intestinal phase III activity; NPY delays intestinal transit. [247] ICV neurotensin delays MMC disruption by a meal, whereas ICV atropine or substance P shortens the fed state. [248] ICV galanin restores MMC cycling during the fed period through opioid pathways. [249] Injection of a GABA antagonist into the dorsomedial hypothalamic nucleus increases jejunal contractions in rats, suggesting physiological regulation by central GABA pathways. [250] ICV GLP-1 increases fecal output, whereas orphanin FQ retards colonic transit. [251], [252] Infusion of CCK into the paraventricular hypothalamic nucleus slows colonic transit by action on CCK-B receptors. [253] ICV thyrotropin-releasing hormone accelerates intestinal transit in rats through cholinergic and serotonergic pathways and evokes colonic GMCs. [254] ICV injections of a $_2$-adrenergic receptor agonists, morphine, and leu-enkephalin blunt the increase in external anal sphincter activity elicited by pudendal nerve stimulation. [255] A large body of evidence indicates that corticotropin-releasing factor (CRF) is a physiological mediator of stress effects on the lower gut. Many stressors are associated with intracerebral CRF release. In mice, ICV CRF mimics the stressful effects of cold on intestinal transit. [256] In rats, vagotomy and naloxone prevent ICV CRF inhibition of intestinal transit, suggesting the importance of vagal and opioid pathways. [257] MMC inhibition by ICV CRF in dogs is associated with suppression of motilin cycling. [258] ICV CRF and stress increase colonic activity in rats by action on the locus ceruleus and the hypothalamic paraventricular nucleus. [259], [260] CRF-related peptides, including urocortin and sauvagine, also stimulate colonic transit. [261] The effects of CRF and stress on intestinal function are reversed by CRF antagonists, supporting a physiological role for this peptide. [262] CRF acts through activation of CRF $_1$ receptors, whereas urocortin acts on receptors of the CRF $_2$ subtype. [261], [263] The ability of CRF antagonists to block the increase in colonic contractions evoked by interleukin-1 $_\beta$ indicates a role for central CRF in pathophysiological inflammatory stress. [264] The effect of a CRF receptor antagonist to block the increase in colonic transit elicited by NPY infusion into the paraventricular nucleus indicates that hypothalamic pathways projecting to the brainstem regions direct gut stress responses. [265] Vasopressin may be an intermediate transmitter, because vasopressin antagonists block the effects of emotional stress and ICV CRF on colonic motility in rats. [266] CRF-stimulated defecation in rats may be mediated by serotonin release with action on 5-HT $_3$ receptors. [267]

Immune Modulation Inflammatory conditions may be associated with altered intestinal and colonic motility. Oral albumin evokes diarrhea in rats sensitized by intraperitoneal egg albumin injection, (i.e., antigen sensitized). [268] This intestinal anaphylaxis is associated with MMC disruption and induction of propagating, high-amplitude, clustered contractions, which are prevented by the 5-HT antagonists methysergide and cinanserin and the prostaglandin synthesis inhibitor indomethacin. [269] Similarly, colonic antigen challenge to egg albumin–sensitized rats increases colonic myoelectric activity. [270] The importance of afferent pathways in mediating these responses is shown by the ability of capsaicin to prevent antigen effects in the small intestine. [271] The role of mucosal mast cells is demonstrated by the abilities of the mast cell stabilizers and degranulation inhibitors (doxantrazole, cromoglycate, eucalyptus bioflavonoids [Quercetin]) to blunt antigen-induced intestinal and colonic motor responses and diarrhea. [270] Furthermore, mast cell degranulation evoked by BrX-537A inhibits antigen-evoked colonic myoelectric activity in rats through vagal afferent fibers and 5-HT $_3$– and substance P–dependent pathways. [272] However, other studies show participation of nonvagal pathways as well. Histologically, granulated mast cells are reduced at sites of antigen challenge. [273] In rat colon longitudinal muscle, antigen-induced contraction results from IgE-mediated mast cell activation, which then evokes release of contractile stimulants. [274] The effects of intestinal anaphylaxis on intestinal function in antigen-sensitized animals may involve central nervous system activation. In sensitized rats, egg albumin MMC disruption is associated with increased c-*fos* expression in the nucleus tractus solitarius and lateral parabrachial and paraventricular hypothalamic nuclei through vagal afferent pathways. [275] Intestinal infections also disrupt gut motor function. In rats, *Yersinia enterocolitica* and *E coli* alter MMC cycling through free radical generation. [276] Similarly, fasting intestinal myoelectric activity is increased with induction of spike potential bursts in rats infested by *Hymenolepsis diminuta*. [277] Gastrointestinal transit is slowed and ileal smooth muscle is thickened in mice infected with *Schistosoma mansoni*. [278] Infection with *Nippostrongylus brasiliensis* enhances jejunal motor responsiveness to carbachol and neurokinin A, an effect prevented by mast cell degranulation with BrX-537A. [279] Increased responses to CCK after infection with this organism are blocked by vagotomy. [280] Information on the role of the immune system in gut function has been provided by study of the nematode *T spiralis,* which produces trichinosis. Infection with *T spiralis* reduces jejunal myenteric neuron membrane potential and increases neuronal metabolic activity. [281] Structural damage to the ICC network with slow wave destabilization also is observed. [282] In rats, *T spiralis* infection disrupts intestinal motility and induces GMCs. [283] In previously infected rats, subsequent exposure to *T spiralis* larvae evokes muscle contraction, which can be blocked by a 5-HT antagonist and the mast cell stabilizer doxantrazole. [284] Jejunal muscle from *T spiralis*–infected rats exhibits increased responses to the muscarinic agonist carbachol, CCK, and 5-HT, in addition to enhanced peristalsis. [285], [286] In contrast to its excitatory effects on smooth muscle, *T spiralis* inhibits myenteric nerve activity and reduces acetylcholine and norepinephrine release, with peak effects 6 days after infection. [287] *T spiralis* reduces the intestinal content of substance P by 73% and VIP by 59%, and markedly inhibits NO synthase type 2 gene transcription, protein expression, and enzyme activity. [288], [289] The effects of *T spiralis* infection on smooth muscle and myenteric nerves may persist for 1 to 2 months after acute infection resolves (Fig. 11-12). [290], [291]

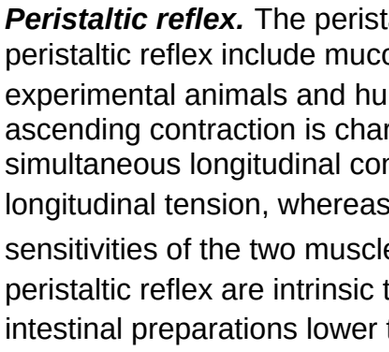

FIGURE 11-12. Contractile responses of intestinal muscle tissues to carbachol (*open bars*) and potassium chloride (*black bars*) at various time points after infection with *Trichinella spiralis*. Both stimuli evoke exaggerated contractions for 42 days after acute infection. (From ref. [291].)

Several immune mechanisms may underlie the effects of infection with *T spiralis*. Macrophages and lymphocytes penetrate intestinal longitudinal muscle, and their cellular protrusions contact myocytes. [292] The inhibition of myenteric nerve activity accompanying *T spiralis* infection is preserved in athymic rats, suggesting participation of T-cell–independent pathways. Conversely, the induction of increased contractions by carbachol and 5-HT is not observed, indicating T-cell–dependent responses as well. [285], [287] Reconstitution of CD $_4$ T cells to mice that are athymic, CD $_4$ cell deficient, or major histocompatibility complex II deficient restores the enhanced muscle contractility, confirming the role of T cells. [293] The ability of an interleukin-1 (IL-1) antagonist to prevent the neural effects of *T spiralis* infection suggests a role for IL-1 release, likely from macrophages. Increased muscle contraction with during infection with *T spiralis* is blunted in IL-5–deficient mice, indicating a role for this interleukin as well. [294] Sustained increases in smooth muscle cyclooxygenase-2 have been observed in mice infected with *T spiralis*. [295] Selective in vitro cyclooxygenase-2 inhibition reduces smooth muscle responses to agonist stimulation.

Internal Stimuli

Localized Reflexes

Peristaltic reflex. The peristaltic reflex is demonstrable in the small intestine and colon and produces aboral propulsion of lumenal contents. Stimuli that evoke the peristaltic reflex include mucosal pinching, hypertonic saline infusion, and insertion of a solid bolus. The peristaltic reflex consists of two phases that are observable in experimental animals and humans: an excitatory response proximal to stimulation (ascending contraction) and a distal inhibition (descending relaxation). [88], [296] The ascending contraction is characterized by simultaneous circular muscle shortening and longitudinal muscle relaxation, whereas the descending relaxation involves simultaneous longitudinal contraction and circular relaxation. Distention of guinea pig ileum to pressures of 0.5 to 1.5 cm H $_2$O, induces isolated increases in longitudinal tension, whereas at 1.5 to 3.0 cm H $_2$O, the longitudinal tension increase is followed by a propagative circular contraction, indicating differential sensitivities of the two muscle layers. [297] Afferent neuron activation is needed to elicit the peristaltic reflex. Cell bodies of the primary sensory neurons initiating the peristaltic reflex are intrinsic to the intestinal wall. [298] Radial stretch is the most potent stimulus for inducing the reflex. [51] Faster stretching and the use of longer intestinal preparations lower the threshold for peristalsis. [299] Receptors that sense radial stretch are mucosal in location, because stripping the mucosa or applying

lumenal topical anesthetics abolishes the reflex. Nonmucosal receptors also are suggested by experiments in which blunted peristaltic reflexes persist despite chemical destruction of the mucosa by silver nitrate or tannic acid. [300] Transmitters that mediate the peristaltic reflex have been extensively studied. Ascending contractions are partially inhibited by atropine at low levels of stimulation, whereas tachykinin receptor antagonists or antisera block contractions induced by intense radial stretching, indicating dual cholinergic and tachykinin mediation. [297], [301] Acetylcholine, substance P, and neurokinin A are released by radial stretch. [301] Muscarinic M_1 receptors participate in interneuronal transmission, whereas M_3 receptors mediate the smooth muscle contraction. [302] In guinea pig preparations, NK_1, NK_2, and NK_3 receptors all participate in peristalsis in concert with cholinergic pathways. [303], [304] The mediators of the descending relaxation likely are VIP and NO because both are released during peristalsis. [305] NO synthase inhibitors such as *N*-?-nitro-L-arginine and *N*-nitro-L-arginine methyl ester inhibit descending relaxations elicited by colonic distention. [46], [306] Capsaicin-sensitive afferent neurons mediate both ascending and descending components of the peristaltic reflex. [307] Other peptidergic neurons participate in the reflex. It is hypothesized that stretch activates aborally projecting somatostatin neurons that inhibit the activity of opioid neurons causing a reduction in met-enkephalin release. [308] The decrease in met-enkephalin produces relaxation by VIP and NO release. d-Opioid receptor antagonists act synergistically with 5-HT_4 receptor agonists to facilitate colonic peristalsis, also indicating a physiological modulatory role for opioids in the peristaltic reflex. [309] Serotonin is released with gut distention and lowers the threshold for evoking the peristaltic reflex, indicating an important role for this transmitter. [310] Mucosal stimulation initiates the reflex by activating 5-HT_4/5-HT_{1P} receptors on sensory neurons containing CGRP in human intestine and 5-HT_4/5-HT_{1P} and 5-HT_3 receptors in guinea pig colon. [311] In human colon, the 5-HT_3 antagonist granisetron has no effect on the ascending contraction or descending relaxation. [228] In isolated human, rat, and guinea pig colon tissue, 5-HT_4 agonists activate CGRP pathways that evoke ascending substance P release and descending VIP release (Fig. 11-13). [312] In guinea pig colon, 5-HT_3 and 5-HT_4 receptors may be arranged in parallel in the mediation of the peristaltic reflex. [313] In this species, selective 5-HT_3 and 5-HT_4 receptor antagonists are additive in their inhibition of colonic peristalsis. [314] In marmoset small intestine, it is hypothesized that 5-HT_4 receptors are activated by low concentrations of 5-HT, whereas higher concentrations produce 5-HT_3 receptor activation. [315]

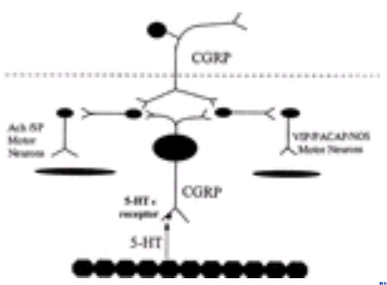

FIGURE 11-13. Neural pathways underlying the peristaltic reflex. Mucosal stimulation evokes 5-HT release, which activates release of calcitonin gene–related peptide (*CGRP*), which then stimulates ascending motor pathways containing the contractile agents acetylcholine (*Ach*) and substance P (*SP*) and descending motor pathways containing the relaxant agents vasoactive intestinal polypeptide (*VIP*), nitric oxide (*NO*), and pituitary adenylate cyclase–activating peptide (*PACAP*). (From ref. [312].)

Other peptides can modulate the peristaltic reflex, including GABA and PACAP. Endogenous purinergic pathways suppress peristalsis by activation of P_2 receptors. [316] Stimulation of cannabinoid CB_1 receptor pathways inhibits peristalsis in guinea pig ileum. [317] The demonstration that a CB_1 antagonist increases activity in mouse colon suggests that endogenous cannabinoids may physiologically modulate peristalsis. [318] In rat duodenum, ascending contractions are blocked by CCK by simultaneous activation of CCK-A and CCK-B receptors. [319] Activation of endothelin ET_A receptors stimulates peristalsis in guinea pig small intestine, whereas ET_B receptor occupation inhibits peristalsis. [320] The ability of an ET_B antagonist to enhance peristalsis suggests a physiological modulatory role for ET_B receptors. Although traditionally considered to be mediated by intrinsic nerves, some evidence suggests that extrinsic pathways may modulate the peristaltic reflex. In guinea pig colon, sympathetic nerve stimulation inhibits cholinergic components of the reflex. [321] In isolated tissues, extrinsic denervation decreases basal CGRP levels and abolishes peristaltic reflexes activated by muscle stretch but not mucosal stimulation. [322] In these models, extrinsic sensory pathways are postulated to mediate responses to stretch, whereas intrinsic pathways activate peristalsis with mucosal stimulation. That CGRP antagonists abolish peristalsis evoked by both stimuli indicates CGRP involvement in both extrinsic and intrinsic pathways.

Rectoanal inhibitory reflex. Rectal distention produces an abrupt volume-dependent decrease in internal anal sphincter pressure, known as the *rectoanal inhibitory reflex.* The reflex also is activated by rectal electrical stimulation. In contrast, external anal sphincter pressure increases on rectal distention. The rectoanal inhibitory reflex permits efficient defecation on rectal filling, whereas reflex external sphincter contraction prevents accidental leakage of rectal contents until they may be volitionally evacuated. The reflex also may be important for anal canal sampling to discriminate among solids, liquids, and gas. The rectoanal inhibitory reflex is mediated by intrinsic neural pathways between the rectum and the internal sphincter, although some investigators suggest a role for spinal pathways. [323], [324] Rectal sensory fibers are responsible for activating the reflex, although fibers in the pelvic floor muscles may play some role. The reflex is abolished by rectal transection at the anal verge, but it can regenerate within 2 years of surgery in humans. [325] Internal anal sphincter relaxation in response to rectal stimulation is a consequence of VIP and NO release. [326]

Extended Reflexes

Inhibitory intestinointestinal reflex. The inhibitory intestinointestinal reflex represents a possible model for ileus. It is characterized by profound motor inhibition of up to several hundred centimeters of intestine as a consequence of abrupt stretching or dilation of a localized intestinal segment. This is associated with slow wave disruption generating dysrhythmic myoelectric activity. [327] In humans, the inhibitory effects of distention are more pronounced in the proximal small intestine than in the ileum. [328] The relevance of the reflex is that when distention results from mechanical obstruction or another cause, the bowel responds with decreased motility and tone, thus serving a protective function. In contrast to peristalsis, the intestinointestinal reflex is not mediated by mucosal receptors, because excision of the mucosa and submucosa has no effect. Instead, removal of the longitudinal muscle prevents the reflex. In dogs, abrupt distention of an excluded but not extrinsically denervated intestinal segment abolishes spike activity both in the excluded loop and the intact intestine through splanchnic pathways. [329] The reflex is abolished by spinal cord transection below T7, indicating a need for intact thoracolumbar spinal pathways.

Intestinal reflexes involving the stomach. *Enterogastric and enteropyloric reflexes* are defined as the respective inhibition of gastric emptying and stimulation of pyloric motility by small intestinal stimulation. Duodenal distention reduces intragastric pressure, inhibits antral motility, and induces pyloric contractions. [330] Capsaicin-sensitive vagal afferents mediate the inhibitory response to low volumes, whereas spinal afferents mediate the response to high volumes of duodenal inflation. [331] Similarly, delays in gastric emptying evoked by duodenal carbohydrate and protein perfusion are associated with increased vagal afferent activity and are inhibited by capsaicin treatment of vagal and spinal afferents. [332], [333] Intrinsic pathways are involved in pyloric responses, because duodenal transection prevents induction of pyloric contractions by duodenal distention. [331] Conversely, duodenal transection does not block inhibition of antral contractions or the delay in gastric emptying induced by duodenal distention, indicating mediation by pathways other than ascending intraduodenal nerves. [331] In some models, enterogastric reflexes are blocked by the CCK antagonist MK-329. [332], [334] The magnitude of the enterogastric response depends on the stimulus intensity, its nature, and the length and region of intestine that is stimulated. Exposure of 15 cm of duodenum to hydrochloric acid inhibits gastric emptying, whereas lactic acid has no effect. [335] Perfusion of 150 cm of intestine with glucose induces maximal inhibition, whereas exposure of 15 cm has no effect on gastric emptying. [336] Duodenal peptone perfusion is more effective than equicaloric glucose perfusion. [333] Complementary to enterogastric reflexes, gastric distention abolishes fasting duodenojejunal motor activity and delays intestinal transit. [337] This gastroduodenal inhibitory reflex is unaffected by vagotomy but is reduced by celiac plexus sectioning or by small intestinal denervation, showing mediation by nonvagal pathways. [338] Mediation of this reflex by NO release in the celiac plexus also has been reported. [339]

Ileal brake. Gastric motility is inhibited more by ileal glucose perfusion than by duodenal administration. [340] Similarly, ileal short-chain fatty acid perfusion potently reduces antral contractions and reduces transpyloric flow. [341], [342] Ileal lipid or carbohydrate perfusion also reduces duodenal and jejunal motility and proximal intestinal transit more potently than proximal perfusions. [343] These inhibitory nutrient effects define the *ileal brake,* which likely serves a protective function to prevent the distal intestine from being overwhelmed by massive nutrient loads. Lipids are the most potent stimulators of the ileal brake, with oleate being 20-fold more potent than glucose at inhibiting gastric emptying. [344] Mediators of the ileal brake are incompletely characterized. a $_1$-Adrenergic receptors and ß $_1$-adrenergic receptors, opioid, and 5-HT_3 antagonists blunt ileal lipid-induced motor inhibition. [345], [346] Naloxone antagonizes the ileal brake only when administered to the proximal intestine, indicating a dependence on opioid pathways located on the efferent end of the reflex. [347] Ileal lipids and short-chain fatty acids release GLP-1, neurotensin, and peptide YY (PYY). [348], [349] and [350] Intravenous PYY prolongs the duodenal MMC cycle length and delays intestinal transit, mimicking the effects of ileal nutrients. [349] PYY immunoneutralization accelerates intestinal transit inhibited by ileal lipids, confirming dependence of the ileal brake on endogenous PYY. [351] Inhibition of duodenal motility by ileal protein is reversed by a GLP-1 receptor antagonist, indicating a role for this peptide as well. [352]

Extended colonic reflexes. Ileal distention evokes colonic relaxation, whereas colonic distention retards intestinal transit, reduces ileal motility, and disrupts

intestinal slow wave cycling. [353], [354] Sectioning the splanchnic nerves and ablating the prevertebral ganglia abolish these colonic reflexes, indicating mediation by extrinsic sympathetic pathways. [355] Topical anesthesia of the rectum prevents inhibition of intestinal contractions by rectal distention, indicating participation of mucosal receptors. [353] Colonic perfusion of mixed nutrients inhibits duodenal fasting activity. [356] Colonic distention delays the onset of MMC activity by activation of nicotinic ganglionic receptors. In dogs, the effects of ileal distention on colonic tone are not solely mediated by adrenergic, nicotinic, or NO pathways. Colonic perfusion of lactose and short-chain fatty acids reduces gastric tone, indicative of a colonic brake. [357] The role of PYY in the mediation of the colonic brake is uncertain, although colonic perfusion of short-chain fatty acids evokes PYY release. [358] Colonic stimulation also evokes reflex responses within the colon. Inflation of a distal colon balloon inhibits motility of a proximal colonic loop through a $_2$-adrenergic receptor–mediated pathways. [359] Distension of the rectosigmoid junction distention elicits increased rectal pressure and anal relaxation, with resultant expulsion of a rectal balloon. [360] This rectosigmoid-rectal reflex is postulated to facilitate defecation. Conversely, sigmoid colon distention increases rectosigmoid junction pressure by activation of mucosal receptors, possibly promoting fecal retention. [361], [362]

CORRELATION OF MOTOR PATTERNS WITH SMALL INTESTINAL AND COLONIC TRANSIT

Small Intestinal Transit

Propulsion of small intestinal contents depends on the lumenal caliber, wall tone, and amplitude of phasic contractions. Scintigraphic studies report a mean intestinal transit time of 221±49 minutes in healthy humans, with a range of 131 to 322 minutes. [363] Many studies report no effect of age or gender, although some have observed slower intestinal transit in women. [364], [365] As expected from manometry studies, transit in the upper intestine is more rapid than distally. In rats, transit across the proximal half of the intestine is 30 minutes versus 2.5 hours in the distal half. [366] In contrast to the stomach, where solids and liquids are handled differently, [131] I-labeled solids and ^{99m}Tc-DTPA–labeled water are propelled through the intestine at similar speeds. [367], [368] However, evidence suggests that the ileum may selectively retain bran while allowing liquids to pass into the colon. [369] Small intestinal nutrient transit depends on the caloric density and the nutrient class. Inert substances such as guar have little effect on total intestinal transit time. [370] In studies of different protein solutions, intestinal transit slowed in proportion to the calories delivered, with a resultant increase in the amount of protein absorbed in the proximal intestine, thus maintaining a constant level of absorption across a broad range of nutrient loads. Similarly, intralumenal lipids delay intestinal transit in a manner dependent on their caloric density. [371] Proteins tend to delay small intestinal transit to greater degrees than lipids. [368]

Combining manometry with cinefluoroscopy has permitted the correlation of fasting and fed patterns with the movement of intestinal contents. Intestinal transit of inert substances is four times faster in phase III than in phase I of the MMC. Fifty percent of total flow occurs during phase III, which efficiently clears the small intestine of retained material. [164] Transit also occurs in phase II, with rapid propulsion occurring during the transition from phases II to III. On cineradiography, transit during phase III is characterized by intermittent boluses of 4 to 5 cm in length separated by 1- to 2-cm ring contractions. [372] After eating, the distribution of intestinal contents becomes more uniform. In dogs and humans, postprandial transit is faster and exhibits lesser fluctuations than during fasting. [164]

Colonic Transit

Colonic transit in healthy persons is characterized by a slow movement of lumenal contents from the cecum to the rectum over 1 to 2 days. Mean transit times are slightly faster in men, with associated increases in fecal weight. [373], [374] Middle-aged women tend to exhibit slower transit than younger women. [365] /SUP>Propulsion through the different colonic regions is not uniform. Ingested radiopaque markers dwell in the rectosigmoid colon the longest both in men and women, indicative of a storage function for this region. [375] Prolonged residence of markers in the ascending colon also has been observed. Early radiographic observations noted retropulsion from the pacemaker area in the transverse colon to the ascending colon, with proximal retention of feces. However, as fecal volume in the ascending colon increases, retroperistaltic patterns give way to lumenally occlusive, aborally propagating contractions. Solids and liquids are handled differently in discrete regions of the colon. Solid residue is initially retained in the ascending colon, whereas liquids are propelled aborally. [376] In the transverse colon, solids and liquids are propelled similarly. Studies using nonabsorbable isotonic electrolytes show that the distal colon exhibits significant fluid retentive capabilities, suggesting that this region regulates stool output during diarrheal conditions. [377] With defecation, different regions exhibit different emptying efficiencies, with evacuation of 20% of marker from the right colon, 32% from the left colon, and 66% from the rectum. [378]

SPHINCTERIC FUNCTION OF THE LOWER GASTROINTESTINAL TRACT

Ileocecal Junction

The ileocecal junction exhibits characteristics distinct from the ileum and colon; it has a localized high-pressure zone in animal models that is not abolished by neural toxins. Manometric recordings in dogs show a basal pressure of 30 to 40 cm H_2O, with phasic contractions greater than 100 cm H_2O. [379] In humans, a high-pressure zone is less reliably observed, although phasic contractions are often noted. [380] Studies in patients with temporary ileostomies demonstrate high-pressure regions 5 cm in length, with mean pressures of 10 mm Hg (Fig. 11-14). [381] Slow waves and spike potentials migrate across the canine and feline ileocecal junction into the colon. [382] In dogs, more than 50% of MMCs traverse the ileocecal junction in dogs, but, in humans, the structure participates in very few MMC cycles. [383] In dogs, more than 80% of phase III complexes traversing the canine ileocecal junction evoke colonic contractions. [355] In scintigraphic studies, fasting flow across the canine ileocecal junction is maximal before phase III, whereas in humans, changes in flow do not correlate with MMC phases. [383] Eating increases motor activity and flow across the ileocecal junction that, in dogs, are maximal 4 hours after a meal. [384] In humans, meals increase ileocecal junction tone and the proportion of time occupied by phasic activity. [381] GMCs and DCCs readily traverse the ileocecal junction and decrease ileocecal junction phasic and tonic activity. [381], [383]

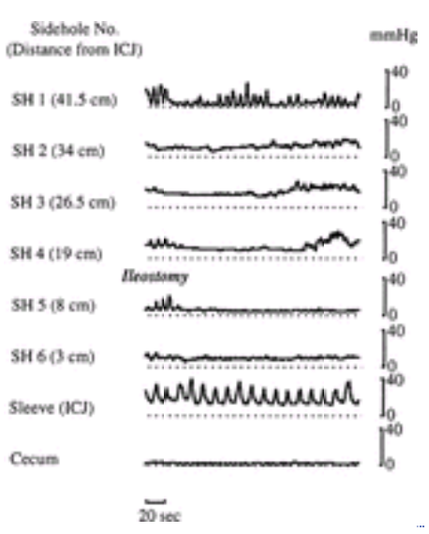

FIGURE 11-14. Pressure recordings from sideholes (*SH1 to 6*) in the ileum, a sleeve sensor in the ileocecal junction (*ICJ*), and the cecum from patients with ileostomies. The ileocecal junction exhibits increases in tone and phasic motor activity unrelated to basal ileal or cecal motility. (From ref. [381].)

The ileocecal junction safeguards against fecal reflux from the colon into the ileum. Attempts to propel material in retrograde fashion across the structure meet with resistance. In humans and animals, surgical excision of the ileocecal junction increases ileal bacterial counts, suggesting that the structure maintains relative sterility of the ileum. [385] In canine and human tissues, colonic distention evokes reflex ileocecal junction contraction, which is unaffected by transection of vagal or pelvic nerves. [380], [381], [386] Conversely, splanchnic nerve transection blocks the reflex, indicating the importance of extrinsic sympathetic pathways. The anatomic conformation of the ileocecal junction likely contributes to this response in that at its point of insertion into the cecum, it is maintained at a

constant acute angulation by fibrous connections. Severance of this fibrous tissue such that the acute angulation is lost renders the ileocecal junction incompetent, and coloileal reflux results. [387]

The role of the ileocecal junction as a barrier to aboral flow from the ileum into the colon is less clear. Early studies showed that the structure does not impede ileal liquid transit. Some manometric studies have reported reflex ileocecal junction relaxations with ileal distention, whereas others have noted reflex contractions. [388] Colonic filling from the ileum is characterized by bolus movements separated by intervening periods of stasis, suggesting that the ileum regulates cecal delivery. [389] Studies with Heidelberg capsules show lag times of 0.8 to 2.5 hours for this passage of solids across the junction, but other investigations show no discrimination of solid versus liquid passage into the cecum. [390] Furthermore, patients with surgical resection of the ileocecal junction exhibit normal transit of radiolabeled beads, suggesting little importance as a regulator of forward flow. [391] However, excision of a long segment of small intestine and removal of the ileocecal junction accelerate transit, showing that the structure can be a barrier to aboral propagation under conditions of high flow.

Anus and Pelvic Floor

The mean length of the anal canal is 2.8 cm, shorter around its circumference in women than in men. [392] There is a symmetric, functional region of elevated pressure extending above this level that helps to maintain fecal continence. Maximal pressures occur in the distal 1 to 2 cm of the anus, but pressures greater than intrarectal levels are measured 6 cm above the most proximal aspect of the anus. The internal anal sphincter provides 85% of the resting anal tone, which in humans is 40 to 80 mm Hg (Fig. 11-15). With voluntary contraction of the external anal sphincter, pressures exceed 150 mm Hg. [393] Maximal squeeze pressures are higher and squeeze durations are longer in men, but resting tone is similar in men and women. [394] Both resting tone and maximal squeeze pressure decrease with increasing age. [395] Age-related changes include decreased external sphincter thickness but increased internal sphincter thickness. [392] With sudden rectal distention, the contribution of the internal sphincter drops to 40% of the resting pressure, whereas the structure contributes 60% of the tone with constant rectal stimulation. [48] Ambulatory manometry records 14 to 19 spontaneous anal relaxations occurring per hour while awake and 4 per hour during sleep, each lasting 16 to 19 seconds. [183] Some of these relaxations are correlated with flatus passage.

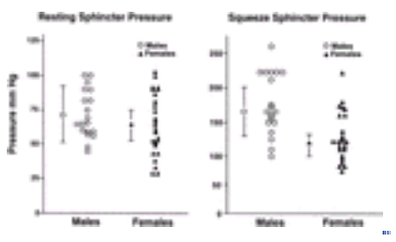

FIGURE 11-15. Resting anal sphincter pressure and maximal anal squeeze pressure of healthy men and women. (From ref. [394].)

The internal anal sphincter exhibits smooth muscle cell characteristics that facilitate its sphincteric function. Spontaneous electrical activity occurs in three regions: an upper region 15 to 20 mm from the anal verge with a frequency of 6.8 cpm, a transitional region with a frequency of 15.9 cpm, and a lower region within 5 mm of the anal verge with a frequency of 24.1 cpm. [396] Tone is generated in the two lower regions, whereas relaxant responses are observed in all regions with electrical depolarization.

Coordination of Defecation Passage through the colon promotes fecal dehydration, such that on reaching the rectum the stool is semisolid to solid. The rectum exhibits a compliant wall that allows it to serve as a reservoir for fecal material until it can be expelled. The internal anal sphincter provides tone to prevent accidental loss of stool, whereas the external sphincter voluntarily contracts if unwanted loss of feces is impending. In contrast to most striated muscle structures, the external anal sphincter and puborectalis muscle exhibit spontaneous tone, which promotes fecal continence. Indeed, maximal anal canal squeeze pressures are observed where the puborectalis overlaps the external sphincter. [397] The uppermost loop of the external sphincter, formed from the deep external sphincter muscle, attaches anteriorly on the pubis. The intermediate loop, formed from the superficial external sphincter, attaches posteriorly to the coccyx. The base loop, formed from the subcutaneous external sphincter, attaches to the perianal skin. Tight contraction of the three loops produces anal occlusion. Electromyographic studies indicate that the pelvic floor musculature behaves as a single muscle, with all muscle groups activating in response to a localized stimulus. [398] The anorectal angle created by the puborectalis muscle provides a functional obstruction to accidental loss of stool at rest. [399] Epithelial nerve endings in the rectum and anus allow the differentiation of solids, liquids, and gases before volitional expulsion. The rectum is innervated with ganglion cells and nerve fibers that mediate activities of the rectoanal region, including the rectoanal inhibitory reflex. The rectum has few free or organized nerve endings and is insensitive to most stimuli. In contrast, the transitional zone above the pectinate line, the anal crypt region, and the anal canal possess many free nerve endings and organized nerve endings that sense anal canal contents. Defecation involves the interaction of several different structures in and surrounding the rectum and anus. Tonic puborectalis contraction maintains an anorectal angle of 90° to preserve continence. Sitting erect contributes to continence by tightening the anorectal angle. [400] With defecation, puborectalis relaxation produces a more acute rectoanal angle (110°), and the internal anal sphincter relaxes. Fecal evacuation is aided by assuming a position in which the hips are flexed, further opening the rectoanal angle. Rectal contraction increases lumenal pressure to provide a propulsive force for defecation. Contraction of the rectus abdominus muscles, diaphragm, and terminal aspects of the other levator ani muscles increases intra-abdominal pressure and provides additional force. With straining, there is a physiological descent of the pelvic musculature of about 1 cm; this value is increased in incontinent patients. [401] After fecal passage, a rebound contraction of the external sphincter and pelvic floor muscles occurs. In contrast to defecation, the muscular events associated with flatus passage do not open the rectoanal angle. Rapid abdominal pressure increases, and pelvic floor muscle contractions, coupled with colonic contractions and increased rectal pressure, force gas past the acutely angled anorectum with retention of feces. CHAPTER 12

Gary M. Mawe, Peter L. Moses, and Maria J. Pozo

MOTILITY OF THE BILIARY TRACT

Understanding biliary tract function is a clinically significant goal. In the United States alone, more than 20 million people have gallstones or have had a cholecystectomy. Furthermore, the total direct costs associated with biliary tract disease, which amount to billions of dollars annually, are greater than the costs for any other gastrointestinal ailment, including colorectal cancer and peptic ulcer disease. [1] Abnormal motility is a hallmark of biliary tract disorders, including those of both calculous and acalculous origins; therefore, it is important to understand how motility of the gallbladder and sphincter of Oddi (SO) are normally regulated and what changes in these structures lead to dysmotility under pathophysiological conditions.

This chapter provides an overview of the current knowledge of biliary tract motor activity. Because motility primarily involves the activities of two cell types, neurons and smooth muscle, the chapter is organized to provide a summary of the basic physiology of the nerves and smooth muscle in the gallbladder and SO, with clinical correlations provided whenever possible. These sections also describe how the nerves and smooth muscle of these organs function during the bile retention and bile flow phases of the feeding cycle. Finally, a section at the end of the chapter describes what is currently known about the roles of nerves and smooth muscle in the biliary tract under pathophysiological conditions.

GALLBLADDER

The incidence of abnormal gallbladder motility in patients with biliary disease is high, and therefore evaluation of gallbladder motility is a common diagnostic approach for patients with clinical evidence of biliary dysfunction. Functional radiographic imaging (biliary scintigraphy) is the most common means of evaluating biliary motility. Functional biliary scintigraphy is performed after administration of a chemical analog of cholecystokinin (CCK) to a patient who has previously received iminodiacetic acid radiotracer. Radiographic images are captured over a 20- to 30-minute period to determine the gallbladder ejection fraction, which is calculated using a standard time-activity curve. Functional scintigraphy has an estimated sensitivity of greater than 82%, a specificity of greater than 87%, and a positive predictive value for detecting abnormal gallbladder function of greater than 90%. [2], [3] and [4] It is therefore a valuable tool for predicting whether a given patient's symptoms will be resolved by cholecystectomy. Numerous reports suggesting that patients with diminished gallbladder emptying, as determined by functional scintigraphy, benefit from laparoscopic cholecystectomy further support this approach. [5]

Given that biliary tract dysmotility is so prevalent in gallbladder disease, a comprehensive understanding of the neurons and smooth muscle that are responsible for gallbladder contractile activity is critical. Determination of the cellular mechanisms that are responsible for normal and pathological gallbladder motility is difficult in humans; therefore, much of what is known about the structure and function of gallbladder neurons and smooth muscle is derived from animal studies.

Gallbladder Neurobiology

The wall of the gallbladder consists of a mucosal layer with an underlying lamina propria, a muscularis layer, and a serosal layer. Neural networks can be found in each of these layers, and these neural networks are interconnected by nerve bundles. The morphology of nerves of the gallbladder have been investigated in many species including human, rhesus monkey, pig, dog, cat, marmoset, guinea pig, North American opossum, Australian brush-tailed possum, and mouse. [6], [7], [8], [9], [10], [11] and [12] The serosal plexus is the most prominent network of nerves in the gallbladder. It contains small, irregularly shaped ganglia that are connected by bundles of unmyelinated axons. The serosal plexus is connected to nerve bundles that follow the extensive vascular distribution in this layer. The neural plexus of the muscularis, which does not contain ganglia, is prominent in humans and other larger species. The mucosal plexus consists of nerve bundles that travel in the lamina propria, with branches that pass through the mucosa and often terminate near the epithelial cells. In some species, including humans, the mucosal plexus contains occasional small ganglia consisting of one to three neurons.

The structure of gallbladder neurons has been studied in animal models by injecting individual neurons with intracellular markers. [10], [13] Gallbladder neurons of these species are simple in structure when compared with intestinal neurons, because they consist only of a cell body and one or two long processes with no appreciable dendritic arborization. The axons typically pass from the ganglion of origin into interganglionic fiber bundles, where they travel for some distance before terminating in the muscular plexus. Unlike ganglion cells in the submucosal plexus of the bowel, gallbladder neurons do not project to the vascular nerve bundles, indicating that gallbladder ganglion neurons do not contribute to the modulation of vascular resistance in the gallbladder.

Neuroactive Compounds in Gallbladder Nerves

Gallbladder neurons. Evaluating the influence of gallbladder neurons on gallbladder function requires the identification of the neurochemical phenotypes of these cells. The complexity of the enteric nervous system is reflected by the large number of neuroactive compounds that are found in the neural plexuses of the gut. Studies of the neurotransmitter content of gallbladder neurons have revealed that many putative neurotransmitters also exist in this system. However, unlike in the gut, where distinct populations of cholinergic and noncholinergic neurons exist, all gallbladder neurons are apparently cholinergic because all are immunoreactive for the essential biosynthetic enzyme for acetylcholine choline acetyltransferase (ChAT). [9], [14] In the guinea pig, the most extensively studied species, the overall population of cholinergic neurons can be divided into two distinct subpopulations based on chemical coding patterns. [15], [16] The larger population, representing more than 80% of the neurons, is immunoreactive for substance P, neuropeptide Y (NPY), somatostatin, and orphanin FQ (OFQ, also known as nociceptin), as well as ChAT. The remaining neurons are immunoreactive for ChAT, in addition to vasoactive intestinal polypeptide (VIP), pituitary adenylate cyclase–activating polypeptide (PACAP), and nitric oxide synthase (NOS). Chemical coding of gallbladder neurons has also been described in other species, including human. [9], [11], [12], [17], [18] Most human gallbladder neurons express VIP, NPY, somatostatin, and PACAP, and most of these neurons are also tachykinin immunoreactive. [9], [11], [12], [17] NOS immunoreactivity and nicotinamide adenine dinucleotide phosphate (NADPH) dehydrogenase staining has also been reported in a small subset of human gallbladder neurons, but unlike the pattern seen in the guinea pig, the NOS-positive neurons are VIP negative. [17]

Sympathetic nerve fibers. Catecholamine histofluorescence and antibodies directed against the biosynthetic enzymes tyrosine hydroxylase (TH) and dopamine ß-hydroxylase have been used to identify the sympathetic postganglionic nerves in the wall of the gallbladder. [6], [8] Injection of axon tracers into the gallbladder wall demonstrates that sympathetic postganglionic projections to the gallbladder arise in the celiac ganglia. [8] Sympathetic postganglionic nerves pass along serosal blood vessels, and they are also abundant in the ganglionated plexus of the gallbladder, with numerous axonal varicosities surrounding gallbladder neurons. [8] In the perivascular plexus of the guinea pig and the human gallbladder, the sympathetic nerve fibers also are immunoreactive for NPY, and our research in the guinea pig has confirmed OFQ immunoreactivity. [16]

Sensory nerve fibers. It is not yet possible to distinguish sensory (afferent) fibers that arise from spinal ganglia versus those from nodose ganglia; however, the ganglionated plexus of the gallbladder clearly is rich in afferent nerve fibers that are immunoreactive for both substance P and calcitonin gene–related peptide (CGRP).[8], [9], [14] These nerves are likely to be extrinsic primary afferent fibers because gallbladder neurons are not immunoreactive for CGRP.[9], [12] The substance P/CGRP–immunoreactive nerve fibers are abundant in ganglia, in interganglionic fiber bundles, and in the perivascular plexus. Within the ganglia, the substance P/CGRP fibers appear to ramify and give rise to processes that terminate on gallbladder neurons. Substance P/CGRP–positive nerve fibers also are immunoreactive for PACAP,[16] suggesting that activated afferent nerves can release tachykinins, CGRP, and PACAP.

Electrical and Synaptic Properties of Gallbladder Neurons

Electrical properties. The electrical properties of gallbladder neurons have been studied in guinea pig, opossum, and human.[10], [13], [19] Unlike enteric neurons, gallbladder neurons can be classified into a single group on the basis of their electrical properties. They are relatively inexcitable, because they rarely exhibit spontaneous action potentials, and they fire stimulus-induced action potentials only at the onset of a depolarizing current pulse. These features indicate that gallbladder neurons are normally quiescent and must be driven by excitatory inputs to release their neurotransmitters onto their target tissues, such as smooth muscle. The action potential of the gallbladder neuron consists of a rapid upstroke that involves the influx of Na^+ and Ca^{2+} ions. An afterhyperpolarization of moderate duration that can be divided into an early and a late phase follows the action potential. These early and late phases involve two sequential Ca^{2+}-activated K^+ conductances.[13] The early phase is mediated by large-conductance, Ca^{2+}-activated K^+ (BK) channels, as well as by delayed rectifier K^+ channels. The late phase is sensitive to apamin, a selective blocker of small conductance, Ca^{2+}-activated K^+ (SK) channels. The late phase of the afterhyperpolarization apparently contributes to the inexcitability of gallbladder neurons because inhibition of this phase dramatically increases the excitability of these cells.[13]

Synaptic inputs. Gallbladder neurons are not inherently active and therefore must be driven by synaptic inputs to send signals to the smooth muscle. Fast excitatory postsynaptic potentials (EPSPs) and slow EPSPs, but not inhibitory synaptic potentials, can be elicited by focal stimulation of interganglionic axon bundles.[10], [13], [19] Fast excitatory synaptic input to gallbladder neurons is the principal driving force in the neuromuscular axis of the gallbladder. Stimulation of interganglionic nerve bundles, or cystic nerves, elicits fast EPSPs in essentially all gallbladder neurons.[10], [13], [19], [20] Fast EPSPs in the gallbladder are mediated exclusively by acetylcholine, as evidenced by the finding that they are completely abolished by the nicotinic receptor antagonist hexamethonium. Gallbladder neurons receive a significant input from vagal preganglionic nerves. Stimulation of vagus nerves in vivo elicits gallbladder contraction.[21], [22] and [23] Furthermore, neurons in the dorsal motor nucleus of the vagus are labeled after retrograde axonal tracers are injected into the gallbladder wall.[8] These vagal postganglionic projections represent the major source of nicotinic synaptic input to gallbladder neurons.[20] In animals that have been vagotomized, cystic nerve stimulation does not elicit a synaptic response. Therefore, unlike the ganglia of the intestines, in which most fast synaptic inputs arise from other ganglion cells, fast synaptic input to gallbladder neurons is mainly derived from vagal preganglionic nerve terminals. However, in about 20% of the neurons tested in vagotomized preparations, stimulation of interganglionic fiber bundles elicits a fast EPSP, indicating that interganglionic communication among gallbladder neurons does exist. Stimulation of interganglionic connectives at high frequency (10–20 Hz) elicits a slow EPSP in 20% to 30% of gallbladder neurons.[10], [13], [24] The slow EPSP consists of a depolarization of up to 8 mV, lasting about 1 minute. Unlike slow excitatory synaptic events in the gut, which involve a decrease in K^+ conductance, the slow EPSP in gallbladder ganglia is associated with a decrease in input resistance and is mediated by an opening of nonselective cation channels. The slow EPSP in gallbladder ganglia is mediated by the release of peptides from extrinsic afferent fibers that may be associated with the subjective experience of biliary pain. A subset of the sensory fibers in the wall of the gallbladder is activated only by noxious stimulation of the biliary system, indicating that these are pure visceral nociceptors.[25] Within the gallbladder, the pain afferents are likely to be immunoreactive for both substance P and CGRP.[8], [9], [26] In the gut, substance P is released from the peripheral endings of sensory nerve fibers as part of the process of inflammation.[27] Capsaicin, which causes peptide release from small-diameter afferent fibers, induces the release of substance P and CGRP when it is applied to the gallbladder in vitro.[26] When applied to gallbladder neurons, tachykinins and CGRP, as well as capsaicin, cause a membrane depolarization that is mediated by neurokinin 3 receptors and resembles the slow EPSP.[24], [28] Furthermore, neurokinin 3 receptor blockade inhibits the stimulus-induced slow EPSP and the depolarization caused by capsaicin.[24] Therefore, sensory fibers that pass through gallbladder ganglia can act locally to modulate ganglionic output by synapsing on gallbladder neurons and increasing their excitability. This local axon reflex circuit may contribute to a cycle that induces the subjective experience of biliary pain in gallbladder disease. Increased ganglionic output caused by slow EPSPs may lead to increased gallbladder contractility. If bile outflow from the gallbladder is inhibited or obstructed, pressure may then increase to higher levels and may lead to further activation of sensory fibers. The activated sensory fibers would then elicit additional stimulation of gallbladder neurons, leading to further increases in intralumenal pressure and enhanced perception of pain.

Gallbladder Smooth Muscle Cells

Gallbladder smooth muscle cells are arranged in interposed bundles that are oriented in various directions within the muscularis of the gallbladder.[29] Within each bundle, these smooth muscle cells appear to be coupled because intact cells have a very low input resistance;[30] although, on ultrastructural examination, gap junctions are relatively sparse.[29]

The Action Potential: Ca^{2+} and Voltage-Activated K^+ Channels The electrical properties of gallbladder smooth muscle cells have been investigated in intact preparations using intracellular microelectrodes and in isolated myocytes using patch clamp recording techniques.[30], [31] Intact gallbladder smooth muscle cells generate spontaneous action potentials that consist of four phases:[30]

1. A rapid depolarization upstroke
2. A transient repolarization downstroke almost to the resting membrane potential
3. A plateau phase
4. A repolarization back to the resting membrane potential.

Spontaneous action potentials typically occur at a frequency of 0.3 to 0.4 Hz, which is significantly higher than the frequency of slow wave action potentials in smooth muscle of the gut. Two of the principal channels that are involved in the gallbladder smooth muscle action potential are the L-type Ca^{2+} channel and the delayed rectifier K^+ channel. The L-type Ca^{2+} channel blocker, nifedipine, abolishes the gallbladder smooth muscle action potential in intact tissue, as well as the voltage-activated inward current in isolated cells.[30], [31] The amplitude and duration of the spike and plateau phases of the action potential are augmented by the voltage-activated K^+ (K_V) channel blocker, 4-aminopyridine, and most of the voltage-activated outward current is mediated by K_V channels.[30], [32] Whereas dihydropyridine-sensitive Ca^{2+} channels and K_V channels are clearly involved in the action potential of gallbladder smooth muscle, the mechanisms responsible for pacing of the action potential and the generation of the plateau phase have not been resolved.

BK Channels Inhibition of BK channels with tetraethylammonium or charybdotoxin does not affect the action potential shape or the membrane potential of gallbladder smooth muscle. However, BK channels have been identified in single-channel recordings from gallbladder smooth muscle.[30] Charybdotoxin and tetraethylammonium cause a slight decrease in the voltage-activated outward current. We have demonstrated that BK channels are responsible for spontaneous transient outward currents in gallbladder smooth muscle.[33] These currents are activated by local Ca^{2+} release events (i.e., sparks) from the endoplasmic reticulum, and they are potentiated by caffeine and inhibited by ryanodine. Although the functional relevance of sparks and transient outward currents in gallbladder smooth muscle is not completely understood, they are likely to play a role in the regulation of gallbladder smooth muscle excitability because they are inhibited by CCK.

ATP-Sensitive K^+ Channels Another type of K^+ channel that has been identified in gallbladder smooth muscle is the ATP-sensitive K (K^+-ATP) channel.[34], [35] and [36] Direct activation of the K^+-ATP channel with lemakalim or pinacidil causes a prolonged hyperpolarization that is associated with an elimination of spontaneous action potentials. Activation of K^+-ATP channels is responsible for the inhibitory effects of CGRP and agonists of H_2 receptors for histamine.[35], [37] Receptor-mediated opening of the K^+-ATP channel in gallbladder smooth muscle involves the activation of the cyclic AMP (cAMP)–adenylate cyclase–protein kinase A signal transduction cascade.[34], [36] Activation of protein kinase C inhibits K^+-ATP channel activity in gallbladder smooth muscle,[36] but gallbladder smooth muscle K^+-ATP channels are not as prone to inhibition by protein kinase C as other smooth muscle cell types. Because activation of protein kinase A is a major mechanism for inhibition of smooth muscle, and because the effects of forskolin are completely blocked by glibenclamide,[34] it is likely that K^+-ATP channels are actively involved in receptor-mediated relaxation of gallbladder smooth muscle.

Gallbladder Emptying

Neuroendocrine Control of Gallbladder Contraction Numerous neurotransmitters and hormones are capable of causing gallbladder contraction, as demonstrated in functional studies involving measurement of gallbladder pressure or muscle strip tension (Fig. 12-1). The three compounds that clearly participate in gallbladder contractile events are CCK, acetylcholine, and tachykinins.

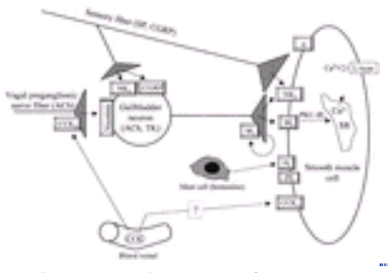

FIGURE 12-1. Excitatory transmitters, hormones, inflammatory mediators, receptors, and ion channels that have been identified in the neuromuscular axis of the gallbladder. Nerve terminals are represented by *triangles,* receptors are represented by *framed boxes,* and ion channels are represented by *boxes with arrows* indicating the direction of ion flow. a is an adrenergic receptor. *ACh,* acetylcholine; *CCK,* cholecystokinin; *CGRP,* calcitonin gene–related peptide; *EP,* prostaglandin E; *H,* histamine; *IP* $_3$*,* inositol 1,4,5-trisphosphate; *M,* muscarinic; *NK,* neurokinin; *PKC,* protein kinase C; *SP,* substance P; *SR,* sarcoplasmic reticulum; *TK,* tachykinins.

Cholecystokinin. One of the first and most significant hormones to be identified, CCK, was named in 1928 by Ivy and Oldberg [38] for its ability to contract the gallbladder. The mechanisms of CCK action in the gallbladder are described in greater detail later, in the section devoted to postprandial gallbladder contraction.
Acetylcholine. As described previously, all gallbladder neurons are cholinergic, and stimulus-induced release of acetylcholine from these neurons results in a contraction of gallbladder smooth muscle. Although M $_1$ to M $_4$ muscarinic receptors have been reported in the gallbladder, [39], [40], [41] and [42] the main muscarinic receptor subtype in the smooth muscle cells is M $_3$, whose activation induces smooth muscle contraction. [39], [40] Parkman and colleagues [42] demonstrated that the M $_1$ and M $_2$ receptors may provide an automatic feedback mechanism in the gallbladder because they are located on nerve terminals. Activation of M $_1$ receptors promotes transmitter release and M $_2$ receptor activation inhibits transmitter release. M $_2$ activation is linked to the phospholipase D–protein kinase C pathway, [43] whereas activation of M $_3$ receptors leads to phosphatidylinositol hydrolysis by phospholipase C as well as an inhibition of cAMP formation. [43], [44]
Tachykinins. Tachykinins are prevalent in the nerves of the gallbladder, including extrinsic afferent nerves as well as gallbladder neurons and their axons. Tachykinins produce a direct, concentration-dependent contraction of the isolated gallbladder, with a rank order potency of neurokinin A ? neurokinin B ? substance P, [23], [26], [45] which is a characteristic of neurokinin 2 receptors. In the gallbladder, the binding of tachykinins to neurokinin receptors is linked to protein kinase activation. [45] The finding that tachykinins are coexpressed with acetylcholine in gallbladder neurons indicates that these compounds may act together to promote gallbladder emptying on vagal stimulation.
Postprandial Gallbladder Contractions Postprandial gallbladder contraction is triggered by gastric emptying leading to the release of CCK from enterochromaffin cells in the epithelial lining of the duodenum. Although the concept that CCK acts as a hormone to cause gallbladder emptying is well established, it is also likely that CCK acts at several sites to promote functional gallbladder motility (Fig. 12-2). The most direct means of gallbladder contraction is for hormonal CCK to act on receptors located on gallbladder smooth muscle, which expresses the CCK-A but not the CCK-B receptor. [46] It is likely that low-affinity CCK-A receptors are present on gallbladder smooth muscle, because the EC $_{50}$ for the CCK-induced gallbladder contraction is in the 10- to 50-nM range. [47], [48] and [49] However, it is unclear whether the CCK receptors on gallbladder smooth muscle are a normal physiological site of action for CCK, because postprandial concentrations serum concentrations of CCK are in the 10- to 20-pM range, [50], [51] which is far lower than the threshold necessary for a direct action of CCK on gallbladder muscle strips. Therefore, a neural mechanism must be involved in the prokinetic effects of postprandial CCK release.

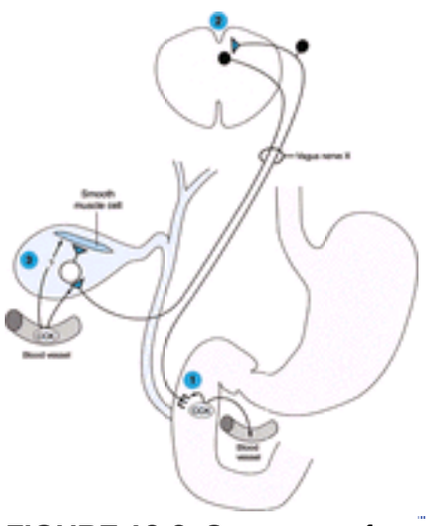

FIGURE 12-2. Sequence of events leading to postprandial gallbladder contraction: *(1)* cholecystokinin (CCK) released from the duodenal mucosa activates vagal afferent fibers and enters the bloodstream; *(2)* increased vagal afferent activity leads to increased vagal preganglionic output; *(3)* within the gallbladder, hormonal CCK acts at physiological concentrations on receptors located on vagal preganglionic nerve terminals in gallbladder ganglia. Activation of these presynaptic receptors leads to an increase in acetylcholine release and enhanced activation of gallbladder motor neurons. CCK may also act directly on gallbladder smooth muscle, but the receptors at this location appear to be low-affinity CCK-A receptors, which normally would not be activated by physiological concentrations of CCK.

Meal-induced gallbladder contractions and contractions induced by *physiological* concentrations of CCK in vivo are significantly attenuated by neural blockade in several species, including human. [51], [52], [53], [54], [55], [56], [57], [58], [59] and [60] Furthermore, hexamethonium, which blocks the vagal preganglionic input to gallbladder neurons, inhibits CCK- and meal-induced gallbladder contractions. [51], [57], [58] These data indicate that CCK can act on nerves to promote gallbladder motility. Results of electrophysiological studies suggest that CCK does not have a direct effect on gallbladder neurons, but it does have a potent presynaptic excitatory effect on nerve terminals in gallbladder ganglia, thereby increasing the release of acetylcholine onto gallbladder neurons. [10], [20], [61] CCK increases the amplitude of the cholinergic fast EPSPs in gallbladder ganglia, and typically converts subthreshold synaptically mediated depolarizations to responses that are accompanied by one or more action potentials. [10], [61] The action of CCK in gallbladder ganglia peaks at 1.0 nM and has a median effective concentration (EC $_{50}$) of 33 pM. Furthermore, in the presence of 10 pM CCK, synaptic currents increase about 20%. Thus, the neural action of CCK in the gallbladder occurs within the physiological concentration range. The nerve terminals that are sensitive to CCK are vagal preganglionic nerve terminals because these synaptic inputs are eliminated by vagotomy, as previously described. [20] Vagal afferent nerve fibers in the duodenum are another likely site of action for CCK released from enterochromaffin cells. Subdiaphragmatic vagal afferent fibers are sensitive to CCK, and postprandial physiological responses, such as increased gastric motility and pancreatic secretion, have been attributed to CCK-mediated increases in vagal afferent activity. [62], [63] After a meal, CCK stimulates vagal afferent nerve fibers, which act in the vagal motor complex to increase the rate of firing of vagal preganglionic neurons. Furthermore, CCK acts in gallbladder ganglia, as previously discussed, to increase the amount of acetylcholine released from the vagal motor terminals each time they are activated. The question remains: If CCK is normally acting through the neural mechanisms described, how does CCK-induced gallbladder emptying still occur (albeit diminished) after vagotomy or after liver transplantation with the donor gallbladder intact? The answer to this question probably lies in the fact that gallbladder emptying involves increased gallbladder tone in concert with a decrease in resistance at the SO. As described later, it is likely that the circuitry responsible for the CCK-induced decrease in SO resistance is left intact after vagotomy or liver transplantation. Therefore, changes in SO tone, in combination with the myogenic tone of the gallbladder, may lead to the flow of bile. Another potential mechanism for CCK-induced gallbladder emptying after vagotomy is that gallbladder denervation could lead to a sensitization of gallbladder smooth muscle, resulting in a leftward shift of the concentration-effect curve for CCK. This phenomenon is observed in patients who have had a truncal vagotomy—gallbladder contraction in response to CCK is significantly enhanced. [64]
Gallbladder emptying after vagotomy may be mediated through an enterobiliary neural reflex. Studies in the guinea pig and the Australian possum have demonstrated that the gallbladder receives projections from neurons located in the myenteric plexus of the duodenum. [8], [65] It is plausible that lumenal stimuli or mucosal CCK release may result in the activation of these neurons, which directly signal the gallbladder. Whereas the latter scheme could not contribute to gallbladder emptying after liver transplantation, the enterobiliary circuitry may contribute to gallbladder emptying after truncal vagotomy.
Interprandial Gallbladder Contractions During phase II of the migrating myoelectric complex (MMC), there is an increase in gallbladder pressure, accompanied by a transient flow of bile from the gallbladder to the duodenal lumen. This interprandial gallbladder motor response, which occurs in association with elevated antral and duodenal motor activity, has been demonstrated in several species including human, and it is thought to help maintain the enterohepatic circulation of bile salts. [66]
The mechanisms responsible for the phase II gallbladder contraction have not been clearly resolved, but they appear to involve a neural component because spontaneous and motilin-induced gallbladder contractions are reduced or abolished with atropine or hexamethonium. [67] However, it is not clear whether the neural

component involves the activation of a vagal reflex or whether it is limited to actions on intrinsic reflex circuits of the bowel. In one study, performed in dogs, inhibition of vagal reflex activity by transient vagal chilling or by acute vagotomy led to a decrease in MMC-related gallbladder emptying. [68] In contrast, MMC-related contractile activity is relatively normal after chronic vagotomy. [69], [70] and [71] If the biliary motor response that accompanies the MMC does not involve an extrinsic neural circuit, it may involve direct neural interactions between the gut and the biliary tree, or humoral factors may contribute. The gastrointestinal hormone motilin is thought to initiate the MMC because plasma motilin levels increase during or just before the onset of MMC activity, and exogenous motilin administration initiates an early burst phase of the MMC in the upper gastrointestinal tract, [72], [73] including the gallbladder. [52] Exogenous administration of motilin, or motilin analogs such as erythromycin, increases gallbladder motor activity, [74] and motilin induces the contraction of isolated gallbladder myocytes. [75] However, it is not yet clear how endogenous motilin would directly activate MMC-related gallbladder activity, which is primarily limited to phase II, because peak levels of motilin in the serum correspond to phase III of the MMC, when the gallbladder is quiescent.

Remaining Questions Related to Biliary Tract Contractility Although much has been learned in the last 2 decades regarding postprandial and interprandial gallbladder contractions, the mechanisms of excitation-contraction coupling in gallbladder smooth muscle cells remain less clear. A few studies, involving measurement of the percentage of shortening of gallbladder myocytes, have elucidated the intracellular pathways that mediate agonist-induced responses, whereas precisely how the activation of M_3 or CCK-A receptors leads to Ca^{2+} mobilization and contractile protein activation requires further clarification. Intracellular electrophysiological studies have shown that gallbladder smooth muscle cells generate spontaneous action potentials that are likely to be associated with increases in global Ca^{2+} and probably contribute to the basal tone of the gallbladder. Unfortunately, the generation of these events is not understood, nor is it known whether they are modulated in response to neurohormonal signals. Because gallbladder dysmotility is clearly a predisposing factor to a variety of clinical disorders, a thorough understanding of how basal tone in the gallbladder is maintained and how agonists contract gallbladder smooth muscle will advance the understanding of clinical biliary disease and may lead to therapeutic alternatives.

Gallbladder Filling

During fasting, gallbladder filling is related to the rate of hepatic secretion from the liver and the resistance to flow through the SO into the duodenum. During this process, hepatic secretory pressure is relatively high (=25–30 mm Hg), as is SO pressure (~11–30 mm Hg), whereas pressure within the biliary tree is maintained at a relatively low level (~5–15 mm Hg) because of the gallbladder's ability to accommodate newly synthesized bile. [66] The accommodation of the gallbladder during fasting relies on the ability of the epithelium to concentrate bile and on the receptive expansion of the gallbladder. The gallbladder therefore contributes to the modulation of pressure within the biliary system, and its contribution is likely to involve both passive and active mechanisms.

Passive Filling The fibroelastic properties of the gallbladder wall likely facilitate filling, allowing the organ to expand as bile is routed from the biliary tree to the gallbladder. The sheer size of this organ, relative to other structures in the biliary tree, favors the passage of bile into the gallbladder. According to the law of Laplace, tension in the wall of a hollow elastic structure is proportional to the product of pressure times diameter. Because the diameter of the gallbladder is significantly greater than that of the bile ducts, the path of least resistance would be gallbladder filling and expansion while the SO is resisting bile flow. As the gallbladder fills and its diameter increases further, the propensity for bile to flow into the gallbladder increases. Although this principle has never been applied to the gallbladder, many visceral structures that undergo expansion, including the urinary bladder, the alveoli, the heart, and the eyeball, have been shown to behave according to the law of Laplace. Since the early 1990s, several stretch-activated channels have been identified. Although this has not yet been investigated in the gallbladder, it is highly likely that gallbladder smooth muscle cells express stretch-activated channels that are activated as gallbladder tone increases slightly as a result of filling. These could be channels that induce a depolarization of the smooth muscle resulting in increased gallbladder basal tension or channels that elicit hyperpolarization and decreased tension. In cardiac myocytes, a stretch-sensitive channel with the properties of the BK channel has been identified. [76] As described previously, BK channels in gallbladder smooth muscle are responsible for spontaneous transient outward currents that are activated by sparks—local, ryanodine-sensitive, Ca^{2+}-release events. [30], [33] It remains to be determined whether the open-state probability of these channels and associated spontaneous transient outward current activity are altered by changes in smooth muscle tension or whether other, yet to be identified channels exist in gallbladder smooth muscle and contribute to the maintenance of myogenic tone during gallbladder filling.

Active Filling Several candidates exist as potential mediators of active gallbladder relaxation and resultant gallbladder filling (Fig. 12-3). Neurotransmitters that have an inhibitory effect on gallbladder smooth muscle include CGRP, norepinephrine, VIP, PACAP, and NO. Humoral factors that relax the gallbladder include pancreatic peptide and somatostatin. However, it is difficult to determine which of these compounds actually contribute to normal physiological gallbladder expansion, because many of their effects on the gallbladder have been observed at supraphysiological concentrations. Several potential schemes could contribute to this process, as described in the following discussion.

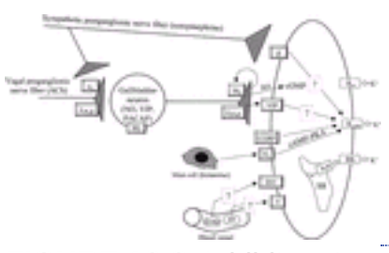

FIGURE 12-3. Inhibitory transmitters, hormones, inflammatory mediators, receptors, and ion channels that have been identified in the neuromuscular axis of the gallbladder. Nerve terminals are represented by *triangles,* receptors are represented by *framed boxes,* and ion channels are represented by *boxes with arrows* indicating the direction of ion flow. a_2 and ß are adrenergic receptors, and *d, ?*, and *μ* are opioid receptors. *ACh,* acetylcholine; *BK,* large-conductance Ca^{2+}-activated K^+ channel; *CGRP,* calcitonin gene–related peptide; *PE,* prostaglandin E; *H,* histamine; K_{ATP}, ATP-sensitive K^+ channel; K_V, voltage-activated K^+ channel; *M,* muscarinic; *NO,* nitric oxide; *PACAP,* pituitary adenylate cyclase–activating peptide; *PKA,* protein kinase A; *PP,* pancreatic polypeptide; *RyR,* ryanodine receptor; *SOM,* somatostatin; *SR,* sarcoplasmic reticulum; *SST,* somatostatin receptor; *VIP,* vasoactive intestinal polypeptide; *Y,* neuropeptide Y/PP receptor.

Release of inhibitory neuroactive compounds from gallbladder neurons. In the bowel, distinct subpopulations of enteric neurons (i.e., inhibitory motor neurons) act to decrease muscle tone. Compounds that have been proposed to contribute to relaxation of intestinal smooth muscle include NO, VIP, PACAP, and ATP. As mentioned previously, subsets of gallbladder neurons are immunoreactive for VIP or PACAP, [12], [15], [16] and [17] and they are immunoreactive for NOS. [12], [14], [16], [17] The neuroactive peptides VIP and PACAP cause relaxation of resting or precontracted gallbladder muscle strips from several species including human, [77], [78], [79] and [80] probably through the activation of adenylate cyclase. VIP is released by nerves in the gallbladder in response to electrical stimulation of the vagus nerves, further evidence of its neurotransmitter capability. [81], [82] In addition, relaxant responses to exogenous VIP vagal stimulation can be antagonized by VIP antisera. [79] Evidence indicating that NO relaxes gallbladder smooth muscle includes the finding that inhibition of NOS results in increased gallbladder tone and an enhancement of agonist-induced contractions. [83], [84] NOS inhibition also reduces stimulation-induced neurogenic relaxations, and NO donors have an inhibitory effect on gallbladder tone. [83], [84], [85] and [86] CGRP, which is present in extrinsic sensory fibers, can decrease tension in gallbladder muscle strips and cause a hyperpolarization of gallbladder smooth muscle cells. It is unlikely, however, that CGRP released from gallbladder afferent fibers contributes to relaxation because tachykinins are co-stored with CGRP in these nerve fibers, [8], [9], [14] and tachykinins have an excitatory effect on gallbladder smooth muscle. [23], [26], [45], [87] Carbon monoxide may also play a role in gallbladder function. The enzyme that synthesizes carbon monoxide, heme oxygenase 2, is present in canine gallbladder nerves, and copper protoporphyrin IX, an inhibitor of heme oxygenase, inhibits nonadrenergic noncholinergic stimulus-induced relaxations. [88] In the bowel, ATP is a mediator of nerve-induced relaxations. However, it is unlikely that ATP contributes to gallbladder relaxation because the application of exogenous ATP leads to a gallbladder contraction. [89] Despite the results described, it is difficult to conceive how gallbladder neurons could provide an unambiguous inhibitory signal to gallbladder smooth muscle because all gallbladder neurons express ChAT and therefore are likely to be cholinergic and excitatory. [9] Activation of these neurons would lead to the release of acetylcholine and other compounds such as NO or VIP, thus providing the gallbladder smooth muscle with a mixed signal.

Increased sympathetic neural activity in the gallbladder. Another possibility is that gallbladder relaxation involves the release of norepinephrine from sympathetic nerves. Stimulation of the splanchnic nerves leads to a decrease in gallbladder tone, [90], [91] and [92] indicating that sympathetic activity contributes to interprandial gallbladder filling. It is likely that activation of sympathetic neural inputs can lead to decreased gallbladder tone through the direct effects on gallbladder smooth muscle and by inhibiting vagal input to gallbladder neurons. Behar and colleagues demonstrated that electric field stimulation–induced relaxation of cat gallbladder muscle strips can be completely blocked by the ß-adrenergic receptor antagonist, propranolol, whereas receptor antagonists or NOS inhibition have no effect. [80] These data are consistent with reports demonstrating that sympathetic nerve stimulation can result in gallbladder relaxation and indicate that, at least in larger species, sympathetic nerves may promote gallbladder filling through direct actions on gallbladder smooth muscle. In addition to relaxing gallbladder smooth muscle directly, sympathetic nerves may facilitate gallbladder filling by decreasing vagal tone in the organ. Yamasato and Nakayama [92] reported that stimulation of sympathetic nerves, at intensities lower than necessary to relax the gallbladder directly, results in a decrease in the excitatory response to vagal stimulation.

Furthermore, application of exogenous norepinephrine or release of norepinephrine from sympathetic nerves causes activation of a $_2$-adrenergic receptors located on vagal terminals in gallbladder ganglia and suppression of vagal synaptic input to gallbladder neurons. [20], [93] In smaller species, relaxations are not elicited in muscle strips in response to electric field stimulation, whereas in larger species, including human, relaxations can be activated even without precontraction of the tissue. The interspecies variation may be associated with differences in the distributions of sympathetic nerve fibers. In the guinea pig, TH-immunoreactive nerve fibers are restricted to the vascular and ganglionated plexuses. In larger species, TH-immunoreactive nerves are distributed throughout the muscularis as well as the ganglionated and vascular plexuses. Taken together, these data support the suggestion that sympathetic activity can cause a decrease in gallbladder tone by inhibiting the vagal input to gallbladder neurons and through direct effects on gallbladder smooth muscle. However, it is still unclear whether such a system is active primarily at times of physiological stress or whether it contributes to the normal accommodation of the gallbladder wall during interprandial filling. Indeed, in models of hemorrhagic shock, gallbladder contractility is significantly decreased. [94]

Humoral factors that relax gallbladder smooth muscle. Because pancreatic polypeptide relaxes gallbladder muscle strips, [95] this peptide has been implicated as a potential contributor to gallbladder filling. Furthermore, elevated pancreatic polypeptide levels have been implicated in the origin of clinically significant biliary stasis, as is seen in patients with diabetes mellitus. [96] Increases in pancreatic polypeptide levels have been measured in response to liquid test meals, intraduodenal feeding, and CCK infusion. [97], [98] However, there is no correlation between pancreatic polypeptide levels and gallbladder motor activity in healthy individuals, [99] indicating that pancreatic polypeptide probably does not contribute to interprandial gallbladder filling. Pancreatic polypeptide may play an indirect role in the control of gallbladder motility by modifying pancreatic secretion or intestinal motility, but this has not been resolved. Somatostatin is another compound that may contribute to gallbladder filling, because several lines of evidence indicate that somatostatin decreases gallbladder contractility. Long-term therapy with the somatostatin analog octreotide for diseases such as acromegaly [100], [101] and the existence of somatostatin-secreting tumors [102] both interfere with gallbladder contractility. Gallbladder hypomotility in celiac disease has been associated with elevated somatostatin levels, increased gallbladder fasting volume, and decreased CCK release. [103] In addition to its well-known inhibitory effect on the release of mucosal CCK, somatostatin can act locally to decrease gallbladder motility. Somatostatin decreases CCK- and carbachol-induced gallbladder contractions, gallbladder pressure, and the release of acetylcholine from gallbladder muscle strips. [104], [105] Somatostatin also inhibits CCK-induced gallbladder contractions in isolated cells. [106] In healthy subjects, somatostatin enhances gallbladder relaxation and reduces CCK secretion in the late postprandial phase. [107] Although these results infer an association between somatostatin and gallbladder volume under pharmacological or pathological conditions, there is no direct evidence to indicate that somatostatin plays a physiological role in gallbladder filling.

SPHINCTER OF ODDI

The SO oversees the flow of about 3 L of bile and pancreatic juices per day, and it is the busiest nonvascular intersection in the body. Because of its vast interspecies variation in morphology and function, it has been the subject of more controversy than any other structure in the gastrointestinal tract. The tasks of the SO are to regulate the flow of bile and pancreatic juices into the duodenum, to facilitate gallbladder filling, and to prevent the reflux of lumenal contents from the duodenum into the biliary tree. Although the precise mechanisms of SO function are not yet fully understood, research has demonstrated that changes in SO motility involve neurohormonal regulation of nontraditional neural circuits that orchestrate coordinated signals from SO ganglia to the surrounding circular smooth muscle.

Sphincter of Oddi Neurobiology

Most studies of SO ganglia have involved the guinea pig and the Australian possum. Therefore, most of the following information relates to ganglia in the SO region of these two species; of note, considering the aforementioned interspecies variation. [108]

Morphology of the Sphincter of Oddi Ganglia Ganglia in the guinea pig SO are similar in shape and density to the ganglia of the myenteric plexus of the duodenum. [109], [110] In fact, interganglionic nerve bundles can be traced between the myenteric plexus of the duodenum and that of the SO. [109] Most of these neurons have Dogiel type I morphology, consisting of a single long process and several short processes that measure less than the diameter of the cell body. The processes of SO neurons typically leave the ganglionated plexus to innervate the smooth muscle of the SO, and therefore most SO neurons are thought to be motor neurons.
Neurotransmitters of the Sphincter of Oddi Immunohistochemical studies have revealed the presence of numerous neuroactive compounds in SO nerves. [113], [114], [115], [116], [117], [118], [119], [120], [121], [122], [123], [124], [125], [126], [127], [128], [129] and [130] For example, among the species investigated, there is evidence of acetylcholine, NO, VIP, tachykinins, CGRP, NPY, OFQ, somatostatin, enkephalin (ENK), galanin (GAL), serotonin (5-hydroxytryptamine; 5-HT), peptide histidine isoleucine (PHI), gastrin-releasing peptide, and bombesin. The most thorough investigation of neurochemical content and distribution in the SO has been conducted in the guinea pig. Guinea pig SO ganglia consist of two major subpopulations of neurons: those that are immunoreactive for ChAT and those that are immunoreactive for NOS. [110], [111] The cholinergic (ChAT-positive) neurons, which are thought to be excitatory motor neurons, represent about two thirds of the population and are also immunoreactive for tachykinins and/or ENK. The nitrergic neurons, which are thought to be inhibitory motor neurons, are also immunoreactive for either VIP or NPY, but not for both. SO neurons have also been found to be immunoreactive for bombesin, [112] OFQ, [113] and 5-HT [114]; whether these compounds are expressed by cholinergic or nitrergic neurons is not yet known. Nerve fibers, thought to be extrinsic afferent axons, are immunoreactive for tachykinins and CGRP and are abundant in the ganglionated plexus of the guinea pig SO. [110] TH-immunoreactive, sympathetic postganglionic nerves also are abundant in guinea pig SO ganglia and nerve bundles. [115] Less is known about the colocalization of various compounds in other species. Considerable neurotransmitter diversity exists, and a nitrergic innervation of the SO has been reported in all species where this has been investigated. In the human SO, neural immunostaining has demonstrated NOS, VIP, PHI, NPY, CGRP, GAL, somatostatin, tachykinin, and ENK, and histochemical staining was positive for NADPH dehydrogenase. [11], [116], [117] and [118] Nerve fibers of the rhesus monkey SO are immunoreactive for ENK, NPY, and TH, and NADPH dehydrogenase staining also has been reported. [11], [119] In the pig, immunoreactivities for NOS, VIP, NPY, GAL, PHI, CGRP, tachykinin, and bombesin have been reported. [18], [117], [120] Feline SO nerves have been shown to be VIP and tachykinin immunoreactive. [23], [79], [121], [122] In studies of the Australian possum SO, ChAT, TK, GAL, gastrin-releasing peptide, and somatostatin immunoreactivities have been demonstrated, [123], [124], [125] and [126] and NADPH dehydrogenase staining suggests a nitrergic innervation. [127]
Electrophysiology Thus far, the electrophysiological properties of SO neurons have been investigated exclusively in the guinea pig. SO neurons can be classified as tonic or phasic cells on the basis of their active electrical properties. [109] Tonic cells are quite excitable, often exhibiting spontaneous activity and generating action potentials throughout a depolarizing current pulse. Phasic cells, in contrast, are relatively inexcitable, without spontaneous activity, and are capable of generating action potentials only at the onset of a depolarizing current pulse. An extensive study combining intracellular recording and dye injection, along with chemical coding, has revealed that there is no relationship between the electrical properties of SO neurons (tonic versus phasic) and their chemical coding patterns (cholinergic versus nitrergic). [128] Therefore, it is conceivable that the excitability of SO neurons shifts between excitable and inexcitable states, possibly in response to some humoral or neural signal. This type of neuroplasticity could be associated with changes in SO activity that occur during the feeding cycle. Stimulation of interganglionic fiber bundles in the SO elicits fast EPSPs in most neurons and slow EPSPs in about 25% of the cells, whereas inhibitory postsynaptic potentials are detected in about 10% of the neurons. [109], [115], [129] Fast EPSPs are mediated by nicotinic receptors, and fast excitatory synaptic input to SO neurons arises in part from the myenteric plexus of the duodenum. Neural connections between the duodenum and the SO are discussed in greater detail in the later discussion of SO postprandial activity. Slow EPSPs are mediated, at least in part, by the release of tachykinins from extrinsic sensory fibers, and they involve the activation of neurokinin 3 receptors. [129] Sympathetic postganglionic nerves, by releasing norepinephrine, initiate inhibitory postsynaptic potentials in SO neurons and inhibit fast EPSPs through actions on presynaptic nerve terminals. [115]

Sphincter of Oddi Smooth Muscle

Human and animal studies of the SO have established that the sphincter is not a simple and passive smooth muscle portion of the biliary system. Rather, it exhibits basal tonicity, spontaneous phasic contractions, and peristaltic activity that modulates bile flow into the duodenum. [130], [131] and [132] The human SO normally is characterized by prominent phasic contractions that are superimposed on a modest basal pressure. [133] In a landmark study, pressures were recorded from the human SO to determine the effect of neurohumoral mediators on SO function. [134] The basal SO pressure was 4 mm Hg higher than the common bile duct or pancreatic duct pressures. Pronounced phasic contractions superimposed on the basal SO pressure occurred at a frequency of 4.1 per minute. The phasic SO contractions were about 100 mm Hg in amplitude and 4.3 seconds in duration. These contractions were unique to the SO and did not exist in the duodenum, the common bile duct, or the pancreatic duct. The phasic contractions were altered by intravenous infusions of CCK, glucagon, and secretin, suggesting a neurohumoral component to the modulation of SO motility in the human.

In general, the interpretation of the actions of various compounds in the SO has been difficult because most compounds mediate their effects both through direct actions on the smooth muscle and indirect neural responses. For example, exogenously administered CCK has a direct contractile effect on SO smooth muscle as well as contractile and relaxant effects that are mediated by neurotransmitters release. The neurally mediated effects of CCK are species specific; both contraction and relaxation are detected in species whose sphincter acts as a pump, [135] and simple relaxation is detected in species such as human and cats where the sphincter

acts primarily as a resistor. [136], [137] and [138]

Electrical field stimulation of the SO evokes a twitchlike contraction followed by relaxation. [127], [139], [140] and [141] Muscarinic blockade in the presence of guanethidine alters this pattern to simple relaxation, [139], [140], [142] consistent with the existence of inhibitory nonadrenergic noncholinergic innervation. NO is the primary inhibitory neurotransmitter in the SO. [127], [140], [143], [144] Neurally released NO increases cAMP and cGMP levels in SO smooth muscle, [143], [145] and it induces the activation of K^+-ATP channels. [146] This pathway may be important in the physiological regulation of the bile duct pressure, because NOS blockers increase SO resistance to flow, [142] and NO donors inhibit SO contraction frequency and decrease basal pressure. [116]

Postprandial Decreases in Sphincter of Oddi Resistance

Release of CCK from enterochromaffin cells in the duodenum results in changes in SO function that promote the flow of bile in concert with increased gallbladder motility. In some species, including human, cat, dog, and Australian brush-tailed possum, this mainly involves a decrease in SO tone. [56], [137], [147], [148] and [149] In other species, such as guinea pig, rabbit, and North American opossum, CCK release leads to a pumping response that involves rhythmic fluctuations in SO tension. [47], [150], [151] and [152] In the opossum, bile flow appears to involve peristalsis through the particularly long SO region characteristic of this species. Regardless of the species or the type of response, it appears that the physiological effect of CCK is to decrease resistance and therefore to promote bile flow.

The effect of CCK on SO tone involves a neural mechanism, because the CCK-induced increase in bile flow through the SO is inhibited by muscarinic blockade with atropine or by complete neural blockade with tetrodotoxin. [56], [57], [150], [151] and [152] Furthermore, inhibition of VIPergic signals with VIP antiserum, or NO release by NOS inhibitors, suppresses CCK actions. [153], [154] These observations led to the theory that CCK alters SO tone through a hormonal effect on SO neurons. Indeed, the application of CCK to guinea pig SO neurons causes a prolonged depolarization and bursts of action potentials. [155] However, as for gallbladder smooth muscle, the concentration-dependent nature of this response is out of the physiological range. [50], [51] These data indicate that the neural mechanism by which CCK decreases SO resistance probably does not involve a direct action of hormonal CCK on SO neurons. One possibility is that CCK, released locally at high concentrations from enterochromaffin cells, has a paracrine effect on SO neurons, and another possibility is that CCK acts on duodenal neurons that provide regulatory input to SO ganglia.

Evidence is mounting in support of the concept that CCK released from duodenal enterochromaffin cells activates duodenal enteric neurons, and these neurons signal SO ganglia, initiating postprandial changes in SO function (Fig. 12-4). [156] In the guinea pig [157] and the Australian possum, [65] retrograde axonal tracing studies have confirmed the existence of a direct neural projection from the myenteric plexus of the duodenum to the SO. In the guinea pig, the neurons of this duodenum-SO projection are cholinergic, [157] and neurons in SO ganglia receive nicotinic excitatory synaptic input from the duodenal myenteric plexus. [158] Experiments involving electrical recordings from duodenal neurons that were retrogradely labeled from the SO have demonstrated that all of these neurons express CCK receptors, and many of these neurons are intrinsic primary afferent neurons. [157] Intrinsic primary afferent neurons in the intestines are known to send projections to the lamina propria, where they may be activated by local release of CCK from enterochromaffin cells. [159], [160] and [161] These data support the view that CCK released from duodenal enterochromaffin cells could initiate changes in SO resistance by way of a local neural circuit. However, the involvement of this neural circuit in postprandial changes in SO tone is not certain. Other potential functions for this circuit include the mediation of changes in SO tone that accompany interprandial bile flow during phase II of the MMC, as discussed in the next section. Alternatively, it may provide a means of increasing SO tone when lumenal pressure in the duodenum is elevated, thus inhibiting the flow of duodenal contents into the biliary tract.

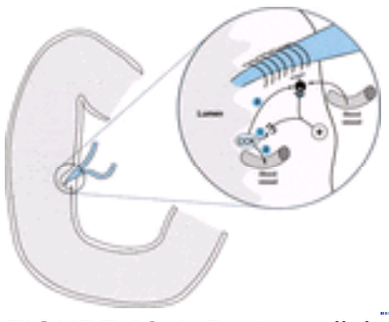

FIGURE 12-4. Postprandial relaxation of the sphincter of Oddi. Cholecystokinin (*CCK*) released from the duodenal mucosa activates inhibitory motor neurons in sphincter of Oddi (SO) ganglia, which, in turn, decrease the basal tone of the SO. CCK probably causes a relaxation of the SO by activating duodenal neurons that provide synaptic input to SO ganglia (1). Hormonal CCK may activate SO neurons, but these neurons are not sensitive to the concentrations of CCK that are found in the serum (2). Another possibility is that locally released CCK acts directly on SO neurons through a paracrine mechanism (3).

Interprandial Sphincter of Oddi Activity

Between meals, SO resistance is maintained by phasic contractions of the smooth muscle that are superimposed on a basal level of tonic pressure that is adequate to route hepatic bile to the gallbladder. During the fasting state, bile flowing toward the small bowel is diverted into the gallbladder by the resistance encountered at the SO—resistance maintained by basal and phasic contractions. Thus, intraductal pressures are increased, and bile flow is diverted to the region of lowest resistance, the cystic duct and gallbladder. High pressures in the biliary system also trigger relaxation and compliance of the gallbladder. Resistance at the SO and increased compliance of the gallbladder allow for the diversion of most of the bile away from the gut and into the gallbladder. There are, however, interprandial changes in SO activity that correspond to phase II of the MMC.

The interprandial SO activity associated with the MMC involves a decrease in SO resistance that accompanies increased gallbladder motor activity and bile flow. However, the MMC-related flow of bile does not depend on increased gallbladder motility, because dogs that have undergone cholecystectomy also exhibit cyclic bile flow that corresponds to the MMC. [162] Changes in SO activity that accompany the MMC have been documented in many species, including human. [67], [162], [163] As for the gallbladder, the mechanisms underling the MMC-related changes in SO activity are not entirely clear; however, it appears likely that the duodenum-SO neural circuitry is involved. After truncal vagotomy, MMC-related SO activity is normal in the opossum. Furthermore, relocation of the duodenal papilla in the opossum, which leaves the blood supply and extrinsic nerves intact but eliminates myoneural continuity between the duodenum and the SO, leads to a marked reduction in electrical activity of the SO during phases II and III of the MMC. [164] In addition, surgical relocation of the duodenal papilla reduces the responsiveness of the SO to motilin. [165] Together, these data support the concept that an intrinsic neural circuit mediates the interprandial SO motor response, but because some cyclic activity remains after translocation of the SO, it is likely that vagal reflex activity or humoral factors also are involved.

PATHOPHYSIOLOGY OF THE BILIARY TRACT

Mechanisms of Biliary Stasis in Cholesterol Disease

The gallbladders of patients with cholesterol gallstones often demonstrate abnormal motility. These patients have increased residual gallbladder volume interprandially, as well as decreased gallbladder emptying after a meal [166], [167] or in response to exogenous CCK administration. [166], [168] Furthermore, gallbladder muscle strips from patients with cholesterol gallstones demonstrate impaired contractile response to a variety of stimuli, as compared with gallbladder muscle strips from patients with pigment stones. [169], [170]

Decreased gallbladder smooth muscle contractility appears to be a critical link in the chain of events that leads to cholesterol gallstone formation and associated disease. Ground squirrels and prairie dogs that are fed a high-cholesterol diet undergo a progressive increase in cholesterol saturation in the bile, a decrease in gallbladder contractility, and, ultimately, cholesterol stone formation. [171], [172] If the decrease in gallbladder motility is offset by the administration of the prokinetic

agents cisapride or erythromycin, the formation of cholesterol crystals is prevented in cholesterol-fed ground squirrels. [173], [174] Conversely, if gallbladder stasis is pharmacologically induced by the administration of a CCK-A antagonist, gallstone formation occurs in animals that are fed either a normal diet or a cholesterol-enriched diet. [175]

These clinical and basic scientific data indicate that gallstone formation results from an elevation in cholesterol concentrations within the bile and an associated decrease in gallbladder contractility. The decrease in contractility is directly linked to cholesterol enrichment. Gallbladder smooth muscle that is exposed to cholesterol-rich liposomes exhibits diminished contractility similar to that observed in human gallbladders with cholesterol stones and in animals fed a high-cholesterol diet. [176] These results support the hypothesis that cholesterol itself can have a direct effect on gallbladder smooth muscle.

Two possible sites for the contractile defects caused by cholesterol are the cell membrane and the contractile machinery of gallbladder smooth muscle cells. However, the possibility that cholesterol disrupts the contractile machinery of these cells has been largely excluded. No difference is detected between the contractile responses of gallbladder muscle strips from control and cholesterol-fed ground squirrels that are exposed to the Ca^{2+} ionophore A-23187, which facilitates access of Ca^{2+} to the contractile proteins and causes contractions. [177] Therefore, it is likely that the primary smooth muscle defect in cholesterol gallstone disease does not reside in the contractile apparatus, but rather involves a disruption in the agonist-induced mobilization of Ca^{2+}. This may result from impaired ligand binding or altered ion channel activity.

To test whether cholesterol enrichment alters gallbladder smooth muscle ion channel activity, we exposed whole-mount preparations and isolated myocytes to cholesterol-loaded cyclodextrins. [178] Elevated membrane cholesterol results in a disruption of spontaneous action potentials, a decrease in the depolarization caused by the L-type Ca^{2+} channel opener Bay K 8644, and a suppression of voltage-activated Ca^{2+} currents. Conversely, K_V currents and K^+-ATP channels are not affected by cholesterol enrichment. In addition to altering Ca^{2+} channel activity, cholesterol enrichment of the membrane alters the activation of cytosolic membrane receptors. For example, the hyperpolarization to CGRP is suppressed after cholesterol enrichment, even though the channel that mediates this response, the K^+-ATP channel, is not altered by cholesterol. Furthermore, gallbladders from patients with cholesterol stones have impaired CCK receptor binding as compared with those from patients with pigment stones. [179] These data indicate that cholesterol enrichment results in selective deficits, rather than a nondiscriminatory disruption of membrane protein function, and that the biliary stasis associated with cholesterol stone formation is likely to involve altered Ca^{2+} channel and receptor function.

Acalculous Cholecystitis and Gallbladder Dysmotility

Conditions other than elevated biliary cholesterol also lead to decreased gallbladder contractility and cholecystitis, with or without stones. For example, biliary colic in the absence of gallstones is an increasingly prevalent complication among patients in the intensive care unit and in patients without predisposing illness. [180], [181] and [182] This condition, commonly referred to as *acute acalculous cholecystitis,* is often associated with trauma or extensive surgery. In a retrospective chart review over 53 months in a tertiary care center, 27 cases of acalculous cholecystitis were observed. Of these cases, 52% occurred in the intensive care unit and 63% occurred in patients recovering from unrelated surgical procedures, and acalculous cholecystitis accounted for 14% of all cases of acute cholecystitis. [183] The mortality rate for all patients with acalculous cholecystitis was 41%, illustrating the potential lethality of this clinical entity.

The development of acalculous biliary colic, like cholesterol-related gallbladder disease, appears to involve decreased gallbladder motility leading to an increase in the resting volume of the gallbladder and cholecystitis. [184], [185] and [186] The clinical complexity of a critically ill patient makes it difficult to sort among interrelated factors and to determine the origin of a complication such as acute acalculous cholecystitis. Factors implicated in the pathophysiology of acalculous cholecystitis include parenteral feeding, altered bile composition, ischemia, infection, and functional obstruction of gallbladder outflow. [184], [185] and [186] Decreased gallbladder motility may also result as a consequence of therapeutic agents that surgical patients and trauma victims receive to alleviate pain. A summary of the major findings in these areas follows.

Parenteral Feeding During total parenteral nutrition (TPN), biliary stasis and hypomotility have been well documented, contributing to the development of biliary dilation, sludge accumulation, and acute cholecystitis. In most patients, TPN induces gallbladder stasis but does not increase the biliary lithogenic index. [187] Interruption of the enterohepatic circulation and gallbladder stasis are part of the pathogenesis as a consequence of the lack of a natural stimulus for CCK release. However, during prolonged enteral nutrition, plasma CCK levels are significantly increased and gallbladder contractility is preserved, thus minimizing the risk of acute acalculous cholecystitis. [98] Furthermore, intravascular infusion of CCK in human or animal models ameliorates the hepatobiliary dysfunction caused by TPN. [187], [188] Increased circulating levels of CCK also can be induced by intermittent, rapid intravenous infusion of amino acids. [189], [190] However, continuous administration of amino acids for longer than 2 hours (as occurs in TPN) is accompanied by a decline in CCK release. [191] Taken together, these findings indicate that intravenous administration of amino acids or CCK may circumvent the biliary dysmotility associated with TPN, but therapy of this kind would probably be most beneficial if it is administered periodically, rather than continuously.

Opiate Analgesic Administration Another important factor leading to gallbladder stasis in the critically ill patient is opiate analgesic administration. In addition to acting as potent analgesics, opiate compounds are well known for their ability to alter gastrointestinal motility. Therefore, we have investigated the actions of opioid agonists at various sites along the neuromuscular axis of the gallbladder. [192] Although opioid agonists had no detectable effect on gallbladder neurons or gallbladder smooth muscle cells, selective agonists of the d, ?, and µ receptor subtypes caused a potent decrease in the amplitudes of fast EPSPs in gallbladder ganglia and neurogenic contractions of gallbladder smooth muscle. Furthermore, immunoreactivities for all three receptor subtypes were observed in the ganglionated plexus of the gallbladder. These data indicate that opioid agonists have a potent inhibitory effect on gallbladder motility by decreasing the release of acetylcholine and other excitatory neurotransmitters. The sites of action include both the vagal terminals in gallbladder ganglia and the neuromuscular terminals of gallbladder neurons. Because opioid agonists also increase SO resistance, bile flow is likely to be severely inhibited by opioid compounds, and continued administration of these substances may contribute to the onset of acalculous cholecystitis.

Inflammatory Mediators The cause-and-effect relationship between biliary stasis and acalculous cholecystitis is not well understood. However, the actions of several proinflammatory agents that are likely to be involved in acute cholecystitis have been investigated. These include histamine, prostaglandins (PGs), and reactive oxygen species. Histamine is a well-recognized inflammatory mediator that can be released from mast cells to cause vasodilation, increased vascular permeability, gastric secretion, and contraction of bronchiolar and gastrointestinal smooth muscle. The gallbladder wall is rich in histamine-containing mast cells, which are distributed in the mucosa and muscularis and serosa layers. [193] In gallbladder smooth muscle, both H_1 and H_2 histamine receptors are present, with H_1 receptors causing contraction and H_2 receptors mediating relaxation. [193] However, the net effect of histamine in gallbladder muscle strips is contraction. [193], [194] Furthermore, activation of H_1 receptors is associated with a depolarization of intact gallbladder smooth muscle, and activation of H_2 receptors is associated with a hyperpolarization that is mediated by the opening of K^+-ATP channels. [37] In contrast to the ganglia of the gut, where histamine has dramatic effects, no actions of histamine are detected in gallbladder ganglia. [37] Although there is no direct evidence for a role of histamine in gallbladder inflammation, it is possible that acute cholecystitis is associated with mast cell infiltration and degranulation. Thus, endogenously released histamine may exert an excitatory effect on gallbladder smooth muscle, resulting in a prokinetic protective effect. PGs, particularly PGE_2, have been shown to be intimately associated with cholecystitis. [195] Early studies of diseased human gallbladders have demonstrated that both the mucosa and the muscularis of the organ produce high levels of PGE_2. [196] Furthermore, a correlation between severity of inflammation and PGE_2 concentrations has been described. [197] PG release may be prolonged or augmented by bradykinin, because gallbladder distention and progressive inflammation stimulate local bradykinin formation, thereby stimulating PG release from the inflamed gallbladder. [198] The concept that PGs play a role in cholecystitis is supported by human and animal model studies that have shown that symptoms of acute cholecystitis are significantly reduced by the cyclooxygenase inhibitor indomethacin. [199] PGE_2 has been shown to cause a concentration-dependent contraction of the gallbladder, [200] as well as a significant reversal in net fluid movement from absorption to secretion, including an increase in mucin secretion. [201], [202] These actions are consistent with a cytoprotective role for PGE_2 in the gallbladder, at least in acute inflammation, acting by expelling gallbladder contents and preserving mucosal integrity. However, PGE_2 also has been shown to decrease gallbladder ganglionic output by hyperpolarizing gallbladder neurons, [203] thereby inhibiting neurogenic contractions of the gallbladder. Thus, the direct contractile effects of PG may contribute to the pain reported by patients suffering acute cholecystitis, because these contractions would not be accompanied by SO relaxation. Furthermore, the neural effects of PG in the gallbladder would lead to a decrease in postprandial contractions because, as previously described, excitatory neural activity is involved in normal postprandial gallbladder emptying. Therefore, in acute cholecystitis, PGs may contribute to gallbladder dysmotility by causing the gallbladder to contract when it normally would not and by preventing the gallbladder from contracting when it normally would.

Reactive Oxygen Species Another potential contributor to changes in gallbladder motility during the inflammatory state is the generation of reactive oxygen species, such as H_2O_2, $O_2^{-}\cdot$, $OH^{-}\cdot$, monochloramine, and peroxynitrite. As observed with histamine and PGs, contradictory effects of reactive oxygen species on gallbladder motility have been reported. For example, reactive oxygen species induce a reduction in agonist-induced gallbladder contraction, whereas others have a direct contractile effect. [86], [204] The exact importance of these inflammatory mediators in acute acalculous cholecystitis remains to be determined.

Sphincter of Oddi and Postcholecystectomy Syndrome

During the fasting state, bile flow into the small bowel is diverted into the gallbladder by the resistance at the SO because of the basal and phasic contractions previously described. After cholecystectomy, the pressure reservoir represented by the gallbladder is lost, and the ability of the biliary tree to accommodate hepatic bile is compromised. In most persons, bile manages to flow through the SO interprandially, without dramatic increases in pressure within the biliary tree. In a subset of the population, however, bile does not flow as readily through the SO, leading to increased intrabiliary pressure and postoperative pain. [205], [206] In some patients with postoperative biliary pain, biliary manometry has demonstrated abnormal pressure profiles in the SO with changes in amplitude, frequency, and direction of contractions. [206], [207] and [208] In an attempt to alleviate the pain experienced by these patients, endoscopic sphincterotomy, stent placement, and surgical sphincteroplasty have all been used, with variable results. [209]

OVERVIEW

Although the neuromuscular reflexes of the gallbladder and SO appear to be less complicated than those of the bowel, bile retention and bile flow require coordinated neuromuscular reflex interactions. Normal gallbladder filling requires relatively high basal pressure in the SO, in concert with an expansion of the gallbladder. This increase in gallbladder diameter requires the passive fibroelastic features of the gallbladder wall as well as myogenic and neurohormonal relaxation of gallbladder smooth muscle. Postprandial bile flow occurs in response to the release of CCK from the duodenal mucosa. To contract the gallbladder, CCK acts locally to activate vagal afferent nerves, and it also acts within gallbladder ganglia to increase acetylcholine release from vagal preganglionic nerve terminals. CCK release also leads to a decrease in the resistance of the SO by activating inhibitory motor neurons in SO ganglia, by way of a duodenal-SO neural circuit.

A common feature of biliary tract disease is abnormal motor activity. In cholesterol gallstone disease, decreased motility involves a disruption of Ca^{2+} channels in gallbladder smooth muscle and a decrement in the ability of agonists to bind to membrane receptors. Acalculous cholecystitis is also associated with biliary stasis, but the contributing factors have not been clearly resolved. Likely causes include decreased CCK release resulting from parenteral feeding, opioid inhibition of excitatory neurotransmission in the gallbladder when opiate analgesics are administered, and the effects of inflammatory mediators. As detailed in this chapter, much has been learned about how gallbladder nerves and smooth muscle operate. However, a clearer understanding of the precise subcellular mechanisms of gallbladder smooth muscle excitability and contractility will aid in the development of clinical strategies for preventing biliary stasis and subsequent biliary disease.

CHAPTER 13

John Del Valle and Andrea Todisco

GASTRIC SECRETION

The stomach is a complex organ capable of secreting a great variety of products into the gastric lumen, vasculature, and interstitium. Although hydrochloric acid (HCl) is the primary gastric secretion, the stomach also secretes pepsinogen, mucus, bicarbonate (HCO_3^-), intrinsic factor (IF), prostaglandins, regulatory peptides, and other chemical messengers. This chapter discusses each of these, with particular emphasis on gastric acid secretion. Classic human and whole animal studies are integrated with more recent information gained at the cellular and molecular level, and this integrated model of acid secretion is placed within the fabric of current clinical practice.

Although it may appear to be axiomatic that the stomach secretes HCl, general acceptance of this fact occurred only after centuries of contention and controversy. Baron [1] attributed the 17th century Flemish physician Jean-Baptiste van Helmont with the first recognition that acid in gastric juice caused digestion. He thought it was derived from the spleen. About the same time, Sylvius, a professor of medicine in Leyden, proposed that gastric acid was a chemical digestive factor but thought it was secreted by the pancreas. For more than a century, there were numerous reports that acid was not present in gastric juices or, if acid was found, that it was a product of fermentation. Even the possibility of secretions arising from the stomach was in doubt, because many investigators asserted that gastric fluid was retained saliva.

The issue was settled by William Beaumont, [2] who demonstrated conclusively in 1825 and 1826 that Alexis St. Martin, a patient with a posttraumatic gastrocutaneous fistula, secreted gastric juice that could dissolve food inside and outside the stomach. Beaumont sent bottles of this gastric juice to three chemists, all of whom demonstrated it to be acidic.

Baron [1] gives credit to William Prout for the first qualitative and quantitative assessment of the composition of gastric juice in his article of 1823 entitled, “On the Nature of the Acid and Saline Matters Usually Existing in the Stomachs of Animals.” Prout identified free HCl in the gastric juice of rabbits, hares, horses, calves, dogs, and humans. In February 1824, two German workers, Tiedemann and Gmelin, unaware of Prout’s work, reported to the French Academy their proof that gastric acid was HCl. However, rival French workers reported that gastric acid was lactic acid, and this view held sway with many authorities throughout the 19th century despite the work of Prout, Tiedemann, and Gmelin.

Other workers who should be recognized are Schmidt, who showed in a series of experiments in 1852 that HCl was present in resting juice, and Dodds and Robertson, [3], [4] who, in 1930, demonstrated that the lactic acid in gastric juice was a product of fermentation.

The study of the regulation of gastric acid secretion also has a long history. William Beaumont reported that “fear and anger suppressed secretion by the stomach.” [2] Pavlov [5] showed that the sight and smell of food were powerful stimuli of gastric acid, and by introducing innervated and denervated gastric pouches, he established methods to study regulation of acid secretion that have prevailed for almost a century. One of his colleagues, Bechterew, [6] reported in his 1911 investigations into electrical stimulation of the frontal cortex as a stimulus of acid secretion that the effect was inhibited by vagotomy. In 1905, Edkins [7] demonstrated that extracts of canine antral mucosa stimulated acid secretion when they were injected intravenously into dogs. He thought this was caused by the presence in the mucosa of a chemical stimulator of acid secretion, which he called *gastrin.* Although similar observations were made by Lim in 1922, [8] studies of this mucosal factor were confounded by the presence in tissues under study of histamine, another powerful stimulus of acid secretion. [9] Gastrin remained a hypothetical substance until 1964 and 1965, when Gregory and colleagues, [10] having purified gastrin from hog antral mucosa, determined its structure and synthesized it in its biologically active form.

Inhibitory influences on acid secretion have been studied for many years. In 1929, Feng and colleagues [11] described a hormonally mediated inhibitor of acid secretion that was released after fat was placed in the duodenum. They called this putative hormone *enterogastrone.* Since then, there have been many attempts to identify this agent. Although it is beyond the scope of this chapter to highlight the discovery of each of the regulatory peptides implicated in acid secretion, special mention should be made of the isolation from ovine hypothalami of somatostatin, a powerful endocrine and exocrine inhibitor, by Brazeau in Guillemin’s laboratory in 1973. [12]

Until the late 1970s, considerable controversy surrounded the relative roles of gastrin, acetylcholine, and histamine in mediating acid secretion. Some researchers proposed that histamine was the final common pathway for acid stimulation. In a series of studies, Gillespie and Grossman [13] showed that these secretagogues potentiated the effects of each other, and these investigators proposed that there were individual receptors for these ligands on the parietal cell membrane. Soll and colleagues [14], [15] confirmed this hypothesis by demonstrating receptor characteristics for gastrin, acetylcholine, and histamine on isolated canine parietal cells. Somatostatin receptors have also been identified on these cells. [16]

ANATOMY OF GASTRIC MUCOSA

A detailed understanding of gastric mucosal structure provides insight into the functional events occurring during gastric secretion. The epithelial lining of the stomach lumen consists of thick, vascular folds, called rugae, invaginated with microscopic gastric pits. Each pit opens into four to five gastric glands. The epithelial cells lining

the gastric glands are highly specialized and different from the surface epithelial cells. Glands from the cardiac region of the stomach provide the transition from esophageal squamous epithelium to gastric columnar epithelium. They contain mucous and endocrine cells and comprise less than 5% of the gastric gland area. Most gastric glands (75%) occur in the oxyntic mucosa and are responsible for acid secretion (Fig. 13-1). They include parietal, chief, mucous neck, endocrine, and enterochromaffin cells. [17] The pyloric glands cover the gastric antrum and pylorus and contain gastrin cells (G cells), mucous cells, and other endocrine cells. Each of these cell types has evolved into a highly specialized secretory cell that contributes to gastric secretion.

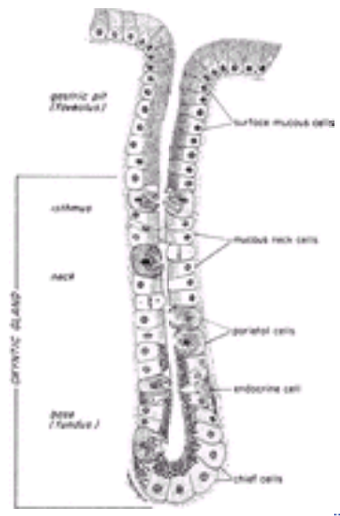

FIGURE 13-1. Oxyntic gastric gland. (Adapted from Ito S, Winchester RJ. The final structure of the gastric mucosa in the bat. J Cell Biol 1963;16:541.)

Cells

The parietal or oxyntic cell is the most distinctive cell of the gastric mucosa. It is usually found in the neck or isthmus of oxyntic glands bulging into the glandular lumen. The unstimulated parietal cell has prominent cytoplasmic tubulovesicles and an apical intracellular canaliculus lined with stubby microvilli. On stimulation, a dense meshwork of intracellular canaliculi rapidly forms while tubulovesicles disappear. [18], [19] The canaliculi contain a large number of elongated microvilli formed by extensive microfilaments that have a central cytoskeletal core of actin filaments stabilized by other proteins. It is across this apical canalicular surface that HCl is secreted. Acid secretion is an active transport process and requires significant amounts of energy. To provide this energy, parietal cells have numerous mitochondria, which account for 30% to 40% of total cellular volume. [20]

One prominent feature of parietal cells is their lack of the microvillous glycocalyx that is present on other cells in the gastric glands. Parietal cells are characterized by basolateral membrane folds that increase surface area for HCO_3^- exchange. The functional importance of these features is discussed in later sections of this chapter.

Chief cells are pepsinogen-secreting exocrine cells found in the base or fundus of oxyntic glands. Zymogen granules containing proenzymes are located in the apical cytoplasm and release their contents by exocytosis. The apical membrane has a few short microvilli covered by a thin coating of glycoprotein or glycocalyx. An abundant rough endoplasmic reticulum extends upward from the basal cytoplasm toward the apical granules. Functional characterization of chief cells has been aided by the ability to obtain relatively pure populations of chief cells.

Mucous neck cells are located in the isthmus or neck region of oxyntic glands (see Fig. 13-1). A transition zone from mucous neck cells to surface mucous cells appears near the junction of gastric glands and gastric pits. The mucous neck cells are the stem cell precursors for all of the gastric epithelial cells, including the surface mucous, parietal, chief, and endocrine cells. [21], [22]

Mucous neck cells differ in appearance from surface mucous cells. All mucous cells synthesize large amounts of mucin in prominent Golgi stacks, and these glycoproteins are transported by vesicles to large apical mucous granules. Mucous neck cells contain acidic glycoproteins, indicating sulfated forms, and surface mucous cells contain a neutral mucosubstance. [23], [24] Mucous granules are larger and often paranuclear in mucous neck cells compared with surface mucous cells. Mucous neck cells have abundant ribosomes and moderate amounts of rough endoplasmic reticulum. Their function as secretory cells and mucosal stem cells is different from the presumed function of surface mucous cells in mucosal defense. Surface mucous cells line the gastric pits and cover the entire lumenal surface of the stomach. They migrate up from the gastric pits and are replaced every 1 to 3 days. [25] They are thought to protect the stomach from injury by acid, pepsin, ingested materials, and pathogens by secreting mucus and HCO_3^- to form a protective gel. The apical portion of the surface mucous cell is packed with secretory granules. Short microvilli extend from the apical membrane and are covered by a glycocalyx. Secretion of granular mucus appears to occur by exocytosis, apical expulsion, and cell exfoliation. [26]

There are many different types of endocrine cells scattered throughout the gastric mucosa. Their secretory products have important endocrine and paracrine effects on acid secretion. Immunohistochemical techniques have enabled characterization of these cells based on their secretory granule contents. [20], [27] Gastric endocrine cells secrete gastrin, somatostatin, and enteroglucagon. Other morphologically distinct gastric endocrine cells may contain additional candidate hormones, but they await further characterization.

Gastric endocrine cells can be classified as open cells, which have apical membranes in contact with the glandular lumen, or closed cells, which are located near the epithelial basement membrane and do not border on the lumen of the gland. The prototypical open endocrine cell is the G cell. The basilar portion of the cell is packed with secretory granules, [28] from which gastrin is released by basilar exocytosis or emiocytosis, [29] consistent with the rapid postprandial appearance of the hormone in the bloodstream. The apical portion of the cell narrows until only a small microvillous border opens on the glandular lumen. The apical membrane may contain lumenal receptors that can detect amino acids or their amine derivatives, which are thought to stimulate G cells during feeding. [30], [31] The model of a closed gastric endocrine cell is the fundic somatostatin cell (D cell). By immunohistochemical staining, these cells are revealed to have long, slender processes that terminate on or near parietal and chief cells. [32] These processes presumably mediate the paracrine effect of somatostatin.

The primary cell containing mucosal histamine in the dog stomach is the mast cell. [33] Histamine-containing mast cells also occur in the human stomach. Mast cells from canine fundic mucosa have been enriched by elutriation and shown to contain characteristic dense granules that stain metachromatically. [34] Some species, including rats and humans, have histamine in endocrine-like cells that contain large granules and have the characteristic appearance of enterochromaffin-like (ECL) cells. [35] The relative proportion of these two histamine cell types in humans is unknown. Although in situ morphologic studies have not been definitive, it appears that these cells exist in the lamina propria in proximity to the glandular cells. The functional characteristics of these cells are discussed in later sections of this chapter.

The origin of gastric epithelial cells and the molecular events important in their differentiation are becoming increasingly clear. Electron microscopic examination and the measurement of DNA synthesis in gastric cells indicate that the isthmus of the gastric gland (see Fig. 13-1) constitutes the proliferative zone for the stomach. [36], [37] and [38] Within this region are three populations of cells that do not contain granules and are characterized on the basis of their Golgi apparatus. Parietal cells originate from precursor cells (preparietal cells), which mature as they migrate toward the neck and base of the gland. Karam and colleagues [39] demonstrated that there is functional heterogeneity of parietal cells along the pit-gland axis. Using quantitative morphometry, these investigators observed that parietal cells in the isthmus and neck of the rabbit gastric gland responded to secretagogues in an appropriate manner, whereas those in the base showed minimal morphologic change after exposure to different stimuli. The factors responsible for decreased function of senescent parietal cells are unclear.

Molecular approaches with various transgenic mouse models have been used to unravel the molecular signals directing differentiation of the distinct gastric cell lineages. Li and colleagues [40] capitalized on the unique expression of the ß subunit of H^+,K^+-ATPase in parietal cells to target expression of the simian virus 40 T

antigen (SV40TAg) to gastric glands. These investigators successfully amplified the population of preparietal cells in this animal model and noted a block in cell differentiation accompanied by hypochlorhydria and iron deficiency. In addition, SV40TAg-induced preparietal cell proliferation was accompanied by apoptosis, which appeared to occur in a p53-independent manner. The block in the development of mature parietal cells in this model was accompanied by the absence of zymogenic cells. This key observation supported the novel concept that potential signals are generated by mature parietal cells, which, in turn, are important in regulating the differentiation of other cell lineages within the stomach. This hypothesis was further confirmed by analyzing gastric glands of transgenic mice in which parietal cells were ablated by diphtheria toxin. [41] In addition to inhibited development of mature parietal cells, these investigators observed that differentiation of zymogenic cells was blocked, with accumulation of pre-neck cells and amplification of pit cells. Together, these studies are consistent with the hypothesis that interactions among different cell lineages are important in regulating cell differentiation in the stomach.

Studies of genetically engineered mice in which the cholecystokinin B (CCK-B) receptor or the peptide gastrin have been ablated demonstrate the development of gastric mucosal atrophy accompanied by a reduced number of parietal and ECL cells. These findings confirm the importance of gastrin in gastric mucosal cell development and differentiation. [42], [43] Similarly, ablation of the genes encoding the histamine H_2 receptor (H2R) has revealed the presence of a series of morphologic abnormalities of the gastric mucosa. [44] In particular, the stomach of H2R knock-out mice exhibits a markedly hypertrophic gastric mucosa with enlarged folds and elevated gastrin levels. Immunohistochemical analysis of the gastric mucosa of these mice demonstrates increased numbers of parietal and ECL cells. The parietal cells of these animals, however, appear to be smaller than in the wild-type mice, exhibiting enlarged secretory canaliculi with a lower density of microvilli and few typical tubulovesicles in the narrow cytoplasm. As a consequence of these morphologic changes, the H2R-deficient mice demonstrate abnormalities in secretagogue-stimulated gastric acid secretion. In particular, both gastrin and histamine fail to stimulate gastric acid secretion, whereas the cholinergic agonist carbachol retains the ability to induce gastric acid secretion to a level identical to that observed in the wild-type mice.

Interestingly, the enlargement of the secretory canaliculi and reduced number of microvilli and tubulovesicles also occur after the selective deletion of either the H^+,K^+-ATPase a [45] or ß [46] subunits in mice. Moreover, targeted deletion of the Na^+/H^+ exchanger isoform 2 (NHE2) gene appears to lead to a significant decrease in the number of parietal and zymogenic cells and to a marked increase in parietal cell degeneration, suggesting that NHE2 plays an important role in parietal cell viability. [47] The exact mechanisms responsible for these observations have not yet been characterized.

Significant alterations in gastric mucosal morphology and gastric acid secretion were also detected in mice deficient in the trefoil factor 2 (TFF2)/spasmolytic polypeptide (SP) gene. [48] TFF2/SP is a small polypeptide secreted by the gastric mucous neck cells. [48] Expression of TFF2/SP appears to be increased at sites of gastrointestinal ulceration and inflammation, suggesting that it may play an important role in the stimulation of reparative and cytoprotective mechanisms. [48] TFF2/SP-deficient mice appear to have an increased number of activated parietal cells, gastric acid secretion is increased, and gastrin is undetectable. In addition, these animals exhibit decreased gastric mucosal thickness and proliferation rates, and increased susceptibility to indomethacin-induced gastric ulcerations. [48] Taken together, these observations suggest that TFF2/SP promotes mucosal healing through the stimulation of cell proliferation and the inhibition of gastric acid secretion. The precise mechanisms responsible for TFF2/SP-mediated inhibition of gastric acid secretion remain to be elucidated.

Innervation

As is the case for the entire gastrointestinal tract, the stomach is innervated by the central and enteric nervous systems. This innervation mediates secretion and motor activity through efferent fibers and detects chemical or mechanical stimuli by means of afferent fibers. A full description of the enteric nervous system's structure and function is found in Chapter 2.

Central efferents are carried by the parasympathetic vagal branches and the sympathetic greater splanchnic nerve. [49] Vagal preganglionic fibers arise from the dorsal motor nucleus of the brain stem and descend to the thorax, where they branch to form an esophageal plexus. These fibers merge into anterior and posterior vagal trunks just before they cross the diaphragmatic esophageal hiatus. The anterior trunk gives off a gastric branch that runs along the lesser curvature and supplies the anterior surface of the stomach down to the pylorus. Pyloric branches innervate the antrum, pylorus, and proximal duodenum. The posterior vagal trunk provides a similar gastric branch that supplies the posterior surface of the stomach. The preganglionic fibers synapse in intramural ganglionated plexuses. Postganglionic fibers may be the final motor neurons or interneurons communicating with the enteric nervous system. Parasympathetic stimulation usually causes an increase in secretory and motor activity. Gastric sympathetic efferents emerge from spinal cord segments of T5 through T9. These preganglionic fibers run along the greater splanchnic nerve and synapse in the celiac ganglion. Postganglionic axons extend to the stomach and enter it in association with blood vessels. These sympathetic fibers provide rich innervation to the gastric blood vessels and the myenteric and submucous plexuses. In general, sympathetic stimulation causes a counterbalancing inhibition of gastric secretory and motor activity and constriction of blood vessels.

Afferent sensory neurons are exemplified by mucosal chemoreceptors and myenteric mechanoreceptors. These receptors communicate with the central and the enteric nervous systems. Afferent nerve processes account for about 80% of vagal fibers and 20% of the greater splanchnic nerve's fibers. [50], [51] The incoming information carried by these nerves is processed in central sensory nuclei and initiates neurally mediated gastric reflexes. Sensory neurons in enteric ganglia also initiate local reflexes such as gastric peristalsis. Cross talk between central and enteric fibers occurs continually in the enteric plexus as it modulates the effects of motor neurons.

Vasculature

Gastric mucosal blood flow maintains epithelial integrity and is an essential component of mucosal defense. The stomach receives its blood supply from the celiac axis through six major arteries. The right and left gastric arteries supply the lesser curvature and extend over the anterior and posterior surfaces of the stomach. In a similar fashion, the left and right gastroepiploic arteries supply the greater curvature. Short gastric arteries from the splenic artery perfuse the upper stomach, and the gastroduodenal artery serves the pyloroantral region. These arteries provide large arterioles that pierce the gastric muscle wall.

The microvasculature of the stomach is illustrated in Figure 13-2. The entering arterioles provide smaller arterioles that extend to the submucosal plexus and to the muscle layers. [52] A capillary layer in the muscle drains into the venous collecting system. The afferent arterioles supplying the submucosal plexus are innervated by sympathetic fibers coursing with the entering blood vessels. The submucosal arteriolar plexus does not communicate with the venous plexus directly but rather provides mucosal arterioles to the base of the gastric glands. The mucosal arterioles branch into capillaries that ascend perpendicularly between the glands to the epithelial surface. These ascending capillaries interconnect horizontally, forming a lattice around the gastric glands. Ascending capillaries receive HCO_3^- secreted from the basolateral surface of stimulated parietal cells and carry it to the surface epithelium. This phenomenon is called the *alkaline tide.* At the surface epithelium, the HCO_3^- can assist in buffering any H^+ ion back-diffusion. At the mucosal surface, the fenestrated capillaries empty into venules that drain into the submucosal venous plexus and efferent veins that follow the course of the primary arterial branches. [53] This anatomic arrangement allows muscle layer blood flow to be in parallel with mucosal flow while submucosal flow is in series with the mucosa. This type of microvascular system allows selective decreases in mucosal blood flow while muscular blood flow is maintained.

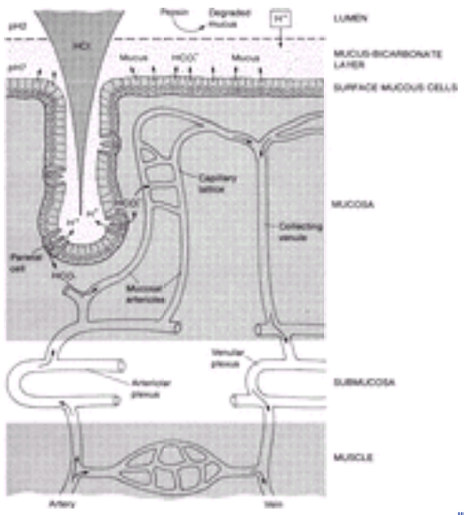

FIGURE 13-2. Gastric microvasculature. (Adapted from ref. [52] and Koelz HR, Fimmel CJ. Garner A, et al. The stomach and duodenum. In: Kern F, Blum AL, eds. The gastroenterology annual, 3rd ed. New York: Elsevier, 1986:28.)

Mucosal blood flow accounts for 70% to 80% of total gastric blood flow in basal and stimulated states. [54], [55] Previous studies using aminopyrine clearance techniques suggest that stimulation of acid secretion increases mucosal blood flow, but interpretation of these results must be tempered by the knowledge that acid secretion affects aminopyrine clearance and may account for the apparent increase in mucosal blood flow. [56] Acid secretagogues appear to have no effect on mucosal blood flow using more recently developed indicator-dilution techniques. When gastric perfusion pressures are adequate, gastric acid secretion varies independently of blood flow. [57] These conclusions have challenged the long-held hypothesis that secretagogue stimulation induces a parallel increase in acid secretion and mucosal blood flow. [58]

The innervation of the gastric microvasculature partially reveals the mechanisms regulating mucosal blood flow. The submucosal arterioles appear to be innervated by sympathetic nerve fibers. [59] When stimulated, these fibers constrict the arterioles and decrease mucosal blood flow temporarily. [60], [61] After 3 to 4 minutes of prolonged sympathetic stimulation, flow increases. [62] This response has been described as autoregulatory escape from adrenergic vasoconstrictor influence. [63] Anatomic details support these physiological findings and suggest a regulatory function at the level of the submucosal arterioles. [59]

REGULATION OF ACID SECRETION

The regulation of acid secretion can be subdivided into the supracellular influences that have been the focus of classic physiology since Beaumont and the cellular mechanisms that have been elucidated more recently. This section concentrates on supracellular influences and reviews the in vivo studies of acid secretion.

Integrated Control

The integrated mechanisms that control acid secretion can be viewed as an arrangement of regulatory strata. These include neural control in two forms: long reflex or cephalovagal arcs and local intragastric reflex arcs. A second tier of control is exerted by humoral substances acting in an endocrine fashion, such as gastrin, or in a paracrine manner, such as histamine. Somatostatin may function as an endocrine and paracrine factor. The role of many such peptides remains uncertain. The direct influence of chemical factors is an additional tier of regulation, typified by the stimulatory action of amino acids and amines on gastrin release and the inhibitory effect of gastric acid on gastrin release.

These strata are not distinct but rather are closely intertwined; when discussing the phases of postprandial acid secretion, Grossman [64] asserted that the individual contributions made by the various phases could not be differentiated. Nevertheless, classic physiology has attempted to isolate and study factors that influence acid secretion. The results indicate that there are three principal stimuli of parietal cell acid secretion: histamine, acetylcholine, and gastrin. The principal inhibitory secretagogue appears to be somatostatin, although other chemical modulators, including peptides, growth factors, and prostaglandins, may also have roles.

When reviewing these in vivo studies, several confounding facts should not be forgotten. First, acute responses should be differentiated from chronic adaptive changes. For example, the effect on gastrin and somatostatin cell number during acute achlorhydria differs from the changes seen in chronic achlorhydria. [65] By analogy, data in studies using vagotomy may signify the chronic adaptive response to achlorhydria rather than the effect of withdrawal of vagal innervation alone. Second, acid secretagogues potentiate the response to one another. This central point, which is crucial to the understanding of studies of supracellular and cellular regulation, was first appreciated by Grossman. [64] He defined a potentiated response as one in which the effect of two agents in combination is greater than the sum of their separate effects when administered alone. Gillespie and Grossman [13] demonstrated in dogs with Heidenhain pouches that the acid secretory response to a combination of Urecholine (bethanechol chloride) and gastrin or to Urecholine and histamine greatly exceeded the maximal response to gastrin, histamine, or Urecholine alone (Fig. 13-3). These investigators subsequently demonstrated the corollary effect using antagonists of acid secretion. Metiamide, an H_2 receptor antagonist, inhibited acid secretion stimulated by histamine, pentagastrin, 2-deoxyglucose (which activates central vagal stimulation), and food. Atropine sulfate also inhibited the response to all of these stimulants except histamine. [66] With great perception, Grossman deduced that there were receptors for histamine, gastrin, and acetylcholine on the parietal cell that interacted with one another. Because of these interactions, it is impossible to predict the relative importance of each secretagogue on the basis of individual in vivo stimulation or inhibition studies. The phenomenon of potentiation is the basis for the efficacy of many of the acid-reducing therapies for peptic ulceration, especially the use of H_2 antagonists. A third problem is that stimulatory and inhibitory influences are active simultaneously. This is true in the basal interprandial and the postprandial state.

Methods for Measuring Acid Secretion

Animal studies have used dogs, rats, rabbits, and mice. There are great species differences in basal secretion and responsiveness to secretagogues. [67] Classic studies of dogs have used vascularly perfused isolated pouches of gastric mucosa. The fundic pouches with intact vagal innervation are called *Pavlov pouches,* and vagotomized fundic pouches are called *Heidenhain pouches.* It is assumed that secretion from a vagally innervated fundic pouch is an accurate index of secretion from the main stomach. [64] These gastric pouches have been used to define many aspects of regulation of gastric acid secretion, including cephalic influences, the role of gastrin, long cephalovagal and local reflex neural arcs, and the inhibitory feedback control of acid secretion by intralumenal acid.

Aspiration of gastric juice is the simplest and most widely used method of estimating acid secretion in humans. To perform these tests, a fine-bore nasogastric tube is inserted under fluoroscopic control into the most dependent part of the stomach under fluoroscopic control of a fasted volunteer, and several measurements are made: basal acid output (BAO), which estimates resting secretion, and maximal acid output (MAO) or peak acid output (PAO), which estimates the acid secretory

response to an exogenous secretagogue. BAO is measured by aspirating the gastric contents for four consecutive 15-minute periods. The H^+ ion concentration of the aspirate is estimated by titration with a basic solution of known concentration. The BAO is expressed as mEq H^+ per hour and is the sum of the measured acid output in four unstimulated test periods. The expected range for BAO in healthy adults is 0 to 11 mEq H^+ per hour (Fig. 13-4). [68] The measurement of BAO is usually combined with the measurement of MAO or PAO. In this test, acid output is stimulated by a supraphysiological dose of an exogenous secretagogue. This is usually pentagastrin, which may be administered by a subcutaneous or intramuscular injection (6 µg/kg) or by continuous intravenous infusion (6 µg/kg/h). Other secretagogues that have been used are histamine or a histamine analog, betazole. [17] The PAO is calculated by multiplying by 2 the sum of the two highest outputs recorded in the four test periods. The MAO is the sum of acid output of four consecutive 15-minute collection periods. The expected range for PAO in healthy adults is 10 to 63 mEq per hour (see Fig. 13-4). [68]

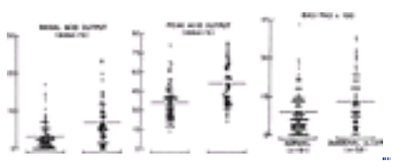

FIGURE 13-4. Basal acid output (*BAO*), peak acid output (*PAO*), and BAO/PAO ratio in 91 healthy adults and in 58 patients with duodenal ulcers. (From ref. [68] .)

MAO and PAO are a reflection of the total number of parietal cells, also called the *parietal cell mass,* [69] which is influenced by gender, body weight, lean body mass, and age. [70] MAO and PAO are lower in women than men because of a smaller parietal cell mass and a lower sensitivity of that parietal cell mass to exogenous secretagogues. [71] Stimulated acid output in children is comparable to that in adults when expressed as a function of body weight, but acid secretion declines in the elderly. [72] , [73]

BAO, MAO, and PAO underrepresent actual basal and stimulated acid secretion, because these methods do not account for acid lost through the pylorus, acid neutralization by gastric HCO_3^- and refluxed duodenal juice, and acid losses resulting from back-diffusion of H^+ through the gastric mucosa. Nonetheless, these measurements have proved useful in defining the pathophysiology of peptic ulcer disease [68] and in diagnosing Zollinger-Ellison syndrome.

Another method of estimating acid secretory ability was introduced by Fordtran and Walsh using continuous in vivo intragastric titration. [74] By this means, the acid secretory response to the physiological stimulation of ingested food is estimated. Continuous intragastric titration requires placement of a double-lumen tube into the most dependent part of the stomach, usually under fluoroscopic visualization. One lumen allows frequent sampling of small volumes (2–3 mL) of gastric contents. The pH of the sample is immediately measured, and the gastric juice is returned to the stomach. The port of the second tube is positioned 10 cm proximal to the sampling port and is used to infuse $NaHCO_3$. Throughout the study, the gastric pH is maintained at an arbitrary value, usually pH 5.5, by infusing $NaHCO_3$. A homogenized meal buffered to pH 5.5 is eaten. The amount of $NaHCO_3$ necessary to maintain the pH of the gastric juice at pH 5.5 is a measure of the postprandial acid secretory response. Because this is a cumbersome procedure, it has not gained widespread use outside specific research investigations. However, continuous intragastric titration has proven to be a useful method of measuring postprandial acid secretory responses. [75] , [76]

A different approach to studying continuous acid responses is to measure intragastric pH by using an indwelling probe or radiotelemetric capsule. [77] , [78] This does not estimate total H^+ concentration because it does not account for the volume of gastric juice and buffering capacity. Further studies with these techniques are required before their specific utility in humans can be determined.

Basal or Interprandial Acid Secretion

Basal unstimulated acid secretion exhibits a circadian variation, with the highest secretion at night and the lowest in early morning. [79] This variation is not matched by changes in circulating serum gastrin levels. In humans, vagotomy greatly reduces or abolishes interprandial acid secretion in patients with duodenal ulcer. [69] , [76] , [80] The caveats expressed about the influence of potentiation and chronic adaptive changes on studies of the effect of vagotomy on gastric endocrine and exocrine responses are pertinent when interpreting these data, although vagotomy does not affect parietal cell number. [81] Twice-daily administration of an H_2-antagonist to patients with a duodenal ulcer reduces interprandial acid secretion, although it does not abolish it. [76] This suggests that H_2 receptor activation is also capable of influencing BAO. It appears likely that basal interprandial acid secretion is the result of combined cholinergic and histaminergic stimulation.

The cholinergic regulation of basal gastric acid secretion is complex. In dogs with gastric pouches, denervation of the antral pouch markedly reduces resting output of acid from the main innervated stomach and from the denervated fundic pouch without changing plasma gastrin levels. [82] This suggests there is a local interneuronal reflex arc innervated by the vagus and independent of plasma gastrin that carries acid stimulatory signals from the antrum to the fundus. These data are mirrored in humans; the small amount of basal acid secretion found in some patients who have undergone vagotomy can be abolished by antrectomy plus vagotomy. [80]

Stimulation of Acid Secretion

The physiological stimulus for acid secretion is food. Traditionally, food-stimulated acid response has been described in three phases: cephalic, gastric, and intestinal. These phases refer to the sites of origin of the stimuli and do not imply mechanisms by which acid secretion is stimulated or inhibited. These phases occur concurrently, not consecutively. The acid secretory response at any instant represents the sum of all the stimulatory and inhibitory influences.

Cephalic Phase The nervous system's influence on gastric acid secretion was first recognized by William Beaumont and Pavlov. In 1928, Farrell [83] showed that the vagus was the sole gastrocephalic neural link involved in gastric secretion, and this observation remains valid. The cephalic phase contributes in some degree to total postprandial acid but was estimated by Richardson and colleagues [84] to be as much as 50%. Feldman and Richardson [85] studied the relative contribution of thought, sight, smell, and taste of food to the cephalic phase of gastric acid secretion in humans (Fig. 13-5). Merely discussing appetizing food for 30 minutes without sight, smell, or taste produced an average of 66% of the total cephalic response estimated by the time-honored method of modified sham feeding. Serum gastrin levels also significantly increased. The sight of food or smell of food alone, although still producing significant acid secretion and gastrin release, was a considerably less potent stimulus than conversation. These data show by subtraction that taste is also an important component of the cephalic phase.

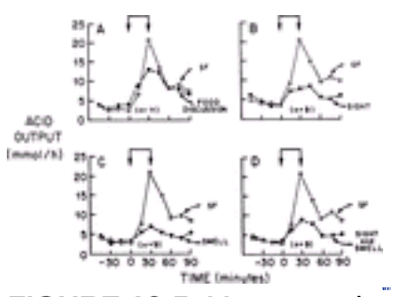

FIGURE 13-5. Mean gastric output in the same persons in response to sham feeding (*SF*), compared with (**A**) discussion of favorite foods, (**B**) sight of appetizing food, (**C**) smell of appetizing food, and (**D**) a combination of sight and smell. (From ref. [85] .)

The mechanisms by which the senses stimulate acid secretion are less certain. Bechterew [6] induced acid secretion in dogs by electrically stimulating the frontal cortex. This effect was lost in vagotomized animals. Two other forms of study have been used: electrical stimulation of various sites in the brain and injection of putative neuromodulatory substances into the brain. The putative ligands include peptides; classic neurotransmitters such as acetylcholine, ?-aminobutyric acid agonists, and catecholamines, and prostaglandins. There are many interrelated mechanisms by which cephalovagal input mediates the cephalic phase of stimulated

acid secretion. Vagal innervation acts directly on parietal cells. This was deduced from studies of dogs with antral and fundic gastric pouches. Denervation of the antral pouch reduced or abolished the serum gastrin response to sham feeding but did not abolish acid secretion by the vagally innervated fundic pouch. [82] Corroborative evidence for this mechanism is afforded by the demonstration of acetylcholine receptors on isolated canine parietal cells. A second pathway in the cephalic phase of gastric acid secretion is the release of circulating gastrin from the gastric antrum. The thought, sight, or smell of food and modified sham feeding increase serum gastrin levels. [80] Isolated canine gastrin cells possess acetylcholine receptors. The plasma gastrin response to sham feeding in humans is regulated by intragastric pH and is not observable when gastric pH is maintained at pH 2.5. [86] This effect also is atropine sensitive. However, vagal control of postprandial gastrin release is complex. Low doses of atropine, a muscarinic antagonist, enhance rather than reduce the gastrin response to sham feeding, insulin-induced hypoglycemia, or feeding. [87], [88], [89], [90] and [91] Similarly, parietal cell vagotomy, although markedly reducing acid secretion, enhances gastrin release in response to sham feeding, [87], [92] insulin-induced hypoglycemia, [93] or intragastric nutrient infusion. These effects are independent of changes in intragastric pH. [89] This result suggests that the vagus carries cholinergic fibers that, in the absence of atropine, mediate directly or indirectly an inhibitory control of gastrin release. Studies of dogs with Heidenhain pouches and gastric fistulae demonstrate that truncal vagal denervation reduces gastrin release but elevates acid secretion by the pouch. [94] These data can be interpreted to suggest cholinergic release of a substance that can inhibit acid secretion independently of its effects on gastrin release. Although the nature of this substance has yet to be elucidated, somatostatin is one candidate. [91] However, Feldman and colleagues [88] were unable to demonstrate a rise in the level of plasma somatostatin in humans during sham feeding, and the role of somatostatin in regulating the cephalovagal control of gastric acid secretion whether directly on the parietal cell or by inhibition of gastrin release remains uncertain. To define more precisely the role of gastrin in sham feeding–mediated gastric acid secretion in dogs, Kovacs and colleagues [95] developed a monoclonal antigastrin antibody capable of immunoneutralizing circulating gastrin in vivo. By means of this antibody, these investigators demonstrated that immunoneutralization of gastrin leads to a significant inhibition of sham feeding–stimulated gastric acid output, suggesting that gastrin released by central vagal stimulation is an important mediator of sham feeding–stimulated gastric acid secretion in dogs. The components of the central nervous system involved in modulating gastric secretion include the dorsal motor nucleus of the vagus (DMNV), the nucleus tractus solitarius (NTS), and the hypothalamus. The DMNV supplies stimulatory efferent fibers to the stomach through the vagus nerve. [96], [97] Stimulation of the DMNV results in activation of gastric secretion, [98], [99] whereas ablation of this nucleus abolishes the secretory process. [100] It appears that the role of the DMNV is not to initiate secretion, [101] but instead to integrate central input from the hypothalamus and visceral input from the NTS. Regions of the hypothalamus important for regulating gastric secretion include the ventromedial hypothalamus, which appears to provide tonic inhibition, [102], [103] the lateral hypothalamus, and the adjacent medial forebrain bundle, which together mediate secretion in response to hypoglycemia. [104], [105] and [106] Visceral afferents and taste fibers deliver input into the NTS, demonstrating its potential involvement in stimulating gastric secretion in response to taste. The NTS is also thought to mediate stimulation of acid secretion in response to hypoglycemia. [107] Sympathetic and vagal afferents relay sensory information (mechanical, chemical and thermal) from the stomach to the central nervous system. [108] Peptidergic factors also play an important role in modulating central nervous system–regulated gastric secretion. Direct injection of peptides into the brain has led to the discovery of factors that either stimulate or inhibit gastric secretion. [109] The peptides observed to either activate or inhibit gastric acid secretion by central injection are summarized in Table 13-1. This represents a partial summary of these peptides, the result of the numerous elegant studies examining this important subject. [109], [110], [111], [112], [113], [114], [115], [116], [117], [118], [119] and [120]

INHIBITORS	STIMULANTS
CRF	TRH
β-endorphin	Somatostatin
Bombesin	NPY
Neurotensin	Galanin
Calcitonin	PYY
CGRP	Ghrelin
Interleukin 1	Orexin A

Note: CRF, corticotropin-releasing factor; CGRP, calcitonin gene–related peptide; TRH, thyrotropin-releasing hormone; NPY, neuropeptide Y; PYY, peptide YY.

TABLE 13-1 Peptides that Affect Gastric Acid Secretion After Injection Into the Central Nervous System

Gastric Phase When food enters the stomach, it initiates the gastric phase of acid secretion. This is usually divided into two components: a physical component caused by distention of the stomach and a chemical component in which chemical effectors interact with gastric cells. The acid secretory response to distention results from presumed stretch receptors in the gastric tissue. This response is the stereotypical long vasovagal reflex arc. Distention of the gastric fundus and corpus in humans stimulates acid secretion. The effect is almost abolished by proximal gastric vagotomy and at least in part is independent of changes in serum gastrin levels. [121], [122] and [123] Distention-induced acid secretion is a complex phenomenon in which antral and fundic responses can be viewed separately. Antral distention produces gastrin release in dogs [124] and humans. [125] Debas and associates [124] called this the *pylorooxyntic reflex.* In dogs with antral and fundic pouches, this response was inhibited by antral acidification [124]; however, in humans, albeit those with intact stomachs, it appeared to be independent of lumenal pH. [125] In dogs, the pH sensitivity of the antral distention response required an intact cerebrovagal link to the antrum. In humans, low-dose atropine, which inhibited the acid secretory response to antral distention, nonetheless enhanced the elevation of serum gastrin levels. This suggests that there is an atropine-sensitive inhibitory pathway restraining the gastrin response to antral distention. Fundic distention in dogs with vagally innervated fundic pouches and vagally innervated antral pouches produces gastrin release and acid secretion. [126] Both responses are lost when the antral pouch is maintained at pH 2.5. This vasovagal reflex has been called the *oxyntopyloric reflex.* There is a similar vagally dependent acid stimulatory response to fundic distention in humans, but it appears not to be mediated through elevated serum gastrin. [121] The roles of histamine and acetylcholine in mediating distention-induced acid secretion are unclear. As may be predicted from our knowledge of the potentiation interrelations of the three principal secretagogues—gastrin, acetylcholine, and histamine, the acid response to gastric distention in humans is abolished by vagotomy or cimetidine. [127], [128] However, this may indicate the facilitory effect of background secretion of these secretagogues only. Gastric release of acetylcholine or histamine in response to distention has not been shown. Food interacts with the gastric mucosa to cause acid secretion in a manner that is independent of stretch by the food bolus. At least four constituents of food produce this stimulatory effect: peptic digests of proteins, ethanol, coffee, and Ca^{2+}. Whole proteins are poor stimuli of gastric acid secretion, but peptic digests of the same proteins are effective. [129] The breakdown products of protein, amino acids, and amines produce acid secretion principally through the release of gastrin. [31], [130], [131] The aromatic amino acids phenylalanine and tryptophan are the most potent stimuli of gastric acid secretion and gastrin release in vivo. [132] Their amine derivatives may contribute significantly to this response. [31], [130] Circulating gastrin is the principal mediator of postprandial gastric acid secretion. This has been demonstrated in human studies in which the increment in plasma gastrin that occurred after an intragastric infusion of amino acids or ingestion of a protein-rich meal was reproduced with an intravenous infusion of gastrin, and a similar acid secretory response to endogenous and exogenous gastrin was observed. [75], [131] These studies suggest that, despite the cephalovagal component to gastrin release, it is the chemical response to protein breakdown products that is the principal stimulus for postprandial gastrin. [131] Although amines and amino acids can cause gastrin release by direct action on the G cell, [31], [132] this phenomenon must be viewed within the larger orchestrated physiological response to ingested nutrients. Nutrients stimulate the release of many peptides into the circulation, including somatostatin, CCK, secretin, gastric inhibitory peptides, enteroglucagon, and peptide YY, which may influence acid secretion directly or by affecting gastrin release. Integrating these data with data derived from whole-animal physiology has proven difficult. Atropine enhances gastrin release in many circumstances, although according to the in vitro model previously described, inhibition or no change would be expected. Agents that block the gastrin response to bombesin do not affect the gastrin response to food. Studies in humans suggest also that ß-adrenergic innervation may play a role in gastric acid secretion. Administration of terbutaline, a $ß_2$-adrenergic receptor agonist, enhances serum gastrin but inhibits acid secretion in response to intragastric infusion of a homogenized meal. [133] Although it is likely that numerous neurohumoral mediators such as somatostatin and gastrin-releasing peptide and cholinergic and adrenergic innervation are significant factors in postprandial gastrin release, their relative roles in the integrated physiology of gastrin release remain as yet undefined. Studies of humans have demonstrated a modest acid stimulatory response or no response to direct intragastric infusions of pure alcohol. [134], [135] and [136] Red wine and beer, however, are potent stimuli of acid secretion and serum gastrin. [134], [135] and [136] These effects are probably caused by amines or amino acids in the beverage that stimulate gastrin release and not by a direct effect of its alcohol content. Caffeine stimulates acid release in humans. [137] McArthur and colleagues [138] showed that many household beverages were potent acid stimuli, including Tab, coffee, beer, and milk, each of which caused a pentagastrin-stimulated MAO of greater than 70%. Decaffeinated coffee was a potent stimulus, showing that it is not only the caffeine in coffee that is an acid stimulant. These studies did not attempt to control for the cephalic phase of acid secretion, nor was gastrin measured; it is therefore impossible to draw conclusions about the mechanisms that underlie these observations. Oral ingestion of calcium carbonate stimulates gastrin release and acid secretion in humans. [139] This action is independent of acid buffering capacity and is presumed to be an effect of dissociated Ca^{2+}.

Intestinal Phase The entry of chyme into the small intestine initiates the intestinal phase of the acid secretory process. The primary stimulatory factors are distention, proteins, and the products of protein digestion. [140], [141] Quantitating the significance of the intestinal phase to the stimulatory limb of acid secretion has proven controversial, perhaps because there are definite potentiation phenomena between the acid secretory response to intestinal nutrients and gastrin or histamine. [142] Serum gastrin levels do not appear to mediate the intestinal phase of acid secretion in dogs or humans. [141], [143] The acid stimulatory response to intestinal nutrients is preserved in vagotomized animals, indicating that circulating stimuli are involved to some degree. [144] This role may be filled in part by circulating amino acids, which have been shown to stimulate acid secretion without elevating serum gastrin. [145] There have been numerous attempts to isolate a distinct acid stimulatory peptide hormone (i.e., enterooxyntin) from small bowel mucosa, albeit without convincing success. [146], [147], [148] and [149]

Inhibition of Acid Secretion

Cephalic Influence Evidence suggesting that there may be cephalic inhibitory influence acting on gastric acid secretion comes from intracerebral microinjection studies. [150] Several of the peptides that can lead to this inhibitory event after intracerebroventricular injection are outlined in Table 13-1. It appears that vagal fibers carry inhibitory and stimulatory messages to the parietal cells. As with the cerebral microinjection studies in which gastric acid is stimulated, however, there are no data to indicate which, if any, of these observations are relevant to the cephalic phase of gastric acid secretion. In addition, the complex response of stimulated serum gastrin levels to low-dose atropine described previously suggests that there are vagal inhibitory influences on gastrin release.

Gastric Mediation Just as vagal inhibitory fibers have been implicated in the cephalic acid secretory response, there appear to be vagally mediated inhibitory neural arcs involved in the distention-induced acid secretory response. Studies of dogs and humans led Debas and colleagues [124], [151], [152] to conclude that antral distention in addition to stimulating serum gastrin release results in the release of an inhibitor of acid secretion. Whether this effect is humoral or neurocrine is not clear, but it does depend on an intact vagus. Gastrin release in response to nutrients, sham feeding, and antral distention is inhibited by the presence of acid in the gastric antrum. [86], [124], [153] An intralumenal pH of 3 appears to be the threshold for initiating this response. [154] The mechanisms of this negative-feedback loop probably include somatostatin release as a paracrine or endocrine gastrin inhibitor. [154] Evidence from in vitro human studies suggest that gastric acid regulates somatostatin release locally in the stomach and postprandial circulating somatostatin. [155], [156] An alternative mechanism for the inhibition of gastrin release at low intralumenal pH is that an acidic milieu causes amines to be protonated, and as charged particles, they are not taken up by G cells. [157] This cannot be the complete answer because, at pH 2.5, cephalovagal stimulation of gastrin is inhibited. [86] It is probable that somatostatin acts directly on the parietal cell to inhibit acid secretion by means of paracrine or endocrine pathways. [16], [158]

Intestinal Inhibition The observation that nutrient infusion into the small intestine inhibits acid secretion is an old one. Feng and colleagues [11] proposed that fat infusion into the small bowel inhibited acid secretion by the release from the small bowel mucosa of a circulating inhibitory hormone they called enterogastrone. There have been at least seven candidate peptides for this role: somatostatin, neurotensin, gastric inhibitory peptides, peptide YY, secretin, CCK, and galanin. [159], [160], [161], [162], [163], [164], [165], [166] and [167] It is probable that enterogastrone is not a single entity but rather a physiological response to more than one circulating acid inhibitor.

CELLULAR BASIS OF ACID SECRETION

Analysis of the regulatory effects of gastric secretagogues in vivo has provided important insight into the mechanisms of acid secretion in animals and umans. Interactions among neurocrine, paracrine, and endocrine signals and their effects on the parietal cell ultimately must be studied in the intact organism. However, the complexity of the regulatory effects converging on the parietal cell makes integrated in vitro analysis a necessity. In vitro models of acid secretion include gastric mucosa preparations, gastric glands, and isolated enriched parietal cells. Gastric endocrine cells effecting acid secretion have also been enriched and analyzed. These models have provided an understanding of the cellular events leading to acid secretion.

In Vitro Models

Isolated preparations of intact gastric mucosa allow the study of secretory events while maintaining all the mucosal cell types in their usual cellular environment. Cell polarity, tight junctions, gap junctions, desmosomes, and certain paracrine effects are maintained in such models. Physiological neurocrine and endocrine effects are absent but can be mimicked by bathing one or both surfaces with the desired neurotransmitter or hormone. One such model, the isolated bullfrog mucosa, has been used to study histamine release and acid secretion. [168] Mucosal strips are bluntly dissected and are mounted as a sheet between two sides of a Lucite chamber. A flow-through system can be used to ensure rapid changes of the serosal solution. Acid secretion into the mucosal solution is measured with a pH stat by maintaining the pH at 7.0 with isotonic 15 mM NaOH. Other types of mucosal studies use explants maintained in organ culture or fragments of mucosa suspended in tissue culture solutions. [169], [170] and [171] Studies using these types of models have been supplanted by gastric gland and isolated cell studies.

The initial steps in the preparation of glands and cells are similar. [172], [173] The gastric mucosa is bluntly dissected away from the submucosa, finely minced, and then dispersed with pronase or crude collagenase. The viability rate of parietal cells obtained with this technique generally exceeds 95% as judged by trypan blue exclusion.

After digestion of the gastric mucosa, the glands can be separated from the cells and debris by several sedimentation washes at unit gravity. The large size of the glands allows them to sediment rapidly, essentially free of nonglandular material. Separation of isolated cells can be achieved by velocity and density separation techniques. Counterflow elutriation is a velocity separation technique that separates cells predominantly on the basis of size. [173] Enriched fractions routinely contain 50% to 70% parietal cells that maintain their viability and biologic activity. Antral G cells and fundic D cells have also been enriched by elutriation. [174] A second purification step using a density gradient can be added to enrich parietal or endocrine cells further.

There is a potential limitation in using isolated parietal cells for physiological studies. After the cells are separated from the microenvironment found within the gastric mucosa, their ability to respond to secretogogues in a tissue-specific fashion diminishes within 8 to 10 hours after isolation (Del Valle and Yamada, unpublished observations). To circumvent this problem, Chew and Ljunstrom [175] developed a system for culturing isolated parietal cells so they retain differentiated structure and function for as long as 72 hours after isolation. These cultured cells express receptors for the appropriate secretagogues and maintain expression of parietal cell–specific genes such as H^+,K^+-ATPase. This model provides an important tool for characterizing the multiple factors involved in regulating parietal cell physiology.

Gastric secretion has been analyzed in different species with each of these models. Species variety may account for certain discrepant results occasionally observed with different models. Many analyses of the cellular events controlling acid secretion have used canine gastric mucosal cells enriched by counterflow elutriation. The data obtained using canine cells can be correlated with the large body of data obtained with in vivo acid secretory studies in dogs. Moreover, canine parietal cells have several features in common with human parietal cells.

Indirect measures of parietal cell function have been developed to quantitate the biologic effect of various secretagogues and inhibitors. The development of these assays has made it possible to correlate the binding of ligands with their functional effects. Oxygen consumption has been shown to correlate with HCl secretion in both in vivo and ex vivo studies. [176], [177] Oxygen consumption in isolated enriched parietal cells increases in response to gastrin, carbachol, and histamine, probably reflecting the activity of the proton pump. [173] Glucose oxidation can also be used as a measure of parietal cell metabolic activity. [178] Morphologic transformation of parietal cells in response to secretagogues produces dramatic changes in cell appearance. Resting cells are filled with tubulovesicles, and stimulated cells rapidly develop a dense intracellular canalicular network communicating with the cell's apical surface. Nomarski optics can visualize this transformation in living cells, and fluorescent microscopy with acridine orange can show the accumulation of fluorescent dye in the newly generated acid spaces. [179]

The accumulation of weak bases in membrane-bound acid spaces is the basis of the [^{14}C]aminopyrine uptake assay. [15], [180] Uncharged aminopyrine is lipid soluble and easily crosses cellular membranes. On entering an acidic compartment, aminopyrine is protonated and loses its lipid solubility. This sequestration of [^{14}C]aminopyrine correlates with intracellular acid formation and is the most commonly used assay for parietal cell stimulation. Other methods involving measurement of the proton pump association with canalicular membranes and correlation of morphologic changes in parietal cells with functional measurement of acid production using fluorescence microscopy techniques hold promise for the dynamic study of parietal cell physiology. [181], [182] and [183]

Receptors

Separation of gastric cells into highly enriched cell populations has made it possible to identify and characterize specific receptors on each cell type. [184] Purified cells maintain intact receptors through the separation procedure and bind radiolabeled ligands specifically. The binding of a ligand should correlate with a functional assay over the same dosage range to confirm that a specific cell type has biologically active receptors. An example is the correlation of carbachol binding to parietal cells and the induction of aminopyrine uptake by carbachol.

After functional receptors have been demonstrated, they can be characterized in binding studies with available receptor agonists and antagonists. Further characterization of receptors has been achieved by solubilizing them from cell membranes and cross-linking them to specific radiolabeled ligands. The solubilized

form of the receptor can be examined for size, subunit structure, or ligand-induced autophosphorylation.

The receptors can be purified, their amino acid sequence analyzed, and their genes eventually cloned. The application of molecular biologic techniques to the study of cell surface receptors has greatly enhanced our understanding of their structure and function. Several receptors that are critical for gastric secretory function have been cloned. These include the histamine H_2, somatostatin, M_3 muscarinic, and gastrin or CCK-B receptors. [185], [186], [187] and [188] Analysis of the amino acid sequence of these cloned receptors indicates that they belong to the family of heptahelical or G protein–linked receptors. Structurally, these receptors consist of a single amino acid chain, containing seven hydrophobic domains, that presumably traverses the cell surface membrane (i.e., transmembrane regions). Through studies using recombinant molecular technology (e.g., site-directed mutagenesis, chimeric receptor studies), the structural components of G protein–linked receptors important for ligand binding and biologic action have been elucidated, and several general characteristics of this receptor family have emerged. For example, the specificity of ligand binding can be determined by the hydrophobic transmembrane regions of the receptor and the extracellular domains. Furthermore, coupling to the G proteins that are responsible for secretagogue-mediated signal transduction involves interaction principally with the third intracellular loop of the receptor. Receptor regulation (e.g., uncoupling, sequestration, down-regulation) appears to involve kinase-mediated phosphorylation events targeted to serine and threonine residues found within the carboxyl terminal portion of these receptors. Detailed structure-function analyses of the receptors important in gastric secretory function are in progress.

The question of whether acid secretagogues act directly or indirectly on parietal cells could be answered after isolated parietal cell preparations were developed. Initial studies showed that histamine, carbachol, and gastrin increased canine parietal cell oxygen uptake. [173], [189] Later studies revealed that [^{14}C]aminopyrine accumulation was also increased by each of these secretagogues. [14], [15] By using isolated rabbit gastric glands, somewhat different results were obtained; aminopyrine accumulation could be demonstrated in response to histamine and carbachol but not to gastrin. [180] These differences may reflect species variability. For example, rabbits, which are known to feed continuously, may not have developed the ability to marshal an acid secretory response to intermittent bolus feeding as mediated by gastrin. Alternatively, these differences may reflect differences in the methods of study. The experiments of Del Valle and colleagues [190] have demonstrated marked increases in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in response to administration of gastrin 17 in single isolated rabbit parietal cells, suggesting that gastrin receptors are present on rabbit cells as well.

The concept that secretagogues such as acetylcholine and gastrin directly activate parietal cells was placed in doubt by a study that demonstrated the expression of histamine H_2, gastrin, and muscarinic receptors on immunocytes found in gastric lamina propria instead of on parietal cells. [191] This controversial issue was revisited by Diaz and colleagues. [192] Using in situ hybridization histochemistry and autoradiography with a highly selective H_2 receptor radioligand (^{125}I-aminopotentidine), a specific signal for H_2-specific gene transcripts was detected only within parietal cells of the gastric epithelium. The discrepant results obtained by these two investigative teams may be attributed to the less sensitive oligonucleotide probes used by the former group as compared with the highly specific H_2 receptor antisense riboprobe used by the latter. The classic secretagogues described earlier can clearly act directly on gastric parietal cells as initially postulated by multiple investigators, and the possibility that receptors for these ligands are also located on immunocytes in the lamina propria should not be excluded.

Although the critical role of the H_2 receptor in regulating gastric acid secretion had been well established, the structural components of this receptor that determine H_2 selectivity were unknown. The success of Gantz and associates [185] in cloning the gene encoding the H_2-histamine receptor provided the essential tools required for studying this question further. Key areas of homology in the structures of the H_2-histamine and ß$_2$-adrenergic receptors suggested specific transmembrane amino acids that could be important for histamine binding. On the basis of studies involving the expression of H_2-histamine receptors with site-directed mutations, a model for histamine binding and action on the H_2 receptor has been proposed. [193] An aspartic acid residue (Asp98) in the third transmembrane domain is essential for histamine binding and action, and an aspartic acid (Asp186) in the fifth transmembrane defines H_2 selectivity. A threonine (Thr190) in the fifth transmembrane domain is important in establishing the kinetics of histamine binding but is not essential for H_2 selectivity.

The presence of a specific muscarinic receptor on canine parietal cells is supported by specific blockade of carbachol's biologic effects with atropine. The dissociation constant for atropine inhibition of carbachol-induced aminopyrine uptake, 1.3 nM, is consistent with dissociation constants observed with muscarinic receptors in other tissues. [15] In addition to inducing oxygen uptake and aminopyrine accumulation in a dose-dependent manner, carbachol produces a parallel increase in the turnover of membrane inositol phospholipids. [194] Pharmacological studies indicate that the parietal cell muscarinic receptor is of the M_3 subtype, which has been confirmed by the molecular cloning of this receptor. [195], [196] Rat parietal cells have also been shown to have M_3 muscarinic receptors that stimulate aminopyrine uptake, increase inositol phospholipid turnover, and bind [*N*-methyl-^{3}H]scopolamine. [197]

Gastrin receptors have been localized to isolated rat [198] and canine [14] parietal cells. Binding studies with purified parietal cells reveal specific binding that is rapid and saturable. Proglumide, a CCK or gastrin receptor blocker, inhibits gastrin binding and stimulation of parietal cell function. CCK-8 is equipotent with gastrin 17 in displacing radioligand and in stimulating aminopyrine uptake. [14] This suggests that the parietal cell gastrin receptor binds and responds to either ligand in a similar fashion. The gastrin receptor has been characterized further by cross-linking studies in two species. Using canine parietal cell membranes, cross-linking studies with ^{125}I-gastrin 2–7 revealed a single gastrin receptor with a molecular weight of 74 kd. [199] Half-maximal inhibition of radiolabeled gastrin binding in these canine parietal cell preparations was 3×10^{-10} M, in agreement with the potency of gastrin in stimulating aminopyrine uptake. [14] Similar studies with detergent extracts of porcine gastric mucosal membranes using ^{125}I-[Nleu^{15}]gastrin 2–17 as a ligand resulted in the cross-linking of a 78-kd binding protein. [200] In contrast to the studies using canine parietal cells, however, 50% inhibition of binding required 2×10^{-6} M [Nleu^{15}]gastrin 17. The apparent reduction in affinity may be an artifact of the extraction technique used. In both species, the receptor appears to be a single protein with no disulfide-linked subunits. These studies confirm the presence of a specific gastrin receptor on parietal cells. The gastrin receptor appears to be coupled to membrane inositol phospholipid turnover and protein kinase C (PKC) activation. [194], [201]

Kopin and colleagues [188] isolated a cDNA clone encoding the gastrin receptor found on parietal cells. They determined that it is a member of the G protein–linked receptor family and, when expressed, it has a molecular weight similar to that reported in the receptor cross-linking studies. Expression of the cloned receptor confirmed that it is coupled to membrane inositol phospholipid turnover and mobilization of $[Ca^{2+}]_i$. Song and colleagues [202] cloned the gene encoding the human gastrin or CCK-B receptor and localized it to a region of chromosome 11 (11p15.4). It appears that the gene produces two different receptor proteins as a result of alternative RNA splicing. The functional difference between the two receptor isoforms remains to be established.

As with many peptides, gastrin is synthesized as a precursor molecule that undergoes posttranslational processing to become a C-terminus amidated product, which is presumed to be the sole biologically active form of this hormone. [203] Indeed, posttranslational processing intermediates of gastrin, specifically the C-terminus glycine-extended form (G-Gly), serve as substrate for amidation, are stored in gastric tissues, and are secreted into the circulation with amidated peptide reaching plasma concentrations roughly equivalent to those of processed gastrin.

The question whether posttranslational processing intermediates of gastrin exert a biologic effect was addressed by Seva and colleagues. [204] These investigators demonstrated that G-Gly exerts growth promoting effects by activation of non–CCK-B receptors. [204] This finding demonstrated that glycine-extended intermediates of prohormone processing have independent and hitherto unrecognized important biologic actions. Subsequently, Kaise and associates [205] showed specific binding of [^{125}I-Leu^{15}]-G2-17-Gly to gastric canine parietal cells, which was dose-dependently displaced by G2-17-Gly but not by gastrin or by the specific gastrin/CCK-B receptor antagonist L365,260. Thus, gastric parietal cells appear to express specific and distinct receptors for both gastrin and G-Gly.

The role of G-Gly in gastric acid secretion has been the focus of ongoing investigative efforts. An early study conducted in isolated canine gastric parietal cells demonstrated that G-Gly was at least four orders of magnitude less potent than gastrin in stimulating gastric acid secretion. [206] Interestingly, inhibition of gastrin amidation by copper chelation with diethyldithiocarbamate led to an unexpected increase in both basal and gastrin-stimulated gastric acid outputs, suggesting that chronically elevated levels of G-Gly could have a stimulatory effect on the gastric secretory process. [207] Higashide and colleagues [208] demonstrated that infusion of G-Gly alone did not stimulate gastric acid secretion in rats. However, administration of G-Gly in combination with gastrin significantly potentiated the response observed in the presence of gastrin alone, further supporting a physiological stimulatory role for G-Gly on gastric acid secretion. [208] Chen and associates [209] observed similar potentiating effects on gastric acid secretion after administering G-Gly in combination with gastrin to gastrin-deficient mice. Interestingly, in these animals, G-Gly infusion did not affect the number of either ECL or parietal cells, the proliferation rate of the fundic epithelium or the level of expression of H^+,K^+-ATPase. Administration of G-Gly, however, appeared to prevent the formation of vacuolar canaliculi and lipofuscin bodies, suggesting that G-Gly could synergize with gastrin

to stimulate gastric acid secretion by preventing parietal cell degradation. [209]

Another possible mechanism for these observations was presented in a study performed in cultured canine gastric parietal cells. [205] Preincubation of parietal cells with G-Gly enhanced the acid secretory response of the cells to histamine, whereas acutely administered G-Gly had no effect. [205] G-Gly dose-dependently increased both the expression and transcription of the gene encoding the a subunit of H^+,K^+-ATPase, suggesting that G-Gly may have a functional role in potentiating gastric acid secretion by enhancing the expression of the gene encoding the protein responsible for H^+ generation. [205] Although these observations are in apparent discordance with those reported in the study of the gastrin-deficient mice, it is possible that these genetically engineered animals exhibit developmental abnormalities in the mechanisms regulating the expression of H^+,K^+-ATPase. Alternatively, these findings may reflect species-specific differences regarding the ability of G-Gly to induce H^+,K^+-ATPase gene expression.

The effects of somatostatin on isolated enriched canine parietal cells have been evaluated. Somatostatin dose-dependently inhibits histamine-induced aminopyrine uptake and cAMP production and pentagastrin-stimulated aminopyrine accumulation. [16] Somatostatin binding sites have been identified using ^{125}I-[Leu^{8}-D-Trp^{22}-Tyr^{25}]somatostatin 28 as radioligand. Somatostatin 14 and somatostatin 28 are equally potent at displacing bound ligand and at inhibiting aminopyrine accumulation. Scatchard analysis of the binding data revealed two binding sites with dissociation constants of 3.2×10^{-9} M and 2.1×10^{-7} M, respectively. Crude membranes prepared from 95% to 100% pure parietal cells were incubated with ^{125}I-[Leu^{8}-D-Trp^{22}-Tyr^{25}]somatostatin 28 and cross-linked with disuccinimidyl suberate. [210] After solubilization, a single sharp band with no disulfide linkages was identified corresponding to a membrane receptor with a molecular weight of 99 kd. These parietal cell somatostatin receptors may be activated by means of a direct paracrine effect mediated by long cytoplasmic processes that extend from fundic mucosal D cells and appear to terminate on parietal cells. [32] Endocrine inhibition of acid secretion by postprandial serum somatostatin may also be mediated through these receptors.

Five members of the somatostatin receptor family (SSTR1–SSTR5) have been cloned. [180] and characterized with distinct pharmacological properties and tissue distribution. All five SSTR subtypes are expressed throughout the rat gastrointestinal tract and, specifically, in all layers of the gastric mucosa. [211] The development of highly specific and selective agonists [212] has led to more precise functional characterization of these different somatostatin receptors. In particular, SSTR2 appears to mediate the inhibition of gastric acid secretion in rats, dogs, and humans, [212], [213] and [214] a finding confirmed by selective ablation of the *SSTR2* gene. [215] Moreover, Prinz and colleagues [216] demonstrated that SSTR2 is the predominant somatostatin receptor subtype expressed on rat ECL cells, where it mediates the inhibition of histamine release. Therefore, although all five SSTRs are expressed in the stomach, SSTR2 appears to be the receptor subtype most involved in regulating the gastric secretory process.

The presence of other receptors on parietal cells has been suggested but awaits confirmation. Prostaglandins E_2 (PGE_2) and I_2 (PGI_2) inhibit histamine-stimulated aminopyrine accumulation and cAMP generation in enriched canine parietal cells. [217] These agents have no effect on aminopyrine uptake induced by gastrin, carbachol, or dibutyryl cAMP. Specific binding sites for PGE_2 exist in porcine fundic mucosa with subcellular membrane fractionation, suggesting localization to the plasma membrane. [218], [219] and [220] Prostaglandins have displaced bound [^{3}H]PGE_2 and inhibited histamine-stimulated aminopyrine uptake in isolated rabbit parietal cells. [221] Together, these findings strongly suggest the presence of prostaglandin receptors on parietal cells. Ding and colleagues [222] confirmed this observation by documenting gene expression of the prostaglandin receptor subtypes EP_3 and EP_4 on rat gastric parietal cells.

Although it is fairly clear that H_3 receptors are expressed on ECL cells, serving a role in autocrine regulation of histamine release, their presence on parietal cells remains controversial. The H_3 receptor agonist methylhistamine is a potent stimulant of aminopyrine uptake in isolated cultured rabbit parietal cells. [223] This observed stimulatory effect can be blocked by the H_2 receptor antagonist ranitidine, placing in question the selectivity of the H_3 receptor agonist and the significance of the H_3 receptor in parietal cell physiology.

The sympathetic arm of the autonomic nervous system may be expected to counterbalance the stimulatory effect of muscarinic receptors on acid secretion. Although it is possible that ß-adrenergic agonists may inhibit acid secretion through stimulation of somatostatin release [224] and inhibition of histamine release by fundic mucosal mast cells, [184], [225] direct studies with parietal cells support the presence of stimulatory ß-adrenergic receptors. [226]

Epidermal growth factor (EGF) and transforming growth factor-a (TGF-a) have been implicated in the inhibitory modulation of gastric acid secretion. [227], [228] and [229] TGF-a shares structural homology with EGF and is expressed within parietal cells. Several studies have demonstrated that parietal cells express the receptor for EGF, which recognizes EGF and TGF-a. [230], [231] Both these growth factors inhibit parietal cell function in a similar fashion. [232], [233], [234] and [235] TGF-a is secreted by parietal cells, and it may function as an autocrine regulatory factor. The presence of secretin, glucagon, or opioid receptors on parietal cells has been suggested but requires confirmation.

Beales and Calam [236] have suggested that parietal cells may express receptors for cytokines. In a series of studies conducted in isolated rabbit gastric parietal cells, tumor necrosis factor-a and interleukin-1ß were shown to inhibit gastric acid secretion, as assessed by the accumulation of the weak base aminopyrine, both in the basal state and after stimulation with histamine, gastrin, and carbachol. [236] In contrast to these observations, Yakabi and colleagues [237] reported that interleukin-8 enhanced in vivo gastrin-stimulated gastric acid secretion in rats. Thus, cytokines appear to have complex regulatory effects on gastric acid secretion, which might be mediated, at least in part, by a direct action of these agents on the gastric parietal cells.

An overview of the interactions of ligands and receptors involved in acid secretion is provided in Figure 13-6. The parietal cell has stimulatory receptors for gastrin, acetylcholine, and histamine. Several lines of evidence suggest that parietal cells in humans may be exposed continuously to basal levels of acetylcholine and histamine. Gastrin can account for most of the postprandial increase in gastric acid secretion. [131] Although a portion of the postprandial response is the result of a direct effect of gastrin on parietal cells, a significant component may be caused by the ability of gastrin to stimulate histamine release from ECL cells (see the section on histamine). The parietal cell also has inhibitory somatostatin receptors that counteract the secretagogue effects. Vagal nerve fibers may enhance their acid stimulatory effect through stimulatory muscarinic receptors on G cells and inhibitory muscarinic receptors on D cells. [224] Adrenergic fibers appear to stimulate D-cell secretion and inhibit release by histamine-containing cells, counterbalancing the vagal effects. [225] Gastrin and CCK stimulate parietal cells and D cells. [238] Gastrin-releasing peptide acts as a neurotransmitter that stimulates G cells, and somatostatin may function as a paracrine G-cell inhibitor. [239], [240] and [241] Further structural and functional analyses of each of these receptors will greatly enhance the understanding of gastric secretion.

Intracellular Signal Transduction

As previously described, the gastric parietal cell is a complex biologic structure that is controlled by a broad variety of growth factors, hormones, and

neurotransmitters. These agents interact with specific receptors on the cell surface, initiating a flow of information that moves to the cell nucleus along highly organized and complex signal transduction pathways. Once in the nucleus, these signals are known to activate specific programs of transcriptional events that lead to the expression of specialized cellular functions. Numerous signal transduction pathways have been studied and characterized in the gastric parietal cells.

Receptors linked to adenylate cyclase influence intracellular levels of cAMP. Such receptors are coupled to inhibitory (G_i) or stimulatory (G_s) GTP-binding proteins (Fig. 13-7). [242] G_i attenuates adenylate cyclase activity, decreasing cAMP levels. The ability of pertussis toxin selectively to block the actions of G_i can be used experimentally to dissect second messenger pathways. G_s, which increases adenylate cyclase activity and cAMP levels, can be stimulated selectively by cholera toxin. Increases in cytoplasmic cAMP levels result in activation of cAMP-dependent protein kinases and consequent phosphorylation of various intracellular proteins that appear to mediate the effects of the ligand-receptor interaction.

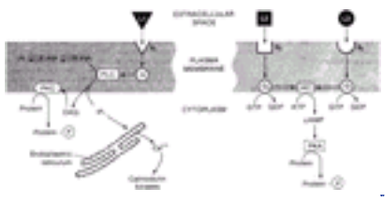

FIGURE 13-7. Signal transduction pathways in parietal cells. Ligands (*L*) interact with receptors (*R*) to initiate the target cell response. The **left panel** shows the membrane inositol phospholipid pathway activated by gastrin and acetylcholine (*L1*). A guanine nucleotide–binding protein (*G*) activates phospholipase C (*PLC*), which hydrolyzes phosphotidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol (*DAG*) and inositol 1,4,5-trisphosphate (IP_3). DAG activates protein kinase C (*PKC*), which phosphorylates (*P*) target proteins, whereas IP_3 induces intracellular calcium mobilization, which activates kinases. The **right panel** depicts the cAMP pathway used by histamine (*L2*) and somatostatin (*L3*) in parietal cells. The histamine receptor (R_2) acts through a stimulatory G protein (G_s), which activates adenylate cyclase (*AC*) and generates cAMP. An increased level of cytoplasmic cAMP activates protein kinase A (*PKA*) and results in phosphorylation of parietal-cell effector proteins. The somatostatin receptor (R_3) activates an inhibitory G protein (G_i), which inhibits adenylate cyclase and decreases cAMP generation.

A second major intracellular signal transduction cascade involves the turnover of membrane phospholipids, specifically the inositol phospholipids. Receptors are linked to this pathway through a G protein, and the initial events that are activated by occupancy of their receptor lead to phospholipase C–induced hydrolysis of phosphatidylinositol bisphosphate (PIP_2) to diacylglycerol and inositol triphosphate (IP_3). [243] IP_3 causes the release of Ca^{2+} from intracellular stores, and diacylglycerol promotes the translocation of a Ca^{2+}-phospholipid–dependent protein kinase (i.e., PKC) from the cytoplasm to its active site on the cell membrane. [244], [245] Increases in $[Ca^{2+}]_i$ activate various Ca^{2+}-dependent enzyme systems, such as the calmodulin kinases, and promote the translocation and activation of PKC.

Although the classic teaching had been that receptor activation is linked to a single signal transduction cascade, it is evident that interaction between postreceptor signaling pathways can occur at multiple levels. [187] One example of this in gastric secretion is the ability of the H_2 histamine receptor to stimulate through separate pathways an increase in cAMP and $[Ca^{2+}]_i$. [246] Del Valle and colleagues [246] have confirmed that stimulation of the cloned canine H_2 receptor can lead to an increase in adenylate cyclase and IP_3 or $[Ca^{2+}]_i$ activity through independent pathways.

Histamine's acid stimulatory action appears to be mediated primarily through its ability to increase cAMP production in parietal cells. [247] This increase parallels histamine's ability to stimulate aminopyrine uptake and oxygen consumption. Histamine increases cAMP-dependent protein kinase activity in enriched rabbit parietal cells. [248] The substrates for this enzyme activity have not been fully characterized, but they are thought to mediate the effects of histamine stimulation. [249]

The acid stimulatory actions of gastrin and carbachol appear to be mediated by Ca^{2+}-dependent pathways. Gastrin and carbachol exert similar effects on membrane inositol phospholipid turnover in parietal cells. Both agents induce a time-dependent decrease in PIP_2 and increase in the formation of IP_3. [194] These effects parallel increases in [^{14}C]aminopyrine accumulation. The increase in IP_3 may mediate the mobilization of $[Ca^{2+}]_i$ observed in parietal cells stimulated with gastrin or carbachol. In the case of carbachol, increased $[Ca^{2+}]_i$ may occur as a result of enhanced mobilization of Ca^{2+} from intracellular stores or through influx of extracellular Ca^{2+} across the cell membrane. [250], [251] and [252] It is presumed that the elevated levels of cytoplasmic Ca^{2+} then activate several enzyme cascades, including the calmodulin kinase family and, in concert with diacylglycerol, the second product of PIP_2 breakdown, PKC. Gastrin and carbachol dose-dependently increase membrane-associated PKC activity. [201] Although gastrin and carbachol increase membrane inositol phospholipid turnover and PKC activity in canine gastric parietal cells to a similar degree, carbachol is a more potent stimulant of acid production. [201] Takeda and associates [253] observed that carbachol is more efficacious than gastrin in stimulating the entry of extracellular Ca^{2+} into parietal cells. It appears that these two secretagogues regulate the entry of Ca^{2+} into parietal cells by distinct mechanisms. Gastrin stimulated Ca^{2+} entry from extracellular sites by opening Ca^{2+} channels that are linked to the ability of this stimulant to deplete $[Ca^{2+}]_i$ stores. Carbachol opens similar Ca^{2+} channels and opens channels that are not regulated by the depletion of $[Ca^{2+}]_i$ pools. These differences in Ca^{2+} regulation may account for the more potent stimulatory action of carbachol on canine gastric parietal cells.

Furthermore, research suggests that the induction of $[Ca^{2+}]_i$ release in response to gastrin but not carbachol is a function of activation of the cAMP pathway. [254] In fact, incubation of rabbit parietal cells with gastrin in the presence of the histamine H_2 receptor blocker cimetidine inhibits gastrin-mediated increases in $[Ca^{2+}]_i$. The addition of dibutyryl adenosine 3',5' phosphate in addition to cimetidine completely restored this response, suggesting that in the rabbit, H_2 receptor activity potentiates the effect of gastrin on parietal cell function. Athmann and colleagues [255] confirmed these observations, demonstrating that in isolated rabbit gastric glands, ranitidine blocks $Ca^{2+}]_i$ release induced by gastrin (1 nM). Interestingly, these investigators also reported that a supraphysiological, tenfold higher dose of gastrin (10 nM) induced a Ca^{2+} signal that was not inhibited by ranitidine. [255] The specific intracellular targets and the biologic significance of this ranitidine-insensitive Ca^{2+}signal remain to be elucidated.

Although it appears that the plateau or steady phase of carbachol-mediated increases in Ca^{2+} is essential for activation of the secretory process, [256] this may not be the only signaling event important in muscarinic receptor–mediated acid secretion. Similar Ca^{2+} levels can be achieved with the calcium ionophore, ionomycin, and the Ca^{2+}-ATPase inhibitor thapsigargin, [257] but a corresponding increase in acid production similar to that observed with carbachol is not observed. The additional signaling events linking M_3 receptor activation and acid secretion require further investigation, but they may include differential activation of downstream kinase pathways.

Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) is one of the best-characterized targets of intracellular Ca^{2+}. Tsunoda and colleagues [258] demonstrated that carbachol can lead to the activation of CaMKII in parietal cells. The specific components of the carbachol-activated signaling cascade are for the most part unknown. Parente and colleagues [259] have reported the purification and cloning of a novel phosphoprotein, designated Ca^{2+}-sensitive phosphoprotein of 28 kd (CSPP28), from rabbit parietal cells. This protein was phosphorylated by CaMKII in response to cholinergic stimulation, but not when cells were treated with phorbol esters. CSPP28 may represent an important element in Ca^{2+} signal transduction, but its specific role in parietal cell biology remains unknown. Because CaMKII regulates cytoskeletal function, this protein kinase may play a role in the dramatic morphologic transformation of parietal cells during stimulation.

Carbachol-mediated stimulation of various cell types leads to alterations in cell volume that are linked to the regulation of ion channel conductance. Negulescu and colleagues [260] examined the role of parietal cell volume in regulating carbachol-mediated changes in cytosolic Ca^{2+}. These investigators observed that carbachol-mediated opening of Ca^{2+} channels leads to the loss of ions and water from the parietal cell and subsequent cell shrinkage. The decrease in cell volume

may inhibit Ca $^{2+}$ channels, providing a feedback mechanism to reduce further cell shrinkage resulting from ion fluxes.

The action of PKC in parietal cells is complex. Direct activation of PKC with phorbol esters results in enhanced acid secretory activity, [261] and inhibition of PKC by the specific inhibitor Ro 31-8220 blocks carbachol-stimulated aminopyrine uptake in isolated rat parietal cells. [262] However, phorbol ester pretreatment of canine parietal cells with phorbol esters decreases the stimulatory effects of subsequent treatment with carbachol and gastrin, [261] whereas Ro 31-8220 potentiates [^{14}C]aminopyrine uptake from isolated rabbit gastric glands stimulated by both carbachol and histamine. [263] Numerous factors may account for these contradictory observations. PKC may induce down-regulation of muscarinic and gastrin receptors on parietal cells. [261] The mechanism for this effect is unclear but may involve receptor phosphorylation. In addition, because PKC comprises a large family of proteins with different biochemical and functional properties, [264] species-specific differences in both the function and the cellular localization of PKC isoforms may exist. [263] Chew and colleagues [263] analyzed the different PKC subtypes in rabbit parietal cells and reported abundant levels of both the novel isoforms PKC-e and PKC-µ and of the atypical isoforms PKC-?, PKC-?, and PKC-?. In contrast to a previous study performed in canine parietal cells, [265] low levels of the classic isoforms PKC-a and ß were measured in the rabbit parietal cells. These investigators observed, with a confocal microscope, that PKC-e was localized to a parietal cell compartment that bore resemblance to that containing filamentous actin, suggesting that PKC could negatively regulate gastric acid secretion through phosphorylation and modification of cytoskeletal proteins. [263] A newer protein kinase, protein kinase D (PKD), has been characterized and found to be induced by phorbol esters. [266], [267] Although it is currently unknown whether PKD or other related protein kinases are present in gastric cells, this intriguing finding supports the hypothesis that some of the effects of phorbol esters on acid secretion could be mediated by protein kinases other than PKC. Further studies will clarify the function of PKC in the stomach.

In addition to these well-established signal transduction pathways, mammalian parietal cells express multiple members of a family of protein kinases known as mitogen-activated protein kinases (MAPKs). [268], [269] and [270] In particular, parietal cells appear to express the extracellular signal–regulated protein kinases (ERKs), [268], [270] the Jun N-terminal kinases (JNKs), [271] and the p38 kinases, [272] molecules known to regulate multiple important cellular functions [273], [274] (Fig. 13-8). The ERKs are important elements in a cascade of biochemical reactions that involves the small GTP-binding protein Ras, as well as upstream protein kinases such as Raf and MAPK/ERK. [275], [276] ERK activation is known to target numerous cellular proteins, including downstream protein kinases such as 90-kd S6 kinase (RSK) [275], [276] and transcription factors, such as Elk-1, that regulate the activity of the promoter of the early response gene c- *fos* through the serum response element (SRE). [277], [278] These kinases appear to play a crucial role in the process of amplification, integration, and transmission of extracellular signals from the cell surface to the nucleus, leading to the induction of cellular growth and proliferation and, in some systems, cellular differentiation. [274], [275] and [276]

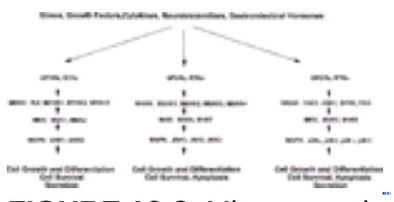

FIGURE 13-8. Mitogen-activated protein kinase (*MAPK*) pathways in the gastric parietal cells. Many different extracellular signals activate kinase cascades that lead to the induction of members of the MAPK family of protein kinases. These include the extracellular signal–regulated protein kinases (*ERK*), p38 kinases, and the Jun N-terminal kinases (*JNKs*). These protein kinases appear to regulate several important cellular functions, including growth, apoptosis, survival, differentiation, and secretion. *GPCRs,* G protein–coupled receptors; *RTKs,* receptor tyrosine kinases.

Several studies have examined the regulation of ERKs by gastric acid secretagogues. Takeuchi and colleagues [270] reported that carbachol was the most potent inducer of ERK2 activity in isolated gastric canine parietal cells. Gastrin and EGF had weaker stimulatory effects, whereas histamine induced no response. The effect of carbachol appeared to be independent of Ca $^{2+}$ signaling. PD98059, a selective inhibitor of the upstream ERK activator, MEK dose-dependently inhibited both carbachol- and EGF-stimulated ERK2 activity. [270], [279] Similarly, Nakamura and associates [268] observed that carbachol and EGF induced the ERKs in isolated rabbit parietal cells.

The functional relevance of ERK activation in the stomach has been the focus of continued investigation. Initial studies reported the divergent effect of EGF on gastric acid secretion. Under acute conditions, EGF had an inhibitory effect on acid secretion, whereas prolonged administration of EGF increased both basal and maximal acid secretion in vivo and acid production in isolated parietal cells in vitro. [269], [280], [281] Some studies suggested that these effects of EGF could be mediated by the activation of protein tyrosine kinases because they were fully reversed by the addition of protein tyrosine kinase inhibitors. [269], [280] In addition, Chew and associates [269] observed that inhibition of the chronic stimulatory effect of EGF by these agents was associated with a decrease in phosphorylation of a 44-kd protein identified as an ERK isoform. Taken together, these results suggested that both the ERKs and an unidentified protein tyrosine kinase were likely to be important in the regulation of the gastric parietal cells.

Our understanding of the function and physiological role of the ERK pathway has been significantly enhanced by the use of PD98059. To examine the importance of ERK activation in gastric acid secretion further, Takeuchi and colleagues [270] tested the effect of PD98059 on carbachol-stimulated uptake of [^{14}C]aminopyrine. Acute inhibition of the ERKs by PD98059 led to a small increase in [^{14}C]aminopyrine uptake and to complete reversal of the inhibitory effect of EGF on parietal cell activation induced by either carbachol or histamine. [270] In contrast, exposure of the cells to PD98059 for 16 hours reversed the chronic stimulatory effect of EGF on [^{14}C]aminopyrine uptake induced by carbachol, leading the investigators to conclude that whereas the acute effect of the ERKs on gastric acid secretion appears to be inhibitory, the activation of transcription factors and of early gene expression could produce chronic stimulatory effects (Fig. 13-9). [270] Further research has shown that the acute inhibitory effect of EGF on gastric acid secretion could be mediated by a PKC-dependent pathway. [265] Thus, because PKC has been shown to activate c-Raf, a kinase involved in the activation of the ERKs, [282] it is possible that the acute inhibitory effect of EGF on aminopyrine uptake could be mediated by a signaling cascade involving activation of PKC, c-Raf, and MEK, leading finally to induction of the ERKs. Furthermore, Kaise and associates [281] demonstrated that EGF is able to induce transcription of the a subunit of the H $^{+}$,K $^{+}$-ATPase gene through a novel EGF-response element (ERE) located between bases–162 and–156 (5'-GACATGG-3') relative to the cap site. This ERE is homologous to the 3' half-site of the c- *fos* serum response element. Accordingly, the authors suggested that the stimulatory effect of EGF on gastric acid secretion could be mediated by induction of the H $^{+}$,K $^{+}$-ATPase gene. [281] Although a direct link between induction of the ERKs and c- *fos* and stimulation of the H $^{+}$,K $^{+}$-ATPase gene has not been yet demonstrated, it is possible that this gene may contain specific DNA regulatory elements that receive input from signaling pathways involving the ERKs and c- *fos*.

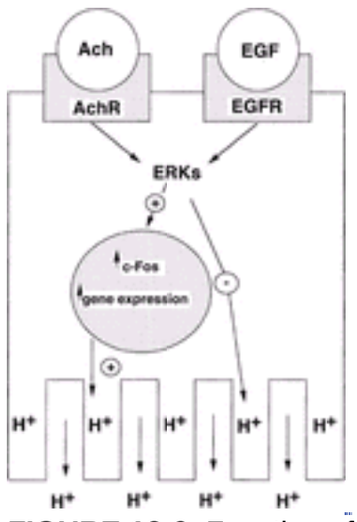

FIGURE 13-9. Function of the extracellular signal–regulated protein kinases (*ERKs*) in the gastric parietal cells. Both acetylcholine (*Ach*) and epidermal growth factor (*EGF*) induce a cascade of events in parietal cells that results in ERKs activation. Whereas the acute effect of the ERKs on gastric acid secretion appears to be inhibitory, the activation of transcription factors and of early gene expression may be responsible for their chronic stimulatory effects.

p38 kinase is another member of the MAPK family of protein kinases. [273] Like the MAPKs, p38 kinase is regulated by a multistep cascade of biochemical reactions. One of the first steps in the complex chain of events that leads to the induction of p38 kinase is the activation of Rac and Cdc42, small GTP-binding proteins belonging to the Rho family of GTPases. [273] These molecules are responsible for the induction of downstream protein kinases such as the dual-specificity kinases MKK3 and MKK6, which, in turn, phosphorylate p38 kinase on both tyrosine and threonine residues, leading to its activation. [273] Research indicates that p38 kinase is activated in response to both physical and chemical stress, cytokines, hematopoietic growth factors, neurotransmitters such as carbachol and isoproterenol, and CCK. [272], [273], [283], [284] Activation of p38 kinase has been linked to regulation of programmed cell death, skeletal muscle differentiation, organization of the cellular cytoskeleton, and phosphorylation of transcription factors. [273], [284], [285], [286] and [287] Pausawasdi and colleagues [272] used SB-203580, a specific p38 kinase inhibitor, [286] to investigate the regulation and the functional relevance of p38 kinase in carbachol-stimulated gastric acid secretion. These investigators have observed that SB-203580 dose-dependently potentiates carbachol induction of aminopyrine uptake in isolated and cultured canine gastric parietal cells, suggesting that p38 kinase has a negative regulatory effect on gastric acid secretion. [272]

Because p38 kinase is known to play an important role in the organization of the actin cytoskeleton, [273], [284] a possible mechanism of p38 kinase–induced inhibition of gastric acid secretion could involve changes in the actin cytoskeleton of the gastric parietal cells. The cytoskeleton is an important element in secretagogue-stimulated gastric acid secretion because, during this process, the parietal cell undergoes dramatic morphologic modifications that lead to the translocation of H^+,K^+-ATPase from cytoplasmic tubulovesicular structures to the apical plasma membrane. [18], [19] and [20] Accordingly, p38 induction could result in phosphorylation of cytoskeletal proteins and in significant changes in the organization of the actin cytoskeleton. These events could be responsible for alterations in the process of H^+,K^+-ATPase insertion into the parietal cell apical membrane and for the inhibition of gastric acid production.

Considering the lack of specific JNK inhibitors, it is unclear whether these kinases are involved in the process of gastric acid secretion. However, studies conducted in canine parietal cells have suggested that JNK activation may be an important step in the parietal cell response to stress and inflammation. [271]

Another signal transduction pathway that has been shown to play an important role in the mediation of some of the physiological actions of EGF is that involving phosphoinositide 3-kinase (PI_3-K) and protein kinase B/Akt. [287], [288], [289] and [290] Three major isoforms of Akt have been identified and described thus far. [288] Whereas Akt 1 and Akt 2 are ubiquitously expressed, Akt 3 appears to be expressed predominantly in the brain, heart, and kidney. [290] Activation of Akt is known to induce cellular growth and survival and to promote the expression and maintenance of highly differentiated cellular phenotypes. [287], [288], [291], [292] Furthermore, Akt has been shown to contribute to the regulation of vesicular trafficking and endocytosis. [292] Akt is homologous to the PKA and PKC families of protein kinases, [288], [293] and its activity is regulated by growth factors through the induction of PI_3-K. [288], [293] Phosphorylation of Akt appears to be critical for its activation. [288], [293], [294] The major phosphorylation sites required for activation of Akt 1 have been identified as threonine 308 and serine 473, which are the target of the phosphoinositide-dependent kinases 1 (PDK1) and 2 (PDK2), respectively. [288], [293] Similarly, Akt 2 and Akt 3 are also phosphorylated on serine and threonine residues (Thr309 and Ser474 in Akt 2 and Thr305 and Ser472 in Akt 3) by PDK1 and PDK2 (Fig. 13-10). [288], [290] Todisco and associates [295] reported that EGF regulates the expression of the H^+/K^+-ATP-ase a subunit gene through a signal transduction pathway that involves the activation of Akt. These findings suggest a novel role for Akt in the regulation of the secretory function of the gastric parietal cells.

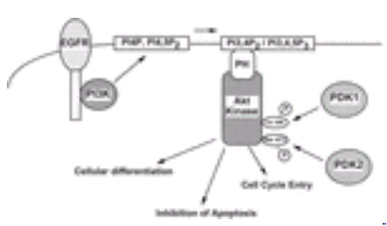

FIGURE 13-10. Activation and function of the Akt signal transduction pathway. Akt is a serine-threonine protein kinase involved in the regulation of numerous important cellular functions such as inhibition of apoptosis and stimulation of cellular growth and differentiation. Induction of Akt requires the recruitment of the kinase to the plasma membrane by phosphoionositide 3-kinase–mediated phosphorylation of membrane phospholipids and phosphorylation of Ser 473 and Thr 308 of Akt by the phosphoinositide-dependent kinases PDK1 and PDK2. PI4P, phosphatidylinositol-4-phosphate; $PI4,5P_2$, phosphatidylinositol-4,5-bisphosphate; $PI3,4P_2$, phosphatidylinositol-3,4-bisphosphate; $PI3,4,5P_3$, phosphatidylinositol-3,4,5-triphosphate; PH, pleckstrin homology domain.

The mechanism by which somatostatin inhibits parietal cells has been explored. [295] In the case of histamine-stimulated acid secretion, somatostatin appears to inhibit the generation of cAMP through an inhibitory guanine nucleotide–binding protein that regulates adenylate cyclase activity. However, somatostatin is also able to inhibit acid secretion induced by dibutyryl cAMP. The stimulatory effects of gastrin and carbachol are also inhibited without altering the turnover of membrane inositol phospholipids or the activation of PKC induced by these agents. Somatostatin appears to act on parietal cells at a site distal to the activation of the intracellular signal transduction cascades. This action may be mediated through the induction of protein dephosphorylation, the inhibition of cellular secretion, or some other yet undetermined mechanism. [296], [297] and [298] For example, somatostatin inhibits the induction of the early response gene c-*fos* in canine parietal cells stimulated by both carbachol and histamine. [299] As in many other physiological systems, c-*fos* plays an important role in cellular activation. Thus, the ability of somatostatin to inhibit c-*fos* expression may represent an important regulatory mechanism in gastric parietal cell physiology.

Regulation of Parietal Cell Genes

The stimulation of parietal cells induces several cellular events, including morphologic transformation, rapid changes in enzyme location and activity, and opening of ion channels. The resting parietal cell contains a collapsed canalicular system and cytoplasmic tubulovesicles containing the gastric proton pump, H^+,K^+-ATPase. The stimulated cell rapidly develops a richly interdigitating intracellular canalicular system bulging with microvilli with concomitant loss of cytoplasmic tubulovesicles (Fig. 13-11). [19], [300] The microvilli have a central cytoskeletal core of actin filaments stabilized by other proteins. [301] These filaments appear to mediate the fusion of tubulovesicles with the canalicular system. This fusion translocates H^+,K^+-ATPase from vesicular membranes to the canalicular membrane, where it actively pumps H^+ ions in exchange for K^+ (Fig. 13-12). [302], [303] For each proton that is secreted, an intracellular OH^- ion is generated. This alkaline challenge is handled by

carbonic anhydrase II (CAII)–mediated conversion of OH^- to HCO_3^-, which is exchanged for Cl^- at the basolateral membrane.

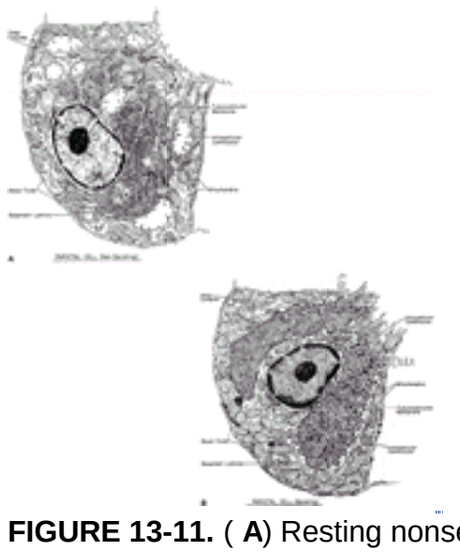

FIGURE 13-11. (**A**) Resting nonsecretory parietal cell. (**B**) Stimulated acid secretory parietal cell. The stimulated cell develops a richly interdigitating intracellular canalicular system that bulges with microvilli. There is a concomitant loss of cytoplasmic tubulovesicles. (From ref. [20].)

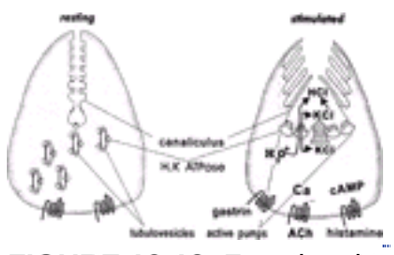

FIGURE 13-12. Functional transformation of a secreting parietal cell. This model illustrates a resting parietal cell (**left**) with collapsed secretory canaliculi and cytoplasmic tubulovesicles expressing H^+,K^+ATPase and a stimulated parietal cell (**right**) with formed secretory canaliculi expressing active H^+,K^+-ATPase pumps. (Adapted from ref. [343].)

There are many proteins involved in generating and secreting gastric acid. Stimulation of parietal cells presumably involves the activation of nascent proteins and the induction of the genes responsible for these effector molecules. The effect of acid secretagogues on the genes coding these enzymes and structural proteins has been analyzed.

The induction of specific gene transcription has been studied in isolated canine parietal cells. [304] Significant increases in CAII RNA levels were induced by carbachol, gastrin, and histamine. Maximal stimulation was reached within 20 minutes for histamine and carbachol and within 60 minutes for gastrin. To determine whether the observed increases in mRNA levels were the result of increased transcription or decreased degradation, nuclear run-off experiments were performed. They revealed increased transcription within 15 minutes for each agent. H^+,K^+-ATPase mRNA levels were also induced in the same fashion as for CAII. [305] This coordinated induction of both enzymes could be blocked with the competitive inhibitors of each secretagogue.

Because CAII appears to be the catalyst of the reaction responsible for the elimination of OH^- produced in the generation of H^+, increased transcription of CAII RNA in stimulated parietal cells could result as a secondary effect of the induction of H^+,K^+-ATPase. To explore this possibility, parietal cells were pretreated with omeprazole, an agent known to inactivate H^+,K^+-ATPase irreversibly. [306] Under these circumstances, carbachol still induced CAII RNA, with the same kinetics as in untreated cells. Carbachol appears to stimulate CAII gene expression without dependence on OH^- ion generation by H^+,K^+-ATPase.

Secretagogues stimulate actin expression. Although actin often is used as a control or housekeeper gene for such studies because its expression tends to remain constant, in the case of the parietal cell, actin plays a crucial role in the acid secretory process. The induction of actin gene expression may serve as a particularly useful marker for acid secretion instead of using H^+ generation. This type of analysis can elucidate the effect of acid secretagogues on parietal cell function at the molecular level.

Muraoka and associates [307] undertook an extensive evaluation of the regulatory elements controlling H^+,K^+-ATPase gene expression. They transfected cultured canine gastric parietal cells with reporter gene constructs composed of the first exon and various lengths of the 5'-upstream regulatory region of the canine H^+,K^+-ATPase a subunit ligated to a luciferase reporter plasmid. Their data indicate that basal transcriptional activity of the H^+,K^+-ATPase gene is mediated through binding of the nuclear transcriptional factor SP1 to the 5'-GCTCCGCCTC-3' nucleotide sequence residing between bases –47 to–38 relative to the putative cap site. [307]

Shigehiko and Maeda and their colleagues [308], [309] identified regions within the promoters of both the a and ß subunits of the H^+,K^+-ATPase gene that were recognized by gastric-specific nuclear proteins. These investigators subsequently cloned two novel nuclear proteins, named GATA-GT1 and GATA-GT2, from pig gastric mucosa. These bound specifically to the sequences (G or C)RR(G or C)NGAT(A or T)RY, in which R and Y are unspecified purine and pyrimidine bases, respectively. GATA-GT1 and GATA-GT2 belong to the family of the GATA transcription factors that are known to play an important role in tissue-specific gene expression. [309] Northern blot analysis of several different tissues revealed that these nuclear proteins were expressed predominantly in the gastric mucosa and to a lesser degree in the intestine, but not in the brain, heart, liver, kidney, spleen, or lung. [308] Maeda's group speculated that these transcription factors were responsible for the specific expression of the H^+,K^+-ATPase gene in the gastric mucosa.

Acid Secretory Processes

The gastric epithelium secretes a fluid of almost isotonic HCl through an active transport process. Acid is secreted at a pH of 0.8, but the parietal cell cytosolic pH is about 7.2. The parietal cell alone is responsible for this remarkable H^+ ion concentration gradient of 2.5 million–fold. Significant amounts of mitochondrial energy are required when the parietal cell is signaled to transform from a relatively quiet resting state to an actively secreting state. Dramatic changes in cellular membranes, cytoskeletal architecture, membrane ion conductances, and ATPase activities are only a portion of the events that accompany cell activation. Equally impressive is the compressed time frame over which these changes occur. It has been suggested that the family of isoenzymes, kinase/phosphocreatine (CK/DCr), which catalyze the exchange of high-energy phosphate groups between phosphocreatine and ADP, are involved in parietal cell transformation. The CK/DCr system couples to the K^+-ATPase [310] and the Ca^{2+}-ATPase found in sarcoplasmic reticulum. [311] The isoform BB-CK (B, brain) has been identified in the parietal cells of different species, [312] and this enzyme appears to colocalize with H^+,K^+-ATPase in purified vesicles prepared from porcine parietal cells. These data suggest that H^+,K^+-ATPase may obtain the required ATP generated by the BB-CK colocalized in the same cellular compartment. [313]

The stimulation of parietal cells induces the formation of a dense apical meshwork of intracellular canaliculi packed with long microvilli. [314] The apical cell membrane surface area increases five- to tenfold after stimulation. This increase coincides with the disappearance of most of the cytoplasmic tubulovesicles seen in the resting

parietal cell. The mechanism of this increase in surface area appears to be the fusion of tubulovesicles and apical membrane. Immunocytochemical studies using a monoclonal antibody to H^+,K^+-ATPase demonstrate the translocation of the enzymes from tubulovesicles in the resting cell to the apical membranes in the stimulated cells, supporting the concept of secretagogue-induced membrane fusion and enzyme redistribution. [302] The fusion of tubulovesicles with the apical membrane is directed by cytoskeletal microfilaments composed of actin and other regulatory proteins. Membranes are recycled back to the tubulovesicles as cells return to the resting state, a process that also appears to be mediated by actin-containing microfilaments. [301] These microfilaments anchor at regularly spaced intervals in the apical membrane and do not appear to associate with resting tubulovesicles. Cytochalasins, agents that inhibit actin polymerization, inhibit acid secretion. [315] Colchicine and vinblastine also are capable of inhibiting acid secretion. [316] These studies indicate the essential importance of actin-mediated H^+,K^+-ATPase translocation in the initiation of acid secretion.

Forte and colleagues [317] have analyzed in detail the biochemical and functional properties of actin in the gastric parietal cells. In a series of elegant studies, these authors have demonstrated that most parietal cell actin exist in the filamentous form (F-actin), which is an important component of the apical cell microvilli, whereas only a small fraction appears to be in the monomeric state (G-actin).

In some systems of regulated vesicular transport, F-actin is known to form a meshwork of filaments just beneath the cell surface, creating a barrier for the recruitment of vesicles to the apical plasma membrane. According to this model, F-actin depolymerization to the monomeric G form facilitates vesicle translocation. In contrast to this theory, Forte's group [317] did not detect any significant changes in the steady-state ratio of F-actin and G-actin during the process of parietal cell activation by the gastric acid secretagogues. Thus, although these observations do not exclude the possibility that rapid exchange between F-actin and G-actin may occur, it appears that during induction of gastric acid secretion, the parietal cell maintains actin in a highly polymerized state. [317]

These investigators [318] also demonstrated that the parietal cells contain pools of actin that display considerable functional differences. Using latrunculin B, a compound known to bind and inhibit the function of G-actin, they demonstrated that whereas G-actin is important for lammellipodia formation, F-actin, which is less sensitive to latrunculin B, appears to play a crucial role in the process of secretagogue-stimulated gastric acid secretion. In fact, alteration of F-actin function by either a high dose of latrunculin B or by cytochalasin D, an agent known to fragment F-actin filaments, resulted in inhibition of gastric acid secretion. [318]

Hanzel and colleagues [319] have identified one of the membrane proteins involved in parietal cell cytoskeletal transformation as ezrin, an 80-kd membrane protein found in several cell types. Ezrin is associated with the actin filaments in the microvilli of stimulated parietal cells and is phosphorylated during cAMP-mediated stimulation. Actin, an important structural protein for cellular scaffolding, is expressed as several isoforms, including the ß and ? subtypes found in parietal cells. [320] In a series of elegant experiments using ultrastructural immunocytochemistry and biochemical protein purification, Yao and associates [321] confirmed that ß-actin is localized in canalicular microvilli and in the apical portion of parietal cells. [321] The authors also reported the selective association of ezrin with ß-actin. These important observations have begun to shed light on the potential role of ezrin in parietal cell secretion. Moreover, they support the novel concept that actin isoforms may be distributed in different cellular domains, exerting differential functions by association with isoform-specific actin-binding proteins.

The molecular events regulating the dramatic recycling of H^+,K^+-ATPase–containing membranes have been the focus of intense investigative efforts. Study of other cell systems has begun to elucidate the important factors in the secretion process. One such family of factors has been the low-molecular-weight GTP-binding proteins. [322] The members of this superfamily of proteins have certain characteristics: molecular weights of 20 to 30 kd, significant homology with the oncogenic peptide Ras, ubiquitous expression, and involvement in a host of cellular functions, including vesicle trafficking. Several members of the Rab category of Ras proteins are expressed in gastric parietal cells. [323], [324], [325], [326] and [327] Rab 25, Rab 324, and Rab 11 (previously thought to be Rab 2) [325], [326] have been identified in rabbit parietal cells. More importantly, these specific proteins cosegregate with a-H^+,K^+-ATPase during parietal cell activation, suggesting a role for these small GTP-binding proteins in membrane recycling. [325], [327] The importance of Rab 11a in the process of parietal cell activation has been demonstrated by Duman and colleagues. [328] Transduction of isolated and cultured rabbit parietal cells with an adenoviral vector expressing a dominant negative Rab 11a gene led to a block in the translocation of the H^+,K^+-ATPase to the apical plasma membrane and to the inhibition of gastric acid secretion. [328]

Developments in the field of cell biology have shed light on the molecular pathways important in cellular secretory processes. Work in neuronal systems and yeast have demonstrated the potential involvement of highly conserved protein complexes in vesicle fusion and docking, such as the soluble *N*-ethylmaleimide–sensitive factor attachment protein receptors (SNAREs). [329], [330] These can be vesicle-related (v-SNARE) or target membrane–related (t-SNARE), binding to each other to provide a molecular framework for the attachment of soluble factors. [331] Members of these protein families include VAMP-2 (vesicle-associated membrane protein-2, identified as a v-SNARE in brain), and the syntaxin 1A/1B and SNAP-25 (synaptosome-associated protein), which are categorized as t-SNAREs and are thought to play a role in the recycling of synaptic vesicles. [332] The secretory carrier membrane proteins or SCAMPs found in pancreatic zymogen granules and synaptic vesicles may also play a role in vesicle recycling. Calhoun and Goldenring [327] have explored the potential role of these novel trafficking-related proteins in the parietal cell secretory process. The involvement of VAMP-2, SCAMP, Rab 11, and Rab 25 in membrane trafficking was determined by immunoisolation of highly purified parietal cell tubulovesicles. These investigators reported that VAMP-2, SCAMPs, and the two Rab proteins were present on H^+,K^+-ATPase–containing tubulovesicles and suggested that Rab proteins take part in the assembly of the SNARE complex. These observations support a theory originally proposed by Forte that parietal cell tubulovesicles may be derived from a cell surface recycling system.

Other studies have demonstrated that the cytoskeletal proteins actin, spectrin, and ankyrin co-purify with the H^+,K^+-ATPase from parietal cell microsomal membranes and cosegregate with H^+,K^+-ATPase in resting and secreting parietal cells. Ankyrin may mediate the interaction of H^+,K^+-ATPase with the structural membrane proteins actin and spectrin and may thereby function to maintain the polarized distribution of the enzyme to the apical portion of the parietal cell. Festy and colleagues [333] screened a cDNA bank of rabbit gastric fundic mucosa by two-hybrid assays and demonstrated that the rabbit H^+,K^+-ATPase binds through its amino-terminal end to the spectrin binding domain of ankyrin III. The two proteins bind directly to one another, constituting an important anchoring system for the H^+,K^+-ATPase to the plasma membrane. [333]

Studies of H^+,K^+-ATPase activity have been performed using membrane vesicles obtained from resting and stimulated parietal cells. [314] Vesicles from light microsomal membrane fractions, presumably containing the tubulovesicles, exhibit most of the H^+,K^+-ATPase activity in resting parietal cells. [334] Heavier membrane vesicles associated with microfilaments contain the majority of H^+,K^+-ATPase activity in stimulated parietal cells. The membranes of these acid-secreting vesicles have a K^+-Cl^- cotransport system that is lacking in membrane preparations from resting cells. [335]

Studies have confirmed that H^+,K^+-ATPase requires extracellular K^+ for electroneutral exchange with H^+. [336], [337] It appears that concomitant with membrane or enzyme translocation, associated K^+ and Cl^- conductances are activated. [335] Opening of this conductance as it moves from tubulovesicles to the canalicular membrane allows H^+,K^+-ATPase to generate H^+. The K^+-Cl^- conductance is intimately associated with H^+,K^+-ATPase, and its function is required for acid secretion. Several other ion channels are involved in maintenance of cellular homeostasis during acid secretion. A schematic representation of parietal cell conductances and pumps is shown in Figure 13-13. Each H^+ ion that is generated results in formation of an intracellular OH^- ion, which reacts with CO_2 in a reaction catalyzed by CAII to form HCO_3^-. A mechanism located on the basolateral membrane permits the exchange of intracellular HCO_3^- for extracellular Cl^-. This Cl^- provides part of the intracellular pool for transport by the apical K^+-Cl^- conductance system. Several types of Cl^-/HCO_3^- exchangers have been described. The one expressed in parietal cell basolateral membranes has been identified as the anion exchanger 2. [338] Parietal cells also express the Na^+-H^+ exchanger NHE1 on basolateral membranes, but to a much lesser degree than in mucous neck and chief cells. Moreover, the level of CAII expression appears to correlate with the level of NHE1 expression in these same cells. The low level of NHE1 in parietal cells may suggest that another exchanger such as NHE4 [339] may play a more important role in the acid secretory process. Although not shown in Figure 13-13, a Na^+-HCO_3^- cotransporter has also been located on parietal cells. [340] The role of this cotransporter in maintaining parietal cell homeostasis has not been determined.

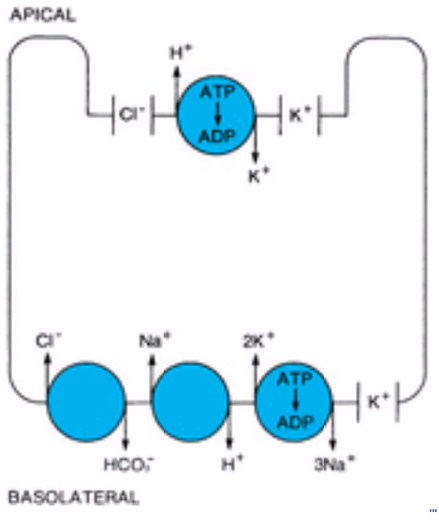

FIGURE 13-13. Ion transport pathways in parietal cells. The apical membrane contains the H $^{+}$,K $^{+}$-ATPase pump and K $^{+}$ and Cl $^{-}$ conductances. The basolateral membrane also has a K $^{+}$ conductance, Cl $^{-}$/HCO $_{3}$ $^{-}$ exchange, Na $^{+}$/H $^{+}$ exchanges, and Na $^{+}$,K SUP>+-ATPases to maintain cellular homeostasis during secretory and resting states.

A second mechanism located on the basolateral cell membrane provides for exchangers of extracellular Na $^{+}$ for intracellular H $^{+}$. The Na $^{+}$ or H $^{+}$ and Cl $^{-}$/HCO $_{3}$ $^{-}$ exchangers are coupled functionally as cellular pH monitors handling excess acid or base loads, respectively. Although physically separate, these exchange mechanisms act as a functional basolateral Na $^{+}$ and Cl $^{-}$ cotransport mechanism. The basolateral membrane also has a K $^{+}$ conductance, which allows intracellular K $^{+}$ to follow the concentration gradient. K $^{+}$ uptake by the parietal cell can occur by means of a basolateral Na $^{+}$,K $^{+}$-ATPase or Na $^{+}$ pump, which appears to translocate three intracellular Na $^{+}$ ions for two extracellular K $^{+}$ ions. The net effect of these ion channels is to maintain cellular homeostasis in the face of HCl secretion. The osmotically active HCl generated in the canalicular lumen results in the flow of H $_{2}$O across the cell. This flow leads to the formation of gastric fluid associated with acid secretion. The gastric H $^{+}$,K $^{+}$-ATPase or H $^{+}$ ion pump has been studied in detail. [341] This membrane protein is a member of the P-ATPase family that includes Na $^{+}$- or K $^{+}$- and Ca $^{+}$-ATPases. Structural homology between these family members suggests that they probably diverged from a common ancestor molecule. [342]

Significant progress has been made toward understanding the structural characteristics of the gastric H $^{+}$,K $^{+}$-ATPase. [343] This critical enzyme in parietal cell biology consists of two subunits, a and ß. The a subunit is larger. The amino acid sequences of the rat, porcine, and rabbit enzymes have been deduced from the corresponding cloned cDNA structures. [344], [345], [346] and [347] Interspecific conservation of the a subunit is greater than 97%; the protein length ranges from 1033 amino acids in the rat to 1035 residues in the rabbit. The gene corresponding to the human a subunit has been cloned and sequenced; [326] it contains 22 exons and has a corresponding deduced protein length of 1035 amino acids.

Several experimental procedures have been used to establish the secondary structure of the a subunit (Fig. 13-14). Initial hydropathy plots of the deduced amino acid sequence suggested that this protein was anchored by seven to nine potential transmembrane domains with a large cytoplasmic site containing an ATP-binding region. [344] Although still controversial, more recent studies capitalizing on a combination of proteolytic cleavage of the enzyme, in vitro translation experiments, and inhibitor-binding studies suggest that the a subunit may contain ten transmembrane segments with a large cytoplasmic domain. [343] The cytoplasmic domain is presumed to include ATP-binding, phosphorylation, and energy transduction sites. Labeling studies suggest that the proton pump inhibitors omeprazole, lansoprazole, and pantoprazole bind to the cysteine residues located at positions 813 and 822. These residues lie near a predicted extracytoplasmic loop between transmembrane domains 5 and 6, and they are thought to be essential for proton pump inhibition of H $^{+}$,K $^{+}$-ATPase. [348], [349] and [350] Elucidation of the tertiary structure of this enzyme requires high-resolution crystallography studies.

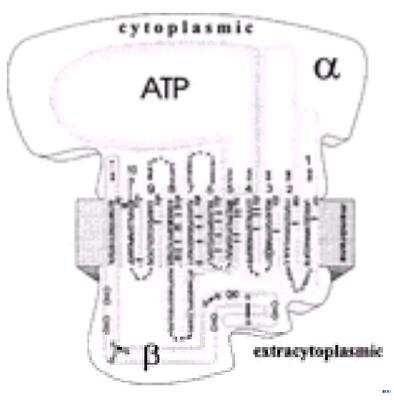

FIGURE 13-14. Model of the two-dimensional structure of the H $^{+}$,K $^{+}$-ATPase illustrating the a and ß subunits. The a subunit contains ten putative transmembrane domains. Hydrophilic amino acids within the postulated membrane anchored domains are shown. (Adapted from ref. [343].)

The cDNA of the H $^{+}$-K $^{+}$-ATPase ß subunit has been isolated and sequenced from several species, including rabbit, [351] rat, [352], [353] and [354] hog, [355] mouse, [356] and human. [357] The average length of this subunit ranges from 290 to 294 amino acids, and hydropathy plots suggest a single transmembrane domain. Although the role of the ß subunit has not been established, several lines of investigation suggest that it may be important for assembly and stabilization of the functional a subunit. Insight into the functional role of the H $^{+}$,K $^{+}$-ATPase ß subunit has been gained by studies conducted in transgenic animals. [358] Courtois-Coutry and colleagues [358] noted that the cytoplasmic tail of the H $^{+}$,K $^{+}$-ATPase ß subunit displays a four-residue sequence homologous to tyrosine-based endocytosis signals. Mutation of this motif's tyrosine and expression of the mutated H $^{+}$,K $^{+}$-ATPase ß subunit in transgenic animals led to constitutive secretion of acid and to the continuous expression of the mutated H $^{+}$,K $^{+}$-ATPase at the cell surface. Thus, the H $^{+}$,K $^{+}$-ATPase ß subunit appears to play an important role in the process of H $^{+}$,K $^{+}$-ATPase internalization and in the termination of gastric acid secretion. [358]

The timing of the association between a and ß subunits of the H $^{+}$,K $^{+}$-ATPase and the initial steps in cellular trafficking for this enzyme have been determined. Crothers and associated [359] used the method of in vivo protein metabolic labeling in conjunction with subcellular fractionation to examine these issues in rabbit parietal cells. These investigators observed that the a and ß subunits associated early in the endoplasmic reticulum. Moreover, the newly synthesized H $^{+}$,K $^{+}$-ATPase migrated sequentially through at least three distinct membrane pools. Future studies should reveal the impact of pharmacological manipulation on synthesis and trafficking of this important enzyme in parietal cells.

H $^{+}$,K $^{+}$-ATPase can be inactivated completely by omeprazole, lansoprazole, rabeprazole, and pantoprazole. These compounds become cyclic in the presence of acid and react with available sulfhydryl groups to form a covalent interaction that irreversibly inactivates the enzyme. The blockade of proton transport is virtually complete and has been used clinically as described in Chapter 66.

OTHER GASTRIC SECRETORY PRODUCTS

Histamine

Histamine plays a critical role in regulating gastric acid secretion through the activation of the parietal cell H_2 receptor. There is evidence that histamine mediates in part the stimulatory effect of other secretagogues (e.g., gastrin, carbachol) on parietal cells. The relative importance of the two histamine-containing cell types found in the stomach (i.e., mast cells, ECL cells) in regulating gastric acid secretion has been the source of some debate. The ratio of the two cell types in gastric mucosa depends on the species examined. Early studies using isolated mast cells obtained from canine gastric mucosa indicated that gastrin and cholinergic agents did not stimulate histamine release, and this observation was used to support the contention that these secretagogues induced acid secretion by direct action on parietal cells rather than by stimulating histamine release. However, these data were at odds with studies demonstrating that pentagastrin stimulated the release of histamine from gastric mucosal preparations. Chuang and colleagues [360] shed light on this controversy by successfully isolating and characterizing a population of non–mast cells from canine oxyntic mucosa that contain histamine and have the morphologic characteristics of ECL cells. Gastrin nd carbachol stimulate histamine release from ECL cells when they are isolated and cultured. It is possible that the secretagogue actions of gastrin and carbachol can be mediated, at least in part, through the action of histamine. Such studies reinforce the concept that regulation of gastric acid secretion involves a complex interplay between multiple pathways and receptors.

Development of the isolated ECL cell model has facilitated the study of this important source of gastric histamine. Gastrin-stimulated histamine release from ECL cells occurs through the CCKB/gastrin receptor, which is coupled to a Ca^{2+} signaling pathway. [361], [362] Histamine release is also stimulated by factors that increase cAMP, such as agonists of the ß-adrenergic receptor, forskolin, and pituitary adenylate cyclase–activating peptide (PACAP). [361], [363] Research indicates that the PACAP type I receptor subtype regulates histamine release and $[Ca^{2+}]_i$ mobilization. [364] As one would anticipate, ECL cells are also under inhibitory restraints. Somatostatin binds to an SSTR2 receptor subtype, inhibiting histamine release and Ca^{2+} signaling. [365] Histamine appears to regulate its own release through an H_3 receptor subtype located on ECL cells, thus creating an autocrine feedback loop. [361] Peptide YY has also been observed to inhibit histamine release through a Y_1 receptor subtype. [363]

Histamine is generated in ECL cells by decarboxylation of histidine by the enzyme histidine decarboxylase (HDC). [366], [367] HDC is transcriptionally activated by both gastrin and acetylcholine. Studies by Hocker and colleagues [368], [369] have demonstrated that gastrin stimulates HDC transcription through a PKC- and MAP kinase–dependent pathway. In view of reports demonstrating the development of ECL hyperplasia and gastric carcinoid tumors in animals receiving large doses of proton pump inhibitors, there has been increased interest in understanding the regulation of ECL cell proliferation. [370] Both in vivo and in vitro studies have demonstrated that gastrin has a direct proliferative effect on these cells, thus supporting the concept that hypergastrinemia resulting from potent acid suppression is responsible for increased ECL proliferation in these animal models. [371], [372], [373], [374], [375], [376] and [377] The relevance of these observations to human physiology is unclear, considering the studies demonstrating that the human ECL cell is terminally differentiated and is not capable of undergoing proliferation. [378]

An attempt to determine the relative importance of histamine-containing mast cells and ECL cells in the regulation of gastric acid secretion was made by Stechschulte and colleagues. [379] These investigators observed that mast cell–deficient mice had about 50% of the normal quantity of gastric histamine in addition to diminished basal and stimulated acid secretory activity. They concluded that non–mast cell histamine may account for only part of the basal and stimulated gastric secretory response.

Pepsinogen

The secretion of pepsinogen by the gastric mucosa occurs in response to food ingestion, as described by Langley in 1886. [380] Pepsinogens are inactive proenzymes that are autocatalytically cleaved under acidic conditions to generate their active form, pepsin. The proenzyme is synthesized in exocrine chief cells found at the base of oxyntic glands and in mucous neck and mucous cells in cardiac, oxyntic, and pyloric glands. [381] Chief cells package pepsinogen in apical granules, where it is stored until the cells are stimulated. Stimulation of chief cells by various secretagogues induces exocytosis of granule contents into the glandular lumen. Concomitant stimulation of parietal cells provides the acidic lumenal conditions needed for rapid production of pepsin, the major acid protease activity in the stomach. Pepsin is a member of the group of proteolytic enzymes classified as aspartic proteases. [382] Members of this enzyme family are found in an array of organisms extending from plants and retroviruses to humans. The stomach is the best source of aspartic proteases in mammals, and pepsin is the representative member.

This protease initiates protein digestion and is particularly active in proteolysis of collagen, a major protein component of meat. Peptides generated by the proteolytic activity of pepsin act as signals for secretion of digestive hormones such as gastrin and CCK. These peptide signals initiate the coordinated digestive response necessary for the absorption of nutrients.

Pepsinogens have been electrophoretically separated into seven isozymogens. [383] Five fractions (i.e., fractions 1 through 5) that migrate toward the anode rapidly are immunologically similar and have been named group I pepsinogens (PGI or PGA). Group II pepsinogens (i.e., fractions 6 and 7) migrate slightly slower in gels and are antigenically similar (i.e., PGII, PGC, or progastricsin). Both groups are active in acidic conditions (pH 2–3.5) and are inactivated at a pH higher than 5. Despite these similarities, many biochemical and immunochemical differences between PGI and PGII are the subject of intense investigation.

The distribution of the two pepsinogen groups in gastrointestinal tissues varies. Although both groups are found in the gastric body, group I pepsinogen being the most abundant, only group II pepsinogens are found in the gastric antrum, proximal duodenum, and the Brunner glands. The presence of different isozymogens could be the result of multiple gene loci, multiple alleles at a single gene locus, alternate posttranscriptional processing of RNA, or posttranslational modifications of primary gene products. Genetic analysis has revealed that the two groups have different gene loci. A human pepsinogen I gene has been isolated, sequenced, and localized to chromosome 11q12-13. [384], [385] and [386] Analysis of its locus indicates the presence of multiple pepsinogen I genes. [387] This type of multigene protein polymorphism is rare and suggests that the pepsinogen gene complex is undergoing evolutionary gene duplication and selection. Other mechanisms of isozymogen diversity, such as posttranslational modification, may also be active.

Taggart and colleagues [388] isolated and sequenced the cDNA and gene coding human pepsinogen II (PGC, progastricsin). Analysis of the genomic clones suggests there is a single *PGC* gene located on chromosome 6. Structural comparisons between PGI (i.e., PGA) and PGII (i.e., PGC) demonstrate that they share 60% nucleotide and 50% amino acid identity. No immunologic cross-reactivity was detected between the two groups of human pepsinogens A and C. This lack of immunologic cross-reactivity may result from divergent evolution of sequences located on the surface of the enzymes, in contrast to the highly conserved sequences at the biologically active sites of the zymogen located within the binding cleft of the enzyme.

The stimulation of pepsinogen secretion has been analyzed in intact animals, gastric mucosal preparations, gastric glands, and isolated chief cells. Despite the use of different species in these models, certain generalizations about the mechanisms of chief cell activation are supported by the data. Acetylcholine and its analogs appear to stimulate chief cells directly through muscarinic receptors. [389], [390] Other neuronal mediators, such as gastrin-releasing peptide, may also mediate vagal stimulation of pepsinogen secretion. [391] The adrenergic agonist isoproterenol has a stimulatory effect in vitro, [392] although the physiological significance of this effect has not been demonstrated in intact animals. The ability of histamine to stimulate pepsinogen secretion remains controversial, and conflicting data preclude any definitive conclusion. [381]

Although gastrin stimulates chief cells only weakly, CCK-8 is a potent stimulus of pepsinogen secretion in vitro. [393] The finding that peripherally administered CCK in vivo only weakly stimulates pepsinogen secretion may reflect CCK's function as a neurocrine, rather than endocrine, mediator of chief cell stimulation. Alternatively, it may reflect the mixed effects of a direct stimulatory effect on chief cells and an indirect inhibitory effect such as could be mediated by CCK-induced somatostatin release.

Secretin has been reported to stimulate pepsinogen secretion in vivo and in vitro. [393], [394] The intracellular signal transduction mechanisms activated by the various chief cell secretagogues have been analyzed. Secretin, isoproterenol, and vasoactive intestinal polypeptide stimulate pepsinogen release through cell surface receptors linked to the activation of adenylate cyclase and cAMP formation. [381] Several peptide hormones including somatostatin, neuropeptide Y, and peptide YY have been found to inhibit pepsinogen release from isolated chief cells through a pertussis toxin–sensitive mechanism. Other secretagogues, such as cholinergic agonists and CCK, stimulate pepsinogen release in chief cells by activating the IP_3 and $[Ca^{2+}]_i$ signaling pathway. [395] and [396] Activation of the chief cell muscarinic receptor leads to a modest increase (15%) in PKC enzyme activity while stimulating a threefold increase in pepsinogen secretion. [397] Of interest, doses of carbachol capable of inducing pepsinogen release did not alter PKC activity, suggesting that other pathways independent of PKC, such as changes in cytosolic Ca^{2+}, may be sufficient for enzyme release. However, a maximal stimulatory effect of carbachol on pepsinogen release was achieved only at doses that also led to PKC activation. From these data, it appears that PKC, although not essential for enzyme release, may be involved in modulating the maximal response achieved by activation of the

muscarinic receptor.

Further insight into the postreceptor events involved in secretagogue-mediated pepsinogen secretion have been gained. The involvement of the Ca^{2+} signaling pathway as an important mechanism for chief cell activation has been reaffirmed. [398] Moreover, it appears that the increase in cytosolic Ca^{2+} is important for the ability of ligands such as CCK-8 to potentiate the stimulatory effect of agents such as secretin, which activates cAMP production in chief cells. This potentiation in pepsinogen release occurs independent of the Ca^{2+} source (intracellular or extracellular). As is the case in other cell systems, the Ca^{2+}/CaMKII is also involved in Ca^{2+}-mediated pepsinogen secretion. [399] Protein phosphatase-2B (calcineurin) is a Ca^{2+}/calmodulin-dependent serine/threonine protein phosphatase involved in signaling of cells from a variety of tissues. [400], [401] Raufman and colleagues [402] demonstrated that gastric chief cells express this phosphatase and that it modulates Ca^{2+}-induced potentiation of the cAMP signaling pathways at the level of adenylate cyclase. [403] Moreover, this specific phosphatase appears to be involved in Ca^{2+}-induced pepsinogen secretion by facilitating phosphorylation of a specific 55-kd cytoskeletal protein, which, in turn, regulates exocytosis.

As in gastric parietal cells, Rab proteins appear to be involved in chief cell intracellular trafficking. [404], [405] Specifically, Rab3 proteins appear to regulate pepsinogen secretion at one of the final steps of exocytosis. [404] Chief cells also express two isoforms of Rab-GDP-dissociation inhibitor (Rab-GDI), [405] which are proteins that, in addition to inhibiting the dissociation of GDP from Ras, inhibit the binding of GTP to GDP-bound Rab, thus removing Rab proteins from membranes. [406], [407] and [408]

The mechanism by which PKC modulates (i.e., augments) Ca^{2+}-induced pepsinogen secretion is unclear. A member of the family of proteins known as MARCKS (myristoylated alanine-rich C kinase substrate) has been suggested to play an important role in mediating the cross talk between PKC and Ca^{2+} calmodulin-stimulated pepsinogen secretion. [409] Specifically, a MARCKS protein may serve as a Ca^{2+}/calmodulin buffer, which, on phosphorylation, releases calmodulin from membranes and makes it available to bind and activate other signaling proteins such as Ca^{2+}/calmodulin kinase II and calcineurin. [410] In a series of immunologic and biochemical studies, Raufman's group presented evidence to suggest that an acidic 72-kd-protein (pp72) serves as a MARCKS protein in chief cells. It appears that PKC-induced phosphorylation and Ca^{2+}/calmodulin binding compete for similar regions on pp72. Therefore, PKC may enhance Ca^{2+}-induced pepsinogen secretion by phosphorylating MARCKS, decreasing its affinity for calmodulin, and facilitating activation of downstream targets important for pepsinogen secretion such as Ca^{2+}/calmodulin kinase II and calcineurin. [410]

An additional signaling pathway involved in pepsinogen secretion is the nitric oxide (NO) system. [411], [412] Gastric chief cells express a Ca^{2+}/calmodulin–dependent NO synthase that initially was observed to mediate pepsinogen secretion stimulated by leukotrienes (LTB_4, LTC_4, LTD_4, and LTE_4). [411] This pathway also appears to be involved in the action of Ca^{2+}-dependent agonists such as carbachol, gastrin, CCK, thapsigargin, and Ca^{2+} ionophore.

Pepsinogens are found in the gastric secretions, serum, urine, and seminal fluid. [413], [414] Their physiological role in nongastric fluids is unknown. Measurement of pepsinogens in these fluids is performed with specific radioimmunoassays. [413] Attempts to correlate serum pepsinogen groups with risk of peptic ulcer disease have proven to be of modest clinical value (see Chapter 66). Azuma and colleagues, [415] studying Japanese patients with gastric ulcers, found no genetic polymorphism for the pepsinogen A gene, but observed a 100-base pair insertion-deletion restriction fragment–length polymorphisms in the pepsinogen C gene. Genotypes that contained the small fragment were significantly more common in patients with gastric body ulcers than in patients with angular or antral ulcers or in controls. The clinical implication of this interesting observation has not been determined. Advances in our understanding of pepsinogen physiology and pathophysiology may lend these measurements new clinical significance.

Mucus

Gastric epithelium is partially protected from acidic autodigestion by a mucous gel that covers the entire surface of the stomach (for further discussion of gastric mucosal defense mechanisms, see Chapter 66). This gel acts as a barrier, protecting the gastric mucosa from acid, pepsin, bile salts, alcohol, and other injurious agents. The barrier consists of an unstirred layer of mucus, HCO_3^-, surface phospholipids, and water. A prominent pH gradient extending from the lumen (pH 2) to the epithelial cell surface (pH 7) is maintained by this gel. [416] Bhaskar and colleagues [417] shed light on the physical-chemical basis for the barrier function of gastric mucus. In a series of elegant in vitro experiments, these researchers demonstrated that injection of HCl through solutions of porcine gastric mucin produces viscous fingering patterns that depend on pH, mucin concentration, and acid flow rate. If the pH is greater than 4, discrete fingers are observed; at a pH of less than 4, these fingers are not seen, and HCl does not penetrate the mucin solution. Acid secreted by the gastric gland that exists in a pH 5 to 7 environment can penetrate the mucus gel layer through narrow fingers. In contrast, HCl in the gastric lumen (pH 2) is prevented from diffusing back to the epithelium by the high viscosity of the gastric mucus gel on the lumenal side.

Mucin, a high-molecular-weight glycoprotein, is secreted by surface mucous cells, mucous neck cells, and glandular mucous cells. Polymerization of mucin subunits by means of disulfide bonds is essential for the formation of the hydrated gel. [418] The precise structural organization and approximate molecular weight of mucin polymers are unknown. Two significantly different models of gastric mucin polymerization have been proposed and are described in other reviews. [419], [420] The peptide backbone of mucin contains many serine, threonine, and proline residues (>40% molecular weight) that serve as the amino acid anchors for the glycosyl residues that branch from the protein. Partial and complete cDNA clones for mucin have been isolated, and deduced peptide sequences confirm this amino acid preponderance. [421], [422], [423] and [424] The structural analysis indicates that the mucin backbone contains extended arrays of tandemly repetitive peptides rich in threonine or serines that are potential sites for *O*-glycosylation.

Multiple mucin gene products are expressed at various sites. Specific cDNA clones coding mucins found in submaxillary glands, tracheobronchial tree, and intestinal mucosa have been isolated and characterized. [425], [426], [427] and [428] Toribara and colleagues [424] isolated a cDNA clone coding human gastric mucin, which is characterized by tandem repeat sequences rich in threonine, serine, and proline. [424] This gene is expressed primarily in the stomach and the gallbladder and has been localized on chromosome 11 (11p15.4-11p15.5). The unique gastric mucin has been called MUC6. The mucin that is synthesized in the rough endoplasmic reticulum undergoes vesicular transport to the Golgi apparatus for glycosylation. The major portion of mucin is heavily glycosylated, and nonglycosylated or "naked" regions of the peptide are joined to other mucins by disulfide bridges. The initial peptide-carbohydrate linkage involves glycosidic bond formation between *N*-acetylgalactosamine and the hydroxyl groups of serine or threonine residues. This type of *O*-linked glycosylation involves the addition of individual carbohydrate moieties, rather than the transfer of preassembled oligosaccharides, to gradually lengthening chains. [429] Fucose, galactose, *N*-acetylglucosamine, and *N*-acetylgalactosamine make up more than 95% of the sugar moieties in each chain. [430] Each mucin peptide contains up to several hundred linear or branched-chain oligosaccharides. This high carbohydrate content (>50% by weight) results in a highly viscoelastic substance that expands when hydrated. These properties may be essential to the protective function served by gastric mucus.

The intracellular transport of mucin proceeds through the cis-, medial-, and trans-Golgi cisternae before transfer to the apical mucous granule. Cytoplasmic transport vesicles presumably bud off Golgi membranes and transfer mucus to its target organelles. Fusion of vesicle and granule membranes results in gradually enlarging mucous granules that ultimately pack the apical cytoplasm. Intact microtubules appear to be needed for transport of secretory granules from the Golgi apparatus to the cell surface. Basal secretion of mucus occurs continually throughout the life span of mucous cells. [431] In vitro pulse labeling of human mucous granules reveals that intracellular transit and release occurs in 20 to 24 hours. In contrast to basal secretion, stimulation of mucous cells results in fairly rapid fusion of granular and apical cell membranes or extrusion of mucous granule contents. Fusion of subjacent mucous granules enhances the secretory response. This process is called *compound exocytosis* and results in a dramatically cavitated apical cell surface during stimulated secretion.

Study of the regulation of mucous cell secretion has been impeded by the inherent difficulties in quantitatively retrieving and measuring secreted mucus. Hydration of secreted mucus forms a viscous gel that adheres to mucosal cells. Attempts to quantify mucus secretion by morphologic methods, [432] release of radiolabeled glycoproteins, [433] and radioimmunoassay [434] have met with only limited success. Despite these limitations, several factors that affect mucin secretion have been identified and can be summarized.

Cholinergic agonists stimulate secretion in a portion of gastric mucous cells, but adrenergic neurotransmitters do not appear to influence release of secretory granules. Gastrin and CCK may increase feline gastric lumenal carbohydrate content, but the source of this presumed mucus secretion has not been determined. [435] Similarly, secretin has also been shown to increase the carbohydrate content of secreted gastric mucus in humans, but the cellular origin of this effect also is unknown. [436] PGE and PGF have been reported to stimulate the release of soluble and insoluble mucin from gastric mucosa, with a resultant increase in mucous gel

thickness. [437], [438] This increase may be produced by prostaglandin-induced HCO_3^- secretion, creating an outward alkaline flow carrying previously secreted mucins from gastric crypts and glands. [439] After gastric mucosal injury has occurred, multiple inflammatory and immune cytokines may be present in the mucosa. It seems plausible that these factors directly or indirectly stimulate mucous cell secretion as part of the reparative process. [418] Candidate secretagogues include leukotrienes, immune complexes, and mast cell histamine.

Boland and colleagues [440] established a system for isolating and culturing canine gastric mucous cells and demonstrated that the cells synthesize and secrete mucin and phospholipids. [440] Mucin glycoprotein and surface-active phospholipids may form a biochemical complex that is analogous to pulmonary surfactant, and it is this complex that may be critical for providing the gastric epithelium its protective barrier. PGE_2 may enhance mucosal defense through the release of surface-active phospholipids by gastric mucous cells. Other studies have demonstrated that the same secretagogues that stimulate gastric acid secretion (e.g., histamine, gastrin, carbachol) can stimulate mucin synthesis and release of surface-active phospholipids. [441], [442] Gastrin, in particular has been shown to stimulate the biosynthesis of mucin from surface mucus cells of the rat through NO-dependent mechanism, because NO synthase inhibitors were able to block the stimulatory action of gastrin. [443] These observations suggest that gastric acid secretion (i.e., aggressive factor) and gastric mucosal defense are regulated in a coordinated or parallel fashion.

Mucous cells presumably have various receptors mediating stimulatory effects on their basolateral membrane, but no specific receptors have been demonstrated on these cells. Part of the difficulty in performing radioreceptor binding studies in this cell type is the high level of nonspecific ligand binding to the mucous gel. Functional studies have suggested that carbachol, histamine, and gastrin act directly on gastric mucous cells. Seidler and Pfeiffer [444] demonstrated that acetylcholine stimulates IP_3 formation, $[Ca^{2+}]_i$ mobilization, and mucin release from isolated gastric mucous cells. However, neither dibutyryl AMP nor phosphodiesterase inhibitors have been shown to stimulate mucin release from intestinal mucous cells. [445] Conversely, a Ca^{2+} ionophore has been shown to induce visible loss of mucous granules from guinea pig gastric mucosa and to increase the thickness of the mucous gel. [446] Together, these results suggest that gastric mucous cells may be stimulated by secretagogues that use the Ca^{2+}-mediated intracellular pathways.

Research has indicated that activation of protease-activated receptor 2 (PAR-2) leads to the secretion of gastric mucus through the release of calcitonin gene–related peptide and tachykinins from sensory neurons, suggesting a novel mechanism for the regulation of mucus secretion in the stomach. [447] Much remains to be learned about the regulation of gastric mucous cell secretion in the basal and stimulated states.

Bicarbonate

Gastric mucosal defense depends on a mucus-HCO_3^- barrier coating the entire lumen of the stomach. This barrier exists as a gel with a pH gradient that provides a neutral microenvironment at the epithelial surface. The gradient is generated by the secretion of HCO_3^- by gastric surface mucous cells. HCO_3^- uptake at the basolateral membrane and secretion at the apical membrane are metabolically dependent processes. [448] CA, the enzyme responsible for HCO_3^- generation, has also been localized to the apical matrix and microvillous cores of surface epithelial cells. [449] HCO_3^- secretion appears to be mediated by a Cl^- and HCO_3^- exchange mechanism on the lumenal surface of gastric epithelial cells. [450] In addition to active secretion, passive efflux of HCO_3^- presumably occurs through a paracellular route. Mucosal delivery of HCO_3^- ions is enhanced by fenestrations of the capillaries supplying the epithelial cells. [53] The relative proportion of passive and active HCO_3^- secretion in basal and stimulated states has been difficult to determine and depends on the type of model studied.

Several models have been used to measure gastric HCO_3^- secretion. Mucosal membranes can be mounted in chambers and bathed with appropriate solutions. [451], [452] and [453] Titration of lumenal secretions is used to calculate HCO_3^- release. In vivo measurements have been performed in fundic and antral pouches and are described elsewhere. [454], [455] In humans, gastric HCO_3^- secretion can be measured in vivo by back-titration after complete pharmacological inhibition of acid secretion. [456] Another technique involves rapid perfusion of the stomach (30 mL/min), with continuous measurement of PCO_2 and pH in the gastric aspirate. [457] HCO_3^- and H^+ secretion can then be calculated by the Henderson-Hasselbalch equation. This technique relies on the assumption that all lumenal CO_2 results from neutralization of H^+ ions by HCO_3^-. A third approach uses a two-component model that calculates gastric HCO_3^- secretion from measurements of gastric juice volume, H^+ concentration, and osmolality. [458] This model assumes a fixed relation between the osmolality of plasma and that of gastric secretions such that a decrease in osmolality occurs only as a result of H^+ and HCO_3^- neutralization. This method results in a higher calculation of gastric HCO_3^- secretory rate (2300 µEq/h) than obtained with other methods (400 µEq/h).

Because of the quantitative differences observed with the various methods used, Odes and colleagues [459] performed detailed in vivo and in vitro studies using the different techniques outlined. They observed that in the acid-suppressed stomach, gastric HCO_3^- is accurately determined by back-titration. However, measurement of HCO_3^- in the acid-secreting stomach is not accurate with any of the methods tested. Despite these quantitative differences, responses to various stimuli are qualitatively similar with all the techniques.

Regulation of gastric HCO_3^- secretion is an important component of gastric mucosal defense. Sham feeding and electrical stimulation of the vagus induce gastric HCO_3^- secretion. [460], [461] and [462] This neural control mechanism is effectively blocked by atropine and benzilonium bromide. Intravenous infusion of cholinergic agents such as bethanechol also stimulate HCO_3^- and H^+ secretion. [456], [458] The coordinated stimulation of acid and HCO_3^- secretion by vagal transmitters is not reproduced by gastrin or histamine. Local regulation of HCO_3^- secretion is initiated by the presence of lumenal acid. Studies using canine denervated pouches [463] and isolated frog mucosal strips [464] suggest that a humoral factor that stimulates HCO_3^- secretion is released in response to lumenal acid. Although exogenous prostaglandins have been shown to stimulate gastric and duodenal HCO_3^- secretion, the physiological role of endogenous prostaglandins in HCO_3^- control is less clear. [448], [465] The inhibition of gastric HCO_3^- secretion is not well characterized. Vagal stimuli and lumenal acid appear to stimulate surface mucous cells to secrete HCO_3^-. Acid stimulation also results in delivery of HCO_3^- from the parietal cells to the surface epithelium by ascending mucosal capillaries (i.e., the alkaline tide). These regulatory controls ensure simultaneous secretion of gastric acid and HCO_3^-.

Intrinsic Factor

IF, a 45-kd glycoprotein present in gastric secretions, is essential for the absorption of cobalamin (vitamin B_{12}) in the terminal ileum by receptor-mediated endocytosis. Its existence was first postulated by Castle in 1929. [466] Human IF is synthesized and secreted by parietal cells. [467] Parietal cells also are the source of IF in cats, rabbits, monkeys, guinea pigs, and oxen. [444] In rodents such as the rat and mouse, chief cells produce IF, and its source in pig is gastric mucous cells. [469], [470] The structure of rat IF, as deduced from a cDNA clone, indicates a primary amino acid sequence of 421 amino acids, with a putative signal sequence of 22 amino acids. [470] The cobalamin-binding domain is thought to reside in the NH_2-terminal half of the protein. There is 80% identity between the predicted amino acid sequences corresponding to rat and human IFs. [471] The single human IF factor gene, located on chromosome 11, and the human IF appears to have a high degree of conservation with monkey, rat, mouse, and cow IFs.

IF is secreted in amounts far exceeding that necessary for cobalamin absorption. [472] Secretion of IF is stimulated by the same pharmacological agents as acid secretion—pentagastrin, histamine, and cholinergic agonists—but this secretory response is not linked to acid secretion. [473] For example, omeprazole does not alter basal or stimulated IF secretion in humans, nor does it alter the absorption of labeled cobalamin. [474], [475] The intracellular responses mediating IF secretion involve the cAMP pathway when stimulated by histamine. [473] Whether pentagastrin and acetylcholine, which appear to act through Ca^{2+}-phospholipid–dependent pathways when stimulating acid secretion, act in a similar fashion when stimulating IF secretion is unknown.

Inhibitory regulation of IF secretion is poorly understood. Somatostatin inhibits histamine- or pentagastrin-stimulated IF secretion in isolated guinea pig gastric glands. [476] EGF is reported to inhibit histamine-stimulated IF secretion in rabbit isolated gastric glands and in humans. [477], [478] The physiological significance of these

observations is unknown.

IF resists digestion by gastric acid and proteolytic enzymes under normal circumstances. A rare kindred with cobalamin malabsorption caused by an abnormal IF that was susceptible to acid and proteolysis has been reported. [479] An absence of IF secretion occurs rarely in persons, usually children, with normal acid secretion. [480], [481] The discussion of the significance of IF in health and disease is continued in Chapter 20.

Human tissue studies have demonstrated that IF is expressed not only in parietal cells, but also in gastric chief cells and enteroendocrine cells. [482] The expression of IF in these latter sites appears to be lower than the level of expression in parietal cells. Some investigators have suggested that the principal reason for the differential expression of IF in different cell types lies in the variation between untranslated region of the human and rat's gene, [483] however, the observation that IF can also be expressed in human chief cells goes somewhat against this theory. [482] Questions still remain regarding the interspecific variation in IF expression and the cellular pathways that regulate IF synthesis and secretion.

Prostaglandins

The role of prostaglandins in gastric acid secretion and mucosal defense has been an area of active research. Prostaglandins are 20-carbon fatty acid derivatives that have diverse biologic activities and are produced in many different tissues. They are synthesized from arachidonic acid, a product of enzymatic cleavage of cell membrane phospholipids by phospholipases, particularly phospholipase A_2. [484] Cyclooxygenase rapidly metabolizes free arachidonic acid to cyclic endoperoxides that are transformed to various prostaglandin subtypes by tissue-specific processing enzymes (Fig. 13-15). PGE_2 and PGI_2 (or prostacyclin) are synthesized and secreted by the gastric mucosa of various species. The presence of these two predominant forms in homogenates of gastric mucosa has been confirmed by bioassay, radioimmunoassay, and gas chromatography with mass spectrometry. Biosynthetic studies using radiolabeled arachidonic acid have confirmed that gastric mucosa can synthesize both these prostaglandins. The specific mucosal cell types synthesizing the various prostaglandins have not been identified. Although canine and rat parietal cell fractions appear to form several prostaglandin subtypes, other cells, such as mucous and chief cells, may also synthesize prostaglandins.

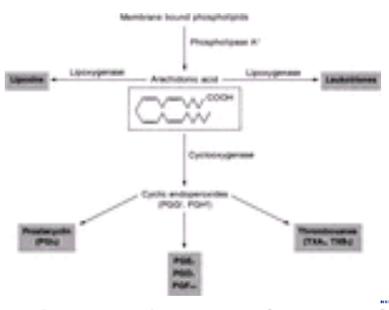

FIGURE 13-15. Pathways of arachidonic acid metabolism.

Gastric prostaglandins are likely to have paracrine effects on other gastric mucosal cells. One example is direct inhibition of acid secretion by prostaglandins. Studies of canine parietal cells show that PGE_2 decreases [^{14}C]aminopyrine accumulation and cAMP production. [217] This effect appears to be mediated through prostaglandin receptors activating inhibitory guanine nucleotide–binding proteins. [485] Inhibition of parietal cells could be one effect of a prostaglandin-mediated negative-feedback loop regulating gastric acid secretion.

Prostaglandins may also function as lumenal hormones. PGE_2 has been demonstrated in the gastric juice of several species, including humans, cats, dogs, and rats. [484] Secretion of PGE_2 into lumenal fluid is maximal during pentagastrin-stimulated acid secretion. The presence of prostaglandins in gastric juice and gastric mucosa may facilitate the diverse cytoprotective functions ascribed to these agents, in addition to their antisecretory effects. These functions include the following: stimulation of mucus, phospholipid, and HCO_3^- secretion; enhancement of mucosal blood flow; reduction of mucosal H^+ ion back-diffusion; and stimulation of mucosal cell turnover. Prostaglandins may function in this way to mediate mucosal defense.

Prostaglandin deficiency may predispose to gastric mucosal injury. Cyclooxygenase inhibitors such as aspirin and non-steroidal antiinflammatory agents produce a spectrum of mucosal injuries in the stomach. Immunization against prostaglandins has caused ulcers in rabbits. [486], [487] Part of the cause of these ulcerations is a decrease in prostaglandin-mediated mucosal defense. These observations have served as the basis for the development of prostaglandins for use in the treatment of acid or peptic diseases of the stomach (see Chapter 66).

CLINICAL IMPLICATIONS OF GASTRIC SECRETION

Gastric acid secretion is a well-studied process with a history involving many of the legendary names in gastrointestinal research, such as Beaumont, Pavlov, and Grossman. There are few bodily functions that have been examined so completely in vivo and in vitro as the stomach in processing food and initiating the digestive process. It should be remembered, however, that human patients with no stomachs can live normal lives if they are provided with vitamin B_{12}.

Disorders Associated with Increased Acid Secretion

Despite the landmark discovery of *Helicobacter pylori* and its central role in the pathogenesis of peptic ulcer disease, gastric acid continues to be an important factor in the equation leading to disruption of gastric and duodenal mucosal integrity. The mechanisms by which this bacterium, which resides in the gastric mucosa, produces duodenal ulcerations remain unknown. Abnormalities in the gastric secretory process have been described in patients with *H pylori* and duodenal ulcers. This subject is discussed in greater detail in Chapter 66, but a brief overview is included here. Patients with duodenal ulcers who are infected with *H pylori* have a threefold elevated BAO and an increased maximal acid response to gastrin as compared with *H pylori*–negative volunteers. [488] A more dramatic difference is noted between these groups of patients when the gastric acid response to gastrin releasing peptide is examined. A sixfold increase in BAO occurs in those infected with *H pylori*. These abnormalities are reversible with eradication of the organism. Additional abnormalities observed in *H pylori*–infected individuals include increased basal and meal-stimulated gastrin levels [489], [490] and decreased gastric somatostatin levels. [491] More recent work has demonstrated that infection with *H pylori* may result in alteration of the pathways important in inhibiting gastric secretion. Specifically, *H pylori* infection in patients with duodenal ulcers decreases the inhibitory action of CCK. This defect in CCK-mediated inhibition is corrected after eradication of *H pylori.* [492], [493] Olbe and colleagues [494] observed that infection with this bacterium blocked antral distention–mediated inhibition of gastrin release and acid secretion in a manner that was reversible with *H pylori* eradication. Of note, the abnormality occurred independent of duodenal ulcer status. From these data, it is theorized that dysregulation of acid secretion in patients infected with *H pylori* leads to the delivery of greater amounts of acid to the duodenum that, in turn, promotes ulcer development. The observation that a block in antral distention–mediated inhibition of acid secretion occurs independent of ulcer formation suggests that other factors must be involved in the pathogenesis of this common disorder. Although these are interesting theories, the role of gastric secretory abnormalities in *H pylori*–mediated peptic ulcer disease is not established.

Zollinger-Ellison syndrome is a disorder in which there is autonomous hypersecretion of gastrin by an islet cell tumor, usually situated in the pancreas. There is gross hypersecretion of acid in the basal state and a poor response to exogenous secretagogues. The BAO usually is greater than 15 mmol per hour, and the ratio of BAO to MAO usually is greater than or equal to 0.6. These tests are useful for differentiating hypergastrinemia caused by Zollinger-Ellison syndrome from the more common situation in which serum gastrin levels are elevated as a consequence of achlorhydria.

Retained gastric antrum syndrome is a rare consequence of antrectomy and Billroth II gastrojejunostomy, in which the gastric secretions are directed away from a distal segment of unresected antrum. Because the antral segment is not in contact with the acidic gastric contents, the normal negative-feedback loop in which gastrin release is inhibited at low intralumenal pH concentrations is not activated. This results in unrestrained secretion of gastrin and continuous stimulation of acid secretion. Some patients with retained antrum syndrome have recurrent peptic ulceration.

Excess production of histamine is an unusual cause of gastric acid hypersecretion. It is found with systemic mastocytosis, foregut carcinoid tumors, and basophilic leukemia. Even rarer causes of significant hypersecretion are extensive resections of the small bowel and raised intracranial pressure. [495], [496]

Disorders of Gastric Acid Hyposecretion

The most common hyposecretory disorder is chronic atrophic gastritis. This condition is accompanied by hypochlorhydria or achlorhydria. Because of the absence of gastric acid, the negative-feedback control of gastrin release is interrupted, and these patients have elevated serum gastrin levels, frequently as high as 1000 pg/mL or more. [497] These patients may be misdiagnosed, on the basis of hypergastrinemia, as having Zollinger-Ellison syndrome unless acid secretory studies are performed.

Chronic atrophic gastritis often is accompanied by an absence of IF secretion. This deficiency leads to pernicious anemia, a disease characterized by the failure of cobalamin absorption in the terminal ileum and megaloblastic anemia. These patients usually display circulating antibodies to IF and parietal cells, which may have an etiopathogenetic role in inducing or maintaining IF or acid hyposecretion. [498], [499] There are rare cases, usually among children, of IF hyposecretion in the presence of normal acid secretion. [480], [481]

Reduced acid and pepsin secretion often occurs in patients with gastric ulcers, gastric polyps, and gastric carcinoma. Hyposecretion of gastric acid is common after partial gastrectomy or vagotomy procedures.

Several reports have documented decreased gastric acid and IF secretion in patients with advanced acquired immunodeficiency syndrome (AIDS). [500], [501], [502] and [503] In contrast, similar abnormalities have not been observed in the early stages of human immunodeficiency virus (HIV) infection. [503], [504] Although the pathogenesis of these secretory abnormalities is unknown, preliminary research has demonstrated several secretory and parietal cell morphologic abnormalities in HIV-infected patients. [505] Despite the limited number of patients examined, several interesting observations were made. Fasting gastric pH and IF concentrations were significantly different in patients with AIDS and in the early stages of HIV infection as compared with a group of healthy volunteers. As previously noted, MAO output and Schilling test (1 and 2) results were decreased only in AIDS. At the histological level, vacuolar degeneration (light microscopy), reduced tubulovesicles, and dilated intracellular canaliculi with loss of microvilli (electron microscopy) were observed in gastric biopsy specimens obtained from HIV-infected patients. Moreover, there was evidence of HIV antigens (gp120, gp41, p24, and p17) in parietal cells obtained from patients in both the early and late stages of HIV infection. Although a preliminary report, the histological findings are quite dramatic and suggest that HIV may be directly responsible for infecting and altering parietal cell structure and function.

Pharmacology of Acid Secretion

The advances in the pharmacology of acid secretion suppression mirror the advances in the physiological understanding discussed in the preceding sections of this chapter. Pharmaceutical products that interact at almost every stage of acid secretory regulation are available. H_2 receptor antagonists are the prototypical acid secretory antagonists. These agents reduce but do not abolish stimulated acid secretion. Because of the influence of potentiation, H_2 antagonists are able to reduce acid secretion in response to histamine or to pentagastrin and acetylcholine. They are effective in promoting ulcer healing.

PGE and PGI selectively inhibit histamine-stimulated parietal cell function in vitro. One mechanism for this effect of PGE analogs is their interaction with the pertussis toxin–sensitive guanine nucleotide–binding regulatory protein of adenylate cyclase in the parietal cell basolateral membrane. PGEs are effective inhibitors of acid secretion in vivo. [505] Part of this action may reflect prostaglandin-mediated release of somatostatin. [506] Enprostil, a PGE agonist, inhibits serum gastrin levels. [505]

Direct interference with the parietal cell proton pump is possible using substituted benzimidazoles (e.g., omeprazole), which inhibit acid secretion by blocking parietal cell H^+,K^+-ATPase. [507] These agents inhibit the acid secretory effects of all known stimuli. [507] They are the most powerful antisecretory agents available for use in humans and can produce absolute achlorhydria. [508] Compared with cimetidine, benzimidazoles are more effective in relieving symptoms and in healing ulcers in patients with duodenal ulcers. [509], [510] Just as achlorhydria resulting from chronic atrophic gastritis and pernicious anemia causes marked hypergastrinemia, omeprazole-induced achlorhydria also is accompanied by sustained hypergastrinemia. The knowledge that gastrin is a growth-promoting hormone has raised concerns that long-term administration of omeprazole may promote gastric tumor formation, as can occur in patients with pernicious anemia or after gastric surgery for chronic duodenal ulcer. [511], [512] and [513]

CHAPTER 14

Marshall H. Montrose, Stephen J. Keely, and Kim E. Barrett

ELECTROLYTE SECRETION AND ABSORPTION: SMALL INTESTINE AND COLON

The goal of this chapter is to review the cellular, molecular, and regulatory aspects of fluid and electrolyte transport in the mammalian intestinal tract. The intestine can absorb vast quantities of fluid from the intestinal lumen. This is a vital function, because of the presentation of about 9 L of fluid are presented to the intestine each day (Fig. 14-1). Greater than 98% of this fluid load is absorbed to preserve health. In addition to its ability to absorb fluid, the intestine also is capable of secretion. In fact, most of the daily fluid load originates from secreted rather than ingested fluids. Fluid secretion is necessary to aid in the digestion and absorption of nutrients, by maintaining a fluid environment for the mixing of food with digestive enzymes. The balance between absorptive and secretory processes is closely regulated. There is normally a net absorption of fluid, but certain conditions may result in excessive stimulation of secretion, which can overwhelm the combined absorptive capacity of the small and large intestines and can result in the pathological condition of secretory diarrhea. The most dramatic example is cholera; patients can experience drastic fluid loss in the stool of up to 20 L per day. [1]

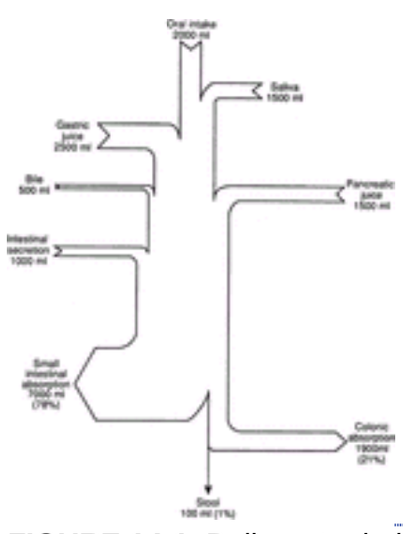

FIGURE 14-1. Daily water balance in the healthy human gastrointestinal tract. The amount of oral intake varies among individuals depending on the types of meals taken. Note that even in health there is a significant secretory flux of fluid from the intestine (1000 mL). The small intestine is responsible for absorbing almost 80% of the daily fluid load, largely in association with nutrient uptake. The colon absorbs most of the remaining fluid, with an efficiency of about 95%, leaving only about 1% of the daily fluid load to be lost to the stool. (From Barrett KE, Dharmsathaphorn K. Transport of water and electrolytes in the gastrointestinal tract: physiological mechanisms, regulation and methods for study. In: Narins RG, ed. Maxwell and Kleeman's clinical disorders of fluid and electrolyte metabolism, 5th ed. New York: McGraw-Hill, 1994:493.)

Intestinal fluid movement is predominantly controlled by the active transport of Na^+, K^+, bicarbonate (HCO_3^-), and Cl^- ions across the intestinal epithelium. Fluid follows the direction of electrolyte movement to maintain isotonicity between the intestinal lumen and tissue compartments. In addition to this vital role in fluid homeostasis, electrolyte transport has important roles in other physiological processes. For example, mucosal protection in the duodenum is dependent on duodenal secretion of HCO_3^-. [2], [3] Plasma electrolyte homeostasis is affected by electrolyte transport in both the colon and the kidney. [4] The uptake of peptides, amino acids, sugars, and bile acids requires various specialized ion-dependent transport mechanisms in the small intestine. [5], [6] and [7]

Many dramatic advances have been made in understanding intestinal electrolyte transport from the molecular to the whole-tissue level. Molecular cloning of transport, regulatory, and structural proteins has provided new insight into the regulation of electrolyte transport processes at the molecular level and has defined the underlying basis for genetic disorders of intestinal transport. Advances in cellular biochemistry have shown how different second messenger pathways interact with one another, with transport proteins, and with the cytoskeleton to allow the intestinal epithelium to respond appropriately to changes in the extracellular environment. Enhanced knowledge of epithelial development and tight junctional structure has increased the understanding of cellular diversity and of how the epithelium acts as a barrier to lumenal toxins. At the whole-tissue level, our knowledge of intercellular communication among the mucosal immune system, the enteric nervous system, and the intestinal epithelium is growing constantly. This chapter therefore emphasizes molecular mechanisms of intestinal epithelial ion transport processes as well as the intracellular and extracellular factors involved in their regulation.

INTESTINAL EPITHELIUM

Structural Properties of Epithelial Cells

The intestinal epithelium is a continuous monolayer of cells (i.e., enterocytes) lining the entire lumen of the gut. It simultaneously forms a barrier to the nonselective movement of substances between the body and gut lumen and expresses proteins that permit the selective transport of desired substances. The capacity of the intestine to absorb and to secrete is enhanced by the massive surface area of the epithelium, which is greatly amplified (by about 600-fold in the small intestine) by folds, villi, and microvilli. In addition, regulated contractions of the intestinal smooth muscle layer can increase or decrease the flow of lumenal contents, allowing

optimal contact time of nutrients and fluids with the epithelium.

Two essential features of the intestinal epithelium (and all other epithelia) that enable it to conduct its barrier and electrolyte transport functions are the ability of the component cells to form homotypic intercellular tight junctions and the ability to develop functional polarity. The basis for these features is discussed below.

Tight Junctions The intestinal epithelium forms a continuous barrier with each cell joined to its neighbors by apical junction complexes. These structures, which are composed of tight junctions and adjacent adherens junctions, link neighboring cells close to the apical pole. The junctional complexes form a regulated barrier to the movement of substances, not only between the cells but also within the plane of the epithelial cell plasma membrane. In response to the movement of ions and other solutes through epithelial cells, counterions and fluid can be driven paracellularly by chemical and osmotic gradients through the tight junctions, which behave as selective pores. At the ultrastructural level, freeze-fracture techniques reveal that epithelial tight junctions consist of a dense network of protein strands. [8] In general, the number of strands constituting the tight junction is directly related to the permeability of the pore. [9] Tight junction permeability is not constant along the length of the intestinal tract and generally decreases aborally. Recent years have seen an explosion in our knowledge of the molecular architecture of tight junctions (Fig. 14-2). [10] Many of the transmembrane components of tight junctions have been identified. [11] The first of these was occludin, a 65-kd transmembrane protein inserted into the plasma membrane in such a way as to expose two hydrophobic extracellular loops rich in glycine and tyrosine residues. [12], [13] These loops are believed to interact with partners on adjacent cells to form homotypic intercellular bonds (see Fig. 14-2). However, although occludin undoubtedly is involved in the formation of tight junctions, studies of occludin knock-out mice, in which intestinal tight junction structure and function appear to be unaltered, [14] indicate that other proteins are likely to be involved. This led to the discovery of the claudins, a family of proteins that, to date, consists of 20 members ranging in sequence identity from about 10% to 70%. With a molecular weight of about 22 kd, claudins are considerably smaller than occludin, but they are structurally similar in that they possess intracellular amino and carboxy termini and two extracellular loops. Claudins exhibit stronger adhesion characteristics than occludin, and several lines of evidence suggest they may be the primary sealing and pore-forming components of the tight junction. [10], [15] Claudins also display a varied tissue distribution, which may explain the high degree of heterogeneity in tight junction permeability between different tissues. [16] Evidence suggests that claudins also may be involved in regulating the ionic selectivity of tight junctions. Paracellin, a member of the claudin family, has been identified in renal epithelial cells, where it appears to confer cation, particularly Mg^{2+} and Ca^{2+}, selectivity on the tight junctions of the thick ascending limb of Henle. [17] Another transmembrane component of tight junctions is junctional adhesion molecule (JAM). [18], [19] and [20] A member of the immunoglobulin superfamily, JAM is structurally unrelated to claudins and occludin. In addition to regulating the sealing and permeability of tight junctions through the formation of intercellular homotypic bonds, JAM may play a role in regulating leukocyte migration through the tight junction. [18]

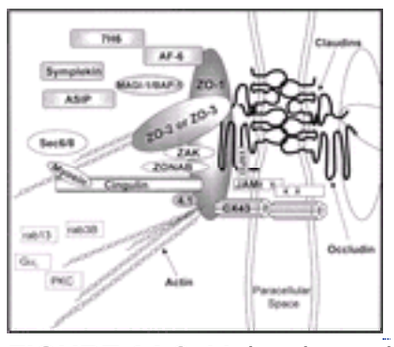

FIGURE 14-2. Molecular architecture of epithelial tight junctions. The transmembrane proteins occludin, the claudins, and junctional adhesion molecule (*JAM*) are the pore-forming constituents of the tight junction. Each of these proteins forms extracellular homotypic contacts with partners on neighboring cells. It is thought that the claudins, of which there are multiple isoforms, confer ionic selectivity on the tight junction. On the intracellular face of the tight junction, claudins and occludin associate directly with the ZO proteins, ZO-1, ZO-2, and ZO-3. Through several motifs that allow protein-protein interactions, the ZO proteins are, in turn, associated with the cellular actin cytoskeleton and a variety of intracellular signaling proteins that are involved in modification of tight junction permeability. *ASIP,* atypical PKC–isotype-specific interacting protein; *BAP-1,* BAI-associated protein; *PKC,* protein kinase C; *VAP,* vesicle-associated membrane protein (VAMP)-associated protein; *ZONAB,* ZO-1–associated nucleic acid–binding protein. (From ref. [10]. Copyright 2000 by the American Physiological Society.)

On the cytoplasmic face of tight junctions, occludin, claudins, and JAM are associated with a myriad of intracellular regulatory proteins. The most thoroughly studied of these are the zonula occludens (ZO) proteins: ZO-1, ZO-2, and ZO-3. [21], [22] and [23] These are members of a class of proteins called the *membrane-associated guanylate kinase homologs* (MAGUKs), a family of proteins characterized by a complex multidomain structure. [23] In addition to a guanylate kinase domain, these proteins contain several motifs involved in protein-protein interactions, including SH3 domains, [24] PDZ domains that bind integral membrane proteins, [25], [26] and docking sites (YEXV motif) for the SH2 domains of nonreceptor tyrosine kinases. [27] A novel ZO-1 interacting protein has been identified in kidney epithelial cells, which adds an exciting new dimension to the way in which ZO-1 may regulate cell function. [28] This protein, termed *ZONAB* (for ZO-1–associated nucleic acid–binding protein), is a transcription factor that preferentially activates the ErbB2 promoter. ErbB2 is a receptor tyrosine kinase involved in cell growth and differentiation. Thus, ZO-1 may play a fundamental role in regulating epithelial dynamics. Many other proteins also have been localized to tight junctions, including cingulin, the 7H6 antigen, low-molecular-weight G proteins, heterotrimeric G proteins, and tyrosine kinases. [29], [30] and [31] Although the functions of several of these proteins have yet to be elucidated, the aggregation of diverse signaling proteins at tight junctions clearly suggests that these structures are closely regulated. Apical junction complexes appear to be linked to the cytoskeleton by actin microfilaments, which form a dense perijunctional ring underlying the tight junctions. Actin microfilaments also appear to make direct contact with tight junction proteins including the ZO proteins and occludin. [32] Agents causing elevations in intracellular second messengers, such as Ca^{2+} and cyclic adenosine 3',5' monophosphate (cAMP) alter junctional permeability, probably through mechanisms involving contraction of the cytoskeleton and the perijunctional ring. [33] Other signaling molecules believed to be involved in the regulation of tight junction permeability include protein kinase C, myosin light-chain kinase, mitogen-activated protein kinases, and phosphatidylinositol 3-kinase (PI3-K). [34], [35], [36] and [37] Extrinsic factors, such as migrating neutrophils, [38] mucosal pH, [39] and dietary and bacterial toxins [40] also regulate tight junction permeability. Epithelial tight junction permeability also may be regulated by the absorption of nutrient-derived solutes, such as glucose. [35] Increases in lumenal glucose concentrations activate SGLT1, a cotransporter that couples glucose uptake to a favorable electrochemical gradient for Na^{+} absorption. Increased SGLT1 activity is associated with increases in tight junction permeability through an indirect mechanism involving the Na^{+}/H^{+} exchanger, NHE3. [41] This, in turn, reduces the barrier properties of the epithelium, leading to solvent drag of fluid and subsequent increased uptake of such solutes through the paracellular route. The validity of this solvent drag hypothesis has been questioned because increased paracellular flux in the presence of lumenal glucose has not been observed in all experimental models. For example, at SGLT1 substrate concentrations likely to exist in the intestinal lumen, the paracellular pathway contributes little (i.e., less than 5%) to the observed uptake of sugar from the intestinal lumen. [42] However, more recent in vivo studies in humans have shown that Na^{+}/glucose transport may dramatically increase paracellular absorption up to 45%. [43] Thus, despite the uncertainty of the solvent drag hypothesis and of its contribution to fluid absorption under normal conditions, both in vivo and in vitro studies provide convincing evidence that coupling between transcellular and paracellular pathways for solute transport can exist within the same cell. In summary, the opening of tight junctions can have significant consequences for intestinal physiology because as tight junctions become more permeable, the barrier to toxigenic substances, nutrients, electrolytes, and water is diminished.

Functional Polarity For fluid movement to occur, intestinal epithelia must transport solutes in a vectorial fashion Vectorial transport requires functional polarity of the epithelial cells, in which the proteins involved in electrolyte transport are asymmetrically distributed between the apical (lumen-facing) and basolateral (serosa-facing) domains of the cellular plasma membrane. Epithelial polarity is important not only for the differential localization of ion transport proteins but also for the localization of receptors for various neurotransmitters and other regulatory mediators. Many intestinal epithelial receptors, such as those for acetylcholine, histamine, and neuropeptides, are expressed only on the basolateral side, which is not surprising considering that the basolateral domain of the epithelium is in intimate contact with enteric nerves and cells of the mucosal immune system. Conversely, receptors for endogenous or exogenous substances delivered through a lumenal route (e.g., guanylin or bacterial enterotoxins, respectively) are found on the apical pole of epithelial cells. Some receptors are expressed bilaterally, such as those for adenosine and kinins. [44], [45] The cellular mechanisms responsible for differential localization of membrane proteins to the apical and basolateral domains of epithelial cells are only beginning to be understood. Extracellular contact, either between adjacent cells or between cells and the extracellular matrix, appears to be an important cue for the development of this epithelial polarity. [46], [47] Important components for sorting proteins to the apical or basolateral compartments are the trans-Golgi network, the cytoskeleton, and various biochemical signals that regulate membrane trafficking events. In the trans-Golgi network, proteins destined for the apical and basolateral membranes are sorted into distinct vesicles. The role of the cytoskeleton is demonstrated by the observation that depolymerization of the cytoskeleton results in the delivery of normally apical proteins to the basolateral membrane. [48], [49] Specific biochemical signals on the targeted proteins preferentially direct membrane proteins to either the apical or the basolateral domain. Basolateral sorting signals usually are short cytoplasmic peptides that contain a conserved tyrosine-based motif. In contrast, apical sorting signals typically are found in the extracellular domain and often involve *N*-glycosylation of the protein. It has been proposed that proteins

bound for the apical membrane are shipped from the Golgi network in glycosphingolipid rafts, and clustering of proteins into these rafts occurs by means of their glycophosphoinositol anchors. [46] It is also thought that specific peptide sequences, or single amino acid residues, within a particular protein may play an important role in directing membrane trafficking. [50] Within the membrane, mechanisms also exist that help to direct and maintain polarity. For example, it is believed that the plasma membrane contains targeting patches in which specific docking molecules, such as target membrane–related soluble *N*-ethylmaleimide–sensitive factor attachment protein receptors (t-SNAREs), are found. Such docking molecules have the ability to recognize specific proteins on the surface of transport vesicles, such as vesicle-related SNAREs (v-SNAREs). [46] The cytoskeleton also helps to anchor some proteins at specific sites within the membrane, and tight junctions act as a "fence" to prevent free movement of proteins between the apical and basolateral domains within the plane of the membrane.

Epithelial Organization and Diversity

In addition to the common epithelial features described, there is a wide diversity in cell type and function within the intestinal epithelial layer. This diversity is apparent along the length of the intestine (the jejunocolonic axis) and among the cells that constitute an individual crypt and villus unit (the crypt-villus axis).

Crypt-Villus Axis The predominant cells within the intestinal epithelium are the enterocytes, the transporting epithelial cells that perform the absorptive and secretory functions of the intestine. In general, the proteins specifically involved in digestion and absorption are expressed at highest levels in the enterocytes near the villus tip, whereas the proteins involved in secretion are most abundant in crypt enterocytes. Thus, there is a functional heterogeneity in electrolyte, fluid, and nutrient transport along the crypt-villus axis. Indeed, for many years it was believed that absorption and secretion were spatially distinct processes, with absorption occurring only across villus cells and secretion restricted to the crypts. [51] However, it has become apparent that this scheme was an oversimplification. Studies of the rat small intestine demonstrate that secretory mechanisms may be present in some villus cells. [52] Further, although colonic crypt cells secrete Cl^- in response to neurohumoral agonists, they constitutively absorb Na^+ and water in the absence of secretory stimuli. [53] These physiological observations are complemented by new information about the cellular expression of individual transport proteins, discussed in the section "Electrolyte Transport Proteins." Other epithelial cells also contribute to and regulate the functions of the transporting cells. Goblet cells located in the crypts secrete mucus. [54] Paneth cells also located in the crypts contribute to mucosal defense by producing antibacterial substances (e.g., lysozyme, defensins). [55], [56] They also may have a role in regulating epithelial development or repair by producing growth factors. [57] Enteroendocrine cells, which are interspersed between the enterocytes, contain a variety of hormones, neuropeptides, and serotonin. [58] These mediators can be released in response to various lumenal stimuli, including bacterial toxins and distention, and may act in a paracrine fashion to alter epithelial ion and fluid transport. [59] All four epithelial cell types are replenished constantly from stem cells found near the base of each crypt. As cells divide, most are pushed upward along the crypt toward the villus tip, from which they are shed after a period of 4 to 7 days. [60], [61] The 4- to 7-day cycle is completed when the migrating cells undergo apoptosis at the villus tip (or surface epithelium in the colon) and are shed into the lumen or reabsorbed.

Jejunocolonic Axis The intestinal tract also is heterogeneous along its longitudinal axis, reflecting the different functions of each intestinal segment. The proximal segments of the small intestine absorb large volumes of fluid against relatively small electrochemical gradients. Resistance across the epithelium of the small intestine is low. The duodenum, jejunum, and ileum exhibit regional differences in terms of electrolyte, nutrient, vitamin, mineral, and bile acid transport. The colon has two distinct areas characterized by functional differences in electrolyte transport. The epithelium of the proximal colon exhibits intermediate resistance between leaky and tight, whereas the distal colon has a semitight epithelium that absorbs Na^+ against a steep gradient. Perfusion studies have shown that electrolyte concentrations in the intestinal lumen mirror those of plasma in all intestinal segments except the distal colon, where the Na^+ concentration is reduced and that of K^+ is increased. [62] Differential sensitivities to various secretagogues, aldosterone, amiloride, and amiloride analogs have been found between the proximal and distal colon. [63], [64] A clinical correlate to these physiological observations is the finding that surgical removal of the right colon is associated with diarrhea and salt wasting, supporting the theory of a specialized function for this segment of the intestine. [65]

Regulatory Cells

Epithelial ion transport is regulated by a wide array of extracellular stimuli, which include lumenal factors and blood-borne, neuronal, and immunologic mediators (Fig. 14-3). Histological examination of the lamina propria reveals various immune cell types (the mucosal immune system), an extensive neuronal network (the enteric nervous system), and enteroendocrine cells that are interspersed among the cells of the epithelial layer. The epithelium also has an underlying layer of specialized mesenchymal cells called *myofibroblasts.* Mediators released from all these cell types contribute to the regulation of epithelial transport function; both the mucosal immune system and the enteric nervous system integrate regulation of epithelial transport.

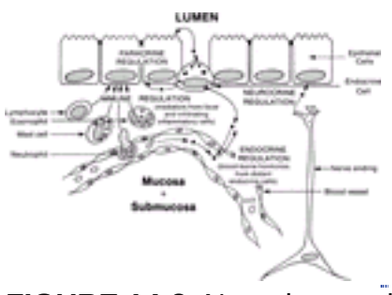

FIGURE 14-3. Neurohumoral and immune regulation of the intestinal epithelium. Endocrine cells in the crypt region release peptides and other substances across either their basolateral or apical membranes. In many cases, local diffusion of these bioactive substances can regulate nearby ion transporting cells (paracrine regulation). These substances, or others from more distant endocrine organs, also can enter the bloodstream to regulate the function of distant portions of the epithelium (endocrine regulation). Enteric nerve endings release peptides and other neurotransmitters that regulate both the epithelium and muscle layers (neurocrine regulation). Immunologic effector cells (e.g., mast cells, eosinophils, neutrophils, and lymphocytes) in the lamina propria can also be simulated to release substances that regulate the epithelium (immune regulation).

Neuroendocrine Cells Enteroendocrine cells and enteric nerves effect paracrine regulation of epithelial function. Enteroendocrine cells are specialized cells located in the crypt region that contain various messengers released in response to lumenal stimuli. [56] These messengers relay signals to coordinate the reaction of both local and distant epithelial cells. Nerve endings of neurons of the submucosal plexus are located close to the intestinal epithelium. Neural connections also run between the submucosal and myenteric plexuses; this may be important in coordinating epithelial transport with gut motility. The central nervous system also plays a role in the regulation of fluid and electrolyte transport by way of the vagus nerve. Endocrine regulation provides distant coordination among different portions of the gastrointestinal tract and between the gut and other organs. This coordination results from the release of peptides or neurotransmitters into the bloodstream.

Immune Cells The gastrointestinal tract is extremely rich in immune effector cells, [66], [67] and this is not surprising considering its continuous exposure to bacterial, viral, and dietary antigens. Immune cells of the gut are contained primarily within the lamina propria and consist of lymphocytes, plasma cells, mast cells, and phagocytes. Classically, the mucosal immune system is broadly divided on a functional basis into afferent and efferent components, the afferent component consisting of lymphocyte-mediated antigen recognition and presentation, and cytokine production, which, in turn, recruit the efferent component consisting of mast cells, phagocytes, and their mediators. In recent years, however, the division between the afferent and efferent arms of the mucosal immune system has become blurred as it becomes more apparent that practically all cells within the intestinal mucosa are involved in both the initiation and propagation of mucosal immune responses. It is also clear that, in addition to their classical immunomodulatory functions, many cytokines produced by lymphocytes also affect both epithelial barrier function and ion transport. [68], [69] and [70] Regulation of intestinal ion transport by mast cells, phagocytes, and their mediators has also been demonstrated. [66], [71], [72]

Myofibroblasts Myofibroblasts form a continuous sheath underlying the basement membrane of the intestinal epithelial layer. Through the production of growth factors, cytokines, and extracellular matrix proteins, these cells are believed to play an important role in regulating epithelial cell growth and differentiation. [73] Studies by Berschneider and Powell and their associates [74], [75] have demonstrated that this fibroblastic sheath may also contribute to the regulation of epithelial transport. On stimulation by an array of neuroimmune mediators, myofibroblasts produce prostaglandins, which act in a paracrine fashion to stimulate epithelial Cl^- secretion. Exposure of myofibroblasts to cytokines, such as tumor necrosis factor a (TNF-a) and interleukin-1, further increases the potentiating effect of fibroblasts on agonist-stimulated Cl^- secretion, as a result of up-regulated cyclooxygenase expression. [76] Endothelial cells, which line the blood vessels within the mucosal layer, may act like myofibroblasts in that they produce prostaglandins in response to inflammatory stimuli, which could stimulate epithelial secretion in a paracrine fashion. [77]

PRINCIPLES OF EPITHELIAL TRANSPORT

Transepithelial and Housekeeping Transport

Substances may traverse the intestinal epithelium by multiple routes. Transcellular processes require entry of electrolytes across one membrane barrier, transit through the cell cytosol, and exit across the opposite membrane. The functional polarity of epithelial cells is the basis for this net (vectorial) movement of electrolytes through the asymmetric distribution of different membrane transport proteins in the opposing apical and basolateral membranes of the cells. Paracellular transport is the passive flux of electrolytes and water across tight junctions. Paracellular flux occurs entirely extracellular to the epithelial cells and can only produce vectorial transport as a dissipation of the transepithelial chemical and electrical gradients established by active transcellular transport.

Types of Transmembrane Transport

Charged species such as ions cannot traverse the lipid core of the plasma membrane. This is vital to life, because the regulation of cellular biochemistry is dependent on the tight control of intracellular ionic composition. Therefore, specialized proteins are inserted into the plasma membrane to mediate and regulate ion movement. Ions can cross the membrane through these proteins with either the consumption of cellular energy (active transport) or by flowing down existing electrical and/or chemical gradients (passive transport). Overall, transepithelial transport involves a combination of both active and passive transport mechanisms. Ultimately, all of the net transepithelial transport mechanisms discussed in this chapter require at least one active transport step to drive vectorial transport. In these cases, net passive transport of a substance through the paracellular or transcellular route occurs only in response to transepithelial electrochemical gradients established by the active transport processes.

In addition to the distinction of active versus passive transport across a membrane, all transport reactions also can be grouped into one of two classes: electrogenic or electroneutral. *Electrogenic* transport moves net charge across the membrane either by the flux of single ions (e.g., ion channels) or by combinations of transport substrates whose charge is unequal (e.g., Na^+/glucose cotransporter). Because no aqueous solution can have unequal amounts of cations and anions, electrogenic transport requires compensatory flux by another electrogenic transport process to maintain electrical neutrality. Very often, electrical neutrality is maintained by compensatory paracellular transport of an oppositely charged ion through the tight junctions. *Electroneutral* transporters also mediate a net flux of ions, but they do so without moving net charge across the membrane during a transport cycle. Electroneutral transporters may mediate an exchange of equal charges across the membrane (e.g., Na^+/H^+ exchanger), or a cotransport of equal and opposite charges (e.g., $Na^+/K^+/2Cl^-$ cotransporter). Importantly, the electrical gradient across the membrane is not a driving force affecting electroneutral carriers, and so the rate and direction of transport by electroneutral carriers are determined solely by the transmembrane chemical gradients of the transported ions. As discussed later (see the section “ Transepithelial Electrolyte Transport ”), combinations of different transport proteins can also result in overall transepithelial transport that is either electrogenic or electroneutral.

Fluid Transport

Physiology of Water Flux Water is crucial to physiological processes, and the amount of water in the intestinal lumen is closely regulated. A large amount of water is secreted by various gastrointestinal organs to facilitate digestive and other intestinal processes (see Fig. 14-1). The daily fluid load varies according to the amount and composition of meals, but it approximates 9 L. In healthy humans, 65% to 80% of the secreted or ingested water is absorbed in association with nutrient and electrolyte absorption in the small intestine, so the colon receives only 1500 to 2000 mL. [78] The colon absorbs most of this remaining fluid with high efficiency; thus, normally, fluid excretion in the stool is only about 100 mL. [79]

Molecular Mechanisms of Water Transport Researchers are still developing an understanding of how water crosses the intestinal epithelium. One general principle, however, is that water always flows across membranes in response to electrolyte and/or osmolyte fluxes. The net movement of electrolytes causes local accumulation of osmolytes, which drives compensatory water diffusion to balance osmolarity. In most cases, water molecules are moved into and out of the lumen by passive processes requiring no further input of cellular energy beyond that required to cause electrolyte transport. There are multiple routes for passive water diffusion across epithelia. If the actively transported electrolytes accumulate in the small extracellular spaces between adjacent epithelial cells (during absorption) or in the gut lumen (during secretion), there is an osmotic driving force for water to equilibrate through the tight junctions. This is believed to be the mechanism for fluid absorption in the proximal small intestine. Conversely, if the electrolyte accumulates intracellularly, there is a driving force for water to equilibrate across the cell membrane, which provides a transcellular route for water transport. The transcellular route is predicted to be more important in tight epithelia (e.g., the distal colon), because ion flow through the tight junctions is restricted in this setting. Like ions, water has difficulty crossing lipid membranes; therefore, membrane proteins must enhance water transport across these barriers. Attention has focused on two classes of proteins that increase water permeability across intestinal membranes: aquaporins and Na^+-dependent solute transporters. Aquaporins are a gene family that function as water channels in the plasma membrane. Since their initial discovery, [80] three aquaporin isoforms have been suggested to contribute to intestinal water transport. AQP3 has been shown to be abundant in the surface/villus cells of the colon, jejunum, and ileum, although whether AQP3 is apical [81] or basolateral [82], [83] remains controversial. In contrast, AQP4 has been shown reproducibly to be a basolateral protein in the small intestine and colon, but its predominant location—crypt cells or surface/villus cells—is uncertain. [82], [84] The AQP8 isoform also has been found in surface/villus cells of the jejunum and colon. [82] At present, the only functional evidence that links any specific isoform to intestinal water transport comes from AQP4 knock-out mice, which showed a modest (30% to 40%) decrease in water absorption by the proximal colon. [84] This highlights redundant pathways for intestinal water flux under normal circumstances. Another important route for transcellular water flux is through Na^+-dependent solute transporters. SGLT1 moves about 210 to 260 water molecules across the membrane each time it transports two Na^+ ions and a single glucose molecule into the cell, possibly in the form of water molecules that hydrate the cotransporter glucose-binding site. [85] Results suggest that other cotransporters also enhance water fluxes. [86] Water may be a transport substrate of SGLT1 even under isotonic conditions, [87], [88] although evidence suggests that part of SGLT1-stimulated water flow is the result of microscopic osmotic gradients driving conventional passive water diffusion. [87] Independent of the precise model, it has been estimated that the absorption of up to 5 L of water per day could be mediated by SGLT1 alone. [85] In the intestine, water transport is regulated indirectly by the regulation of electrolyte transport. When electrolytes and osmolytes remain in the intestinal lumen (e.g., lumenal lactose in lactase-deficient subjects, or during active electrolyte secretion), lumenal hyperosmolarity decreases water absorption. The opposite is also true: when molecules are absorbed and leave the lumen, they increase water absorption. Use of this osmotic driving force constitutes the basis for oral rehydration solutions, in which a low-osmolarity substrate (e.g., starch) in the lumen is digested (e.g., to glucose) and the products are avidly absorbed (e.g., by SGLT1), thus stimulating water absorption. [89]

ELECTROLYTE TRANSPORT PROTEINS

This section describes the building blocks of epithelial transport—individual membrane transport proteins. Different combinations of these transport molecules are expressed in individual cells to perform specific electrolyte transport events. Many electrolyte transport proteins have been cloned, providing unprecedented information about their structure and function. In many cases, there have also been striking advances because mutations in these proteins underlie inherited diseases of intestinal transport. The electrolyte transport proteins known to exist in gastrointestinal epithelia and their participation in transepithelial electrolyte transport are summarized in Table 14-1. The following sections emphasize cloned transport proteins that are expressed in the intestine. Because each transport protein is a member of a gene family of related protein isoforms, it is sometimes unknown which isoforms participate in particular transepithelial intestinal electrolyte transport mechanisms. Moreover, some important transport proteins remain to be cloned, and some proposed mechanisms of transepithelial transport remain more speculative than confirmed.

TRANSPORT PROTEIN	POLARITY	GENES	TRANSEPITHELIAL FUNCTION	NOTES
ATPase pumps				
Na^+, K^+-ATPase	Basolateral	α1, subunit: ATP1A1; β1, subunit: ATP1B1	Ion active transport	α1/β1 dimer is the only intestinal epithelial isoform
H^+, K^+-ATPase	Apical	α subunit: ATP4A; ATP4B?/ATP4A2	Colonic K^+ and SCFA absorption	β subunit needed for function
Exchangers and cotransporters				
Na^+/glucose cotransporter	Apical	SGLT1	Solute-coupled Na^+ uptake	Example of Na^+-coupled cotransporter
H^+/peptide cotransporter	Apical	PEPT1	Proton-coupled osmotic absorption	Example of proton-coupled cotransporter
H^+/monocarboxylate cotransporter	Apical and basolateral	MCT1	SCFA absorption?	SCFA transporter
Na^+, H^+ / $2CO_3^-$ cotransporter	Basolateral	NBC3	CO_2 and H^+ secretion	
Na^+/H^+ exchangers	Apical	NHE3	Small intestinal electroneutral Na^+ absorption	
	Apical	NHE2	(Electroneutral Na^+ absorption?); HCO_3^- secretion?	Potential role in colonic Na^+ absorption
	Basolateral	NHE1	HCO_3^- secretion	Ubiquitously expressed, cellular pH regulation
Cl^-/HCO_3^- exchangers	Apical	CLD, (AE1?)	Electroneutral Cl^- and K^+ absorption, HCO_3^- secretion	AE1 controversial
	Basolateral	AE2, (AE1?)	Electroneutral Cl^- absorption?	AE2 controversial
Na^+/Cl^- cotransporter	Unknown	NCCT	(Electroneutral NaCl absorption?)	Putative apical NaCl uptake mechanism
K^+/Cl^- cotransporter	Unknown	KCC1	Electroneutral K^+ or Cl^- absorption	Basolateral route for KCl exit
Channels				
Na^+ channel	Apical	α subunit: SCNN1A (ENaCα); SCNN1B (ENaCβ); SCNN1G (ENaCγ)	Electrogenic Na^+ absorption	Amiloride-sensitive channel; others may exist
Cl^- channels	Apical	CFTR	Cl^- secretion	cAMP activation, also conducts bicarbonate
	Apical	CLCN2	Cl^- secretion?	Ca^{2+} activated
	Apical	CIC-2	Cl^- secretion?	Outwardly rectifying; volume sensitive; Outwardly rectifying
K^+ channels	Endosomal	CIC-5	Cl^- secretion?	
	Apical	Unknown	K^+ secretion	
	Basolateral	KVLQT1, ISK1	K^+ secretion, electrogenic and solute-coupled Na^+ absorption	
HCO_3^- channel	Apical	Unknown	HCO_3^- secretion	May be CFTR

TABLE 14-1 Key Epithelial Transport Proteins and Their Participation in Transepithelial Electrolyte Transport

ATPase Pumps

Ultimately, a transport ATPase is required to provide the necessary driving force for net transepithelial ion transport to occur in mammalian cells. Among the known transport ATPases, the Na^+,K^+-ATPase and H^+,K^+-ATPase are the best understood and have well-established roles in intestinal electrolyte transport. These proteins have related sequences (60% to 70% homology), and both are members of the P-type ATPase multigene family, so named because all members of this family become phosphorylated during part of the transport cycle. Other ATPases exist, but they have less certain roles in intestinal transport physiology. Ca^{2+}-ATPase in the basolateral membrane may contribute to transcellular Ca^{2+} absorption stimulated by vitamin D. [90], [91] Deeper uncertainties exist about ion-dependent ATPases that have been identified by biochemical assays, but that have not yet been shown to mediate ion transport (e.g., HCO_3^--ATPase, Cl^--ATPase, and Mg^{2+}-ATPase).

Na^+,K^+-ATPase In the presence of Mg^{2+}, the Na^+, K^+-ATPase catalyzes the efflux of three Na^+ ions from the cell and the uptake of two K^+ ions at the expense of hydrolyzing one ATP molecule per cycle. [92] Because more cation is pumped out than is replaced, the Na^+ pump is electrogenic and generates a negative intracellular electrical potential. Na^+, K^+-ATPase is localized basolaterally and is expressed in all intestinal epithelial cells. [93] It acts to maintain a low intracellular Na^+ concentration and a high intracellular K^+ concentration. The Na^+ electrochemical gradient then is used as a driving force for Na^+ influx through Na^+ channels or through the many secondary active cotransporters and exchangers for which Na^+ is required (Fig. 14-4, Fig. 14-5 and Fig. 14-6). Inactivation of the Na^+, K^+-ATPase with cardiac glycosides such as ouabain will inhibit all these active transport mechanisms in the intestine.

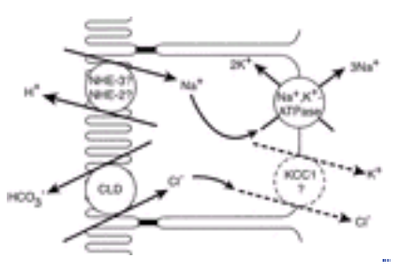

FIGURE 14-4. Electroneutral NaCl absorption in the small intestine and colon. As described in the text, apical NaCl entry through Na^+/H^+ and Cl^-/HCO_3^- exchange is the most strongly supported model in mammalian intestine, although directly coupled NaCl cotransport remains a possibility. In both models, Na^+ exits the cell through the basolateral Na^+,K^+-ATPase, but the route of Cl^-efflux is more speculative.

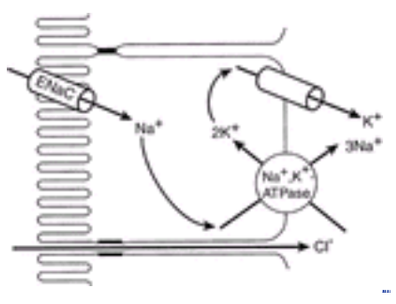

FIGURE 14-5. Electrogenic Na^+ absorption in the distal colon. Na^+ enters cells at the apical membrane through Na^+ channels and leaves cells at the basolateral membrane through the Na^+,K^+-ATPase. Details of the model are described in the text.

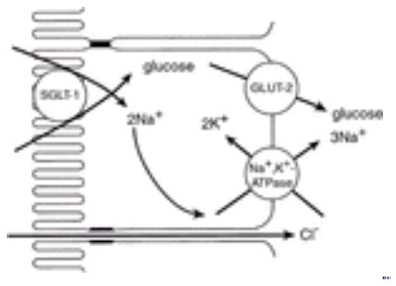

FIGURE 14-6. Solute-coupled Na^+ absorption in the small intestine. The model presents the mechanism for glucose as a generic solute and is representative of Na^+-coupled absorption of glucose, many amino acids, certain B vitamins, and bile salts. Details of the model vary among solutes because of differences in the charge of different solutes and the stoichiometry with transported Na^+ ions. Details of the model are discussed in the text.

The Na^+ pump exists in the membrane as a heterodimer of a and ß subunits, and the a1/ß1 isoforms of these subunits predominate in the intestine. [94] The a subunit is an integral membrane protein with at least eight transmembrane segments, [95] and it contains the ouabain binding site and all ion binding and catalytic sites. [96] The ß subunit has no known role in mediating ion transport, but it is an integral membrane protein essential for chaperoning the heterodimer through correct assembly and membrane targeting. [97], [98]

H^+,K^+-ATPase In several species, the apical membranes of cells in the distal colon contain H^+, K^+-ATPase activity. Similar to the gastric H^+, K^+-ATPase to which it is related, the colonic form mediates cellular efflux of H^+ into the gut lumen in exchange for K^+ uptake, with hydrolysis of ATP providing energy. [99] Activity of this pump is variably inhibited by the Na^+, K^+-ATPase inhibitor ouabain and the gastric H^+, K^+-ATPase inhibitor SCH28080, suggesting that the colonic enzyme shares common structural features with both of these pumps. [100], [101], [102], [103], [104] and [105] One reason for the variability in inhibitor responses is that a second, ouabain-insensitive K^+-ATPase probably exists. [100] Moreover, because the only cloned isoform of the colonic H^+, K^+-ATPase is not inhibited by SCH28080, there is

some controversy about whether it is the predominant apical isoform. [102] Antibodies detect H^+,K^+-ATPase protein in both the surface cells and crypt cells, although the cloned isoform may be predominantly expressed in the surface cells. [102], [105] Unlike the Na^+,K^+-ATPase, the colonic H^+,K^+-ATPase does not play a dominant role in regulating intracellular levels of its transported ions. Although cytosolic pH can be measurably affected by the activity of H^+,K^+-ATPase, other transporters (e.g., Na^+/H^+ exchangers) are likely to have greater impact on control of the resting cytosolic pH. [106], [107] In the distal colon of the guinea pig, protons secreted by the colonic H^+, K^+-ATPase are important for stimulating uptake of lumenal short-chain fatty acids (SCFAs), facilitating absorption of SCFAs in their nonionized (i.e., protonated) form. [108] The colonic H^+, K^+-ATPase also is important for K^+ absorption, especially in infant animals who need to retain more K^+ than adults to avoid growth retardation. [109] Both an a and a ß subunit of the colonic H^+,K^+-ATPase have been cloned. [110], [111] Coexpression of the a subunit with either the cloned HKß or a heterologous ß subunit (either from gastric H^+,K^+-ATPase or Na^+,K^+-ATPase) is sufficient to reconstitute observable H^+,K^+-ATPase activity in the plasma membrane. [112], [113] Evidence suggests that the ß subunit of the Na^+,K^+-ATPase may serve this role physiologically, as it associates with the HKa subunit in the apical membrane of colonocytes. [114] The a subunit is predicted to have multiple transmembrane spanning segments, [110] but no detailed mapping of functional sites has been reported.

Exchangers and Cotransporters

Using a limited number of ATPase pumps, abundant assortments of electrolytes and solutes are actively transported across the intestinal epithelium. This is possible because many different carrier proteins convert the energy of Na^+ or proton gradients into net transport of other electrolytes and solutes. In addition to these secondary active exchangers and cotransporters, the passive transporters play a key role in facilitating movement of ions across the plasma membrane at faster rates than could be expected by simple diffusion.

Na^+-Solute Cotransporters Many food-derived products including glucose, amino acids, and vitamins, as well as endogenous lumenal solutes such as bile acids, are taken up by specific Na^+-coupled cotransport proteins in the apical membrane of enterocytes. These cotransporters are the predominant route by which such diverse substances enter the body and are also responsible for driving the majority of Na^+ and water absorption after a meal. Most of these cotransporters are found in the small intestine, where organic nutrients are predominantly absorbed. Among the mammalian Na^+-coupled nutrient transporters, the intestinal Na^+/glucose cotransporter (SGLT1) was the first to be cloned and has been studied the most extensively. [115] Each transport cycle of the protein results in the uptake of two Na^+ ions and one glucose molecule. Its electrogenic nature renders the cotransporter sensitive to changes in membrane potential. [116] SGLT1 functions as a single polypeptide chain, but its topology is controversial. Between 11 and 14 transmembrane segments have been proposed, and results have conflicted in assigning the C-terminal to either the intracellular or extracellular domain. [117], [118] Despite these uncertainties, studies of chimeras between SGLT1 and a related cotransporter (SGLT2) have ascertained that the C-terminal portion of SGLT1 contains the sugar-binding site. [119] Further, a naturally occurring missense mutation near the C-terminal (R499H) was found in a patient with glucose-galactose malabsorption, and the mutant protein had a tenfold lower sugar affinity than the wild-type protein but no alteration in Na^+ affinity. [120] Similar approaches are being used to evaluate the mechanisms certain cloned intestinal Na^+/amino acid, Na^+/bile acid, and Na^+/vitamin cotransporters. [116] These Na^+-coupled nutrient cotransporters are predicted to contribute to water and Na^+ absorption in the intestine, but they are discussed in more detail in Chapter 16, Chapter 19, and Chapter 20.

H^+-Solute Cotransporters The intestinal proton-coupled peptide cotransporter (PEPT1) is expressed in the apical membrane of small intestinal cells and can transport a wide variety of dipeptides and tripeptides. The cloned transporter is electrogenic, and the proton activation kinetics suggest a 1:1 stoichiometry of proton:dipeptide transport for uncharged peptide substrates. [121], [122] From the standpoint of fluid and electrolyte absorption, the major contribution of PEPT1 is to stimulate water transport. PEPT1 remains an enigma for transport physiologists because of its capacity to accommodate an extremely broad range of peptide substrates. The molecular basis of this promiscuity is not fully understood. A cloned proton-coupled monocarboxylate cotransporter (MCT1) has been identified in membranes of both small and large intestine epithelial cells. [123] MCT1 functions to reproduce nonionic diffusion through coupling flux of monocarboxylate anions and protons. [124] The transporter is inhibited by a-cyano-hydroxycinnamates, and lactate is a favored substrate. [124] Evidence suggests a physiological role for colonic MCT1 as a route for basolateral SCFA flux from cells as part of transcellular SCFA absorption, but there are conflicting reports about the ability of a-cyanohydroxycinnamates to affect SCFA fluxes in colonocytes [125], [126] and the localization of MCT1 to either the apical or basolateral membrane. MCT1 may be most important physiologically in the transport of monocarboxylates that are too hydrophilic for efficient flux by nonionic diffusion through the lipid bilayer.

$Na^+/K^+/2Cl^-$ Cotransporter $Na^+/K^+/2Cl^-$ cotransport is present in the basolateral membrane of certain intestinal epithelial cells, and it participates in electrolyte secretion. This cotransport is electroneutral because each transport cycle moves equal numbers of cations (1 Na^+ plus 1 K^+) and anions (2 Cl^-) into the cell. The $Na^+/K^+/2Cl^-$ cotransporter plays a key role in Cl^- secretion as the predominant route for basolateral Cl^- uptake, [127] and it also participates in K^+ secretion by providing a second route for basolateral K^+ uptake in addition to the activity of Na^+,K^+-ATPase. [128], [129] The $Na^+/K^+/2Cl^-$ cotransporter isoform NKCC1 is expressed in predominantly the basolateral membrane of human colonic intestinal epithelial cells. [130], [131] It functions as a single polypeptide chain, and it has 12 putative transmembrane segments. [130] NKCC1 is inhibited by bumetanide and furosemide, which affect anion binding to the transporter. [132] A distinct Na^+/Cl^- (or $Na^+/K^+/Cl^-$) cotransporter has been proposed to exist in the apical membrane of enterocytes, as part of the electroneutral Na^+ absorptive mechanism. Similar apical cotransporters have been cloned from the kidney medulla, where they participate in Na^+ reabsorption, [133] and one highly homologous isoform (with as yet untested function) is expressed in the human small intestine and colon. [134] However, although strong evidence supports the physiological importance of apical Na^+/Cl^- cotransport for Na^+ absorption in winter flounder intestine, [135], [136] mammalian intestinal epithelial cells likely use other mechanisms to mediate electroneutral Na^+ uptake (see the following sections).

Na^+/H^+ Exchangers Na^+/H^+ exchange activity is present in all segments of the small intestine and colon. It is defined as the tightly coupled uptake of one Na^+ ion in exchange for the efflux of a proton. [137], [138] This electroneutral exchange reaction is important for intracellular pH regulation, as well as transepithelial Na^+ absorption. Na^+/H^+ exchange is observed in both the apical and basolateral membranes of epithelial cells from small intestine [139] and colon. [140], [141], [142] and [143] Four cloned isoforms of the Na^+/H^+ exchanger (NHE) gene family have been detected in gastrointestinal epithelia. The NHE1 isoform is present in virtually all cells of the body and is believed to be responsible for cellular pH regulation. [144] NHE1 is found in the basolateral membrane of intestinal epithelial cells. [145] NHE2 and NHE3 are predominantly epithelial isoforms of the exchanger that are expressed in the apical membranes of intestinal cells. [146] NHE4 is also expressed in gastrointestinal tissues (predominantly stomach) but there is no evidence that NHE4 contributes to transport responses in the small or large intestines. Each epithelial NHE isoform has a distinct distribution of mRNA abundance along the small and large intestines, which varies among species. [147], [148] There are also gradients of NHE isoforms and Na^+/H^+ exchange function along the crypt-to-villus and crypt-to-surface axes. Based on immunoreactivity, NHE1 is expressed at all sites along these axes, [145] but NHE3 is expressed preferentially on the villus in the small intestine and on the surface and in the upper third of the colonic crypts. [149] In contrast, functional apical Na^+/H^+ exchange activity has been observed along most of the ileal villus-crypt axis using isolated membranes [139] and in the colonic crypts using optical approaches to study either crypts in situ or in isolation. [150], [151] All NHE isoforms have 10 to 12 predicted transmembrane segments with cytoplasmic C- and N-termini. [146] Overall, NHE isoforms are 50% to 60% homologous within a species, with the C-terminal cytoplasmic tail having the most sequence divergence. The C-terminal portion is important for second messenger regulation of NHE isoforms, and several portions of this domain have been identified as crucial for mediating the effects of Ca^{2+}, calmodulin, cAMP, activation by intracellular protons, and growth factors. [146], [152], [153], [154] and [155] Evidence also suggests that, in some cases, NHE regulation requires accessory phosphoproteins, because signaling pathways do not always alter phosphorylation of NHE proteins. [156] As demonstrated by kinetic studies, all isoforms have different affinities for Na^+ and different inhibition constants for amiloride and other inhibitors, reflecting their different primary structures. [146] NHE2 and NHE3 are apical membrane proteins in intestinal cells, [146] and therefore they may contribute to Na^+ absorption. Several results suggest that NHE3 probably is responsible for electroneutral Na^+ absorption in the small intestine. First, mineralocorticoids increase the rate of ileal brush border Na^+/H^+ exchange; this correlates with an increase in the abundance of NHE3 mRNA without an effect on mRNA for NHE1 or NHE2. [157] Second, the dose-dependent inhibition of Na^+ and water absorption in dogs by dimethylamiloride is most consistent with NHE3 inhibition. [158] Finally, the patterns of second messenger regulation of Na^+ absorption and NHE3 expression are closely matched (i.e., inhibition by Ca^{2+} and stimulation by phorbol esters), but differ from the responses of NHE2. [146] Conversely, in rabbit ileum, evidence suggests that NHE2 and NHE3 each contribute about equally to basal Na^+ uptake in brush border vesicles. [159] Deeper controversy is emerging about the contribution of each NHE isoform to colonic Na^+ absorption. Evidence suggests that colonic NHE2 may play a role in regulating this process. [160], [161] In rat proximal colon, evidence shows that NHE2 is the predominant contributor to basal Na^+ absorption, [162] although the role of NHE3 seems more dominant in isolated membrane vesicles from the same tissue. [160], [163] Overall, it appears that the role of NHE3 predominates, at least in mice, because NHE3 knock-out mice have obvious diarrheal disease, whereas NHE2 knock-out mice have no identified intestinal disorder. [164], [165]

Cl^-/HCO_3^- Exchangers Cl^-/HCO_3^- exchange in the apical membrane acts in concert with Na^+/H^+ exchange to mediate electroneutral NaCl uptake in colonocytes

and small intestine cells. [152], [166] Unlike the apical membrane Na^+/H^+ exchange, which is expressed predominantly in villus cells of the small intestine, Cl^-/HCO_3^- exchange appears to be equally prevalent in the apical membranes of both crypt and villus cells, suggesting that it contributes to other transport mechanisms in addition to NaCl absorption. [139] In the colon, apical Cl^-/HCO_3^- exchange is observed predominantly in the surface cells, although Cl^-/OH^- exchange remains relatively active in crypt membranes. [167] This and other kinetic evidence suggests that apical Cl^-/HCO_3^- and Cl^-/OH^- exchange may not be mediated by the same protein in either the small intestine or colon. [166], [167] and [168] Molecular biologic approaches have identified many candidate proteins that may perform the apical Cl^-/HCO_3^- exchange reaction. Multiple isoforms of the anion exchanger (AE) gene family are expressed in the small and large intestines. Among the three known AE2 transcripts (AE2a, AE2b, AE2c1), AE2a and AE2b are abundant in the intestine, and, like most AE2 epitopes, they are located basolaterally. [84], [169], [170] Results have also suggested the presence of an apical AE1 isoform and a basolateral AE3 isoform in the intestines, but their existence remains highly controversial. [170], [171] The function and localization of these and other unidentified AE isoforms remain to be confirmed. A more definite role in intestinal Cl^- absorption has been assigned to the CLD gene product (formerly called DRA). Mutations in CLD are responsible for congenital chloride diarrhea, [172] a disease characterized by a chloride-rich, acidic stool. The protein is known to be expressed in the apical membrane of colonocytes. [173] CLD is the strongest candidate for an apical Cl^-/HCO_3^- exchanger in the small intestine and colon, with ion transport measurements demonstrating that CLD is a Cl^-, HCO_3, and divalent anion transporter. [174], [175] and [176] CLD mutations identified in patients with congenital chloride diarrhea do, in fact, lead to defective anion transport. [176]

Other Exchangers and Cotransporters In addition to those described earlier, other intestinal electrolyte cotransporters have been cloned, including Na^+/PO_4^- and Na^+/SO_4^- cotransporters. [177], [178] However, it remains to be established whether these proteins contribute to the observed active transport of SO_4^- and PO_4^- across the intestinal epithelium. [179] An intestinal K^+/Cl^- cotransporter has also been cloned. [180] This cotransporter is a logical mechanism for electroneutral basolateral exit of K^+ and Cl^- from intestinal epithelial cells that absorb K^+ and/or Cl^- in an electroneutral fashion, and its expression increases during dietary potassium depletion. [181], [182] In addition, numerous transport proteins can be defined functionally in isolated membrane vesicles, but are not yet cloned. These include $SCFA/HCO_3^-$ exchange and an electrogenic Na^+-HCO_3^-(OH^-) cotransporter. The roles of these transport reactions in epithelial transport remain to be established.

Ion Channels

An ion channel acts as a gated pore that is selective for certain ions. [183], [184] Open channels are passive pathways for electrolyte movement. *Gating* controls the amount of time that the pore spends in an open versus closed configuration. A single open channel conducts a rapid flux of ions across the membrane with a characteristic *unitary conductance* (one pS ~500 univalent ions per millisecond). The conductance of a given channel is an intrinsic biophysical signature, whereas gating of epithelial channels is most often regulated by second messengers. Compared with ion channels in excitable cells, membrane voltage has only modest effects on gating of epithelial channels, although this should be distinguished from the large effect of membrane voltage on the magnitude of ionic currents across the open channel, a completely separate feature.

Na^+ Channels Apical Na^+ channels contribute to electrogenic Na^+ absorption in many distal colonic epithelia. Epithelial Na^+ channels are selective for Na^+ (>10:1 versus K^+), have 5 pS unitary conductances, and are *inwardly rectifying* (i.e., they mediate cation efflux less efficiently than cation influx). [185], [186] Epithelial Na^+ channels are inhibited by nanomolar concentrations of phenamil and amiloride analogs, but the profile of inhibitor sensitivity is distinct from that of Na^+/H^+ exchangers. [186] Studies show that not all electrogenic Na^+ flux is equally sensitive to the same channel inhibitors. [187], [188] and [189] It is currently unclear whether this is the result of different regulatory or structural states of the known epithelial Na^+ channel, or whether a second biochemically distinct and amiloride-insensitive Na^+ channel exists in some portions of the colon. [190] The amiloride-sensitive epithelial Na^+ channel (ENaC) is composed of three subunits: a, ß, and ?. The subunits share 35% homology, and each is an integral membrane protein predicted to span the membrane twice. [191], [192] Expression of the ß and ? subunits is required to target the channel to the plasma membrane efficiently. [192] This is consistent with the observation that certain activating mutations in the ß or ? subunits (see the later discussion of Liddle syndrome) cause increased expression of Na^+ channels in the membrane as well as increased activity of the expressed channels. [193], [194] In contrast, a glycine near the N-terminal of the a subunit is involved in channel gating. [195] Although the predicted minimum configuration of the epithelial Na^+ channel is a heterotrimeric protein, it is likely that the native channel is more complex. Biochemical purification suggests that five or six polypeptides of widely different molecular weight are components of the channel. Some of these components may be differentially glycoslyated forms of the known subunits, but some of the peptides have been identified as regulatory proteins and cytoskeletal elements that modify channel function. [190]

Cl^- Channels Apical Cl^- channels are essential components of Cl^- secretion. Cl^- secretion in all parts of the intestine and colon is controlled predominantly by the ability of specific second messengers to regulate channel gating and localization. However, multiple Cl^- channel types are observed in intestinal epithelial cells, sometimes making it difficult to assign a functional role to individual proteins. A cAMP-activated channel in the apical membrane is known to participate in hormone-stimulated Cl^- secretion, and it is encoded by the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) that is responsible for cystic fibrosis. [196] The normal CFTR channel is selective for Cl > Br > I, has a unitary conductance of 8 to 10 pS, and is *nonrectifying* or *linear* (i.e., it conducts ions with equal efficiency in either an inward or outward direction). [197] The CFTR protein also is able to mediate the conductance of other ions (notably HCO_3^-) [198], it participates in a subset of cAMP-regulated apical membrane endocytosis and exocytosis events, [199] and it regulates the activity of other Cl^- and Na^+ channels. [200], [201], [202] and [203] The CFTR channel is a single polypeptide with 12 membrane-spanning domains, two cytoplasmic nucleotide-binding domains, and a “regulatory” (R) domain that contains most of the phosphorylation sites. [196], [204] It has been shown that CFTR Cl^- channel gating is complex, involving coordinated phosphorylation of multiple R-domain serine residues and ATP hydrolysis at, and interaction between, the two nucleotide-binding domains. [204] In healthy intestine, agonists acting through cAMP or Ca^{2+} stimulate Cl^- secretion. However, in patients with cystic fibrosis, neither cAMP nor Ca^{2+} is able to elicit Cl^- secretion. [205] This is in contrast to airway epithelia of patients with cystic fibrosis, where a Ca^{2+}-activated Cl^- channel functions in the absence of normal CFTR. [206] The reasons underlying the failure to detect such a Ca^{2+}-activated channel in the intestine of patients with cystic fibrosis is not yet understood at a molecular level, but it could involve the lack of an appropriate channel protein, a defect in the ability of CFTR to regulate another anion channel, and/or the existence of negative regulatory mechanisms in the intestinal epithelium (see the section “ Regulation of Electrolyte Transport ”). Molecular cloning has revealed other candidate Cl^- channels. ClC-2 and ClC-5 are cloned Cl^- channels that are expressed in intestine. [207], [208] and [209] ClC-5 is particularly intriguing because it is expressed only in kidney and colon and it has a permselectivity of I>Cl, is outwardly rectifying, but is not activated by cAMP. [207] Because ClC-5 is located in endosomes of intestinal epithelial cells, [209] it could be inserted into the plasma membrane upon appropriate regulatory signals. ClC-2 is expressed in the apical membrane of intestinal epithelial cells, and it may contribute to Cl^- secretion. [210], [211] Because ClC2 was apparently operational in CFTR knock-out mice, it is unlikely to be one of the proteins that requires CFTR to function. [211] /SUP>ClC channels are activated by cell swelling and, at a minimum, probably participate in the ion efflux necessary for cell volume regulation. [212], [213]

K^+ Channels K^+ channels in the apical membrane of epithelial cells are involved in K^+ secretion, and K^+ channels in the basolateral membrane are involved in Cl^- secretion. K^+ channels also are involved in electrogenic Na^+ absorption and Na^+-coupled solute absorption, but the polarity of involved K^+ channels involved in these processes is less certain. The characterization of apical K^+ channels has come predominantly from biophysical and physiological studies. The presence of apical K^+ channels has been inferred indirectly by adding lumenal K^+ channel blockers (e.g., barium and tetraethylammonium [TEA]) and monitoring the effects on global electrical properties of the rat colonic mucosa. [214], [215] Treatment with aldosterone increases the apical K^+ conductance, suggesting an increase in K^+ channel activity or number. [216] A preliminary report identified an apical 210-pS K^+ channel in rat distal colon as a candidate for the predominant apical K^+ conductance. [217] Basolateral K^+ channels have been studied more extensively. Patch clamping has identified a basolateral channel in human and rat colonic crypts that was selective for K^+ (49:1 versus Na^+), and it had a unitary conductance of 23 pS. [218], [219] Open probability of this channel was increased four- to tenfold by cAMP or micromolar Ca^{2+}, and the channel was blocked by quinidine and diphenylamine carboxylate (DPC), but not by TEA. [218], [220] The second messenger sensitivity of the 23-pS channel suggests that it contributes to both Ca^{2+}- and cAMP-stimulated Cl^- secretion. A second K^+ channel with unitary conductance of 138 pS has also been observed in human colonic crypts. The 138-pS channel has a distinct inhibitor profile; it is inhibited by TEA and quinidine, but not DPC, and it is highly K^+ selective (190:1 K:Na). [220] rSK1 and KVLQT1 channels have emerged as basolateral K^+ channels in the colon that respond to Ca^{2+} and cAMP, respectively. [221], [222] /SUP>

TRANSEPITHELIAL ELECTROLYTE TRANSPORT

The preceding section reviewed th*transmembran*e transport proteins that serve as basic building blocks for intestinal electrolyte transport of +, K +, Cl -, and HCO_3^-. This section discusses how these proteins are combined to produce the major *transepithelia* electrolyte transport events observed in the intact intestine.
