Colonoscopy probably is more accurate than radiology in demonstrating subtle mucosal abnormalities in the colon. When compared with high-quality, double-contrast barium enemas, this benefit applies primarily to the detection of polypoid lesions less than 1 cm in diameter and the early, preulcerative changes of IBD. However, this benefit must be balanced against the higher cost and complication rate of colonoscopy. The colonoscopist is unsuccessful in advancing the endoscope to the cecum in about 10% of patients, [65] but the cecum is almost always seen on barium enema studies.

We recommend contrast examination of the colon for patients with symptoms that could be caused by diseases of the colon (e.g., abdominal pain, constipation, change in bowel habit, and anemia). Colonoscopy is generally the examination of choice for the evaluation of uncertain radiologic findings, for removal or biopsy of lesions found at barium enema, and for the evaluation of patients who are at high risk for developing colorectal cancer or who are positive for fecal occult blood.

Indications

Although radiologic examination of the colon may be performed for a wide variety of indications, the most common include the following: detection of colorectal polyps and cancer; assessment of the type, extent, and severity of IBD; diagnosis of diverticular disease and its complications; evaluation of extrinsic mass lesions involving the colon; and evaluation of the rectum.

Colorectal Polyps and Cancer The barium enema is a valuable diagnostic test for patients with symptomatic colorectal cancer. It is a valuable technique for diagnosing the primary lesion and for detecting synchronous carcinomas elsewhere in the colon. The double-contrast barium enema has an overall accuracy of about 95% in diagnosing colorectal cancer. However, there appears to be an irreducible minimum error rate of about 5%, primarily the result of perceptive error. [66] The double-contrast barium enema is also used to evaluate patients who have overt rectal bleeding or occult blood in the stool on routine screening tests for colorectal cancer. In such cases, the goal is to detect invasive carcinomas and small adenomas that are precursors of colonic carcinoma (Fig. 152-18). These adenomatous polyps should be removed endoscopically to prevent the subsequent development of cancer. [67]

FIGURE 152-18. Example of a coexisting carcinoma and benign adenoma in the same patient. Notice the polypoid carcinoma (*black arrows*) in the transverse colon and small tubulovillous adenoma (*white arrow*) in the distal sigmoid colon.

The double-contrast barium enema also has a role in the surveillance of patients with conditions that are known to predispose patients to the development of colorectal carcinoma. Such high-risk patients include those with a personal or family history of colon cancer or polyps and those with a history of chronic ulcerative colitis. For these high-risk groups, we recommend a screening program that alternates colonoscopy and double-contrast barium enema to maximize the diagnostic yield. Contrast examination of the colon may also have a role in the routine screening of patients for colorectal cancer. Eddy and colleagues suggested that annual fecal occult blood testing and barium enema every 5 years may be the most cost-effective way of reducing the mortality from colorectal cancer. [68]
Inflammatory Bowel Disease Radiologic examination of the colon serves a variety of purposes in patients with known or suspected IBD. It can establish the presence of disease in patients who have not had prior sigmoidoscopy and in those who have had a egative sigmoidoscopy because the disease did not involve the rectosigmoid colon. It can also define the extent of disease in the colon. This information is particularly important in patients with ulcerative colitis because the risk for developing carcinoma is related to the extent of colonic involvement. Radiologic examination of the colon can differentiate ulcerative from granulomatous colitis. In typical cases, ulcerative colitis is characterized on double-contrast radiographs by a granular mucosa involving the rectum and extending proximally to a variable degree (Fig. 152-19A). In contrast, granulomatous colitis is characterized by a progression from discrete aphthous ulcers (see Fig. 152-19B) to transmural disease with deep ulcers, fissures, fistulas, and abscesses. The rectum is often spared, and colonic involvement tends to be discontinuous and patchy.

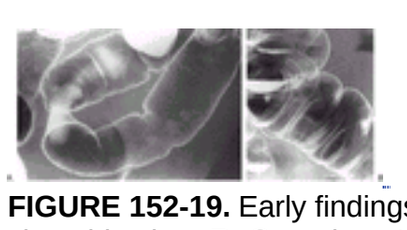

FIGURE 152-19. Early findings of inflammatory bowel disease detected by a double-contrast barium enema. **A:** Ulcerative colitis with typical granular mucosa in the sigmoid colon. **B:** Granulomatous colitis with discrete, aphthous ulcers in the transverse colon.

Radiologic examination also can detect the complications of chronic ulcerative or granulomatous colitis, including the development of strictures, abscesses, fistulas, and inflammatory or postinflammatory polyps. In patients who develop colonic carcinoma, the tumor can be diagnosed, and in some cases, the development of dysplasia or "precancer" can be recognized on double-contrast studies. [69]
Diverticular Disease Diverticular disease is one of the most common afflictions of Western society. The presence of massive diverticulosis poses a particular dilemma in interpreting double-contrast studies because the multiplicity of ring shadows makes it difficult to differentiate diverticula from polyps. As a result, single-contrast studies may be easier to interpret than double-contrast studies in patients with severe diverticular disease. Diverticulitis is a complication of diverticulosis in which a diverticular perforation leads to the formation of a pericolic abscess. Because barium may extravasate into the abscess, it is important to control the flow of barium into the colon in these patients. We therefore prefer single-contrast technique when a barium enema is performed for suspected diverticulitis (Fig. 152-20). In recent years, however, CT has increasingly been used as the primary radiologic modality in patients with suspected diverticulitis because of its relatively high sensitivity and specificity for diagnosing this condition. [70]

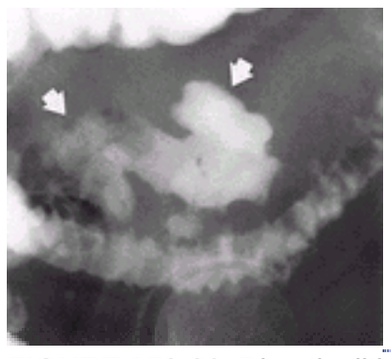

FIGURE 152-20. Diverticulitis with pericolic abscess. Barium has extravasated from a perforated diverticulum into an abscess (*arrows*). Notice the diverticula in the sigmoid colon.

Extrinsic Mass Lesions In patients with abdominal or pelvic masses, the barium enema is a useful technique for determining whether the colon is displaced, compressed, or actually invaded by these lesions. The barium enema can also detect intraperitoneal seeding of the colon by metastatic tumor, inflammatory lesions, or endometriosis. In many cases, the barium study must be correlated with CT or other cross-sectional imaging modalities to determine the true extent of disease in the abdomen.

Rectum When barium enemas were performed primarily by the single-contrast technique, the rectum was not considered to be in the province of radiology. With the use of the double-contrast technique, the rectum has become one of the simplest portions of the large bowel to evaluate radiographically. The anatomy of the rectum, including the columns of Morgagni and the valves of Houston, can be demonstrated in exquisite detail. [71] Radiologic evaluation of the rectum is particularly important for the diagnosis of rectal tumors, IBD, and other unusual conditions, such as the solitary rectal ulcer syndrome. [72] The double-contrast examination can also detect rectal carcinomas that are missed by digital rectal examination and proctoscopy [73] (Fig. 152-21). The routine double-contrast barium enema, therefore, should include a careful examination of the rectum.

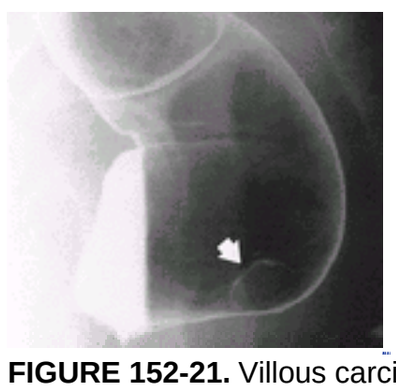

FIGURE 152-21. Villous carcinoma (*arrow*) of the posterior wall of the rectum that had been missed on prior digital and proctoscopic examinations.

Contraindications

The barium enema examination is generally a safe procedure, but there are several conditions for which the study is contraindicated or should be performed with extreme caution. These conditions include toxic megacolon, ischemic colitis, or other diseases in which the bowel wall is friable and more likely to perforate during the procedure. When a colonic perforation is suspected, the radiologic examination should be performed with water-soluble iodinated contrast material that can be reabsorbed from the peritoneal cavity if extravasation occurs.

Complications

The most feared complication of the barium enema is colonic perforation. [74] When this complication occurs, the perforation usually involves the intraperitoneal portion of the colon. Extravasated barium in the peritoneal cavity may be seen outlining loops of bowel. Surgical treatment is usually required. On some double-contrast barium enemas, a colonic perforation may manifest as only a pneumoperitoneum without extravasation of barium into the peritoneal cavity. If these patients are aggressively treated with intravenous fluids and antibiotics, surgery may be avoided in some cases.

Retroperitoneal perforations usually result from laceration of the rectum by an inflated retention balloon on the enema tip in cases of diffuse rectal disease, such as ulcerative or radiation proctitis. In such cases, barium may be observed radiographically in the rectal wall or in the perirectal soft tissues. Because of the risk for rectal laceration, it is our practice not to inflate the retention balloon routinely. When the balloon is required in patients who have poor anal sphincter tone, it should be inflated under careful fluoroscopic control after barium has been instilled into the rectum.

Despite occasional complications, the barium enema examination is a safe, simple, and relatively inexpensive procedure. It provides reliable information about the nature and extent of mucosal disease and about disease within and outside the bowel wall. Most patients undergo barium enema to rule out colonic neoplasm and IBD, and a double-contrast study is the best radiologic technique for evaluating these individuals. In other patients with suspected diverticulitis or colonic obstruction, a single-contrast barium enema may be performed. Whether single- or double-contrast technique is used, the barium enema examination has few contraindications, and the complications can be minimized by careful attention to the clinical history and examination technique. In complicated or difficult cases, correlation of the radiologic and endoscopic findings may be necessary to clarify the nature and extent of colonic disease.

ULTRASONOGRAPHY

INTRODUCTION

Basic Principles of Diagnostic Ultrasound

Ultrasonography is complex and technically challenging. It requires knowledge of physics, instrumentation, ultrasound anatomy, pathology, and, most important, scanning technique. Small handheld scanners make the concept of ultrasonography as an extension of the physical examination a real possibility. Those wishing to use ultrasonography, however, must learn the technique adequately, or erroneous results are inevitable. At least 4 months of full-time intensive training is needed for those wishing to perform even the simplest ultrasonographic evaluation.

Ultrasound refers to frequencies of sound above the audible range—about 20 to 20,000 cycles per second (20 to 20,000 Hz). Diagnostic ultrasonography uses sound frequencies far higher than this, in the 1 to 20 million Hz range (i.e., 1 to 20 MHz). Diagnostic ultrasound systems transmit sound pulses into the body. The echoes reflected from tissue are then processed to produce ultrasound images. The heart of a modern transducer is a complex array of specially manufactured piezoelectric elements that convert electrical energy into sound waves when transmitting and then convert the faint returning sound into electrical signals that can be processed into images.

In sonograms, the depth of any tissue is determined by timing how long it takes an echo to return, then calculating depth (distance from the transducer) based on an assumed average velocity of sound in human tissue. This is the pulse-echo principle. The earliest returning echoes arise from tissue reflectors closer to the transducer; later echoes come from progressively deeper reflectors. The exact anatomic location of each reflector may be calculated from the known direction of the

sound beam in the body and the measured time of arrival of its echo. Repeated pulses are used to generate a two-dimensional image of the region interrogated.

Acoustic interfaces reflect sound and generate the echoes that make up the returning ultrasound information. Acoustic interfaces occur where two tissues of different acoustic impedance are in contact. Acoustic impedance is related to tissue density and the speed of sound in the tissues. The greater the acoustic impedance difference between the two tissues at an interface, the greater the percentage of incident sound reflected and the stronger the returning echo. This explains why ultrasound cannot “see through” gas or bone. The soft tissue–bone and soft tissue–gas interfaces have huge acoustic impedance differences, causing nearly all sound to be reflected. Clearly, if nearly all the sound beam is reflected, tissues deep to the bone or gas will not be imaged.

The amplitude (loudness) of echoes reflected from any given tissue is represented by different shades of gray. Most ultrasound images use a black background display. With this display convention, whiter shades of gray represent higher-amplitude echoes. Descriptively, echo-free structures are said to be *anechoic*. *Isoechoic* means identical in echogenicity to another tissue. *Hypoechoic* means lower in echogenicity than another tissue, whereas *hyperechoic* (or *echogenic*) means higher in echogenicity than another tissue.

The ultrasound beam is progressively attenuated (weakened) as it travels deeper into the body. Soft tissues are more attenuative than fluid-filled structures. Cystic structures cause little attenuation of sound, so that tissues deep to the gallbladder or liver cysts appear more echogenic (brighter echoes) than do neighboring areas at a similar depth. This is called *distal acoustic enhancement* or *through-transmission* of sound.

There is a tradeoff between the use of high-frequency and low-frequency transducers in ultrasound imaging. Low-frequency sound penetrates tissue effectively, facilitating good images of deep tissues (e.g., large livers). Higher-frequency transducers produce higher-resolution images but cannot penetrate sufficiently well to produce images deeper than relatively superficial structures. As a practical matter, abdominal organ ultrasonography is done with lower-frequency transducers (3 to 7 MHz). When the bowel itself (e.g., appendiceal ultrasound) is evaluated, higher-frequency transducers (5 to 10 MHz) are generally used. It is generally best to choose the highest-frequency transducer that allows adequate penetration.

Artifacts are a significant problem in ultrasound imaging. They may be related to equipment problems, but unavoidable artifacts caused by the interaction of sound and tissue are the most troublesome. Reverberation of sound between tissue and the face of the transducer can obscure detail, most notably in the near field. Blockage of sound results in acoustic shadowing—a “void” in the image deep to the structure causing shadowing. Acoustic shadowing may be complete or partial. Reflection, refraction, or absorption of the sound beam may cause acoustic shadowing. Shadowing occurs deep to obstructing objects (such as gallstones, bone, or gas) or deep to curved interfaces at the margin of cysts. Shadowing is one of the diagnostic criteria for gallstones; it can be useful in distinguishing gas or calcification from other highly echogenic reflectors. The mirror image and multipath reflection artifacts can cause tissue to appear at an incorrect depth or location, simulating, for example, liver tissue above the diaphragm, or an apparent double inferior vena cava (IVC). Side-lobe and partial thickness artifacts may lead to spurious hazy echoes that are most evident when superimposed on echo-free structures (e.g., the gallbladder). Comet-tail artifacts appear as highly echogenic “tails” deep to small intense reflectors, such as small air bubbles, surgical clips, small cholesterol crystals, and shotgun pellets.

Tissue harmonic imaging is a newer gray-scale technique that results in less image artifact. It uses the nonlinear sound produced by the ultrasound beam passing through tissue to produce images. This is distinct from conventional ultrasound, which produces images from echoes (reflected sound). Because of the decrease in artifact, tissue harmonics are becoming more popular as a way to obtain gray-scale images.

Doppler Ultrasonography

Doppler ultrasonography is a virtually routine component of many modern ultrasonographic examinations. It adds dynamic, real-time flow information to the morphologic images provided by gray-scale imaging. Flowing blood is detected by its Doppler frequency shift. Stationary soft tissue lacks a Doppler frequency shift; echoes without a Doppler shift are ignored in the production of flow images.

Color Doppler ultrasonography passively and automatically displays color-coded flow information superimposed on all or a selected portion of the gray-scale image. It detects flow and displays both flow direction and frequency shift (a rough estimate of flow velocity). Flow direction is usually displayed as red or blue; velocity estimates are depicted as different hues or a change in color saturation. Color Doppler ultrasonography is invaluable when flow detection or global anatomic information about blood flow is needed. The ability of color Doppler ultrasonography to display flow passively in real time minimizes the chance of missing flow in an unexpected area. It facilitates comparison of flow in different anatomic locations. Color Doppler ultrasonography has the advantage of displaying both flow and anatomic information in a real-time image, which is much easier to understand than a combined gray-scale and spectral “duplex Doppler” display.

Spectral Doppler acquires detailed flow information from a small area (the sample volume or range gate). Spectral Doppler is often erroneously called *duplex Doppler*. In fact, both color and spectral Doppler are duplex—both display flow and morphologic information simultaneously. Spectral Doppler is useful when detailed quantitative information about flow velocity or pulsatility is important (e.g., in liver transplantation). Spectral Doppler information is displayed graphically as a time-velocity waveform, scrolled out across the screen. Spectral Doppler information can also be processed into an audible signal that is very useful to experienced examiners. For example, arteries can be distinguished from veins audibly, and the higher-pitched sound of stenosis can be useful in detecting arterial narrowing. In many situations, color Doppler ultrasonography is first used to survey a vessel to facilitate fast and accurate spectral Doppler sample volume placement.

Ultrasound Contrast Agents

As of this writing, however, no ultrasound contrast agent has received U.S. Food and Drug Administration approval for radiologic imaging. Limited approval has been granted for cardiac ultrasonography. Although in its infancy in the United States, significant contrast research, as well as daily clinical use, is occurring worldwide. Use of these agents improves the diagnostic power of ultrasound imaging and may expand ultrasound’s current role into diagnosis of conditions for which computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine are dominant. Most new ultrasound contrast agents are intravenously injected microbubbles.

Microbubble ultrasound contrast agents enhance the useful ultrasound signal reflected back to the ultrasound transducer. The increased signal is depicted as an increase in echogenicity [1] or increase in signal strength. Ultrasound contrast agents thus affect gray-scale imaging as well as color or spectral Doppler imaging.

Vascular enhancement may involve several types of improvement in examination quality. First, greater portions of vessels are seen, and smaller, deep vessels are visible. Second, spectral Doppler signal from a vessel is increased. Third, vascular signals are enhanced, so that flow, stenosis, and thrombus determinations are made with more confidence. [2]

Even though some ultrasound contrast agents do not enter the tissues, all traverse both large vessels and small capillaries. Thus, on gray-scale imaging, they can appear to enhance an entire organ rather than merely its large arteries and veins. Gray-scale enhancement is a new method of ultrasound imaging that may dramatically change ultrasonographic tumor evaluation and diagnosis. [3]

Gray-scale enhancement with harmonic imaging dramatically increases the conspicuity of the ultrasound signal from microbubbles. Harmonic imaging takes advantage of the resonance of the microbubbles during insonation. Benefits of harmonic imaging and other techniques include a significantly increased signal-to-noise ratio of the image.

Strengths and Weaknesses Compared with Other Modalities

When ultrasonography can image the area of clinical interest, it is a nearly ideal modality. The ability of diagnostic ultrasonography to display flow and soft tissue in real time is unique among imaging techniques. Its spatial resolution is superior to CT and MRI. It is safe and tolerated well by patients. When needed, ultrasound can be performed quickly and at the bedside. Unfortunately, there are many circumstances in which optimal, or even adequate, images cannot be obtained. The single most important problem is the inability of ultrasonography to see beyond gas–soft tissue and bone–soft tissue interfaces. This makes comprehensive survey scanning essentially impossible. CT, especially, and MRI are better survey modalities.

Many abnormalities displayed automatically on whole-body CT or MRI are either impossible or very difficult to visualize ultrasonographically. Finally, ultrasonography is technically challenging—scanning to obtain optimally diagnostic images is more of an art than a science. Producing acceptable diagnostic images

ultrasonographically is usually harder than obtaining acceptable CT or MRI images. Ultrasonography, however, is often superior to CT and MRI in patients who are uncooperative, unable to hold their breath, or unable to remain relatively still during examination. Ultrasonography is often superior in patients with little body fat. This makes ultrasonography very useful in pediatric imaging, for example. Patient factors that impede optimal ultrasonography include extreme obesity and limited cutaneous access, such as burns, incisions, dressings that cannot be removed, and cutaneous gastrointestinal (GI) enterostomies.

LIVER

Indications for Ultrasonography

Primary indications include suspected or known cirrhosis, suspected liver abscess, suspected liver tumor, suspected vascular abnormalities, trauma, and transplantation. Ultrasonography can also be used to characterize abnormalities found on other imaging examinations. Its safety and relatively modest cost make it an ideal means to assess the therapeutic response of known lesions, or to sequentially follow liver lesions of questionable significance. Ultrasonography is often a simple and effective way to guide percutaneous aspiration, drainage, biopsy, or tumor ablation.

Patient Preparation and Technique

Hepatic ultrasonography can be performed without special preparation. Because the other upper abdominal organs are often evaluated with the liver, an overnight fast or 8 to 12 hours of a clear liquid diet is recommended to decrease bowel gas and distend the gallbladder. It is difficult to image the entire liver, even in the best circumstances. Difficult areas include the superficial liver above the costal margin, the left tip of the lateral segment of the left lobe, and the ventral subdiaphragmatic regions. [4]

The liver is best imaged with the patient in the supine and left lateral decubitus positions, starting with 3- to 7-MHz curved linear array transducers. A subcostal acoustic window should be used first, supplemented with intercostal scans. Small sector transducers should be used to image areas inaccessible with the larger curved linear transducers. The liver surface (usually the ventral left lobe) should be evaluated for nodularity with a near-field optimized 5- to 12-MHz linear array transducer. It is easier to appreciate subtle nodularity during real-time examination than on hard-copy images. Routine color-flow imaging is useful in patients with suspected liver pathology. Optimal color-flow and spectral Doppler ultrasonography of the liver generally requires relatively low frequency (2- to 3-MHz) scanning and good acoustic access.

Normal Anatomy

The liver parenchyma is of uniform medium echogenicity, interspersed with vessels and fissures. The liver parenchyma is slightly less echogenic than the spleen, equal to or slightly more echogenic than the renal cortex, and isoechoic or somewhat less echogenic than the pancreas.

The liver has three lobes—the large right lobe, the left lobe, and the small caudate lobe. Ultrasonographic landmarks can be used to segregate the liver into lobes and segments (Fig. 153-1 and Fig. 153-2). Fissures and ligaments can be identified because they are echogenic, fat-containing structures. Portal veins, with their accompanying bile ducts and hepatic arteries, make up the portal triad. These triads are encased in echogenic fibrofatty tissue. This echogenic margin is, as a practical matter, the feature that allows differentiation from hepatic veins. Portal veins, hepatic veins, hepatic arteries, and bile ducts can also be identified with Doppler imaging. Within the porta hepatis, the left and right bile ducts lie anterior to the portal veins. This relationship is not constant more peripherally. A transverse sonogram through the porta hepatis is one of the simplest methods for determining the presence of intrahepatic biliary obstruction.

FIGURE 153-1. Normal hepatic veins. Transverse ultrasound of the upper portion of the liver shows the right hepatic vein *(RHV),* middle hepatic vein *(MHV),* and left hepatic vein *(LHV)* entering the inferior vena cava. Note the relative paucity of echogenic material around the hepatic veins, a characteristic that distinguishes them from portal veins, which have peripheral echogenic fibrofatty tissue. The middle hepatic vein separates the right and left lobes. The right hepatic vein and left hepatic vein separate the segments of the left and right lobes.

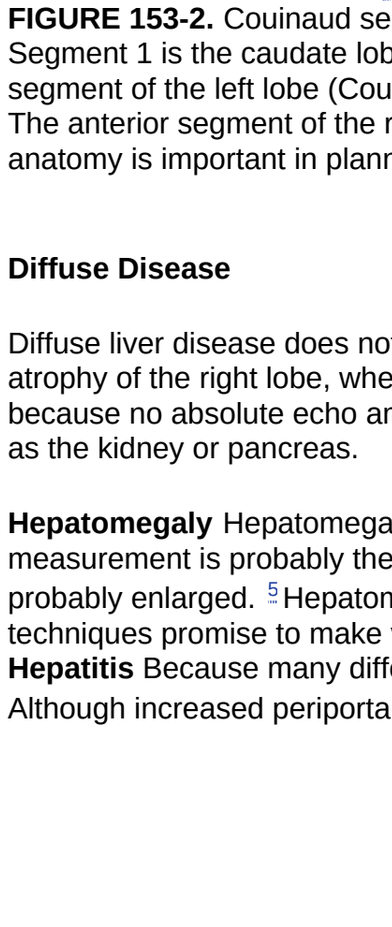

FIGURE 153-2. Couinaud segments. Transverse sonogram through the left and right portal vein, the axis through which the liver is divided into Couinaud segments. Segment 1 is the caudate lobe, bordered ventrally by the fissure for the ligament of venosum (*curved arrow*) interposed between the caudate lobe, and the lateral segment of the left lobe (Couinaud segments 2 and 3). The medial segment of the left lobe is composed of Couinaud segments 4a (cephalically) and 4b (caudally). The anterior segment of the right lobe is composed of segments 5 and 8 and the posterior segment of the right lobe of segments 6 and 7. Couinaud segmental anatomy is important in planning hepatic surgery.

Diffuse Disease

Diffuse liver disease does not always cause distortion of liver anatomy or architecture. This can make ultrasonographic detection difficult. Liver surface nodularity and atrophy of the right lobe, when present, can be useful signs of cirrhosis. Parenchymal echogenicity may be increased in diffuse disease but is difficult to evaluate because no absolute echo amplitude standard exists (analogous to CT attenuation numbers). Liver echogenicity is judged by comparison with adjacent organs, such as the kidney or pancreas.

Hepatomegaly Hepatomegaly can be difficult to diagnose objectively with ultrasonography. The normal span of the adult liver is 15 to 17 cm. The most reliable measurement is probably the sagittal dimension from the dome to the tip of the right lobe, measured at the midclavicular line. If this exceeds 15.5 cm, the liver is probably enlarged. [5] Hepatomegaly can be confidently diagnosed when the liver extends caudal to the right kidney and the left lobe is of normal size or larger. New techniques promise to make volumetric measurements feasible in the future.

Hepatitis Because many different diseases cause hepatic inflammation, ultrasonographic findings are variable. The liver is generally normal in acute viral hepatitis. Although increased periportal echoes coupled with decreased parenchymal echogenicity have been described, [6], [7] in a recent series, only 19 of 791 patients had this

pattern. [8] In the same study, there was no difference in ultrasound findings between a normal control group and patients with acute viral hepatitis. Striking irregular gallbladder wall thickening is sometimes present in patients with acute hepatitis, especially hepatitis A. [9] Direct inflammation and edema cause wall thickening, sometimes reaching 20 mm (normal, less than 3 mm). Hepatomegaly and inhomogeneous patchy or diffuse increased echogenicity are common in chronic hepatitis and are related to the amount of fatty infiltration and fibrosis present. The liver surface is smooth, unless cirrhosis is present. Enlarged arteries are noted on color Doppler ultrasonography because of increased arterial flow. This may cause a double-channel sign on gray-scale images that can potentially be confused with biliary dilation. Lymph nodes may be seen in the hepatoduodenal ligament. [10] Ultrasound findings in alcoholic hepatitis depend on the amount of fibrosis or fat present. Patchy, irregular, increased parenchymal echogenicity is usually present. The liver is often enlarged, but the surface is usually smooth, in contrast to the nodularity sometimes detected in cirrhosis. Similar to chronic hepatitis, the arteries may be enlarged.

Fatty Infiltration Severe fatty infiltration often results in an enlarged liver with diffuse increased echogenicity (Fig. 153-3). Acoustic penetration may be decreased, resulting in indistinctness of the diaphragm. The liver surface is smooth. Fatty infiltration is often patchy or focal. Focal fat appears as an area of increased echogenicity. A less affected region ("spared" area) may appear as a conspicuous hypoechoic area. Both focal fat and spared areas have a tendency to be pyramidal, with flame-shaped tapered margins. Frequent locations include the region of the porta hepatis, near the falciform ligament, the dorsal left lobe, and the caudate lobe. Although both focal fatty infiltration and focal sparing can simulate neoplasm, [11], [12] and [13] an appreciation of the usual appearance and location generally suffices to avoid confusion. Occasionally, noncontrast CT scanning, MRI, or biopsy may be required to clarify the diagnosis. Geographic fatty infiltration typically has well-defined margins between areas of greater and lesser involvement.

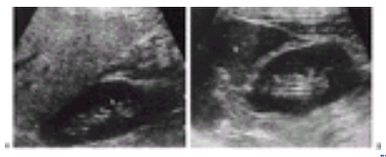

FIGURE 153-3. Fatty infiltration of the liver. Longitudinal sonogram (**A**) of the liver shows that the liver is much more echogenic than the right kidney (*k*). The echogenicity of the splenic parenchyma (*S*) and left renal cortex sonogram (**B**) are nearly equivalent. This internal comparison of the liver and spleen to adjacent kidneys allows a more reliable determination of the increased liver echogenicity associated with fatty infiltration.

Cirrhosis Ultrasonographic findings of cirrhosis include changes in the shape of the liver, parenchymal inhomogeneity, and nodularity of the liver, notably at the surface. Intrahepatic vessels may be indistinct. Unfortunately, these signs are both insensitive and insufficiently specific to diagnose cirrhosis reliably. The caudate and left lobes tend to be relatively less affected by cirrhotic scarring than the right lobe. This sometimes results in a small right lobe with left and caudate lobe hypertrophy, especially in hepatitis B. Ratios comparing the size or volume of the caudate to the shrunken right lobe have been used to diagnose cirrhosis. [14], [15] These ratios may not be practical, however, because a large series revealed a sensitivity of 43% and an accuracy of 79% for the caudate lobe–to–right lobe ratio. [16] Evaluation of the smoothness or nodularity of the liver surface using a high-resolution linear array transducer is useful. [17], [18] and [19] Surface nodularity may be the only ultrasonographic sign of irrhosis. Some studies have not confirmed the usefulness of evaluating surface nodularity. [19] We believe that the specificity for macronodular cirrhosis is good, although micronodular cirrhosis is often missed. The only other significant cause of surface nodularity is multiple subcapsular tumor nodules, usually from metastasis. Color Doppler ultrasonography may detect portal vein flow reversal or portal collaterals, prompting the diagnosis of portal hypertension. These may be the only findings indicating severe liver disease in an otherwise normal study. Enlarged tortuous arteries are sometimes imaged by color Doppler ultrasonography in cirrhotic livers. This finding, similar to "corkscrew" arteries seen angiographically, probably occurs because of truncation of arteries from liver atrophy related to cirrhosis, coupled with the increased arterial flow [20] that occurs when portal venous flow decreases. Focal fatty infiltration, hepatocellular carcinoma (HCC), regenerating nodules (adenomatous hyperplastic nodule), or other focal lesions may occur in a cirrhotic liver. A liver mass in a cirrhotic patient strongly suggests the possibility of HCC.

Hepatic Vascular Disease

Portal Hypertension Ultrasonographic evaluation of portal hypertension includes evaluation of the portal venous system and a search for portosystemic collaterals. The normal main portal vein measures slightly more than 1 cm in diameter. Although portal vein size is not useful, a lack of respiratory variation in size may be useful in diagnosing portal hypertension. [21] Normally, blood flows toward the liver (hepatopedal) in portal veins. Reversed (hepatofugal) flow, although often associated with collaterals, [20] may be the sole indication of portal hypertension. Other portal flow abnormalities include bidirectional flow and, rarely, nearly static blood flow. Ultrasound contrast agents can be useful in aiding the detection of flow in the main portal vein and other hepatic vessels. [22] Detection of portal collaterals may prompt diagnosis of unsuspected portal hypertension, or reinforce it when suspected. Portal collaterals should be sought with color Doppler ultrasonography because they are often invisible on gray-scale images. The most common collaterals are left gastric (coronary) and paraumbilical veins. Left gastric collaterals, although by far the most prevalent, are often difficult to image because of their deep location. Paraumbilical veins are easier to image because they are superficial. They arise from the ventral tip of the left portal vein and usually flow caudally through the ligamentum teres, where they communicate with superficial peritoneal collaterals. Other types of portal collaterals occur, including retroperitoneal, splenorenal, splenoretroperitoneal, short gastric, and omental.

Therapeutic Portosystemic Shunts Color Doppler ultrasonography often displays surgical shunts, [23] even when they are inapparent on preliminary gray-scale images. Transjugular intrahepatic portosystemic shunt stents can be evaluated by spectral and color-flow Doppler before, after, and sometimes during the procedure. Shunt thrombosis can be reliably diagnosed only when no anastomotic flow is seen with color Doppler ultrasonography. Only direct visualization of the shunt itself should be used to determine patency or thrombosis. Secondary signs of shunt thrombosis, such as hepatopedal intrahepatic portal flow, [23] may be misleading. [24]

Venous Thrombosis Ultrasonographically, intralumenal echoes suggest clot, but they are not diagnostic. When hypoechoic or anechoic, clot may be virtually invisible without color Doppler. Anechoic thrombus is rare in neoplastic invasion but is fairly common with bland clot. Color Doppler ultrasonography highlights clot by displaying flow around the clot and in adjacent patent vessels. [20] Portal venous thrombosis can result from neoplastic invasion, septic portal thrombosis (pylephlebitis), and pancreatitis. We believe that thrombosis in portal hypertensive patients [20], [25] is considerably more common than the 1% previously reported. [26] Color Doppler ultrasonography is unrivaled in diagnosing partially occluded vessels. Small residual flow channels are automatically displayed in color. Clot resolution or progression can be documented on serial examinations. Contrast agents may be useful in difficult cases. Cavernous transformation of the portal vein, resulting from main portal vein clot, consists of prominent hepatopedal portal collaterals. In acute portal vein thrombosis, color Doppler ultrasonography may reveal small acute hepatopedal portal collaterals, invisible on gray-scale ultrasonography. This may be a precursor to cavernous transformation of the portal vein.

Budd-Chiari Syndrome Ultrasonography, especially with color Doppler imaging, is the preferred screening technique for evaluating patients with suspected Budd-Chiari syndrome. [27] Gray-scale findings include hepatic vein abnormalities: absence, stenosis, dilation, irregularity, and abnormal or absent junction with the IVC. The IVC may itself be occluded or stenosed. Less specific changes include caudate hypertrophy, atrophy and enlargement of the other lobes and segments, and parenchymal inhomogeneity. Absent or reversed hepatic venous flow and intrahepatic hepatic vein–to–hepatic vein "spider web" collaterals are diagnostic of Budd-Chiari syndrome. A flat hepatic vein waveform, lacking the normal phasic fluctuation, indicates hepatic vein compression–a finding that, although nonspecific, supports the diagnosis of Budd-Chiari syndrome. Other collaterals seen in Budd-Chiari syndrome include hepatic vein–to–portal vein collaterals with portosystemic shunting (e.g., through enlarged paraumbilical veins, esophageal varices) and hepatic veins to systemic veins.

Other Vascular Diseases Ultrasonographic findings in hepatic venoocclusive disease are nonspecific changes related to fibrous obliteration of microscopic central hepatic lobular venules. These findings, not universally present, include thickened gallbladder wall, abnormal or reversed portal venous flow, [28] and increased hepatic artery peripheral resistance. [29] Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), characterized by telangiectasias, arteriovenous (AV) fistulas, and aneurysms, involves the liver in about one third of patients. Gray-scale findings include enlarged hepatic arteries and increased echogenicity from fatty infiltration or cirrhosis. [30], [31] Color Doppler ultrasonography reveals enlarged, tortuous, arteries with high-velocity flow. Color Doppler ultrasonography clarifies the potentially confusing gray-scale appearance that may mimic biliary dilation. Visualization of hepatic AV fistulas is variable and probably depends on their size. Color Doppler ultrasonography can be used to diagnose and follow hepatic pseudoaneurysms and AV fistulas, to assess the results and adequacy of vascular interventional procedures without recourse to angiography, and to demonstrate portal and hepatic vein malformations. Thrombosis or occlusion of the hepatic artery are the most common causes of hepatic infarction. [32] Ultrasonographically, infarcts are usually peripherally located, hypoechoic, wedge-shaped lesions. Others are round and centrally located. In the acute phase, the infarcts are ill-defined, hypoechoic lesions that evolve into more anechoic or cystic areas. [33] After hepatic infarction, cystic collections of bile may develop (bile lakes).

Focal Liver Disease

All standard noninvasive imaging modalities are insensitive detectors of focal hepatic disease, with individual lesion detection rates ranging from 38% to 66% for MRI and CT. [34], [35] Focal hepatic lesions are frequently missed with one modality, then detected with another. Although ultrasonography is less sensitive than CT and MRI, modern ultrasonography can perform well in detecting focal liver disease. [36], [37] and [38] Arterial and portal venous phase imaging with ultrasound contrast agents can

increase both the detection and characterization of lesions in patients with cirrhosis or liver metastasis. [39], [40] Ultrasound contrast enhancement may prove useful in differentiating benign from malignant tumors [2], [3], [41], [42] and [43] (Fig. 153-4).

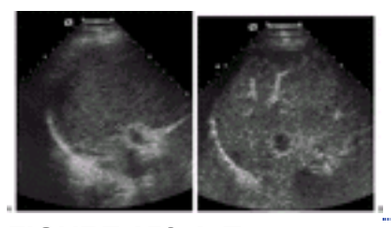

FIGURE 153-4. Transverse ultrasound image through the medial segment of the left lobe in a patient with prior right hepatectomy for metastatic disease from adenocarcinoma of unknown primary. **A:** Precontrast gray-scale image shows a mass that is difficult to see (*cursors*). **B:** Postcontrast gray-scale image shows a small hypoechoic metastasis (*cursors*). Note that the surrounding liver is hyperechoic, consistent with increased vascularity with respect to the metastasis.

The main strengths of ultrasonography are its ability to guide biopsy and to characterize common benign lesions (cysts, hemangiomas), its safety, and its low cost. Its weaknesses include its inability to image the entire liver in some patients and its inferiority to CT in detecting extrahepatic disease. Ultrasound-guided biopsy is more efficient and cost-effective, even when lesions are initially detected with some other modality. Ultrasonography may be used to evaluate resectability of primary or metastatic liver tumors. Color Doppler ultrasonography improves detection of focal lesions, especially anechoic or hypoechoic lesions. Some tumors are more conspicuous because of increased flow compared with normal liver: focal nodular hyperplasia (FNH), most HCCs, some metastases, and occasionally other masses. [44], [45] and [46] Color and spectral Doppler can be used to help discriminate among benign and various types of malignant liver tumors. [47], [48], [49] and [50]

Simple Cysts The prevalence of simple cysts increases with age. [51] When a cyst is found in a young patient, other diseases should be considered, including autosomal dominant polycystic disease, von Hippel–Lindau disease, and conditions simulating simple cysts, such as echinococcal disease, residua from trauma or infection, and cystic neoplasia. Ultrasonography is usually superior to CT and MRI for evaluating cysts. Simple cysts are usually well-defined, echo-free, round or oval lesions with imperceptible walls and good through-transmission (Fig. 153-5). Thin septations are frequent and should not suggest a different diagnosis. Thicker septations are generally a sign of a complicated cyst or of a cystic neoplasm.

FIGURE 153-5. Simple liver cyst. This 2.5-cm cyst is anechoic, has imperceptible walls, and has prominent through-transmission (*(whiter area,* deep to the cyst). There is a thin septation within the cyst (*arrow*). Thin (but not thick) septations are perfectly compatible with diagnosis of a classic simple cyst.

Hepatic Polycystic Disease Ultrasonographic findings include multiple, often contiguous simple cysts. Irregular shape and septae are common. Hemorrhage or infection may cause debris-like echoes within one or more cysts. [52] About one half of patients have renal cysts. Von Meyenburg complex is a rare disorder characterized by multiple small cystic hamartomas of the bile ducts that may be detected with CT or ultrasonography.

Other Cystic Lesions Acquired cysts may occur as a result of trauma or infection. [53], [54] and [55] Neoplasms that simulate simple cysts are unusual; metastases from squamous cell carcinoma, GI stromal tumors, and cystic adenocarcinomas occasionally do this. Hepatobiliary cystadenoma is a rare neoplasm probably arising from bile duct epithelium. These lesions are predominantly multicystic with varying amounts of solid tissue. [56], [57] and [58] The liver is the most frequently involved organ in hydatid (echinococcal) disease. A spectrum of ultrasonographic findings from purely cystic to solid-appearing pseudotumors occurs. Internally, wavy bands of delaminated endocyst (the “water lily” sign) may be noted. [59] Daughter cysts, sometimes surrounded by echogenic debris (“matrix”) are frequent. Calcifications, varying from tiny to massive, are often present. A densely calcified cyst usually indicates a dead, inactive lesion. Previously considered contraindicated, percutaneous drainage and treatment are gaining wider acceptance.

Pyogenic Liver Abscess When liver abscess is suspected clinically, ultrasonography is the preferred screening modality. Ultrasonographically, pyogenic liver abscesses have a variable appearance (Fig. 153-6). Typical features include irregular margins and a primarily hypoechoic mass. Irregular areas of increased echogenicity are frequent. On occasion, a diffusely hyperechoic appearance may be noted, owing to microbubbles from gas-forming organisms. Diffuse microabscesses, often associated with biliary obstruction, may cause a confusing ultrasonographic pattern of increased irregular hepatic echogenicity. Clusters of small low-echogenicity lesions may also be noted. [60] Septic portal venous thrombosis (pylephlebitis), which may be imaged ultrasonographically, may lead to liver abscess. [61]

FIGURE 153-6. Pyogenic liver abscess. This transverse sonogram of the right lobe of the liver shows a mixed echogenicity, predominantly hypoechoic liver abscess at the hepatic dome. The lesion is not well defined medially, a feature of pyogenic liver abscess on ultrasonography.

Amebic Liver Abscess Amebic liver abscesses tend to have a round or oval shape and hypoechoic appearance with fine, homogeneous, low-level echoes throughout. Image findings alone are rarely sufficient to distinguish amebic from pyogenic liver abscesses. [62] Amebic liver abscess can have ultrasonographic patterns that are bizarre, including diffuse increased echogenicity, debris levels, and prominent heterogeneity. When it is unclear clinically if an abscess is amebic or pyogenic, percutaneous diagnostic aspiration should be performed (necessary in 15% of patients in our institution). In contrast to pyogenic liver abscesses, percutaneous drainage of amebic liver abscess is rarely indicated. [63] Therapeutic aspiration provides no objective benefit when compared with the use of oral amebicidals alone. [64]

Candidiasis Candidiasis, occurring in leukemic and other immunocompromised patients, causes multifocal hypoechoic lesions typically smaller than 2 cm. Four distinct ultrasonographic patterns of hepatic microabscesses from candidiasis have been described by Pastakia and associates. [65] These include discrete hypoechoic nodule, a bull’s-eye configuration, a discrete echogenic focus with variable degrees of acoustic enhancement, and a wheel-within-a-wheel appearance. Internal echogenic foci produce the target or wheel-within-a-wheel appearance. [66], [67] Echogenic lesions and lesions larger than 2 cm are much less common.

Benign Neoplasms

Cavernous Hemangioma Cavernous hemangioma, the most common benign hepatic neoplasm (prevalence, 1% to 4%), rarely causes clinical symptoms. Although ultrasonographic findings are often classic, hemangiomas must often be evaluated further to exclude more significant lesions, especially in patients with malignancy. Small hemangiomas are usually well-defined, echogenic lesions with enhanced through-transmission [68] (Fig. 153-7). Larger hemangiomas frequently diverge from this pattern. Mixed-echogenicity lesions and even hypoechoic hemangiomas may occur.

FIGURE 153-7. Small hepatic hemangioma. This transverse sonogram at the level where the hepatic veins enter the inferior vena cava (*I*) reveals a well-defined, white, echogenic focus that is virtually diagnostic for hepatic hemangioma.

Typical small hemangiomas in a patient without evidence of malignancy should be followed by ultrasound in 3 to 4 months. Hemangiomas rarely change on serial exams. [69] Lesions in patients with malignancy should be evaluated further with T2-weighted MRI or 99mTc-tagged red cell blood pool single photon emission computed tomography scanning. Preliminary results suggest that addition of ultrasound contrast agents may be sufficient to diagnose incidentally detected hemangiomas at ultrasound confidently [3], [70] (Fig. 153-8). CT and MRI may fail to identify small (less than 1 cm) hemangiomas detected with ultrasound. If needed, thin-needle biopsy is a reasonable and safe way to evaluate hemangiomas, [71], [72] provided skilled cytologic consultation is available.

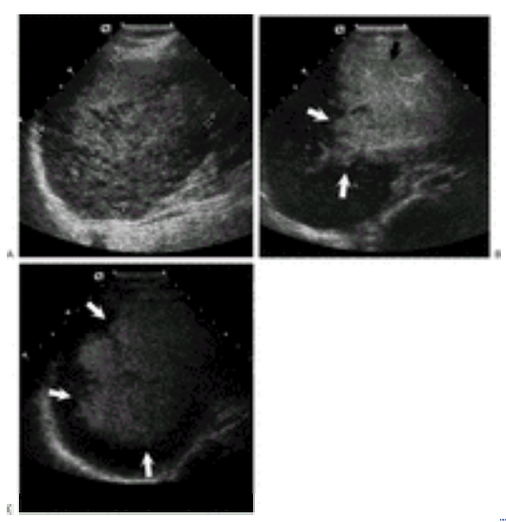

FIGURE 153-8. Atypical hemangioma (stable for 11 years): transverse gray-scale ultrasound image through the right lobe. **A**: Precontrast shows large ill-defined heterogenous mass (*cursors*). **B**: Postcontrast, normal liver (*black arrow*) and the medial wall of the hemangioma (*white arrow*) enhance. **C**: At 90 seconds postcontrast administration, a larger volume of tissue with delayed enhancement is seen (*arrows*).

Focal Nodular Hyperplasia and Liver Cell Adenoma FNH is a clinically insignificant lesion, whereas liver cell adenoma (LCA) can cause morbidity and mortality because of hemorrhage and, occasionally, malignant degeneration. The ultrasonographic features of FNH and LCA are variable. There is a tendency for FNH to be more homogeneous than LCA. FNH often has mildly increased echogenicity compared with normal parenchyma, whereas LCAs are usually hypoechoic and more inhomogeneous. [73], [74], [75], [76] and [77] On color-flow imaging, FNH usually has markedly increased flow, sometimes with vessels radiating peripherally from a central feeding artery. [42]

Malignant Neoplasms

Hepatocellular Carcinoma Advanced HCC is almost always multifocal, making it difficult to distinguish from metastatic disease (Fig. 153-9). Small HCCs (less than 5 cm) are often (75%) hypoechoic. [78] As HCCs grow, they tend to develop hypoechoic peripheral rims. [79] With further progression, lesions become more numerous and heterogeneous. Fatty metamorphosis may cause increased echogenicity and confusion with hemangioma. [80] Hepatic or portal venous invasion should suggest the diagnosis of HCC, although other liver tumors may invade veins. [81] Rarely, HCC invades the bile duct. About three fourths of patients with HCC have identifiable internal color flow, compared with one third of those with metastases. Most HCCs show very abnormal corkscrew tumor vessels both at the center and at the periphery with ultrasound contrast agents, a pattern distinct from benign tumors. [3] Fibrolamellar HCC, which accounts for 2% of HCCs but 25% to 50% of HCCs in young adults, is typically a single well-circumscribed lesion in an otherwise normal liver. Other features include a “central scar” and calcification, both of which also occur in other subtypes of HCC and lesions of other histology. [77]

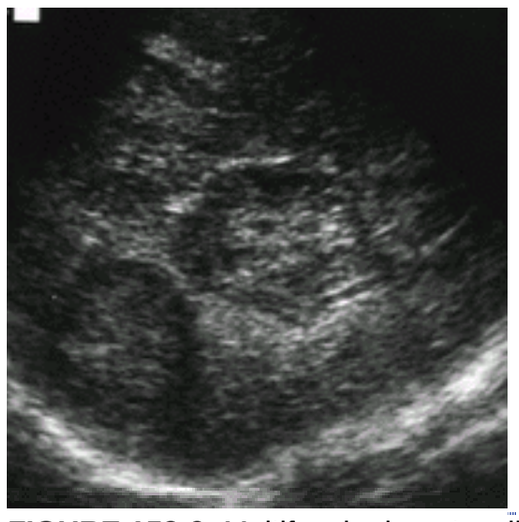

FIGURE 153-9. Multifocular hepatocellular cancer. A transverse sonogram shows multiple tumor nodules in the right lobe of the liver. Some of these are hypoechoic, and others have echogenic centers with hypoechoic rims.

Hepatic Metastasis Metastatic disease, the most common liver malignancy in North America, is multifocal in 90% of patients. Virtually any ultrasonographic appearance may occur. Metastatic lesions, whether diffuse or focal, are usually heterogeneous. Hypoechoic halos or target or bull’s-eye patterns with rings of varying echogenicity are common. Ill-defined infiltration with focal nodularity is another frequent pattern. Metastases that simulate simple cysts or classic hemangiomas are uncommon. Predominantly fluid-filled, presumably necrotic metastases occur most frequently with squamous cell carcinoma, sarcomas, and ovarian and testicular carcinoma. Calcified lesions, especially mucinous adenocarcinoma, may occur. Although ultrasonographic appearance is a poor predictor of the primary tumor, certain patterns are suggestive. Large to moderate-sized hyperechoic metastases should suggest the possibility of a colonic primary. Lesions with fluid-fluid levels

(representing intralesional necrosis and hemorrhage) are often found with metastatic GI stromal tumors. Distinction between metastasis and HCC occasionally requires ultrasonographically guided biopsy. Invasion of the portal or hepatic veins suggests HCC rather than metastasis. Even though portal venous invasion in metastatic disease has been reported in as many as 8% of patients, [82] our experience suggests a lower prevalence.

Human Immunodeficiency Virus Infection The liver is often involved by neoplasm (non-Hodgkin lymphoma, Kaposi sarcoma) or by opportunistic infection in patients with human immunodeficiency virus (HIV) infection. Ultrasonographic findings of uncertain cause, such as decreased periportal echogenicity or focal hyperechoic areas, are frequent. High- and intermediate-grade HIV-related B-cell lymphomas cause focal liver lesions more frequently than other lymphomas. These are usually hypoechoic masses that may exhibit increased peripheral color flow. Kaposi sarcoma usually infiltrates the liver, causing little or no ultrasonographic abnormality. Kaposi sarcoma may cause focal masses and increased periportal echogenicity. [83] Multiple echogenic foci, often imaged more clearly ultrasonographically than with CT, may give a starry-sky pattern with disseminated *Pneumocystis carinii* infection. [84] This pattern also occurs with mycobacterial or cytomegalovirus infection. [85] On occasion, disseminated *Pneumocystis* infection results in larger calcifications or large, hypoechoic lesions.

Other Focal Lesions Hepatic lymphoma and leukemia are usually microscopic. Only about 5% cause ultrasonographically detectable focal liver lesions. [86] The lesions are usually anechoic or hypoechoic, although other patterns occur. [87] Chloroma of the liver, associated with myelogenous leukemia, can be hypoechoic or echogenic. HIV-related lymphomas cause more frequent and conspicuous focal lesions than other lymphomas. Hepatic sarcomas are rare. Angiosarcomas and undifferentiated embryonal sarcomas are usually large, internally inhomogeneous masses. [88] Hepatic epithelioid hemangioendothelioma, a rare vascular sarcoma, [89] starts as a multinodular tumor, coalescing as it grows. It is usually hypoechoic compared with normal liver. Hypertrophy of the uninvolved normal liver may occur. Adenomatous hyperplastic nodules in cirrhotic livers (regenerating nodules) are premalignant lesions that, when visualized, are usually hypoechoic and may have a thin echogenic rim. [90] Intrahepatic extramedullary hematopoiesis may cause inhomogeneous, mainly hypoechoic, masses. [91] Mesenchymal hamartoma of the liver is usually a large, mainly cystic mass with septae of variable thickness and solid internal tissue. [92] Intrahepatic hematomas may cause ultrasonographically visible masses.

Trauma

CT is the mainstay for evaluating hemodynamically stable patients with suspected blunt hepatic trauma. Ultrasonography can be used effectively to detect hemoperitoneum, but it has a rather limited role in the initial diagnostic evaluation of hepatic trauma. A high percentage of liver and other parenchymal injuries are missed ultrasonographically. [93] Ultrasonography may be valuable in the follow-up of nonoperated patients and in diagnosing posttraumatic complications, including biloma, vascular pseudoaneurysms and AV fistulas, and abscesses.

Liver Transplantation

Ultrasonography, especially Doppler imaging, is important in evaluating liver transplantation candidates and potential donors. [94] Ultrasonography can be useful in defining portal hypertension–related collaterals, detecting portal vein clot, delineating spontaneous or surgical portosystemic shunts, and detecting HCC in the native liver.

After transplantation, ultrasonography can screen for hepatic arterial occlusion. [95] Absent flow on color Doppler and decreased peripheral resistance, measured by resistive index, [96] are signs of arterial compromise. The use of ultrasound contrast agents may improve the accuracy and speed of examination in transplant recipients. When abnormalities are noted, arteriographic evaluation and intervention are often indicated. [97] Hypoechoic infarcts or intrahepatic fluid collections may result when arterial occlusion occurs. Cholangiography is generally needed to detect bile duct injuries reliably because ultrasonography may miss 50% of bile duct complications. [98] Posttransplantation fluid collections include abscess, biloma, seroma, lymphocele, and hematoma. [99]

Overview of Hepatic Imaging

The main strengths of hepatic ultrasonography are its ability to characterize common benign lesions (cysts, hemangiomas) and to guide percutaneous procedures, its safety, its excellent patient tolerance, and its low cost. In the near future, the application of ultrasound contrast agents to the liver may extend the utility of ultrasound from a screening examination to a lesion-detection and diagnosis modality. Its weaknesses include inability to image the entire liver in some patients and inferiority to CT in detecting extrahepatic disease. When liver abscess is suspected clinically, ultrasonography. The ability of ultrasonography to image in any oblique plane often makes it superior to CT and MRI in localizing lesions to an anatomic hepatic segment when evaluating resectability of a liver tumor.

In experienced hands, ultrasonographically guided liver biopsy is often quicker and easier than CT guidance. Ultrasonography can directly visualize the needle tip as it is placed in the lesion, facilitating biopsy of small lesions and lesions in uncooperative patients. Ultrasound-guided biopsy is more efficient and cost-effective, even when lesions are initially detected with some other modality. Despite the advantages of ultrasonography, CT-guided biopsy is often more popular with radiologists because it almost always shows needle location. Ultrasonographic needle visualization may be difficult or impossible when the liver is echogenic or when acoustic access is imperfect. Newer ultrasonographic techniques that enhance needle-tip visualization and improved biopsy guides promise to make ultrasonographically guided biopsies easier.

Ultrasound contrast enhancement also may be useful in delineating residual tumor after ablation. Viable tumor can be identified and targeted for retreatment with ultrasound contrast during or after ethanol [100] or radiofrequency ablation. Interestingly, US failed to demonstrate flow in residual tumor before contrast enhancement, an indication of the potential usefulness of ultrasound contrast agents in these patients.

GALLBLADDER

Indications for Ultrasonography

Ultrasonography is the imaging method of choice for the initial evaluation of all suspected diseases of the gallbladder. It is particularly valuable in patients with acute right upper quadrant pain and possible acute cholecystitis. [101], [102] Ultrasonography is highly reliable in detecting tiny gallstones and is useful for evaluating focal or diffuse abnormalities of the gallbladder wall. [103] Biliary ultrasonography has several distinct advantages compared with scintigraphy and CT. It is less expensive and can be performed rapidly without patient preparation or contrast agents. Unlike biliary scintigraphy, ultrasonography is not organ specific and may provide important diagnostic information regarding the liver, pancreas, and peritoneal cavity. Ultrasonography can readily be performed in patients with abnormal liver function that may preclude scintigraphy. Finally, ultrasonography may be used to guide percutaneous cholecystostomy in critically ill patients at the bedside.

Patient Preparation and Technique

In patients undergoing ultrasonography for acute right upper quadrant pain and possible acute cholecystitis, no prior preparation is necessary, and patients can be imaged directly from the emergency room. Patients undergoing elective ultrasonography to evaluate the gallbladder should be fasting for a minimum of 6 hours. This will ensure adequate distention of the gallbladder to visualize small stones and facilitate imaging of the gallbladder wall.

Normal Anatomy

Except in the rare instance of agenesis, the normal gallbladder can be visualized in virtually all fasting patients [104], [105] as a pear-shaped, fluid-filled structure along the inferomedial aspect of the right lobe of the liver. The gallbladder is typically less than 12 cm in length and is up to 3 cm in anteroposterior diameter. The normal gallbladder wall measures less than 3 mm. In addition to agenesis, other rare anomalies of the gallbladder that may be diagnosed with ultrasonography include duplication and septations between the fundus and body (Phrygian cap). [106]

Gallstone Disease

Stones as small as 3 to 5 mm can be easily visualized ultrasonographically. The characteristic ultrasonographic appearance is an intralumenal echogenic focus casting a distal acoustic shadow (Fig. 153-10). It may be difficult to document acoustic shadowing in all patients with small gallstones. By varying the patient's position, mobility of the gallstones may be demonstrated in a high percentage of patients. Demonstrating mobility helps to differentiate small stones from polyps

arising from the gallbladder wall that will not change in position.

FIGURE 153-10. Gallstones in a patient with adenomyomatosis. Note the intralumenal gallstone *(curved open arrow).* There is an intramural gallstone (*straight open arrow)* within a diffusely thickened gallbladder wall (*arrow*) as a result of adenomyomatosis.

Although ultrasonography is accurate for detecting stones within the gallbladder, once stones migrate into the cystic duct, they are often very difficult to visualize. [107] It is important to perform parasagittal images of the neck, gallbladder, and cystic duct region in patients with right upper quadrant pain. The identification of impacted cystic duct stones strongly suggests cystic duct obstruction.

Echogenic abnormalities within or adjacent to the gallbladder at times may ultrasonographically mimic gallstones. These include polyps, tumefactive sludge, surgical clips, and air bubbles. Gallbladder polyps are echogenic mucosal lesions that do not shadow. Sludge within the gallbladder is never a normal finding. It generally indicates lack of gallbladder emptying with precipitation of cholesterol or calcium bilirubinate crystals. At times, sludge crystals may adhere together as “tumefactive” sludge and mimic a gallstone or mucosal mass. Gas within the gallbladder may be due to surgically created biliary-enteric anastomoses, endoscopic biliary procedures, or gas-forming infection from emphysematous cholecystitis.

Acute Cholecystitis

The most important ultrasonographic findings to confirm the diagnosis of acute cholecystitis are gallstones, gallbladder wall thickening, and a positive ultrasonographic Murphy sign. [101], [102] The ultrasonographic Murphy sign differs significantly from the clinical sign. It refers to focal, unequivocal tenderness directly over the visualized gallbladder when pressure is applied by the transducer. In a prospective study of 497 patients with acute right upper quadrant pain, the combination of gallstones and a positive Murphy sign had a 92% positive predictive value for acute cholecystitis. [101] Gallbladder wall thickening (greater than 3 mm) and pericholecystic fluid in the appropriate clinical setting are secondary findings of acute cholecystitis, but both nonspecific findings may be due to a variety of other disorders. Biliary scintigraphy should be performed whenever the ultrasonographic findings are equivocal.

In a small percentage of patients (5% to 10%), acute cholecystitis develops in the absence of gallstones or cystic duct obstruction. [108] Conditions implicated in acalculous cholecystitis include trauma, major surgical procedures, hyperalimentation, burns, sepsis, and other severe intercurrent illnesses. The ultrasonographic findings in early acalculous cholecystitis are often subtle and nonspecific. In a small percentage of patients, the gallbladder may be normal early in the clinical course. [109] Generalized symmetric thickening of the gallbladder wall is frequently not due to cholecystitis and must be interpreted with caution. It may be due to such diverse conditions as hepatitis, fluid overload, portal hypertension, or hypoalbuminemia. In the appropriate clinical setting, gallbladder wall thickening with a positive ultrasonographic Murphy sign is suggestive of acute acalculous cholecystitis. The sensitivity of ultrasonography for the diagnosis of acalculous cholecystitis, however, is substantially less than with calculous cholecystitis, in the range of 63% to 67%. [110] Interval follow-up studies performed at 24 to 48 hours may be valuable in demonstrating progressive gallbladder wall edema or the development of fluid.

In patients without acute right upper quadrant pain, stones within a contracted gallbladder often indicate chronic cholecystitis. Shrinking of the gallbladder wall is a common associated finding. Marked contraction of the gallbladder around a large stone results in the wall-echo shadow sign, and there is prominent acoustic shadowing from the gallbladder fossa.

There are several ultrasonographic features that, in the appropriate clinical setting, may suggest gangrenous cholecystitis. These include pericholecystic fluid, intralumenal membranes (due to sloughed mucosa or fibrinous debris), and asymmetric thickening of the gallbladder wall [110] (due to intramural microabscesses or hemorrhage). A high percentage of patients with gangrenous cholecystitis do not have a positive ultrasonographic Murphy sign. [111] In critically ill patients with suspected gangrenous cholecystitis, ultrasonography may be useful to guide percutaneous cholecystostomy even at the bedside.

Perforation of the gallbladder with pericholecystic abscess is a major cause of sepsis and morbidity from acute cholecystitis. [112] Pericholecystic abscesses appear ultrasonographically as complex fluid collections in direct contiguity with the gallbladder. Mural necrosis may be identified ultrasonographically as a focal loss of the normal reflectivity of the gallbladder wall. Inflamed omental and pericholecystic fat has been noted adjacent to pericholecystic abscesses. These fatty structures “wall-off” the abscesses from the greater peritoneal cavity. Hyperemia of the inflamed omental fat may be demonstrated with color Doppler imaging. [113]

Gallbladder Tumors

Most benign neoplasms of the gallbladder originate from the mucosal surface of the gallbladder and are either adenomatous or cholesterol polyps [114], [115] (Fig. 153-11). Small polyps are often incidental findings that, when less than 5 mm in diameter, are of no cause for clinical concern. Enlarging gallbladder polyps on serial sonograms or polyps greater than 1 cm in diameter are usually an indication for cholecystectomy owing to the slight increased risk for carcinoma.

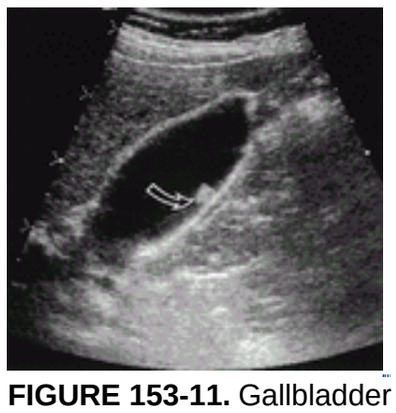

FIGURE 153-11. Gallbladder polyp. Note the echogenic mucosal mass without an acoustic shadow (*arrow*).

The ultrasonographic findings of gallbladder carcinoma are variable and include a polypoid mucosal lesion or focal or irregular thickening of the gallbladder wall, sometimes associated with an extramural mass. [116] In advanced cases of gallbladder carcinoma, patients may present with a large mass arising from the gallbladder fossa. [116] Direct hepatic invasion and nodal metastases may also be demonstrated ultrasonographically. However, in many instances, CT is required to delineate more precisely the extent of tumor and to detect distant spread of the disease.

Other Conditions

Adenomyomatosis and cholesterolosis are benign disorders of the gallbladder that are classified as hyperplastic cholecystoses. [114], [115] Cholesterolosis typically results in either single or multiple small mucosal polyps. It is due to the subepithelial accumulation of cholesterol-laden histiocytes that ultimately extend to the mucosal surface. Adenomyomatosis causes either focal or diffuse hypertrophy of the normal Rokitansky-Aschoff sinuses and smooth muscle within the gallbladder wall. Crystals and debris may be trapped within the sinuses of the hypertrophied wall and produce echogenic foci with echogenic comet-tail artifacts.

BILE DUCTS

Indications for Ultrasonography

The ability of ultrasonography to detect dilated bile ducts and the level of biliary obstruction makes it the technique of choice for evaluating jaundiced patients. Ultrasonography can also detect the cause of obstruction, albeit with less accuracy. Infectious cholangitis and conditions such as HIV cholangiopathy are indications for ultrasonography. Ultrasonography can detect and assess, with the help of color Doppler, resectability of cholangiocarcinoma and other tumors affecting the bile ducts.

Patient Preparation and Technique

Biliary ultrasonography is best performed after an overnight fast or 8 to 12 hours of a clear liquid diet. Because distention of the gallbladder is desirable, fatty foods should be avoided. The biliary tree is best imaged with the patient in the supine and right anterior oblique positions, starting with 3- to 7-MHz curved linear array transducers. A subcostal acoustic window should be used first, supplemented with intercostal scans. Sector or other small-footprint transducers are often useful to image the extrahepatic bile duct and the cystic duct of the gallbladder. Transverse compression views of the pancreatic head region with large-footprint curved linear transducers are useful to visualize the intrapancreatic bile duct, where about 90% of symptomatic common duct stones are located. [117] Color-flow imaging is useful to differentiate the bile ducts from vessels and to detect hyperemia in and near the gallbladder.

Normal Anatomy

Ultrasonography routinely displays the normal intrahepatic and extrahepatic ducts. The normal extrahepatic bile duct (common duct) runs ventral to the main portal vein (Fig. 153-12) and to the left of the proper hepatic artery. The internal diameter of the normal extrahepatic bile duct is 5 mm or less, although elderly patients and patients with cholelithiasis may have 6- to 9-mm internal-diameter ducts. The distal common duct is usually seen within the pancreatic head and has a somewhat smaller caliber. The intrahepatic bile ducts may be seen ventral to the left and right portal veins. The normal internal diameter of the main left and right intrahepatic bile ducts is about 1 mm.

FIGURE 153-12. Normal common bile duct. This long-axis view of the normal common bile duct *(CBD)* shows the relationship of the bile duct to the portal vein (*PV*). Note that the right hepatic artery *(RHA)* passes ventrally (above) the bile duct. This occurs in 10% of patients. In 90% of patients, the right hepatic artery passes between the portal vein and the bile duct. The common bile duct enters the pancreatic parenchyma. IVC, inferior vena cava.

Bile Duct Obstruction

Stones are the most common cause of distal bile duct obstruction. Tumors are a more frequent cause of proximal bile duct obstruction. Ultrasonographically, dilated intrahepatic bile ducts are tubular anechoic structures that demonstrate posterior acoustic enhancement. Centrally, in the porta hepatis, dilated ducts are usually ventral to the portal veins. Peripheral ducts have a variable relationship to the portal veins. The “too many tubes” sign is the classic pattern indicative of intrahepatic biliary dilation. Color Doppler is useful to distinguish veins and enlarged arteries from dilated bile ducts, simplifying detection of abnormal ducts and preventing misidentification of vessels as bile ducts.

Surprisingly, normal bile duct size is controversial. Obstruction is rarely present when the extrahepatic bile duct is 5 mm or less in maximal internal diameter. Nondilated obstruction may be seen in cholangiocarcinoma or sclerosing cholangitis. Bile ducts with maximal internal diameters of 10 mm or more are almost always obstructed. In most patients, 6- to 9-mm ducts (“gray-zone”–sized ducts) are not obstructed, but rather are that size because of breakdown of the elastic fibers within the duct wall. Patients older than 50 years of age are given 1 mm per decade in duct diameter. For example, a 7-mm duct should be considered normal in a 70-year-old patient. Patients with cholelithiasis often have 6- to 9-mm-diameter ducts. We postulate that this is caused by degeneration of elastic tissue within the duct wall from transient obstruction caused by recurrent passage of stones. This is analogous to the increased residual diameter of a deflated balloon that has been repeatedly blown up and deflated. Rarely, an unobstructed duct 10 mm or larger may be found. Administration of a fatty meal may aid in evaluating gray-zone–sized ducts. A decrease of 2 mm in duct size after a fatty meal indicates normal bile dynamics and excludes obstruction. If the extrahepatic duct enlarges after the fatty meal, obstruction is likely.

Distal bile duct obstruction causes extrahepatic bile duct dilation and often intrahepatic bile duct dilation. Intrahepatic duct dilation is almost always a sign of obstruction, although rare exceptions are seen. Thus, intrahepatic dilation is specific for obstruction, but it is less sensitive than extrahepatic bile duct dilation. Obstruction at sites other than the distal duct results in proximal dilation, with a normal-caliber distal duct.

Choledocholithiasis Choledocholithiasis occurs in at least 15% of patients with cholelithiasis. Conversely, 95% of patients with common duct stones also have gallstones. [118] The prevalence of choledocholithiasis in patients with gallstones increases with age. [119] A shadowing echogenic focus in the bile duct is virtually diagnostic of cholelithiasis (Fig. 153-13). Shadowing may be difficult to demonstrate in some impacted stones. Potential pitfalls include the Mirizzi syndrome, air in the bile duct, extrabiliary calcifications, or surgical clips. On occasion, a completely stone-filled duct may be confused with a gas-containing segment of bowel. Extrahepatic biliary dilation is present in 70% to 94% of patients with choledocholithiasis. [120], [121] Although stones in normal-sized ducts can be identified, these are probably harder to detect than stones in dilated ducts.

FIGURE 153-13. Common duct stone. This long-axis view of the intrahepatic and extrahepatic bile ducts reveals two echogenic common duct stones (*arrows*). Note the cystic duct (*curved arrow*) entering the common duct dorsally.

Bile duct stones are harder to detect than gallstones, with optimal reported sensitivity of 75% to 80%. [122] The difficulty relates to gas sometimes obscuring the distal duct and the lack of echo-free bile around impacted stones. About 90% of proximal, suprapancreatic duct stones (about 10% of cases) are detected. [123] Meticulous technique is necessary to achieve optimal sensitivity. A prospective Finnish trial reported detection rates of only 22% for ultrasonography and 25% for CT in patients with choledocholithiasis. [123]

Infectious Cholangitis

Contrast CT is probably the best screening examination in patients with severe cholangitis. [124] Ultrasonography is the study of choice in patients with clinically less severe cholangitis. Diffuse bile duct wall thickening is often present. [125] Debris in the bile duct suggests the presence of pus and, hence, infectious cholangitis. Liver abscesses can be identified.

Recurrent Pyogenic Cholangitis Recurrent pyogenic cholangitis (also known as Oriental cholangiohepatitis) is characterized by recurrent bacterial cholangitis promoted by strictures and primary bile duct stones that may occur in any part of the biliary tree. Gallstones and liver abscesses are frequent. [126] Ultrasonography is the preferred initial imaging modality. [127], [128] Most patients have huge stones with dramatic shadowing that can obscure the biliary tree. The soft, mudlike stones are often of medium echogenicity, however, and may lack acoustic shadowing. This appearance can mimic sludge, pus, blood, or even neoplasm within the biliary tree. Markedly dilated intrahepatic and extrahepatic ducts are the rule. It is not unusual for duct size to exceed 2 cm. [129] Ultrasonography is limited in patients with prior biliary enteric anastomosis because intraductal gas obscures both the ducts and intrahepatic calculi. Gas may also make detection of liver abscesses difficult.
Human Immunodeficiency Virus–related Cholangiopathy HIV-related cholangiopathy is a diffuse biliary tract disease affecting the gallbladder and the bile ducts. More than 80% of patients have alkaline phosphatase levels greater than twice normal, but bilirubin is usually normal or minimally elevated. [129], [130] and [131] Ultrasonography, although less sensitive than endoscopic retrograde cholangiopancreatography, is useful in evaluating patients suspected of having HIV-related cholangiopathy. [131] Smooth or irregular thickening of the bile duct wall (45%) and biliary dilation (about 70%) are frequent abnormalities. [132] Biliary dilation often occurs in association with ampullary stenosis. An echogenic nodule at the end of the common duct, thought to represent an edematous ampulla of Vater, has been described. Striking thickening of the gallbladder wall with prominent wall striations suggestive of acute acalculous cholecystitis may occur. [129], [131], [133]

Tumors

Cholangiocarcinoma Primary bile duct tumor, cholangiocarcinoma, has two forms: peripheral cholangiocarcinoma and hilar cholangiocarcinoma (Klatskin tumor). [134], [135] In the United States, peripheral cholangiocarcinoma is three times more common than hilar cholangiocarcinoma. In Japan, hilar and peripheral cholangiocarcinoma occur in equal numbers. [136] Peripheral cholangiocarcinoma is usually a large tumor. Hilar cholangiocarcinomas present earlier with ductal obstruction and jaundice and are more difficult to image because the tumors are smaller. Cholangiocarcinoma is usually hypoechoic (Fig. 153-14), but isoechoic and hyperechoic tumors may occur. [137]

FIGURE 153-14. Cholangiocarcinoma. Transverse sonogram in the region of the porta hepatis shows biliary dilation and a hypoechoic mass (*M*).

Color and spectral Doppler ultrasonography are useful in determining whether cholangiocarcinoma is resectable. [138], [139] Cholangiocarcinoma is unresectable when one of the following is present in both the left and right lobes: lobar atrophy, vascular invasion, or obstruction of two or more sectorial (segmental) ducts. Vascular invasion, narrowing, and tumor contiguity are readily demonstrated with color Doppler ultrasonography. Duct involvement can be diagnosed when a duct is obstructed by a mass or when wall thickening or an intraductal mass is identified. When two or more ducts peripheral to the left or right hepatic duct are involved by the mass, sectorial (segmental) duct involvement is present. Sectorial ducts are those that arise from different liver segments and join to form the main left and right hepatic ducts. *The ultrasonographic evaluation of the bile ducts should be performed before stenting, if at all possible.* Stenting may cause mural and periductal hemorrhage or edema that can obscure or simulate tumor. It may also interfere with identification of dilated sectorial ducts by decompressing them.
Biliary Cystic Neoplasm Biliary cystic neoplasms (formerly called biliary cystadenoma and cystadenocarcinoma) are rare. Lesion morphology ranges from completely cystic with a few thin septations to cystic with thick septations and large amounts of internal soft tissue. Thick, sometimes papillary septations and larger amounts of internal soft tissue characterize the mesenchymal variant, which has a greater potential for malignant behavior.

Other Conditions

Biliary Parasites Biliary parasites such as *Ascaris* species or *Clonorchis sinensis* may infest the biliary tree and cause secondary biliary tract obstruction. [140] Ultrasonographically, the adult *Ascaris* organism may be visualized as a tubular structure within the bile ducts or gallbladder. The flukes of *C sinensis* are small and not generally visible with ultrasonography. However, aggregates or clumps of parasites may be identified within the extrahepatic bile duct or within the gallbladder.
Mirizzi Syndrome Mirizzi syndrome is biliary obstruction caused by a gallstone impacted in the cystic duct or gallbladder neck. Extrinsic compression and inflammation obstruct the extrahepatic bile duct. Ultrasonography may suggest the diagnosis when a stone is impacted in the neck of the gallbladder, proximal bile duct dilation is present, and the distal common bile duct is normal.
Choledochal Cysts Of the four main types of choledochal cysts, about 90% of cases involve dilation of the extrahepatic bile duct (type I). Ultrasonographically, there is obvious dilation of the extrahepatic duct, often associated with varying degrees of intrahepatic dilation. Dilation may be cystic (IA), focal (IB), or fusiform (IC). Other types include choledochal diverticula (type II), choledochocele (type III), and multiple intrahepatic or extrahepatic cysts (type IV). [141]
Caroli Disease Caroli disease is cystic dilation of the intrahepatic bile ducts. Some cases are associated with a choledochal cyst (Todani type 4A). Ultrasonographically, Caroli disease is characterized by multiple small cystic areas that may or may not appear to communicate with the unaffected bile ducts. A central vessel identified with Doppler ultrasonography supports the diagnosis. Other findings include renal cysts, cirrhosis, or liver abscess.
Bilomas Bilomas are encapsulated bile collections caused by rupture, usually traumatic, of the biliary tree. [142] Large asymptomatic bilomas are not rare. Ultrasonographically, bilomas are usually well-defined anechoic collections with striking through-transmission of sound. Detection of a lesion with this appearance 2 to 6 weeks after liver trauma strongly suggests the diagnosis. [143] Occasionally, bilomas are more complex, with internal debris and septations and less pronounced through-transmission, which are features that may also occur with abscesses. In these cases, needle aspiration can exclude infection and confirm the presence of bile by laboratory analysis for bilirubin. Bilomas discovered incidentally in asymptomatic patients generally do not require treatment; they resolve spontaneously within a few weeks. Imaging studies alone cannot always distinguish bilomas from abscesses, chronic hematomas, or hepatic cysts. Percutaneous drainage, when required, is often an effective alternative to surgery. [142], [144]

PANCREAS

Indications for Ultrasonography

Although CT remains the most sensitive means of evaluating pancreatic disease, modern ultrasound technology and new scanning techniques (oral contrast, compression scanning) are reestablishing ultrasonography as a useful and clinically relevant pancreatic imaging technique. Ultrasonography is indicated in all patients with acute pancreatitis, not to evaluate the pancreas itself but rather to detect gallstones and biliary dilation. CT is superior to ultrasonography in evaluating potential complications of pancreatitis, but ultrasonography may be used to follow pancreatitis-associated fluid collections and can guide biopsy, drainage, and aspiration of selected pancreatic lesions. Ultrasonography is the primary imaging method to screen patients with jaundice or abdominal pain. Thus, ultrasonography may detect acute or chronic pancreatitis or reveal pancreatic masses. Ultrasonography may be more effective than CT in determining whether a lesion is pancreatic or contiguous to the pancreas. Ultrasonography is occasionally useful to characterize abnormalities noted on CT, determining, for example, whether a lesion is cystic or solid.

Patient Preparation and Technique

Pancreatic ultrasonography is easier after the patient has fasted overnight or for at least 6 hours. This improves visualization of the gallbladder and minimizes GI gas. The spatial resolution of ultrasonography is better than that of CT and MRI when conventional scanning parameters are used. In some patients, however, CT is needed to visualize the pancreas adequately. With ultrasonography, optimal pancreatic visualization requires that intervening GI content (gas and fluid) be displaced by compression or by filling the gut with water or GI contrast material. For the head and body, we prefer compression, using 3- to 7-MHz curved array transducers. Compression results in better resolution—the transducer is closer to the pancreas. The left lateral decubitus position may be useful, with visualization of the pancreatic head through the gallbladder or liver. Oral administration of water may be helpful if compression is unsuccessful.

The tail of the pancreas is more difficult to image. Routine pancreatic scanning should include coronal and axial views through the spleen and left kidney. The normal tail is usually not seen, but lesions invisible on other views, especially pseudocysts, are occasionally delineated. Water or contrast in the stomach is useful for imaging the tail. Right anterior oblique positioning is useful to view the tail though the water-containing stomach. Color-flow imaging can assess vascular complications of pancreatitis and delineate vascular relationships to pancreatic neoplasms.

Normal Anatomy

The normal pancreatic parenchyma is finely homogeneous and isoechoic to hyperechoic compared with liver parenchyma. The pancreas is a retroperitoneal organ that lies draped over the spine, aorta, and IVC. The pancreatic head is medial to and intimately related to the sweep of the second and third portions of the duodenum. The head is ventral to the IVC and medial to the superior mesenteric artery and vein (Fig. 153-15). In cross section, the round and sonolucent common bile duct is seen in the posterior head, sweeping caudally and to the right as it passes into the duodenum. The body lies ventral to the aorta, splenic vein, and superior mesenteric artery, behind the stomach (with the collapsed potential space of the lesser peritoneal sac between). The pancreatic tail nestles into the splenic hilus and is closely related to the upper pole of the left kidney.

FIGURE 153-15. Normal pancreatic head. The pancreas (*P*) is more echogenic than the hepatic parenchyma (*L*). Note the anatomic relationship of the duodenum (*D*) to the pancreatic head. The rounded anechoic areas within the pancreatic head are the gastroduodenal artery (anteriorly) and the common bile duct (*curved arrow*).

Acute Pancreatitis

Evaluation with ultrasonography is mandatory for all patients, even alcoholic patients, during their first attack of acute pancreatitis. Ultrasonography in patients with acute pancreatitis focuses on the gallbladder and bile ducts—the gallbladder for stones (as a cause of pancreatitis) and the bile duct for choledocholithiasis and obstruction.

The reported prevalence of acute pancreatitis–associated abnormalities varies widely—33% to 90% of patients. Pancreatic echogenicity typically decreases in acute pancreatitis because of interstitial edema but can be considered abnormally hypoechoic only when echogenicity is less than liver parenchyma. Because the normal pancreas may be more echogenic than the liver, echogenicity is normal in many patients with acute pancreatitis. In patients with echogenic livers from fatty infiltration, the normal pancreas may be relatively hypoechoic, simulating the findings of pancreatitis. This is called *pseudopancreatitis*. Rarely, echogenicity may actually increase with acute pancreatitis, owing to hemorrhage, necrosis, or fat saponification. With newer ultrasonographic systems, inhomogeneity of the parenchyma is often evident in acute pancreatitis.

Enlargement of the pancreas in acute pancreatitis is probably almost universal. Unfortunately, enlargement may be difficult to judge because pancreatic size before the onset of pancreatitis is unknown and varies widely from individual to individual. It is not unusual to detect extrapancreatic inflammatory changes even when the pancreas appears normal. Thus, extrapancreatic abnormalities may be the only ultrasonographic findings that suggest the diagnosis of acute pancreatitis. Hypoechoic inflammation is often seen around the pancreas, in the anterior retroperitoneal spaces bilaterally, in the transverse mesocolon, around splanchnic vessels, and elsewhere. [145] Acute fluid collections, pseudocysts, and abscesses may be imaged. Color and spectral Doppler ultrasonography may be useful in detecting pancreatitis-associated vascular complications, such as pseudo- aneurysms and portal thrombosis.

Acute Pancreatic Fluid Collections and Pseudocysts Acute pancreatic fluid collections and pseudocysts are the most common complications of pancreatitis. Pancreatic fluid collections consist of a combination of pancreatic juice, edema fluid, hemorrhage, and necrotic tissue resulting from acute pancreatic inflammation, enzymatic autolysis, and pancreatic ductal disruption. Two features distinguish a pancreatic pseudocyst from an acute fluid collection: persistence past 4 to 6 weeks, and a well-defined wall (fibrous pseudocapsule). [146] Acute fluid collections occur in about 30% to 50% of patients with severe pancreatitis, but more than half of these regress spontaneously. CT is more sensitive than ultrasonography in diagnosing acute pancreatic fluid collections and pseudocysts. [145] Once an acute pancreatic fluid collection is identified with CT or ultrasonography, serial studies should be performed to document either resolution or persistence as a pseudocyst. If ultrasonography shows the pancreatic fluid collection well, it is the most cost-effective method for serial evaluation. CT should be performed immediately before any surgical drainage of a pseudocyst, to identify any lesions not detected by ultrasonography. Acute fluid collections and pseudocysts have a variable ultrasonographic appearance depending on the associated internal hemorrhage and debris. Acute fluid collections may be anechoic to hyperechoic but are generally hypoechoic with internal debris. Enhanced through-transmission is almost always present but is variable in degree. Color Doppler ultrasonography should be used to ensure that all discrete cystic-appearing areas are not pseudoaneurysms.

Pancreatic Abscess and Infected Pancreatic Necrosis The two major infectious complications of acute pancreatitis are infected pancreatic necrosis and pancreatic abscess. Pancreatic abscess is a circumscribed collection of pus that contains little or no necrosis. Infected pancreatic necrosis is a region of infected nonviable pancreatic parenchyma. Pancreatic abscess is associated with a lower mortality rate (7% to 33%) than is infected pancreatic necrosis (about 40%). [147] Necrosis is diagnosed by contrast CT—no enhancement of the pancreatic parenchyma corresponds to necrosis. Currently, ultrasound cannot diagnose pancreatic necrosis. Contrast CT, because of its superiority to ultrasonography as a survey modality, is preferred if infectious complications are sought. Unfortunately, image findings alone cannot distinguish infected from uninfected collections, [148] so that aggressive use of CT- or ultrasound-guided needle aspiration is mandatory to diagnose

infection. The treatment of infectious complications of pancreatitis is controversial. Localized pancreatic abscess responds well, albeit imperfectly, to percutaneous drainage. Van Sonnenberg and colleagues [149] reported successful cure in 69% of patients with pancreatic abscess by percutaneous drainage alone.
Hemorrhage and Vascular Complications Erosion of small vessels is the most frequent cause of pancreatitis-associated hemorrhage. It may result in bleeding into the pancreatic bed or the pancreatic duct or in a pseudocyst. Peripancreatic pseudoaneurysm [150] is rare but potentially catastrophic. Pseudoaneurysms occur most often in the splenic artery (42%), gastroduodenal artery (22%), and small peripancreatic arteries (25%). Contrast CT and Doppler ultrasonography can identify pseudoaneurysms, but smaller pseudoaneurysms (i.e., less than 1 cm) are more reliably diagnosed angiographically. Inflammation from acute pancreatitis may cause venous occlusion. The splenic vein is most commonly affected and may result in gastric varices. The superior mesenteric or portal veins are also occasionally involved. Color Doppler ultrasonography and contrast CT may be very useful to diagnose pancreatitis-related thrombosis in the portal venous system.

Chronic Pancreatitis

Image findings are poor predictors of the clinical severity of chronic pancreatitis, [151] although patients with severe exocrine insufficiency are more likely to have abnormal pancreatic size and contour irregularity. [152] Multiple calcified stones located within the main or branch pancreatic ducts are the hallmark of chronic pancreatitis, usually alcohol related. Ultrasonography is less sensitive than CT in detecting pancreatic calcifications. On occasion, the pancreas is diffusely hyperechoic. This may be difficult to judge ultrasonographically because the pancreas is normally more echogenic than adjacent parenchymal organs like the liver. Bolondi [153] believes that dilation of the main pancreatic duct is the most reliable sign of chronic pancreatitis. The double-duct sign (dilation of pancreatic and bile ducts) may occur not only in pancreatic carcinoma but also in chronic pancreatitis. [154] Glandular atrophy or fatty infiltration may occur, making evaluation of the pancreas difficult ultrasonographically. Chronic asymptomatic pseudocysts may be found in patients with chronic pancreatitis.

Focal masses that can simulate neoplasm occur in about one third of patients with chronic pancreatitis. Calcification within the mass is strongly suggestive, but not definitive, of chronic pancreatitis. Uncalcified isoechoic or hypoechoic masses may require endoscopic retrograde cholangiopancreatography or biopsy to exclude malignancy. [151]

Neoplasms

Ultrasonography is the primary imaging method to screen patients with jaundice or abdominal pain. Thus, ultrasonography often detects pancreatic masses. Ultrasonography may be useful to characterize the internal architecture of masses, information that may be useful in classifying neoplasms. Ultrasonography may detect a carcinoma as an area of decreased echogenicity within the gland when no morphologic or attenuation abnormality is noted on CT. [155]

Ductal Adenocarcinoma Ultrasonographically, pancreatic carcinoma is typically a hypoechoic mass that deforms the gland's morphology (Fig. 153-16). Occasionally, pancreatic carcinoma is echogenic. A few scattered calcifications or cystic areas may occur occasionally (about 5% each). [156] Secondary findings of carcinoma include ductal dilation (biliary and pancreatic; see Fig. 153-16), vascular and extraglandular invasion, and metastatic disease. Pseudocysts, related to obstruction of a pancreatic duct, have been reported in as many as 11% of patients, [157] although in our experience, carcinoma-related pseudocysts are less frequent.

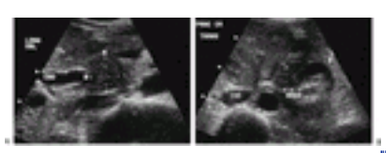

FIGURE 153-16. Pancreatic carcinoma with obstruction of the bile duct. **A**: The long-axis view of the common bile duct shows a 3.5-cm mass (highlighted by calipers A and B) that obstructs the common bile duct (*CBD*). **B**: A transverse sonogram obtained with the patient in the right anterior oblique position shows the mass (*arrows*). The mass is hypoechoic, compared with the normal pancreatic parenchyma (*p*). IVC, inferior vena cava; LRV, left renal vein.

Most recent discussions of imaging in pancreatic and periampullary neoplasms have almost totally ignored ultrasonography [158], [159] despite a 1988 study, which showed that gray-scale ultrasonography was useful in assessing resectability. [160] We and others have shown that color Doppler ultrasonography can effectively assess resectability, specifically vascular involvement by tumor, with accuracy comparable to that of CT. [161], [162], [163] and [164]
Ductal Adenocarcinoma Variants Many histological variants of pancreatic ductal adenocarcinoma are indistinguishable on images from tumors with the usual histological features. Acinar center cell carcinoma and pleomorphic giant cell carcinoma can be larger and exhibit central necrosis. [165] Mucinous ductectatic carcinoma and mucin hypersecreting carcinoma are variants of ductal adenocarcinoma. [165], [166] These lesions have markedly dilated, mucin-filled, pancreatic branch ducts, usually in the pancreatic head. Ultrasonographically, mucinous ductectatic carcinomas show multiple sonolucent, dilated ducts. A discrete mass may not be evident. Mucin hypersecreting carcinoma usually has more extensive ductal dilation.
Cystic Pancreatic Lesions The most common cystic pancreatic neoplasms are serous cystic neoplasm (microcystic adenoma) and mucinous cystic neoplasms. [167] Morphologically, microcystic adenomas comprise many tiny cysts, most smaller than 2 cm. The most distinctive feature, present in about one half of tumors, is a central radial fibrotic scar that frequently calcifies. Ultrasonographically, microcystic adenomas are echogenic in regions where there are many tiny cysts. Through-transmission is frequent. Hypoechoic, larger cysts may be seen. Calcifications are imaged more often with CT than ultrasonography. Microcystic adenomas are almost universally benign. [168] Mucinous cystic neoplasms consist of large cysts, usually easily imaged with CT or ultrasonography. Most are located in the tail or body of the pancreas and are much more common in female patients. Calcifications occur in about 20% of these neoplasms (compared with about one half of serous and microcystic neoplasms). Ultrasonography usually reveals a mass with internal cysts of variable size. Unilocular lesions may occur. The septations may be few or many, thin or thick, and polypoid. The internal architecture is often shown to better advantage by ultrasonography than CT. Mucinous cystic neoplasms may be confused with rarer cystic neoplasms such as papillary cystic tumor, cystic islet cell tumor, lymphangioma, cystic metastases, or nonneoplastic lesions, such as pseudocyst, abscess, and echinococcal disease. [169] Solid and papillary epithelial neoplasm, a low-grade malignancy found most frequently in young female patients, tends to be large and well encapsulated. Tumors can be mostly solid, mixed cystic and solid, or almost entirely cystic. Less common cystic neoplastic tumors include papillary cystic tumor, cystic islet cell tumors, and acinar cell cystadenocarcinoma. Simple cysts of the pancreas are uncommon. They occur sporadically or in association with von Hippel–Lindau syndrome and, rarely, in renal polycystic disease.
Endocrine Tumors It is difficult to image functional islet cell tumors; they are usually small when the patient presents with hormonal abnormalities. Insulinomas and gastrinomas are frequently less than 2 cm in diameter. In contrast, "nonfunctional" islet cell tumors can be large at the time of presentation. Ultrasonographic detection rates are 25% to 60% for insulinomas [170] and about 20% for gastrinomas. [171] Ultrasonographically, islet cell tumors are usually hypoechoic, well-defined, and round or oval in shape. Intraoperative ultrasonography (IOUS) is useful in localizing occult neoplasms.

GASTROINTESTINAL TRACT

Indications for Ultrasonography

The most common indication for GI tract ultrasonography is evaluation of the patient with right lower quadrant pain and possible appendicitis. Ultrasonography may also be useful in the diagnosis of diverticulitis, small bowel obstruction, and bulky mesenteric or GI neoplasms. One of the more useful applications of ultrasonography of the GI tract is endolumenal ultrasound to stage the depth of GI tract neoplasms. This is discussed in Chapter 154.

Patient Preparation and Technique

Patients undergoing ultrasonographic evaluation for possible GI tract abnormalities typically require no special preparation. Patients with right lower quadrant pain and possible appendicitis can be imaged immediately after initial assessment in the emergency room. Evaluation of the stomach and duodenum may be facilitated by having the patient drink sufficient water to distend the upper GI tract. A water enema may be useful in selected patients to evaluate pelvic masses.

Graded compression ultrasonography is the most important technique for evaluation of possible appendicitis and other focal GI tract abnormalities. [172] This technique takes advantage of the fact that lesions infiltrating the bowel wall alter its compressibility. The normal GI tract can be readily compressed by the sonologist when moderate pressure is applied with the transducer. However, inflammatory or neoplastic disorders of the bowel alter its compressibility and render it relatively noncompressible. [173], [174]

Ultrasonography has a number of important advantages compared with CT in evaluating the GI tract. Real-time observation of bowel peristalsis is possible with ultrasonography. Delineation of layers of the bowel wall (most importantly, the echogenic submucosal layer) is also readily apparent with ultrasonography. Rapid multiplanar imaging can be performed and vascular flow can be assessed without contrast agents with the use of color and power Doppler (the most sensitive form of color Doppler ultrasonography). [175], [176] Finally, ultrasonography is an interactive technique, and the patient can be scanned at the site of maximal pain and tenderness to correlate symptoms with anatomic abnormalities. It should be noted, however, that ultrasonography is often unable to image all the lumenal GI tract mesentery and subperitoneal space reliably because of bowel gas.

Graded compression is generally performed with a high-resolution linear array transducer (5 to 10 MHz) depending on the depth of the structures to be imaged. For most other GI studies, a 5-MHz curved array transducer yields the best results.

Normal Anatomy

Standard abdominal transducers do not delineate all five layers of the bowel wall. The echogenic submucosal layer, however, is clearly visible and serves as a constant anatomic feature that is an extremely useful landmark to identify an intra-abdominal structure as a bowel loop. Pathological processes that cause ulceration and necrosis of the bowel lead to either focal or global loss of visualization of the echogenic submucosa. [177] Primary neoplasms involving the bowel wall may result in focal bowel wall thickening, referred to as the *target sign* or *pseudokidney sign*. [178] Tumor infiltrating the bowel wall appears as a hypoechoic mass (mimicking the cortex of the kidney). The echogenic mucosal surface lumen is preserved, mimicking the fat-containing hilum of the kidney. Gas trapped within ulcerating lesions involving bowel wall may result in high-amplitude echoes with acoustic reverberation artifacts within the submucosal layers of the bowel wall.

Color Doppler ultrasonography may be a useful adjunct to gray-scale imaging in evaluation of patients with focal bowel wall thickening. [175], [176] Increased arterial flow within the involved segment suggests either inflammation or infection; diminished or absent flow suggests intramural hemorrhage, ischemia, or infarction. The vascularity of GI tract tumors is variable, but in general, adenocarcinomas are hypovascular.

Acute Appendicitis

In patients with an uncertain clinical diagnosis of appendicitis, ultrasonography is preferred to CT in women of childbearing age, pediatric patients, and thin, adult male patients. CT is preferred in patients who are obese or if appendiceal perforation is suspected. [179] The ultrasonographic criteria for diagnosing acute appendicitis include a noncompressible appendix measuring 7 mm or more in greatest anteroposterior diameter [180] (Fig. 153-17). An appendix measuring 5 mm or less is virtually always normal. Appendices measuring 5 to 6 mm are equivocal for appendicitis, and clinical observation, repeated ultrasonography, or both should be considered. [180] In a patient with right lower quadrant pain, the presence of an appendicolith within a noncompressible appendix generally indicates acute appendicitis regardless of the size of the appendix. In some patients, early acute appendicitis is confined to the distal tip of the appendix. [181] It is therefore important always to visualize the entire length of the appendix to evaluate for distal appendicitis.

FIGURE 153-17. Acute appendicitis. Note distended appendix (*A*) with dilated tip (*cursors*).

Diverticulitis

In most patients, CT is the imaging method of choice to evaluate patients who present with left lower quadrant pain and possible sigmoid diverticulitis. [182] This is particularly true in septic patients with possible paracolonic abscesses that may require percutaneous or surgical drainage. [183] Nevertheless, ultrasonography may play a useful role as a screening examination in patients with pelvic pain and unclear signs and symptoms of diverticulitis. The ultrasonographic findings in acute diverticulitis include focal mural thickening of the bowel and increased echogenicity of the mesenteric fat with hyperemia on color Doppler imaging. [184] In some patients, the infected colonic diverticulum may be identified as an echogenic intramural focus due to either gas or echogenic pus within the diverticulum. [184] On occasion, ectopic gas bubbles may be identified in the sigmoid mesentery due to their characteristic high-amplitude linear echoes and distal reverberation artifacts.

Enteritis and Colitis

The ultrasonographic findings of enteritis or colitis are often nonspecific. [185] Typical findings include focal areas of mural thickening of the bowel, often with associated adjacent adenopathy. There is lack of compressibility of the involved segment with graded compression. Increased color-flow Doppler may be demonstrated with high-frequency probes. Fibrofatty mesenteric masses may be identified as focal echogenic areas in Crohn's disease. In general, CT is superior to ultrasonography in identifying mesenteric abscesses, colovesicular fistulas, and retroperitoneal abnormalities that accompany Crohn's disease. [185]

Mesenteric Adenitis

In the presence of a normal appendix or ultrasonography, the identification of enlarged mesenteric lymph nodes is highly suggestive of mesenteric adenitis. There may also be associated thickening of the terminal ileum. [186] Once this diagnosis is suggested, patients should be observed clinically without surgery intervention. Symptoms of mesenteric adenitis typically resolve spontaneously without specific therapy. Color Doppler may be useful to highlight the hypoechoic lymph nodes adjacent to the flow in mesenteric vessels.

Intestinal Obstruction

Ultrasonography and CT may play an important role in the patient with possible small bowel obstruction. [187] The characteristic ultrasonographic features are dilated fluid-filled loops with increased peristalsis on real-time examination. Fluid-filled levels and echogenic intralumenal debris may also be seen within the dilated, obstructed bowel. In any patient with possible obstruction, a specific attempt should be made to identify a transition zone between dilated and nondilated bowel. This is often the most specific finding to confirm the diagnosis of obstruction. On occasion, ultrasonography may identify GI tract tumors, mesenteric masses, abscesses, and other intra-abdominal pathology that caused the obstruction. The appearance of intussusception is characteristic on ultrasonography because there is a target appearance of the invaginated intussusceptum. A crescent-shaped intralumenal area of echogenic fat representing invaginated mesentery is identified at the level of the lead point.

Gastric outlet obstruction may be diagnosed whenever marked dilation of the stomach is noted with a collapsed duodenum. In selected patients, however, gastroparesis may have a similar appearance. Closed-loop obstruction characteristically results in a single U-shaped aperistaltic loop of dilated bowel (Fig. 153-18). Hyperperistaltic bowel is noted proximal to this loop.

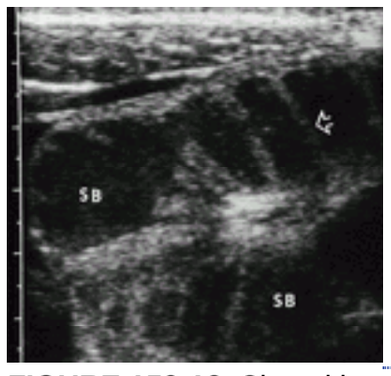

FIGURE 153-18. Closed loop small bowel obstruction. Dilated U-shaped loop of small bowel (*SB*) represents closed loop obstruction.

Small Bowel Infarction

In most patients with suspected mesenteric ischemia and small bowel infarction, CT, mesenteric angiography, or both are performed emergently. However, in selected patients, ultrasonography may be performed owing to confusing signs and symptoms on clinical presentation. Mural thickening of the small bowel wall due to either intramural hemorrhage or edema may be visualized as a noncompressible area of mural thickening. [175], [176] In the appropriate clinical setting, absence of vascular flow on color and, more specifically, power Doppler suggests the diagnosis of ischemia.

Gastrointestinal Tract Tumors

In patients with palpable abdominal masses, ultrasonography is often valuable in identifying the organ of origin of the lesion. As previously noted, the pseudokidney sign may be due to tumors infiltrating through muscular elements of the bowel wall (Fig. 153-19). Caution must be observed, however, in that focal inflammatory or ischemic processes may mimic neoplasms on ultrasonography. Endoscopy, barium studies, and CT are often required to establish a more precise diagnosis. Both lymphoma and GI stromal tumors result in bulky, exophytic masses that are typically hypoechoic on ultrasonography. Areas of liquefied hemorrhage or necroses are more typical of GI stromal tumor.

FIGURE 153-19. Pseudokidney sign of gastrointestinal tumor. Sagittal sonogram of midabdomen demonstrating a mass (*arrows*) that resembles a kidney.

PERITONEAL CAVITY

Indications for Ultrasonography

The most common indication to evaluate the peritoneal cavity with ultrasonography is to search for intraperitoneal fluid collections such as ascites, abscesses, or hemorrhage. Ultrasonography is useful not only to identify intraperitoneal fluid collections but also to guide percutaneous needle aspiration for definitive diagnosis. Solid peritoneal masses representing either primary or metastatic tumors may also be detected on occasion with ultrasonography. However, CT is the preferred imaging modality in patients with a clinical suspicion for peritoneal metastases.

Patient Preparation and Technique

Scanning of the pelvic peritoneal spaces is easier when the bladder is full. The distended bladder provides an excellent acoustic window to evaluate the cul-de-sac or retrovesical recess. However, the remainder of the peritoneal cavity can readily be imaged with little or no patient preparation. In general, a curved 3.5- or 5-MHz transducer provides adequate penetration for a general abdominal survey to detect intraperitoneal fluid in the upper peritoneal compartments. Where access is difficult, sector transducers may be useful. High-resolution linear arrays (5 to 7.5 MHz) are best for evaluation of superficial peritoneal implants and omental abnormalities.

Intraperitoneal Fluid Collections

Ultrasonography excels in demonstrating even minute quantities of intraperitoneal fluid (Fig. 153-20). With endovaginal scanning, small amounts of intraperitoneal fluid may routinely be demonstrated in the cul-de-sac as a normal finding in ovulating women. In the upper abdomen, free intraperitoneal fluid first collects in the hepatorenal fossa, which is the most dependent portion of the supramesocolic peritoneal cavity. [188] As fluid increases within the peritoneal cavity, it involves the subphrenic, subhepatic, and intraloop compartments. [189] Massive ascites typically displaces bowel loops centrally unless tethered by adhesions. [190]

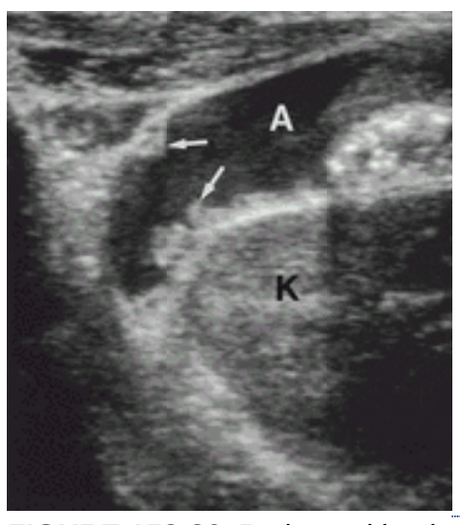

FIGURE 153-20. Peritoneal implants from mesothelioma. Transverse scan of right lower quadrant demonstrates ascites (*A*) and plaquelike peritoneal implants (*arrows*). K, right kidney.

Uncomplicated serous fluid collections are typically anechoic. On ultrasonography, complex fluid characteristically demonstrates internal debris, septations, and low-level echoes. The differential diagnosis of complex intraperitoneal fluid includes hemorrhage, infection, and carcinomatosis. On occasion, long-standing bland ascites may contain internal septations and be loculated. However, ascites that is not infected generally has no mass effect and passively conforms to its intraperitoneal components. Intraperitoneal abscesses, on the other hand, typically exhibit mass effect and may displace adjacent bowel or adjacent solid organs. It is not always possible to differentiate loculated bland ascites from an abscess by ultrasonographic criteria alone. Therefore, diagnostic needle aspiration is often required.

Intraperitoneal Abscesses

CT and ultrasonography have greatly facilitated the diagnosis of intra-abdominal abscesses. [191], [192], [193] and [194] With both modalities, the predominant finding is a localized fluid collection with mass effect. Gas bubbles and an air-fluid level may be present in some patients but are not identified in most intra-abdominal abscesses. Ultrasonography is the imaging method of choice for hepatic, pericholecystic, and pelvic abscesses. CT is superior to ultrasonography in patients with pancreatic, retroperitoneal, paraspinous, intraloop, or gas-forming abscess. [192] In the postoperative setting, CT is often preferred to ultrasonography owing to frequent problems with access as a result of open wounds and surgical drains.

The ultrasonographic appearance of intra-abdominal abscesses is variable and depends on the presence or absence of septations and solid debris. [194] Also, there is considerable overlap with the ultrasonographic appearance of other complex intraperitoneal fluid collections, such as lympho- celes, bilomas, pancreatic pseudocysts, postoperative seromas, and hematomas. Because of the attenuation of sound by proteinaceous debris, many intra-abdominal abscesses demonstrate little if any enhanced through-transmission of sound. Thus, an intra-abdominal abscess may ultrasonographically mimic a solid hypoechoic mass. [194] This pitfall should always be kept in mind in a febrile patient. Color Doppler may be of value in resolving this dilemma because liquefied abscesses lack internal vascularity. Intra-abdominal enteric abscesses are often walled off by adjacent mesenteric or omental fat. In some patients, it may be possible with ultrasonography to identify adjacent abnormal bowel to identify the cause of the abscess (i.e., appendicitis or diverticulitis). Both CT and ultrasonography may be valuable for guidance of percutaneous needle aspiration for confirmation of an abscess and subsequent catheter insertion for definitive therapy. [191]

Tumors of the Peritoneum, Mesentery, and Omentum

The most common intraperitoneal neoplasms are metastatic carcinomas. Most of these lesions are tiny, plaquelike implants on the surface of the bowel or mesentery that cannot be imaged with any current diagnostic techniques. In the presence of ascites, peritoneal implants may be detected by ultrasonography as solid masses arising from the peritoneum or mesentery surrounded by peritoneal fluid (see Fig. 153-20). Thickened septations may also be demonstrated ultrasonographically. Diffuse infiltration of the omentum is a characteristic finding in patients with ovarian metastases, carcinomatosis from GI tract malignances, and primary omental tumors. Primary neoplasms involving the omentum, such as mesotheliomas, can be imaged with graded compression ultrasonography using high-frequency linear array transducers. [195] Diffuse omental infiltration (“omental caking”) typically results in a broad, bandlike mass anterior to the transverse colon. Because of its superficial location, these abnormalities are often best imaged with a high-resolution linear array transducer.

Pseudomyxoma peritonei, an unusual form of peritoneal carcinomatosis caused by mucinous adenocarcinomas of the appendix, ovary, or colon, [196] results in gelatinous intraperitoneal masses that cause subtle scalloping of solid viscera, such as the liver and spleen. Echogenic intraperitoneal masses containing debris may be detected ultrasonographically.

Mesenteric masses may often be best imaged with ultrasonography using a graded compression technique and color Doppler imaging. Adenopathy with the dorsal and ventral leaves of the mesentery may be noted to encase the mesenteric vessels highlighted by color Doppler. Primary mesenteric and peritoneal tumors such as mesothelioma cannot be distinguished from the more common metastatic peritoneal tumors.

INTRAOPERATIVE ULTRASONOGRAPHY

IOUS is an important and rapidly developing diagnostic imaging technique. It provides indispensable information that influences clinical management and choice of surgical procedure at the time of surgery. [197] Several recent technical advances have made IOUS even more effective, including the miniaturization of transducers, the use of spectral and color Doppler, and, most recently, the development of laparoscopic ultrasonography.

Indications

In gastroenterology, IOUS is most often used in evaluating patients who are candidates for surgical resection of primary or metastatic hepatic malignancies. [198] It is essential for optimal detection of all liver lesions and is far superior to all preoperative imaging, including MRI and CT portography. It is even better than surgical inspection and palpation. [199], [200] and [201] IOUS is also important in intraoperative pancreatic imaging–searching for small occult tumors, assessing tumor extension, and detecting metastatic disease in draining lymph nodes and the liver. Laparoscopic ultrasonography is important in gallbladder surgery, replacing intraoperative cholangiography in some centers. Laparoscopic ultrasonography has also been used to stage patients with bowel malignancies, particularly gastric tumors.

IOUS guidance facilitates more accurate and safer biopsy of deep-seated nonpalpable lesions and small lesions adjacent to critical vascular structures. It can effectively guide drainage of cysts, pseudocysts, and other fluid collections encountered intraoperatively. IOUS guidance is very useful for tumor ablation with cryosurgery, alcohol injection, or hyperthermic ablation with radiofrequency, laser, or microwave energy sources.

Patient Preparation and Technique

IOUS requires no patient preparation beyond that required for the surgical procedure itself. For the liver, the optimal frequency is 5 MHz, and the optimal probe design is a T-shaped probe, which images perpendicularly to the electrical cord (side-fire probe). Transducers of 5 MHz achieve sufficient penetration to scan the entire liver from the anterior surface. Anterior surface scanning is best because it is faster and allows the best acoustic coupling. [202] The pancreas is scanned with high-resolution 7.5-MHz end-fire transducers (i.e., the imaging surface is inline with the electrical cord). These higher-frequency transducers provide adequate penetration because the pancreas is much thinner than the liver. Similarly, an end-fire 7.5-MHz probe is suitable for evaluation of the gallbladder and common bile duct.

Some transducers are designed to tolerate sterilization using ethylene oxide, obviating transducer covers. Transducers are sometimes cleaned by immersion in glutaraldehyde for 30 to 60 minutes. Most practitioners, however, use sterile sheaths to cover the probes and their cords. A small amount of sterile gel is used as a coupling agent. If needed, sterile saline can be used to moisten the surface of the organ scanned.

Liver

The principal uses of liver IOUS include detection of occult primary or metastatic tumors; demonstration of lobar and segmental anatomy and of vascular supply and drainage, including accessory and anomalous vasculature; assessment of resectability and planning appropriate lobar, segmental, or nonsegmental resection; and guidance for biopsy, aspiration, or therapeutic ablation.

The superb spatial resolution of IOUS allows for consistent imaging of cysts as small as 1 to 3 mm and solid nodules as small as 3 to 5 mm. This far surpasses the usual lower limit of about 1 cm for detection of solid lesions by preoperative imaging techniques. IOUS detects 25% to 35% more lesions in the liver than preoperative imaging—most of these are 1 cm or smaller in size. [199], [200] Although some of these lesions are on the surface and can be seen or palpated by the surgeon, most additional lesions are detected only by IOUS. CT arterial portography can demonstrate 85% to 90% of the IOUS-detected lesions, [201] but there is an attendant decrease in specificity, with false-positive results owing to tiny hepatic cysts and hemangiomas, as well as perfusion artifacts. [203], [204] Experience with liver imaging is crucial to evaluate tumor extent accurately and to avoid misinterpretation of other incidentally discovered but benign lesions and pseudolesions as malignancy. Malignant tumors of similar size tend to look very much alike in each individual patient. Therefore, if two distinctly different-appearing nodules of similar size are present, one should strongly consider alternative diagnoses. Coexistent hemangiomas, for example, are common.

Hepatic pseudolesions are common, frequently caused by focal fatty infiltration or focal spared areas within a diffusely fatty liver. Pseudolesions often occur in

predictable locations such as at the porta hepatis and bare area of the liver adjacent to the gallbladder. They frequently have geometric shapes, such as triangular or rectangular configurations.

IOUS evaluation of the hepatic vasculature is often important in determining resectability. IOUS can accurately assess tumor invasion, as commonly occurs with HCC. IOUS can readily and completely delineate tumor thrombi, which generally render the patient inoperable. Periportal and celiac adenopathy, another finding that renders the patient inoperable, also can be demonstrated. The presence of an inferior accessory right hepatic vein should always be determined. This accessory hepatic vein can be torn during mobilization of the liver. Its presence can allow for a more extensive left trisegmentectomy than would otherwise be an option.

With experience, IOUS-guided biopsy (performed freehand) is feasible, even for small, deeply situated lesions. IOUS guidance is indispensable in hepatic cryosurgical tumor ablation, both for accurate placement of the cryoprobes and for real-time assessment of the expanding cryolesion. IOUS monitoring of the expanding cryolesion is critical to ensure complete treatment of the entire tumor and tumor-free margins extending into the adjacent hepatic parenchyma. [205] Both thermal ablation and alcohol ablation also require accurate ultrasound guidance, whether performed percutaneously or intraoperatively.

Pancreas

IOUS is the most accurate technique for localizing islet cell tumors of the pancreas. With spatial resolution of 3 to 5 mm, high-resolution IOUS scanning can detect even small nonpalpable lesions. Most islet cell tumors are homogenous and therefore relatively hypoechoic when compared with the more highly echogenic pattern of the pancreas. [170] These lesions are also usually hypervascular, and color-flow imaging can be helpful in lesion detection. Insulinomas are usually solitary, benign, and hypoechoic, [206] but in any IOUS study for islet cell tumors, the pancreas and peripancreatic and periportal lymph nodes should be evaluated for metastatic disease. Gastrinomas are often multiple and frequently extrapancreatic in location, often being found as intramural nodules in the duodenum. Gastrinomas are also found in tissue near the pancreas and duodenum and in adjacent lymph nodes.

IOUS is useful to assess the resectability of pancreatic ductal adenocarcinoma. Invasion of the superior mesenteric vein is often found, even after negative preoperative imaging, and precludes resection of even small pancreatic head tumors. IOUS, with gray-scale and color-flow imaging, can delineate these findings effectively. IOUS may demonstrate unanticipated hepatic metastases, peripancreatic and portal lymphadenopathy, or other sites of metastatic disease, leading to surgical bypass or other palliative procedures. There is a growing experience and enthusiasm for using laparoscopic ultrasonography for local staging of cancer of the head of the pancreas, particularly to evaluate vascular invasion. [207], [208]

IOUS can also assess cystic neoplasms of the pancreas. In particular, IOUS can generally diagnose microcystic cystadenoma (serous cystic neoplasm), which is virtually always benign. If the cyst cavities are consistently very small (a few millimeters in diameter) and there are no solid components, nodules, or irregular septal thickening, a relatively confident diagnosis of microcystic adenoma can be made. This may obviate pancreatic resection and its attendant morbidity.

Some authors believe IOUS is useful in patients undergoing surgery for pancreatitis with ductal obstruction or for pancreatic pseudocyst drainage. [209] The size, extent, internal contents, and site of origin of pseudocysts and other peripancreatic fluid collections can easily be demonstrated. Real-time guidance may facilitate drainage of these fluid collections. If the pancreatic duct is obstructed proximal to a pseudocyst, then mere cyst drainage may not be sufficient, and drainage or stenting of the pancreatic duct may also be required for complete therapeutic resolution. Color-flow imaging may be important in evaluating fluid collections for the presence of pancreatitis-associated pseudoaneurysms.

In chronic pancreatitis patients with focal masses and biliary obstruction, IOUS assessment of the pancreas may allow for a definition of “a mass within the mass.” This finding is suggestive of concurrent pancreatic carcinoma. IOUS may allow accurate biopsy of small tumor sites surrounded by a fibrotic mass of chronic pancreatitis. Conversely, the lack of identification of any discrete mass within a fibrotic or calcified area of chronic pancreatitis may suggest that the biliary obstruction is benign in nature. If biopsy has also failed to demonstrate cancer, a more conservative biliary bypass procedure may be elected.

Biliary Tract

Intraoperative assessment of the gallbladder is rarely necessary. Laparoscopic ultrasonography has been advocated as an effective method to demonstrate possible anatomic anomalies accurately, in hope of preventing unanticipated surgical complications. [210], [211] IOUS and laparoscopic ultrasonography can effectively evaluate the extrahepatic bile ducts for choledocholithiasis. [212] IOUS can accurately assess tumors of the gallbladder and biliary tract, just as it does tumors of the liver and pancreas. [213] It may be difficult to determine the precise site of duct obstruction intraoperatively by inspection and palpation. IOUS can provide indispensable information regarding tumor resectability and can help determine which type of biliary bypass is feasible. If the central location of the tumor prevents resection and hepaticojejunostomy, IOUS can be used to identify substantially dilated peripheral bile ducts that may be suitable for use in internal drainage.

Laparoscopic Ultrasonography

Laparoscopic ultrasonography has shown promise in evaluation and staging of tumors in the liver, pancreas, biliary tract, stomach, and colon. [214] Laparoscopic staging can identify patients with advanced or metastatic disease, obviating inappropriate lap- arotomies in patients who have limited life expectancy. Further technological improvement will likely lead to more widespread and effective use of laparoscopic ultrasonography in the future.

CHAPTER 154

Michael B. Kimmey and Peter Vilmann

ENDOSCOPIC ULTRASONOGRAPHY

Gastrointestinal endoscopy has revolutionized the diagnosis and treatment of upper and lower digestive tract mucosal diseases, but endoscopic evaluation of abnormalities of the walls of hollow gastrointestinal organs and their surrounding structures has been limited. Endoscopy may suggest the presence of a mass within or outside the gastrointestinal wall, but it cannot elucidate the character or obtain tissue to allow pathological diagnosis of the mass.

The spatial resolution of extracorporeal imaging techniques has limited the use of those technologies. Transcutaneous ultrasound (US) and computed tomography (CT) cannot differentiate the causes of increased wall thickness or evaluate the depth or localization of a specific abnormality of the gastrointestinal wall. Magnetic resonance imaging (MRI) still requires prolonged imaging times, producing significant motion artifacts that impair resolution.

These deficiencies in conventional imaging techniques prompted the development of endoscopy combined with ultrasound (endoscopic ultrasound or EUS) in the early 1980s in an effort to obtain more information about diseases of the gastrointestinal tract and its surroundings. [1], [2] Further technical advances resulted in the capability of EUS-guided tissue sampling to help differentiate malignant from benign lesions and more recently the provision of EUS-guided therapy. This chapter outlines the principles and indications for EUS and reviews the types of EUS equipment. We review the role of EUS and EUS-guided tissue sampling in the management of patients with digestive diseases, giving particular attention to how EUS compares with other imaging modalities.

H3>TECHNICAL CONSIDERATIONS

Ultrasound Physics and Image Interpretation

Principles of US imaging are outlined in Chapter 153. A few concepts that are pertinent to the combination of US with endoscopy should be emphasized. Increasing the frequency of a US system augments the ability of the US beam to resolve tissue structure, however, tissue penetration of the US beam is reduced with higher frequencies. Placing the US transducer next to the mucosa of the gastrointestinal tract avoids the necessity of having a US beam penetrate far into the tissue and avoids bone and gas-filled organs that reflect US. Higher US frequencies can be used (5 to 30 MHz) to resolve two points as close as 0.2 mm from each other in the direction of the US beam. [3], [4] US waves require the presence of a liquid or soft tissue medium between the US transducer and the target tissue. EUS transducers must be placed directly against the mucosa, or there must be fluid between the transducer and the mucosa. Placing the transducer directly against the mucosa is the simpler of the two alternatives and often is used when extramural structures are being examined. This technique limits examination of the gastrointestinal wall, however, because echoes from structures close to the transducer may not be in the optimal focal zone of the US transducer, and the superficial wall layers may be compressed. [5] By putting water directly into the lumen or into a balloon around the transducer, the mucosa and adjacent structures can be imaged clearly.

Knowledge of what generates echoes within tissue is helpful in interpreting EUS images. Echoes are produced when acoustic energy is reflected back to the transducer. An echo occurs when there is nonhomogeneity within a tissue or when the acoustic wave encounters a change in the acoustic impedance between adjacent tissue types. [6] Tissue inhomogeneities are responsible for most of the echoes coming from a homogeneous organ, such as the liver or pancreas. The microscopic structure of these organs determines the magnitude of the echoes. In many tissues, fat and collagen are responsible for the brightest echoes. For example, a fatty liver is more echogenic than a normal liver. Within the gastrointestinal tract, collagen and fat are found primarily in the submucosa and subserosal or mesenteric fat, probably accounting for the echogenicity of these tissue layers. The overall layered appearance of the gastrointestinal wall is a composite of echoes from the tissue layers and the echoes produced at the boundary or interface between tissue layers.

The US image of the normal gastrointestinal wall usually consists of five layers [6] (Fig. 154-1). However, the number of layers is dependent on the ultrasonic frequencies used. Frequencies from 5 to 12 MHz produce 5 layers while higher frequencies like 20 or 30 MHz depict 7 to 9 layers. Most commonly, there are 3 echogenic layers separated by 2 echo-poor layers (Fig. 154-2). The first echogenic layer, beginning at the mucosal surface, is thin and is produced by the interface between lumenal fluid or the balloon around the transducer and the mucosa. The second layer is echo poor and represents the remainder of the mucosa. This layer was formerly attributed to the muscularis mucosae; however, the normal muscularis mucosae is too thin to account for all of the second layer. [6] The muscularis mucosae usually is obscured by an echo occurring at its interface with the lamina propria so that the location of the muscularis mucosae corresponds to the most superficial part of the third (submucosal) layer. If the muscularis mucosae is thicker than the interface echo, a separate thin hypoechoic layer is seen between this interface echo and the underlying submucosal layer. [7], [8] The third US layer is the easiest layer to recognize because it is the most echogenic. This layer corresponds to the submucosa but is thicker because it also includes the interface between the submucosa and muscularis propria. [6] The fourth layer is echo poor and corresponds to the muscularis propria. In areas with a well-developed inner circular and outer longitudinal muscle component, a small amount of connective tissue between the muscle layers may produce a line of echoes within the muscularis propria. [6], [7] The fifth layer is echogenic but of variable thickness. If no subserosal fat or inflammation is present, this echogenic layer corresponds to the serosa and the interface between the serosa and the surrounding tissue. The layer can be thick in the rectum, where there is often abundant echogenic perirectal fat.

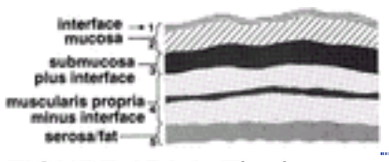

FIGURE 154-1. The layers of the normal gastrointestinal wall as seen on ultrasound images. The ultrasound image comprises echoes arising from the anatomic layers and from the acoustic interfaces between tissue layers.

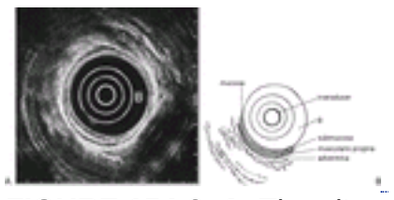

FIGURE 154-2. A: The ultrasound image of the normal gastroesophageal junction made with a 12-MHz mechanical sector scanning ultrasound endoscope. **B:** All the anatomic layers, including mucosa, submucosa, muscularis propria, and adventitia with surrounding structures, are seen in this image made through a water-filled balloon (*B*).

The appearance of organs in the mediastinum and abdomen is roughly similar to that seen with transcorporeal US. The higher resolution of EUS however often provides much greater detail. When the transducer is in the esophagus, the great vessels, parts of the heart, the posterior mediastinum, aortopulmonary window, and subcarinal region can be evaluated. The liver and spleen are homogeneous and of intermediate echogenicity; the normal pancreas has a characteristic “salt and pepper” appearance. The liver usually can be differentiated from the spleen by the bright echoes adjacent to intrahepatic portal venous branches. The kidneys are easily recognized by the characteristic appearance of the urinary collecting system. In most patients, the left adrenal gland can be seen cephalad to the upper pole of the kidney as a seagull-shaped, echo-poor structure. Large arteries and veins in the upper abdomen are key landmarks for orienting EUS images and include the aorta, celiac, and superior mesenteric arteries and the inferior vena cava, portal, splenic, and superior mesenteric veins.

Many efforts have been made to differentiate malignant from benign lymph nodes by analysis of US features such as size, shape, echogenicity, internal echo pattern, and the character of their outer margin. [9], [10] and [11] Malignant lymph nodes are usually echo poor, are similar in echogenicity to the primary neoplasm, and have sharply defined boundaries with adjacent tissue. The internal echoes from the nodes can be homogeneous or inhomogeneous. Benign nodes tend to have poorly defined boundaries with the surrounding tissue and may be hyperechoic. When nodes are over 1 cm in diameter, hypoechoic, and have rounded distinct borders, there is an 80% to 100% probability of malignant involvement. [12], [13] It has become increasingly clear, however, that the diagnosis of a malignant lymph node by EUS image appearance has significant limitations, which has led to the increased use of EUS-guided needle aspiration for pathological confirmation of suspicious nodes. [14], [15]

Instrument Types

US endoscopes can be classified according to the type of endoscope and the type of US system (Table 154-1). The largest worldwide experience has been with the use of a mechanical sector scan on the end of a forward oblique-viewing endoscope. Development of this instrument began in 1979 and has progressed through several generations of improved devices that produce a 360-degree radial scan with US frequencies varying between 5 and 20 MHz. The US transducer at the end of the endoscope is rotated by a motor mounted on the proximal shaft of the endoscope. Optical viewing is achieved through a forward-oblique lens mounted on the side of the endoscope near the transducer. A small biopsy channel allows aspiration or biopsy, but the catheter path does not coincide with the imaging plane, limiting its use for EUS-guided tissue sampling and intervention. [16], [17] Mechanical sector scanning endoscopes have been modified in several ways for special circumstances. A longer forward-viewing variation was developed for use in the colon by omitting a 30-degree sector of the US image to allow passage of fiber bundles to the endoscope tip. [18] Another modification is the removal of viewing optics and the addition of a wire-guided, tapered tip to allow use within tight esophageal strictures. [19]

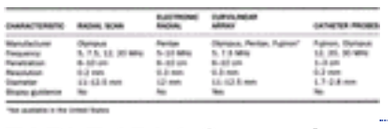

TABLE 154-1 Comparison of Endoscopic Ultrasound Systems

Electronic curved-array US endoscopes are used increasingly as indications for fine-needle aspiration and interventional EUS have been clarified. [17], [20], [21] The US array is mounted along the long axis of the tip of a forward-oblique viewing endoscope. The array of transducer elements is slightly convex to the endoscope, and their signals are processed electronically to produce a 100-degree sector scan that is aligned with the endoscopic image, allowing direct visualization of needles during tissue sampling. Switchable US frequencies of 5 and 7.5 MHz are available. Another advantage of this system is color Doppler capability, which allows the direction of blood flow within vessels to be displayed. [22] This technology is helpful in delineating retroperitoneal and other blood vessels and as an adjunct to guided tissue sampling to avoid unintended puncture of vessels. [14] An electronic radial scanning endoscope has been made. It produces a 270-degree image with a variable frequency between 5 and 10 MHz.

Another method of combining US and endoscopy is to place a US probe through the channel of conventional endoscopes. [23], [24], [25], [26] and [27] These probes contain a US transducer element at the tip of a catheter that rotates or is mechanically moved in a linear direction along the gastrointestinal wall. These probes vary in frequency from 12 to 30 MHz, producing high-resolution images with limited tissue penetration and are most useful for imaging small, endoscopically visible intramural lesions and small mucosal lesions such as early cancer. Placing a water-filled balloon around the transducer may improve image resolution in some situations. [28] Although these systems have been used in the pancreatic and bile ducts, clear indications for intraductal imaging have not yet been established. [29]

Imaging Technique

Detailed descriptions of imaging techniques and the proper positioning of a US endoscope have been published and are beyond the scope of this chapter. [30], [31] Patients are prepared for the procedure as they would be for a standard upper endoscopy. After an overnight fast, topical anesthesia to the oropharynx and intravenous sedation are administered. The US endoscope then is passed blindly through the mouth and into the stomach. The endoscope is directed to the area of clinical interest by the use of a combination of endoscopic views and the US image. Esophageal imaging is accomplished by withdrawing the instrument to the position of interest and imaging performed through the water-filled balloon surrounding the transducer.

The US endoscope is visually directed into the duodenal bulb and descending duodenum for imaging the ampulla of Vater, pancreatic head, distal common bile duct, gallbladder, right lobe of the liver, and retroperitoneal lymph nodes. The water-filled balloon method is used most commonly in the duodenum, although mucosal polypoid structures may be imaged better by placing water in the duodenal lumen. US visualization of the common bile and pancreatic ducts, aorta, inferior vena cava, and portal vein are important landmarks to guide imaging in the duodenum (Fig. 154-3). Imaging from within the stomach also is directed by prior knowledge of the area of clinical interest. Lesions of the gastric wall are identified first by endoscopic vision. The US transducer then is directed over the abnormality. Usually, water is

placed through the endoscope's channel into the lumen for imaging in the stomach.

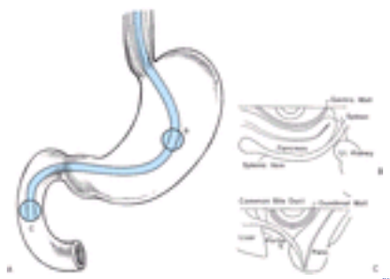

FIGURE 154-3. Position of the ultrasound endoscope (**A**) when imaging from the stomach (**B**) and the duodenum (**C**) is shown. The relative positions of the abdominal organs to the ultrasound transducer when it is in the stomach and the duodenum are also diagrammed.

The body of the pancreas is imaged through the antrum and body of the stomach. The pancreatic tail can be imaged through the fundus of the stomach. Pancreatic imaging is aided by identifying the superior mesenteric artery and vein and the splenic vein posterior to the pancreas and by following the course of the pancreatic duct (see Fig. 154-3). The spleen, left adrenal, left kidney, and left lobe of the liver also can be imaged through the gastric fundus.

Transrectal US is best performed after full colonic purge to avoid artifacts from retained feces. The US endoscope is inserted into the rectum and guided with endoscopic vision into the sigmoid colon or to the level of an obstructing neoplasm. Imaging is accomplished through a water-filled balloon as the probe is withdrawn. Areas of particular interest within the rectum also can be scanned by infusing water into the lumen. Use of a curvilinear array instrument will often allow passage to the splenic flexure. [32]

Optimal performance of EUS requires specific training and substantial experience. The degree of difficulty of EUS is comparable to that of therapeutic endoscopic retrograde cholangiopancreatography (ERCP). [33] Attending EUS courses and studying cross-sectional anatomy and EUS atlases are helpful but should be supplemented by supervised, hands-on training. [33]

Fine-Needle Aspiration

Since EUS imaging is not equivalent to histological analysis, tissue sampling is being increasingly used to confirm the diagnosis. Because EUS can visualize even minute lesions that are not visible with other imaging modalities, the combination of EUS and guided biopsy has the potential to obtain conclusive diagnostic information from such lesions. It is also advantageous to obtain tissue from lesions that are visible with other imaging modalities but are located in areas that are not readily accessible. Several publications have demonstrated that EUS-guided biopsy from imaged lesions is possible in most cases. [34], [35], [36], [37], [38], [39], [40] and [41] Both lesions in the gastrointestinal wall itself as well as lesions lying adjacent to the wall may be punctured through the esophagus, stomach, duodenum, or rectum.

Detailed descriptions of EUS-guided fine-needle aspiration (FNA) technique have been described in several publications. [38], [39], [42], [43] Several different aspiration needles are commercially available including reusable and disposable varieties. A full-length steel needle with a stylet is recommended to provide sufficient stiffness to penetrate hard lesions. After the target is outlined ultrasonically by direct transducer contact with the gastrointestinal wall, the needle with the stylet is introduced through the biopsy channel of the endoscope. The needle then is advanced out of the housing catheter so that reflections from the needle tip are seen ultrasonically.

The stylet then is withdrawn a few millimeters, and the needle is pushed into the lesion under ultrasonic guidance before the stylet is removed completely. A vacuum is applied to the needle by means of a 10-mL syringe, and the needle is advanced further into the lesion and moved back and forth under ultrasonic guidance. [44] The vacuum is equilibrated while the tip of the needle is in the lesion. An alternate technique for sampling lymph nodes without suction has been reported to provide adequate diagnostic material that is less bloody. [15] The needle finally is removed, and the aspirated material is expelled and smeared onto glass slides. The aspiration is repeated until sufficient material is obtained; the presence of a cytopathologist is helpful in making this differentiation. [40] Between two and five passes usually are required to obtain an adequate specimen.

Normally, the aspiration procedure lasts 5 to 20 minutes. The time used depends on the location of the puncture target. FNA from the esophagus is usually fast, whereas FNA of hard lesions in the head of the pancreas may require more time. Patient discomfort in connection with the procedure is limited to that experienced as a result of the EUS examination itself. The overall complication rate for FNA of solid masses (e.g., bleeding, infection, perforation) is less than 1%. [40] Infections following aspiration of cystic lesions occur in up to 14% of cases when prophylactic antibiotics are not given. [40] Antibiotics are not used routinely but should be considered when performing transrectal biopsy and when aspirating cystic lesions. [45] Major bleeding, pancreatitis, and air embolism are rare events. [17], [46], [47] Tumor seeding of a needle tract is a theoretical complication, but has not yet been described following EUS-guided FNA.

The indications for EUS-guided biopsy continue to evolve. The procedure should be considered in patients when lesions suspicious for malignancy are detected on conventional imaging modalities that are within or adjacent to the gastrointestinal tract. [39], [40] Also, lesions suggestive of malignancy that are detected only by US and not by conventional modalities may be biopsied if an aspirate positive for malignancy could change patient management. Indications for EUS-guided FNA are listed in Table 154-2.

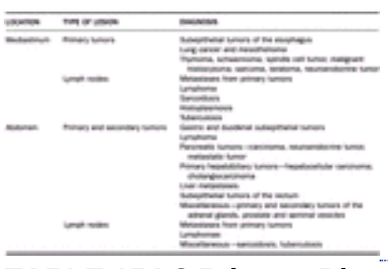

TABLE 154-2 Primary Diagnoses That May Be Obtained by Endoscopic Ultrasound–Fine-Needle Aspiration (EUS-FNA)

ENDOSCOPIC ULTRASONOGRAPHY OF THE UPPER GASTROINTESTINAL TRACT

Focal Intramural and Extramural Mass Lesions

Focal abnormalities of the upper gastrointestinal wall often are suspected based on the results of radiographic and endoscopic examinations. Contrast radiographs may reveal a smooth, rounded defect impinging on the lumen, or the endoscopist may encounter a bulge covered with normal mucosa. The clinical significance of these masses can be difficult to ascertain but may be facilitated by knowing whether the mass is intramural or extramural and whether it is benign or malignant. EUS can be useful in defining the location of the mass and can direct FNA to determine whether it is malignant.

Intramural masses arise from a well-defined US layer that corresponds to one of the histological layers of the gastrointestinal wall. [48], [49] Extramural masses may compress the outer echogenic layer of the gut wall or, if malignant, may disrupt normal layer structure. In a series of 139 patients with suspected intramural or extramural masses of the upper gastrointestinal tract, EUS correctly identified the mass as intramural (80 cases) or extramural (59 cases) in every patient. [48]

Gastrointestinal stromal tumors (GIST) are the most commonly encountered focal intramural masses in the upper gastrointestinal tract. They are differentiated ultrasonographically by their presence within the fourth US layer, corresponding to the muscularis propria. They are hypoechoic and usually expand the hypoechoic fourth layer but do not disrupt the boundaries between the third and fourth or fourth and fifth layers (Fig. 154-4). Occasionally, GISTs are seen as well-marginated hypoechoic masses between the second and third layers. In these instances, the tumor probably has arisen from the muscularis mucosae. Most small GISTs are round and homogenous. Although EUS cannot distinguish reliably between benign and malignant GISTs, features that suggest malignancy include diameter greater than 3 cm, irregular outer borders, central ulceration, and the presence of enlarged regional lymph nodes [50], [51] and [52] (Fig. 154-5). Other causes of focal intramural lesions can be imaged with EUS. Duplication cysts are identified most commonly as smooth, anechoic masses within the distal esophagus, but they can occur anywhere in the gastrointestinal tract. [53] Esophageal and gastric carcinoid tumors cause well-defined hypoechoic nodules in the second or third US layers. Lipomas are differentiated by being echogenic and clearly marginated and usually are located in the third (submucosal) layer. [48] Ectopic pancreas, submucosal cysts (Fig. 154-6), gastric duplications, granular cell myoblastoma, metastatic cancer, and eosinophilic granuloma also have been imaged with EUS. [48], [49] Endometriomas may be imaged within or adjacent to the colon and rectum.

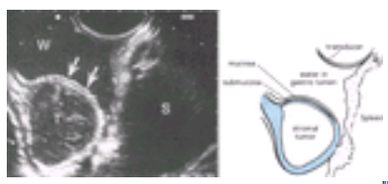

FIGURE 154-4. A gastric stromal tumor (*T*), formerly called a leiomyoma, is imaged through water (*W*) in the gastric lumen using a curvilinear array ultrasound endoscope. The overlying mucosal and submucosal layers (*arrows*) show that this tumor is contiguous with the muscularis propria layer. The spleen (*S*) is also seen adjacent to the stomach wall.

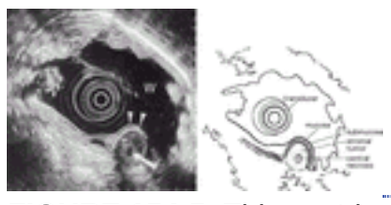

FIGURE 154-5. This gastric stromal tumor (*T*) imaged with a radial scanning echoendoscope through water (*W*) in the gastric lumen is covered by mucosa and submucosa (*arrowheads*) and has a central hypoechoic area (*arrow*), probably due to necrosis.

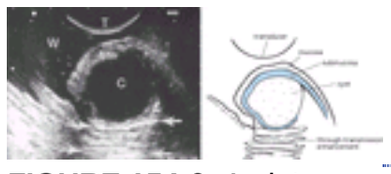

FIGURE 154-6. An intramural cyst (*C*) is imaged with a curvilinear array echoendoscope after putting water (*W*) in the gastric lumen. There is normal overlying mucosa (*m*) and submucosa (*sm*). Note the enhancement of echoes from the area underneath the cyst (*between the arrows*). This phenomenon (termed *through transmission*) occurs because the fluid-filled cyst causes less impedance to the ultrasound beam than does the surrounding tissue.

The origins of extramural mass lesions often can be deduced by identification of contiguous structures. When enlarged or of normal size, the aorta, liver, gallbladder, spleen, and splenic artery or vein may compress the gastrointestinal tract. [54] Hepatic cysts and pancreatic cystic neoplasms or pseudocysts also are identified by their surrounding organs. [55] Malignant extramural lesions such as bronchogenic carcinoma, hepatic and pancreatic malignancies, and malignant lymph nodes may compress or invade the outer layers of the gastrointestinal wall.

EUS-guided biopsy of lesions within the gastrointestinal wall have a lower diagnostic value and higher rate of inconclusive biopsies than EUS-guided biopsy of extramural lesions. [40], [56] In a multicenter study of 554 lesions taken by biopsy in 457 patients, 115 lesions were located within the gastrointestinal wall. [40] The accuracy of EUS-guided FNA cytology of 12 submucosal tumors was 50%, with one half of the biopsy specimens being inadequate. In cases of GISTs, although cytology demonstrated spindle cells in four of seven cases, the single case of a malignant GIST was not diagnosed. EUS FNA was performed in 103 lesions arising in the gastrointestinal wall, exclusive of stromal tumors with a sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of 61%, 79%, 100%, 76%, and 67%, respectively.

Esophageal Carcinoma

The diagnosis of esophageal carcinoma is usually not difficult with esophagoscopy and biopsy. Staging this tumor to plan appropriate therapy is more difficult. Endoscopy or radiography defines the longitudinal extent of tumor growth but does not define depth of invasion. CT and EUS have been used to evaluate the depth of invasion into the esophageal wall, to detect spread to mediastinal and celiac lymph nodes, and to detect invasion of other mediastinal and thoracic structures. EUS is the only imaging modality that can differentiate among mucosal, submucosal, and muscular involvement with esophageal carcinoma, and it can accurately determine the depth of invasion in more than 80% of early cases [57], [58], [59], [60], [61] and [62] (Table 154-3). Most patients have spread of esophageal carcinoma outside the muscularis propria at presentation. EUS and CT accurately detect about 90% of cases with mediastinal invasion. [57], [58], [59], [60], [61] and [62] EUS is more sensitive than CT in detecting aortic (Fig. 154-7), pericardial, and diaphragmatic involvement with carcinoma. [57], [58], [59], [60], [61], [62] and [63] The dynamic nature of EUS, with the ability to detect moving structures in real time, may contribute to the accuracy of this technique in detecting invasion of these viscera. Patients with extraesophageal organ involvement with cancer (T4 stage) detected by EUS have similar survival rates when treated surgically or by nonoperative methods. [63]

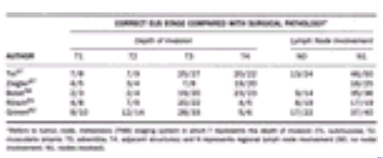

TABLE 154-3 Endoscopic Ultrasound Staging of Esophageal Carcinoma

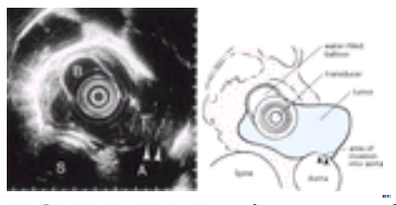

FIGURE 154-7. A large esophageal cancer (*T*) invades the tissue around the esophagus and invades the descending aorta (*A*) at the *arrows.* The thoracic spine (*S*) is posterior to the mass. Imaging has been aided by filling a balloon around the radial scanning transducer with water (*B*).

EUS is more accurate than CT in detecting lymph node involvement in patients with esophageal cancer. [57], [58], [59], [60], [61], [62] and [63] The limitations of CT in detecting enlarged mediastinal lymph nodes in patients with esophageal cancer are well known; about 50% of cases of esophageal cancer are understaged by CT. Lymph nodes as small as 5 mm in diameter can be visualized with EUS. The accuracy of EUS in detecting mediastinal lymph node involvement is about 70% to 80% (see Table 154-3). [57], [58], [59], [60], [61] and [62] Limitations of EUS in detecting lymph node involvement include false-positive results caused by enlarged inflammatory nodes and, to a lesser degree, false-negative results caused by microscopic metastases in normal-sized nodes. CT correctly identifies the presence or absence of mediastinal lymph node involvement in only 20% to 50% of cases, with good specificity but limited sensitivity. [57], [58], [59], [60], [61] and [62] CT and mediastinoscopy, however, can detect some groups of lymph nodes that are not imaged with EUS, such as those separated from the esophagus by the lung or trachea. The number of abnormal lymph nodes detected by EUS correlates with 5-year survival following esophagectomy. [64]

EUS-guided biopsy of lymph nodes should be used whenever possible to confirm the presence of malignant involvement. [65], [66] Avoidance of the primary tumor in the needle path is important to avoid contaminating material from the node with the primary neoplasm. Confirmation of celiac lymph node involvement is especially important as these represent metastases in patients with middle and upper esophageal cancers. [66] EUS-FNA of lymph nodes in esophageal cancer has been reported to change management in 60% of patients. [65] The sensitivity, specificity, PPV, and NPV of EUS-FNA for the detection of malignancy in lymph nodes in a large multicenter study was 93%, 100%, 56%, and 92%, respectively. [40]

EUS and CT are complementary in the detection of distant metastases from esophageal carcinoma. EUS has a sensitivity of greater than 90% in detecting celiac lymph node metastases when it is possible to pass the endoscope through the malignant stricture. [57] In comparing the overall accuracy of EUS and CT, the accuracy of both modalities is about 70% to 80%, because the US endoscope cannot pass through 20% to 50% of malignant strictures. [57], [58], [59], [60], [61] and [62], [67], [68] and [69] The ability to pass through malignant esophageal strictures however has been improved with the development of smaller diameter US endoscopes with more tapered tips. [66] CT is also more sensitive than EUS in detecting hepatic metastases, especially in the right lobe.

EUS is more accurate than CT in predicting nonresectability of esophageal cancer: 91% for EUS versus 39% for CT. [70] Prediction of resectability by EUS may be higher for adenocarcinoma than for squamous cell carcinoma because of the difficulty in recognizing microscopic submucosal spread of disease in the latter. Detection of local anastomotic recurrence by EUS is sensitive but relatively nonspecific when only thickening is used as a criterion; the false-positive rate is 5% to 20%. [71]

The role of EUS before and after neoadjuvant chemoradiation is evolving. Imaging alone does not distinguish between residual tumor and scar following chemoradiation so imaging findings should be confirmed with FNA whenever possible. [72] The presence of celiac adenopathy and T4 stage on EUS imaging should not preclude the patient receiving preoperative chemoradiation since tumor can be sterilized from these locations in some patients. [73] A reduction of the maximum cross-sectional area of the primary tumor measured with radial EUS imaging before and following chemoradiation has been reported to correlate with survival following surgery. [74], [75]

Gastric Carcinoma

The greatest experience with EUS in the staging of gastric cancer comes from Japan, where the incidence of this tumor is high. EUS has the potential for detecting the depth of invasion of gastric neoplasms because of the clear layers seen on US images of the gastric wall. Because gastric cancer confined to the mucosa and submucosa has a better outcome with surgical resection than does more advanced disease, EUS can contribute significantly to the management of patients who have early gastric cancer. For example, EUS findings are used to select candidates for endoscopic mucosal resection. [76] The depth of invasion is seen as a disruption in the normal layer structure or diffuse thickening of the normal layers by infiltrating scirrhous carcinomas. [76], [77], [78] and [79] EUS accurately predicts the depth of malignant invasion into the gastric wall in about 80% of patients [61], [62], [77], [78] and [79] (Table 154-4). Accuracy rates of over 90% are achieved in differentiating early (i.e., confined to the mucosa or submucosa) from advanced (i.e., invasion of the muscularis propria or deeper) gastric cancer (Fig. 154-8 and Fig. 154-9). Cell type and the degree of differentiation do not significantly affect the staging accuracy of EUS. The depth of invasion may be overestimated if there is an ulcer scar or inflammatory reaction below the cancer. [77] Underestimation of the depth of invasion occurs when microscopic invasion of deeper layers occurs or the serosal interface echo cannot be well seen.

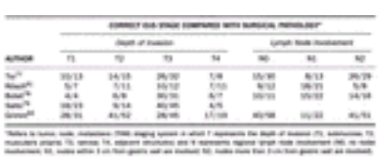

TABLE 154-4 Endoscopic Ultrasound (EUS) Staging of Gastric Carcinoma

FIGURE 154-8. An electronic radial scanning endoscope has been used to image this early gastric cancer. The cancer invades the submucosa (*arrows*) making this a T1 tumor.

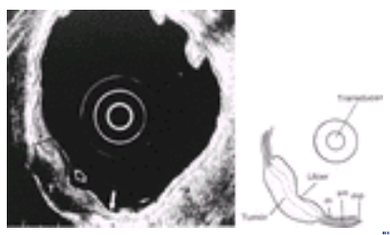

FIGURE 154-9. This advanced gastric cancer has raised borders and a central ulceration (*open arrow*). The tumor mass (*T*) arises from the normal wall (*arrow*), where layers corresponding to mucosa (*m*), submucosa (*sm*), and muscularis propria (*mp*) can be seen. The cancer invades the fat and other tissue around the gastric wall.

The accuracy of EUS in detecting gastric cancer in extraintestinal lymph nodes is less well established. About 75% to 80% of malignant regional lymph nodes are detected by EUS, but false-positive results are seen in as many as 50% of benign nodes. [9], [78], [80] False-negative results occur most commonly in cases of microscopic metastases in normal-sized nodes. The role of EUS-FNA in patients with gastric cancer is similar to that discussed previously for esophageal cancer. [40], [56], [81] EUS can stage the depth of invasion and detect lymph node metastases more accurately than high-quality CT scanning. [78] Compared with pathological evaluation of the resected specimen, EUS correctly predicts depth of invasion and lymph node involvement in 78% to 91% and 50% to 78% of cases, respectively. [77], [78] CT scanning correctly predicted depth of invasion and lymph node involvement in 42% and 48% of cases, respectively. [78] Overall staging was significantly more accurate with EUS (73% correct) than with CT (45% correct). [78]

The invasion of gastric cancer into surrounding structures may be detected with EUS, and malignant involvement of the pancreas and liver has been described. [77] The accuracy of predicting resectability in gastric cancer is higher than CT, reaching about 95%. Because of the limited penetration of EUS, however, CT scans are necessary for the detection of most hepatic metastases. [77], [78]

Gastric Lymphoma

Lymphomas involving the stomach can present as an infiltrating or polypoid mass lesion or as a gastric ulcer. [82], [83] and [84] Endoscopic biopsy may reveal the diagnosis, but biopsies may be nondiagnostic when the bulk of the tumor is below the mucosa. EUS can detect the extent of lymphomatous involvement of the gastric wall in infiltrating and ulcerative gastric lymphomas [83], [84] (Fig. 154-10). The depth of wall invasion, involvement of surrounding organs such as the pancreas or liver, and the presence of enlarged lymph nodes can be assessed by EUS. Reduction of tumor size after chemotherapy also has been documented by EUS imaging. [83], [84] EUS appears to be more sensitive than CT scanning in detecting the presence of intramural invasion, extragastric spread, and regional lymph node involvement.

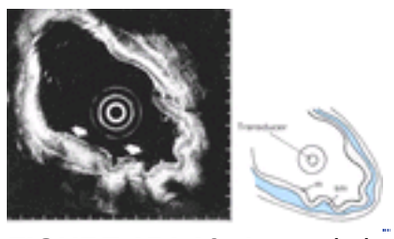

FIGURE 154-10. A gastric lymphoma has caused thickening of the ultrasound layers corresponding to mucosa (*m*) and submucosa (*sm*) in the region under the *arrows.*

Preliminary studies suggest that EUS can help in the decision of whether to treat gastric mucosa-associated lymphoid tissue (MALT) lymphoma with antibiotics for *Helicobacter pylori* infection or systemic chemotherapy; patients with thickening confined to the mucosa and submucosa on EUS usually respond to antibiotics alone. [85], [86]

Ampullary Carcinoma

Carcinoma of the ampulla of Vater occurs infrequently compared with pancreatic cancer, but it is important to recognize the tumor because patients often present with jaundice when the tumor is resectable. Five-year survival after surgical resection of ampullary cancer can be expected for about 40% of patients. Surgery is radical and carries a mortality rate of up to 10%. It would be useful to have preoperative assessment of those patients most likely to benefit from the surgery. EUS offers more accurate staging than other imaging studies in the preoperative staging of these tumors. [87], [88], [89], [90], [91], [92] and [93]

EUS detects the normal five layers of the duodenal wall adjacent to the papilla. The common bile duct and pancreatic duct converge at the papilla, with the portal vein lying immediately adjacent to the bile duct. EUS can detect tumor masses as small as 8 mm in diameter within the papilla. EUS also correctly predicts the depth of invasion of the tumor with respect to involvement of the muscularis propria or subserosa in as many as 80% of patients. [87], [88], [89], [90], [91], [92] and [93] Invasion of the pancreatic parenchyma and the existence of lymph node metastases also can be detected with EUS. The limitations of EUS in the staging of ampullary carcinoma include failure to detect very small tumors, failure to visualize liver metastases, and false-positive interpretation of inflammatory lymph nodes. [87], [88], [89], [90], [91], [92] and [93] If therapeutic plans are changed by the presence of malignant lymph nodes, EUS-FNA should be used to confirm the presence of malignancy. [94]

Most ampullary neoplasms can be diagnosed accurately by a combination of endoscopy with biopsy and ERCP. The role of EUS is in demonstrating the size and depth of invasion of the tumor, the presence of involved regional lymph nodes, and the presence of portal or superior mesenteric vein invasion. [87], [88], [89], [90], [91], [92] and [93] Larger studies with long-term follow-up are needed to determine whether the results of EUS imaging predict which patients will have long-term survival after surgical resection.

Upper Gastrointestinal Wall Thickening

EUS can detect a thickened gastrointestinal wall. The upper limit of normal wall thickness has not been defined rigorously but is probably about 3 to 4 mm. The degree of lumenal distention and balloon compression can affect layer visualization and wall-thickness measurements. [5] There are several causes of gut wall thickening, some of which can be differentiated by using EUS imaging. The first two US layers, corresponding to the mucosa, are thickened in severe esophagitis and gastritis, superficially growing MALT lymphomas, foveolar hyperplasia, Ménétrier disease, Kaposi sarcoma, and gastrinoma. The fourth layer, corresponding to the muscularis propria, may be thickened in response to distal obstruction. [6] All four layers may be thickened in the stomach adjacent to an ulcer or with gastric lymphoma or linitis plastica. [83] A few studies have addressed the role of EUS in the diagnostic approach to large gastric folds. EUS has a nearly 100% specificity but a lower sensitivity for detecting malignancy. [95], [96]

Portal Hypertension

The course and mural location of esophageal and gastric varices can be determined by EUS. Varices are imaged within the submucosa and in the periesophageal or perigastric soft tissue. [97] Small submucosal varices are easily compressed and may be missed when imaging with the water-filled balloon method. After sclerotherapy, submucosal varices are obliterated, but periesophageal collaterals may not be affected. [98], [99] EUS detects gastric varices and may prove useful in differentiating gastric varices from large rugal folds. Large extragastric venous collaterals in patients with portal hypertension can also be detected by EUS.

Peptic Ulcer Disease

The depth of mucosal lesions may be difficult to gauge by routine endoscopic examination but can be examined with EUS. The second US layer is thickened by edema around erosions, but the third layer is not penetrated. Ulcers may extend into the third or fourth layer or completely into the subserosal region. The gastric wall may be diffusely thickened in the region around an ulcer, and inflammatory changes may obscure the normal layered appearance of the surrounding wall. EUS also may aid in differentiating benign from malignant gastric ulcers, but false-positive and false-negative results limit its use; mucosal biopsy is always recommended to exclude malignancy.

ENDOSCOPIC ULTRASONOGRAPHY OF ORGANS ADJACENT TO THE UPPER GASTROINTESTINAL TRACT

Lung Cancer

EUS can detect and, with FNA, provide a tissue diagnosis in patients with lung cancer. Primary tumors adjacent to the esophagus can be best approached via the transesophageal route which can provide a tissue diagnosis even when bronchoscopic methods fail. [100], [101], [102], [103] and [104]

An emerging role for EUS-guided FNA is in the staging of non–small-cell lung cancer. [105], [106], [107] and [108] The presence of cytologically confirmed malignancy in subcarinal and contralateral mediastinal lymph nodes precludes curative surgery and therefore reduces costs associated with mediastinoscopy and thoracotomy [108], [109] (Fig. 154-11). A Japanese study of 132 lung cancer patients demonstrated a sensitivity of 54% and a specificity of 98% for EUS in the evaluation of mediastinal lymph node metastases. [105] The sensitivity increased to 81% when right superior mediastinal lymph nodes (lymph nodes located anterior to the trachea) were excluded from calculations. Another study demonstrated an accuracy of lymph node evaluation by EUS of 72% but a sensitivity of only 67%. The lower sensitivity was explained by the high proportion of patients with anthracosilicosis. [108] In the latter study, CT demonstrated only 47% of the lymph nodes, and 67% of these lymph nodes were malignant. EUS is regarded as more accurate than CT in preoperative staging of lung cancer, especially when imaging results are confirmed by FNA.

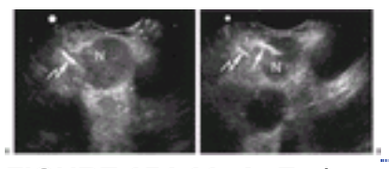

FIGURE 154-11. A: Endoscopic ultrasound (EUS) from the esophageal lumen identified an 18-mm subcarinal lymph node (*N*) in a patient with non–small-cell lung cancer. The trachea (*curved arrow*) is seen at the left of the image. **B:** EUS-guided fine-needle aspiration (*straight arrow*) obtained malignant cells.

EUS-FNA is complementary to mediastinoscopy for staging non–small-cell lung cancer. If enlarged lymph nodes in areas adjacent to the esophagus are imaged on CT, EUS-FNA is more cost-effective than mediastinoscopy in confirming malignancy within the nodes. [109], [110]

Other Thoracic Extraesophageal Structures

EUS may detect other mediastinal or pulmonary abnormalities as incidental findings or because they compress the esophagus. EUS can reveal the cause of these compressions and exclude a primary esophageal lesion. Causes of esophageal compression other than lung cancer that have been detected by EUS include mediastinal cyst, bronchogenic cyst, aberrant right subclavian artery, thoracic aortic aneurysm, teratomas, and mediastinal pseudocysts. Hodgkin disease, tuberculosis, histoplasmosis, sarcoidosis, metastatic cancer, and neuroendocrine and neurogenic tumors can also be diagnosed by EUS-guided-biopsy. [111], [112] and [113]

Acute Pancreatitis

EUS has been used in the setting of suspected gallstone pancreatitis and is more sensitive than transabdominal US for the detection of common bile duct stones in this setting. [114] EUS can also be useful in defining the cause of unexplained acute pancreatitis. Microlithiasis, occult common bile duct stones, small pancreatic neoplasms, and pancreas divisum can be found in up to 75% of this population. [115], [116] Due to the lower risk of complications, EUS should be considered as an alternative to ERCP in this group of patients.

Chronic Pancreatitis

The diagnosis of chronic pancreatitis is not difficult in the patient with steatorrhea, glucose intolerance, and pancreatic calcification on plain abdominal radiographic films. Early cases, however, may be more subtle, defying diagnosis using conventional diagnostic tests. EUS has been proposed as a sensitive, specific imaging tool for the diagnosis of chronic pancreatitis. High-resolution US images of the pancreas can be made through the posterior gastric wall and through the medial wall of the duodenum. Because there is no intervening intestinal gas, EUS is able to image the entire pancreas in most cases; the head and tail of the pancreas are seen more often with EUS than with transcutaneous US. The normal pancreas has a homogeneous, fine granular appearance when imaged with EUS. The pancreatic duct has clearly defined walls with an overall diameter of 2 to 3 mm. Endosonographic features of chronic pancreatitis include ductal dilation with or without calculi, echogenic duct walls, pseudocysts, and a heterogeneous pancreatic parenchyma with focal hypoechoic and other echogenic areas [117], [118] and [119] (Fig. 154-12). Early chronic pancreatitis may be diagnosed by EUS at a stage when other modalities are unable to demonstrate any structural signs of disease. However, the specificity of these findings is uncertain since many of the EUS features of chronic pancreatitis can be seen in alcoholics without clinical evidence of pancreatitis. [120]

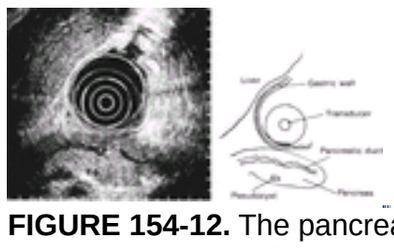

FIGURE 154-12. The pancreas of a patient with chronic pancreatitis is imaged through the posterior gastric wall with a 7.5-MHz ultrasound endoscope. A dilated pancreatic duct (*pd*) and a small pancreatic pseudocyst (*c*) are seen as well as a heterogeneous echo texture within the pancreatic parenchyma.

Mass lesions within a chronically inflamed pancreas may be inflammatory or malignant. It may be impossible to differentiate between these possibilities with transcutaneous US, CT, and ERCP. Although evaluation of EUS with rigorous, blinded, histologically confirmed studies is not available, there are endosonographic features that may help to differentiate between these causes of a pancreatic mass. [121], [122] Inflammatory lesions are favored by the presence of a homogeneous hypoechoic mass with smooth boundaries. Malignant lesions are suggested when a heterogeneous mass with irregular contours, often in a lobulated pattern, is imaged. The sensitivity and specificity of these imaging findings however are not sufficient to differentiate reliably between malignancy and focal chronic pancreatitis; therefore EUS-guided biopsy should be used whenever possible to confirm the presence of suspected malignancy.

Pancreatic Carcinoma

One of the first targets for EUS imaging was pancreatic cancer. [121] The early detection of this usually lethal neoplasm has eluded other diagnostic modalities. The increased spatial resolution of EUS may allow detection of smaller, resectable neoplasms in a few patients whose symptoms are vague. [121] More recently, the use of

EUS to detect premalignant changes in members of pancreatic cancer families has also been described. [123]

EUS has been used to image malignant pancreatic masses, to investigate whether malignant lymph nodes are present, and to detect the presence of vascular invasion that would preclude surgical resection. [41], [87], [88], [121], [124], [125] and [126] EUS is more sensitive than transcutaneous US, axial CT, and angiography in detecting masses smaller than 3 cm in diameter, and it is more accurate than the other imaging modalities in assessing tumor size. Masses as small as 10 mm in diameter can be imaged by EUS. [121] Most pancreatic neoplasms are hypoechoic, but a few may be hyperechoic on EUS imaging. EUS can also detect cystic pancreatic neoplasms and metastases to the pancreas. [55], [127], [128] Enlargement of lymph nodes around the porta hepatis, aorta, celiac trunk, and splenic artery can be detected by EUS. Accurate prediction of lymph node status in 70% to 80% of patients undergoing surgery has been reported. [41], [87], [88] EUS is more sensitive than CT in detecting regional lymph node involvement; [88] however, because of false-positive lymph node diagnoses in up to 50% of cases by EUS imaging, malignant involvement should be confirmed with FNA if therapeutic management might be affected. [41], [94], [129], [130] and [131] Approximately 30% of patients with pancreatic carcinoma undergoing EUS will be found to have FNA-positive malignant lymph nodes. [94]

Major vessel invasion by a pancreatic neoplasm precludes curative resection. Morbidity and mortality resulting from pancreaticoduodenectomy could be prevented in many patients if a reliable method of detecting vascular invasion were available. EUS can detect portal vein and splenic vein involvement by pancreatic neoplasms [87], [88], [126] (Fig. 154-13). EUS is more sensitive than angiography and axial CT for detecting neoplastic involvement of the portal vein, including the region of its confluence with the superior mesenteric vein. [88] The accuracy of locoregional cancer staging with newer helical CT scanners may be comparable to staging with EUS. [92], [93], [132], [133] and [134] EUS is not as reliable for detecting superior mesenteric vein invasion or major arterial (e.g., celiac, hepatic, splenic, superior mesenteric) encasement by tumor. [88], [135] The radial and curvilinear array instruments appear to be comparable in staging accuracy for pancreatic cancer. [136] EUS-FNA is increasingly used to obtain a tissue diagnosis in patients with pancreatic cancer (Fig. 154-14). The diagnostic values of FNA for pancreatic masses in a large multicenter study were a sensitivity of 86%, a specificity of 94%, a PPV of 100%, an NPV of 86%, and an accuracy of 88%. [40] Other studies have also described the use of EUS-guided FNA in managing patients with pancreatic cancer. [41], [56], [126], [129], [130] and [131], [137], [138], [139], [140], [141] and [142] The detection of unresectable masses, malignant nodes outside the area of planned resection, and liver metastases avoid the morbidity and cost of major surgery. [130], [131]

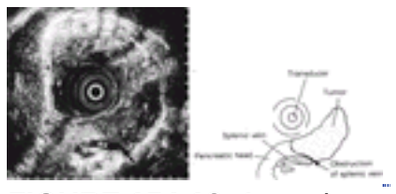

FIGURE 154-13. A carcinoma of the body of the pancreas (*T*) is shown (*arrow*) to obstruct the splenic vein (*sv*) in this transgastric endoscopic ultrasonographic image.

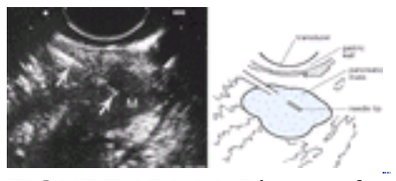

FIGURE 154-14. Biopsy of a pancreatic mass (*M*) with a needle (*arrows*) passed through the stomach wall into the mass under ultrasound guidance.

Islet Cell Neoplasms

The anatomic localization of hormone-producing pancreatic tumors is important for guiding their surgical resection. Most of these neoplasms arise from islet cells within the pancreas, although a significant number are found elsewhere in the abdomen. Conventional transcorporeal imaging with US and CT detects fewer than one third of cases, probably because of the small size of the tumors. MRI and selective arteriography also may fail to localize the neoplasm. Careful examination of the pancreas with EUS by experienced endosonographers detects about 75% of islet cell neoplasms within the pancreas not found on CT scanning. [143], [144] and [145] Islet cell neoplasms are usually round, homogeneous, and hypoechoic compared with the surrounding pancreas. Masses as small as 5 mm in diameter can be imaged by EUS. [143], [144] and [145] All patients who have a clinical diagnosis of an islet cell neoplasm that has not been localized with other imaging techniques should undergo preoperative EUS to localize the neoplasm and facilitate surgical planning. Octreotide scanning and EUS appear to be complementary in the preoperative localization of gastrinomas. [146] Although EUS-guided FNA can confirm the diagnosis of an islet cell neoplasm, this is not required in the setting of a well-defined clinical syndrome and documented excessive hormone secretion.

Gallbladder and Bile Ducts

The close proximity of the common bile duct and gallbladder to the duodenum and distal stomach allows EUS imaging of these organs. The detection of choledocholithiasis and the characterization and staging of bile duct and gallbladder neoplasms have been studied by EUS.

Transcutaneous US detects more than 95% of gallbladder stones but detects only approximately 30% of common duct stones. EUS may detect stones in the bile duct by imaging from the descending duodenum or duodenal bulb. [147], [148], [149] and [150] Common bile duct stones can be identified when EUS is used to evaluate the patient with a dilated bile duct or jaundice of unknown cause. If a common duct stone is suspected from transcutaneous imaging procedures or on clinical grounds, ERCP should be undertaken rather than EUS because it allows removal of the stone; however, EUS has comparable sensitivity to that of ERCP in detecting bile duct stones and represents a noninvasive diagnostic test without the risk of pancreatitis that accompanies ERCP. [114], [148], [149] and [150] Intraductal catheter probes can also aid in the detection of small stones missed by cholangiography. [151], [152] A French study of patients with choledocholithiasis demonstrated a sensitivity for stone detection of 97% for EUS compared with 25% for abdominal ultrasonography and 75% for CT. [149] Preliminary studies also demonstrated that microlithiasis may be diagnosed by EUS with a sensitivity as high as 95% in patients with negative abdominal US but in whom there is a strong clinical suspicion of gallstone disease. [153], [154]

EUS has been used to stage carcinoma of the bile duct and gallbladder. As with pancreatic carcinoma, the detection of major portal venous invasion by the neoplasm is probably the most clinically relevant role for EUS. Small-diameter catheter probes placed in the bile duct at percutaneous transhepatic cholangiography or ERCP also may prove useful for this indication. [29], [155] EUS-guided FNA can also facilitate obtaining a tissue diagnosis in the majority of patients with hilar cholangiocarcinoma. [156] Prospective studies are needed to define the roles of EUS, CT, and angiography in staging bile duct and gallbladder neoplasms.

Liver

EUS has not been used extensively in imaging the liver. Although portions of the left lobe are imaged from the stomach and part of the right lobe from the stomach and duodenum, inadequate penetration prevents imaging of the entire liver. Transcutaneous US and CT provide a more complete examination of the liver than does EUS, although no prospective comparisons of these modalities in the detection of focal liver abnormalities are available. The better resolution of EUS does allow detection of small metastases in parts of the liver immediately adjacent to the stomach and duodenum that cannot be imaged with extracorporeal imaging techniques. [157], [158] EUS-FNA of these metastases has yielded a tissue diagnosis in nearly all cases and often leads to a change in patient management. [40], [157], [158]

TRANSRECTAL ULTRASONOGRAPHY

US imaging from within the rectal lumen has been applied to the diagnosis of benign and malignant diseases of the rectum. The diagnosis of inflammatory bowel disease and its complications has been investigated in a few studies, but most experience has been accumulated in the staging of colorectal neoplasms. Most of these imaging studies have been performed without the use of endoscopic viewing, but the same examination can be done using a US endoscope with similar results.

Inflammatory Bowel Disease

Transcutaneous ultrasonography has been used to detect wall thickening and define the location and extent of intestinal involvement in patients with Crohn's disease and ulcerative colitis. [159] An in vitro study, however, showed that changes in the US layers of the intestinal wall do not reliably differentiate ulcerative colitis from Crohn's disease; [160] it is unlikely, therefore, that even transrectal US would be able to differentiate these two entities. Catheter probe ultrasonography has also been used to demonstrate wall thickening in patients with ulcerative colitis; however, the clinical use of this examination is not clear. [161] The detailed images of pararectal tissues may allow detection of abscesses or fistulae. Abscesses appear as hypoechoic or anechoic areas adjacent to the rectal lumen. Fistulous tracts, with connections to the skin, anus, and vagina, also can be identified by EUS; [162] however, MRI may be a better method in the evaluation of complex fistulae. [163]

Rectal Carcinoma

Transrectal ultrasonography has been evaluated for preoperative staging and the detection of postoperative recurrence of rectal cancer. The depth of cancer invasion into the rectal wall and surrounding tissue and the presence of malignant perirectal lymph nodes have been evaluated using transrectal US imaging (Fig. 154-15). The accuracy of this modality has been compared with CT imaging, but no rigorous studies have been done to show that use of transrectal US changes patient management or influences survival from rectal cancer. Because preoperative radiotherapy may downstage T4 cancers and neoadjuvant chemotherapy may improve survival in patients with T3 cancers, rectal ultrasonography should be used in the preoperative evaluation of these patients. Confirmation of T1 distal rectal cancer is also important if transanal or endoscopic mucosal resection is being considered.

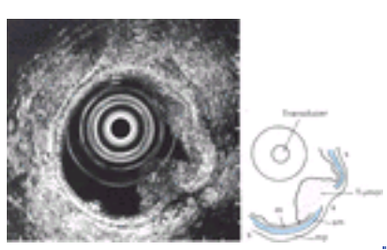

FIGURE 154-15. A polypoid rectal cancer (*T*) invades the submucosa (*sm*) and muscularis propria (*mp*) but does not extend into the subserosal fat (*s*). The boundary between the muscularis propria and the subserosal fat is not disrupted under the tumor (*arrows*).

Most studies of transrectal US staging of rectal cancer have a predominance of extensive lesions, especially those with involvement beyond the muscularis propria [164], [165], [166], [167], [168], [169], [170], [171] and [172] (Table 154-5). Transrectal US correctly predicts invasion beyond the muscularis propria in about 85% of cases. The accuracy of detecting the extent of invasion within the rectal wall is only about 70%. Overstaging the extent of invasion within the wall may be caused by distortion of the US image by inflammation in the tissue layer beneath the cancer. [164] Lymph node involvement by rectal cancer has been studied by using transrectal US which is accurate in detecting lymph node involvement in about 75% of cases [164], [168], [169] and [170] (see Table 154-5). As with esophageal, gastric, and pancreatic cancer, the US appearance of malignant lymph nodes is nonspecific; malignancy within suspicious nodes should be confirmed with EUS-FNA whenever possible. [40], [56] Lymph nodes smaller than 5 mm in diameter usually are missed on trans- rectal ultrasonography. [173]

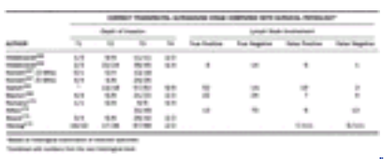

TABLE 154-5 Endoscopic Ultrasound Staging of Rectal Cancer

Transrectal US has been used in an effort to detect early recurrences after the resection of rectal cancer. Postoperative recurrences usually are detected as mass lesions but also may have an infiltrating appearance. [32], [174], [175], [176] and [177] Anastomotic and extrarectal recurrences may be detected by transrectal US when CT scans are negative or equivocal. [32], [174] A false-positive US diagnosis of recurrence may be the result of inflammatory or fibrotic tissue. EUS-guided biopsy of extralumenal masses should allow differentiation of recurrent cancer from fibrosis. [32], [176], [177] Transrectal US staging of rectal cancers has been compared with clinical staging schemes that are largely based on the result of a digital rectal examination. [178] US staging is more accurate than clinical staging, especially in detecting invasion beyond the muscular wall and in staging tumors proximal to the reach of the examining finger.

Rectal cancer staging by transrectal US also has been compared with staging by CT and MRI. Transrectal US and CT are both accurate in determining whether the cancer is confined within or has spread beyond the muscularis propria in 65% to 90% of cases; [168], [170], [178] however, CT cannot detect lesser degrees of wall invasion. [178] CT is also less accurate in detecting enlarged perirectal lymph nodes. [170] These differences in the accuracy of staging by transrectal US and CT are not clinically significant if only major surgical resection is contemplated. However, if less invasive therapies, including transanal excision and endoscopic mucosal resection, are used, the additional information provided by US could aid significantly in management planning. [179], [180] MRI may prove to be as accurate as rectal US for staging rectal cancer. [181] The ability of MRI in differentiating fibrosis from neoplasm is a particular advantage. The availability of rectal surface coils for MRI may allow even further improvements in resolution. [182]

Anal Sphincter Defects

The internal anal sphincter as well as the external anal sphincter, puborectalis sling, and pelvic muscles can be visualized by EUS or blind rectal US. This method is useful in visualizing anal sphincter defects and planning therapy for patients who have fecal incontinence. [183], [184]

INTERVENTIONAL ENDOSONOGRAPHY

Endoscopic US scanning has become an integral part of modern gastrointestinal endoscopy. With the aid of high frequency ultrasonic transducers, it is possible to image a wide range of different disorders located inside and adjacent to the gastrointestinal tract. This has stimulated interest in monitoring endoscopic therapeutic procedures. EUS-guided therapy can either be performed as an EUS-directed procedure with simultaneous endosonographic monitoring, or as an EUS-assisted procedure in which the endoscopic therapeutic procedure follows the EUS examination.

EUS-assisted therapy can be performed either with radial scanning transducers, longitudinally scanning transducers, or with miniprobes. EUS has been used prior to endoscopic cystogastrostomy, [185] submucosal tumor resection, [186], [187] and [188] mucosectomy, [189], [190], [191] and [192] treatment of vascular lesions, [193], [194] and [195] and steroid injection into resistant esophageal strictures. [196] Examples of EUS-directed therapy with simultaneous monitoring include pancreatic pseudocyst drainage, [197], [198], [199] and [200] abscess drainage, [199], [200] celiac plexus nerve block in patients with pain due to chronic pancreatitis or pancreatic cancer, [201], [202] and [203] injection of vessels

such as esophageal varices and local vascular malformations, [204], [205] botulinum toxin injection in patients with achalasia, [206] and cytoimplant placement in patients with advanced pancreatic cancer. [207]

ESTABLISHED INDICATIONS

The ability of EUS to examine the detailed structure of the bowel wall and adjacent organs has made it a useful tool in the investigation of many gastrointestinal disorders. More than many other techniques, EUS has been evaluated extensively, but its clinical value in routine practice continues to evolve. Although the accuracy of EUS in staging gastrointestinal and pancreatic malignancy is firmly established, debate continues as to the impact of this information on patient outcome. The American Endosonography Club published a prospective multicenter study on the impact on management in 428 patients. [208] It concluded that EUS findings alter clinical management in 75% of patients, with a change of major consequence in approximately one third. The recommendations and guidelines from several international groups on endoscopic ultrasonography have also been published and provide a concise review of accepted indications for EUS [209], [210] and [211] (Table 154-6).

DIAGNOSTIC	INTERVENTIONAL
Subepithelial mass definition	Endoscopic mucosal resection
Mediastinal mass definition*†	Treatment of vascular lesions
Lung cancer staging*†	Transmural pseudocyst drainage
Large gastric folds	Celiac plexus neurolysis
Esophageal cancer: local and regional staging*	
Gastric cancer: local and regional staging*	
Ampullary cancer: local and regional staging	
Pancreatic cancer	
Diagnosis of small masses*†	
Evaluation of resectability*†	
Pancreatic endocrine tumors: preoperative localization†	
Other abdominal masses*† (adrenal, lymphoma)	
Chronic pancreatitis: diagnosis†	
Choledocholithiasis: diagnosis†	
Rectal cancer: local staging	
Anal sphincter defects (incontinence)	

*EUS-guided fine-needle aspiration may be helpful in selected situations.
†EUS should be used in conjunction with other imaging tests.

TABLE 154-6 Indications for Endoscopic Ultrasonography (EUS)

FUTURE TRENDS

EUS is a relatively new imaging modality that is still evolving. The technique has been limited to relatively few expert centers throughout the world. New instruments that allow EUS-directed tissue sampling are expected to expand the clinical value of this procedure. In the future, instruments with biplane transducers allowing for an ultrasonic examination in two planes may increase its value even further. Color Doppler, duplex scanning, and pulsed Doppler capabilities are available today but need further evaluation. [22] Three-dimensional EUS is presently under development, [212], [213] although its clinical relevance is not known. More studies on EUS-guided aspiration biopsy and comparison with other techniques are awaited to define the exact indications for this technique. Also, development of new needle types that obtain core biopsies for histological analysis is expected. New endoscopes with larger working channels will allow new applications such as transintestinal placement of large drainage catheters in pancreatic pseudocysts or abscesses. [197], [199] Additional well-designed studies are needed to evaluate the impact of EUS and EUS-guided biopsy on patient management and outcome.

CHAPTER 155

Alec J. Megibow

APPLICATIONS OF COMPUTED TOMOGRAPHY TO THE GASTROINTESTINAL TRACT

Computed tomography (CT) scanning is widely accepted by the medical community; virtually every practicing physician, and patient for that matter, has familiarity with the appearance of CT images, and their applications throughout the body. The significance of this breakthrough in diagnostic imaging was recognized by the entire scientific community by awarding Godfrey N. Hounsfield and A.M. Cormack with the Nobel Prize in 1979. It was estimated in 1997 that 87% of practicing radiologists interpret CT images; only plain film radiography and fluoroscopy being more widely performed, according to the American College of Radiology (*ACR Bulletin,* February 1997, Volume 53). Continuous motion (helical or spiral) CT has replaced conventional sequential acquisitions, and now this is being replaced by multidetector row (multislice) systems. [1] These systems permit the acquisition of a continuous stream of image data which allows for:

- significantly shortened acquisition times
- the real beginning of increased reliance on three-dimensional data.

Perhaps the most important consequence of this wide dissemination and technologic advancements is the increasing use of CT as a routine method of x-ray examination, challenging the role of the plain film and intraluminal studies. [2]

COMPLICATIONS

CT scanning is so widely disseminated and routinely used in clinical practice it becomes increasingly difficult to be mindful that there are inherent risks associated with the procedure which should be considered before any patient is referred for scanning. Radiation exposure and intravenous contrast administration account for the two broad categories of complications.

Radiologists have expressed concern over increasing radiation dose to patients (particularly children) directly resulting from increasing use of CT scanning. [3] The average effective doses for the abdomen are 12.85 and 19.62 mSv for spiral and conventional CT, respectively. Typical multiple-scan average doses are in the range of 10 to 40 mGy for body scans. [4] Dose can be decreased by lowering tube current without loss of diagnostic quality. Calculation of effective dose will allow investigators to optimize acquisitions across body habitus, types of contrast, and clinical application. [5] Radiation doses are increased when multislice CT scanners are used.

Complications associated with intravenous contrast administration are grouped as:

- minor reactions (rashes, urticaria, nausea, and vomiting)
- serious reactions (anaphylaxis, cardiorespiratory compromise, or contrast-induced renal failure).

The incidence of minor reactions is clearly diminished by using low osmolar agents. Although serious reactions can occur with low osmolar agents, they are given in a higher risk population of patients and are probably safer. However, these agents offer no statistically verifiable safety from fatal complications [6] and have no proven safety in patients with impaired renal function. One survey documented that intravenous contrast material is administered for 90% (median) of abdominal and pelvic CT examinations; nonionic contrast material is used in 68%. [6a] We believe in selective use of low osmolar agents as provided in the guidelines developed by the American College of Radiology.

THE HOLLOW VISCERA OF THE GASTROINTESTINAL TRACT

Techniques

CT abnormalities in the lumenal gastrointestinal tract are recognized by identifying a thickened bowel wall. [7], [8] The suspicious bowel loop must be distended before confident, accurate recognition of pathological wall thickening can be made. Orally and rectally administered agents provide either positive (a “white” bowel using orally or rectally administered 1.5% to 2% water soluble contrast or 2% barium suspension) or negative contrast (gray or black bowel using plain water, gas-producing granules, or insufflated air). In practice, a combination is used. When a clinician reviews a CT scan, the first parameter he or she should evaluate is the adequacy of bowel opacification. Unfilled loops can be mistaken for pathological masses, and significant abnormalities may be obscured. High-density compounds, such as metal and barium, cause severe, image degrading artifacts. If these materials are in the region of imaging interest, the scans should be delayed until they can be cleared. Preliminary localizing radiographs should identify monitoring lines which can be moved. When planning multiple imaging tests for an individual patient, CT should be scheduled *before* barium studies because it may take several days for the barium to clear sufficiently to allow adequate CT examination.

Using intravenous contrast-enhanced images expands the diagnostic range of CT. Essential in the evaluation of the solid abdominal viscera, intravenous contrast enhancement improves conspicuity of pathological processes in evaluation of the alimentary canal by increasing the level of confidence in diagnosing a thickened loop as truly diseased. This refines the differential diagnosis by highlighting attenuation differences *within* the thickened loop, or by accentuating the “vascularity” of a bowel-related mass thereby allowing assessment of histological type and neoplastic potential. [9] Variations in blood supply of pathological processes demand a tailored approach to intravenous contrast administration protocols. Hepatic studies in cirrhotics looking for hepatocellular carcinoma are given intravenous contrast in a different manner than patients with colon cancer in whom the presence or absence of liver metastases is questioned. Pancreas studies are performed so that a rendered angiographic display can be generated from the source data and presented with the axial images.

Esophagus

For evaluation of masses, CT scanning aids in assessing local extension, locoregional lymphadenopathy, and thoracic and abdominal metastases. Conversely, secondary effects of mediastinal processes on the esophagus may be easily imaged aiding in surgical planning. In patients with suspected esophageal perforation, with or without thoracic trauma, CT can localize effusions and evaluate the status of adjacent lung. [10]

Neoplasms All esophageal neoplasms appear on CT as focal, asymmetric, soft tissue attenuation masses arising from the wall or as concentric wall thickenings. These findings are nonspecific and can be seen in benign and malignant tumors and in inflammatory conditions. [11]
Malignant neoplasms. Carcinoma of the esophagus typically appears on CT as a focal eccentric mass or as concentric thickening of the esophageal wall, neither of which is a specific finding. The role of CT in esophageal carcinoma includes staging the extent of disease (highest use in detecting extraesophageal disease), evaluating patients after treatment for therapy responses, and evaluating the complications of surgical therapies. Therapy success or failure can be based on documentation of the development of enlarged mediastinal or upper abdominal lymphadenopathy, lung nodules, or liver and adrenal metastases. CT criteria for extensive esophageal cancer include demonstration of local invasion (aorta, diaphragm, tracheobronchial tree), distant lymphadenopathy, and distant metastases. Local extension is the most difficult parameter to accurately diagnose. Contact angles of more than 45 degrees have been suggested to accurately predict aortic invasion, although several studies have shown this finding to result in frequent overstaging. [12] Pathological lymphadenopathy can be more reliably determined when regional adenopathy of more than 5 mm in the short axis is used as a criterion. [13] CT has been shown to be as accurate as fiberoptic bronchoscopy in assessing tracheobronchial invasion. If minimal disease is present, procedures such as endoscopic ultrasound (EUS) may be necessary for accurate preoperative staging. [14] Postsurgical complications can be detected by demonstrating anastomotic leaks, which occasionally are seen only on CT scans and are not detected by standard contrast esophagography. Although the site of the leak may be demonstrated, CT provides no histological specificity; squamous cell carcinoma, adenocarcinoma, lymphoma, and metastatic disease to the esophagus have similar CT appearances. Esophageal stromal tumor should be considered when there is a prominent exophytic component to the mass. [15]
Varices Esophagogastric varices are easily detected with contrast-enhanced CT and diagnosis is improved using helical CT techniques. CT has additional use in that it can show extraserosal varices, which may be underestimated by EUS. Thickening of the esophageal wall, a scalloped contour, and enhancing intralumenal protrusions after a contrast bolus injection are seen. [16] Low attenuation in the esophageal wall in patients with other stigmata of portal hypertension should suggest a history of sclerotherapy.
Esophagitis Esophagitis may produce thickening of the distal esophageal wall. CT is neither sensitive nor specific for this finding. CT does not aid in the differentiation of distal abnormalities caused by either carcinoma or severe esophagitis. CT may be useful in recognizing distal esophageal changes in immunocompromised patients who can go on to endoscopic evaluation for specific etiology.

Stomach

CT can evaluate the position of the stomach, the lumenal contour, the gastric wall, surrounding lymph nodes, peritoneal ligaments, and relation to surrounding viscera. The distended gastric wall should measure less than 5 mm. At the esophagogastric junction and the pyloric canal, the wall may be up to 1-cm thick and still be normal. The wall displays a uniform enhancement pattern following intravenous contrast administration. Use of negative contrast allows assessment of the distribution of the rugal fold pattern in the proximal stomach. Changes in positioning may be necessary to maximally distend regions of the stomach where the wall is questionably thickened. There have been initial investigations of three-dimensional imaging capabilities in improving evaluation of the stomach and perigastric relationships. [17]

Neoplasms Gastric carcinoma appears as a region of focal, variably thickened gastric wall. Polypoid and scirrhous forms (with or without ulceration) are encountered. Scirrhous tumors (linitis plastica) can be difficult to diagnose as the degree of wall thickening is less than in polypoid tumors. [18] Gastric cancer spreads along the perigastric peritoneal reflections through intramural lymphatics, by peritoneal seeding, and hematogenously (Fig. 155-1). Lymphatic submucosal spread into the esophagus occurs in approximately 30% of patients with tumors in the gastric fundus. Extension into the serosa allows tumor access to the supporting mesenteries of the stomach providing pathways into omentum, kidney, liver, pancreas, transverse colon, and spleen. Proximal lesions can extend into the diaphragm and the aorta.

FIGURE 155-1. Gastric carcinoma—patterns of spread. A gastric carcinoma is identified by a thickened wall in the proximal stomach. A nodular density is seen along the greater curvature aspect of the lesion representing peritoneal seeding (*arrow*). Multiple hepatic metastases are evident in the enhanced liver, indicative of hematogenous spread.

With single-slice helical CT, using thin sections and intravenous contrast, resultant density discrimination improves staging accuracy over conventional CT. In a Japanese study, overall T-staging was correct in 66% (27 of 41), despite a large number of “early” carcinomas that might bias the sample against CT accuracy, [19] implying that results should be improved in populations where patients present with more advanced disease. Dedicated imaging protocols have yielded detection of lesions in greater than 95% of patients and detection of lymph node disease in approximately 71%. [20] Gastric lymphomas produce significantly greater wall thickness than carcinoma, although this finding is of limited value for differential diagnosis in individual cases. Following intravenous contrast enhancement, lymphoma masses minimally enhance and remain homogeneous, as opposed to the more frequently heterogeneous adenocarcinoma. In cases presenting with fold hypertrophy, there may be demonstrable clefts between the thickened folds extending through the wall into the extraserosal tumor. [21] CT cannot be used to screen for mucosa-associated lymphoid tissue (MALT) in patients with chronic *Helicobacter pylori* infections. [22] CT is accurate for detecting complications such as perforation and fistulization. Metastatic disease to the stomach may be indistinguishable from primary adenocarcinoma. Particular attention should be focused on the gastric antrum in patients with carcinoma of the breast, where a linitis plastica appearance resulting from breast metastases has been reported.
Stromal Tumors A wide variety of stromal tumors occur in the stomach. Spindle cell lesions are the most common. [23], [24] CT is useful in displaying the predominant tissue (particularly in recognizing fat). Malignant lesions are larger and present as huge abdominal masses. The attachment site may be quite small considering the size of the mass. The CT appearance correlates with biologic behavior of the mass (i.e., large malignant lesions with wide areas of liquefaction are easily recognized on CT whereas, because of scant viable tissue, numbers of mitoses may be limited and true malignant potential of a lesion may be less well appreciated). [25], [26] An exophytic growth pattern is unusual, although it has been reported for adenocarcinoma.
Inflammatory Diseases CT scanning has no primary indication for the evaluation of inflammatory gastric diseases. However, they may result in a focal or diffuse wall thickening. The thickened wall will display some degree of low attenuation, reflecting edema in the gastric wall. Only scattered reports of cases of neoplasm display this finding. [27]

Small Intestine

The key to evaluation of the small intestine lies in adequate opacification with orally administered contrast material. Typically, 500 to 600 mL of dilute contrast material should be administered 1 to 2 hours before examining the abdomen to provide opacification of the small bowel and avoid mistaking fluid-filled or nondistended loops for abnormal masses. Oral metoclopramide aids in gastric emptying and filling of the terminal ileum. There has been growing interest in the use of negative contrast agents in small bowel evaluation engendered by the increasing use of three-dimensional imaging.

Neoplasms Two large categories of benign lesions include adenomatous polyps and stromal tumors. The latter are more commonly encountered at imaging. Leiomyoma, the most common stromal lesion, appears as a rounded, soft tissue attenuation with an exophytic growth pattern. Lipomas can be definitively diagnosed by the recognition of fat attenuation within the mass. Adenocarcinoma of the small intestine produces soft tissue attenuation wall thickening and irregular narrowing of the lumen which can lead to obstruction. This lesion is most frequently seen in the periampullary duodenum, and may be a cause of biliary obstruction. Malignant lesions demonstrate exophytic or intramural mass, central necrosis, and ulceration. [28] The radiologic manifestations of lymphoma of the small intestine are classified as aneurysmal, constrictive, nodular, ulcerative, mesenteric, and sprue forms. The morphologic patterns of nodular, ulcerative, and aneurysmal disease are best visualized with CT. [29], [30] Acquired immunodeficiency syndrome (AIDS)-related lymphomas display two main patterns on CT: single or multiple segments with homogeneous, circumferential wall thickening, or single or multiple cavitary lesions. The gross morphologic features, distribution pattern, degree of wall thickening, and length of involvement are similar in AIDS-related and non–AIDS-related lymphomas. [31] Carcinoid tumor results in a well-described, specific CT appearance resulting from the intense desmoplasia incited by the tumor. The primary small bowel lesion often goes undetected. The CT appearance is characterized by radially oriented linear densities in the perienteric fat. A lymph node mass (frequently calcified) is present centrally. Bowel loops are drawn toward the center. [32] The mesenteric desmoplasia may produce ischemia thickening the involved loops. Metastatic disease to the small bowel results from blood-borne (embolic) metastases, peritoneal seeding, or from direct extension from a contiguous lesion. Each has a recognizable CT appearance. Embolic metastases are commonly seen from

melanoma, Kaposi sarcoma, and breast carcinoma [33] (Fig. 155-2). Discrete masses eccentrically localized along the bowel circumference are present. Tethering of the mesenteric border of individual bowel loops in the presence of changes of peritoneal carcinomatosis is indicative of seeded metastases. Variable degrees of partial obstruction are common. Nodular thickening of the mesenteric reflections is observed. These findings are seen in metastatic ovarian, colonic, breast, and lung carcinoma.

FIGURE 155-2. Metastatic melanoma multiple soft tissue attenuation masses are readily identified in the wall of the jejunum (*arrows*).

Nonneoplastic Diseases

Crohn's disease. One of the earliest applications of CT in the alimentary tract was the evaluation of Crohn's disease. [34] Axial display and markedly expanded contrast resolution compared to plain film and barium radiography make CT ideal in displaying the transmural inflammation, effects in local fat, and global assessment of disease. [35] The affected bowel wall displays variable degrees of mural thickening. When intravenous contrast is administered, submucosal hypoattenuation, reflecting submucosal edema, may be seen. This "target sign," although nonspecific for Crohn's disease, was first described in this entity [36] (Fig. 155-3). This appearance may be mimicked in long-standing disease from deposition of submucosal fat. The bowel becomes "isolated" in a "sea" of hypertrophied fat. CT definitively establishes this fatty proliferation as a cause of separation of bowel loops. The fatty proliferation is seen with hypervascularity in the local mesentery. [37] Linear nonvascular densities are correlated with the presence of sinus tracts or fistulae. When these are identified on CT, barium studies are necessary to precisely map their relationships. Local lymphadenopathy (generally not greater than 15 mm) is associated with these findings. Increased density in the fat reflects inflammatory exudate and when contained, frank abscess. Intra-abdominal abscess is not uncommon, with severe, steroid-refractory relapses of Crohn's disease being present in about one third of patients. CT is superior to indium 111 leukocyte scintigraphy, which is sensitive to inflammation but poor in documenting extent. Indium 111 leukocyte scintigraphy is the most specific method to image "active inflammation."

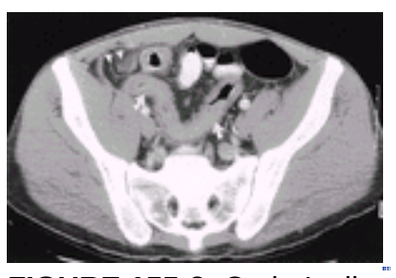

FIGURE 155-3. Crohn's disease—ileum. A loop of ileum possesses a thickened wall (*arrows*). Note the stratification of density in the wall. Central lucency represents edema. Increased density in the adjacent mesenteric fat results from the transmural inflammatory process (*arrowheads*).

CT findings simulating Crohn's disease have been described in a variety of infectious processes including: *Yersinia, Shigella, Salmonella,* [38] and *Mycobacterium tuberculosis.* Specific radiologic diagnosis is impossible; findings must be interpreted in context of patient presentation. In patients with AIDS, cytomegalovirus (CMV) infection frequently produces distal ileitis resembling Crohn's disease.

Vascular diseases. Using helical and multislice CT, enhancement levels of normal bowel reach levels between 110 to 120 Hounsfields. [39] A wide variety of conditions produce abnormalities at all levels of the small intestinal vasculature. The most severe forms of ischemia result from emboli to the superior mesenteric artery. These patients rarely come to CT. "Small vessel" diseases are most likely to manifest on CT. These include diseases such as lupus erythematosis, graft-versus-host disease, polyarteritis nodosa, and radiation enteritis. All result in relatively short segments of thickened intestinal wall with prominent submucosal edema. Intramural hemorrhage, whether secondary to vasculitis, excessive anticoagulation, or trauma, results in high-attenuation wall thickening. [40] Variable degrees of obstruction may be present from the compression of the lumen secondary to the intramural hematoma. Frank infarction is difficult to diagnose clinically and by CT. The infarcted portion generally displays a thin wall and fluid-filled lumen. [41] In advanced cases, linear pneumatosis may be present in the bowel wall (Fig. 155-4). Pneumatosis may be seen in the absence of infarction.

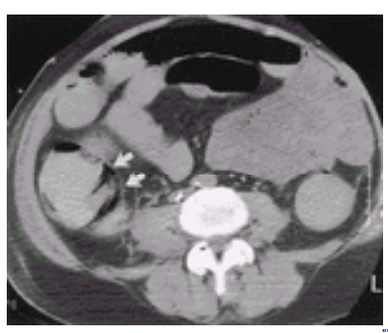

FIGURE 155-4. Bowel infarction—visualized bowel loops are distended, fluid-filled, and airless. Linear streaks of intramural air (*arrows*) are identified in the cecum. The patient expired despite attempt at surgical resection.

Trauma. CT is widely used in the evaluation of blunt abdominal trauma. [42] Solid organ injury is relatively easily detected; the significance of subtle findings indicative of severe mesenteric injuries are becoming more frequently recognized. [43] If mesenteric infiltration, bowel wall thickening, extravasation of vascular or enteric contrast agent, and free air are visualized, sensitivity, accuracy, and specificity are 62%, 82%, and 97%, respectively. [44] CT can contribute to early surgical management which may have been delayed if only clinical signs were incorporated into decision making. [45]

Small bowel obstruction. CT findings of obstruction are similar to traditional radiographic findings: disparate dilation of proximal bowel loops compared with more distal ones. Comparative studies have shown that CT is superior to plain film radiography in detecting intestinal obstruction and in determining the cause of obstruction. [46] Studies have shown CT sensitivities ranging from 90% to 95% in detecting obstruction, with no false-positive examinations (Fig. 155-5). CT establishes the etiology in a majority of cases. [47] The major contribution of CT in these patients is the ability to detect signs of strangulation. These signs include thickening and edema in affected loops (ischemic signs) and mesenteric clouding, ascites, or infiltration (mesenteric signs) [48] (Fig. 155-6). The combination of multiple findings has improved reliability in predicting obstruction as compared to any single sign in isolation. [49]

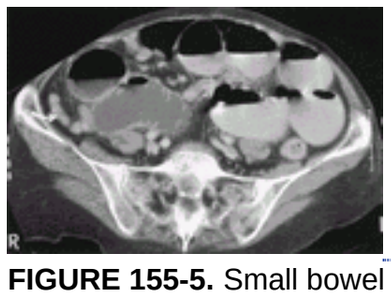

FIGURE 155-5. Small bowel obstruction—computed tomography findings. Dilated small bowel loops occupy most of the abdomen. Collapsed distal ileal loops are recognized (*curved arrow*). This pattern is diagnostic of small bowel obstruction.

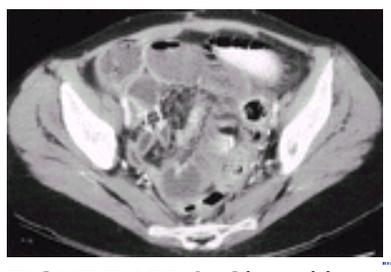

FIGURE 155-6. Closed loop obstruction—high-grade obstruction is evident. Note the converging of two adjacent narrowed loops at the transition to collapsed lumen (*curved arrows*). This appearance is diagnostic of a closed loop strangulated small bowel obstruction and considered as an indication for immediate surgical decompression.

CT can change management by accelerating surgical treatment in obstructed patients resulting in verifiable improvements in outcome. [50], [51] CT efficacy decreases in patients with chronic obstructive symptoms and low-grade obstruction. For these patients, barium radiography, especially by enteroclysis, is the method of choice. [52]

Colon

CT is useful in the evaluation of many colonic disorders. Because CT shows both the colonic wall (generally <3 mm) and surrounding pericolic fat, extension of pathological processes into the surrounding pericolic fat offers improved staging of tumors and preoperative assessment of complex inflammatory reactions in a single examination, thereby facilitating both diagnosis and treatment decisions.

Neoplasms

Malignant neoplasms. A thorough preoperative evaluation is essential in selecting appropriate operative therapy and for sequencing surgery with available adjuvant treatments. [53] These decisions are based on the anatomic location of the primary tumor(s) and the presence or absence of metastatic disease. An additional element in rectal cancer patients is assessment of transmural penetration and the distance from the anal verge. Although EUS excels in local staging of accessible lesions, CT provides the most efficient methodology by which *all* of these components can be comprehensively evaluated. Results from a multi-institutional study reported 74% accuracy for CT assessment of wall invasion; the sensitivity in evaluating lymph node metastases was 48%. CT demonstrated an 85% accuracy and 97% specificity in detection of liver metastases. [54] The detection of colorectal carcinoma depends on the degree of colonic distention and adequacy of the preparation. [55] In the unprepped bowel, all but the largest lesions will be overlooked. Adenocarcinoma appears as a soft tissue attenuation focal mass, which focally or circumferentially thickens the bowel wall. Using air insufflation and a colon preparation, detection was increased from 68% to 95% [55] (Fig. 155-7).

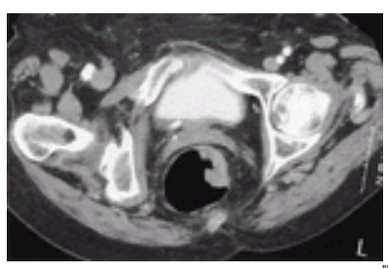

FIGURE 155-7. Rectal carcinoma. An ulcerated mass is visualized along the left wall of the rectum. No obvious extension into perirectal fat is seen.

Transmural invasion is suggested when streaky, spikelike soft tissue attenuation changes are seen in the peritumoral fat. The main limitation of CT staging is understaging the extent of local disease, with few overstaging problems. CT is useful in identifying complications of colorectal cancer such as perforation (Fig. 155-8), obstruction, and synchronous lesions. These may be clinically silent but their presence impacts on long-term survival. The negative predictive value of CT has been estimated at 90%. [56] Although most surgeons have come to rely on preoperative CT scanning to survey the abdomen and pelvis, there is no routine agreement regarding widespread use. [57]

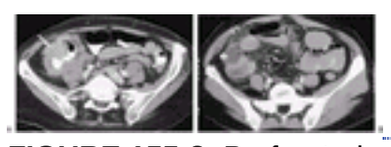

FIGURE 155-8. Perforated cecal carcinoma. **A:** A bulky mass is present in the cecum (*arrow*). Note the spikelike borders typical of an invasive lesion. **B:** An abscess collection (*arrow*) is identified. Note the peritoneal reaction (*arrowheads*); it is impossible to differentiate between local peritonitis or peritoneal seeding.

CT plays an adjunctive role in evaluating recurrent disease after abdominoperineal resection or colonic resection. CT is capable of demonstrating locally recurrent pelvic masses, lymphadenopathy, and liver metastases. Locally recurrent rectal cancer appears as spiculated densities or a fibrous soft tissue layer around the rectum; when the abnormal tissue is attached to the perirectal fascia or extends beyond it, positive predictive value is high. [58] CT or ultrasound (US) imaging combined with colonoscopy has been shown to detect recurrent colon cancer at a lower total cost per patient than routine use of carcinoembryonic antigen (CEA), physical examination, and chest x-ray. [59] However, use may be greater in tumors arising in the abdomen as opposed to the pelvis.

CT colonography (virtual colonoscopy). The ability of helical CT to acquire a continuous volumetric data set, three-dimensionally, allows application of rendering techniques which result in a display of the lumenal (mucosal) surface of the colon, a process known as CT colonography or “virtual colonoscopy”. [60] Extensive evaluation of virtual colonoscopy has occurred since the late 1990s. [61], [62] Uniform distension, multiple positions, and meticulous bowel preparation are absolutely necessary to achieve diagnostic results. Patient table time is less than 3 minutes, more time is necessary for processing of the data. Most investigators have abandoned the “fly-through” movie relying on two-dimensional multiplanar reformatted images and use three-dimensional movies as a static problem-solving technique. [63], [64] Virtual colonoscopy will not compete with colonoscopy, however it *will* compete with barium enema, and investigators have used this technique to “finish” incomplete colonoscopy [65] (Fig. 155-9). The accuracy of polyp detection depends on size of the lesion. In a widely quoted study, virtual colonoscopy identified all 3 cancers, 20 of 22 polyps that were 10 mm or more in diameter (91%), 33 of 40 that were 6 to 9 mm (82%), and 29 of 53 that were 5 mm or smaller (55%). [62] Of the 69 adenomatous polyps, 46 of the 51 that were 6 mm or more in diameter (90%) and 12 of the 18 that were 5 mm or smaller (67%) were correctly identified. [62] It is hoped that virtual colonoscopy will eventually make full colonic evaluation accessible to a greater number of patients than presently take advantage of colorectal cancer screening programs and aid in polyp detection.

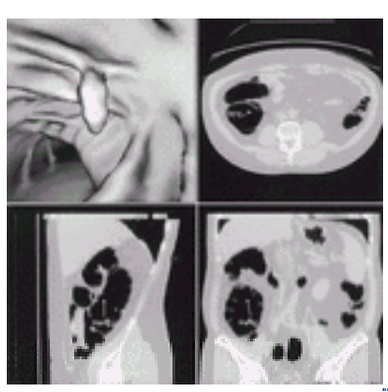

FIGURE 155-9. A 1-cm pedunculated adenoma in the ascending colon. This computed tomography (CT) colonoscopic view (**upper left panel**) identified this

pedunculated polyp. Reformatted “conventional” CT images in axial, coronal, and sagittal planes are included in the data display (**other panels**). The patient was referred following an incomplete colonoscopy, taking advantage of the patient preparation. Repeat colonoscopy was successful to the cecum and the polyp was removed.

Nonneoplastic Diseases

Diverticulitis. In those patients in whom the clinician requires imaging clarification or confirmation of a diagnosis of diverticulitis, CT is the primary, and in most instances, the only necessary test. [66], [67] Although CT and lumenal radiography have equal accuracy in *establishing* the diagnosis, CT is clearly superior in determining whether abscess is present and in documenting the extent of the inflammatory mass [68] (Fig. 155-10). When abscess is present, resection of the perforated segment with anastomosis is desirable, however if the field is contaminated by pus, temporary colostomy may be necessary. Percutaneous abscess drainage reduces surgical morbidity and allows a primary anastomosis. [69]

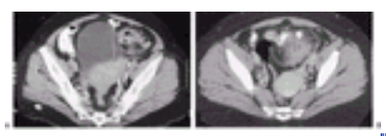

FIGURE 155-10. Diverticular abscess (**A**). Increased density in the fat of the sigmoid mesocolon indicates diverticulitis (*open arrow*). **B:** An abscess (*arrow*) is defined within the dense inflammatory response.

CT is excellent in diagnosing diverticulitis as a cause of fistulae arising from the colon, particularly those to the urinary bladder or the vagina. [70] The major limitation of CT is the inability to assess the integrity of the colonic mucosa, and perforated neoplasm may be overlooked; [71] this is estimated to be a problem in approximately 10% of cases. In these individuals, lumenal evaluation with either endoscopic or contrast radiography is indicated. [72]

Appendicitis. CT has emerged as the primary imaging modality in patients suspected of acute appendicitis. [73] Outcome-based studies [74], [75] have documented an impact on negative appendectomy rates in patients who have undergone CT imaging. CT has similar accuracy to US, although the negative predictive value of CT is significantly higher. [76] Local expertise and body habitus (thinner patients for US and larger patients for CT) should dictate the use of US or CT. The diagnosis is dependent on visualizing an abnormal appendix. Defining criteria include a dilated, thick-walled tubular structure, which brightly enhances following intravenous contrast [77] (Fig. 155-11). Periappendiceal inflammatory changes may be minimal, even when the appendix is found to be gangrenous at surgery. Although it is possible to recognize findings of acute appendicitis on unenhanced studies, [78] we *strongly* believe that intravenous contrast and oral contrast and acquisition using thin sections [79] are essential in patients *referred* for evaluation of right lower quadrant pain.

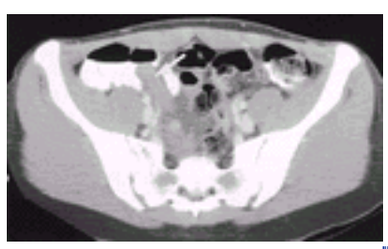

FIGURE 155-11. Appendicitis. No periappendiceal inflammation is present. The appendix is recognized as a tubular structure with a thick, hyperdense wall and a fluid-filled lumen (*arrow*). Cecal opacification with orally administered contrast is essential.

Differential diagnosis of right lower quadrant inflammatory diseases includes cecal diverticulitis, [80] epiploic appendagitis, [81] and right-sided colitis. CT may not be able to predict neoplasm obstructing the appendiceal orifice.

Colitis. For most patients with a known diagnosis of acute colitis, CT offers little information. CT is most useful in those with nonspecific symptoms, directing the workup to an unsuspected colitis. [82] As in small bowel diseases, submucosal lucency representing edema can be seen on enhanced scans. In an attempt to suggest a specific diagnosis, one evaluates mural thickness and enhancement pattern, distribution of bowel involvement, and associated mesenteric and small bowel disease. The mean colon wall thickness in Crohn’s colitis is significantly greater than in ulcerative colitis. Exclusive involvement of the right colon and small bowel is more frequent with Crohn’s and infectious colitis. Abscess is associated almost exclusively with Crohn’s colitis. [83] An accordion-like appearance of the colon can be seen in a variety of acute colitides. [84] CT is not indicated in workup of patients with ulcerative colitis. The disease is recognized by a continuously thickened segment of intestinal wall, displaying a targetlike appearance. Fat hypertrophy in the presacral region is seen. In patients with long-standing colitis, fat deposition within the wall may occur. [85] CT is not sensitive enough to monitor these patients for the development of carcinoma. In Crohn’s colitis, CT has additional use in that pericolic disease is frequent. CT has unique application in the evaluation of perianal complications. [86] CT findings in pseudomembranous (*Clostridium difficile*) colitis produces dramatic wall thickening, as an almost uniform accompaniment of pseudomembranous colitis [87] (Fig. 155-12). The diagnostic sensitivity decreases without the use of intravenous contrast. [88] CMV colitis has a similar appearance to pseudomembranous colitis. Ischemic colitis appears as a focal area of wall thickening with intramural lucency. [89] In most cases, local ascites is present. Care should be taken to rule out a distal obstructing carcinoma. [90] Similar symptoms may be produced by hemorrhagic *Escherichia coli* infection. [91] Neutropenic colitis has a predilection for the terminal ileum and right colon.

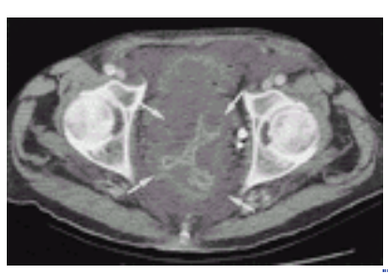

FIGURE 155-12. *Clostridium difficile* proctocolitis. There is massive thickening of the colonic wall; the serosal margin is identified by the arrows. The central Y-shaped density represents a markedly hyperemic mucosa; the wall thickness is entirely edematous. This patient presented with a postoperative fever; no diarrhea or rectal bleeding was noted.

THE SOLID ORGANS OF THE GASTROINTESTINAL TRACT

Liver

Techniques The technique of examination of the liver is based on whether the study is to be performed to:

- exclude any amount of hepatic disease
- determine the precise disease burden for preoperative planning
- characterize known masses seen on other imaging studies.

Separating these imaging tasks allows the radiologist to optimize contrast administration, acquisition speed, and timing. Hepatic parenchymal enhancement following a rapid bolus infusion of *intravenous* contrast administration is characterized by three distinct phases: a hepatic artery phase, a portal phase, and an equilibrium phase. The hepatic artery phase, useful in detection of hypervascular lesions and hepatocellular carcinoma (HCC), will last between 30 to 50 seconds following the initiation of injection. All hepatic lesions are supplied by the hepatic artery and it is during this time that these lesions are brightly enhanced because background parenchyma has not reached peak enhancement. At approximately 70 to 90 seconds, peak hepatic enhancement is achieved (portal phase). Peak enhancement maintains itself for approximately 30 seconds and then slowly decays. Most scanning is performed during this portal phase because this is the time when there are maximal differences in attenuation between normal liver parenchyma and most masses. Delayed scanning during the “equilibrium phase” will result in decreased

lesion conspicuity. [92] Software modifications are available to time the beginning of scanning with peak enhancement. [93] Unenhanced scans are important in patients with suspected “hypervascular” lesions, including metastases from renal, thyroid, breast, islet-cell, and carcinoid tumors and HCC. [94] In patients with cirrhosis in whom HCC is suspected, noncontrast scans are especially important due to the changes in hepatic artery/portal vein hepatic supply. The clinician should communicate a specific clinical history or suspicion of these diagnoses to the radiologist for proper examination. [95] With helical/spiral CT, images of the entire liver can be acquired in a single breath hold (20–30 seconds depending on the length of the liver). Using multislice CT, the liver can be scanned in 12 to 15 seconds allowing better use of hepatic artery phase imaging. Following the hepatic arterial images, the liver can be immediately rescanned to capture peak parenchymal enhancement during the portal vein phase. [96] This technique is referred to as “dual-phase” helical CT. [97] Many perform a “three-phase” study recognizing the role of the unenhanced scans (Fig. 155-13). In order to achieve a diagnostic arterial phase image, contrast must be power injected at a rate exceeding 4 mL/s. We reserve this technique almost exclusively for detection of HCC. [98], [99] Intravenous portal-phase, contrast-enhanced helical CT has been reported as sensitive (91%) for detecting malignant hepatic tumors measuring larger than 1 cm but relatively insensitive (56%) for tumors smaller than 1 cm. [100] The availability of multislice CT facilitates simultaneous lesion characterization and detection because both phases of hepatic enhancement are accessible from the same dose of intravenous contrast. [101] Additionally, three-dimensional display improves localization. These results are slightly superior to results of nonhelical CT, although lesions smaller than 1 cm remain elusive.

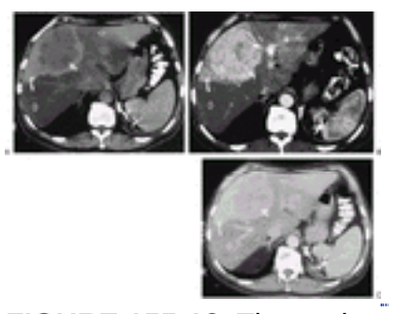

FIGURE 155-13. Three-phase liver examination. This figure illustrates several basic principles of liver imaging with helical computed tomography. A lesion seen on the noncontrast image (**A**) (*straight arrow*) is hypodense to surrounding hepatic parenchyma (*curved arrow*). This segment of parenchyma is denser than the majority of the fatty infiltrated liver (*open arrows*). **B:** An “arterial phase” image resulting in bright enhancement of the lesion with less enhancement of the background liver parenchyma. **C:** The portal phase reveals the lesion to be almost equal in density to the surrounding “normal” liver parenchyma. This perilesional parenchyma is brighter than the maximally enhanced fatty liver due to perilesional circulatory effects.

If documenting the exact number and location of liver metastases is imperative, such as before contemplated resection of apparently isolated metastases, angiographic-assisted CT improves sensitivity. CT-portography (CTAP) has the highest reported sensitivity for detecting focal liver masses, approaching that of intraoperative US. [102] The improved sensitivity may lead to better patient selection for resection of metastases. [103] The volumetric data set from helical and particularly multislice acquisitions allows for angiographic and three-dimensional volume-rendered data displays; these aid in lesion localization and surgical planning. [104] Improvements in contrast sensitivity afforded with magnetic resonance imaging (MRI) have significantly reduced the use of CTAP in most clinical practice today compared to the late 1990s. In our practice, which includes a large number of transplant patients in whom hepatic surgery is dependent on accurate demonstration of entire tumor burden, CTAP is almost never performed.

Diffuse Diseases

Fatty infiltration. Fatty infiltration of the liver may occur in a diffuse or focal distribution. This intracellular fat lowers the liver’s CT attenuation reversing the relation to splenic enhancement as judged on unenhanced scans. [105] Focal fatty deposition can be confused with hepatic space-occupying lesions. Lack of displacement of adjacent vessels, location, and the rapid change with time can be helpful in differentiation. [106] When problematic, the presence of focal fat can be established by biopsy or “chemical shift” MRI.

Cirrhosis. Characteristic CT features can be seen in patients with advanced cirrhosis. The right lobe and medial segment of the left lobe are often decreased in size, but the lateral segment of the left lobe and caudate lobe are enlarged. [107] Additionally, cirrhotic livers demonstrate irregular, nodular liver margins’ apparent widening of the intrahepatic fissures and the porta hepatis as the liver retracts and shrinks. Associated changes of portal hypertension, with varices and venous collaterals, commonly occur. [16] Enhancement of the cirrhotic liver is similar to normal liver during the arterial phase, but may be slightly less dense during the portal phase. [108] A normal CT does not exclude the diagnosis of cirrhosis as fibrosis may still be severe on liver biopsy. The distorted liver appearance caused by cirrhosis obscures many small tumors on CT scans. Considering the worldwide frequency of hepatitis C, the number of cases is expected to increase. Using conventional CT imaging, Miller and associates [109] reported detecting HCC in only 68% of cirrhotic patients with tumor. Incorporating arterial phase helical CT scanning improves to an additional 30% to 40% of HCC tumor nodules over portal venous phase imaging alone. [110] Correlation with subsequent transplant specimens has shown that while arterial phase imaging for detecting HCC in cirrhotic patients is a significant improvement over conventional or portal venous contrast imaging, lesions less than 2 cm in size still go undetected more often than not. [111] While the significance of dysplastic nodules remains a controversial issue, it is known that CT is poor at detecting dysplastic nodules in cirrhotic livers. [112] Sarcoidosis may simulate macronodular cirrhosis. Associated retroperitoneal adenopathy and nodular changes in the spleen suggest the diagnosis. [113]

Other diffuse diseases. Iron deposition and hemochromatosis, whether primary or secondary, increase the attenuation of the liver and spleen on CT scans. [114] CT is valuable in evaluating long-term iron deposition in the reticuloendothelial system from chronic transfusion therapy. The hepatic density may also be increased in patients receiving amiodarone therapy, those with glycogen storage disease, and following gold therapy for rheumatoid arthritis. Despite high-serum copper levels, CT scan of the liver does not show significant elevations over normal attenuation measurements in patients with Wilson disease.

Infections Although CT is not indicated for the primary evaluation of hepatitis, several reports indicate findings suggesting its presence. These should be recognized so that diagnosis and therapy may be expedited. A thickened gallbladder wall with periportal edema may suggest the diagnosis. In patients with cirrhosis due to chronic hepatitis, perihepatic lymphadenopathy is common. [115] Periportal edema may cause this sign in patients with congestive heart failure and secondary liver congestion, hepatitis, or enlarged lymph nodes and tumors in the porta hepatis which obstruct lymphatic drainage. This CT sign has also been observed in liver transplants (probably secondary to disruption and engorgement of lymphatic channels) and in recipients of bone marrow transplants who might develop liver edema from microvenous occlusive disease. [116] Hepatic tuberculosis may appear as a focal mass (tuberculous pseudotumor), an abscess, or result in diffuse liver disease. Hepatic involvement is associated with low attenuation lymphadenopathy and splenic disease. [117] Bacillary angiomatosis results in innumerable dilated sinusoids; high attenuation lymphadenopathy may be seen. A similar appearance has been described in cat-scratch fever. [118] Diffuse calcification throughout the liver has been observed in patients with extrapulmonary *Pneumocystis carinii* infection. [119]

Masses

Cysts. Cysts appear as homogeneous, low attenuation (0–10 Hounsfields) masses having smooth, sharp margins without a perceptible wall. Cysts less than 1 cm may cause concern, particularly in patients with cancer because of artifactually higher attenuation measurements from volume averaging. Assessment of multiplicity and comparison with prior studies is necessary. [120]

Benign neoplasms. Hepatic hemangioma is the most common tumor of the liver. Taking advantage of the improved contrast and temporal sensitivity of helical CT, hemangioma may be accurately and definitively diagnosed in over 90% of cases by CT alone. [121] Criteria include:

- globular enhancement
- lack of continuity of enhancing tissue
- iso-, or hyperdense enhancement relative to the aorta
- peripheral enhancement.

Globular enhancement, isodense with the aorta, is 67% sensitive and 100% specific in differentiating cavernous hemangiomas and hepatic metastases (Fig. 155-14). When demonstrated, no further workup is needed.

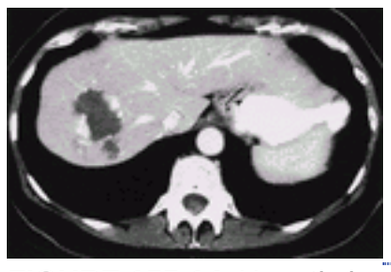

FIGURE 155-14. Hepatic hemangioma. Globular, peripheral enhancement, isodense with the aorta is diagnostic of hepatic hemangioma. When these features are imaged, no further workup is necessary.

Hepatic adenomas and focal nodular hyperplasia (FNH) are vascular lesions that can present with a variety of CT appearances that are often indistinguishable, unless there is hemorrhage (indicating adenoma). [122] Both lesions usually demonstrate homogeneous, increased attenuation as viewed during the hepatic arterial phase of enhancement, rapidly becoming isodense or slightly hypodense as peak portal enhancement is achieved. The identification of a central, stellate, low-density area is helpful in the diagnosis of FNH, seen only in a minority of patients. [123] Patients with fibrolamellar HCC may demonstrate a similar, central low density. Calcification, while rare in FNH, is frequent in fibrolamellar HCC. [124]

Malignant neoplasms. HCC can appear on CT scans as a focal, solitary mass; a multifocal process; or as a diffuse, infiltrating process. These lesions appear hypodense or isodense with normal liver on noncontrast-enhanced images; after contrast administration, larger lesions are predominantly hypodense during portal imaging. Smaller lesions may be isodense during the portal phase and only appreciated during early (hepatic arterial phase) images obtained after rapid (>4 mL/s) contrast bolus. [125] Characteristic appearances of HCC include fibrous capsules, fibrous septa, and mosaic appearances. The fibrous capsules of HCCs are readily detected by CT and MRI. [126] The mosaic pattern is a result of variable tissue composition of HCC. In most patients, enhancing nodules indicate viable tumor cells, and low attenuation areas represent necrosis, fibrosis, or hemorrhage. [127] With the increase in prevalence and incidence of hepatitis B and C worldwide, interest in imaging surveillance of these high-risk populations is gaining momentum. There is considerable interest in regional therapy for HCC, including chemoembolization and radiofrequency ablation. CT imaging aids in localization of foci of tumor for which angiographic administered chemoembolization can be applied. [128] Smaller lesions are amenable to percutaneous alcohol ablation. [129] Liver metastases demonstrate a variety of CT appearances. The majority typically appear hypodense compared with adjacent enhanced liver parenchyma, although vascular lesions can appear hypodense, isodense, or hyperdense, depending on the timing of contrast administration and scanning. Hypervascular metastatic lesions, as are found in renal cell carcinoma, islet-cell tumors, leiomyosarcoma, or thyroid carcinoma, may be better demonstrated on noncontrast-enhanced CT (Fig. 155-15). Metastatic lesions do not have a pathognomonic appearance and can be simulated by HCC, hemangiomas, abscesses, complicated cysts, or hematomas. Analysis of the hepatic artery enhancement patterns of metastases reveal that a complete ring enhancement pattern is a highly specific sign of metastatic liver disease regardless of primary site. [101], [130]

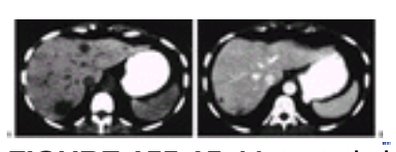

FIGURE 155-15. Metastatic breast cancer. Value of noncontrast scans. **A:** Multiple low-attenuation lesions are seen in an unenhanced image. **B:** Following intravenous contrast, most of the lesions have become inapparent. Care must be taken to insure that consistent contrast protocols are adhered to in oncology patients.

Abscesses. The diagnosis of liver abscess depends heavily on radiologic imaging, particularly US and CT scanning. [131] CT has become the screening procedure of choice for detecting pyogenic liver abscesses, with detection rates as high as 97%. The typical CT features of a pyogenic abscess include a mass hypodense with normal liver parenchyma, often with a contrast-enhanced rim. Gas collections are seen in approximately 20% of cases; internal septations may be seen. The mass usually is of higher density than simple cysts, but overlap in these densities can make it difficult to differentiate a simple cyst from an abscess. [132] Some malignant lesions can simulate liver abscess. Clinical correlation and aspiration are necessary to differentiate the entities. Fungal abscesses usually present on CT as multiple, small, low-density, nonenhancing lesions spread throughout the liver. Although CT is sensitive for detecting these lesions, active disease can evade CT visualization. [133] Almost always caused by *Candida albicans,* biopsy is the only way to establish the specific etiologic diagnosis. Amebic abscesses appear similar to pyogenic lesions as a low-density lesion, usually solitary, but with 20% of patients demonstrating multiple lesions. [134] Echinococcal infection (i.e., hydatid cysts) also appears as low-density cysts, often with internal septations and daughter or inclusion cysts, creating the appearance of a cyst within a cyst. Calcification may be seen in the cyst wall or septations.

Vascular Diseases Increasing awareness of imaging findings secondary to altered hepatic perfusion is the direct result of increasing use of helical CT. Hepatic perfusion disorders are related to:

- portal vein inflow obstruction
- hepatic venous outflow obstruction
- mediastinal or thoracic venous inflow obstruction
- focal liver lesions
- inflammatory processes
- normal anatomic variants
- altered hemodynamics following intrahepatic portosystemic shunts
- idiopathic processes.

General imaging characteristics are those of hyperattenuation on hepatic artery images becoming isodense on portal vein phase images. [135]

Portal vein thrombosis. Portal vein thrombosis can be detected on CT scans by visualizing decreased intralumenal portal vein attenuation values, accompanied on dynamic contrast scans with ringed enhancement from opacification and thickening of the vasovasorum. Chronically extensive collateral formation involving the porta hepatis is called cavernous transformation. [136] Intrahepatic portal vein thrombi produce slow flow peripherally resulting in paradoxical hyperattenuation in the periphery. The changes appear similar whether caused by a primary vascular abnormality with intrinsic thrombosis or secondary tumoral obstruction of the portal venous system, such as HCC. Zonal perfusion abnormalities may be seen in radiation hepatitis. The radiated liver demonstrates decreased perfusion in the portal venous phase. In fatty livers, the radiated portions appear to have normal attenuation because the damaged hepatocytes cannot undergo fatty metamorphosis. [137] Similar changes may be seen in hepatic parenchyma surrounding masses which alter the regional portal vein flow (see Fig. 155-13).

Hepatic venoocclusive disease. CT reveals a variety of findings in hepatic venoocclusive disease (i.e., Budd-Chiari syndrome). Although CT, MRI, and Doppler US can suggest the diagnosis, venography remains the gold standard for evaluation and diagnosis. Because of their noninvasive nature and optimal demonstration of vessel morphology and flow without the use of intravenous contrast, MRI and Doppler US are preferred for screening examinations of suspected patients. Noncontrast-enhanced CT findings include hepatomegaly with a hypodense parenchyma that spares the caudate lobe and perihilar regions of the left lobe. After intravenous contrast administration, the liver parenchyma demonstrates a mottled enhancement pattern. Initially, the greatest contrast enhancement is seen in the caudate lobe and the periportal regions of the left lobe, but a reversal of this pattern is seen on later images. Delayed images generally show a homogeneous enhancement pattern of the liver. Although direct visualization of thrombus within the hepatic vein or inferior vena cava can be demonstrated, in most cases, the hepatic veins are not visualized and may be the clue to the diagnosis. A similar mottled enhancement pattern is present in patients with chronic passive congestion, regardless of etiology. [138]

Hepatic trauma. Abdominal CT scanning makes nonoperative management of liver injury possible. Despite extensive clinical experience, it is not always possible to predict those patients in whom delayed complications may occur. [139] CT findings of liver trauma include foci of low or high attenuation indicating hemorrhage, usually in contact with some portion of the liver surface. If there has not been a prior peritoneal lavage, the presence of hemoperitoneum can be seen on CT as high attenuation intraperitoneal fluid accumulations. Low-attenuation collections diffusely surrounding portal venous branches (termed *periportal tracking*) can be indicative of periportal extension of blood or lymphedema, both sequelae of severe trauma. [140] However, there is not uniform agreement in the significance of this finding, as it can be seen in patients who have been overhydrated during a serious resuscitation. Because of the lack of specificity of this finding, caution is therefore recommended in relying on this finding as a sole indicator of traumatic injury to the liver. The presence of hemoperitoneum and clinical assessment of hemodynamic stability must be considered in conjunction with the CT scan before making an appropriate decision for nonoperative management.

Pancreas

Pancreatic CT requires thin collimation (3–5 mm), overlapped reconstruction, bolus injection of iodinated contrast material (best performed with a power injector), and rapid scanning to improve tumor detection, visualize relationships of peripancreatic vessels, and display findings three-dimensionally for optimized surgical and therapeutic planning (Fig. 155-16). Properly timed contrast-enhanced studies will image the pancreas when its parenchyma is maximally enhanced and the peripancreatic vessels bright white. [141] Accuracy in depicting variations in peripancreatic arterial anatomy, as well as clear depiction of vessel encasement, has resulted in the elimination of invasive angiography. [142], [143] Helical CT facilitates the use of dual-phase imaging where the earlier arterial-based enhancement of the pancreatic parenchyma can be isolated from the generalized organ opacification resulting from widespread distribution of the intravenous contrast dose. [144]

FIGURE 155-16. Carcinoma of pancreas and aberrant right hepatic artery. **A:** *Curved arrow* points to a low-attenuation mass in the head of the pancreas. A dense linear structure is seen posteriorly (*thick arrow*). **B:** A shaded-surface, three-dimensional rendering identifies this vessel as a replaced right hepatic artery arising from the superior mesenteric artery.

Anatomic Variants Pancreas divisum is the most common congenital anomaly of the pancreas. Although this anomaly most often goes unrecognized on CT scans, the pancreatic head can appear enlarged and simulate a mass lesion. Magnetic resonance cholangiopancreatography (MRCP) may be a simple noninvasive method for diagnosis. [145] Agenesis of the dorsal pancreatic duct is identified with CT by visualizing only the head of the pancreas without a body or tail portion, and the condition may be confused with a mass in the head of the pancreas with proximal pancreatic atrophy. [146] Annular pancreas is an anomaly embryologically formed by the ventral anlage of the pancreas as the duodenum rotates, mainly due to hypertrophy of the left ventral bud. According to the fusion pattern of the ventral and dorsal pancreatic ducts, annular pancreas can be divided into three types: type I, divisional annular pancreas; type II, branch annular pancreas; and type III, main duct annular pancreas. Final diagnosis is based on the evidence of ERCP combined with CT. The CT diagnosis is suggested by visualizing a soft tissue collar surrounding the descending duodenum. [147] Thin-section CT may allow visualization of the aberrant pancreatic duct.

Neoplasms

Adenocarcinoma. The major role of imaging in pancreatic carcinoma is detection of a suspected neoplasm and determination of potential surgical resectability. Nonresectability is defined as the presence of either major arterial encasement, hepatic (or other distant) metastases, or lymph node metastases. [148] Realistically, at the time of initial diagnosis, 50% of patients have distant metastases to the liver or peritoneal surface, and more than 80% of the remaining patients have locally advanced tumors. The most common CT finding in adenocarcinoma is a focal mass isodense with the pancreas on noncontrast images and hypodense after intravenous contrast administration. [149] This is more obvious using dual phase helical CT protocols. [150] Segmental pancreatic duct obstruction is a crucial finding and may be the only indicator of an obstructing mass. Detecting evidence of spread to the lymph nodes, around vascular structures, or to the liver may also assist in making the diagnosis. Potentially resectable lesions frequently show minimal findings. [151] Helical CT data provide angiographic information and are useful for surgical planning (Fig. 155-17).

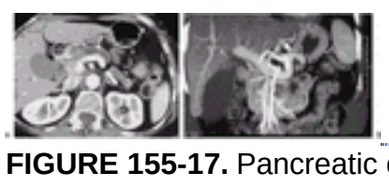

FIGURE 155-17. Pancreatic carcinoma. **A:** A soft-tissue attenuation mass is present in the neck of the pancreas (*straight arrow*). A dilated pancreatic duct is seen proximal to the lesion (*curved arrow*). The normal-caliber common bile duct can be seen immediately posterior to the mass surrounded by normally enhanced pancreatic parenchyma. **B:** Angiographic rendering from the same data set allows appreciation of narrowing without encasement of the superior mesenteric vein (*arrow*). Portions of the superior mesenteric artery and hepatic arteries are also incorporated in this projection.

CT angiographic assessment of pancreatic adenocarcinoma can be reliably accomplished with well-performed, thin-section single, or more optimally multislice CT. CT has been shown to be superior to catheter angiography [142], [143], [152] and slightly better than dedicated MRI [153] in evaluation of vascular invasion. The patterns of collateral formation around the peripancreatic branches of the superior mesenteric vein have improved prediction of tumor extension into this vessel. [154], [155] False-positive CT diagnosis of pancreatic adenocarcinoma has been reported in approximately 8% of patients; patients with focal chronic pancreatitis, metastatic lesions, normal pancreas, lymphoma, and islet-cell carcinoma account for most misdiagnoses. [156] In a large prospective series of 189 patients suspected with pancreatic adenocarcinoma the accuracy of CT in predicting nonresectability was 73%. The negative predictive value of CT (resectable by CT, resectable by pathology) was 28%. The positive predictive value of CT (nonresectable at surgery or by biopsy confirmation) was 89%. [157] Prediction of resectability has slightly improved with implementation of newer technology. [158]

Islet-cell tumors. The vast majority of islet-cell tumors are hypervascular lesions enhancing to a brighter level than enhanced pancreatic parenchyma. This helps differentiate these lesions from adenocarcinoma which are almost always hypodense. There are scattered case reports of cystic islet-cell tumors. [159] Although the nonfunctioning (endocrine quiescent) tumors typically attain large sizes, functioning islet-cell tumors are usually less than 2 cm in diameter. Multiple radiologic techniques can be used for tumor localization, including preoperative and intraoperative US, EUS, CT, MRI, radionuclide scanning, angiography, and venous sampling. [160] There are conflicting claims as to the relative accuracies of these procedures, and many of these investigations are difficult to justify because of their high cost, degree of invasiveness, or lack of precise anatomic information that is obtained. [161] If surgical resection of a neuroendocrine tumor is planned, intraoperative US is the best method to detect nonpalpable masses and to discern the relationship of the tumor to vital adjacent pancreatic ductal anatomy. The choice of preoperative imaging is more controversial, and depends on the clinical problem, local expertise, and availability of imaging techniques. US and contrast-enhanced helical CT using two-phase helical CT in both the arterial and the parenchymal phase are the most commonly used preoperative imaging methods [162] because of their relatively low cost and widespread availability. Radionuclide scanning with ^{111}In DTPA-D- octreotide may be valuable in patients with symptoms of tumor recurrence.

Cystic neoplasms. Most of these lesions are incidentally discovered. [163] The earliest pathological differentiation of the microcystic and macrocystic lesions remains a useful framework, but considerable variation and overlap is becoming more obvious. [164], [165] The ability of CT to definitively differentiate between these two classes of cystic neoplasms is limited. [166] Most published series suggest that while this diagnosis can be suggested on CT, surgical management must be considered as the standard of care. [167], [168] Cyst size is accurately determined by imaging and is the finding with the highest accuracy in classifying these lesions. [169], [170] Microcystic (cysts =1 cm) lesions are almost always serous. These lesions appear as focal masses with innumerable cysts interspersed within a dense fibrous honeycomb. Central calcification occurs in approximately 30% of the lesions. [171] Serous, microcystic cystadenoma is considered benign; there are scattered reports of metachronous adenocarcinoma arising at a distant site in the pancreas of the same patient. [172] Mucinous lesions present as macrocystic (=2 cm) unilocular cysts or as intraductal neoplasms. Peripheral soft tissue nodules, peripheral calcification (in <5% of lesions), and minimal septation aid in radiologic differentiation from microcystic adenoma. Scattered case reports of serous macrocystic adenomas reflect the lack of precision of absolute diagnosis from imaging alone. [173] Using thin collimation, mural nodules can be resolved in malignant lesions (Fig. 155-18). Imaging criteria of benign from malignant mucinous lesions is impossible. Most authorities recommend needle aspiration of the cyst fluid for definitive preoperative diagnosis. [174]

FIGURE 155-18. Mucinous cystadenocarcinoma. A focal lesion in the body of the pancreas (*arrow*) results in proximal pancreatic duct dilation. The lesion has soft-tissue attenuation peripheral projections typical of papillary-mucinous masses.

Intraductal mucinous pancreatic neoplasms are becoming increasingly recognized. [175] These lesions have a wide range of clinical presentation, from small foci of ductectasia with hyperplastic epithelium to frank carcinoma. The most frequent feature of intraductal papillary mucinous tumors is a lobulated multilocular cystic mass located in the uncinate process in contiguity with the dilated main pancreatic duct. [176] In some patients, a bulging papilla and papillary projections in the ducts, which were specific findings, were visualized on CT. When these lesions are branch type, under 2.5 cm, and have no solid components, clinical behavior appears nonaggressive. [177] Main duct-type lesions are virtually always malignant. The possibility of a sequential change from nonpapillary and papillary hyperplasia, via adenoma, to carcinoma in intraductal papillary-mucinous neoplasms associated with mucinous ductal ectasia has been speculated. [178]

Pancreatitis

Acute pancreatitis. Acute pancreatitis presents clinically and to imaging with a variety of forms. Interstitial edematous pancreatitis and necrotizing pancreatitis are the most frequent clinical manifestations; pancreatic pseudocyst and pancreatic abscess are late complications after necrotizing pancreatitis, developing after 3 to 5 weeks. [179] CT has become integrated into the evaluation of virtually all patients suspected of acute pancreatitis, and is considered mandatory in patients suspected of pancreatic necrosis. [180] CT scanning offers excellent anatomic and morphologic representation of the pancreas and peripancreatic tissue. [181], [182] The value of CT is based on its ability to show the presence and distribution of pancreas-related fluid collections (Fig. 155-19) and the presence or absence of pancreatic necrosis (Fig. 155-20). These two prognostic factors are evaluated in the Balthazar severity index. The presence of acute pancreatitis is graded as normal (grade A), gland enlargement (grade B), enlarged gland with peripancreatic edema (grade C), or single (grade D) or multiple (grade E) fluid collections. [183] Pancreatic necrosis on CT is recognized by regional nonenhancement on contrast-enhanced CT scans. [184], [185] The effect of degree of necrosis, combined with CT grading of the appearance of the gland and fluid collections, has greater prognostic implication than either manifestation alone. [186]

FIGURE 155-19. Acute pancreatitis. Peripancreatic fluid extends from the posterior aspect of the gland into the right pararenal and peritoneal retroperitoneal compartments (*arrows*). Note the uniform enhancement of the gland.

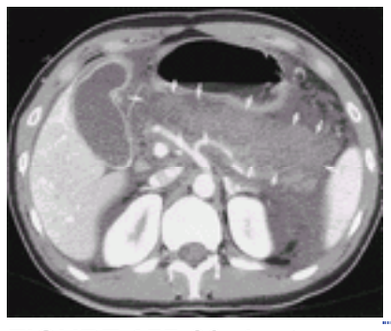

FIGURE 155-20. Acute pancreatitis with pancreatic necrosis. A “ghost” of the pancreas can be discerned (*arrows*). There is no normally enhancing tissue in this case of necrotizing pancreatitis.

The detection of necrosis is one of the primary goals of the imaging study. Intravenous contrast is required to make this assessment. In laboratory rats, intravenous iodinated contrast may increase cellular damage and potentially increase the severity of acute pancreatitis by promoting further necrosis and higher mortality. [187] These findings are not reproducible in other animal models. [188] Most clinicians believe that the importance of establishing the presence of necrosis justifies the preferred use of intravenous contrast. Complications from acute pancreatitis are present in the adjacent fat, [189] biliary tree, [190] peripancreatic veins [191] and arteries, [192] and adjacent bowel. [193] Pseudoaneurysm formation occurs in 2% to 5% of cases. Intravenous contrast and dynamic or helical scanning is required for detection; detection is improved with helical CT supplemented by angiographic renderings. Treatment is aimed at drainage of periarterial fluid collections and possibly embolization of the affected vessel. CT in patients with documented chronic pancreatitis reveals findings in over 90% of cases. These findings, in decreasing order of frequency, include: dilation of the main pancreatic duct, parenchymal atrophy, pancreatic calcifications, fluid collections, focal pancreatic enlargement, biliary ductal dilation, and alterations in peripancreatic fat or fascia. [194] Focal masslike chronic pancreatitis can result in pancreaticoduodenectomy for presumed neoplasm. In a Mayo Clinic series, [194a] 22 of 603 pancreaticoduodenectomies performed between 1956 and 1990 ultimately proved to be for chronic pancreatitis. When a patient with a hypervascular pancreatic mass has a history of alcoholism and pancreatitis, and normal serum levels of CA 19-9, mass-forming pancreatitis should be kept in mind as a differential diagnosis of pancreatic carcinoma. [195] Pseudocyst formation is a well-recognized sequela of chronic pancreatitis. Percutaneous catheter drainage of both infected and noninfected pancreatic fluid has a reported average success rate of 80% and a complication rate of about 15%. [196] Cyst “maturity” is difficult to diagnose by imaging. A visible wall and lack of change over several weeks indicate the patient is most likely a candidate for successful cystogastrostomy.

Biliary Tract

CT performs well at documenting the presence and extent of biliary tract malignant disease and, because of its use as a general survey tool in the abdomen varying forms of bile duct disease are frequently encountered on abdominal CT examinations. US and MRI are superior in the evaluation of calculous disease.

Using current CT technology and intravenous contrast enhancement, normal intrahepatic bile ducts may be visualized in over 40% of normal patients; these should not be confused with ductal dilation. [197] The extrahepatic bile ducts are identified normally in 80% of patients at CT and usually have diameters of 4 to 10 mm. [198] The extrahepatic biliary tree may be up to 10 mm in diameter in patients who have undergone cholecystectomy.

Comparative studies have shown that CT is comparable to US in its ability to detect biliary obstruction and generally exceeds US in the ability to predict the level and cause of biliary obstruction, although some controversy still exists. [199], [200] and [201] If a high degree of suspicion for obstruction exists and if malignancy is strongly suspected, CT is the examination of choice, because it allows the staging of extent of disease in a standard, reproducible fashion with excellent depiction of all regions surrounding the duct and distant sites as well.

Three-dimensional helical CT cholangiography following intravenous infusion of a biliary contrast agent that rivals direct cholangiography for displaying biliary tract anatomy and pathology has been reported. [202], [203] This technique, using postprocessing reconstructions (maximum intensity and shaded surface display projections), has not achieved widespread use due to the invasive nature of intravenous biliary contrast agents and the availability of noninvasive MRCP.

Congenital Anomalies Congenital anomalies of the biliary tract are diagnosed definitively with direct cholangiography, but CT and US can suggest their presence. Congenital anomalies of the gallbladder are rare, consisting mostly of positional variants. The gallbladder can be seen in the left abdomen or in suprahepatic, intrahepatic, and other rare locations. CT can identify these anomalies if the gallbladder is not seen in its usual location at US. Congenital cystic diseases of the biliary tree, including choledochal cysts, choledochoceles, [204] and Caroli disease, can often be diagnosed by demonstrating the dilated biliary tree with appropriate patterns of dilation. Choledochal cysts demonstrate focal dilation of the extrahepatic bile ducts that may be mild and simulate a dilated duct or may be as large as 15 cm in diameter. [205]

Gallbladder Disease CT is an acceptable method of demonstrating gallbladder wall abnormalities. Thickening of the gallbladder wall, although nonspecific, can be a clue to underlying pathology. Unusual right upper quadrant abdominal calcifications can be clarified with CT. CT can document the location of these as stones within the gallbladder, within the gallbladder wall (e.g., porcelain gallbladder), or extrinsic to the gallbladder. CT is able to demonstrate gallstones in 74% to 79% of patients with gallstones; the remainder are isoattenuating with bile and cannot be delineated. [206], [207] This lower sensitivity limits the usefulness of CT in screening for gallbladder disease.

Neoplasms Gallbladder carcinoma is usually far advanced when patients are first seen by a physician, and the CT scans reflect these changes. “Early” gallbladder cancer has been classified on the basis of CT appearance. [208] In the more commonly seen advanced disease, total replacement of the gallbladder lumen by a soft tissue-density mass usually invading adjacent hepatic parenchyma characterizes this lesion. Less common appearances include focal gallbladder wall thickening or polypoid intralumenal masses, similar to those seen with US. [209] The extent of tumor can be depicted on CT in the common regions of spread, including liver, lymph node, and peritoneal metastases and invasion of adjacent organs such as liver and duodenum (Fig. 155-21).

FIGURE 155-21. Gallbladder carcinoma. A bulky mass is present in the gallbladder fossa (*arrows*). The mass widely invades the hepatic parenchyma

The gallbladder can be secondarily involved by tumor from other organs. Direct invasion from adjacent organs is usually by means of porta hepatis metastases, most often from gastric or pancreatic carcinoma. Blood-borne metastases to the gallbladder are uncommon but can be seen most frequently in patients with melanoma.

Cholecystitis The most common CT findings in cholecystitis are gallbladder wall thickening (>3 mm) and cholelithiasis. [210] These findings are neither specific nor sensitive indicators and are also found with gallbladder carcinoma and hyperplastic cholecystosis. Other CT findings suggestive of the diagnosis include an increased attenuation of the bile (>20 Hounsfields) and loss of clear definition of the gallbladder wall (Fig. 155-22). Increased attenuation in the adjacent hepatic parenchyma is a useful indicator of acute inflammation. [211] With more advanced cases, streaky inflammatory changes infiltrating adjacent pericholecystic fat can be seen. Air within the gallbladder wall or lumen in the absence of a history of prior enteric anastomosis or sphincterotomy is virtually pathognomonic of complicated cholecystitis. [212] A low attenuation halo around the gallbladder may indicate edema or minimal fluid collections and is a useful clue in differentiating complicated cholecystitis from carcinoma on CT scans. [213]

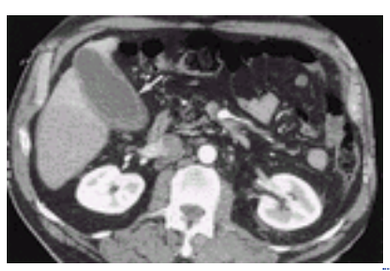

FIGURE 155-22. Acute cholecystitis. The gallbladder wall is thickened (*arrow*). Increased density is present in the hepatic parenchyma adjacent to the inflamed viscus.

Bile Duct Diseases

Neoplasms. Primary bile duct cancers take three forms, mass-forming, periductal infiltrating, and intraductal. [214] Hilar cholangiocarcinoma usually presents centrally near the porta hepatis producing obstruction of the main hepatic ducts and intrahepatic branches. Peripheral intrahepatic cholangiocarcinoma will present as a hypodense hepatic lesion with peripheral enhancement, biliary dilation, capsular retraction, and contrast enhancement on delayed images. [215] All hilar cholangiocarcinomas should be seen on well-performed arterial phase images, and most will be seen during portal venous phase imaging. A characteristic contrast CT feature of cholangiocarcinoma is the delayed retention of iodine diffusely throughout the tumor during equilibrium phase imaging at 8 to 20 minutes following contrast initiation. [216] This retention is seen in tumors with a marked fibrous stroma and can be helpful in delineating the extent of hilar cholangiocarcinoma and in differentiating from HCC. [217] CT is useful in the preoperative assessment of the extent of disease and resectability of cholangiocarcinoma; CT sensitivity for resectability is approximately 60%. [218]

Inflammatory diseases. Acute cholangitis is usually found in patients with underlying biliary tract obstruction. Most such patients demonstrate dilated intrahepatic and extrahepatic bile ducts. Suppurative material within the bile ducts may be seen on CT images as high attenuation debris within the duct lumen. Bile duct wall thickening may be present and appears diffuse and concentric, often demonstrating marked contrast enhancement. [198] Gas can be seen as low-attenuation collections within the biliary tree in cases of infection with gas-forming organisms. Acute suppurative cholangitis can progress to frank liver abscesses, demonstrated on CT scans as low-attenuation areas in the liver in contiguity with the biliary tree. The characteristic findings seen by means of cholangiography in primary and secondary sclerosing cholangitis can also be demonstrated on CT images. Intrahepatic duct stenoses, dilated peripheral ducts with no apparent connection to the central ducts, and irregular intrahepatic duct dilation with a beaded appearance are characteristic CT findings of sclerosing cholangitis. [219] CT findings in the extrahepatic ducts in this condition include duct wall thickening and irregularity, as well as duct wall enhancement after intravenous contrast. Primary sclerosing cholangitis should be considered as premalignant, with more than 15% of patients at risk. [220] Careful search for masses, delayed contrast enhancement, progressive biliary dilation, and thickening of the bile duct wall is required to recognize complicating cancer. [221] Other less common causes of infection can produce characteristic CT images. Recurrent pyogenic cholangitis (also known as Oriental cholangiohepatitis) is found in patients of lower socioeconomic status from Asia. The CT findings include marked intrahepatic and extrahepatic bile duct dilation, sharp tapering of peripheral extrahepatic bile ducts with loss of arborization, giant ductal calculi, and intraductal debris. Organisms such as CMV and *Cryptosporidium* can cause inflammation of the biliary tract in patients with AIDS, resulting in changes on CT, US, and cholangiography similar to those of sclerosing cholangitis, with bile duct wall thickening, multiple strictures, and duct wall contrast enhancement. [222]

Choledocholithiasis. The noninvasive diagnosis of common bile duct stone disease has been simplified with the development of MRCP which has a sensitivity and specificity similar to ERCP. [223] Most patients with obstructive jaundice will undergo US, with CT used as a problem-solving modality. [224] The reported CT sensitivity for common duct stone detection varies from 45% to 90%. [225], [226] The ability to use thin collimation and overlapping image reconstruction available with volume data acquisition of helical CT scanners improves stone detection rates. [227] Noncontrast CT may improve the recognition of choledocholithiasis to more than 90%. [228] The higher figures reflect series with selected patient populations, often patients with known dilated ducts in whom it is easier to visualize stones. The CT appearance of common duct stones parallels that of gallstones and depends on the chemical composition for each stone. Densely calcified stones can be seen as high-attenuation structures within the duct lumen, but most duct stones are isoattenuating with soft-tissue or bile on CT scans. [229] Several processes can simulate duct stones on CT, and care must be taken to avoid misdiagnosis. Critically placed pancreatic calculi, oral contrast in an adjacent duodenal diverticulum, residual contrast material from a prior cholangiogram, and papillary ductal neoplasms can simulate choledocholithiasis.

PERITONEUM

Most gastrointestinal diseases for which CT has use have associated peritoneal findings. Many of these are subtle; recognition of abnormalities requires a systematic evaluation of the peritoneal structures based on understanding of the spread of disease processes within the abdominal cavity. The majority of ligaments and mesenteries in the abdomen are formed from remnants of the ventral and dorsal mesenteries, which suspend the primitive gut. The pelvic ligaments are mainly formed by reflections of peritoneum over the pelvic organs or structures. The mesenteries and ligaments form the boundaries of the peritoneal spaces. Accurate localization

of fluid collections and detection of neoplasms is facilitated when the pathway of spread through adjacent ligaments and mesenteries is understood. [230] For purposes of radiologic diagnosis, the peritoneal cavity can be thought of as an “end organ,” in that the response to a pathological process is similar regardless of etiology.

Neoplasms

Radiologic appearances of the more common peritoneal abnormalities may be thought of in three basic patterns:

- solid but relatively well-defined masses
- cystic-appearing masses
- ill-defined or infiltrative processes.

The most common solid masses to affect these anatomic regions are secondary neoplasms. The various cystic-appearing masses (including cystic lymphangioma, cystic mesothelioma, teratoma, and loculated ascites) and infiltrating masses (such as peritoneal mesothelioma, retractile mesenteritis, desmoid, and carcinoid) must be differentiated on the basis of clinical findings and additional imaging findings (e.g., CT depiction of fat and calcium in teratomas and the radiating appearance of carcinoid). [231]

Peritoneal carcinomatosis is a common finding in patients with abdominal cancer. This form of metastatic disease is most frequent with primary lesions in the ovary, large bowel (including appendix), and stomach; however any primary malignancy may disseminate through the peritoneal cavity. Peritoneal lymphoma (not unique to AIDS patients), [232] peritoneal leiomyosarcoma, [233] and melanoma are reported (Fig. 155-23). Loculated ascites is the most common finding. Bowel wall thickening and irregularity with or without obstruction may occur, the most common site of involvement being at the rectosigmoid junction.

FIGURE 155-23. Metastatic leiomyosarcoma, peritoneum. A bulky mass is present in the Morison pouch (*posterior arrow*). A second mass is present just anteriorly (*anterior arrow*). Ascites is evident.

Tumor involvement of the omentum is visible as soft-tissue attenuation nodular or reticular densities within the peritoneal fat. This can coalesce into an omental cake. [234] Implants may be present without ascites and careful inspection of the omentum [235] and sites of peritoneal ligamentous attachments is necessary to detect these subcentimeter nodules. [236] Pseudomyxoma peritonei has a unique appearance of large, low-attenuation masses distributed within the peritoneal cavity. Calcifications may occur along the periphery. When pseudomyxoma peritonei is suspected, careful attention should be given to the appendix or ovaries as the potential source. Primary peritoneal tumors include a variety of benign mesenteric cysts, stromal neoplasms, lymphoid neoplasms (such as Castelman disease), mesothelioma, and desmoid tumors.

Nonneoplastic Peritoneal Diseases

Enteric inflammatory processes will cause local increased attenuation within the adjacent peritoneal fat; [237] however, one should not diagnose acute generalized peritonitis unless there is evidence of free fluid. In chronic peritonitis, such as in *M tuberculosis* peritonitis, one may see retraction of the parietal peritoneum from the abdominal wall and apparent enhancement of the peritoneal surfaces. [238] In all other ways, the findings may be identical to peritoneal carcinomatosis.

CT diagnosis in patients with an acute abdomen depends on recognition of free air or hemoperitoneum. CT has a higher sensitivity for the detection of pneumoperitoneum than plain x-rays, including upright chest films. [239] When subhepatic free air tracks into the porta hepatis intrahepatic reflections of the peritoneal cavity, it may resemble biliary air. [240] The prevalence of pneumoperitoneum in the postoperative period based on CT findings is greater than that previously reported. Fifty percent of patients may demonstrate free intraperitoneal air 6 days following surgery. [241] In the setting of blunt abdominal trauma, pneumoperitoneum does not necessarily indicate hollow viscus injury. It frequently is secondary to other etiologies, especially dissection of interstitial air from the chest. [242]

Hemoperitoneum is seen most frequently in trauma, [243] acute gynecologic disease, or in hemorrhage from neoplasm. [244] The CT attenuation of hemoperitoneum may be falsely low in the upper abdomen, because the blood products have settled to the dependent portion of the peritoneum (the “hematocrit effect”). In patients with blunt abdominal trauma, scanning through the lower pelvis, regardless of the site of injury, frequently detects hemoperitoneum in the cul-de-sac.

HERNIAS

The diagnosis of abdominal wall hernia is aided by CT. [245] Although most hernias are diagnosed clinically, they may be occult, particularly in obese patients, and a source of abdominal pain. A wide variety of abdominal wall hernias have been described including lumbar, spigelian, obturator, and perineal. When a hernia is suspected as the cause of bowel obstruction, it is important to be able to identify a transition zone within the hernia; if both limbs are dilated, then a “downstream” etiology should be sought. Complications of hernias include incarceration and strangulation. The CT findings are similar to findings seen in strangulated small bowel obstruction. [246]

CT findings of right paraduodenal hernia are encapsulation of small bowel loops in the right midabdomen with looping of arterial and venous jejunal branches behind the superior mesenteric artery. The findings of left paraduodenal hernia are less specific and involve encapsulation of bowel loops at or above the level of the ligament of Treitz with intermittent dilation. [247]

Traumatic diaphragmatic hernia may cause diagnostic difficulty. Left-sided diaphragmatic hernia is easier to diagnose than right. [248] CT can supplant barium studies and nuclear scans. Continuity of the diaphragm should be assessed to aid in differentiation of ectopic organ position due to hernia or diaphragmatic paralysis. Careful history of trauma should be sought.

FUTURE DIRECTIONS

The role of CT continues to expand into that of a “routine” procedure. CT colonography is at the verge of becoming an alternative to barium enema for screening colorectal cancer. As technology allows faster imaging times, improved reconstruction time, and interactive data, a CT scan begins to rival plain film examinations in terms of ease and speed yet surpasses them in terms of information. The increasing availability of volume data and more powerful workstations has resulted in increasing preoperative planning, and more aggressive uses of minimally invasive surgery.

Radiologists are continuously mindful of the cost of CT scanning applied over a larger population. However, the comprehensive nature of the examination, and higher level of diagnostic surgery at the completion of the test improves patient care and may decrease use of more expensive hospital and therapeutic resources.

CHAPTER 156

Eric K. Outwater and Donald G. Mitchell

MAGNETIC RESONANCE IMAGING

Since the development of magnetic resonance (MR) imaging about 18 years ago, the applications for MRI of the gastrointestinal tract have expanded rapidly. MR imaging had been hampered somewhat in the evaluation of the abdomen primarily because of artifacts associated with respiratory and bowel motion. [1] The development of newer fast imaging techniques, however, has overcome these effects of motion, enabling examination of structures and organs that were previously not reliably imaged. These new techniques improve the results of MR imaging of the abdomen, particularly when compared with computed tomography (CT) scanning.

MR imaging has certain advantages over CT. CT relies on the single variable of x-ray attenuation for tissue contrast. All image contrast with CT relies on attenuation, and vascularity of structures can be inferred by the changes in attenuation imparted by intravenous contrast agents. Basic tissue differences seen include: air, calcification and bone, soft tissue, fat, and changes in soft tissue attenuation imparted by intravenous contrast agents. MR imaging, however, has several parameters which distinguish pathological tissues. These include T1, T2, lipid content, magnetic susceptibility imparted by metal ions, such as iron in the liver, and specific characteristics of flowing blood. In addition, various types of contrast agents, some of them targeted receptor agents, have been developed for imaging the abdomen. Finally, newer techniques such as diffusion and perfusion imaging have only begun to be developed for imaging the abdomen. Compared with CT, MR imaging has a range of tissue characteristics with which to build the image, and therefore has a greater potential for tissue characterization.

The risks of CT derive from the radiation dose and from risks of nephrotoxicity of intravenous contrast. Risks of radiation dose may be significant, particularly in younger patients. The probability of a radiation-induced cancer in a young adult undergoing CT of the abdomen and pelvis is about 1/2000 or greater. [2], [3], [4] and [5] The cost of this one-time radiation dose has been estimated at $30/mSv, or $300 per abdominal CT. [2], [5] These considerations lead one author to suggest that MR imaging in younger patients may be cost-effective compared to CT based on considerations of radiation risk alone. [2] Costs associated with irradiation of unsuspected pregnancies have not been assessed.

CT of the abdomen routinely employs iodinated contrast agents for delineation of vascular anatomy, and to increase the tissue contrast between tumors and normal organs. Iodinated contrast agents pose three dangers to patients. These are anaphylactic reaction, renal nephrotoxicity, and osmotic load. Certain patients, such as those with diabetic nephropathy or renal insufficiency from any cause, are at increased risk from renal nephrotoxicity from iodinated contrast agents. It is safer and cost-effective for these patients to be imaged with MR imaging. [6] MR imaging poses significant risk only to patients with certain types of implanted devices such as cochlear implants, cerebral aneurysms clips, or cardiac pacemakers. The risk of anaphylactic reaction associated with available gadolinium agents is very low. These agents have no known cross-reactivity with the iodinated contrast agents used for CT scanning, so these patients may be safely imaged with MR imaging.

In this chapter, we explain some of the tissue characteristics and basic principles of imaging and discuss specific applications and techniques in imaging. A glossary of the terms used in this chapter is supplied in Table 156-1.

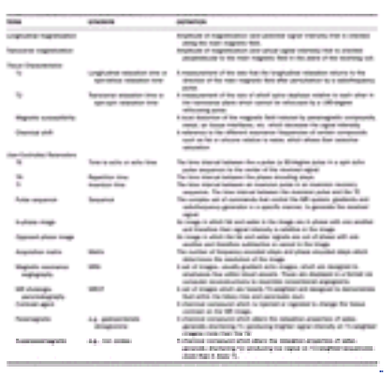

TABLE 156-1 Glossary of Magnetic Resonance (MR) Terms

BASIC PRINCIPLES

Differences in tissue contrast with CT are measured by units called Hounsfield units, which are a measure of x-ray attenuation. In MR imaging, the difference in tissue contrast (white, gray, black) depicted on the image is termed *signal intensity*. High signal intensity refers to structures that are white on the image and low signal intensity refers to structures that are dark on the image. Unlike Hounsfield units in CT, signal intensity units are arbitrary and have no real meaning as absolute numbers.

The terms *T1* and *T2* refer to specific tissue properties that describe the way protons (mostly in water and lipids) behave after being excited by a radiofrequency pulse in a strong magnetic field. [7], [8] Each type of tissue will show a typical T1 and T2. When the image tissue contrast is based mostly on the differences in T1 between the tissues, the image is termed a T1-weighted image (Fig. 156-1). T1 is termed the *longitudinal relaxation rate* and T2 is termed the *transverse relaxation rate* or *spin-relaxation rate*. Structures or fluids that are bright on T1-weighted images have a short (lower) T1 because of greater longitudinal magnetization, and images that are dark have a long T1. Structures containing no water or fat, such as bone or air, also will appear black on a T1-weighted image (see Fig. 156-1).

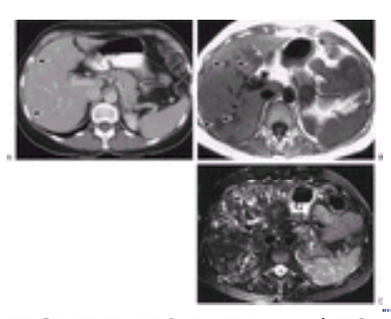

FIGURE 156-1. T1- and T2-weighted images of the abdomen in a patient with islet cell tumor of the pancreas. **A:** Computed tomography (CT) scan of the upper abdomen shows faint hypoattenuating lesions (*arrowheads*) in the liver. The pancreatic body is full but there is no tissue contrast between the parenchyma and the

pancreatic mass (*arrow*). **B:** T1-weighted image shows basic tissue contrast not dissimilar from the CT image. That is, the greatest tissue contrast is between fat and soft tissue and air. However, the intrinsic tissue contrast between the liver lesions (*arrowheads*) and the hepatic parenchyma is greater than the CT. Also, the tissue contrast between the pancreatic mass (*arrow*) and the surrounding pancreatic parenchyma is greater. This allows the discrete pancreatic mass to be visualized. **C:** T2-weighted image shows the liver as lower signal intensity (*darker*) than the hepatic metastases (*arrowheads*). The spleen (*S*) has higher signal intensity than the liver and the fluid in the stomach (*G*) is high signal intensity (*bright*).

The specific parameters chosen to acquire the image on the MR magnet system determine whether an image is T1-weighted or T2-weighted or some other type of image.[7],[8] TE and TR refer to the *echo time* and *repetition time,* respectively. They are parameters chosen by the MR operator to acquire a T1-weighted or T2-weighted image. The specific parameters chosen by the MR technician that determine exactly what kind of image is obtained are the *pulse sequence* or sequence. This sequence therefore describes a set of images covering a specific anatomic area, with identical imaging parameters such as TE, TR, and resolution. *T1-weighted images* have a short TE and a relatively short TR.

Images designed to show contrast based mostly on the T2 values of the tissues are called *T2-weighted.* Such images generally have a long TE and a long TR. Structures that are high signal intensity (white) on the T2-weighted image generally are fluid-containing structures such as cysts, intestinal contents, or gallbladder bile (see Fig. 156-1). Most tissues in the abdomen, such as liver, pancreas, and intestinal wall, have low signal intensity (they are dark) on T2-weighted images.[9] Structures that have a high fluid content or contain more fluid than normal tissues are brighter on the T2-weighted image.[9] Examples of this are cysts and hemangiomas of the liver. Structures such as malignant tumors contain a higher water content than normal tissues, and therefore show higher signal intensity than normal tissues (see Fig. 156-1). T2-weighted images, because of the long repetition time (2–3 seconds), usually take longer to acquire than T1-weighted images and therefore are somewhat more susceptible to motion artifact.

Within a strong magnetic field, protons (hydrogen atoms in water or lipid) have a physical property termed *spin* (angular momentum). These spins can be perturbed by a radiofrequency pulse at a specific frequency, the resonance frequency of the spins.[10],[11] and[12] After this excitation pulse or tip, the spins will emit a radiofrequency wave that can be registered by a receiver called the *receiver coil*. A radiofrequency pulse of sufficient magnitude to tip the spins 90 degrees away from the main magnetic field is referred to as a *90-degree pulse*. Similarly, a radiofrequency pulse that tips the spin 180 degrees is called a *180-degree pulse* or an *inversion pulse*. After tipping the spin 90 degrees, the spins emit a signal termed the *free-induction decay* (FID). This radiowave signal is the basis of the MR signal.

Because it occurs soon after the initial radiofrequency pulse, the FID is not received normally. The FID rapidly decays in signal amplitude because of dephasing of the spins. This means the spins precess out of phase relative to each other because of small differences in the magnetic field strength in the tissues and therefore have no net signal. This effect of signal amplitude decay, because of dephasing, can be overcome by the application of the 180-degree pulse after the 90-degree pulse in order to refocus the spins and bring the spins back into phase with a corresponding rapid increase in signal amplitude. This process is termed the *spin echo* and is used in spin echo sequences, which are the most frequently used sequences in MR imaging.[8] Spin echo sequences can be T1-weighted, T2-weighted, or intermediate-weighted. Intermediate-weighted images use a fairly short TE and a long TR, and are sometimes called proton density-weighted images. They generally have limited usefulness for abdominal imaging.

The signal from the spin echo is localized in space within the body by applying magnetic field gradients. These gradients change the resonance frequency and phase of the spins linearly across the body so that the source of the radio signal can be localized. These gradients are termed the *frequency-encoding* and *phase-encoding gradients*. A map of the location of the signal and the strength of the signal linearly across the body is the image. The complex radio signal received by the receiver coil from the body is decoded into the spatial location of the signals and the strength of the signals by a mathematic algorithm called the *Fourier transform*.

Another way of refocusing the signal after the 90-degree pulse is by the application of bipolar gradients, which are gradients that are switched on in one direction and then are switched on rapidly in the opposite direction.[13] This will cause the refocusing of the FID signal in a manner appropriate for spatial localization of the signal. These sequences are termed *gradient refocused echoes* or *gradient echo sequences.*[14] The advantage of gradient echo sequences is that they are acquired very rapidly, allowing acquisition within a breath-hold period.[15],[16] Gradient echo images designed specifically to image blood flow are termed *magnetic resonance angiography sequences,* because flowing blood appears bright on these sequences.

The resonant frequencies of water differ from the protons in lipid molecules such as adipose tissue or fat. Because of this difference in resonant frequencies, these two populations of protons in the body can be imaged separately, sometimes termed *chemical shift imaging.* The most frequently used method is the application of a radiofrequency pulse which saturates the signal selectively from fat or water.[17],[18] If this is performed at the resonance frequency of fat, it is called a *fat saturation sequence* or *fat saturation image*.

On gradient echo images, fat and water may be out of phase with one another and thus cancel their signal. Whether the fat and water spins are out of phase with one another depends upon the TE.[19] If fat and water are out of phase relative to each other, small volumes of tissue containing both fat and water (such as fatty infiltrated liver) will cancel their signal and appear dark on the image.[19] This type of image is called an opposed-phase image. In contrast, an in-phase image shows the lipid and water protons in the image as bright. In-phase and opposed-phase images are very sensitive to the presence of a small amount of lipid in tissues.[20] These sequences are used to detect fatty liver and the lipid that commonly occurs in adrenal adenomas.[21],[22],[23] and[24]

Magnetic resonance angiography (MRA) refers to a family of pulse sequences that image flow within blood vessels.[25],[26] These pulse sequences take advantage of the fact that flowing blood is bright (high signal intensity) on certain gradient echo sequences (Fig. 156-2). Blood flowing into a slice being imaged is fully unsaturated (i.e., has greater longitudinal magnetization) because it has not experienced prior excitation pulses. This effect renders the blood flowing into the slice as very high signal intensity on the image. Blood flowing through the slice shows less signal intensity because it experiences the excitation pulses used to acquire the data for the image. If thin slices are obtained continuously, preferably with the blood vessel of interest in cross-section, the resulting data can be reconstructed into a data set representing the entire volume of tissue, and then projected into images that resemble conventional angiograms.[25],[26]

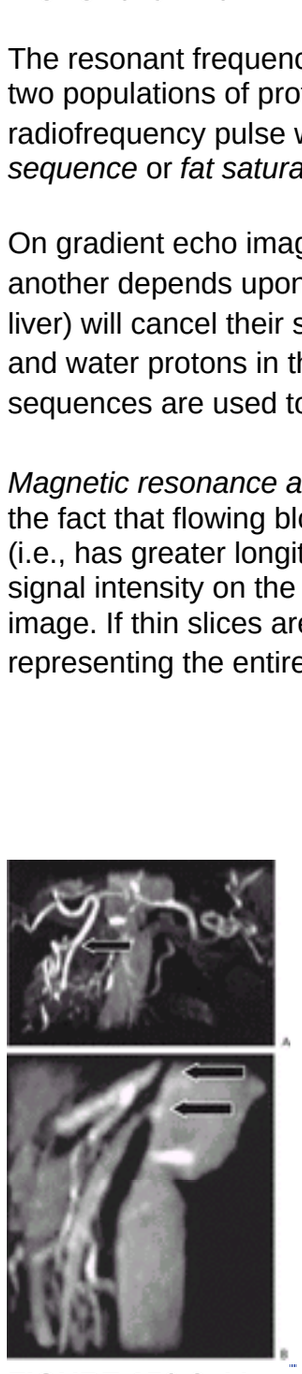

FIGURE 156-2. Magnetic resonance (MR) angiography with gadolinium-enhanced fast three-dimensional gradient echo sequences. **A:** Volume reconstruction images show multiple collateral vessels in and around the pancreatic head and duodenum (*arrow*). **B:** Projection MR angiogram in the lateral projection shows the stenoses of the celiac axis and superior mesenteric artery (*arrows*).

The principle described here is called *time-of-flight MRA.*[25],[26] There are other forms of MRA that rely on different physical principles such as phase contrast angiography, bolus tracking, black blood techniques, and three-dimensional, gadolinium-enhanced MRA (see Fig. 156-2).[25],[27],[28] The description of these

techniques is beyond the scope of this chapter. However these techniques have in common the principle of imaging flowing blood, and not necessarily imaging the vascular structures themselves. They all are susceptible to certain artifacts which give the impression of occluded or stenotic vessels such as slowly flowing blood, turbulent flow, and artifacts from adjacent structures such as metallic surgical clips. The basic goal of these sequences is to increase the contrast between the vessel and surrounding structures dramatically. Thus, the vessels are selectively displayed with markedly higher signal intensity than surrounding stationary tissue (see Fig. 156-2).

An MR technique that simulates MRA, but differs in principle, is the *magnetic resonance cholangiopancreatography* (MRCP) study.[29], [30] The goal of MRCP is to image selectively fluid within the biliary tree and pancreatic duct (Fig. 156-3). Very heavily T2-weighted images are used to achieve this effect. With the very long TEs that are used for these heavily T2-weighted images, virtually all solid tissue has low signal (is dark on the image). By virtue of its long T2, fluid within the biliary tree, the gallbladder, and the pancreatic duct retains signal intensity and therefore appears bright on the image. Like MRA studies, multiple projections in a manner similar to conventional cholangiography or endoscopic retrograde cholangiopancreatography (ERCP) can be obtained.

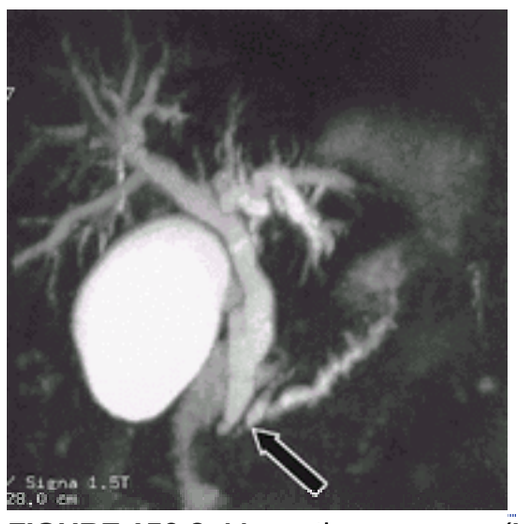

FIGURE 156-3. Magnetic resonance (MR) cholangiography in a patient with pancreatic carcinoma. Projection MR cholangiogram in the slight right anterior oblique view shows a dilated pancreatic duct with dilated side branches, as well as the dilated biliary tree. Both ductal systems are dilated into the pancreatic head and have distal strictures (*arrow*). The MR cholangiogram is made up of heavily T2-weighted thin slices which are then reconstructed into a volume projection by means of a computer algorithm (maximum intensity projection).

Current pulse sequences for imaging the liver are designed for very fast acquisition of images so that motion artifacts are limited or absent. These very fast images generally require improved (high performance) gradient systems. For T1-weighted images, fast gradient echo sequences are used (Fig. 156-4). T1-weighted images that acquire the whole liver as a volume (three-dimensional imaging) can be used for dynamic perfusion studies (see Fig. 156-4) or as MRA studies (see Fig. 156-2) or both.[31], [32] For T2-weighted images, subsecond pulse sequences have been developed so that motion-free images are obtained, whether or not the patient is holding his or her breath.[33] These sequences are called *HASTE, EXPRESS,* or *single-shot fast spin echo sequences,* depending on the manufacturer of the MR system. Echo planar imaging is not a new development but has been adapted to average clinical scanners with improved gradient systems and can also acquire subsecond images.

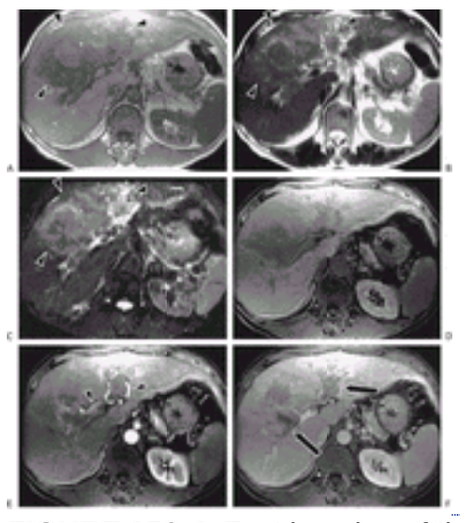

FIGURE 156-4. Fast imaging of the liver in a 56-year-old man with hepatocellular carcinoma. All of these sequences (**A–F**) image the entire liver in a breath-hold period. **A:** T1-weighted gradient echo image shows a large mass (*arrowheads*) in the liver with some areas of high signal intensity. **B:** T2-weighted single-shot fast spin echo image shows the mass as higher signal intensity than the rest of the liver. **C:** T2-weighted echo-planar image with fat saturation also shows the mass as high signal intensity. **D:** T1-weighted three-dimensional gradient echo image before injection of gadolinium chelate. **E:** T1-weighted three-dimensional gradient echo image during the arterial phase of gadolinium chelate enhancement shows hepatic arterial enhancement (*arrowheads*) and patchy enhancement of the tumor. **F:** T1-weighted three-dimensional gradient echo image during the portal phase of gadolinium-chelate enhancement shows tumor thrombus in the right and left portal veins (*arrows*).

Iodinated compounds are used as in CT scanning as injected *contrast agents* that help identify vascular structures and identify areas of abnormality within organs by differences in their vascularity. Injected contrast agents identify vascular structures and identify areas of abnormality within organs by differences in their vascularity.[34] Contrast agents also are available for MR imaging scanning that have functions similar to the iodinated contrast agents used in CT scanning. The most frequently used agent is gadopentetate dimeglumine (see Fig. 156-4).[35] This agent fills the arteries and capillary beds and rapidly diffuses into the interstitium and the sinusoids in the liver.[36] Because of this sequence of events, it is important to rapidly image abdominal organs to capture this temporal progression. In the liver, for example, it is advantageous to image an arterial phase, followed by a portal phase, followed by a delayed phase [37] (see Fig. 156-4). This imaging of the arterial and venous phases is important in the differential diagnosis of liver tumors. Specifically, hypervascular tumors such as hepatocellular carcinomas will be seen better on an arterial phase and may be invisible on delayed phases.[38], [39] and [40] Similarly, other liver tumors such as hemangiomas can be characterized accurately based on their temporal sequence of enhancement with the contrast agent [41], [42] and [43] (Fig. 156-5). Gadolinium-chelate enhanced images are important to detect and characterize vascular abnormalities (see Fig. 156-5).

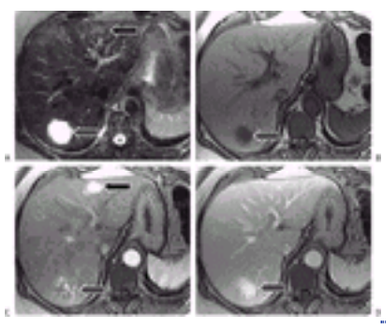

FIGURE 156-5. Contrast agents for imaging the liver: extracellular paramagnetic gadolinium agents. **A:** T2-weighted image of the liver shows a large, very hyperintense (bright) lesion in the posterior segment of the right lobe of the liver (*hatched arrow*). Faintly seen in the anterior aspect of the left hepatic lobe is a slightly hyperintense lesion, which is focal nodular hyperplasia (*black arrow*). Dynamic enhancement patterns of these tumors help in the differential diagnosis. Breath-hold, T1-weighted gradient echo images before (**B**) and after administration of an interstitial contrast agent (gadopentetate dimeglumine). Images acquired during the arterial phase of liver enhancement (**C**) and during the portal phase of liver enhancement (**D**) show differential enhancement patterns of these lesions. The hemangioma (*hatched arrow*) shows nodular peripheral enhancement in (**C**) with progression to complete contrast fill-in (**D**). On the other hand, the small focal nodular hyperplasia shows rapid arterial enhancement (**C**) denoted by the *black arrow* with rapid fading of the contrast to isointensity with the remainder of the liver (**D**).

Agents that are accumulated selectively by hepatocytes and that undergo some biliary excretion have been developed. [44], [45] and [46] These agents show prolonged liver enhancement on T1-weighted images and increase the signal intensity difference between metastases and liver. [44], [45] and [46]

Superparamagnetic iron oxide agents have been approved by the U.S. Food and Drug Administration (FDA) for imaging the liver. [47], [48] and [49] These agents are taken up by normal Kupffer cells in the liver and spleen. Most tumors, such as metastases, contain no Kupffer cells and therefore do not accumulate the agent. Thus, the signal intensity difference between liver and tumors is increased, making tumors more conspicuous on T2-weighted images (Fig. 156-6). Greater sensitivity to metastases using these agents has been reported. [48], [50], [51] and [52] Hepatocellular tumors, such as focal nodular hyperplasia and hepatic adenoma, take up these agents providing a valuable diagnostic tool for evaluating liver tumors. [47], [53], [54]

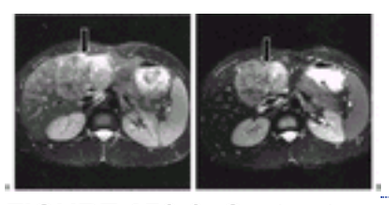

FIGURE 156-6. Contrast agents for imaging the liver: superparamagnetic iron oxides. **A:** T2-weighted image of the liver shows a hyperintense mass in the left lobe of the liver (*arrow*) in a 25-year-old man thought to have focal nodular hyperplasia. **B:** T2-weighted image performed after administration of superparamagnetic iron oxides, which are taken up by reticuloendothelial cells in the liver and cause T2-shortening (low signal intensity) in the liver. The signal intensity of the liver is lower in **B** than in **A,** as is the spleen to a lesser extent. The hepatic tumor is not lower signal intensity, which indicates that it is not likely to represent focal nodular hypoplasia. Resected specimen showed the fibrolamellar hepatocellular carcinoma. Low signal intensity bands in **A** and **B** represent fibrous bands typical of this tumor.

LIVER

Most research on MR imaging in the abdomen has concentrated on focal liver masses. Liver imaging is a frequent examination because many of the CT appearances and ultrasound appearances of focal liver masses are nonspecific, and because MRI has some intrinsic advantages over ultrasound and CT. One of these advantages is that intrinsic tissue contrast on MR imaging is high. What this means is that tumors can be easily detected and characterized without the addition of intravenous contrast materials. [55] Various tissues of liver tumors have different characteristics on T1- and T2-weighted sequences allowing better characterization with MR imaging. The chief disadvantage of MR imaging compared with CT and ultrasound has been that MR images are very sensitive to the presence of motion, such as the movement of the liver with respiratory motion. This disadvantage has been overcome in the last few years by the introduction of rapid pulse sequences for imaging the liver during suspended respiration.

Two characteristics of hepatic imaging of focal liver masses are important. The first is sensitivity, that is, the ability to detect liver lesions of clinical significance. For most patients, this means sensitivity for detection of metastases. Most studies have shown that MR imaging is superior to CT for the detection of metastases. [56], [57], [58], [59], [60] and [61] MR imaging is probably inferior for the detection of metastases when compared with CT arterial portography, [60], [62], [63], [64] and [65] however, it is more specific. [60], [66] MR imaging performed with specialized contrast agents, such as superparamagnetic iron oxides, improves the detection of metastases compared with unenhanced MR imaging. [50], [51] and [52], [58], [65], [67], [68] and [69] The second important characteristic of liver imaging is lesion characterization. The most frequent benign lesions in the liver are hemangiomas and cysts, and these must be differentiated from malignant lesions. MR imaging is superior to CT or ultrasound in lesion characterization because of the multiple tissue parameters that can be evaluated. [55]

One of the fundamental ways in which MR imaging can differentiate liver tumors is by virtue of their behavior on T2-weighted sequences. [55] Both hemangiomas, which are largely blood-filled, and cysts have a high fluid content and therefore a long T2. [42], [70], [71] Metastases and other solid liver tumors have a shorter T2. This difference in T2 values can be exploited by MR imaging to differentiate hemangiomas and cysts from metastases. [42], [70], [71] Specifically, T2-weighted sequences with a long TE (heavily T2-weighted sequences) show that hemangiomas and cysts maintain high signal intensity, and metastases are lower signal intensity. [70] Hepatocellular carcinomas tend to have even lower signal intensity on heavily T2-weighted sequences than metastases.

The enhancement pattern of hemangiomas and cysts also is distinctly different from that of metastases and other solid liver lesions. [72], [73] Because hemangiomas are largely cavernous vascular spaces, the perfusion of contrast agents through these spaces is slow. Typically, hemangiomas show enhancement starting with a peripheral, nodular pattern, and gradually fill in with the contrast agent (see Fig. 156-5). [41], [42] and [43], [74], [75] Metastases and hepatocellular carcinomas, on the other hand, enhance rapidly in the viable portions of the tumor or show poor enhancement in the nonperfused parts of the tumor (Fig. 156-7). Metastases from gastrointestinal primary tumors are often hypovascular in the sense that much of the tumor is made up of small areas of necrosis, desmoplastic reaction, and other hypovascular areas of the tumor.

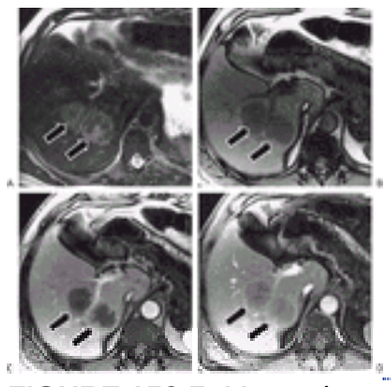

FIGURE 156-7. Magnetic resonance (MR) imaging characterization of malignant hepatic masses. **A:** T2-weighted image shows two metastases from a colorectal tumor in the right lobe of the liver (*arrows*). One can confidently predict that these represent malignant liver lesions based on their heterogeneity and the signal intensity lower than hemangiomas or cysts (compare the degree of signal intensity with the hemangioma in Figure 156-5). T1-weighted gradient echo images performed before (**B**) and after (**C, D**), intravenous injection of gadopentetate dimeglumine show patchy enhancement of these liver tumors with a pattern very different from the enhancement pattern shown for the hemangioma in Figure 156-5. The lack of "fill-in" of the masses with contrast on the delayed enhanced image in (**D**), should be compared to the delayed image of the hemangioma shown in Figure 156-5D.

Most types of malignant lesions in the liver cannot be distinguished from one another on MR imaging. They generally are lower signal intensity than the liver on T1-weighted images and higher signal intensity on T2-weighted images. [76], [77] and [78] An exception is hepatocellular tumors which tend to display characteristic appearances on MR imaging. [79], [80] and [81] The most frequent hepatocellular tumors are regenerating nodules in patients with cirrhosis, and they are slightly hyperintense on T1-weighted images and hypointense to cirrhotic liver on T2-weighted images [82], [83] (Fig. 156-8). In patients with cirrhosis, these nodules are separated by fine strands of fibrovascular tissue which are high signal intensity on T2-weighted images (see Fig. 156-8). [82], [84] MR imaging provides a method for directly visualizing these changes caused by cirrhosis. Larger regenerative nodules in cirrhosis, called *macroregenerative nodules*, are visible as hyperintense masses on T1-weighted images in patients with cirrhosis. These also generally are hypointense to the rest of the liver on T2-weighted images. [82] In addition, their blood supply is derived from the portal vein and enhances during the portal phase of enhancement on dynamic gadolinium-enhanced images.

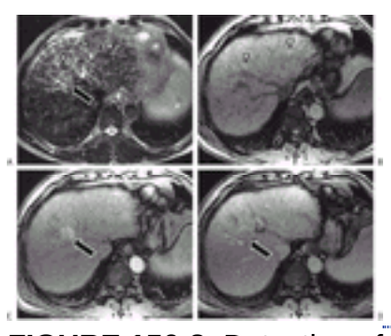

FIGURE 156-8. Detection of small hepatocellular carcinoma in a patient with chronic active hepatitis and cirrhosis. **A:** T2-weighted image shows an abnormal appearance of the liver. Small lower signal intensity nodules (*white arrowheads*) with a network of stranding throughout the liver caused by the fibrovascular septae separating the regenerative nodules of cirrhosis. A faint hyperintense lesion (*black arrow*) is seen adjacent to the middle hepatic vein. **B:** T1-weighted gradient echo image performed in a breath-hold shows faint hyperintensity to the regenerating nodules and cirrhosis. **C:** T1-weighted image performed during the arterial phase of liver enhancement shows rapid enhancement of the small hepatocellular carcinoma (*black arrow*). **D:** Rapid equilibrium of the contrast agent throughout the hepatocellular carcinoma and the remainder of the liver makes the lesion difficult to detect. Imaging during the brief window of arterial phase enhancement is important for the detection of small hepatocellular carcinomas because these malignancies adopt an arterial supply rather than a venous supply.

Hepatocellular carcinomas are frequent complications of cirrhosis. Similar to macroregenerative nodules, they often appear as hyperintense masses on T1-weighted images. [85] However, unlike macroregenerative nodules, they are typically hyperintense on T2-weighted sequences (see Fig. 156-8). [81], [85], [86] They also adopt an arterial supply and enhance during the arterial phase of enhancement on dynamic gadolinium-enhanced images (see Fig. 156-8). [38], [85], [87] Other helpful signs for the diagnosis of hepatocellular carcinomas are the presence of a pseudocapsule and venous invasion. Many hepatocellular carcinomas show steatosis providing a relatively specific diagnostic clue. MR imaging is more sensitive to small hepatocellular carcinomas in those patients with cirrhosis than CT scans. [87]

MR imaging has a greater ability to diagnose and characterize certain forms of diffuse liver disease. These include hepatic steatosis, iron storage disorders, and cirrhosis. Other liver disorders such as hepatitis, drug-induced disorders, alcoholic hepatitis, and Wilson disease do not have specific MR imaging features. Fatty infiltration of the liver from any cause can be detected with specific MR imaging sequences. As discussed previously under "Basic Principles," comparison of in-phase to opposed-phase T1-weighted images is a sensitive measure for the presence of lipid in tissue [22], [88] (Fig. 156-9). These sequences can definitively detect focal or diffuse fatty infiltration of the liver. [22], [89] These sequences also are important for evaluating focal abnormalities discovered on ultrasound or CT because focal fatty infiltration can mimic space-occupying lesions in the liver on these modalities (see Fig. 156-9). [20], [88]

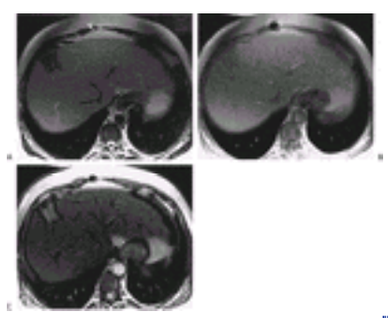

FIGURE 156-9. Opposed phase characterization of a mass suspected on computed tomography. **A:** T2-weighted image shows a masslike area of abnormality in the right lobe of the liver. **B:** In-phase image only faintly shows the abnormality. **C:** Opposed phase gradient echo image shows that the liver is diffusely low signal intensity (compare to in-phase image in **B**), indicating diffuse fatty infiltration. In addition there is slight loss of signal in the area (*arrow*) indicating that this represents a relatively fatty spared area.

Excess iron in the liver can result from primary iron storage disorders (hemochromatosis), iron overload states (e.g., thalassemia), or disordered iron absorption and deposition in cirrhosis (siderotic nodules). In hemochromatosis and iron overload states the iron is deposited diffusely in the liver, giving diffuse and profound low signal intensity on T2-weighted or gradient echo images. [90], [91] However, iron overload states cause severe splenic and liver low-signal abnormality, reflecting the distribution of reticuloendothelial macrophages which take up the excess circulating iron. [92], [93] The spleen is unaffected in primary hemochromatosis, thus allowing for differentiation from iron overload states. [90], [94] Siderotic nodules, which are common in cirrhosis from any cause, result in small nodular low signal intensity foci, distinct from hemochromatosis. [83]

BILIARY TREE

MR imaging has evolved to become a valuable imaging tool for the pancreas and biliary tree (Fig. 156-10).

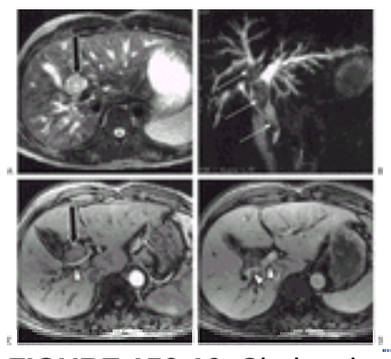

FIGURE 156-10. Cholangiocarcinoma. **A:** T2-weighted image shows a mass (*arrow*) which is hyperintense and lies anterior to the portal vein. The portal vein shows a flow void (black) because of flow within it. **B:** The magnetic resonance cholangiogram shows intrahepatic ductal dilation with separate obstruction of the right and the left ducts. There is an extensive fill-in defect within the common hepatic duct, right hepatic duct, and common bile duct (*arrows*) denoting the extent of the tumor. **C:** Arterial phase dynamic contrast-enhanced T1-weighted image shows the mass (*black arrow*) anterior to the right hepatic artery (*arrowhead*). The demarcation of this vessel argues against extension of the tumor to the porta epatis. **D:** Portal phase contrast-enhanced scan shows the right and the left portal veins (*arrowheads*), again without evidence of invasion. At surgery the ductal wall confined the cholangiocarcinoma. There was no evidence of invasion beyond the duct.

Applications in this area have been aided greatly by the developments in MRA and MR cholangiography, which allow selective visualization of the vascular structures and biliary and pancreatic ducts. MR cholangiography has been shown to be useful for the detection of biliary obstruction, calculi, and normal variants of biliary anatomy that have surgical importance. [30], [95], [96] and [97] The bile ducts appear as high signal intensity with this technique. Calculi appear as low signal intensity filling defects (Fig. 156-11). [98] Unlike CT scanning, where the attenuation of calculi is variable and may approximate that of surrounding soft tissue, calculi identified by MR imaging are almost universally low signal intensity on T2-weighted images. MR cholangiography has been shown to be accurate for the detection of calculi in the common bile duct. [98], [99]

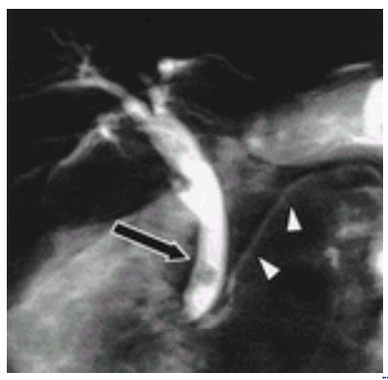

FIGURE 156-11. Magnetic resonance (MR) cholangiographic demonstration of choledocholithiasis. MR cholangiogram in the anterior projection shows a dilated common bile duct containing a calculus (*arrow*). Also displayed is the nondilated pancreatic duct (*arrowheads*).

Because of its ability to image bile ducts, vascular structures, and soft tissue of the hepatic parenchyma in one examination, MR imaging is useful for the detection of cholangiocarcinoma. Cholangiocarcinoma shows a characteristic pattern of enhancement on dynamic-enhanced images. It shows little uptake of contrast on the arterial and portal phases and fairly marked increase in enhancement on delayed images. [100], [101] With hilar cholangiocarcinomas (Klatskin tumors), MR cholangiography can show the multiple obstructed ductal segments. Unlike percutaneous transhepatic cholangiography, which requires separate injection of the different ductal segments if they are completely obstructed, MR cholangiography visualizes all the obstructive ductal segments simultaneously (see Fig. 156-10). Therefore, MR cholangiography can assist in the treatment planning for these tumors. [100], [101]

PANCREAS

The normal pancreas has greater signal intensity than liver on T1-weighted images which is most apparent on fat-saturated T1-weighted images. [102], [103] and [104] This characteristic aids in the detection of small tumors, particularly islet-cell tumors, as well as diffuse diseases such as chronic pancreatitis. Focal tumors of the pancreas appear as low signal intensity on T1-weighted images. [102], [103] Diffuse diseases of the pancreas, such as chronic pancreatitis, also cause diminished signal intensity on T1-weighted images. Typical T2-weighted images are of limited value in evaluating for pancreatic abnormalities because the most frequent types of pancreatic abnormalities (pancreatic carcinoma and chronic pancreatitis) have a prominent fibrotic component and therefore appear as low signal intensity on T2-weighted images, much like the normal pancreatic parenchyma. [102], [103], [105]

MR imaging depicts chronic pancreatitis as a change in signal intensity on T1-weighted images. T2-weighted images are helpful for showing peripancreatic edema and fluid collection such as pseudocysts in acute pancreatitis. On MRCP sequences, pseudocysts, and ductal abnormalities in patients with chronic pancreatitis are visualized. [106], [107] and [108] MRCP has been shown to be a fairly accurate technique for the detection of strictures, pancreatic duct filling defects from plaques or calculi, and ductal dilation which are the hallmarks of chronic pancreatitis. [107], [108] In addition, normal variants such as pancreas divisum and annular pancreas are identified. [106], [109] Fat saturated T1-weighted images are sensitive to the diminished signal intensity that occurs when the gland is replaced by fibrosis in chronic pancreatitis. [110], [111]

In contrast, pancreatic carcinomas show very little difference in signal intensity between tumor and normal pancreas on T2-weighted images (Fig. 156-12). Islet-cell tumors generally appear as high signal intensity on T2-weighted images. [112], [113] Most islet-cell tumors will be fairly conspicuous on T2-weighted images and will stand out from the remainder of the pancreatic parenchyma. Dynamic gadolinium-enhanced studies can be used to assist in identifying small tumors, particularly the insulin-secreting islet-cell tumors. [114] Insulinomas may be particularly difficult to identify on CT or ultrasound.

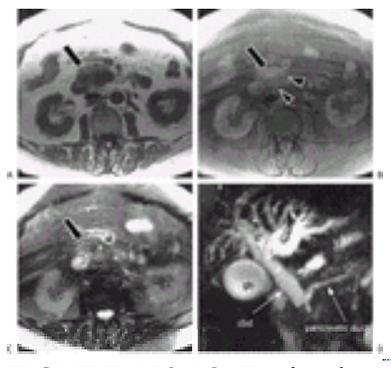

FIGURE 156-12. Evaluation of pancreatic carcinoma. T1-weighted spin-echo image (**A**) shows the pancreatic head (*arrow*), but a discrete mass is difficult to see. **B:** T1-weighted spin-echo fat-saturation image shows that the mass (*arrowheads*) has distinctly lower signal intensity than normal pancreas (*arrow*). T2-weighted fast spin-echo image (**C**) shows that there is heterogeneity to the mass (*arrow*), which has signal intensity characteristics similar to normal pancreatic parenchyma. **D:** Heavily T2-weighted cholangiogram shows dilation of the pancreatic duct in the body and tail. There is also marked dilation of the entire biliary tree because of distal common bile duct (*cbd*) obstruction. Strictures of the common bile duct and pancreatic duct in close proximity comprise the "double duct sign," which is predictive of pancreatic carcinoma.

Several studies have shown that some tumors other than pancreatic adenocarcinomas also are conspicuous on T2-weighted images. [115], [116] This is particularly true of those tumors that have a high mucin content which leads to very high intensity on T2-weighted images. These mucinous and microcystic tumors are recognized by characteristic morphology. [115] T2-weighted images show very high signal intensity of a cluster of septated cysts. MRCP images also show the ductal involvement of ductectatic mucinous tumors. [117]

INTESTINE

In the past, MR imaging had limited value in evaluating the bowel when compared with CT and conventional barium studies. This was mostly because motion of the bowel, either caused by respiratory motion or peristalsis, degraded the MR images. Newer techniques such as single-shot fast spin echo have corrected these problems to a great extent. [118] Antiperistaltic agents also are helpful for reducing bowel-related motion artifacts. Now MR imaging has great potential for evaluating the small bowel and colon, particularly for judging the extent of wall involvement with various pathological processes (Fig. 156-13). MR imaging has been shown to be valuable in assessing the severity and extent of ulcerative colitis and Crohn's disease. [119], [120] and [121]

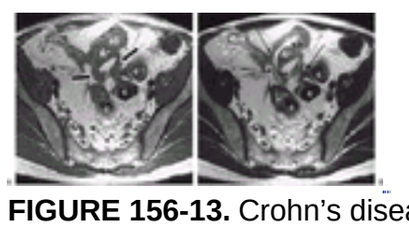

FIGURE 156-13. Crohn's disease with enterocolic fistulae in a 55-year-old man. **A:** Axial T1-weighted image shows a network of fistula tracts (*arrows*) from sigmoid colon (*c*) to ileum (*sb*). **B:** Axial T2-weighted fast spin echo image shows focal breaks in the bowel wall (*thin arrows*) at entrance of the fistula tracts. Note wall thickening in involved portions of the sigmoid colon.

MR imaging is useful for showing the extent of pelvic fistulae from any cause. [122], [123] and [124] T2-weighted images display the muscularis propria of the bowel as low signal intensity. Breaks in the muscularis from fistulae are seen as discontinuities in this layer. [122] Fistulae can be seen without the administration of contrast material (see Fig. 156-13). The high signal intensity of granulation tissue is seen surrounded by low signal intensity fibrosis. Because of the intrinsic soft tissue contrast of T2-weighted images, MR imaging has shown promise for staging gastrointestinal tract tumors, particularly rectal carcinoma. [125], [126] and [127] With high resolution, layers of the rectal wall can be visualized discretely. The muscularis propria appears as a very low signal intensity, while the submucosa appears as higher signal intensity. This has led to preliminary attempts to locally stage rectal carcinoma, with good results reported. [125], [126] and [127] MR imaging is an excellent method to evaluate the pelvis in general and to determine the local extent of tumors.

In addition, MR imaging can be used to evaluate for recurrent tumor after surgery or after radiation therapy. Radiation edema and radiation fibrosis are differentiated from tumor on T2-weighted images and dynamic gadolinium-enhanced images. [72], [73] Fibrosis appears as low signal intensity on T2-weighted images. Recurrent tumor shows nodules of higher signal tissue. [72], [73] Recurrent tumor enhances rapidly during dynamic injection of gadolinium while post-radiation changes enhance more slowly. [72]

IMAGING RECOMMENDATIONS

A wide range of MR imaging systems are available which, both in terms of hardware and software capabilities, provide clinicians with a corresponding range of diagnostic capabilities. In addition, there is a greater range of technical expertise and experience among radiologists in the performance and interpretation of MR imaging studies compared with CT. For these reasons, specific recommendations about the appropriateness of MR imaging examinations are difficult to make. Types of examinations that are well suited to MR imaging and which most radiologists in the community can perform are as follows:

Characterization of a liver mass identified on ultrasound, CT, or other study. Most frequently this would involve distinguishing hemangiomas or cysts from solid liver masses, although MR imaging diagnosis of other liver masses, such as focal nodular hyperplasia or hepatocellular carcinoma, is possible.
Evaluation of the complications of cirrhosis. Specific techniques can identify ascites, collaterals and varices, vascular occlusions, and hepatocellular carcinoma.
Identification of diffuse liver disease such as steatosis or iron deposition. Transfusional iron overload can be distinguished from hemochromatosis.
Identification of small pancreatic masses or exclusion of tumor in the large or bulbous pancreas.
Identification and characterization of a pelvic fistula, specifically perianal fistula and the degree of levator muscle involvement.
Identification of biliary calculi.
Evaluation of any disorders of the liver, biliary tree, or pancreas when the patient is allergic to iodinated contrast medium or is at risk from nephrotoxic effects from iodine (e.g., creatinine > 1.5, diabetic nephropathy).

Clinical situations in which CT may be more effective than routine MR imaging include:

- Routine evaluation of the abdomen and pelvis in a patient with cancer to search for metastases of the liver, lymph nodes, and so forth
- Initial evaluation of obstructive jaundice
- Evaluation of primarily peritoneal or bowel abnormalities
- Abdominal trauma.

FUTURE DIRECTIONS

In the future, refinements of MR imaging in the abdomen and pelvis will focus on more specific contrast agents for hepatic imaging, and the exploration of specialized pulse sequences for use in the abdomen.

The development of specific contrast agents in MR imaging has concentrated on liver-specific agents. A number of these agents are or will be commercially available and FDA-approved. These include superparamagnetic agents that are taken up by Kupffer cells in the liver. [128], [129] These help identify non-Kupffer cell-bearing

tumors such as metastases and most hepatocellular carcinomas with higher contrast, and therefore increased conspicuity, compared with nonenhanced images. Other liver-specific agents are under development, including agents with biliary excretion.

Relatively large volumes or amounts of the iodinated contrast agent are necessary for visualization on routine CT scans. By contrast, MR imaging is very sensitive to small amounts of the contrast agent. For this reason, the development of receptor-specific contrast agents is possible. [130], [131] Receptor-specific agents have been developed for imaging the liver [132], [133] and the pancreas. [131] Other types of superparamagnetic agents have been developed for imaging the lymph nodes. [134], [135] Injected intravenously, these agents are taken up by the lymph nodes over 24 to 48 hours. This may allow imaging of normal- sized, but tumor-bearing nodes because of defects within the contrast-enhanced lymph nodes. These contrast agents afford a degree of tissue characterization that CT scanning does not offer.

Forms of MR imaging used in the brain include diffusion imaging, perfusion imaging, functional imaging, and spectroscopic imaging and are being adapted to the liver and other organs. [136], [137] For example, preliminary evidence suggests that diffusion imaging may predict tumor response to chemotherapy in patients with liver metastases. MR spectroscopy can be used to probe the metabolic state of the liver in diffuse systemic and hepatic disease. [136]

>Uri Ladabaum and Satoshi Minoshima

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) allows noninvasive imaging of physiological parameters within the body, such as metabolic activity and perfusion, using tracers labeled with positron-emitting radioisotopes. In contrast with imaging techniques that reflect primarily anatomic structure, such as computed tomography (CT) and magnetic resonance imaging (MRI), PET reflects biologic functions in tissue. In PET, the spatial distribution and concentration of administered positron-emitting compounds are used to generate cross-sectional images through the body that reflect pathological states or that elucidate physiological processes, leading to applications in clinical practice as well as in research. The principal clinical uses of PET in gastroenterology are in the area of oncology. The potential uses of PET in research are greatly varied. Functional imaging of the central nervous system with PET has been applied in research on visceral pain and perception.

PRINCIPLES AND TECHNICAL CONSIDERATIONS

PET relies on detecting the radiation produced by a systemically administered radiotracer labeled with a positron emitter and determining the distribution of the positron emitter within the subject under study. [1], [2] A small number of proton-rich radioisotopes can decay by emitting a positron (sometimes referred to as a positive electron or an antielectron), whose existence is fleeting. After emission, a positron travels a short path and ultimately combines with an ambient electron. This combination of a positron and electron undergoes a process referred to as annihilation, during which the masses of the positron and electron are converted into electromagnetic radiation in the form of two photons (gamma rays) of equal energy (approximately 511 keV) that travel in nearly opposite directions to each other (Fig. 157-1). PET scanners are designed to detect the photons produced by the annihilation of emitted positrons. Using a computer-assisted image reconstruction method, this information is ultimately used to construct images depicting the concentration of the positron emitter within the object of interest.

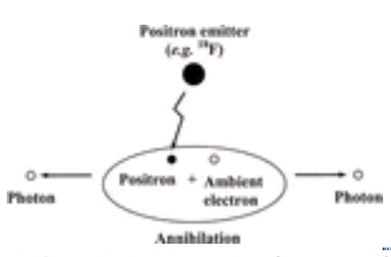

FIGURE 157-1. Positron emission and annihilation. Certain radioisotopes decay by emitting a positron, which travels a short path in tissue and ultimately combines with an ambient electron. This combination of particles undergoes annihilation, during which the masses of the positron and electron are converted into electromagnetic radiation in the form of two photons of equal energy that travel in nearly opposite directions to each other.

Radionuclide Tracers

The first step in PET imaging consists of labeling a suitable molecule with a positron-emitting radionuclide. Positron-emitting isotopes exist for carbon, nitrogen, and oxygen, three prominent atoms in biochemistry. The radionuclides ^{11}C, ^{13}N, and ^{15}O are commonly used in PET imaging in what is sometimes called “isotopic labeling.” [3] ^{11}C-methionine, ^{13}N-ammonia, and ^{15}O-water are examples of PET tracers labeled with these isotopes. In contrast, hydrogen, another important constituent of biochemical molecules, has no positron-emitting isotope. However, positron-emitting isotopes of halogens, most commonly fluorine 18 (^{18}F), can be substituted for a hydroxyl group in what is termed “analogical labeling.” [3] The PET tracer most commonly used in clinical applications is a glucose analog, 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-fluorodeoxyglucose or ^{18}F-FDG).

Examples of radionuclides used in PET and their properties are listed in Table 157-1. [4] Due to the relatively short half-lives of these compounds, a small amount of tracer with high specific activity can be administered, translating into relatively low radiation exposure during the imaging session. [3] Because the quantity of tracer used is very small, there is no risk of pharmacological activity or chemical toxicity. Preparation of PET tracers requires the generation of a positron-emitting radionuclide followed by incorporation of the radionuclide into a molecule of choice. In theory, an unlimited variety of molecules could be labeled. Hundreds of tracers have been labeled with positron emitters, including simple molecules used to measure blood volume and blood flow, amino acids to study protein synthesis, fatty acids and sugars to study metabolic pathways, and specific receptor ligands including pharmaceuticals to map receptor distribution. Positron emitters are generated in accelerators, commonly small medical cyclotrons. [4] The positron-emitting atoms must be incorporated quickly into a tracer molecule as a purified, sterile, isotonic, pyrogen-free solution. [3] This underscores the importance of cooperation among experts in multiple disciplines including physics, chemistry, computer science, imaging, and medicine in the original development of PET and in the maintenance of an active PET program. The short half-life of many radiotracers mandates that they be produced on site, as with ^{15}O-water. However, the comparatively longer half-life of ^{18}F-FDG allows it to be produced at a regional facility, possibly in close proximity to several PET centers. Currently, ^{18}F-FDG is commercially available and distributed for PET imaging in the United States.

RADIONUCLIDE	HALF-LIFE (MIN)	% POSITRON DECAY	DAUGHTER ATOM AFTER DECAY
^{11}C	20.4	99.8	^{11}B
^{13}N	9.96	100	^{13}C
^{15}O	2.07	99.9	^{15}N
^{18}F	109.7	96.9	^{18}O
^{68}Ga	68.1	90	^{68}Zn
^{75}Br	101	76	^{75}Se (radioactive)

Adapted from ref. 4.

TABLE 157-1 Examples of Radionuclides Used in Positron Emission Tomography

2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-fluorodeoxyglucose or ^{18}F-FDG) The use of ^{18}F-FDG for PET applications in oncology rests on the high demand for

glucose by many tumors [5] and the similarities in the initial cellular metabolism of glucose and ^{18}F-FDG. [6], [7] Cells take up glucose and ^{18}F-FDG through specific transporters, and both sugars undergo phosphorylation by hexokinase inside the cell. Whereas glucose-6-phosphate can be a substrate for subsequent reactions in the glycolytic pathway, deoxyglucose-6-phosphate and fluorodeoxyglucose-6-phosphate cannot be metabolized further and are trapped in the cell, where the activity of the reverse enzyme glucose-6-phosphatase is limited. The contrast in ^{18}F-FDG uptake between tumors and metastases compared to surrounding tissue is often detectable.

Data Acquisition and Processing

The second key step in PET imaging comprises detection of photons emitted by the annihilation of positrons, followed by processing of these data to form cross-sectional images. The fact that positron annihilation produces photons traveling in nearly opposite directions serves as a sort of natural collimation and forms the basis for PET detector design and arrangement.

The typical PET scanner design includes multiple pairs of photon detectors oriented opposite to each other in a circular arrangement around a field of view where the subject is placed. [7] "Coincidence detection" refers to the method of accepting photons as indicative of a true positron annihilation only when a pair of photons is detected nearly simultaneously (current time windows are approximately 12 × 10 $^{-9}$ seconds) by an oppositely aligned pair of detectors (Fig. 157-2). Such coincident detection indicates that the photons originated somewhere near the imaginary line connecting the pair of detectors. Current PET scanners contain up to 48 adjacent rings of some 500 detector elements in each ring. Each detector is connected in coincidence with an arc of detectors on the opposite side of the ring. In addition, rings can be connected in coincidence with each other. Standard two-dimensional image acquisition treats individually each pair of adjacent rings, or each "slice" through the subject. More recently, three-dimensional acquisition has been developed, in which all possible coincident detections across rings are used in generating image volume data. Axial fields of view of current scanners are on the order of 15 to 16 cm, but whole body scanning can be performed clinically with axial movement of the scanner table.

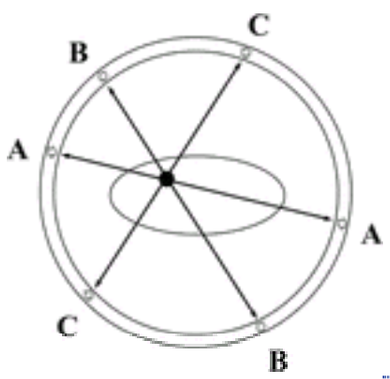

FIGURE 157-2. "Coincidence detection" is the basis for positron emission tomography (PET) detector design. "Coincidence detection" refers to the method of accepting photons as indicative of a true positron annihilation only when a pair of photons is detected nearly simultaneously by an oppositely aligned pair of detectors. In this schematic, accumulation of a PET radiotracer within a lesion (*black circle*) in the PET subject (*oval*) produces three pairs of coincident detections (*A, B* and *C*) in one ring of detectors surrounding the subject.

Corrections to coincident detection counts are often performed before image generation to account for a number of factors, including random coincidences at detector pairs and attenuation of photons inside the subject. [7] Attenuation refers to the scattering or absorption of emitted gamma rays within the subject's body. In present day scanners, attenuation correction is achieved by directly measuring tissue attenuation through the subject using an external radiation source equipped in the scanner. External rotating rods of germanium 68 (^{68}Ge) which are shielded when not in use, are commonly used to perform a "transmission scan" before PET tracer administration. This transmission scan is equivalent to a CT scan that visualizes differences in tissue attenuation within the body for diagnostic purposes.

Computerized mathematical algorithms can be applied for image reconstruction. These usually rely on filtered back projection, the same technique used in radiographic CT. The image produced by this technique represents the "solution" to the question of what spatial and temporal distribution of positron emitter can account for the pattern of coincident detections recorded by the PET scanner. An iterative image reconstruction method based on statistical modeling and segmented transmission data has become available for commercial scanners. This method generally produces better image quality, particularly when count rates are low. Due to a variety of factors, including the short path that positrons can travel before annihilation and the slight deviations in photon direction that can result from residual angular momentum in a positron or electron before annihilation, the intrinsic resolution of modern PET is on the order of 4 to 6 mm.

CLINICAL APPLICATIONS OF PET IN GASTROENTEROLOGY

In recent years, the recognized clinical uses of PET have expanded, particularly in the imaging of tumors. Regarding gastrointestinal cancers, the United States Health Care Financing Administration (HCFA) first announced Medicare coverage in 1999 for ^{18}F-FDG PET in the evaluation of patients with colorectal cancer and rising carcinoembryonic antigen (CEA) levels. In December 2000, HCFA issued a decision memorandum broadening the indications for ^{18}F-FDG PET covered by Medicare to include diagnosis, staging and restaging of non–small-cell lung cancer, colorectal cancer, esophageal cancer, lymphoma, melanoma, and head and neck (excluding thyroid and brain) cancers; myocardial viability studies; and presurgical evaluation of refractory seizures. [8] Additional applications in gastroenterology for which PET has been investigated include imaging of the pancreas, the liver, and neuroendocrine tumors. A survey [9] of 22 institutions found no adverse reactions in over 80,000 positron-emitting radiopharmaceutical administrations, highlighting the extraordinary safety record of PET.

Because anatomic information is often necessary in evaluating patients, including determining the potential resectability of tumor, ^{18}F-FDG PET cannot be considered a substitute for anatomic imaging. However, it can provide important additional information in a variety of clinical situations. In interpreting the values for sensitivity and specificity of PET in the settings discussed subsequently, it is important to recognize that these can be affected by a clinical trial's design, including patient selection criteria and the method for determining the reference gold standard (e.g., conventional imaging, histological confirmation, or clinical follow-up).

Colorectal Cancer

Increased ^{18}F-FDG uptake in hepatic metastases from colorectal cancer was demonstrated at a very early stage in PET technology development. [10] Later studies suggested that ^{18}F-FDG PET could be useful in differentiating recurrent rectal cancer from surgical scar or a nonmalignant mass. [11], [12] When anatomic imaging techniques could not reliably distinguish malignant from nonmalignant tissue, the enhanced glycolytic activity of malignant tissue could be detected by ^{18}F-FDG PET. Subsequently, ^{18}F-FDG PET has been investigated in the evaluation of patients with suspected colorectal cancer recurrence, as well as in preoperative staging of patients with known recurrence and in staging of primary disease. Figure 157-3 shows an example of ^{18}F-FDG PET in a patient with rectal cancer metastatic to the liver.

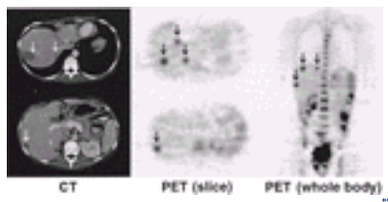

FIGURE 157-3. Imaging with contrast computed tomography (CT) and with ^{18}F-FDG PET in a patient with rectal cancer metastatic to the liver. Contrast CT shows at least three hepatic hypovascular lesions (*white arrows*). Corresponding positron emission tomography (PET) slice images show a total of four hepatic lesions (*black arrows*). Whole body PET shows at least three of the hepatic lesions (*black arrows*). A large focus of uptake in the pelvis is excreted ^{18}F-FDG in the bladder. Uptake is also visible in the right kidney next to the lumbar spine and in the descending colon.

Table 157-2 summarizes studies that have reported on the sensitivity and specificity of ^{18}F-FDG PET in suspected metastatic or recurrent colorectal cancer. [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23] and [24] A metaanalysis of 11 studies yielded overall estimates (and 95% confidence intervals) for the sensitivity of whole body ^{18}F-FDG PET in recurrent colorectal cancer of 97% (95%–99%), and specificity of 76% (64%–88%). [25] For local/pelvic disease, the estimated sensitivity was 95% (91%–98%) and the estimated specificity was 98% (96–99.7%). For hepatic involvement, the estimated sensitivity was 96% (94–99%) and the estimated specificity was 99% (98–100%). While in many investigations ^{18}F-FDG PET images were interpreted visually, some authors have reported higher signal intensity in malignant compared to benign lesions using semiquantitative methods such as the standardized uptake value (SUV) or SUV corrected for lean body mass (SUL), [26] which normalizes signal intensity by radioactive dose injected and body weight, and the target-to-background ratio, which compares signal intensity within and outside a region of interest. [14], [17], [21], [24]

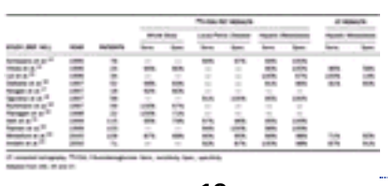

TABLE 157-2 ^{18}F-FDG Positron Emission Tomography (PET) in Suspected Metastatic or Recurrent Colorectal Cancer, with Comparison to CT for Hepatic Metastases

Patients may be suspected of having colorectal cancer recurrence on the basis of symptoms, physical findings, rising CEA levels, or anatomic imaging studies. In a study of 22 patients with previous colorectal cancer resection who had abnormal CEA but normal anatomic imaging studies, 15 patients were ultimately considered to have recurrent disease. Abnormalities were detected with ^{18}F-FDG PET in 17 patients, including the 15 with proven recurrence, yielding a positive predictive value of 89% and a negative predictive value of 100%. [20] The additional value of ^{18}F-FDG PET was examined in 103 patients with suspected or proven colorectal cancer recurrence who also underwent conventional imaging including CT. [22] In 12 of 60 patients considered to have resectable disease on conventional imaging, ^{18}F-FDG PET detected additional disease in 9 and excluded disease in 3, yielding additional diagnostic value in 20%. In 13 patients with inconclusive conventional imaging or isolated elevated CEA, ^{18}F-FDG PET was of additional diagnostic value in 62%.

Accurate staging is of paramount importance to guide potential surgical intervention, including resection of hepatic metastases. In the identification of hepatic metastases of colorectal tumors, ^{18}F-FDG PET has been compared with anatomic imaging as illustrated by studies listed in Table 157-2. [27] An important contribution of ^{18}F-FDG PET appears to be demonstration of hepatic and extrahepatic foci of disease not identified on conventional imaging. However, a study directly comparing ^{18}F-FDG PET results with surgical resection specimens found that ^{18}F-FDG PET detected only 25% of hepatic lesions smaller than 1 cm, compared to 85% of lesions larger than 1 cm. [28]

One study has assessed ^{18}F-FDG PET in the staging of primary colorectal cancer. [29] The sensitivity and specificity of ^{18}F-FDG PET for the primary tumor were 100% and 43%, respectively. For liver metastases, the sensitivity and specificity were 88% and 100%, respectively, compared to 38% and 97%, respectively, for CT. For lymph node metastases, the sensitivity and specificity of ^{18}F-FDG PET were 29% and 96%, respectively, compared to 29% and 85%, respectively, for CT. Thus, the use of ^{18}F-FDG PET appears greater in detecting distant metastasis than local nodal involvement.

The ultimate value of a diagnostic test is manifest in its impact on patient outcomes. Although no data are available comparing outcomes such as life expectancy or quality of life between patients studied or not studied with ^{18}F-FDG PET, several investigators have reported the impact of ^{18}F-FDG PET on medical decision making. In the metaanalysis by Huebner and colleagues, [25] it was estimated that ^{18}F-FDG PET affected management in 29% (95% confidence intervals, 25%–34%) of patients undergoing evaluation for recurrent colorectal cancer. Subsequent studies have reported similar results, with ^{18}F-FDG PET affecting management in 23% of patients undergoing evaluation for possible resection of hepatic metastases [28] and 21% of patients suspected of having metastatic or recurrent colorectal cancer. [24]

The abilities to monitor response to therapy or to assess a patient's candidacy for chemotherapy based on tumor characteristics are potentially of great clinical relevance. Decreases in ^{18}F-FDG uptake after chemotherapy have been shown to correlate with response to chemotherapy. [30], [31] In contrast, because inflammatory tissue may show similar glycolytic activity to that of tumor, ^{18}F-FDG PET may not be able to accurately assess the response to radiation therapy in the short term. [32], [33] However, one pilot study has suggested that ^{18}F-FDG PET might be of incremental value in selecting patients with rectal cancer for sphincter-preserving surgery after preoperative radiation and chemotherapy. [34]

In patients with unresectable liver metastases, PET has been performed with ^{18}F-fluorouracil before 5-fluorouracil chemotherapy to determine its potential role in predicting prognosis. [35] Overall, patients with higher values for ^{18}F-fluorouracil uptake were more likely to achieve stabilization of disease with chemotherapy, but trapping of ^{18}F-fluorouracil varied among metastases, even within the same patient. Quantitative modeling of ^{18}F-fluorouracil uptake has been investigated as a way to optimize treatment schedules for individual patients. [36] It remains to be determined whether these applications will find a role in clinical oncology.

Esophageal Cancer

Figure 157-4 shows an ^{18}F-FDG PET in a patient with a tumor at the gastroesophageal junction, and Table 157-3 presents the results of studies that have compared ^{18}F-FDG PET and CT for staging of esophageal cancer. [37], [38], [39], [40] and [41] The specificity of the two tests appears to be comparable in the evaluation of nodal disease, while the sensitivity of ^{18}F-FDG PET appears to be superior. For both techniques, detecting local nodal involvement is problematic. In one study, the overall accuracy in determining resectability was 88% for ^{18}F-FDG PET and 65% for CT ($P = 0.04$), but neither modality could assess the extent of wall invasion. [39] Differences in accuracy of similar magnitude have been found in other studies. [37], [40], [41] As with colorectal cancer staging, an important contribution of ^{18}F-FDG PET appears to be its ability to detect distant metastases not visible on anatomic imaging, and thus alter management. One group [42] has reported additional diagnostic value in 22% of patients, with upstaging in 15% and downstaging in 7%. Another study [37] reported a change in management based on ^{18}F-FDG PET results in 17% of patients.

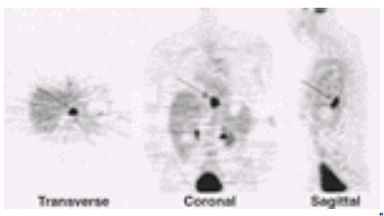

FIGURE 157-4. Whole body ^{18}F-FDG PET in a patient with a tumor at the gastroesophageal junction. A large focus of ^{18}F-FDG uptake due to the tumor (*arrows*) is visible in three orthogonal planes from the whole body PET scan. No regional lymph node metastases were identified, which contributed to pretreatment staging of disease. A large focus of uptake in the pelvis is excreted ^{18}F-FDG in the bladder. Uptake is also visible in both kidneys.

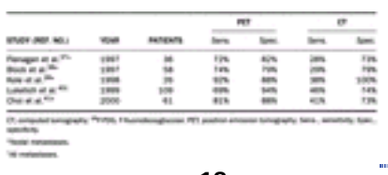

TABLE 157-3 ^{18}F-FDG PET Compared to CT in the Evaluation of Metastases in Esophageal Cancer

In staging potentially operable esophageal cancers, ^{18}F-FDG PET has been compared to the combination of CT and endoscopic ultrasound (EUS). [42] EUS demonstrated a higher sensitivity than ^{18}F-FDG PET for local nodal involvement (81% vs. 33%, $P = 0.027$). In evaluating regional and distant nodal involvement, ^{18}F-FDG PET was more specific than CT and EUS combined (98% vs. 90%, $P = 0.025$), with both testing stra- tegies having similar sensitivity (43% vs. 46%).

The combination of ^{18}F-FDG PET and ^{11}C-choline PET, which relies on uptake of choline by tumors for integration into phospholipids, has been reported to improve the accuracy of PET in staging esophageal cancer. [43] The ^{11}C-choline PET had a sensitivity of 88% for mediastinal lymph nodes, compared to 34% for ^{18}F-FDG PET. However, ^{11}C-choline PET demonstrated 0% sensitivity in the upper abdomen due to high ^{11}C-choline uptake by the liver, compared to 79% for ^{18}F-FDG PET. The combination of both modalities detected 85% of all lymph node metastases.

One study [40] has reported differences in survival based on stratification by initial ^{18}F-FDG PET results. Survival at 30 months was 60% in patients with localized disease compared to 20% in patients with distant disease ($P = 0.01$), suggesting that ^{18}F-FDG PET results may be of prognostic significance. It is not clear how much of this difference may be due to the effects of treatment.

Pancreatic Cancer

The HCFA decision memorandum of December 2000 did not include pancreatic imaging as an approved indication for ^{18}F-FDG PET under Medicare. However, pancreatic imaging is considered a recognized application of ^{18}F-FDG PET by some experts, as reflected by the recommendations of a German interdisciplinary consensus conference. [27]

Table 157-4 presents test performance data from studies that have evaluated ^{18}F-FDG PET in the diagnosis of pancreatic cancer and its differentiation from chronic pancreatitis. [44], [45], [46], [47], [48], [49], [50] and [51] Using ^{18}F-FDG PET may be beneficial in assessing pancreatic masses that are indeterminate for malignancy on conventional imaging. Beyond visual interpretation of images, semiquantitative analysis has demonstrated differences between the signal intensity, such as SUV, in tumor and chronic pancreatitis. [45], [46], [49], [51], [52] In one study, [50] ^{18}F-FDG PET suggested potential alterations in clinical management in 43% of patients.

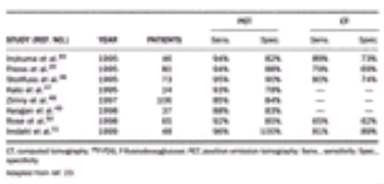

TABLE 157-4 ^{18}F-FDG PET Compared to CT in the Diagnosis of Pancreatic Cancer

Two important factors may affect the results of ^{18}F-FDG PET in pancreatic imaging. First, hyperglycemia can result in false-negative studies in pancreatic cancer. [48], [53] The cancer itself may cause endocrine insufficiency, and hyperglycemia results in greater competition by glucose against ^{18}F-FDG for uptake into cells. In patients with normal serum glucose, for instance, the sensitivity and specificity of ^{18}F-FDG PET in diagnosing pancreatic cancer were reported as 98% and 84%, respectively, compared to 63% and 86%, respectively, in hyperglycemic patients. [48] Second, inflammation can produce ^{18}F-FDG uptake as intense as that seen in tumor, either in the setting of pancreatic masses without clear evidence of acute pancreatitis, or during and after attacks of acute pancreatitis. [54]

Multiple imaging modalities can be used in evaluating patients with suspected pancreatic malignancy. One study [44] reported sensitivity and specificity for four different modalities in patients with suspected pancreatic cancer: 94% and 82%, respectively, for ^{18}F-FDG PET, 89% and 73%, respectively, for CT, 97% and 64%, respectively, for EUS, and 89% and 45%, respectively, for abdominal ultrasound. A subsequent study found sensiti- vity for detecting pancreatic cancer of 87% for ^{18}F-FDG PET, 53% for CT, and 93% for EUS. [55] Overall accuracy values (defined as area under receiver operating characteristic curves, with 1 reflecting a perfect test) for differentiating malignant from benign pancreatic masses have been reported for various imaging strategies. [53] Overall accuracy was 0.86 for ^{18}F-FDG PET, 0.93 for endoscopic retrograde cholangiopancreatography (ERCP), 0.82 for CT, and 0.95 for the combination of ^{18}F-FDG PET and ERCP. In the subgroup of euglycemic patients with contradictory or indeterminate CT and ERCP results, ^{18}F-FDG PET was accurate in 84% of cases.

The role of ^{18}F-FDG PET has also been studied for staging of metastatic disease. For lymph node staging in pancreatic cancer, one study [53] reported ^{18}F-FDG PET sensitivity and specificity of 49% and 63%, respectively, and for hepatic metastases 70% and 95%, respectively. As in colorectal cancer, ^{18}F-FDG PET may miss smaller metastases (<1 cm). A study designed specifically to assess the detection of hepatic metastases of pancreatic cancer found sensitivity of 90% and specificity of 91% for ^{18}F-FDG PET, compared to 69% and 100%, respectively, for CT, and 82% and 100%, respectively, for abdominal ultrasound. [56] In another investigation, the sensitivity of ^{18}F-FDG PET for hepatic and extrahepatic disease was 78% compared to 33% for CT. [55]

Monitoring patients with ^{18}F-FDG PET after therapy has been employed. [57], [58] Survival in patients without measurable pancreatic ^{18}F-FDG uptake 1 month after chemotherapy was improved compared to patients with residual ^{18}F-FDG uptake (319 compared to 139 days, $P = 0.034$). As in colorectal cancer, it remains to be determined whether ^{18}F-FDG PET will find routine clinical applications in determining prognosis or response to treatment, which is likely to depend on whether such determinations influence patient management.

Hepatic Imaging

The role of ^{18}F-FDG PET has been evaluated in hepatocellular carcinoma and metastatic disease to the liver. The sensitivity of ^{18}F-FDG PET for hepatoma is poor. In one study, [59] only 50% of sonographically detectable hepatomas demonstrated increased ^{18}F-FDG uptake, whereas 79% were detectable by CT. None of the well-differentiated tumors were visualized by ^{18}F-FDG PET, compared to 88% of the moderately or poorly differentiated tumors. Similar results were reported in a second study, [60] with ^{18}F-FDG PET showing a sensitivity of 55% in the diagnosis of hepatoma, compared to 90% for CT.

In contrast to poor results in the diagnosis of hepatoma, ^{18}F-FDG PET can be useful in evaluating metastatic disease to the liver. This application for staging specific primary gastrointestinal tumors has already been discussed. One study [61] of patients with various primary tumors and possible liver involvement found sensitivity of 97% and specificity of 88% for ^{18}F-FDG PET compared to 93% and 75% for CT (not statistically different). The use of ^{18}F-FDG PET yielded new information for 23% of patients, including demonstrating liver metastases in 17% when other imaging was equivocal or negative. In patients undergoing CT-guided fine-needle aspiration (FNA) of liver lesions, ^{18}F-FDG PET was positive for malignancy in 96% of cases in which malignancy was diagnosed by FNA, and was negative in 86% of cases where FNA was negative. [62]

The role of ^{18}F-FDG PET has been examined in the setting of hepatic lesions requiring further characterization. In a series of 110 patients with hepatic lesions 1 cm or larger on CT, all liver metastases from adenocarcinomas and sarcomas and all cholangiocarcinomas showed increased ^{18}F-FDG uptake values, whereas only 70% of hepatomas showed increased uptake. [63] All benign lesions had poor uptake, and abscesses showed equivocal or increased uptake. A series of 78 patients with various liver tumors has confirmed that ^{18}F-FDG uptake tends to be lower in hepatocellular carcinoma compared to metastatic disease or cholangiocarcinoma. [64] Case reports have suggested that ^{18}F-FDG PET might be useful in detecting cholangiocarcinoma in patients with primary sclerosing cholangitis. [65], [66] Monitoring the response to chemoembolization is another use of ^{18}F-FDG PET. [67]

Neuroendocrine Tumors

The experience with PET in detecting primary and metastatic neuroendocrine tumors is limited. Carcinoid tumors synthesize serotonin from 5-hydroxytryptophan (5-HTP). An early study with 7 patients suggested that hepatic metastases from carcinoid tumors could be imaged with ^{11}C-5-HTP PET. [68] In 22 patients with neuroendocrine tumors, ^{11}C-L-dihydroxyphenylalanine (^{11}C-L-dopa) PET detected tumor in 50%. [69] In those imaged with both ^{11}C-L-dopa and ^{11}C-5-HTP, results were similar. One study has reported similar overall results for ^{11}C-5-HTP PET and CT in 16 patients with gut carcinoids and 2 with endocrine pancreatic tumors. [70] Although ^{11}C-5-HTP detected more lesions than CT in 10 patients, it is not clear that this is of clinical significance.

Somatostatin receptor scintigraphy (SS-R) is commonly used for imaging neuroendocrine tumors. In 15 patients with neuroendocrine tumors, SS-R was found to be more useful overall than ^{18F}-FDG PET, although SS-R was negative and ^{18}F-FDG PET was positive in 2 patients with less differentiated tumors. [71] A second study with 16 patients found an overall sensitivity of 85% for SS-R in neuroendocrine tumor imaging. Even though it was able to image aggressive tumors, ^{18}F-FDG PET did not seem to provide much additional value. [72] Notably, in this study, CT scans were abnormal in all patients with abnormal ^{18}F-FDG PET and in all but one patient with abnormal SS-R.

The difficulty in detecting pancreatic islet-cell tumors is highlighted by a study in which the sensitivity of ^{18}F-FDG PET was 53%, compared to 53% for ultrasonography, 50% for CT, and 53% for magnetic resonance imaging (MRI). [73] In all cases ^{18}F-FDG PET was negative or equivocal where the other modalities were negative.

APPLICATIONS OF PET IN GASTROENTEROLOGY RESEARCH

The ability of PET to use a theoretically unlimited variety of molecules radiolabeled with different positron emitters to image biologic processes in vivo opens numerous possibilities for PET applications in research. The following studies illustrate the broad range of questions that have been addressed in PET research studies relevant to gastroenterology. An anticolorectal carcinoma monoclonal antibody labeled with copper 64 (^{64}Cu) (radioimmunoPET) has shown 71% sensitivity for imaging tumor foci. [74] ^{11}C-methionine uptake by the pancreas has been investigated by PET as a possible reflection of pancreatic exocrine function. [75] Biliary bicarbonate secretion in humans has been studied after intravenous injection of sodium ^{11}C-bicarbonate. [76] In cholestatic conditions, an impaired response to secretin was observed. Glucose use has been studied with ^{18}F-FDG PET in a patient with hepatoma and hypoglycemia. [77] Model parameters of glucose use did not differ between tumor and liver, and the authors concluded that hypoglycemia was attributable to insulin-like growth factor II-like proteins causing glucose uptake by skeletal muscle and suppression of glucose production. The mechanism and kinetics of percutaneous ethanol injection of hepatomas has been studied with ^{11}C-ethanol. [78]

Neurological abnormalities can accompany various forms of liver disease. The role of ^{18}F-FDG PET of the brain in patients with Wilson disease has demonstrated decreases in regional cerebral glucose metabolism in the cerebellum, striatum, cortex, and thalamus compared to controls. [79] In this study, striatal metabolism was most affected in those patients who had received therapy for the shortest time. Altered cerebral blood flow and metabolism have been observed in patients with severe liver disease and low-grade encephalopathy. [80] Normalization of brain glucose metabolism has been observed following liver transplantation. [81] In patients with hepatic encephalopathy, central benzodiazepine receptor binding has been studied with ^{11}C-flumazenil, with significant increases shown in the thalamus, cerebellum and pons, but not in the cortex or whole brain, when modeling corrected for altered hepatic metabolism. [82]

In animal studies, liver regeneration has been assessed with ^{11}C-thymidine PET, [83] the trafficking of radiolabeled tumor cells in vivo has been assessed with PET, [84] ^{11}C-octanoate PET has been investigated for assessing liver function, [85] and ^{11}C-labeled cholecystokinin receptor antagonists have been synthesized and evaluated. [86]

Functional Brain Imaging and Visceral Sensation

One application that has received intense interest in recent years is functional imaging of the central nervous system as a tool for studying visceral sensation, particularly in the context of visceral hypersensitivity in functional gastrointestinal disorders. [87] In brain activation studies with PET, regional cerebral blood flow (assessed with ^{15}O-water) during a task of interest is compared to regional cerebral blood flow during baseline to identify cerebral regions with increased activation during the particular task. This widely used technique is based on the assumption that regional blood flow is coupled with regional neuronal activity under physiological conditions. In visceral sensation research, the stimulation “task” has consisted most often of visceral distension with a balloon.

In an early study, [88] rectal distension in healthy volunteers led to activation in the pre- and postcentral gyrus and thalamus. In the first study of functional brain imaging in patients with functional gastrointestinal disease, rectal distension in controls but not patients with irritable bowel syndrome (IBS) produced activation of the anterior cingulate cortex, a region implicated in the affective response to pain. [89] A subsequent study with functional MRI reported activation in the anterior cingulate cortex (ACC), prefrontal cortex, insular cortex, and thalamus in most IBS and control subjects, with increased ACC activation in IBS subjects compared to controls. [90] The reasons for the conflicting results in these studies remain to be fully explained. Compared to female subjects with IBS, male subjects with IBS have demonstrated increased activation in the insula, considered a visceral sensory cortex. [91] In this study, insular activation was associated most strongly with distending pressure, whereas anterior cingulate activation was associated more with subjective discomfort.

The cerebral representation of esophageal distension has also been studied with ^{15}O-water PET. [92] During nonpainful stimulation, activation was seen bilaterally along the central sulcus, in the insula, and in the frontal/parietal operculum. Painful stimulation led to greater activation in the same regions, with additional activation of the right anterior insula and the anterior cingulate gyrus, leading the authors to suggest that these latter structures are involved in esophageal pain processing.

Cerebral activation has been investigated with ^{15}O-water PET during gastric distension producing bloating, pain, and nausea. [93] Paralleling increases in distension stimulus and symptoms, progressive increases in activation were observed in the thalami, insulae, anterior cingulate cortex, caudate nuclei, brainstem periaqueductal

gray matter, cerebellum, and occipital cortex. This activation pattern showed important similarities to activation patterns reported in studies of painful somatic stimulation. Due to the high correlation among symptom scores for bloating, pain, and nausea, the specific regions activated during the experience of each individual sensation could not be determined.

FUTURE DIRECTIONS

PET has been called the most sensitive and specific means for studying, through imaging, molecular processes in humans in vivo. [94] The development of a microPET scanner for small animals, combined with rapidly growing experimental capabilities in molecular biology, presents the opportunity to carry out molecular imaging assays in vivo, including studies of gene expression. [95] The kinetics of ^{18}F-labeled oligonucleotides, for instance, have been studied with PET in baboons. [96]

In the clinical arena, the number of clinical PET facilities has grown over time, and PET is becoming an essential diagnostic tool for the management of certain patients with cancer. Given the ability to produce ^{18}F-FDG off-site and its commercial availability in the United States, not all clinical PET centers will require an on-site cyclotron. This may facilitate further the widespread use of PET. Newer tracers, including ^{18}F-labeled radiopharmaceuticals that can be prepared and delivered commercially owing to their relatively long half-life, may ultimately find clinical applications. [97]

The precise role of functional imaging with respect to anatomic imaging remains to be clarified in many clinical conditions. It is conceivable that a well-defined sequence of tests may produce the best information for clinical decision making. [98] New generation PET scanners combined with CT capability (PET-CT scanners) already can provide both functional and anatomic information simultaneously with minimal incremental burden to patients. Sites of abnormal ^{18}F-FDG uptake detected by PET in the abdomen, for example, can be readily localized by simultaneous CT. For correlating functional and anatomic imaging, PET-CT scanners are likely to prove clinically useful.

CHAPTER 158

Arnold F. Jacobson

APPLICATIONS OF RADIONUCLIDE IMAGING IN GASTROENTEROLOGY

Nuclear medicine is a specialty devoted to diagnostic and therapeutic applications of radioactive isotopes (radionuclides) in medicine. The most important attribute of nuclear medicine imaging is its capability for minimally invasive study of organ and organ system physiology and function. This chapter provides an overview of the major clinical applications of radionuclide imaging in gastroenterology, including studies for diagnosis of acute cholecystitis and diseases of the hepatobiliary system; gastrointestinal (GI) bleeding; alimentary tract motility disorders; cavernous hemangiomas of the liver; and inflammatory, infectious, and malignant processes involving the liver, stomach, bowel, and abdominal cavity. Positron-emission tomography (PET), a radionuclide technique that has experienced dramatic growth during the past decade, is discussed briefly in this chapter and more fully in Chapter 157.

THEORETICAL CONSIDERATIONS

Radionuclide imaging is performed after administration of a radiolabeled compound (radiopharmaceutical) that localizes to a specific organ system or the location of an ongoing physiological process. Most radiopharmaceuticals are administered intravenously, although oral, intrathecal, intradermal, and intraperitoneal routes are used in association with some nuclear medicine procedures. Only those structures in which the radiolabeled compound accumulates can be seen externally, with alterations in the normal biodistribution of the administered material, seen as decreased or increased accumulation of the labeled compound, providing information concerning abnormal anatomic or physiological processes. Depending upon rates of uptake and excretion and the physical characteristics of the radionuclides, nuclear medicine imaging is performed as early as a few seconds to as late as 5 to 7 days after radiopharmaceutical administration.

Radionuclides

The radionuclides used in nuclear medicine are chosen based upon the characteristics of the emitted radiation, and either the biologic properties of an element which allow its use in vivo, such as iodine for thyroid imaging, or the physical and chemical properties of an element which allow it to be linked to appropriate compounds or pharmaceuticals, typically as a chelate in a complex. In order to be usable for imaging, an internally administered radioisotope must produce photons (either ?-ray or x-ray) of sufficient energy that the majority will travel through and escape from the body unattenuated. Isotopes with primarily lower energy photons (<60 keV) or particulate radiation such as ß-particles (electrons) are potentially useful for therapeutic pharmaceuticals but are generally avoided for diagnostic radiopharmaceuticals, since these emissions increase the radiation dose to the patient without contributing to imaging information. Isotopes with high energy photons are also avoided because most of these photons pass through the crystal in typical nuclear medicine imaging systems without interacting, resulting in low detection efficiency and statistically low quality images. While radionuclides with photons of 60 to 400 keV are used in conventional nuclear medicine imaging [1] (Table 158-1), there is noticeable deterioration in image quality for studies employing isotopes with energies greater than 200 keV. However, many newer general-purpose nuclear medicine systems have been designed specifically to have the capability for detecting the 511 keV annihilation photons used in PET.

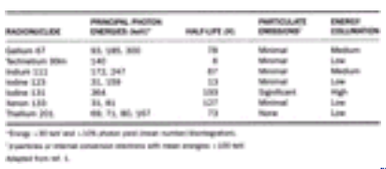

TABLE 158-1 Radionuclides in Common Use in Nuclear Medicine

Radiopharmaceuticals

Nuclear medicine imaging procedures are most effective when the radiopharmaceutical used successfully targets the organs or the physiological process(es) of interest. While most radiopharmaceuticals at best only approach the ideal properties for specific imaging applications, development work continues to produce newer compounds with increased radiochemical binding efficiency or targeted biologic extraction which results in improved imaging characteristics.

Technetium has proven particularly suitable for incorporation into stable complexes and chelates, with all necessary chemical reactions usually taking place in a single vial that contains the compound to be labeled and various reducing agents and stabilizers. Technetium 99m (99mTc), supplied in solution as the pertechnetate anion () from a device called a generator, is added, and after thorough mixing, greater than 95% of the radionuclide is typically bound to the desired compound or complex.

Side effects resulting from administration of nuclear medicine radiopharmaceuticals are extremely rare, with a reported occurrence of minor nonspecific or possible allergic reactions in 2/100,000 doses. [2] Strict adherence to proper techniques for handling blood products also has minimized incidents associated with reinjection of radiolabeled blood components. Even the potentially more antigenic radiolabeled proteins (of both human and mouse origin) in newer approved and investigational radiopharmaceuticals have generally shown excellent safety profiles, similar to those of previous generations of nuclear medicine compounds. [3], [4]

Radiation Dose

The internal radiation dosimetry from a nuclear medicine procedure depends upon the biodistribution and biologic half-life of the radiopharmaceutical, and the physical half-life and characteristics of the radiation emissions of the radionuclide. Compounds that are relatively rapidly cleared from the target organ and the body,

and are labeled with shorter-lived photon-emitting radionuclides, result in lower patient radiation doses. The dominant role of ^{99m}Tc in nuclear medicine, while attributable in part to the element's favorable chemical properties, is also due to its emission of a single ?-photon with energy suitable for imaging, minimal co-emissions of low-energy electrons, and short half-life (see Table 158-1). Target organ doses from nuclear medicine procedures are generally comparable to those received from examinations such as barium x-ray studies or contrast computed tomography (CT).

TECHNICAL APPLICATIONS

Imaging Systems

The ?-camera has been the central component of most clinical nuclear medicine imaging systems for the past four decades. The principal elements of this device are a large, flat crystal of sodium iodide in which incoming ?- and x-ray photons are absorbed and converted into flashes of light; a matrix of photomultiplier tubes that detect and amplify these scintillations; and electronic circuitry which determines the location (X-Y coordinates) of the scintillation events and their intensity, reflecting the energy deposited in the interactions. [1]

An exact image of the radiotracer distribution in a region can be obtained if only those photons emitted perpendicular to the desired imaging plane are detected. While absolute selectivity cannot be achieved due to the isotropic character of ?-photon emissions (in all directions with essentially equal probability), limitation of photon detection adequate for most diagnostic imaging purposes is accomplished through use of a collimator (in essence a sheet of lead containing a large number of small holes) placed in front of the camera face. Low-, medium-, and high-energy collimators are used for different isotopes, depending on the highest energy photon with significant abundance (see Table 158-1), with greater thicknesses of lead required to achieve adequate absorption of scatter and off-angle photons as the energy of the primary photons able to be imaged increases.

The completed scintigraphic image reflects the distribution of scintillation events (counts) detected across the ?-camera crystal during the course of an acquisition. An acquisition may be performed with the camera stationary, producing a spot image of a selected body region, or with either the camera or imaging table moving, resulting in a single image of the total-body distribution of the administered radiopharmaceutical.

While planar ?-camera imaging may be considered analogous to conventional radiography, cross-sectional imaging analogous to x-ray CT or magnetic resonance (MR) imaging also can be done using radionuclide techniques. This method is commonly referred to as single photon emission computed tomography (SPECT). SPECT is typically performed using a rotating ?-camera and either a "step-and-shoot" acquisition, with 32 to 128 planar views obtained while the camera traverses a 180- or 360-degree rotational arc around the patient, or an acquisition obtained during a continuous rotation over the same angular domain. SPECT data are processed using reconstruction algorithms similar to those used in CT or MR, and images are typically displayed in three standard planes: axial (cross-sectional), sagittal, and coronal.

While SPECT systems can have 1, 2, or 3 camera heads, 2-head systems are by far the most commonly used. In-plane spatial resolution with a single-head SPECT system is typically on the order of 10 to 15 mm, while resolution of 7 to 10 mm can be achieved using a dual-head system. Many newer 2-head systems also are capable of performing coincidence detection for imaging positron emitters.

Computers

The computer is an integral part of all modern nuclear medicine imaging systems, providing the capability for quantitation that distinguishes nuclear medicine from most other diagnostic imaging techniques. Each photon detected by the ?-camera is recorded in computer memory as a count in a digital matrix of picture elements (pixels). Each pixel encompasses a range of X-Y coordinates, depending upon the matrix size selected (typically 64 × 64 to 256 × 256 pixels for spot, 256 × 1024 for whole-body images).

Quantitative data are obtained from the stored digital images by determination of the number of counts detected within user-defined regions of interest (ROIs). Such data allow quantitation of organ ratios that reflect the biodistribution of the administered radiotracer. In addition, dynamic acquisitions, with typical image frame rates ranging from 0.25 seconds to 1 minute per image, can be stored in the computer memory and then displayed in a cine format to demonstrate the pattern of change in activity distribution over time. ROIs also can be drawn to generate time-activity curves for determination of uptake, filling, and emptying rates of physiological interest.

IMAGING APPLICATIONS

Liver

Many nuclear medicine procedures provide diagnostic information concerning the functional status of the liver or its involvement by pathological processes. These include examinations that are specific for liver function evaluation (e.g., hepatobiliary scintigraphy) and those that are used to examine the total body for infection (gallium 67 [^{67}Ga], labeled leukocytes) or malignancy (^{67}Ga, labeled peptides and monoclonal antibodies, PET). Specific radiologic imaging of the liver is now mostly the domain of ultrasound, CT, and MR imaging, with traditional radionuclide methods (e.g., colloid scintigraphy) and methods used primarily for research (e.g., cell function and receptor studies) only chosen for highly selected patients.

The conventional radionuclide liver-spleen scan, although important in the early progress of nuclear medicine imaging, is of little relevance in current clinical practice. Taking advantage of the ability of the hepatic Kupffer cells to phagocytose appropriately sized particulate material injected intravenously, the scan is performed following injection of a colloidal preparation of sulfur or albumin labeled with ^{99m}Tc. [5] Following intravenous injection, these labeled colloids are rapidly cleared from the circulation (half-time [T 1/2], 2–3 minutes) by the liver (80%–85% extraction), spleen (10%–15% extraction), and bone marrow (1%–5%). Significant liver disease results in impaired hepatic uptake of colloid and proportionate increases in uptake in the spleen and bone marrow. [6]

Because of its simplicity as an imaging procedure, colloid scintigraphy may occasionally be of use in situations where other imaging modalities are limited, such as for obese patients in whom sonography is inadequate and whose weight exceeds the limit of the CT or MR imaging tables, or for noninvasive evaluation of lesions suspected of being either focal nodular hyperplasia, which normally show colloid uptake, [7] or adenomas, which usually do not. [8] The need to use degree of shift of colloid uptake to the spleen and marrow as an indication of liver cirrhosis severity [6] is rarely encountered in current practice. Colloid imaging, particularly using SPECT, still finds occasional use as a means for identifying residual or accessory splenic tissue in patients after splenectomy, which can be of particular value when other imaging modalities have demonstrated potential sites of infection or tumor, neither of which should show uptake. Comparably specific splenic imaging can also be performed using heat-denatured ^{99m}Tc labeled red blood cells. [9]

Specialized examinations for assessing selected aspects of liver function are primarily used in centers with interest in the study of particular liver diseases. Investigators have taken advantage of the high solubility of xenon in fat to allow estimation of fat content in cirrhotic livers (as determined on biopsy) based upon the amount of retained xenon activity on anterior abdominal images acquired during the washout phase after a period of equilibrium breathing of xenon 133 (^{133}Xe) gas. [10] The investigational compound ^{99m}Tc galactosyl-neoglycoalbumin, whose binding to hepatic binding protein is directly related to hepatic function, [11], [12] also continues to be studied for its potential use in quantifying hepatic functional reserve and prognosis in cirrhotic patients.

Cavernous Hemangiomas

Cavernous hemangiomas are the most common benign liver tumor, and as such they are often observed as incidental findings on abdominal ultrasound and CT examinations. Lesions that display typical echogenicity on sonography or the expected pattern of delayed enhancement on contrast CT usually require no further workup. For lesions with atypical appearance on sonography or CT, or those in patients whose history or clinical findings make it necessary to exclude metastatic involvement of the liver, ^{99m}Tc labeled red blood cell (RBC) imaging of the liver provides an excellent means for demonstrating the greater blood pool within the hemangioma than in the surrounding liver parenchyma. Similar to the findings on contrast CT, the characteristic scintigraphic finding for hemangiomas is mildly decreased or normal labeled-RBC activity immediately after injection, followed by progressive increase in activity over the next 20 to 30 minutes. [13], [14] While observation of this pattern of enhancement on planar imaging is virtually pathognomonic for hemangioma, in general only larger lesions (=2 cm) can be reliably detected in this manner. Smaller lesions, and those that are located deeply within the liver parenchyma, are visualized with increased sensitivity using SPECT, typically performed 1 to 2 hours after the labeled RBC injection to maximize lesion enhancement. Hemangiomas appear as distinct focal areas of increased activity

compared with the surrounding liver parenchyma [15], [16] (Fig. 158-1). For lesions larger than 2 cm, sensitivity of SPECT RBC imaging for hemangioma identification exceeds 90%, which is equivalent to the performance of contrast CT and MR imaging. [17], [18] Hemangiomas down to 1.4 cm can be reliably identified on SPECT with a multihead camera, [19] and some as small as 1 cm can also be imaged. [17], [20] Nevertheless, verification of the etiology of lesions smaller than 1 to 1.5 cm is probably best accomplished with CT or MR.

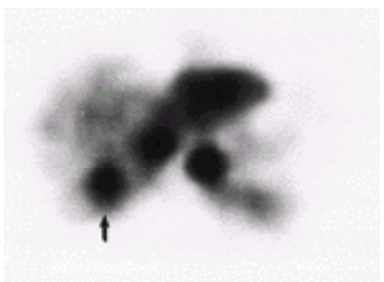

FIGURE 158-1. A 48-year-old man with a new lung neoplasm and an equivocal liver lesion on computed tomography and magnetic resonance imaging underwent single photon emission computed tomography imaging approximately 1 hour after injection of 26 mCi technetium 99m labeled red blood cells (RBCs). Axial image shows a discrete 2.5- to 3-cm focus of increased RBC accumulation in the posterior aspect of the right lobe of the liver (*arrow*), corresponding to the finding on the other cross-sectional modalities and consistent with a liver hemangioma. The centrally located areas of intense activity represent the aorta and inferior vena cava, respectively.

Hepatobiliary System

The most widely used nuclear medicine study examining hepatocyte function and the hepatobiliary system employs ^{99m}Tc labeled iminodiacetic acid (IDA) compounds. [21] Correctly described as hepatobiliary scintigraphy or cholescintigraphy, this procedure is still often referred to as a HIDA scan, in reference to an early IDA compound which was long ago supplanted by superior substituted IDA agents.

IDA compounds enter the hepatocyte via a carrier-mediated pathway, with a mechanism very similar to that of bilirubin. Uptake of the compounds in current use (disofenin, mebrofenin) is considerably less affected by competitive inhibition in the presence of significantly elevated serum bilirubin levels compared to earlier IDA derivatives such as HIDA and PIPIDA. These improved physiological characteristics allow adequate liver uptake and tracer excretion at bilirubin levels as high as 20 to 30 mg/dL. [21]

Hepatobiliary scintigraphy is performed following intra- venous administration of typically 3 to 5 mCi of a ^{99m}Tc labeled IDA compound, although up to 10 mCi may be used when bilirubin levels are significantly elevated. Anterior abdominal images are most often acquired dynamically (one image per minute) over the next 60 minutes, although acquisition of a series of static views (typically every 5 minutes) is an acceptable alternative. A normal study shows rapid uptake of the radiotracer into the liver, with virtually all cardiac blood pool activity cleared by 5 minutes after injection, followed by the liver excretory phase, with sequential visualization of intrahepatic bile ducts, the common hepatic duct, the cystic duct, gallbladder, common bile duct, and small bowel (Fig. 158-2). All of these structures typically are seen by 30 minutes after injection, although visualization of activity in the gallbladder and small bowel within 60 minutes is considered normal. While relative visualization time of the gallbladder and small bowel are not definitely correlated with most hepatobiliary pathology, small bowel visualization prior to the gallbladder likely reflects low basal sphincter of Oddi pressure, with the majority of hepatic bile excreted directly into the small intestine. In contrast, up to 20% of normal individuals have a relatively high resting sphincter of Oddi tone, which potentiates early filling of the gallbladder and results in absence of bowel visualization during the first 60 minutes of a hepatobiliary scan. [22] For such individuals, normalcy of the hepatobiliary system can be demonstrated through stimulation of the gallbladder, either by a fatty ingestion, which releases endogenous cholecystokinin (CCK), or an exogenous-administered cholecystagogue such as sincalide (Kinevac, Bristol-Myers Squibb, New York, NY), the terminal octapeptide of CCK, which produces gallbladder contraction and sphincter of Oddi relaxation, with resultant visualization of radiolabeled bile entering the small bowel.

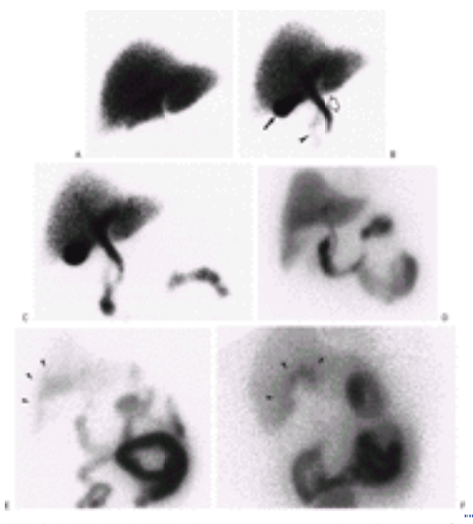

FIGURE 158-2. Images **A–C** are from a 76-year-old man with atypical right upper quadrant pain and fever to 104°F. Ultrasound showed multiple stones but no pericholecystic fluid or gallbladder wall thickening. Technetium 99m (^{99m}Tc) mebrofenin image at 4 minutes postinjection (**A**) shows prompt normal homogeneous uptake throughout the liver. At 10 minutes (**B**), there is visualization of activity in the gallbladder (*arrow*), common bile duct (*open arrow*), and small bowel (*arrowhead*). At 15 minutes (**C**), further transit of small bowel activity is evident. These results exclude the diagnosis of acute cholecystitis with high negative predictive value. For comparison, images **D–F** are from hepatobiliary scintigraphy in a 61-year-old man with a 2-day history of severe right upper quadrant abdominal pain, sonography showing irregular gallbladder wall thickening and shadowing suggestive of either a polyp or stone, temperature of 101.1°F and a white blood cell count of 20.1. Anterior image at 30 minutes (**D**) shows satisfactory uptake of the ^{99m}Tc mebrofenin by the liver and normal appearance of tracer activity in the small bowel. The gallbladder was not visualized to 60 minutes, at which time 4 mg morphine sulfate was administered intravenously; the gallbladder was not seen during an additional 30 minutes of imaging. Increased activity in the liver adjacent to the gallbladder fossa can be seen on the last postmorphine image (**E**) and even more clearly on a subsequent right anterior oblique image (**F**) (*arrowheads*), reflecting the rim sign. At subsequent surgery, necrotizing and suppurative cholecystitis was found, with extension of inflammation into the liver bed.

Hepatobiliary scintigraphy can be used to evaluate both parenchymal liver function and the structural integrity and patency of the various parts of the hepatobiliary tree. Among applications of this method are studies of infants with suspected biliary atresia, [23] patients with primary biliary cirrhosis [24], [25] and sclerosing cholangitis, [26], [27] and individuals who have undergone liver transplantation. [28], [29] Time-activity curves for selected regions of interest in the liver and bile ducts can be used to estimate rates of hepatic uptake and clearance and bile flow. Abnormal bile flow kinetics may be an indication of intrahepatic and extrahepatic biliary obstruction, rejection in transplant patients, and congenital or acquired ductal anomalies. In particular, common bile duct obstruction results in a typical pattern of intrahepatic cholestasis and gallbladder nonvisualization, particularly if the obstruction is more than 24 hours in duration. [30], [31]

Hepatobiliary scintigraphy is most frequently used to evaluate for the presence of acute cholecystitis, reflected by mechanical or functional obstruction of the cystic duct resulting in absence of gallbladder visualization. In the presence of signs and symptoms such as right upper quadrant tenderness, elevated white blood cell count, fever, and gallstones or wall thickening on gallbladder sonography, nonvisualization of the gallbladder by 60 minutes has a sensitivity greater than 95% for the

diagnosis of acute cholecystitis. [32], [33], [34] and [35] The most common pathological reason for a false-positive scan is chronic cholecystitis, which is often associated with low rates of bile flow into the gallbladder and therefore early nonvisualization. Although in patients with chronic cholecystitis there is often sufficient bile flow into the gallbladder to demonstrate visualization by 2 to 4 hours postinjection, current practice is to administer intravenous low-dose morphine sulfate (typically 0.04 mg/kg to a maximum of 4 mg) if the gallbladder is not visualized by 60 minutes. Morphine causes contraction of the sphincter of Oddi, increased intraductal pressure, and increased bile flow into the gallbladder, and results in gallbladder visualization within 30 minutes in the majority of patients with chronic but not acute cholecystitis. Continued absence of gallbladder visualization during this time further supports the diagnosis of acute cholecystitis (see Fig. 158-2). Another indicator of acute cholecystitis seen in some patients is the “rim sign,” a persistent region of activity in the liver adjacent to the gallbladder fossa attributed to edema and localized inflammation in the liver causing impaired clearance of labeled bile. This sign, although only modestly specific, is most often noted in association with more complicated cholecystitis with transmural involvement, such as gangrenous or perforated gallbladder [36], [37] and [38] (see Fig. 158-2).

Morphine can occasionally convert a true-positive into a false-negative study, [39] presumably as a result of the increased intraductal pressure either dislodging a stone or overcoming the high resistance of an edematous but still patent gallbladder neck. Nevertheless, the reported sensitivity of gallbladder nonvisualization on morphine-augmented cholescintigraphy in patients suspected of acute cholecystitis (93%–95%) [40], [41] is only slightly lower than results published in the “pre-morphine” era. It has been suggested that false-positive (for acute rather than chronic cholecystitis), morphine-augmented cholescintigraphy may reflect failure of the pharmacological agent to increase bile flow through the cystic duct, [42] which could conceivably occur if either sphincter of Oddi constriction or rate of production and excretion of radiolabeled hepatic bile were inadequate to produce a detectable change in rate of gallbladder filling.

Hepatobiliary scintigraphy, similar to sonography, must be performed in the fasting state, since postprandially, the gallbladder is contracted and bile flow is diverted almost entirely into the small bowel, producing a false-positive finding of gallbladder nonvisualization. [43] A minimum fast of 4 hours is usually recommended prior to initiation of a study. However, false-positive studies can also occur after prolonged fasting, such as in patients in intensive care units and those on total parenteral nutrition, presumably because the gallbladder becomes atonic and contains concentrated viscous, sludgy bile, which limits entry of new hepatic bile even though the cystic duct is patent. [44], [45] One option in patients who have taken nothing orally for extended periods (>24–48 hours) is to administer a dose of intravenous sincalide 1 to 2 hours prior to beginning the scintigraphic study, thereby potentially producing sufficient emptying of the gallbladder to allow filling to occur following injection of the radiotracer. [46] Reports indicating that regular administration of sincalide can reduce sludge formation in patients on prolonged periods of intravenous alimentation [47] also provide support for the potential use of sincalide pretreatment in diagnostic imaging.

Hepatobiliary scintigraphy can be used to evaluate congenital or acquired structural anomalies of the biliary tree or to examine for abnormalities resulting from operative or traumatic injury. Choledochal cysts are visualized as isolated areas of increased retention of tracer corresponding to the involved region of the bile duct, [48], [49] while sclerosing cholangitis results in multiple scattered areas of retention secondary to ductal stenoses. [26], [27] Visualization of tracer outside the normal ductal pathways is usually indicative of bile leakage, and scintigraphy can therefore be helpful in evaluating patients suspected of bile peritonitis or postoperative or posttraumatic liver or bile duct injury. [50] In postgastrectomy patients, the pattern of bile flow can be examined to assess the functional characteristics of the efferent and afferent limbs, the latter often better demonstrated scintigraphically than by x-ray studies with oral contrast.

A commonly performed, although somewhat controversial, functional evaluation in hepatobiliary imaging is the quantitative measurement of gallbladder response to stimulation by endo- genous or exogenous CCK or its analogs. Following adminis- tration of the ^{99m}Tc labeled IDA compound and sufficient time thereafter to allow liver clearance and maximum gallbladder filling, the oral meal or the intravenous agent is administered. Dynamic images in the anterior or occasionally the anterior oblique projection are acquired on computer as the gallbladder gradually contracts, and these images are then analyzed to estimate the reduction in volume represented by the gallbladder ejection fraction (GBEF). GBEF values are typically compared against results for normal controls studied under the same test conditions. [51], [52] and [53]

The ready availability, ease, and reproducibility of administration of intravenous sincalide have made this agent the most commonly used stimulus for gallbladder contraction in clinical and research examinations. The total dose of sincalide used is typically 0.01 to 0.04 µg/kg, administered as either a short-duration (1 to 3 minutes) bolus or a slow continuous infusion over 15 to 60 minutes. The dose most commonly employed is 0.02 µg/kg, with a higher dose of 0.04 µg/kg only occasionally needed to elicit a response in selected patients. In comparison to the bolus technique, sincalide administered as a continuous infusion produces more complete gallbladder contraction, has better reproducibility, produces fewer symptoms, and is more physiological, which is analogous to the sustained elevation of endogenous CCK that occurs after a meal. In a comparison of 0.02 µg/kg bolus and 30-minute infusion protocols in 23 normal volunteers, the mean GBEFs were 56% and 70%, respectively, with the infusion GBEF higher in 21 subjects (91%). [54]

The value of sincalide-augmented hepatobiliary imaging and more generally the role of GBEF determinations as a guide for therapeutic decision making has long been a subject of controversy. Although early investigators noted a definite relationship between decreased gallbladder contractility and acalculous cholecystitis, later studies often yielded disparate results, with some showing a definite correlation between low GBEF and symptom relief following cholecystectomy, [55], [56] and [57] while others found no correlation between the presurgical GBEF and either severity of gallbladder histopathological changes [58] or relief of symptoms following cholecystectomy. [59] Given that the scintigraphic GBEF can only be determined if the gallbladder is visualized, which is typically not the case in patients with cholecystitis, a study showing that sincalide can be used reliably when the gallbladder is only seen postmorphine is notable. [60] In that study, of 11 patients with abnormal GBEF (defined as <40%, although all had GBEF <20%), all had cholecystitis, including 5 with acalculous disease. Nevertheless, some asymptomatic subjects with normal gallbladder sonography also have low GBEFs, [52], [54] indicating that although sincalide-augmented cholescintigraphy is reliable as a measurement technique, application of its results to therapeutic decision making must be done with care, particularly in judging the clinical significance of biliary dyskinesia.

Scintigraphy has proven useful for examining patients suspected of biliary pain on the basis of sphincter of Oddi dysfunction. Delayed excretion of radiolabeled bile and decreased gallbladder contraction in response to sincalide are both associated with sphincter of Oddi dysfunction documented manometrically. [61], [62] Sphincter dysfunction may also be associated with a paradoxic response to sincalide (i.e., increased sphincter pressure resulting in increased activity in the common bile duct after administration of the cholecystagogue). Several studies have shown significant improvement in bile flow dynamics following sphincterotomy or sphincteroplasty, with symptom relief also correlated with abnormal preoperative emptying kinetics. [62], [63] and [64]

Gastric Mucosa

Radionuclide imaging of the stomach and gastric mucosa is generally limited to investigations of children and young adults with abdominal pain and GI bleeding to identify the presence of ectopic gastric mucosa often associated with Meckel diverticula. Technetium 99m pertechnetate is actively extracted by the mucous-secreting cells in gastric mucosa, thereby providing a means for locating sites of ectopic gastric mucosa. [65], [66] For a Meckel scan, 30 to 100 µCi/kg of ^{99m}Tc pertechne- tate is administered, followed by serial anterior imaging of the abdomen for the next 30 to 60 minutes. [67] Just as the circulating radiotracer is progressively extracted by the gastric mucosa in the stomach, a Meckel diverticulum that contains gastric mucosa will show enhancement of activity over time. Appearance of a focus of pertechnetate uptake outside of the stomach within 10 to 20 minutes, typically in the right lower quadrant of the abdomen, usually is indicative of a Meckel diverticulum. Oblique views of the abdomen and views with the bladder blocked with lead or drained via an indwelling catheter are sometimes done to enhance identification of small focal accumulations in the lower abdomen. Intravenous administration of pentagastrin (6 µg/kg 15 to 20 minutes before pertechnetate injection) or an H2-receptor antagonist (300 mg cimetidine or 50 mg ranitidine 1 hour before pertechnetate injection; pretreatment can also be done using oral preparations for 2 days prior to the study) may result in improved visualization of Meckel diverticula via increasing gastric mucosal uptake, and glucagon (50 µg/kg IV 10 minutes after pertechnetate injection) may produce the same outcome via delaying local clearance of the radiotracer. [67], [68] and [69] Even without use of such pharmacological augmentation, sensitivity and specificity for detection of Meckel diverticula based upon surgical correlation in patients presenting with rectal bleeding and other symptoms are on the order of 85% and 95%, respectively. [65]

Gastrointestinal Bleeding

While most nuclear medicine studies are routine outpatient diagnostic examinations, GI bleeding studies are often performed on an urgent or emergent basis on sometimes hemodynamically unstable patients. The underlying principle of GI bleeding scintigraphy is that an intravascular tracer in circulation at the time of active bleeding will extravasate into the bowel lumen, thereby allowing identification of the bleeding site. The most well-characterized radiopharmaceuticals for this application are ^{99m}Tc labeled colloid and ^{99m}Tc labeled RBCs. These two agents have dramatically different imaging characteristics, in that the former is rapidly cleared from the circulation following intravenous administration, while the latter has prolonged residence in the vascular space. The advantages and disadvantages

of the physiological characteristics of these two agents are discussed subsequently.

The theoretical advantage of a radiotracer agent for GI bleeding studies that is rapidly cleared from circulation is that the initial extravasation of activity into the bowel and its subsequent intraluminal movement can be identified with great precision because of the low tissue background. [70] In the case of radio- labeled colloid, activity rapidly accumulates in the liver and spleen, with the remainder of the abdomen having minimal background counts within a few minutes postinjection. Rates of bleeding as low as 0.05 mL/min have been identified using sulfur colloid imaging in an animal model in which a catheter was used to introduce radiotracer into the bowel at a controlled rate. [71] The major disadvantage of labeled colloid is that the same rapid vascular clearance that allows high-contrast imaging also results in only a few minutes of opportunity for identification of the bleeding site. The intermittent nature of many episodes of GI hemorrhage and the variable interval between the initial presentation with bleeding complaints and the referral of the patient for a scintiscan makes it highly unlikely that active bleeding will be occurring during any short period of study. In two comparative studies with labeled RBCs involving 127 patients with GI bleeding, a bleeding site was identified on colloid scintigraphy in only 7 (5%). [72], [73] Even though multiple repeated colloid injections can be done to improve sensitivity, this is usually not practical as a routine procedure. Ultimately, the intermittent nature of GI bleeding limits the use of colloid as a study agent.

A radiotracer with prolonged blood pool residence provides the best capability for detection of both active and intermittent GI bleeding, and ^{99m}Tc labeled RBCs are most commonly used for this application. [74], [75], [76] and [77] Cells are labeled by a method that does not involve intravenous administration of ^{99m}Tc pertechnetate (either a modified in vitro or totally in vitro technique) to avoid possible uptake and secretion of free pertechnetate by the gastric mucosa in the absence of active bleeding. Once reinjected, the labeled RBCs remain in circulation for as long as the cells are viable, which permits repeated imaging as necessary limited only by the physical half-life of ^{99m}Tc.

Following injection of 20 to 30 mCi of ^{99m}Tc labeled RBCs, anterior abdominal imaging is typically performed for 60 to 120 minutes, depending upon the initial findings and the relative stability of the patient. A continuous dynamic acquisition is definitely preferable to serial static imaging (typically at 5-minute intervals), with a frame duration of at most 60 seconds; rates as rapid as 10 seconds per frame have been reported useful in detecting rapid intermittent bleeding. [78], [79] and [80] Anterior oblique and lateral views are sometimes also obtained to aid in bleeding site localization. In the presence of active bleeding, labeled RBCs enter the bowel lumen and are seen as a focus of increased activity. The two critical features of a positive bleeding study are this initial identification of a focal accumulation of blood, and subsequent observation of its intralumenal movement to more specifically localize the region of bowel that contains the bleeding site (Fig. 158-3). If the patient is too unstable to remain for an extended period in the nuclear medicine department, or if angiographic or surgical procedures to stop the bleeding are pending, it may be necessary to terminate the study as soon as a positive finding is identified, but under most circumstances, further images demonstrating movement of labeled blood allow more accurate discrimination of small from large bowel sources. The dynamically acquired images viewed as a continuous cine loop are particularly effective for demonstrating passage of intralumenal labeled RBCs through the bowel. [67], [79]

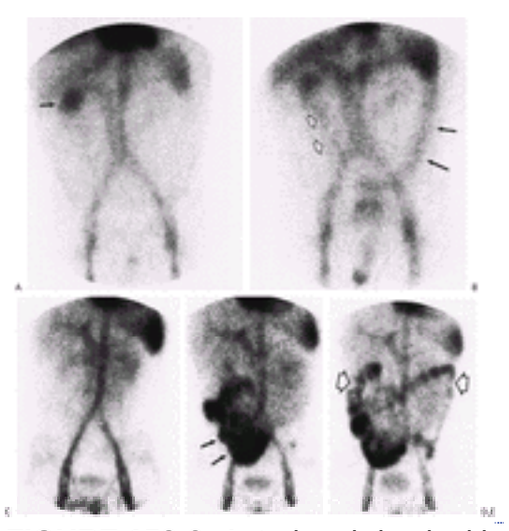

FIGURE 158-3. Anterior abdominal images from two labeled red blood cell gastrointestinal bleeding studies are shown. **A:** Focal accumulation of activity is seen in the right upper quadrant (*arrow*) at 10 minutes after injection at the site of an anastomotic bleed in the right colon, with (**B**) labeled red blood cells seen in the ascending (*open arrows*), transverse, and descending colon (*arrows*) on a later image at 60 minutes as a result of both retro- and antegrade movement of blood. **C:** The images on the right show no definite extravasation at 60 minutes, but (**D**) diffuse intralumenal blood is seen in the distal small bowel (*arrows*) at 4 hours and (**E**) throughout the colon (*open arrows*) at 5 hours. Angiography demonstrated active bleeding at the site of duodenal ulcers seen previously at endoscopy. All scintigraphic images show normal blood pool activity in the liver, heart, and spleen (left to right at the top of each image) and in the major abdominal blood vessels.

The appearance of an intralumenal accumulation of labeled RBC activity, either on initial imaging or during acquisition of a consecutive series of images at a later time, identifies bleeding sites in the stomach, small bowel, or colon with an accuracy exceeding 90%. When bleeding is slow, the initial site visualized may be a location where a sufficient quantity of radiolabeled blood has pooled to allow it to be seen above the abdominal blood pool background. Although this initial visualized site may therefore occasionally be a few centimeters proximal or distal to the primary bleeding location, the discrepancy rarely interferes with correlation of scan findings with those of other procedures (e.g., angiography, endoscopy, surgery).

Active bleeding sites are typically seen during the first 1 to 2 hours of imaging in up to one- third of patients studied. [72], [75], [81], [82] For the remaining patients, options at this point include proceeding with other investigations (endoscopy, angiography, surgery), or obtaining later delayed views. The results on later delayed views indicate whether active bleeding has occurred during the interval between imaging sessions, and several sequences of images can be obtained over the approximately 24-hour period after the original labeled RBC injection during which imaging with acceptable acquisition times is feasible (see Fig. 158-3). As “old” blood which entered the bowel prior to the injection of the labeled cells will not produce a positive scan finding, any intralumenal labeled RBCs can only have entered the bowel subsequent to the start of the study. Stool or blood passed per rectum can also be examined for the presence of ^{99m}Tc using either the ?-camera or a well counter, providing an extremely sensitive method for identifying even trace amounts of extravasated blood which may not have been evi- dent on the abdominal images.

Later delayed images demonstrate intralumenal labeled RBCs in 20% to 46% of patients whose early images are negative, overall about one-third of all patients studied. [74], [81], [82] and [83] However, the location(s) of activity seen on delayed images often does not reflect the site where the labeled blood entered the bowel. While the bleeding site is unlikely to be significantly distal to the location where blood is seen (allowing for the possibility of some retrograde movement of bowel contents), it could be present anywhere proximal to that location. It is relatively common to see diffuse activity in the colon on 18- to 24-hour delayed images, but nevertheless the identified source of bleeding in as many as half of such patients is in the upper GI tract. [82] As a prognostic indicator, positive delayed images (denoting continued bleeding during the study interval) are seen more often in patients with more complicated courses, including those who require more blood transfusions and more frequent intervention by angiography or surgery. [74], [82]

In clinical practice, only early imaging results from radionuclide GI bleeding studies are likely to influence patient management decisions, with later delayed images, although of demonstrated diagnostic and prognostic value, usually considered worth obtaining in only selected cases. A strongly positive early finding might result in prompt angiographic or surgical follow-up, while a subtle positive finding might not alter a preexisting plan to proceed with bowel cleansing followed by colonoscopy. The latter course of action is also typically followed in patients with negative early images. Given that bowel cleansing removes the evidence of interval extravasation of labeled RBCs, there is in fact no value in obtaining late imaging in this situation, and such imaging could even be misinterpreted as false negative. While it is potentially helpful to be able to identify individuals who are most likely to have late-positive imaging, features such as serum blood urea nitrogen (BUN) to creatinine ratios of =25 unfortunately do not translate into a significantly greater probability of bleeding site identification. [84]

The sensitivity for detection of bleeding using labeled RBCs is about 0.1 to 0.2 mL/min, [73] compared with 0.5 mL/min for angiography. Even preceded by a positive bleeding scan, angiograms typically show contrast extravasation in less than half the patients studied. [74], [81], [85] This reflects both the intermittent nature of the majority

of GI bleeding, and the fact that even in the most well-organized imaging department, bleeding may stop in the interval, regardless of the length, between the completion of the bleeding scan and the initiation of angiography. Adjunctive approaches that have been used in an attempt to improve bleeding source identification include scintigraphic studies in association with intravenous heparin to increase the likelihood of bleeding, [86] and intraarterial injections of radiolabeled material through angiographic catheters in patients with negative angiograms.

Gastrointestinal Tract Motility Studies

Gastric Emptying Test meals containing small amounts of radionuclides can be used to study both rates and characteristics of the transit of materials through any portion of the tubular alimentary tract. Of the various methods that have been developed, those for studying gastric emptying are in the widest general use. Both liquid and solid gastric emptying can be examined via serial abdominal imaging in anterior or posterior projections for 60 to 180 minutes following ingestion of a suitable labeled material after an overnight fast. [87], [88] and [89] Images are acquired either as a dynamic sequence at one frame per minute, or as a series of static views typically every 15 minutes, although through use of mathematical models of gastric emptying fewer measurement points may be needed (e.g., images at 0, 1, 2, and 3 hours), reducing the imaging burden on both the patient and the nuclear medicine clinic. [90] Acquisition of both anterior and posterior views (such as is readily achieved with a dual-head camera) allows calculation of the geometric mean tracer activity at each time point. ROIs are routinely drawn around the gastric silhouette to obtain the time-activity curve for emptying, and smaller ROIs may be used to isolate portions of the stomach (e.g., fundus, antrum) to assess peristaltic behavior that may contribute to delays in emptying. The emptying half-time (T 1/2) for the whole stomach is typically determined and compared against results for normal subjects with the same test meal (Fig. 158-4). The time-activity curve can also be analyzed to assess the pattern of emptying, including determination of the duration of emptying delay associated with gastric processing of solids (lag phase).

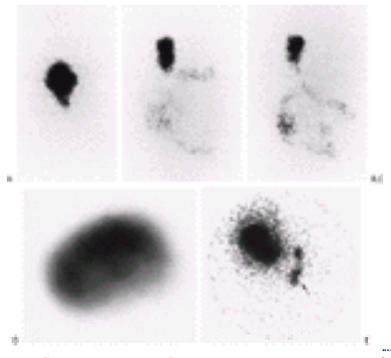

FIGURE 158-4. A 54-year-old man with history of gastroesophageal reflux disease refractory to medical therapy underwent a gastric emptying study to evaluate for a possible gastric motility disorder. Posterior abdominal images shown are from the 2nd minute (**A**), the 25th minute (**B**), and the 60th minute (**C**) of the study. There is gradual progressive clearance of tracer activity from the stomach throughout the study, with an estimated clearance half-time of 26 minutes, within the normal range. For comparison, images **D** and **E** are from liquid gastric emptying studies performed on a 56-year-old man with pyloric stenosis, the first scan before and the second three days after pyloric dilation. The initial examination (**D**) shows no emptying during the first 60 minutes of imaging (posterior image shown). Following dilation, there is substantial improvement in emptying, with activity immediately seen in the duodenum on a 1-minute posterior image (**E,** *arrow*) and gastric emptying half-time of 26 minutes.

Liquid-phase gastric emptying studies are relatively simple to perform, with 100 to 300 µCi of ^{99m}Tc-labeled colloid or indium 111 (^{111}In) diethylenetriamine pentaacetic acid (DTPA) administered in 150 to 300 cc of water, juice, or another suitable liquid, followed by imaging for 30 to 60 minutes. Normal T 1/2 is in the range of 15 to 45 minutes, but may be as short as 5 to 10 minutes. When liquid-phase emptying is abnormal, no further study may be necessary, but in most cases, examination of solid emptying is also appropriate. A variety of test meals have been used for solid gastric emptying studies, typically labeled with 300 to 1000 µCi of ^{99m}Tc colloid. As it is important that the labeled compound not dissociate or separate from the solid test meal in the stomach, one commonly used method involves injecting labeled colloid into an egg through the shell and then cooking the egg, thereby binding the radiotracer in the coagulated protein. A recent multicenter trial used a slice of liver injected at multiple sites with colloid, then fried on both sides, cut up and mixed into chicken stew for ingestion. [90] Liver pate, beef stew, and scrambled eggs have also been used in test meals. [91], [92] Solid gastric emptying studies are performed in essentially the same manner as for liquids, although an imaging acquisition of typically 60 to 120 minutes and occasionally to 3 to 4 hours may be required. Normal curves and derived half-times for gastric emptying depend on the composition (e.g., calories, fat content) and total mass of the test meal. Although efforts continue to standardize test meals (cooked egg and meat stew being most often used), sites that perform sufficient numbers of gastric emptying studies are still best served by establishing normal ranges locally with the specific meal being used to evaluate patients. Mean T 1/2 for solid gastric emptying for different size test meals ranges from 68 to 277 minutes, [90], [92] with T 1/2 usually less than 120 minutes for the smaller meals in common clinical use. [92] Simultaneous examination of liquid and solid gastric emptying can be accomplished using a dual-isotope technique, with the solid labeled with ^{99m}Tc colloid and the liquid labeled with ^{111}In DTPA. The dual-isotope technique is somewhat more physiological in its allowance for ingestion of solids accompanied by some liquid, and permits a more complete analysis of gastric motility in the same length of time required for a standard solid-only emptying study. [89], [92] As a standardized quantitative technique, serial gastric emptying studies are readily used for evaluating the effectiveness of interventions, such as procedures to relieve mechanical obstruction or medications to treat gastroparesis. [93] A baseline study is done prior to initiation of therapy, and a second study is performed subsequent to the procedure or achievement of the optimum response to drugs such as metoclopramide [94] (see Fig. 158-4). Studies using stimulators of the motilin receptors in the stomach such as erythromycin may also be useful in documenting effects of delayed gastric emptying in postsurgical patients, such as those status-postesophagectomy with gastric pull-up, [95] in whom conventional barium swallow x-rays often demonstrate no evidence of mechanical obstruction.

Gastroesophageal Reflux Gastroesophageal (GE) reflux is often identified qualitatively on the images from a conventional gastric emptying study, and a semiquantitative estimate of reflux severity can be derived from determination of the amount of activity in an esophageal region of interest. GE reflux can be quantified in a more systematic manner using an inflatable abdominal binder. Following ingestion of 300 µCi of ^{99m}Tc colloid in 300 mL acidified orange juice in the upright position, baseline images of the chest and upper abdomen are obtained to verify initial esophageal clearance of tracer activity. The patient then is fitted with the abdominal binder, positioned supine under the ?-camera, and imaged as the binder is inflated in stepwise fashion to produce incremental increases in intra-abdominal pressure. Intra-abdominal pressure required to induce GE reflux has been quantified in normal volunteers, and the control data have been used to evaluate results in symptomatic individuals. [87] In patients suspected of pulmonary aspiration secondary to GE reflux, a radiolabeled meal can be consumed in the evening before bedtime. Following a normal night of sleep, the patient is imaged to determine if radiotracer is present in the tracheobronchial tree or the lungs. Detection of activity in the respiratory system above background is objective evidence of the occurrence of aspiration. [96] This study can be repeated following medical or surgical intervention to reduce or eliminate GE reflux and aspiration to assess the effectiveness of those measures.

Esophageal Motility Nuclear medicine techniques can be used to examine esophageal motor function and esophageal transit. The patient is typically instructed to take a small quantity of ^{99m}Tc-labeled liquid into his or her mouth and then to swallow while dynamic ?-camera images of the anterior chest are obtained at a high frame rate, typically 1 to 3 images per second. Additional 15 second per frame imaging for up to 10 minutes, with a dry swallow at the beginning of each frame, may also be performed. Time-activity curves then are obtained for three segments of the esophagus (proximal, middle, and distal), and the timing and coordination of the passage of the tracer is examined. Neuromuscular and collagen-vascular diseases produce characteristic patterns of delayed tracer clearance, while diffuse esophageal spasm results in discoordinate changes in regional activity. Patient study results are commonly compared with data from normal volunteers. [97]

Bowel Motility While motility studies of the stomach and esophagus are technically straightforward because these structures are readily identified on scintigraphic images and therefore discrete regions of interest can be drawn to perform quantitative assessments, similar examinations of the small bowel and colon have proved considerably more difficult. The complex and variable anatomy and spatial orientation of the small bowel make it virtually impossible to isolate specific bowel segments with sufficient clarity to permit detailed analysis of transit times and peristaltic function. For the colon, although the anatomy is more straightforward, it may be difficult to obtain images for analysis that are not seriously compromised by interference from overlapping loops of small bowel. Investigators have nevertheless sought means to employ tracer techniques for assessing bowel motility disorders and have achieved modest success despite the technical limitations. The most well validated of these techniques use various quantitative measures of bowel transit. [89] Several different approaches have been investigated to quantify the movement of intralumenal contents between specific locations in the gut. A standard gastric emptying study can be continued for an additional few hours, and an estimate made of the arrival time of activity in the terminal ileum or cecum. Alternatively, to eliminate dispersal of labeled food throughout the bowel, tracer can be formulated in a nondigestible medium that passes unaltered through the alimentary tract, or it can be placed in a time-release capsule designed to dissolve in the distal small bowel. This latter technique uses an analytic scheme involving determination of the geometric center of colonic activity based upon the relative activity in each of four regions of the colon (ascending, transverse, descending, rectosigmoid) at specific times after ingestion of the radiotracer. From these data, “whole-gut” transit can be evaluated by comparison with results from control populations. [98] As colon or “whole-gut” motility studies usually require more than one day to complete, the

longer-lived isotope ^{111}In is typically used. [99]

Salivary Glands

The physiological behavior of the salivary glands can be studied using the radiotracer ^{99m}Tc pertechnetate, [100], [101] which is taken up by the secretory cells of the salivary glands similar to chloride or iodide anions. Following injection of 5 to 10 mCi, anterior and lateral images of the head and neck are acquired to document the location and relative function of the various glands. Dynamic acquisitions allow the generation of time-activity curves for regions of interest over the salivary glands in order to estimate rates of saliva production and excretion. Saliva secretion can also be stimulated with an acidic substance such as lemon juice to evaluate for possible effects of ductal anomalies, stones, or malignancy on gland clearance.

Inflammatory and Infectious Diseases

Labeled leukocytes are the scintigraphic agent of choice for investigating inflammatory processes involving the bowel. [102], [103] and [104] Mixed leukocyte populations are typically separated from 30 to 60 cc of blood, labeled in vitro with either ^{99m}Tc or ^{111}In, and then reinjected. However, because of differences in labeling efficiency and biodistribution, imaging techniques are usually individualized for the two radionuclides.

Imaging for ^{111}In oxine labeled leukocytes is usually performed 2 to 24 hours postinjection. Delayed imaging at 18 to 24 hours allows time for clearance of normal intravascular activity, particularly noticeable in the lungs early after reinjection, and greater accumulation of labeled leukocytes at abnormal sites, which are typically defined more clearly on later views. Imaging at 2 to 6 hours postinjection is of acceptable quality for abdominal sites where blood pool background is not a major constraint. [102]

There is increased focal uptake of labeled leukocytes at sites of infection or inflammation, the intensity of which is sometimes scored relative to activity at sites of normal uptake such as the liver or bone marrow. For increased activity seen in the bowel, it is necessary to ascertain whether the leukocyte accumulation is in the bowel wall, such as might occur in active inflammatory bowel disease or pseudomembranous colitis, or in the bowel lumen, either sloughed from a local inflammatory process, or transported from a more proximal site in the bowel or from locations such as the nasopharynx or the respiratory tract. GI bleeding or swallowed blood from hemoptysis also can result in intralumenal labeled leukocyte activity. Thus, when initial images demonstrate activity in a region of bowel, additional views are usually obtained a few hours or a day later; intralumenal activity will change its location, configuration, and intensity over time, while inflammation or infection in the bowel itself will display a relatively fixed distribution (Fig. 158-5). Bowel cleansing also can also be used to aid in determining whether activity is intralumenal or intramural.

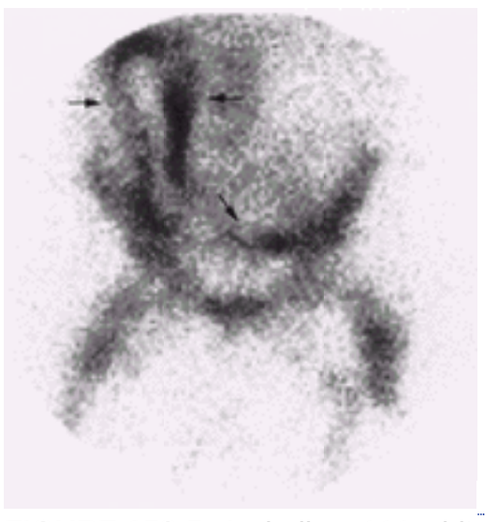

FIGURE 158-5. An indium 111 white blood cell scan was performed on a 50-year-old quadriplegic man to investigate for a source of persistent fever, bacteremia, and elevated white blood cell count. Anterior abdominal image at 24 hours postinjection unexpectedly revealed diffuse increased tracer activity throughout a somewhat redundant colon (*arrows*), which remained essentially unchanged on a follow-up image several hours later (not shown). Sigmoid colon biopsies obtained at colonoscopy several days later revealed chronic active colitis consistent with idiopathic inflammatory bowel disease.

The most common means to label leukocytes with ^{99m}Tc involves use of the brain imaging agent ^{99m}Tc exametazime (Ceretec, Amersham Health, Princeton, NJ), a lipophilic substance which crosses cell membranes with relative ease. [104], [105] The leukocyte labeling efficiency for ^{99m}Tc exametazime is lower than for ^{111}In, but the higher total dose of ^{99m}Tc that can be used compensates for this. Using 10 mCi of ^{99m}Tc exametazime, an average labeling efficiency of 60% results in a considerable gain in detected count rate compared to an injected dose of 0.3 to 1.0 mCi ^{111}In-labeled cells. Technetium 99m exametazime leukocyte imaging is usually performed 1 to 4 hours after injection, although positive scans can sometimes be obtained within 30 minutes or less. Because hepatobiliary excretion of exametazime results in the presence of nonspecific bowel activity in most patients imaged beyond 6 hours postinjection, such later delayed views are generally avoided. Results with early ^{99m}Tc exametazime-leukocyte imaging of inflammatory bowel disease may be superior to those for ^{111}In leukocytes, [106] particularly for less severe disease, where a low sensitivity for the latter agent has been reported. [107] Results for early diagnosis of acute appendicitis in patients with equivocal clinical presentations have also been promising. [108]

Other applications of labeled leukocytes in the abdomen include the identification of abscesses, both intra-abdominal and retroperitoneal, with SPECT sometimes useful for correlation with CT and MR findings. Labeled leukocyte imaging can also confirm the diagnosis of acute cholecystitis in patients with chronic or acalculous gallbladder disease.

Gallium 67 is a radionuclide which avidly binds to iron-binding proteins such as transferrin, and localizes at sites of inflammation and infection primarily due to increased capillary permeability. [109], [110] Once a common nuclear medicine imaging agent, gallium is now typically limited to studies for detecting opportunistic infections (including in the bowel) in immune-compromised patients (e.g., human immunodeficiency infection, organ transplant).

Oncologic Applications

The rapid growth of oncologic PET during the past decade has dramatically altered the role of radionuclide methods in tumor imaging. [111] Whereas nuclear medicine imaging traditionally played only a peripheral, supplementary role in evaluating patients for the presence and extent of malignancies, PET has now taken on a central role in many assessments for staging newly diagnosed tumors and evaluating patients suspected of recurrent disease. With the growth of PET, there has been a decline in use of other radionuclide procedures with established use in oncologic imaging, including gallium scans and newer studies employing radiolabeled monoclonal antibody agents. While gastroenterologic applications of PET are described in Chapter 157, the following discussion of the other still-available and potentially useful oncologic nuclear medicine procedures includes mention of those circumstances where PET would likely be the superior imaging choice.

The most commonly employed adjunctive nuclear medicine scan in oncology has historically been the ^{99m}Tc diphosphonate bone scan, which after four decades in clinical use remains the most effective imaging method for assessing the entire skeleton for malignant involvement (primary or metastatic). [112], [113] Although skeletal involvement by GI tract malignancies is less common than for tumors of the lung, breast, and genitourinary tract, the need to evaluate patients with GI tumors and signs or symptoms potentially reflecting involvement of bone periodically arises. Patients presenting with bone pain, with or without elevation of tumor markers such as carcinoembryonic antigen (CEA) or alkaline phosphatase, will typically undergo radiographic examination of the symptomatic area. Total-body bone scintigraphy, being more sensitive than plain radiographs for detection of metastases, [112], [114] is often obtained next if the radiographic study is negative or equivocal. Even in the circumstance where the radiographic or even an MR imaging examination shows definite evidence of metastatic disease, the bone scan can be helpful for assessing the extent of metastatic involvement throughout the skeletal system. In a review of a 14-year bone scintigraphy clinical database, 114a among 86 patients with history

of colorectal cancer and 37 patients with esophageal cancer evaluated primarily because of bone pain or suspicious radiographs, metastases were identified in 15 (17%) and 10 (27%) patients respectively (Fig. 158-6). These results indicate that in appropriately selected patients, the bone scan remains a useful procedure for identifying or confirming the presence of metastatic disease.

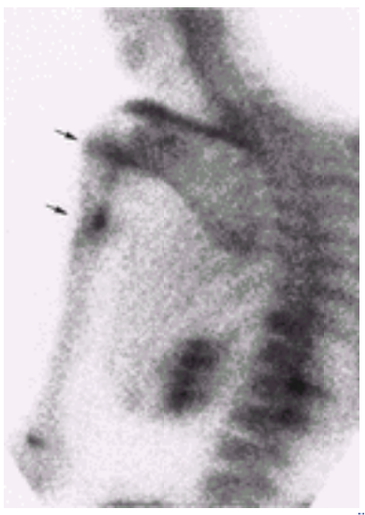

FIGURE 158-6. Bone scan images from a patient with esophageal carcinoma. Posterior oblique image of the left humerus in a 61-year-old man with persistent left shoulder and arm pain and negative radiographs of the area demonstrates foci of increased uptake at the left humeral neck and toward the medial posterior aspect of the proximal left humeral shaft (*arrows*). Metastatic esophageal carcinoma was subsequently confirmed following a pathological fracture of the proximal left humerus requiring surgical fixation.

Another compound with a long history as a tumor imaging agent is ^{67}Ga citrate, whose GI applications have included identification of hepatocellular carcinoma [115] and assessment of the extent of abdominal involvement by lymphoma. [116] Widespread availability of 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-FDG) PET has substantially reduced the role of gallium imaging, despite occasional reports of tumors with increased gallium and normal FDG uptake. [117] While gallium remains an option for sites without PET capability, it is likely that its use will continue to decline, with limitations on supply becoming more severe as production is decreased in parallel with demand.

Another category of radiopharmaceuticals for imaging of malignancy, the monoclonal antibodies, [118], [119] has not had the impact which developers at one time envisioned. In the best multicenter trials, these agents directed against specific cellular antigens have typically been able to identify primary and metastatic lesions with sensitivity and specificity less than 80%. This mediocre performance can be attributed to a number of factors, including the difficulty of producing antibodies of high specificity, the heterogeneity of tumor tissues with respect to cellular antigens, and the sometimes limited access of intravenously administered substances to viable tumor tissue. Although PET has already superceded monoclonal antibody imaging in most large centers, the two U.S. Food and Drug Administration (FDA)-approved agents with applications to gastroenterology are briefly described subsequently.

Antibody agents for diagnostic usage fall into two broad categories, whole antibodies and antibody fragments. The former have a relatively long intravascular residence time, and are primarily cleared by the liver and excreted via the hepatobiliary system. An approved agent in this category with GI applications was satumomab (Oncoscint, Cytogen, Princeton, NJ), an anti-TAG (tumor-associated glycoprotein)-72 antibody labeled with ^{111}In which was indicated for detection of colorectal carcinoma (sensitivity and specificity 69% and 77%, respectively). [3] However, distribution of this agent was discontinued at the end of 2002. Antibody fragments (usually Fab) are smaller protein structures that are cleared more rapidly from the circulation and eliminated primarily via the kidneys, although some liver uptake and gut excretion may occur. The approved agent in this category of relevance to gastroenterology is the ^{99m}Tc labeled anti-CEA antibody arcitumomab (CEA-Scan, Immunomedics, Morris Plains, NJ), a compound with reported sensitivity for recurrent or metastatic colorectal carcinoma of 78% for the abdomen outside the liver and 73% for pelvic lesions. [4] For metastases in the liver, anti-CEA antibody imaging may demonstrate foci of increased or decreased uptake, with the photopenic defects (sometimes surrounded by a rim of increased activity) seen more often with larger lesions, likely as a result of inadequate delivery of the agent to hypoperfused or necrotic tissue. [4], [119] Reports of discordant CEA-Scan and ^{18}F-FDG imaging (one positive, the other negative) leave open a possible continuing role for antibody imaging in tumors with low metabolic activity.

A category of radiopharmaceuticals that has moved into the forefront of development for new nuclear medicine imaging agents is the radiolabeled peptides. As these compounds are of nonbiologic origin, they have several advantages over monoclonal antibodies, including greater flexibility in the molecular design of targeted compounds and lower risk for potential immune-mediated complications. Peptide agents can be designed to bind to specific cell surface receptors, creating possibilities for not only targeted diagnostic applications, but also therapeutic applications. The peptide-imaging agent of particular interest in gastroenterologic oncology is ^{111}In pentetreotide (OctreoScan, Mallinckrodt, Hazelwood, MO), whose primary component is octreotide, a somatostatin analog which binds to cell surface somatostatin receptors.

OctreoScan is used for imaging neuroendocrine tumors whose cells possess somatostatin receptors, including endocrine pancreatic tumors such as gastrinomas, insulinomas, islet cell tumors, glucagonomas, and carcinoid tumors. [120], [121], [122], [123], [124], [125], [126], [127], [128], [129] and [130] Somatostatin receptor imaging has demonstrated sensitivities as high as 90% in patients with gastrinomas and 80% to 100% in patients with carcinoid tumors [131] (Fig. 158-7). Octreotide imaging has proven particularly valuable for detection of functioning occult metastases, frequently outperforming conventional anatomic imaging methods such as ultrasound, CT, and MR imaging in these often difficult localizations. [126], [129], [130] As a further aid in this process, an intraoperative ?-detector can be used to localize sites of increased labeled octreotide uptake, thereby facilitating surgical removal of small deposits of tumor tissue. [132], [133]

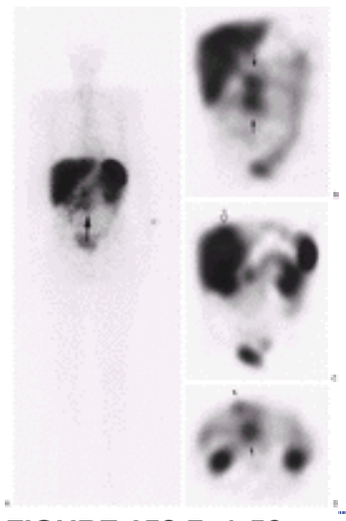

FIGURE 158-7. A 53-year-old man with symptoms suggestive of a carcinoid tumor, including progressively worsening diarrhea and facial and extremity flushing, and abnormalities on abdominal computed tomography (CT), underwent indium 111 octreotide scintigraphy as part of preoperative evaluation. Anterior whole-body image (**A**) shows normal physiological uptake in the liver, spleen, kidneys, colon, and bladder, and abnormal uptake in the right mid-abdomen (*arrow*). This abnormality is better defined on coronal single photon emission computed tomography (SPECT) image (**B**), and correlated with mesenteric deposits of tumor seen on CT. A slightly

more posterior coronal image (**C**) demonstrates a focus of increased uptake superiorly in the liver (*open arrow*), while an axial SPECT image (**D**) shows a second liver abnormality anteriorly in the right lobe (*arrowhead*), as well as the mesenteric mass (*arrow*). The two liver foci corresponded to hypervascular lesions seen on CT. At exploratory laparotomy, a cecal carcinoid with liver and mesenteric metastases was found.

NONIMAGING USES OF RADIOTRACERS

While most routine uses of radiotracers in nuclear medicine involve imaging of internal organ anatomy and physiology, some nonimaging uses of radiotracers can also provide valuable diagnostic information, several of which relate to the GI tract.

The Schilling test is used to ascertain whether vitamin B_{12} deficiency is the result of intrinsic factor deficiency or intestinal malabsorption of other causes. In part I of the test, Vitamin B_{12} labeled with an isotope of cobalt is administered orally in a capsule, and the presence of adequate intrinsic factor in the stomach is judged based upon the amount of labeled B_{12} that is absorbed and excreted in the urine. In an individual with normal secretion of intrinsic factor by the gastric parietal cells, more than 9% of an ingested dose of labeled B_{12} will be excreted in the urine in 24 hours. If a low amount of labeled B_{12} is measured in a 24-hour urine specimen, especially if the amount is less than 4% of the ingested dose, part II of the test is performed, which involves a second 24-hour urine collection following ingestion of radiolabeled B_{12} and intrinsic factor together. If B_{12} malabsorption reflects pernicious anemia/intrinsic factor deficiency, there will be normal B_{12} excretion on the second part of the test. If, on the other hand, B_{12} deficiency is secondary to malabsorption, such as due to bacterial overgrowth or a mucosal deficiency in the terminal ileum, the amount of labeled B_{12} excreted in the 24-hour urine collection will remain low. Both parts of the Schilling test can also be done in one day via simultaneous administration of two different forms of B_{12}—one labeled with cobalt 58 and with no intrinsic factor, the other labeled with cobalt 57 and also containing intrinsic factor. The 24-hour urine collection is performed, and dual isotope measurements are made. The part I Schilling test is sometimes repeated after treatment of the presumed cause of B_{12} deficiency to determine if the mucosal effects of this deficiency have been reversed. This follow-up study is sometimes called a Schilling test part III.

Bacteria that produce high levels of urease, such as *Helicobacter pylori,* can result in the breakdown of ingested C-14 urea, with production of C-14-labeled carbon dioxide which can be quantified in exhaled gases. The C-14 urea breath test is now widely used to assess for the presence and severity of *H pylori* infection.[134] The commercial test kit consists of a capsule containing 1 µCi C-14 labeled urea, which is ingested by the patient, and a Mylar balloon for collecting a sample of exhaled air (PYtest, Ballard Medical/Kimberly Clark, Draper, UT). C-14 activity is determined by counting the sample in a liquid scintillation counter, with a high value (typically =200 disintegrations/min) strongly indicative of the presence of *H pylori*.

SUMMARY

Nuclear medicine applications in gastroenterology take advantage of the quantitative and physiologically relevant information provided by this relatively noninvasive modality. Future improvements in ?-cameras and SPECT systems, advances in radiopharmaceutical development, and expanded availability of PET should insure that nuclear medicine remains at the forefront in the imaging of physiological processes and the new field collectively described as molecular medicine.

CHAPTER 159

Kyung J. Cho

ANGIOGRAPHY

Since the introduction of the newer imaging modalities (including ultrasound [US], computed tomography [CT], and magnetic resonance [MR] imaging), diagnostic angiography has been used less frequently in the evaluation of gastrointestinal (GI) disease. Angiography is currently used to establish a specific diagnosis of mesenteric vascular disease, to localize GI bleeding, to evaluate portal hypertension, to assess tumor extension, to demonstrate traumatic arterial injury, and to obtain the necessary vascular information before percutaneous or surgical intervention. This chapter reviews the vascular anatomy as well as the techniques and role of angiography in the diagnosis and treatment of GI disease.

TECHNICAL CONSIDERATIONS

Conventional film-screen angiography has been largely replaced by digital subtraction angiography (DSA) in GI angiography. DSA requires a smaller amount of dilute contrast medium, causes less discomfort to patients, and reduces the risks for renal toxicity and fluid overload. DSA images may be viewed on a video monitor during and after injection of contrast material.

Two types of iodinated contrast material have been used for angiography: the conventional high-osmolar (ionic) contrast agent has been replaced by the low-osmolar (nonionic) contrast agent. The nonionic contrast agents are more expensive but cause less pain and burning sensation. Patients with a history of contrast media allergy and renal failure benefit from the use of low-osmolar contrast media. [1], [2] and [3]

Carbon dioxide (CO_2) gas has been used as a contrast agent. CO_2 is about 20 times more soluble than air, allowing the intravascular injection of the gas without causing clinically significant embolism. CO_2 angiography is useful for patients with a history of contrast allergy or renal failure. [4] CO_2 can be used as a contrast agent for visualization of the abdominal aorta; renal, mesenteric, and peripheral arteries; and portal and hepatic veins. CO_2 is used as a contrast agent for the diagnosis of GI bleeding, mesenteric arterial occlusive disease, and wedged hepatic venography for visualization of the portal vein. CO_2 is also used as a contrast agent to guide a variety of vascular interventions. [5], [6] and [7] Gadolinium-based contrast medium is used as an alternative contrast to iodinated contrast material for patients with a history of contrast hypersensitivity or renal failure. [8], [9]

Percutaneous Catheterization

Angiography is performed using the percutaneous technique introduced by Seldinger in 1953. [10] The arteries used for GI angiography are the femoral, axillary, and brachial. Of these, the femoral approach is preferable. When the needle is introduced into the artery, the guidewire is inserted through the needle into the abdominal aorta, and a diagnostic catheter is introduced over the guidewire. The technique used for femoral vein catheterization is similar to that used for arterial introduction. The guidewire is inserted into the inferior vena cava, and the catheter is advanced over the guidewire. If thrombosis has occurred in the femoral veins or inferior vena cava, the catheter is introduced by way of an antecubital, brachial, or jugular vein.

General Angiographic Approach

On the day of the procedure, the patient is allowed to take fluids by mouth. Patients usually receive conscious sedation with a narcotic analgesic (Fentanyl) and a benzodiazepine central nervous system depressant (Versed) immediately before and during the procedure. Biplane aortography is performed using a pigtail catheter for the evaluation of the origins of the celiac and superior mesenteric arteries. Otherwise, visceral angiography begins with catheterization of the celiac and superior mesenteric arteries. Selective catheterization of the branches of the visceral arteries is performed as needed: splenic, dorsal pancreatic, and gastroduodenal arterial catheterization for the evaluation of pancreatic disease, and left gastric arterial catheterization for gastric bleeding.

Visualization of the portal venous system is essential in angiographic study for evaluating intra-abdominal masses, vascular diseases, and portal hypertension. The presence or absence of a venous abnormality plays an important role in determining whether the arterial abnormality is neoplastic or arteriosclerotic in nature. Arterial involvement by a neoplasm is usually associated with narrowing or occlusion of the adjacent vein. Visualization of the portal vein requires the injection of a large volume of contrast medium into the superior mesenteric or splenic artery following the intra-arterial injection of 25 to 50 mg of the vasodilator tolazoline.

Under normal conditions, puncture site hemostasis can be achieved with manual compression for 5 to 10 minutes after percutaneous transarterial angiography. No pressure dressing is required. The patient may resume a normal diet after the procedure and ambulate after 4 hours of bed rest.

Transhepatic Portal Vein Catheterization

Percutaneous transhepatic portal vein catheterization [11] is a useful method for evaluating portal hemodynamics, localizing occult islet cell tumors, controlling gastroesophageal variceal bleeding, and performing balloon angioplasty of the portal vein stenosis and recanalization of occluded portal vein. Before puncture of the portal vein, portal vein patency is verified by US, CT, or MR angiography. The venous phase of a celiac or superior mesenteric angiogram is also useful in visualizing the portal vein. Wedged hepatic venography with CO_2 may be performed to visualize the portal vein. After the procedure has been completed, the catheter track is sealed near the hepatic capsule with a gelatin sponge or coil to arrest bleeding from the puncture site.

Transjugular Portal Vein Catheterization

The transjugular approach to the portal venous system is commonly used to create a transjugular intrahepatic portosystemic shunt (TIPS). [12], [13] The right internal jugular vein is punctured under US guidance. A 10-French vascular sheath is advanced into the right atrium. A 16-gauge Colapinto needle is used to puncture the right portal vein near the portal vein bifurcation under fluoroscopic control. When the portal vein is entered, a guidewire is introduced into the portal vein. Over the guidewire a 5-French catheter is advanced into the portal vein, and manometry is performed. For a TIPS procedure, the parenchymal tract is dilated with an angioplasty balloon catheter and covered with metallic stents.

Balloon Occlusion Hepatic Venography

The balloon occlusion method is useful in hepatic venography, facilitating measurement of the wedged hepatic venous pressure. Injection of contrast medium (4 to 5 mL/second for a total volume of 10 to 20 mL) or CO_2 (30 to 50 cc) into the hepatic vein distal to balloon occlusion results in visualization of the portal vein. [14], [15] and [16]

Splenoportography

Since the advent of the imaging modalities and the development of indirect portography (arterial portography), splenoportography is rarely performed. CO_2 is a useful contrast agent for splenoportography. Because of the low viscosity, the gas can be injected using a 22- or 25-gauge needle. Because of the relative safety of the small needle and the lack of the nephrotoxicity of the CO_2, CO_2 splenoportography should be useful in pediatric patients.

RISKS AND CONTRAINDICATIONS

The overall complication rates of transfemoral and transaxillary angiography are 1.73% and 3.29%, respectively. [17] The complications of transfemoral angiography include puncture site complications, complications related to catheter manipulation, contrast material reactions, contrast material toxicity (renal failure), and systemic complications (cardiac and neurologic). Brachial nerve injury is the most serious complication of transaxillary artery catheterization. Nerve injury is less likely to occur with a brachial artery puncture because the brachial plexus is not as close to the brachial artery as it is to the axillary artery. The use of intra-arterial nitroglycerin and calcium-channel blocking drugs is helpful in preventing arterial spasm. Mortality related to the angiographic procedures other than reactions to contrast agents is extremely rare.

The overall mortality associated with the intravenous use of the ionic contrast agents is 1 in 40,000. [18] The risk factors involved in the use of contrast material are renal failure, a history of previous reactions (major and minor), and allergic diathesis. Before the administration of contrast medium for angiography, risk factors for contrast nephropathy should be identified. These include preexisting renal insufficiency, diabetes mellitus, intravascular volume depletion, congestive heart failure, repeated contrast procedures, and multiple myeloma. [19] Recommendations for prevention of contrast nephropathy include use of alternative contrast such as gadolinium-based contrast or CO_2, discontinuation of potential nephrotoxic agents 48 to 72 hours before the procedure, adequate hydration before and after the procedure, use of low-osmolar or iso-osmolar contrast material, and use of minimal volume of contrast material. Pretreatment with 32 mg of methylprednisolone 12 and 2 hours before contrast administration has been advocated to prevent reaction to contrast agents for patients with a history of this complication.

There are no absolute contraindications to GI angiography. Relative contraindications include severe coagulopathy, recent myocardial infarction, congestive heart failure, renal failure, and pregnancy. Patients undergoing brachial or axillary artery puncture or a percutaneous transhepatic procedure are at increased risk for hemorrhagic complications in the presence of coagulopathy or hypertension. Depending on the urgency and nature of the procedure, coagulopathies should be reversed with appropriate treatment.

VASCULAR ANATOMY OF THE ABDOMINAL VISCERA

A thorough knowledge of vascular anatomy of the abdominal viscera is essential in performing and interpreting an angiogram and in planning therapeutic intervention for GI disease.

Arterial Vasculature

The abdominal viscera receive their blood supply from the celiac, superior, and inferior mesenteric arteries. The superior mesenteric artery arises from the ventral aspect of the abdominal aorta 1 to 2 cm below the celiac and above the renal artery. It courses anterior to the third portion of the duodenum and the left renal vein into the mesentery. The celiac artery gives off the left gastric, splenic, and common hepatic arteries (Fig. 159-1). Occasionally, the inferior phrenic or dorsal pancreatic artery originates from the celiac axis. The inferior phrenic artery may arise from the left gastric artery or renal artery, or directly from the aorta. One or more branches of the celiac artery may originate from sources other than the celiac axis: the left gastric artery from the aorta, the splenic artery from the superior mesenteric artery, and the hepatic artery from the aorta, superior mesenteric artery, gastroduodenal artery, or left gastric artery.

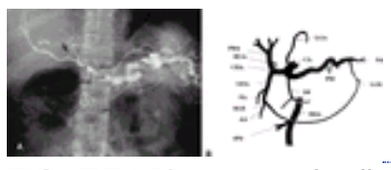

FIGURE 159-1. Normal celiac trunk. **A:** Celiac arteriogram showing standard arterial anatomy. The left gastric (*LGA*), splenic (*SA*), and common hepatic (*CHA*) arteries arise from the celiac trunk (*CA*). The proper hepatic artery (*PHA*) divides into the right and left hepatic arteries. The middle hepatic artery (*arrow*) arises from the right hepatic artery. The right gastric artery (*RGA*) arises from the PHA. **B:** Line drawing of branches of the celiac trunk. *DP,* dorsal pancreatic artery; *PM,* pancreatica magna artery; *LGE,* left gastroepiploic; *PA,* posterior arcade; *AA,* anterior arcade; *RGE,* right gastroepiploic; *IPD,* inferior pancreaticoduodenal; *SMA,* superior mesenteric artery; *GDA,* gastroduodenal artery.

The common hepatic artery divides into the proper hepatic and gastroduodenal arteries. The proper hepatic artery ascends in the hepatoduodenal ligament for a variable distance and divides into a right and a left hepatic artery. The right hepatic artery usually courses behind the common hepatic duct and divides into an anterior and posterior segmental artery. Each of the segmental arteries gives off arterial branches to the superior and inferior subsegments of the liver. The left hepatic artery divides into a medial segmental (middle hepatic) and a lateral segmental artery. Each segmental artery gives rise to superior and inferior subsegmental branches. The middle hepatic artery may arise from a right hepatic, a left hepatic, or a proper hepatic artery. The proper hepatic artery also gives off arterial branches to the bile duct, the portal vein (vasa vasorum), and the subcapsular branches. These nonparenchymal branches may provide collateral circulation to the liver in hepatic arterial occlusion distal to the gastroduodenal artery.

In about half of cases, one or more branches of the hepatic artery arise from sources other than the celiac-hepatic artery. Two types of aberrant hepatic artery may occur: replaced (the origin of the artery is “replaced” and the aberrant artery serves as a substitute), or accessory (additive to the celiac-hepatic artery). According to Michels’ dissection of 200 cadavers, [20] aberrant right hepatic arteries occur in 26% of patients (replaced, 18%; accessory, 8%), most frequently originating from the superior mesenteric artery (17%); aberrant left hepatic arteries occur in 27% of patients (replaced, 15.5%; accessory, 11.5%), most frequently from the left gastric artery (13%).

The gastroduodenal artery usually originates from the common hepatic artery. In 25% of the population, it may have an aberrant origin. The three main branches originating from the gastroduodenal artery are the posterior superior pancreaticoduodenal (posterior arcade), anterior superior pancreaticoduodenal (anterior arcade), and right gastroepiploic arteries. The posterior and anterior arcade arteries join inferomedially and anastomose with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The gastroduodenal artery supplies arterial blood to the stomach, duodenum, pancreas, and bile duct. In the presence of a celiac artery occlusion, the pancreaticoduodenal arcade arteries function as the major collateral pathway to the liver from the superior mesenteric artery. Normally, the gastroduodenal blood flows away from the liver (hepatofugal), but with stenosis or occlusion in the celiac or common hepatic artery, the blood flow is reversed (hepatopetal). Preoperative recognition of flow reversal in the gastroduodenal artery is important in planning resection of pancreatic head tumors and for placement of a hepatic artery infusion catheter for chemotherapy.

The superior mesenteric artery supplies the pancreas, duodenum, small intestine, cecum, ascending colon, and proximal half of the transverse colon. The inferior pancreaticoduodenal and occasionally the dorsal pancreatic arteries originate from the proximal portion of the superior mesenteric artery. The other branches of the superior mesenteric artery are the middle colic, jejunal, ileal, right colic, and ileocolic arteries (Fig. 159-2). A true right colic artery is an inconstant branch (present in 13% of people), and the ascending colon often receives its blood supply from a paracolic arcade fed from the middle and ileocolic arteries. [21] However, Michels and colleagues [22] asserted that any branch proximal to the paracolic arcade that supplies the ascending colon is a right colic artery. With this definition, the right colic artery arises from the superior mesenteric artery in 38%, from a common right colic–middle colic trunk in 52%, and from an ileocolic–right colic trunk in 8% of individuals. The right colic artery is absent in 2% of individuals, and an accessory right colic artery is present in 8% of individuals.

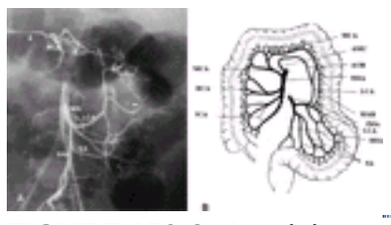

FIGURE 159-2. Arterial supply to the colon. **A:** Arterial phase of an inferior mesenteric angiogram. The inferior mesenteric artery (*IMA*) gives off the left colic (*LCA*), sigmoidal (*SA*), and superior hemorrhoidal (*SHA*) arteries. The middle colic (*MCA*) branch of the superior mesenteric artery anastomoses with the left colic branch of the inferior mesenteric artery through the marginal artery of Drummond (*arrowheads*). Opacification of the middle colic artery is due to forceful injection of contrast medium into the inferior mesenteric artery. **B:** Line drawing of the arterial supply to the colon. *RCA,* right colic artery; *ICA,* ileocolic artery; *AOR,* arc of Riolan; *MCA,* middle colic artery; *SMA,* superior mesenteric artery; *LCA,* left colic artery; *IMA,* inferior mesenteric artery; *SHA,* superior hemorrhoidal artery; *SA,* sigmoidal artery; *AMC,* accessory middle colic artery; *MAR,* marginal artery of Drummond.

The inferior mesenteric artery arises from the anterolateral aspect of the aorta near the level of the L3-4 interspace and courses caudally and to the left for up to 5 cm before giving off the left colic artery (see Fig. 159-2). The ascending branch of the left colic artery supplies the descending colon and a variable amount of the splenic flexure. The inferior mesenteric artery gives off several additional branches to the descending and sigmoid colon before terminating in the superior hemorrhoidal artery. The inferior mesenteric artery communicates through the left colic–middle colic anastomosis to the superior mesenteric artery. It also communicates through the superior hemorrhoidal–middle and inferior hemorrhoidal arterial anastomoses to the internal iliac artery. They function as collaterals in mesenteric arterial or distal aortic occlusion.

Portal Venous System

The portal vein is formed by the junction of the splenic and superior mesenteric veins behind the head of the pancreas (Fig. 159-3) and ascends toward the hepatic hilus in the hepatoduodenal ligament, dorsal and to the left of the bile duct, and to the right of the hepatic artery. The portal vein is joined by the left gastric, right gastric, posterior superior pancreaticoduodenal, and cystic veins. These tributaries provide the portosystemic collaterals in patients with cirrhosis and portal hypertension. The right branch of the portal vein divides into the anterior and posterior segmental branches. The left portal branch divides into the superior and inferior subsegmental branches after giving off branches to the caudate and quadrate lobes. The umbilical vein joins the left portal vein at its bifurcation into the subsegmental branches. It is normally obliterated but may be recanalized in the presence of portal hypertension. The inferior mesenteric vein joins the splenic vein or, less frequently, the superior mesenteric vein. Portosystemic collaterals develop from the inferior mesenteric vein through the superior hemorrhoidal vein to the branches of the internal iliac vein and through the retroperitoneal vein to the inferior vena cava.

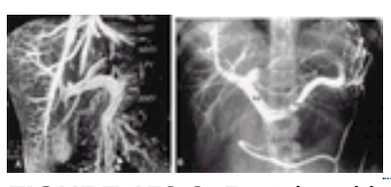

FIGURE 159-3. Portal and hepatic veins. **A:** Magnetic resonance (MR) angiography and three-dimensional contrast MR venography. The celiac and superior mesenteric arteries were normal (not shown). Imaging of the upper abdomen in the coronal plane was performed after intravenous administration of gadolinium. The superior mesenteric, portal, and hepatic veins are visualized. *SMV,* superior mesenteric vein; *MPV,* main portal vein; *RPV,* right portal vein; *LPV,* left portal vein; *RHV,* right hepatic vein; *LHV,* left hepatic vein; *MHV,* middle hepatic vein. **B:** Percutaneous transhepatic splenoportogram with injection of contrast medium into the proximal splenic vein. *LG,* left gastric vein; *GE,* gastroepiploic vein; *SV,* splenic vein; *PV,* portal vein. Venous anastomoses are seen between the short gastric and left

gastric veins and between the left and right gastroepiploic veins.

The portal venous system receives venous blood from the GI tract, the pancreas, the spleen, the gallbladder, and the omentum. Normally, the portal vein blood flows toward the liver (hepatopetal). Reversal in flow (hepatofugal) in any tributaries of the portal venous system indicates the presence of portal hypertension; visualization of the coronary vein or inferior mesenteric vein in the portal venous phase of a superior mesenteric angiogram indicates reversal in flow of these veins functioning as portosystemic collaterals. Reversal of portal vein flow may be partial or complete. Partial reversal of portal flow may occur in the extrahepatic or intrahepatic branches of the portal venous system. Complete reversal of the intrahepatic portal flow may occur in some patients with severe cirrhosis, hepatic vein obstruction, surgical portosystemic shunts, and TIPS. In such cases, the portal vein is the principal outflow conduit of the liver, and the hepatic artery blood leaves the liver through the portal vein. Blood flow direction in the intrahepatic and extrahepatic portal veins can be assessed by Doppler US, direct transhepatic portal vein catheterization, superior mesenteric and celiac angiography, and wedged hepatic venography. When the main portosystemic collateral develops from the umbilical vein, the extrahepatic portal blood flow can be hepatopetal in the presence of hepatofugal intrahepatic portal flow.

CT, US, and MR venography can be used to visualize accurately the portal venous system. [23], [24] and [25] The portal and hepatic venous imaging can be obtained immediately after MR angiography with gadolinium enhancement for arterial examination (see Fig. 159-3). The method is useful when a TIPS procedure, liver transplantation, or resection of intra-abdominal tumors is contemplated.

Hepatic Veins

The hepatic veins begin in the center of the hepatic lobules as intralobular veins. These veins join together to form sublobular veins. The hepatic veins are intersegmental or interlobar in course: the right hepatic vein lies in the intersegmental fissure of the right hepatic lobe, dividing it into the anterior and posterior segments; the middle hepatic vein lies in the interlobar fissure; and the left hepatic vein lies between the medial and lateral segments of the left hepatic lobe. The hepatic veins converge posteriorly and run near the hepatic capsule before emptying into the inferior vena cava (see Fig. 159-3).

The accessory hepatic veins, which originate from the right hepatic and caudate lobes, are small and empty into the inferior vena cava between the main hepatic and renal veins. They function as collaterals in hepatic vein occlusion and occlusion of the hepatic portion of the inferior vena cava. Diagnostic imaging of the hepatic veins may be obtained by spiral CT scanning, [26] US, [27] or MR angiography. [28]

ARTERIAL DISEASE

Arteriography remains the gold standard in the diagnosis of visceral arterial disease. It can provide a specific diagnosis and information on the vascular anatomy and arterial hemodynamics.

Acute Mesenteric Ischemia

Angiography is the most useful diagnostic examination for acute mesenteric ischemia and should be performed urgently (Fig. 159-4). After a lateral aortogram with a pigtail catheter has been obtained, celiac and superior mesenteric arteries are catheterized and injected with contrast medium. When colonic ischemia is suspected, an inferior mesenteric arteriogram is performed. When the celiac, superior, and inferior mesenteric arteries are occluded, the collateral blood supply to these arteries comes primarily from the pelvic branches of the internal iliac arteries through the inferior and middle hemorrhoidal–superior hemorrhoidal arterial anastomoses. Collaterals to the superior hemorrhoidal artery from the middle and inferior hemorrhoidal arteries can be demonstrated by injecting contrast medium into the distal abdominal aorta or internal iliac arteries.

FIGURE 159-4. Superior mesenteric artery embolus. Superior mesenteric angiogram in an elderly woman with atrial fibrillation and abdominal pain. There is an embolus in the superior mesenteric artery (*black arrow*) distal to the second jejunal artery. A small embolus is seen in the jejunal artery (*arrowhead*). The distal mesenteric branches reconstitute through collaterals from the middle colic (*open black arrow*) and jejunal arteries (*open white arrow*).

Acute mesenteric ischemia may be occlusive or nonocclusive in type. The etiology of occlusive mesenteric ischemia includes embolism, atherosclerotic plaques, aortic dissection, neoplasms, and vasculitis. Arteriography can accurately identify the level of occlusion and evaluate collateral circulation. In superior mesenteric artery embolism, the occlusion may be proximal or distal to the middle colic artery. Arteriosclerosis usually involves the origin of the superior mesenteric artery, allowing collateral development through the marginal artery from the inferior mesenteric artery. If the inferior mesenteric artery is occluded, collateral circulation may originate from the middle and inferior hemorrhoidal arteries of the internal iliac arteries.

Nonocclusive mesenteric ischemia is caused by a significant reduction in mesenteric blood flow secondary to cardiac failure or hypovolemic shock. The typical angiographic findings include diffuse mesenteric arterial constriction, slowing of mesenteric arterial flow, and decreased intestinal mucosal staining. Intravenous glucagon or intra-arterial infusion of papaverine into the superior mesenteric artery through a percutaneous catheter is used to relieve mesenteric vasoconstriction.

Colonic Ischemia

Colonic ischemia may be caused by decreased perfusion to the bowel in a low-flow state or by surgical ligation of the inferior mesenteric artery during abdominal aortic reconstruction or abdominoperineal resection surgery. [29] The angiographic findings may be nonspecific: in the early stage, the mesenteric arteries are constricted, and blood flow is slowed with decreased parenchymal vascularity; in the late stage, the colon may appear hypervascular with prominent intramural arteries and increased accumulation of contrast material in the wall of the bowel. Preoperative angiography is necessary to assess the mesenteric circulation because ligation of the inferior mesenteric artery in the patient with superior mesenteric artery stenosis may result in mesenteric ischemia.

Intestinal Angina

At least two of the three splanchnic arteries usually have significant occlusive disease before the syndrome of intestinal angina occurs. [30] Duplex US with spectral analysis is used for screening patients thought to have chronic mesenteric artery occlusive disease. Gadolinium-enhanced three-dimensional (3D) MR angiography is sensitive in assessing patency of the origins of the celiac and superior mesenteric arteries, but its resolution is inadequate for evaluation of mesenteric artery branch stenosis. [31] Demonstration of a patent superior mesenteric artery or an insignificant stenosis of the superior mesenteric artery with patent celiac artery should exclude

the diagnosis of chronic mesenteric ischemia. [32]

Celiac Axis Compression

Celiac axis compression syndrome (median arcuate compression syndrome) is controversial as a cause of abdominal pain. The celiac axis may be narrowed or, in severe cases, occluded by the median arcuate ligament of the diaphragm. Surgical correction of the lesion by decompression or reconstruction of the vessel usually ameliorates the pain. Because balloon dilation is not helpful in eliminating the compression, stent placement is required. [33] Celiac axis stenosis frequently is an incidental finding, with a reported prevalence of 12% to 49%. [34], [35] Lateral aortogram demonstrates a concave impression on the cranial aspect of the celiac axis. The compression usually is accentuated during deep expiration. A superior mesenteric angiogram demonstrates collateral circulation to the hepatic and splenic arteries through the gastroduodenal and pancreatic arcade arteries from the superior mesenteric artery.

Superior Mesenteric Artery Syndrome

The superior mesenteric artery can compress the third portion of the duodenum, causing duodenal obstruction. Such compression is most often found in patients with chronic immobilization with weight loss and a body cast. [36], [37] The upper GI barium examination shows a characteristic oblique indentation toward the right lower quadrant on the third portion of the duodenum, corresponding to the course of the superior mesenteric artery. A narrow aortomesenteric angle corresponding to the site of obstruction is usually found on a lateral aortogram.

Vasculitis

The angiographic findings vary with the type of vasculitis. In polyarteritis nodosa, celiac and superior mesenteric angiograms demonstrate occluded small- and medium-sized arteries and microaneurysms (Fig. 159-5). In ergot or digitalis toxicity, the mesenteric artery branches are narrowed or occluded with collaterals. Angiography is the most sensitive method of visualizing microaneurysms. The angiographic examination should include the renal, celiac, and mesenteric arteries.

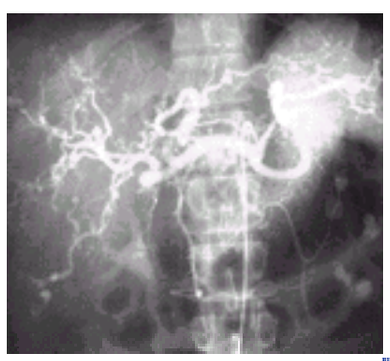

FIGURE 159-5. Multiple microaneurysms in polyarteritis nodosa. Arterial phase of a celiac angiogram shows numerous aneurysms involving the hepatic and pancreatic arteries.

Splanchnic Artery Aneurysms

Splanchnic artery aneurysms and pseudoaneurysms are rare and often found incidentally during angiographic studies for other indications. Angiography usually is necessary to identify the exact site of the aneurysm and its relationship to adjacent vascular structures as well as to plan surgical resection or embolization to prevent catastrophic hemorrhage. [38] Aneurysms occur in virtually all splanchnic arteries.

Splenic artery aneurysms account for 60% of all visceral artery aneurysms. [39] They occur four times more frequently in women than in men and are multiple in 20% of patients. Causes include atherosclerosis, medial fibrodysplasia, multiple pregnancies, pancreatitis, portal hypertension, polyarteritis nodosa, Ehlers-Danlos syndrome, and trauma. In portal hypertension, aneurysms tend to occur at the bifurcation of the intrasplenic branches of the splenic artery. Most atherosclerotic splenic artery aneurysms are asymptomatic, and calcified aneurysms less than 2 cm in diameter require no treatment. On the other hand, aneurysms occurring in pregnant women and those associated with pancreatitis require treatment because of their propensity to bleed. Splenic artery aneurysms can be treated with embolization by the transcatheter approach or percutaneous puncture.

The hepatic artery is the second most common site for splanchnic aneurysm, accounting for 20% of all splanchnic aneurysms. [39] Most hepatic pseudoaneurysms are traumatic in origin and are secondary to blunt or penetrating abdominal trauma, liver biopsy, or the placement of a transhepatic biliary drainage catheter or hepatic arterial infusion catheter. Most spontaneous aneurysms occur in the common hepatic or right hepatic artery. The potential complications of the hepatic artery aneurysms are bleeding into the bile duct or peritoneal cavity and rupture into the portal vein.

Mesenteric aneurysms are arteriosclerotic and may cause GI bleeding or mesenteric ischemia. Celiac axis aneurysms account for 4% of all visceral aneurysms and should be differentiated from pseudocysts when encountered during US or unenhanced CT scanning. A lateral aortogram is necessary to confirm the diagnosis of aneurysms arising from the origins of the celiac and superior mesenteric artery.

Gastroduodenal and pancreatic arterial aneurysms are associated with pancreatitis and pseudocysts. They may cause GI and intraperitoneal hemorrhage. Aneurysms rarely rupture into the pancreatic duct or a pseudocyst. Contrast-enhanced CT usually differentiates pseudocysts and aneurysms. Angiography is required to delineate the vascular anatomy and the exact origin of the aneurysm before surgical treatment or transcatheter embolotherapy.

Abdominal Trauma

Most traumatized patients require radiologic studies to assess the extent of the injury. CT is the initial study used for the evaluation of abdominal trauma. Angiography is indicated to determine the exact site and extent of vascular injury after CT has demonstrated evidence for vascular injury or when a penetrating injury has occurred in the vicinity of major vessels.

VENOUS DISEASE

Occlusion of the portal, mesenteric, splenic, and hepatic veins may be asymptomatic or associated with ascites, hepatic failure, or GI hemorrhage. The newer imaging modalities can diagnose occlusion of the portal and splenic vein by demonstrating intra-abdominal varices and aneurysms in the portal venous system. [24], [40] Duplex scanning is useful in the assessment of patency and direction of blood flow of the portal vein and portosystemic shunts. The portal venous phases of the celiac and superior mesenteric angiograms are used to evaluate portal vein occlusion and aneurysm. An inferior venacavogram and hepatic venogram are performed in patients with suspected Budd-Chiari syndrome.

Portal Vein Occlusion

Angiographic findings include large collateral veins originating from the superior mesenteric vein, ascending in the hepatoduodenal ligament in the venous phase of the superior mesenteric angiogram (Fig. 159-6). The collateral vessels reconstitute the patent intrahepatic portal vein. If the intrahepatic portal venous branches are occluded, the collateral vessels continue to run along the intrahepatic bile ducts, giving the appearance of railroad tracks. [41] In mesenteric vein thrombosis, numerous tiny collateral veins are demonstrated throughout the mesentery without visualization of the superior mesenteric vein in the venous phase of the superior mesenteric

angiogram.

FIGURE 159-6. Portal vein occlusion. Portal venous phase of a superior mesenteric angiogram (oblique view) demonstrates tortuous venous collaterals (*arrow*) running along the hepatoduodenal ligament adjacent to the occluded portal vein. The collateral veins reconstitute intrahepatic portal venous branches. (From Reuter SR, Redman HC, Cho KJ. Gastroenterology angiography. 3rd ed. Philadelphia: WB Saunders, 1986:121.)

The angiographic abnormality of portal vein occlusion due to neoplasms varies with the type of neoplasm. Pancreatic and biliary cancers cause localized narrowing or occlusion of the portal vein without associated tumor vessels. In contrast, portal vein invasion by hepatocellular carcinoma has a characteristic appearance, with abnormal vascular channels coursing within the portal vein branches in the vicinity of the tumors. Arteriovenous shunting is often associated with portal vein invasion by tumors. [42]

Splenic Vein Occlusion

Splenic vein occlusion usually is silent clinically but may cause hypersplenism or gastric variceal bleeding. [43], [44] The diagnosis can be made by dynamic CT, duplex US, and 3D contrast MR venography. Angiography should be performed when the noninvasive studies are inconclusive or when additional vascular information is needed. A celiac or a splenic arteriogram is performed for the diagnosis; the angiographic findings include splenoportal collaterals through the short gastric-coronary and gastroepiploic veins as well as nonopacification of the splenic vein during the venous phase.

Budd-Chiari Syndrome

In Budd-Chiari syndrome, a significant portion of the hepatic venous system is obstructed. CT usually is used as the initial test and may reveal nonuniform contrast enhancement of the liver parenchyma and enlarged caudate lobe. Increased central venous pressure from right heart failure may produce a contrast enhancement pattern similar to that of Budd-Chiari syndrome. MR imaging is useful in identifying the underlying lesions, such as hepatic and vena caval thrombi, and congenital membrane.

Angiography is the most important procedure for the diagnosis of the Budd-Chiari syndrome. Superior mesenteric and celiac angiograms are obtained to see the portal vein and exclude hepatic neoplasms. An inferior venacavogram is obtained to exclude occlusion of or membrane in the hepatic portion of the inferior vena cava. Demonstration of hepatic vein patency excludes the diagnosis of Budd-Chiari syndrome. When the hepatic vein is occluded, the catheter is wedged into the occluded hepatic vein, and contrast medium is injected to visualize the collateral channels (Fig. 159-7). If the right hepatic vein cannot be entered, catheterization of the accessory hepatic vein should be performed. If any of the hepatic veins cannot be catheterized, a 22-gauge needle is inserted into the liver parenchyma using the same technique used for percutaneous transhepatic portal vein catheterization. Injection of iodinated contrast medium or CO_2 usually demonstrates hepatic vein occlusion and collateral veins. [45]

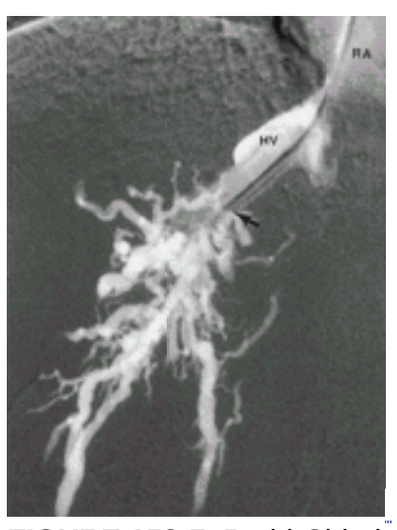

FIGURE 159-7. Budd-Chiari syndrome. Digital subtraction hepatic venogram was performed with contrast injection into the right hepatic vein (*HV*), demonstrating numerous collateral veins pathognomonic of hepatic vein occlusion. The *arrow* indicates the level of hepatic vein occlusion. *RA,* right atrium.

Percutaneous translumenal angioplasty and stent placement has been used to treat Budd-Chiari syndrome caused by obstruction of the hepatic segment of the inferior vena cava. [46], [47] Restenosis or reocclusion occurs frequently at the angioplasty site. Patency of the vein may be improved with use of metallic stents after unsuccessful angioplasty. The transhepatic approach may be used for angioplasty and stent placement for right hepatic vein occlusion causing Budd-Chiari syndrome. [48] The TIPS procedure has been used to treat intractable ascites and bleeding varices from hepatic venous occlusive disease and as an effective bridge to transplantation for hepatic failure associated with Budd-Chiari syndrome. [49]

GASTROINTESTINAL DISEASE

When evaluating GI disease, angiography is indicated for the diagnosis of vascular disease, visualization of vascular anatomy, and diagnosis and treatment of GI bleeding. If active GI bleeding is diagnosed, angiography can be urgently performed for localization of the bleeding site as well as control of the bleeding. The rate of bleeding should be at least 0.5 mL/minute to be detected by selective angiography. Angiography is insensitive in detecting capillary or venous bleeding because of the dilution of the contrast material. A recent study showed that helical CT angiography with intra-arterial injection of contrast medium into the abdominal aorta at the level of celiac axis is useful in detecting GI bleeding of obscure origin and facilitates angiographic localization of the bleeding. [50] Angiography is useful in identifying vascular malformations and vascular neoplasms. A catheter may be placed in the mesenteric branch supplying a vascular malformation preoperatively to facilitate intraoperative localization of the lesion.

Upper Gastrointestinal Bleeding

Once upper GI bleeding is diagnosed, celiac and superior mesenteric angiograms are obtained. If a bleeding site is identified, the bleeding artery is selectively catheterized to control the bleeding. If a bleeding site has not been demonstrated, left gastric and gastroduodenal arteriograms are obtained. If the source of bleeding still has not been identified and nasogastric aspiration reveals dark blood, a catheter may be placed in the left gastric artery for the next 6 to 12 hours. The bleeding may be precipitated by intra-arterial administration of heparin, vasodilators, or thrombolytic agents, allowing accurate localization of the bleeding site and prompt treatment. [51], [52] Prophylactic embolization (left gastric artery embolization for gastric bleeding and gastroduodenal artery embolization for duodenal bleeding) is an acceptable alternative when the massive bleeding has ceased at the time of angiography. [53]

Angiography usually is not helpful in determining the cause of upper GI hemorrhage. Hemorrhagic gastritis is the most common cause of capillary bleeding and may demonstrate a hypervascular stomach with dilated gastric arteries and increased parenchymal staining. Peptic ulceration is the most common cause of arterial bleeding and usually produces no angiographic abnormality. Gastric bleeding usually arises from the left gastric artery and occasionally from the short gastric, right gastric, or gastroepiploic artery. Duodenal bleeding may originate from the celiac or superior mesenteric artery or from both arteries. Angiographically, the arterial bleeding appears as a localized accumulation of contrast material extravasation during the arterial phase of the angiogram. The escaped contrast material persists throughout the venous phase and may outline the mucosa. Selective arterial embolization is an effective means of controlling bleeding from peptic ulceration.

Upper endoscopy should be obtained in all patients suspected of bleeding from the biliary tract (hemobilia) and pancreatic duct (hemosuccus pancreaticus). Once bleeding from the ampulla of Vater is documented, angiography is performed to demonstrate the underlying lesion and rarely contrast extravasation into the bile duct. Hemobilia can be treated by embolizing the feeding artery. Bleeding into the pancreatic duct is amenable to selective arterial embolization of the associated arterial lesions. Aortoenteric fistulae rarely cause GI bleeding, and the duodenum is the most common site of fistulae. Biplane aortography may show a false aneurysm at the aortic anastomotic site.

Percutaneous transhepatic coronary vein embolization may be used to treat variceal bleeding when endoscopy is not available or fails to control the bleeding. Variceal embolization may be necessary if the varices continue to fill after creation of TIPS. TIPS is an effective method of controlling variceal bleeding and is indicated when the bleeding is unresponsive to endoscopic therapy. [54], [55] and [56]

Lower Gastrointestinal Bleeding

Once lower GI bleeding is diagnosed, a superior mesenteric angiogram is performed to detect the bleeding from the small intestine and the right side of the colon. If no bleeding site is seen, a celiac arteriogram is obtained because gastroduodenal bleeding may present as lower GI bleeding. If a radionuclide scan has localized the bleeding to the left side of colon, inferior mesenteric arteriograms are obtained with a coverage area from the rectum to the splenic flexure of the colon. Active bleeding shows a localized accumulation of escaped contrast material during the arterial phase of the mesenteric angiogram, which usually persists through the venous phase (Fig. 159-8).

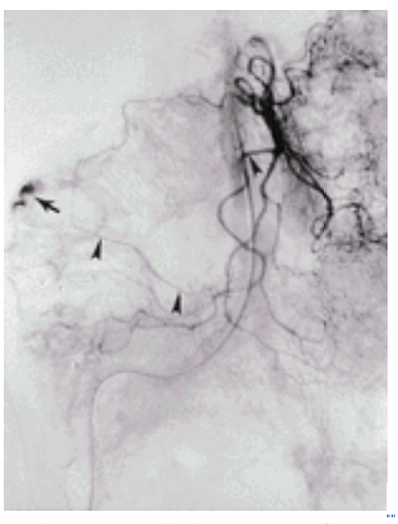

FIGURE 159-8. A superior mesenteric angiogram in an elderly man who developed massive colonic bleeding. Extravasation of contrast medium is seen from the hepatic flexure of the colon (*arrow*). The bleeding was controlled with embolization of the bleeding branch from the right colic artery (*arrowheads*).

Selective infusion of vasopressin is usually effective in controlling the bleeding in up to 80% of patients, but the recurrence rate is as high as 50%. [57] Patients with coronary artery disease should not be treated with vasopressin because of the risk for myocardial infarction. Selective embolization is an acceptable alternative when vasopressin is contraindicated. Superselective catheterization and embolization of the bleeding artery can be achieved with use of the 3-French coaxial catheter system with minimal risk for intestinal necrosis. [58], [59]

Angiodysplasia Angiodysplasia may occur in a variety of pathological types: vascular ectasia, arteriovenous malformations, and capillary telangiectasia. [60] The clinical presentation and angiography allow identification of each type of angiodysplasia. Vascular ectasia usually occurs in the cecum and ascending colon. Most patients are older than 60 years of age. Angiography is useful in identifying the bleeding source. The angiographic findings are usually diagnostic and include a small vascular cluster and blush in the wall of the colon and early, dense opacification of the draining vein [61] (Fig. 159-9). Normal mesenteric angiography usually is accepted for exclusion of vascular ectasia, although data supporting this assumption are not available. Two or more vascular ectasias are frequently present at microscopic examination of the injected specimen, although most patients demonstrate a single vascular lesion at angiography. Endoscopy is superior to angiography in identifying vascular ectasia. If active extravasation is demonstrated, selective arterial embolization is an effective treatment. Arteriovenous malformations are of developmental origin and usually affect people younger than 50 years of age. The angiographic findings include tortuous, dilated arteries with early, prominent veins. The lesions frequently are found in the small intestine and vary in size. Vascular malformations should be differentiated from vascular tumors, such as leiomyomas.

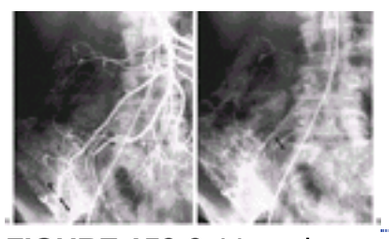

FIGURE 159-9. Vascular ectasia of the cecum. **A:** Arterial phase of superior mesenteric angiogram in a 70-year-old woman with recurrent lower gastrointestinal bleeding. A small vascular lesion (*open arrow*) is demonstrated in the antimesenteric border of the cecum with simultaneous opacification of an entering artery (*arrow*) and a draining vein (*arrowhead*). **B:** Capillary phase of the same angiogram. Notice the early, densely opacified draining vein (*arrow*). The veins from other parts of the bowel have not been opacified.

Capillary telangiectasia may occur in any part of the GI tract and may be associated with Osler-Weber-Rendu disease. The angiographic findings usually include tiny areas of blush without arteriovenous shunting. Hepatic angiography may demonstrate dilated hepatic arteries and increased hepatic parenchymal staining.
Meckel Diverticulum Angiography is obtained only when active bleeding occurs. Angiographically, a Meckel diverticulum appears as a short segment of bowel with increased contrast accumulation supplied by an abnormal branch from the superior mesenteric artery. [62]
Rectal Trauma Inferior mesenteric angiography is performed for localization and treatment of the bleeding. Infusion of vasopressin into the inferior mesenteric artery

is effective in controlling the bleeding. If the patient has coronary artery disease or if vasopressin fails, selective embolization is performed with Gelfoam, Ivalon particles, or microcoils. [63]

Intestinal Varices Scintigraphy and abdominal CT are useful in detecting large varices. Angiography provides the necessary information regarding the location and extent of the varices. The varices are demonstrated in the venous phase of a superior mesenteric angiogram. Percutaneous transhepatic portal vein catheterization may be necessary for evaluation of portal hemodynamics and embolization. TIPS is effective in treating stomal or rectal varices in patients with cirrhosis and portal hypertension. [64]

Neoplasms of the Small Intestine

Leiomyomas Angiography is useful in diagnosing small bowel leiomyomas (Fig. 159-10). The tumors usually are hypervascular with abundant tumor vessels and dense blush. The draining vein usually is densely opacified. Angiographic differentiation between benign and malignant tumors is not possible unless venous invasion or metastasis is demonstrated. [65]

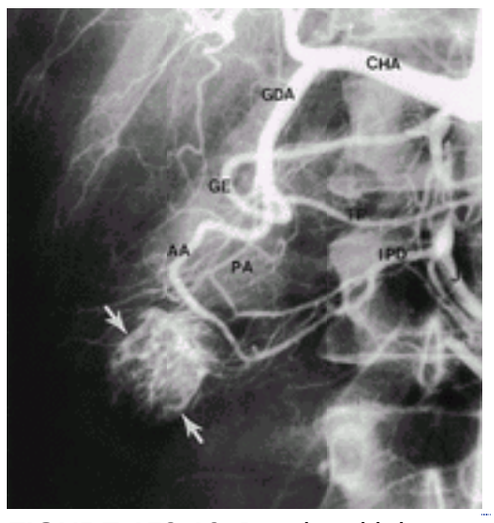

FIGURE 159-10. Duodenal leiomyoma. Late arterial phase of a gastroduodenal arteriogram in a young woman with upper gastrointestinal hemorrhage. A vascular mass (*arrows*) in the second portion of the duodenum receives blood supply from the dilated anterior arcade artery (*AA*). *CHA,* common hepatic artery; *GDA,* gastroduodenal artery; *GE,* gastroepiploic; *PA,* posterior arcade artery; *IPD,* inferior pancreaticoduodenal; *J,* jejunal; *TP,* transverse pancreatic. Surgical removal of the mass confirmed the diagnosis.

Carcinoid Tumors Angiography may be used for diagnosis and staging of carcinoid tumors. The angiographic findings include retraction, kinking, and occlusion of the mesenteric arteries. Carcinoid tumors metastatic to the liver usually are hypervascular with abundant tumor vessels. Venous sampling with hormone assay may be necessary for localizing occult carcinoid tumors, especially those occurring in the ovary and lungs. When the patient with liver involvement has severe carcinoid syndrome, hepatic artery embolization is an acceptable palliative treatment. [66]

Other Tumors Hemangiomas of the small bowel are an uncommon cause of GI bleeding. Angiography may be used to identify small hemangiomas. The angiographic findings include small areas of abnormal vessels with contrast accumulation in the capillary phase, with or without early draining veins. Angiography is not useful in diagnosing adenomas, lipomas, carcinomas, or Kaposi sarcoma.

PANCREATIC DISEASE

Dynamic contrast spiral CT is used to identify a pancreatic mass and assess the extent of the tumor. [67] Angiography is performed to obtain a specific diagnosis, to determine the extent of the tumor, and to demonstrate vascular anatomy. In patients with pancreatitis or pseudocysts, angiography is necessary when surgery is contemplated.

Adenocarcinoma

Conventional and helical CT may be performed to detect the extension of the tumor and involvement of the peripancreatic vessels. [68], [69] Angiography is useful in assessing the extent of the tumor. When any major peripancreatic artery (splenic, hepatic, or superior mesenteric artery) or vein (superior mesenteric, splenic, or portal vein) is involved, the tumor may be unresectable (Fig. 159-11).

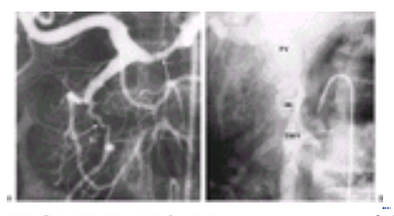

FIGURE 159-11. Unresectable pancreatic cancer. **A:** Hepatic arteriogram (magnification technique). The common hepatic (*a*) and proximal gastroepiploic (*b*) arteries are encased by a tumor in the head of the pancreas. **B:** Portal venous phase of a superior mesenteric angiogram (oblique view). The junction of the superior mesenteric and portal veins is invaded by the tumor (*arrow*). *PV,* portal vein; *SMV,* superior mesenteric vein. (From Shields JJ, Porter DJ, Brady TM, Cho KJ. Angiography of pancreatic disease. In: Dent TL, ed. Pancreatic disease. New York: Grune & Stratton, 1981:93.)

Cystic Tumors

US and abdominal CT can provide the diagnosis of a cystic pancreatic tumor; therefore, angiography is reserved for determining the extent of the tumor and vascular anatomy before surgical resection. Angiographically, microcystic adenomas usually are hypervascular with abundant tumor vessels and blush, whereas mucinous cystic tumors are hypovascular with sparse tumor vessels mimicking a pseudocyst.

Pancreatic Endocrine Tumors

Angiography is infrequently used for localization of islet cell adenomas. Angiographically, islet cell tumors appear as a localized area of contrast material accumulation (tumor blush) with or without tumor vessels (Fig. 159-12). Malignant islet cell tumors may grow into the portal vein. Most hepatic metastases from islet cell carcinomas are hypervascular and are readily detected by hepatic angiography. Angiography is sensitive in localizing insulinomas (accuracy, 60% to 90%), but it is less sensitive in detecting gastrin-producing tumors. Other endocrine tumors, such as vasoactive intestinal peptide–producing tumors (VIPoma), glucagonoma, and somatostatinoma, are usually hypervascular with abundant tumor vessels and can be demonstrated by CT.

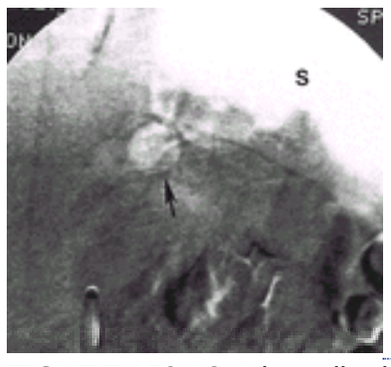

FIGURE 159-12. Islet cell adenoma in a patient with hyperinsulinism. Parenchymal phase of a splenic angiogram (digital subtraction technique) demonstrates a 1-cm diameter tumor blush (*arrow*) in the distal body of the pancreas. *S,* splenic parenchymal staining.

Percutaneous transhepatic venous sampling with hormone assay is a useful method for localizing occult islet cell tumors. This method may be used to localize the source of abnormal hormone secretion to the head, body, and tail of the pancreas as well as to the liver. This is helpful in avoiding blind resection of the pancreas. [70] Simultaneous arterial and venous sampling from the splenic, superior mesenteric, and portal veins can detect a localized elevation of hormone value near the tumor site; adenomas of the body and tail of the pancreas cause a step-up of hormone concentration in the splenic vein, and those of the pancreatic head cause step-ups in the superior mesenteric and portal veins. Simultaneous blood sampling from the hepatic and portal veins helps to determine the presence of hepatic metastases from gastrinomas. [71]

Selective intra-arterial injection of secretin with assay of hepatic venous gastrin has been useful in localizing gastrinomas and hepatic metastases. [72] It involves injection of 30 units of secretin into the splenic, gastroduodenal, proper hepatic, and superior mesenteric arteries as well as blood sampling from the hepatic vein to measure the changes of gastrin concentration. An increase (more than 50%) in gastrin concentration in the hepatic vein after secretin injection localizes the tumor to the part of the pancreas supplied by the artery injected: the gastroduodenal and superior mesenteric artery for the head of the pancreas and the splenic artery for the body or tail. The selective arterial secretin injection test is more sensitive than transhepatic portal venous sampling for localizing occult gastrinomas. [73] An increase in hepatic venous gastrin concentration of at least 25% at 20 seconds or 50% at 30 seconds after hepatic arterial injection of secretin indicates the presence of hepatic metastases. [74] In patients with suspected insulinomas, calcium gluconate is injected intra-arterially, and the level of insulin is measured in the hepatic vein for localization of insulinomas.

Pancreatic Arteriovenous Malformations

These rare vascular lesions may bleed directly into the intestine or into the pancreatic duct. Portal hypertension and varices associated with the malformation may be the cause of the bleeding. Angiography is important in the preoperative diagnosis and localization of the lesion. The lesion may mimic chronic pancreatitis or a vascular tumor.

Vascular Lesions Associated with Pancreatitis

Angiography has little diagnostic use in patients with pancreatitis because the diagnosis is well established clinically. When vascular complications occur, angiography is necessary for the diagnosis of vascular involvement and treatment. In about half of cases of pseudocyst, peripancreatic venous narrowing or occlusion is found. Bleeding associated with pancreatitis may be venous or arterial in origin. Venous bleeding usually results from gastric varices associated with splenic or portal vein occlusion. Venous bleeding rarely results from duodenal varices caused by superior mesenteric or portal vein occlusion. Arterial hemorrhage is a rare but life-threatening complication of pancreatitis, usually secondary to rupture of intrapancreatic or peripancreatic aneurysms. Arteriography is indicated for the diagnosis of arterial bleeding and pseudoaneurysm, and selective embolization should be used as a definitive or preoperative temporizing procedure. [75]

HEPATIC DISEASE

CT is the most useful screening method for hepatic lesions and can be used to distinguish a cystic from solid hepatic lesion. Bolus dynamic CT with CT-arterial portography is the most sensitive imaging modality for detecting hepatic metastases. [76] Delayed CT with the intra-arterial injection of iodized oil into the hepatic artery is useful in detecting small hepatocellular carcinomas. [77] Doppler US and color-flow Doppler imaging are complementary procedures and provide useful information on the vascularity and hemodynamics of liver tumors. Angiography still is important in evaluating liver tumors for the specific diagnosis, for resectability of the tumor, and for therapeutic hepatic artery embolization.

Knowledge of hepatic circulation is important in the performance and interpretation of hepatic angiograms and in planning for hepatic arterial chemotherapy. The liver receives a dual blood supply: about 75% of the total hepatic blood flow comes from the portal vein, and the remaining 25% comes from the hepatic artery. The relationship between the portal vein and hepatic artery is reciprocal: a decrease in portal blood flow results in immediate compensatory increase in the hepatic arterial flow. When portal blood flow is diminished in cirrhosis or obstructive jaundice, hepatic arterial embolization for bleeding or tumors must be undertaken cautiously because the liver in these conditions depends primarily on the arterial blood.

Cavernous Hemangiomas

Cavernous hemangiomas, the most common benign hepatic tumors, are composed of large sinusoidal spaces with fibrosis and thrombosis. CT, MR imaging, and ^{99m}Tc-scintigraphy with the use of single photon emission computed tomography are useful for obtaining a specific diagnosis. [78], [79] The angiographic findings are characteristic, with normal feeding arteries and dense persistent pooling of contrast material through the venous phase of a hepatic angiogram.

Adenoma

The findings of hepatic adenomas on CT, US, and MR imaging are nonspecific. Angiographically, hepatic adenomas usually are vascular, with abnormal vessels and tumor blush. The definitive diagnosis cannot be established on the basis of the angiographic abnormality. When an adenoma bleeds, angiography is necessary to evaluate the extent of bleeding and identify the tumor. If active contrast extravasation is identified, selective arterial embolization is an acceptable alternative treatment. When the patient becomes stable, resection should be performed. Adenomas associated with bleeding may become hypovascular or avascular, making their angiographic localization difficult.

Focal Nodular Hyperplasia

Angiographically, lesions are hypervascular; abundant abnormal vessels show granular contrast agent accumulation, and multiple septa radiate from the central area of scar.

Biliary Cystadenoma

Angiography is performed to define hepatic arterial anatomy and determine the extent of the tumor before surgery. The angiographic findings usually are nonspecific and may demonstrate subtle neovascularity and rimlike staining in the wall of the tumor, mimicking a hepatic abscess, an echinococcal cyst, or a congenital hepatic cyst.

Hepatocellular Carcinoma

Angiography is necessary to define the extent of the tumor, blood supply, and portal venous anatomy. Most hepatomas are hypervascular angiographically, with coarse tumor vessels (Fig. 159-13). Involvement of the extrahepatic portal vein by hepatoma indicates that the tumor is unresectable.

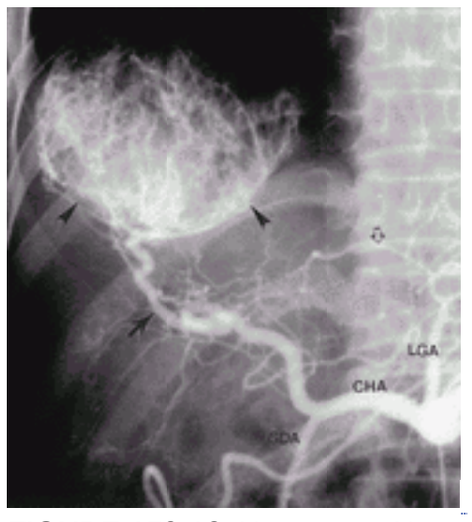

FIGURE 159-13. Hepatoma. Hepatic arteriogram shows a hypervascular mass (*arrowheads*) with tumor blush. Numerous tumor vessels supplied by a dilated right hepatic artery branch (*arrow*) are seen. The left hepatic artery (*open arrow*) arises from the left gastric artery (*LGA*). *CHA,* common hepatic artery; *GDA,* gastroduodenal artery.

Cholangiocarcinoma

Angiography has a limited role in the diagnosis but may be performed to provide a vascular road map and evaluation of portal vein patency when surgical resection is contemplated. The angiographic findings include encasement of the hepatic arterial branches, which may be associated with encasement of the portal vein.

Metastatic Hepatic Neoplasms

Hepatic metastases from renal cell carcinomas, islet cell carcinomas, carcinoid tumors, and medullary thyroid carcinomas are hypervascular, and other metastases are less vascular. Angiography is sensitive in detecting hypervascular metastases. Angiography is performed to determine resectability of hepatic metastases and the presence of the aberrant hepatic arteries before the surgical placement of a hepatic arterial catheter for chemotherapy.

PANHEPATIC ANGIOGRAPHY

Increased resistance to the flow of portal vein blood is the principal cause of portal hypertension. The location of the blockage in portal blood flow may be intrahepatic or extrahepatic. Cirrhosis is the most common cause of the intrahepatic sinusoidal block. Hepatic vein (postsinusoidal) and portal vein (presinusoidal) occlusion produce an extrahepatic block to portal vein flow. An increase in portal vein blood flow secondary to splenomegaly or arterioportal fistulas rarely causes portal hypertension (hyperkinetic).

The term *panhepatic angiography* is used for the angiographic study performed for the evaluation of portal hypertension. It includes celiac, superior mesenteric, hepatic, and splenic angiograms; wedged hepatic and left renal venograms; and manometry. Panhepatic angiography determines hepatic arterial variations, assesses portal hemodynamics, and excludes hepatoma. Visualization of aberrant hepatic arteries is important because accidental ligation of the hepatic artery in the presence of portal hypertension may result in hepatic necrosis. A right hepatic artery that originates from the superior mesenteric artery poses technical difficulty for portacaval shunt surgery.

The hepatic angiogram is necessary to exclude hepatomas and helps determine the hemodynamics of the intrahepatic portal flow. In advanced cirrhosis with reversed portal flow, the portal vein may be visualized in the venous phase of the hepatic arteriogram. High-dose superior mesenteric and splenic angiograms are necessary to see the superior mesenteric, splenic, and portal veins, as well as the portosystemic collaterals. In alcoholic cirrhosis, a pressure measurement from the catheter wedged in the hepatic vein reflects portal vein pressure and is useful in determining whether the location of the obstruction is intrahepatic or extrahepatic. However, wedged hepatic vein pressure is not a useful determinant for the selection of the type of shunt surgery. It is also a poor predictor of prognosis and survival after shunt surgery. Wedged hepatic venography is the most accurate means of assessing morphologic features of the hepatic sinusoids and parenchyma. Manometry of the right atrium, inferior vena cava, and left renal vein is important because the presence of significant elevation of caval pressure may result in incomplete decompression of portal hypertension after portacaval shunt surgery. Likewise, if the left renal vein pressure is elevated, the surgeon may decide to place another type of shunt rather than a distal splenorenal shunt.

TRANSCATHETER THERAPY

Diagnostic angiography should be performed before any trans- catheter intervention for GI disease. Interventional radiologic procedures are reviewed in detail in Chapter 160.

Percutaneous Translumenal Angioplasty and Stent Placement

Surgical therapy (endarterectomy and bypass surgery) for superior mesenteric artery obstruction has significant mortality and recurrence rates. Percutaneous translumenal angioplasty is a safe and effective alternative to surgery in treating intestinal angina resulting from arteriosclerotic occlusive disease of the visceral arteries. Stent placement is required for ostial stenosis or complete occlusion of the celiac and superior mesenteric arteries, failed percutaneous translumenal angioplasty because of elastic recoil, and mesenteric arterial compression by the false lumen of an aortic dissection. [80], [81], [82] and [83] Celiac axis stenosis caused by median arcuate ligament compression is not amenable to angioplasty and thus requires surgery.

Percutaneous translumenal angioplasty is effective in treating Budd-Chiari syndrome caused by a membrane in the inferior vena cava and a stenosis of the hepatic vein. [84], [85] The method may not be possible technically in patients with diffuse hepatic vein thrombosis and sclerosis. Percutaneous transhepatic angioplasty and stent placement has been used to treat portal vein stenosis and postoperative stricture of the portal vein complicating liver transplantation. [86], [87] and [88]

Transcatheter Embolization

Transcatheter embolization is an acceptable alternative to surgery in treating massive arterial bleeding, and aneurysms of the mesenteric, hepatic, and splenic arteries. [89], [90] and [91] Occlusion of the hepatic artery by embolization is safe and well tolerated because the hepatic sinusoidal perfusion can be maintained by collateral circulation and the portal venous blood. Selective hepatic arterial embolization is a safe and effective treatment for traumatic hepatic bleeding, hemobilia, and symptomatic arterioportal fistula. However, hepatic artery embolization in patients with symptomatic hepatic arteriovenous malformations associated with hereditary hemorrhagic telangiectasia is associated with a high risk for hepatic infarction and death. [92] The spleen receives adequate collateral blood flow through the pancreatic arteries after occlusion of the extrasplenic part of the splenic artery. Steel coil is the most frequently used occluding agent and produces arterial occlusion equivalent to surgical ligation. Injection of thrombin into an aneurysm promotes clot formation. A 3-French coaxial catheter system is extremely useful in catheterization and embolization of a mesenteric branch artery. If an aneurysm cannot be catheterized transarterially, a 22-gauge needle is used for percutaneous puncture, and embolization of the lesion is accomplished with microcoils and thrombin.

Thrombolytic Therapy

Thrombolytic therapy may be used for superior mesenteric artery embolism and portal vein thrombosis. A report of thrombolytic therapy for superior mesenteric artery

embolism indicates that the method is safe and effective, with technical success in 90% and clinical success in 70%, [93] but the treatment requires at least 6 to 8 hours of infusion. A percutaneous transhepatic or transjugular approach is necessary for thrombolysis of mesenteric and portal vein thrombosis. The technique involves placement of a catheter into the embolus or thrombus and infusion of a lytic agent. During thrombolysis, the patient should be monitored for bleeding and evidence of bowel infarction in the intensive care unit. Reteplase and alteplase are alternative fibrinolytic agents for catheter-directed thrombolysis of peripheral arterial occlusion. [94], [95] The transcatheter use of a mechanical thrombectomy device, such as AngioJet (Possis Medical Inc, Minneapolis, MN), has been shown to be effective in removing clots.

Hepatic Arterial Infusion Chemotherapy

Regional delivery of antineoplastic agents through a selectively placed arterial catheter produces higher tumor response than systemic infusion. [96], [97] The success of hepatic arterial chemotherapy depends on accurate evaluation of the hepatic arterial anatomy and hemodynamics, and correct catheter placement. To ensure total liver perfusion and drug delivery to the tumor site, the hepatic arterial anatomy is meticulously evaluated by celiac and superior mesenteric arteriograms. Multiple hepatic arteries can be converted to a single hepatic artery using the transcatheter embolization technique to facilitate catheter placement. For example, if an aberrant left hepatic from the left gastric artery is embolized, the left hepatic lobe receives blood supply through intrahepatic collaterals from the right hepatic artery. If the infusion catheter cannot be placed in the proper hepatic artery, the gastroduodenal artery may be occluded by embolization to allow infusion of drugs with a catheter placed in the common hepatic artery.

Hepatic arterial catheters can be placed through a percutaneous approach from the femoral or brachial artery, or surgically. The introduction of the totally implantable pump has improved regional chemotherapy with surgical catheter placement. [98] Radionuclide flow study using ^{99m}Tc macroaggregated serum albumin is the most accurate means of assessing hepatic perfusion pattern after catheter placement. The complications of percutaneous catheter placement are brachial artery thrombosis, hepatic artery thrombosis, catheter displacement, and puncture-site bleeding. The complications of surgical catheter placement are hepatic artery thrombosis, incorrect catheter placement, catheter occlusion, and pump malfunction. Complications related to the toxicity of chemotherapeutic agents are chemical hepatitis, biliary sclerosis, chemical cholecystitis, and gastroduodenal inflammation and ulceration.

Hepatic Tumor Embolization

Hepatic artery embolization is used to palliate hepatic tumors (hepatoma, metastatic neuroendocrine tumors, cholangiocarcinoma, and metastatic colon cancer) when the tumors are unresponsive to hepatic arterial chemotherapy. [99] The patients usually are not candidates for surgical resection. Before embolization, CT of the liver must be reviewed for evaluation of location of tumor, extent of disease, and any associated findings (portal vein occlusion, biliary obstruction). Adequate portal venous flow should be available to maintain hepatic parenchymal vitality. If the intrahepatic portal flow is reversed (hepatofugal), embolization should not be performed or limited to the subsegment containing tumor.

Hepatic arterial embolization results in selective destruction of the tumors exclusively dependent on arterial supply while maintaining the vitality of the normal liver with portal vein blood. Small particles, such as polyvinyl alcohol (Ivalon, 150–250 μm), are used to occlude peripheral arteries to decrease the development of collateral blood flow. Hepatic artery embolization can effectively control symptoms related to abnormal hormone production in most patients with carcinoid and islet cell tumors metastatic to the liver. [100] In patients with hepatocellular carcinoma with portal vein tumor invasion and arterioportal shunt, hepatic artery embolization may result in acute hepatic failure. Embolization of arterioportal shunts may be performed to reverse the portal blood flow from hepatofugal to hepatopetal in direction. Tumor embolization can then be performed with less risk for hepatic failure. [101]

Chemoembolization is the combination of intra-arterial infusion of chemotherapeutic agents and arterial embolization of the tumor vascular bed. [102] The rationale for this method is that concurrent embolization increases the effect of the drug by prolonging exposure of the tumor to the drug and producing tumor anoxia while minimizing systemic drug effects. The occluding materials currently in use include Gelfoam, Ivalon, and iodized oil. Mitomycin C, doxorubicin, cisplatin, and floxuridine are among drugs used for chemoembolization. Hepatic arterial chemoembolization, with Ivalon particles of 150 to 250 μm before and after selective injection of cisplatin, has been shown to be effective in treating hepatic metastases. [103] Chemoembolization material for hepatocellular carcinoma may consist of 10 mg mitomycin C, 50 mg doxorubicin, and 100 mg cisplatin dissolved in contrast medium and sterile water. This is mixed with Ethiodol and Ivalon particles. [104] This emulsion is injected into the hepatic artery until hepatic arterial flow is significantly reduced. Injection of iodized oil into the hepatic artery results in selective accumulation of the oil within most vascular hepatic tumors. This phenomenon has been exploited to deliver antineoplastic agents and radioactive isotopes selectively to hepatic cancers, with intra-arterial injection of a mixture of iodized oil and antineoplastic agents or radioactive iodized oil solution. [105], [106] Chemoembolization is effective in patients with hepatic metastases of neuroendocrine tumors. Intra-arterial injection of iodized oil and doxorubicin into tumor vessels is effective in palliating patients with hepatic islet cell or carcinoid tumor metastases. This method causes less morbidity than embolization of particulate material and permits repeat embolization because the supplying arteries remain patent after embolization. [107], [108] The chemoembolic mixture is composed of 40 to 60 mg of doxorubicin dissolved in 10 mL of contrast medium and 20 mL of iodized oil.

Hepatic artery embolization may be associated with the postembolization syndrome: abdominal pain, nausea, vomiting, and fever lasting 2 to 7 days. Mildly abnormal liver tests are common. Other complications include hepatic necrosis, gallbladder infarction, and gastroduodenal ulcers. Follow-up CT is obtained at 3-month intervals, and repeated embolizations are performed for recurrent tumors.

FORTHCOMING ADVANCES

Noninvasive imaging modalities (spiral CT, 3D contrast MR angiography, color Doppler imaging, and duplex US) will continue to play a primary role in the evaluation of suspected GI diseases. Angiography will be used less frequently but will continue to be used in the preoperative evaluation of vascular disease, portal hypertension, neoplasms of the pancreas and liver, and GI hemorrhage. Therapeutic applications of angiography will expand in the treatment of lower GI bleeding (small and large bowels), vascular abnormalities (arteriovenous fistula and aneurysm), hepatic neoplasms (chemoembolization for primary and metastatic malignancies), mesenteric vascular obstruction (acute and chronic), variceal bleeding unresponsive to endoscopic therapy, intractable ascites, and Budd-Chiari syndrome.

CHAPTER 160

Kyung J. Cho and Grace H. Elta

INTERVENTIONAL RADIOLOGY

The field of interventional radiology has evolved since the introduction of the percutaneous transarterial technique devised by Seldinger in 1953. [1] Interventional radiologists perform a variety of diagnostic and interventional procedures of the circulatory system and nonvascular tracts under imaging guidance. The imaging guidance includes fluoroscopy, ultrasound (US), computed tomography (CT), magnetic resonance (MR) imaging, and conventional and digital subtraction angiography. The interventional radiologic procedures can be divided into vascular and nonvascular procedures. The vascular procedures include infusion, occlusion, dilation, stent placement, and foreign body retrieval. The nonvascular procedures include biopsy, drainage, dilation, and ostomy formation.

VASCULAR INTERVENTION

Control of Arterial Gastrointestinal Bleeding

Angiographic management is indicated for endoscopic failures, especially in poor operative candidates, and for inaccessible sites of bleeding, such as hemobilia. [2] Angiographic therapy for massive gastrointestinal (GI) bleeding includes intra-arterial infusion of vasopressin and selective arterial embolization. The success of angiographic treatment depends on accurate localization of the bleeding site and selective catheterization of the bleeding artery.

Vasopressin Infusion Vasopressin is effective for bleeding from Mallory-Weiss tears, hemorrhagic gastritis, and small bowel and colonic bleeding, [3], [4] but it is less effective for bleeding from a peptic ulcer because ulcers rupture larger arteries. Vasopressin infusion can control lower GI tract bleeding in 80% to 90% of patients, but 40% to 50% of these patients rebleed and eventually require surgery. Therefore, vasopressin infusion is infrequently used for control of lower GI bleeding. When the bleeding site has been demonstrated, a catheter is selectively placed in the bleeding artery. Vasopressin is infused into the left gastric artery for gastric bleeding, into the superior mesenteric artery for small bowel and right colonic bleeding, and into the inferior mesenteric artery for left colonic and rectosigmoid bleeding. Vasopressin infusion may be initiated at the rate of 0.2 U/minute. After 20 minutes of infusion, repeat arteriogram is performed to assess treatment effectiveness. If no bleeding is demonstrated and vasoconstriction is moderate, the infusion is continued for the next 24 hours at the same rate. When the bleeding has stopped, the rate should be reduced to 0.1 U/minute and continued for an additional 6 to 12 hours before termination of the infusion. If the bleeding is not controlled after vasopressin infusion of 0.4 U/minute for 20 minutes, increasing the rate is not recommended; embolization or surgery should be considered. Serious side effects from vasopressin infusion occur infrequently. Most side effects are dose dependent. They are coronary ischemia, arrhythmia, bradycardia, hypertension, bowel ischemia, peripheral vascular ischemia, and oliguria. In patients with a history of coronary artery disease, the infusion should be done with caution and concomitant administration of nitroglycerin.

Selective Arterial Embolization Selective arterial embolization is an effective method of therapy for control of massive upper GI hemorrhage when endoscopic therapy has failed. Selective occlusion of the bleeding artery with embolic agents such as gelatin sponge, polyvinyl alcohol (Ivalon), and microcoils results in prompt cessation of the bleeding, and it usually obviates the need for surgical intervention (Fig. 160-1). It is important to localize the bleeding site before embolization. Prophylactic embolization of the left gastric or gastroduodenal artery for upper GI bleeding can be performed, but endoscopic localization of the bleeding is necessary before embolization. Correction of coagulopathy before and after the embolization reduces the risk for bleeding recurrence. [5] The use of coils as the only embolic agent and concurrent coagulopathy in patients with upper GI bleeding are associated with a high risk for early recurrent hemorrhage. [6] The stomach and duodenum have sufficient collateral pathways; hence, infarction is unlikely to occur after embolization. On rare occasions, patients with previous surgery or those receiving vasopressin therapy after the embolization may develop infarction of the stomach. Duodenal ischemia, duodenal stenosis, and pancreatic necrosis are the potential complications of gastroduodenal artery embolization.

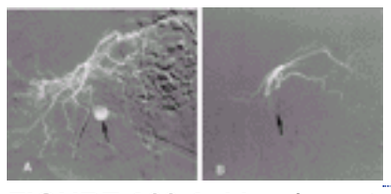

FIGURE 160-1. Massive arterial bleeding from a branch of the left gastric artery. **A:** Superselective left gastric arteriogram (digital subtraction technique). Active bleeding is seen from a branch of the left gastric artery in the body of the stomach. The extravasated contrast medium has formed a pseudoaneurysm (*arrow*). **B:** The bleeding has stopped following microcoil embolization (*arrow*).

Selective arterial embolization is a safe and effective method of therapy for control of lower GI bleeding. [7], [8] Gelfoam pledgets and Ivalon particles are the commonly used embolization agents. The use of a 3-French (3-Fr) coaxial catheter allows catheterization of the extravasating arteria recta for embolization with microcoils. [9] Rectal hemorrhage is usually diagnosed and treated by interventional endoscopy. When the rectum is filled with fresh blood, endoscopic identification of the bleeding site may be difficult. Regardless of the underlying etiology, embolization can be effective in controlling superior hemorrhoidal arterial hemorrhage. [10]

Variceal Embolization

In 1974, Lunderquist and Yang [11] reported the technique of percutaneous transhepatic coronary vein embolization as a means of controlling gastroesophageal variceal bleeding. Portal vein catheterization can also be done using the transjugular, umbilical, and intestinal veins after minilaparotomy. In the presence of massive ascites, coagulopathy, or liver tumors, the transjugular approach is used. Coronary vein embolization can effectively control variceal hemorrhage in 80% of cases, but recurrent bleeding is common because of the development of new gastric and esophageal varices. Coronary vein embolization is infrequently performed because endoscopic therapy is more effective in preventing recurrent hemorrhage. [12]

Rarely, bleeding may occur from the portosystemic collaterals at unusual sites, including the small bowel, colon, rectum, and enterostomy. [13], [14] If the bleeding is unresponsive to conservative therapy, variceal embolization can be performed through the transhepatic or transjugular approach [15], [16] (Fig. 160-2). Transjugular intrahepatic portosystemic shunt (TIPS) usually is preferable for the treatment of bleeding from varices at unusual sites owing to the risk for rebleeding with embolization alone. [17], [18] and [19]

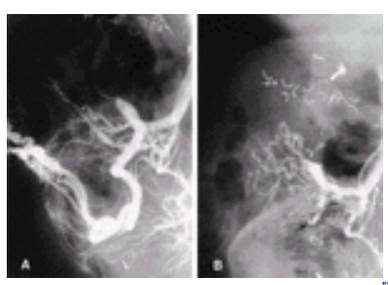

FIGURE 160-2. Transhepatic embolization of stomal varices. Percutaneous transhepatic mesenteric venogram in a 79-year-old woman with a 2-year history of recurrent bleeding from ileostomy varices. The bleeding began 1 year after total colectomy and ileostomy for colon carcinoma. **A:** Transhepatic catheterization of the ileal vein. Contrast medium fills the ileal vein, draining toward the stomal varices (*arrow*). **B:** Transhepatic mesenteric venogram after occlusion of the ileal vein with ethanol and coils. The ileal vein and collateral veins are occluded (*arrow*). The patient required three embolization procedures for recurrent bleeding.

Another reported unusual indication for variceal embolization is chronic recurrent hepatic encephalopathy. [20], [21] Embolization of portosystemic shunts can decrease diversion of portal blood flow through the shunts, resulting in an increase in portal blood flow. Portosystemic shunts amenable to such embolic therapy are splenorenal shunts, gastrorenal shunts, hepatic portal vein–hepatic vein shunts, and ileal vein–gonadal vein communications. Embolization can be done through the transfemoral or transhepatic approach, depending on the site of shunts. Balloon-occluded retrograde transvenous injection of a sclerosing agent is a safe and effective treatment of gastric varices and encephalopathy. [22] The technique involves the retrograde catheterization of the portosystemic collateral vein through the left renal and adrenal veins from the femoral vein. An occlusion balloon is wedged in the collateral vein, and a sclerosing agent is injected through the shunt into the gastric varices. If complete obliteration of the varices is not possible with the retrograde approach, the varices can be embolized by the transhepatic approach or the TIPS if present.

Budd-Chiari Syndrome

Percutaneous translumenal balloon angioplasty (PTA) is an effective therapy in patients with Budd-Chiari syndrome secondary to obstruction of the inferior vena cava (IVC) or hepatic vein. However, recurrence is common, and therefore, stent placement is usually performed. [23], [24] and [25] The transfemoral or transjugular approach is used for IVC obstruction and the percutaneous transhepatic approach for hepatic vein occlusion (Fig. 160-3). When the hepatic venous outflow obstruction extends into the peripheral hepatic veins, requiring portal decompression, TIPS is a viable alternative to surgical shunting and provides a bridge to liver transplantation. [26], [27] When portal, splenic, or mesenteric venous thrombosis is associated with Budd-Chiari syndrome, the thrombi can be dissolved by intrathrombic infusion of a fibrinolytic agent or removed by a mechanical thrombectomy device before placement of a TIPS. The TIPS stent may be extended into the splenic or mesenteric vein to achieve adequate inflow. [28]

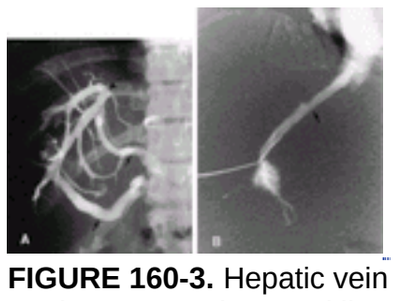

FIGURE 160-3. Hepatic vein stent placement for Budd-Chiari syndrome. Transhepatic hepatic venogram in a 23-year-old woman with right upper quadrant pain and tenderness, ascites, and liver failure. **A:** Transhepatic hepatic venogram. The hepatic vein is occluded (*arrowhead*). The contrast medium fills hepatic venous collaterals (*arrows*), draining toward the inferior vena cava. **B:** Transhepatic hepatic venogram after recanalization of the hepatic vein and placement of a 10-mm diameter Wallstent. The hepatic vein is patent with excellent blood flow (*arrow*). The venous collaterals are no longer filled. The hepatic vein pressure decreased from 29 mm Hg to 7 mm Hg after stent placement. One year later, the patient underwent orthotopic liver transplantation because of occlusion of the stent.

Portal Vein Stenosis

PTA and stent implantation using the percutaneous transhepatic and transjugular approaches are safe and effective in the therapy of portal vein stenosis, including cases complicating liver transplantation. [29], [30] and [31] Although most portal vein stenosis or occlusion is amenable to percutaneous techniques, their long-term efficacy is not known; therefore, follow-up with imaging studies is needed to detect restenosis of the treated lesion. [32]

Mesenteric Vein Thrombosis

Infusion of thrombolytic agents has been used for treatment of portal and mesenteric venous thrombosis. A thrombolytic agent may be administered by peripheral intravenous route or directly into the mesenteric vein through the transjugular [33] or transhepatic [34], [35] approach. Mechanical thrombectomy using a thrombectomy device or a Fogarty catheter can be used for acute portal vein thrombosis. This technique has been used for recanalization of acute portal vein thrombosis complicating TIPS. [36]

Portal vein reconstruction with recanalization and stent placement may be performed in patients with symptomatic chronic splenomesenteric-portal venous thrombosis. [37]

Visceral Arterial Stenosis

Atherosclerotic stenoses of the celiac and superior mesenteric arteries are a common cause of chronic mesenteric ischemia in elderly patients. Surgical revascularization is the standard treatment for clinically significant stenoses of the celiac and superior mesenteric arteries. PTA is a safe and effective alternative to surgical treatment. In a review of 83 reported patients who had PTA of visceral arteries, the initial technical success was 88%; the initial clinical success, 92%; the recurrence rate, 24%; primary long-term clinical success, 76%; successful repeat PTA, 92%; secondary long-term clinical success, 92%; and major complications, 6%. [38] Stent placement has been shown to be safe and clinically effective as an adjunctive treatment to PTA or as a primary therapy in patients with chronic mesenteric ischemia caused by calcified ostial stenoses, high-grade eccentric stenoses, chronic occlusions, and flow-limiting dissection of mesenteric arteries. [39]

PTA and stent placement are usually done through the femoral approach. If the femoral artery cannot be used, the left axillary approach is used. Before the procedure, lateral aortography and selective mesenteric arteriography are performed to evaluate the arterial lesions and visceral arterial circulation. The origin of the artery to be dilated is then catheterized, and the stenosis is then crossed using either a soft-tipped guidewire or a hydrophilic guidewire. The patient is given an intravenous bolus of 3000 to 5000 units of heparin. Over a 0.035-inch (0.89-mm) heavy-duty guidewire, a PTA balloon catheter of appropriate balloon size is placed across the stenosis and dilated to pressures of 5 to 7 atm (Fig. 160-4). If a gradient is greater than 10 mm Hg after balloon dilation or if a hemodynamically significant dissection is seen, a metallic stent is placed. Systemic anticoagulation is not usually necessary after the procedure. PTA should have a limited role in the patient with acute mesentericischemia.

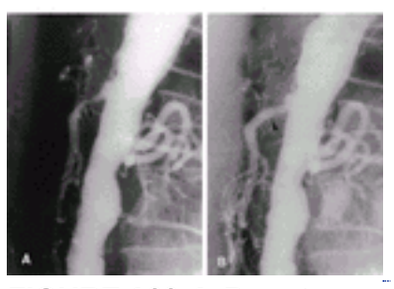

FIGURE 160-4. Percutaneous translumenal angioplasty for chronic mesenteric ischemia caused by mesenteric artery stenoses in a 78-year-old woman. **A:** Lateral aortogram shows occlusion of the celiac and inferior mesenteric arteries and high-grade stenosis of the superior mesenteric artery (*arrowhead*). **B:** After angioplasty, the stenosis (*arrowhead*) has been markedly decreased. Her symptoms markedly improved. She remained asymptomatic for 2 years after angioplasty.

Superior Mesenteric Artery Embolism

Embolism of the superior mesenteric artery is an important cause of acute intestinal ischemia with high mortality rates. Survival is often directly related to early diagnosis by emergency mesenteric arteriography. If an embolus is found in the proximal superior mesenteric artery, surgical treatment usually is indicated. In selected patients with an early diagnosis of peripheral embolism of the mesenteric arteries, intra-arterial thrombolysis may be a therapeutic alternative. [40], [41]

Splanchnic Artery Aneurysm

Selective arterial embolization is safe and effective in treating visceral arterial aneurysms in poor surgical risk patients, particularly those with pancreatitis-associated aneurysms and pseudoaneurysms. [42], [43] The embolization is usually done using the transfemoral approach. Celiac and superior mesenteric arteriograms are performed to evaluate the lesion and arterial anatomy. A 5-Fr catheter is advanced into the feeding artery as close to the lesion as possible. A 3-Fr coaxial catheter system is usually required to place the tip of the catheter close to or in the aneurysm. Coils are the most commonly used embolic agent. Thrombin may be added to the coils to promote clot formation.

If transarterial access to the aneurysm cannot be obtained owing to unfavorable arterial anatomy, the aneurysm is punctured percutaneously using a 22-gauge, skinny needle under ultrasonic or angiographic guidance. After confirmation of the position of the needle in the lesion, microcoils are deposited through the needle using a 0.018-inch guidewire, or thrombin is injected into the aneurysm. [44], [45]

Vascular lesions are uncommon complications of laparoscopic cholecystectomy. Most bleeding complications that occur intraoperatively are treated during the procedure. Any delayed vascular complications, such as hepatic artery pseudo- aneurysm and arteriobiliary fistula, [46] can be treated by selective embolization.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

TIPS is invaluable and has largely replaced surgical shunts in patients with variceal bleeding who fail medical and endoscopic treatment. [47]

TIPS is a nonsurgical method of achieving portal decompression in patients with portal hypertension and variceal hemorrhage. The indications for TIPS are variceal bleeding unresponsive to endoscopic therapy, recurrent variceal bleeding despite endoscopic therapy, portal hypertensive gastropathy, refractory ascites, hepatic hydrothorax, Budd-Chiari syndrome, stomal variceal hemorrhage, and portal venous thrombosis. [48], [49], [50], [51], [52] and [53] TIPS may also be a treatment option for liver transplant recipients with refractory variceal bleeding and intractable ascites. [54] There are no absolute contraindications for creating TIPS. The relative contraindications include elevated right heart pressure, heart failure, fulminant hepatic failure, severe hepatic encephalopathy, uncontrolled systemic infection or bacteremia, unrelieved biliary obstruction, multiple hepatic cysts, extensive primary or metastatic hepatic malignancy, and severe uncorrectable coagulopathy.

Technique

The transjugular approach to the portal venous system and creation of a portosystemic shunt between the hepatic vein and portal vein was developed by Rösch in animals [55] and in humans by Colapinto. [56] Before a TIPS procedure, patency of the portal vein should be demonstrated by imaging methods. US is the most commonly used method for evaluation of portal vein patency. The other methods include CT arterial portography, three-dimensional contrast MR venography, indirect portography (arterial portography), and carbon dioxide (CO_2) wedged hepatic venography.

Preprocedure fresh-frozen plasma or platelet transfusion is given if needed. The procedure can be performed under conscious sedation or a general anesthesia for uncooperative patients. The patient lies on his or her back, and the neck is slightly extended backward and turned to the left during the procedure. The right internal jugular vein is catheterized using a 21-gauge, single-wall puncture needle under real-time US guidance. A 10-Fr vascular sheath is advanced into the right atrium. A 5-Fr catheter is then introduced coaxially, and pressures are measured of the right atrium, IVC, and free and wedged hepatic veins. CO_2 digital subtraction wedged

hepatic venography is performed to see the portal vein.

A 16-gauge Colapinto needle (Fig. 160-5) is advanced over a 0.035-inch Amplatz, superstiff guidewire into the right hepatic vein. The guidewire is removed, and the needle is advanced with fluoroscopic guidance into the expected position of the right main portal vein 3 cm from the portal vein bifurcation. The needle is withdrawn until blood can be aspirated, and contrast medium is injected to see the vascular structure entered.

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

FIGURE 160-5. Colapinto needle used in transjugular intrahepatic portosystemic shunt (TIPS) procedure.

When the portal vein is entered, a guidewire is introduced into the superior mesenteric or splenic vein. The 9-Fr catheter is advanced over the Colapinto needle and guidewire into the portal vein. The needle is removed, and a 5-Fr catheter is advanced into the portal vein. Pressure of the portal vein is measured, and a portal venogram is performed (Fig. 160-6) to see the portal venous system and portosystemic collaterals. The parenchymal tract is dilated with an 8-mm PTA balloon catheter, and a 10-mm diameter metallic stent (see Fig. 160-6) is placed in the tract bridging the distance from the portal to the hepatic vein. Sometimes, more than one stent must be used to cover the tract. The stents are then dilated with a 10-mm PTA balloon to ensure their maximal expansion. Portal and systemic venous pressures are measured, and another portal venogram is obtained (see Fig. 160-6). The residual pressure gradient, the angiographically determined flow into portosystemic collaterals, such as gastroesophageal varices, gastrorenal or splenorenal shunts, and the patient's bleeding status, determine whether embolization is required.

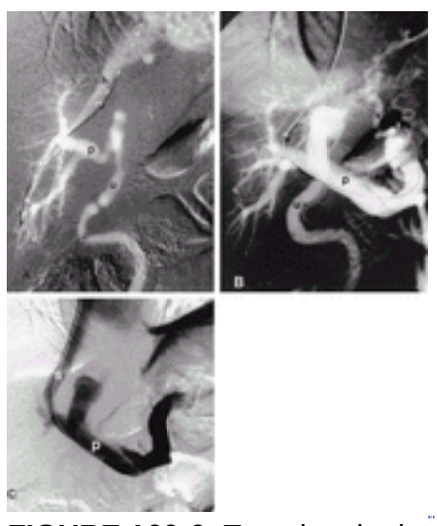

FIGURE 160-6. Transjugular intrahepatic portosystemic shunt (TIPS) in a patient with portal hypertension and variceal bleeding unresponsive to endoscopic therapy. **A:** Carbon dioxide wedged hepatic venogram shows hepatic (*h*), portal (*p*), and recanalized umbilical (*u*) veins. **B:** Transjugular catheterization of the portal vein. The transjugular portal vein catheter has been introduced into the splenic vein from the right hepatic vein. Contrast medium fills the portal (*p*) and umbilical (*u*) veins and esophageal varices (*v*). The portal venous blood flows toward the liver (hepatopetal). **C:** After creation of a 10-mm diameter TIPS shunt, the portal blood (*p*) flows through the shunt (*s*) directly into the right atrium. The intrahepatic portal and umbilical veins are no longer seen, indicating that the blood flows toward the shunt. The bleeding has stopped.

A portosystemic gradient of less than 12 mm Hg after creation of a TIPS is deemed satisfactory. The hemodynamic alterations caused by a TIPS are similar to those caused by H-mesocaval and side-to-side portacaval shunts, but there appears to be slightly better preservation of hepatic portal perfusion following the TIPS. The flow through the shunt can be controlled by modifying the size of the shunt. Portal vein blood flow is usually reversed after creation of a TIPS, and when injected into the portal vein, contrast medium will flow directly toward the shunt into the IVC. The intrahepatic portal venous branches will not fill. No benefit in terms of shunt patency and survival has been demonstrated by using a 12-mm stent. [57] The radial force of the 10-mm stent is greater than that of the 12-mm stent.

Intrahepatic portosystemic shunts can be performed using transmesenteric-transfemoral [58] and transfemoral [59] approaches. The transmesenteric-transfemoral technique involves catheterization of the portal vein through a mesenteric vein through a minilaparotomy [60] and percutaneous transfemoral access to the hepatic vein. The procedure is usually performed in the angiography suite. Through a midline incision, a mesenteric vein branch is cannulated by a 19-gauge needle, a 0.035-inch guidewire is advanced into the portal vein, and an 8-Fr vascular sheath is introduced. A curved blunt direction needle is inserted from the mesenteric side, and a 20-gauge needle is advanced from the portal vein to the hepatic vein in which a radiopaque basket is placed for a target. Once the needle is within the basket, a 0.018-inch, 260-cm long nitinol guidewire is advanced through the needle and retrieved through the femoral sheath. Over the guidewire, a 7-Fr, 100-cm long van Andel catheter is introduced from the femoral side. The liver tract is dilated with an angioplasty balloon catheter, and a 10-mm diameter metallic stent is deployed from the portal vein to the hepatic vein from the mesenteric site to create a shunt.

The transfemoral approach is used in patients with severely stenotic, angulated, or thrombotic hepatic veins, which make the standard jugular approach impossible. The procedure involves the placement of loop snares in the right portal vein and hepatic segment of the IVC and puncture of the IVC from the portal vein side using a sheathed needle. A guidewire is then advanced into the IVC and is snared and withdrawn through the transjugular sheath. A sheathed, 16-gauge Colapinto needle is advanced over the guidewire into the right portal vein. The parenchymal tract is dilated, and a stent is deployed from the main portal vein to the IVC.

TIPS Surveillance

Doppler US is an effective noninvasive screening tool for assessing TIPS patency and detecting increased portosystemic gradient. US examination after placement of a TIPS is obtained before discharge from the hospital and 3, 6, 9, and 12 months after the shunt. If US indicates shunt stenosis or occlusion, portal venography and pressure measurements are performed through the right internal jugular vein. Midshunt velocities of less than 60 cm/second, main portal vein velocities of less than 40 cm/second, or interval change from hepatofugal to hepatopetal intrahepatic portal flow at US examination usually indicates shunt stenosis. [61], [62] Because US screening of TIPS is not 100% sensitive or specific, angiographic evaluation may be required if clinical suspicion for stenosis is high. Helical CT angiography has been used to identify both normal and abnormal TIPS and to image focal or diffuse stenoses of the stents and hepatic vein. [63]

Therapeutic procedures can be performed easily on a failing TIPS in the outpatient setting. Patients whose shunts are occluded at US should undergo revision of their shunts. The shunt is catheterized from the jugular vein, and pressures are measured at the right atrium, IVC, hepatic vein, shunt, and portal vein. A portosystemic gradient of greater than 15 mm Hg usually indicates a malfunctioning shunt, and a portal venogram will disclose a stenosis anywhere from the portal vein to the hepatic vein. An angioplasty balloon catheter with the same size of the shunt can be used to dilate a narrowed shunt. If this is unsuccessful, a metallic stent is placed across the lesion.

Complications

The risks of TIPS vary greatly with the patient's bleeding status at the time of shunt creation. Data suggest that the 30-day survival of patients undergoing TIPS procedure is about 95%. In patients who are actively bleeding and who undergo TIPS, however, a 55% mortality rate has been seen. [64] Major complications include hemoperitoneum, gallbladder puncture, stent malposition, hemobilia, hepatic infarction, renal failure requiring dialysis, hepatic artery injury, accelerated liver failure, severe encephalopathy, cardiac perforation, intraperitoneal hemorrhage, and death. [65], [66], [67] and [68] The reported incidence of new or worsened encephalopathy after

TIPS is 20%. [49], [50] In almost all cases, the encephalopathy occurring after TIPS creation can be controlled medically. A balloon catheter can be used to occlude the shunt temporarily in a patient who develops refractory hepatic encephalopathy. Balloon occlusion of the shunt for more than 12 hours produces shunt thrombosis and improves encephalopathy [69] (Fig. 160-7). If the patient develops variceal bleeding after TIPS occlusion using an occlusion balloon catheter, shunt recanalization can be performed. The flow through the shunt can also be reduced by placing a Wallstent with constriction. [70] Minor complications include transient contrast-induced renal failure, encephalopathy controlled by medial therapy, transient pulmonary edema, and puncture site hematoma.

FIGURE 160-7. Temporary balloon occlusion of transjugular intrahepatic portosystemic shunt (TIPS) for refractory hepatic encephalopathy complicating TIPS placement. Balloon occlusion of the shunt (*arrow*) for 24 hours improved hepatic portal perfusion and encephalopathy. The portal venogram shows hepatopetal blood flow in the right portal vein (*open arrow*). Subsequently, a smaller shunt (7-mm diameter) was placed. One month later, the patient underwent successful hepatic transplantation.

Outcome and Prognosis

Patients with TIPS require intensive follow-up for at least 2 years after shunt placement, with shunt revision frequently being required. Primary shunt patency at 1 year after placement is only 25% to 60% [48], [71], [72]; however, with careful monitoring and treatment of shunt stenoses with balloon dilation, additional stent placement, or both, a primary-assisted patency rate of 83% to 96% can be achieved 1 year after placement. Some patients require more than one reintervention.

Acute and subacute TIPS thrombosis occurs in up to 10% of cases. Rarely, TIPS thrombosis may extend into the portal, splenic, and mesenteric veins. Percutaneous management in such cases includes thrombolysis, balloon embolectomy, suction embolectomy, and basket extraction of clot. Long-term results of each of the treatments are unknown, but a combination of methods may be required to restore mesenteric blood flow through the TIPS. [73]

Inadvertent traversal of bile ducts during creation of the intrahepatic tract results in biliary-to-TIPS fistulae that result in intimal hyperplasia and eventual shunt occlusion. Testing the parenchymal tract with injections of contrast material is useful in detecting inadvertent traversal of the bile duct before stent placement. If stent occlusion is associated with biliary fistula, stent grafts covered with polytetrafluoroethylene can be used to isolate the shunt from the fistula and to help prevent reocclusion. [74], [75]

The long-term patency rate of TIPS remains to be determined. Unless the stenosis rate of TIPS can be reduced, either with covered stents or pharmacological therapy, TIPS will have to be thought of as a temporary treatment of portal hypertension. Even as a temporary treatment, TIPS can effectively control variceal bleeding and stabilize patients who will undergo liver transplantation. As a method to control bleeding in Child's class C patients when other therapy has failed, TIPS is useful. In these patients, who have short life expectancies, a durable procedure is not required.

Operative shunts are clearly more durable than TIPS; thus, it must be determined whether TIPS with frequent follow-up and reintervention or surgical shunts result in longer survival or better quality of life in patients with longer life expectancies who, for medical or social reasons, are not transplantation candidates. Likewise, the role of endoscopic therapy and TIPS in elective treatment of variceal bleeding remains to be determined. TIPS is more effective in preventing recurrent bleeding than endoscopic therapy but produces encephalopathy. Both procedures require repetitive reintervention, and survival rates are similar.

BILIARY INTERVENTION

Percutaneous Transhepatic Cholangiography

Diagnostic information about the biliary tree, bile leakage, or intraductal lesions should first be obtained by noninvasive tests, CT, US, MR imaging, biliary scintigraphy or endoscopic US. When further diagnostic information or the opportunity for therapy is required, the invasive procedures, endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), are indicated. The choice between ERCP and PTC depends on local expertise, indication for the procedure, and the patient's anatomy.

The indications for PTC include (1) differentiation of obstructive from nonobstructive jaundice, (2) identification of the cause of ductal obstruction, (3) delineation of congenital anomalies, (4) determination of the site of biliary leakage, (5) documentation of communication of hepatic abscess with the biliary tree, and (6) visualization of ductal anatomy before percutaneous transhepatic biliary drainage (PTBD).

Contraindications include (1) uncorrectable coagulopathy, (2) history of severe reaction to iodinated contrast medium, (3) uncooperative patient (may require general anesthesia), (4) massive ascites, and (5) the presence of a vascular tumor or arteriovenous malformations. Risks include bleeding, sepsis, bile leakage, and death, with a 3% morbidity rate and a 0.1% mortality. [76]

Technique Coagulation studies are obtained on all patients, and significant abnormalities are corrected by the administration of fresh-frozen plasma, platelets, or both. Because of the high incidence of bacterial colonization of the biliary tree in patients with biliary obstruction, [77] broad-spectrum intravenous antibiotics are administered before and for 48 hours after the procedure. The imaging studies should be reviewed for the presence of intrahepatic masses and the distribution of intrahepatic biliary dilation. The puncture site is chosen in the midaxillary line midway between the costophrenic angle and the lower margin of the liver. Selection of a puncture site caudal to the 10th rib usually helps avoid the pleural space. After the puncture site is selected, the area is washed with povidone-iodine (Betadine) and isolated with drapes. The skin and planned puncture tract are anesthetized with 2% lidocaine. The skin nick is made in the caudal portion of an intercostal space to avoid the intercostal vessels and nerves. Under fluoroscopic control, a 22-gauge, skinny needle is directed, in a plane parallel to the table top, to a position 3 cm cephalad to the hilum of the liver. The position of the hilum is estimated fluoroscopically by observing the position of the dome of the liver and the air in the first and second portions of the duodenum. The stylet is removed, and the needle is connected through a connecting tube to a contrast-filled syringe. The needle is slowly withdrawn while small amounts of nonionic contrast medium are injected. When the needle tip is in the hepatic parenchyma, the contrast agent remains adjacent to the needle tip or opacifies the hepatic sinusoids. When the tip is in a hepatic artery or portal vein, the contrast agent washes out promptly to the liver periphery. When the tip is in a hepatic vein, the contrast agent washes out promptly toward the IVC. When the tip is in a biliary duct, the contrast material flows away slowly to reveal branching ducts as well as the central bile ducts (Fig. 160-8). When the tip is in a lymphatic duct, the contrast material enhances small channels that run toward the liver hilum.

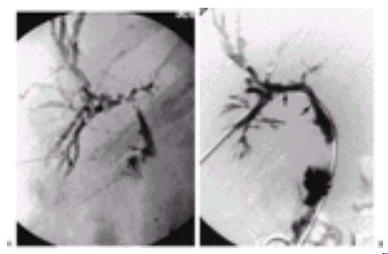

FIGURE 160-8. Percutaneous transhepatic cholangiography and cholangioplasty in a 46-year-old woman who 9 years earlier had undergone orthotopic liver transplantation for primary sclerosing cholangitis. **A:** Contrast medium was injected into a peripheral branch of the right hepatic duct through a 22-gauge needle (*arrowhead*) showing multiple intrahepatic and hilar biliary strictures. Contrast medium flows through the choledochoenterostomy (*arrow*) into the bowel. **B:** Cholangioplasty with a 6-mm diameter balloon catheter improved biliary strictures (*arrows*). The left hepatic duct has been occluded.

If no bile ducts have been encountered by the time the needle has been withdrawn to within 2 to 3 cm of the liver edge, the stylet is reinserted and the needle readvanced to a slightly different position. With dilated ducts, the biliary tree can be punctured almost always within several needle passes. [78] When the intrahepatic ducts are not dilated, additional needle passes frequently are required. For optimal visualization of the left hepatic ducts, or if a left-sided drainage is anticipated, a skin puncture site is chosen below the xiphoid process with the help of real-time US. A peripheral location in a duct of the lateral segment of the left lobe is chosen to be the puncture site so that if drainage is desired, the catheter will have a long segment with multiple side holes within the hepatic duct above the obstruction. The needle is angled parallel to the duct in the axial plane toward the hilum of the liver and at a 30- to 50-degree angle to the table top. The needle is advanced under real-time US guidance, and its position is confirmed with injection of contrast medium. If the site of obstruction has previously been determined by cross-sectional imaging and biliary drainage is to be performed, only a small amount of contrast agent is injected to assist guidewire placement. If a diagnostic study is to be performed, first an attempt is made to aspirate as much bile as possible, although typically, little or no bile can be aspirated through the fine needle because of its viscosity. Any bile obtained is sent for a Gram stain and culture and sensitivity tests. Iodinated contrast medium is slowly injected, and the contrast medium can be seen to flow into the most dependent ducts. Distention of the biliary tree is minimized to avoid causing bacteremia. By tilting the table, the radiologist takes advantage of the higher specific gravity of contrast material, allowing it to flow to opacify ducts not seen with the patient in the supine position. Radiographs are obtained in multiple obliquities, and the needle is removed. The patient is placed on bed rest for 6 hours, and vital signs are monitored. Fine-needle PTC is successful in 98% of patients with dilated ducts and in 70% of patients with nondilated ducts. [76] Major complications of PTC are sepsis, cholangitis, bile leak, hemorrhage, or pneumothorax, occurring in 2% of cases. [77]

Percutaneous Transhepatic Biliary Drainage

Nonoperative biliary drainage can be performed percutaneously or endoscopically in patients with biliary obstruction. Endoscopic techniques should be used when possible because the morbidity of endoscopic approach is lower than that of PTBD. ERCP has a higher failure rate with biliary obstruction at or above the hilar level, making PTBD frequently necessary in these patients (see Fig. 160-8). In technically difficult situations in which endoscopic access has failed, a guidewire can be placed into the duodenum transhepatically to facilitate repeat ERCP and intervention. These “combined procedures” are associated with increased complications but have high success rates.

The indications for PTBD include (1) palliation of obstruction of the biliary tree by tumor, (2) treatment of cholangitis, (3) nonoperative removal of common bile duct or intrahepatic stones when ERCP is unsuccessful, (4) access for dilation of benign biliary strictures, and (5) diversion of bile for treatment of biliary leaks or fistulae.

An uncorrectable coagulopathy is a contraindication for PTBD. Prominent ascites is a relative contraindication because the liver is displaced from the abdominal wall. This displacement can cause buckling of guidewires and catheters between the abdominal wall and liver, making the procedure difficult. Also, in patients with ascites, a risk exists of creating a peritoneal-cutaneous fistula with chronic leakage of ascitic fluid. Paracentesis can be performed before PTBD to minimize these problems.

The complications of PTBD include bleeding, sepsis, cholangitis, bile leakage, hemorrhage, pancreatitis, peritonitis, and death. Immediate significant complications are seen in 5% to 10% of patients. [78], [79] Patients who have chemotherapy-induced biliary sclerosis and obstructive jaundice have a higher incidence of bleeding complications with development of central pseudo- aneurysm following PTBD. [80] After access to the bile duct has been made, the tract may be injected with contrast medium to exclude communication with large vascular structures. If vascular communication is seen, the access should be abandoned, and a new puncture of a peripheral bile duct is made. This technique reduces the incidence of hemobilia. [81] The overall mortality rate reported with PTBD is 1.7%.

Technique The puncture of a bile duct is the same as that for PTC. After a small injection of contrast medium confirms the needle position in a bile duct, a 0.018-inch (0.46-mm) wire is passed through the needle into the bile duct. Over the guidewire, a 6.3-Fr introducing catheter with a stiffening cannula is advanced into the common bile duct. The stiffening cannula and the wire are removed, and bile is aspirated. After the biliary tree has been decompressed, a cholangiogram is performed with injection of contrast medium in the bile duct near the obstruction. The introducer is then exchanged for a 50-cm catheter with an angled tip. The catheter is then advanced to the point of obstruction, and a hydrophilic guidewire is manipulated through the obstruction into the duodenum. The catheter is advanced into the duodenum over the guidewire. The parenchymal tract is then dilated using sequential dilators over a 0.035-inch (0.89-mm) stiff guidewire, and an 8.5-Fr (outer diameter of 2.8 mm), internal-external drainage catheter is advanced into the duodenum, its distal retention loop is formed, and the drawstring is locked at the catheter hub to prevent catheter displacement. The drainage catheter is connected to a drainage bag to allow maximal drainage, which reduces the risk for sepsis. On the second day, the catheter is capped to allow internal drainage only. Once the internal drainage has been established, placement of a biliary endoprosthesis, if desired, is performed. If the guidewire does not traverse the occlusion, an external drainage catheter is placed above the obstruction, and the catheter is allowed to drain externally for 2 to 3 days. After a period of decompression, the obstruction usually can be crossed, and an internal-external drain can be placed. If the drainage is being performed for the treatment of biliary sepsis, no attempt is made to traverse the obstruction. Rather, an external drainage catheter is placed above the obstruction, and a more definitive procedure is performed in several days. Catheter and guidewire manipulation in purulent bile should be minimized because of the profound bacteremia that can ensue. The success rate of PTBD is high, and most malignant biliary obstructions can be crossed. In patients with malignant biliary obstruction, bilirubin levels fall quickly (2 mg/day) after decompression, and patients drained for sepsis defervesce within 24 hours. [82]

Percutaneous Transhepatic Cholangioplasty

An angioplasty balloon catheter can be used to dilate benign biliary strictures through endoscopy, a transhepatic access (see Fig. 160-8), a mature T-tube tract, or a percutaneous transjejunal route. [83] Endoscopic dilation is generally preferred by the patient owing to the lack of an external appliance and has long-term success rates of 70% to 85%, although it requires two to five ERCP sessions. [84], [85] The usefulness of temporary stent placement after cholangioplasty is debated for both the endoscopic and percutaneous routes, and even among those who favor using stents, the stent size and appropriate duration of having the stents in place is controversial. Long-term patency rates of percutaneous cholangioplasty are 67% to 93% for anastomotic strictures, [86], [87] and [88] 76% to 88% for iatrogenic strictures, [86], [87] and 42% to 54% for strictures of primary sclerosing cholangitis. [86], [89] Balloon dilation works well, is less expensive than placing stents, and will not interfere with a future operation, as might a metallic stent. Maccioni and associates [90] reported a 69% 3-year patency rate in a series of patients with anastomotic stenoses and iatrogenic bile duct injuries.

Transhepatic balloon dilation is a safe and effective treatment for biliary stricture in liver transplant recipients. [91] The dilation procedure usually requires multiple sessions (one to six sessions; mean, three). Balloon sizes to be used depend on the estimated size of the duct and are usually 25% to 30% larger than the duct. Balloon size is increased by 1 to 2 mm at each session, and the balloon is inflated two to three times to a pressure of 10 to 12 atm for 10 to 20 minutes. After dilation, an 8.5- to 14-Fr drainage catheter is placed.

Percutaneous Transhepatic Biliary Stent Placement

Internal stents (endoprostheses) can be placed at ERCP or PTC to provide biliary drainage without an external catheter and thus improve quality of life. The problem with internal stents is limited patency, which ranges from 4 months to 1 year. [92], [93], [94], [95] and [96] Endoscopically placed metallic biliary stents have longer patency than plastic stents owing to larger diameters but are not indicated in benign disease or in patients with operable tumors because they are permanent. [95] Endoscopic placement of internal stents is preferable to the percutaneous route because it can be achieved in a single session without the need for temporary percutaneous drainage. Percutaneous endoprosthesis placement is usually reserved for patients who have failed ERCPs or who already have percutaneous access. [97]

Hilar biliary stricture formation is a common complication of orthotopic liver transplantation, occurring in 10% of transplantations. [98] Intrahepatic strictures unresponsive to balloon dilation have been treated with metallic stents with relatively poor long-term patency. Culp and colleagues [99] reported on placement of 61 metallic stents in 36 liver transplant recipients with biliary stricture. Their primary patency rate was 44% at 3 years, with a secondary patency rate of 88%. Major stent-related complications occurred in 26% of their patients. Obstructed stents often require percutaneous drainage and additional stent placement to maintain patency. [100] Therefore, metallic stents play a limited role in the treatment of biliary stricture in the liver transplant recipient. Metallic stents are not generally used for treatment of other benign biliary strictures. [101] In patients with malignant biliary strictures, a significant decrease in bilirubin level occurs in 83% following metallic stent implantation, and 30% of patients develop recurrent jaundice after an average of 97 days. [102]

A variety of plastic and metal stents are in clinical use. Plastic stents require 12- to 14-Fr sheaths for placement, whereas metal stents can be placed through 7-Fr sheaths (Fig. 160-9, Fig. 160-10 and Fig. 160-11). Stent placement is usually done through the existing percutaneous transhepatic tract (Fig. 160-12) or endoscopically. The most common size of metallic stents is 10 mm in diameter and 4 to 8 cm in length, longer than the 10- to 14-Fr plastic stents. After the stent has been placed, an external drainage catheter is left above the stent for 48 hours and withdrawn after demonstration of stent patency.

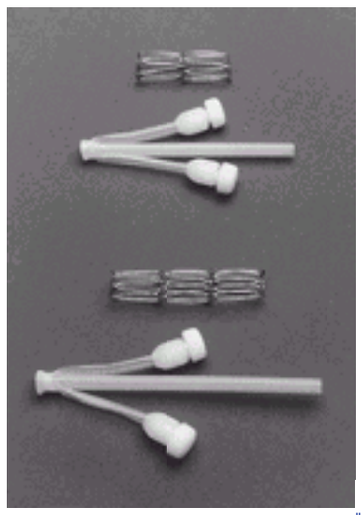

FIGURE 160-9. Two- and three-body Gianturco-Rösch stents and their loading devices.

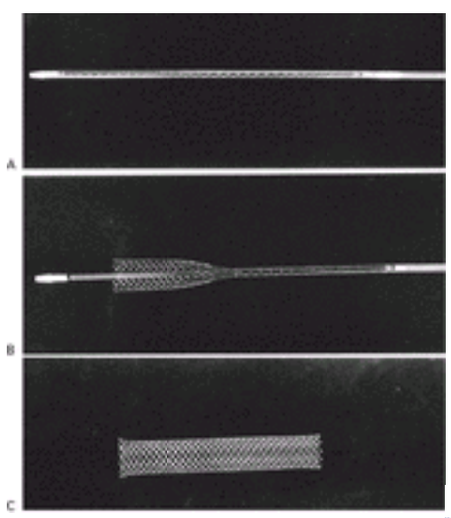

FIGURE 160-10. The Wallstent (**A**) in its constrained, elongated form, between two coaxial catheters and (**B**) partially deployed with the outer catheter partially pulled back over the inner catheter. **C:** The fully deployed stent.

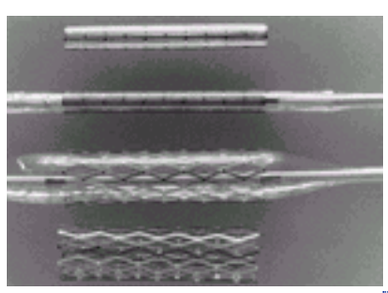

FIGURE 160-11. The Palmaz stent. From *top* to *bottom:* the stent; the stent mounted on an angioplasty balloon; the stent expanded to the size of the balloon on balloon inflation; and the stent after removal of the balloon.

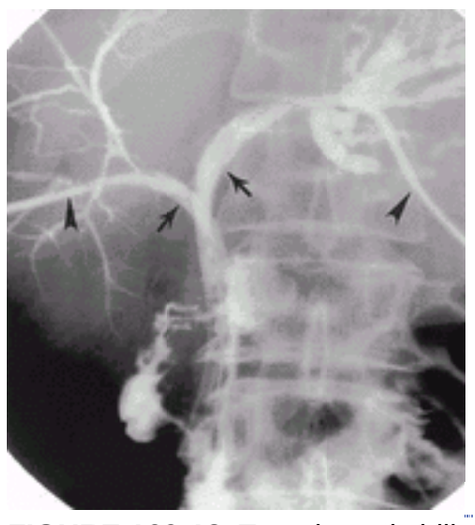

FIGURE 160-12. Transhepatic biliary stent placement in a 61-year-old man with Klatskin tumor. After bilateral percutaneous transhepatic drainage catheter placement for 6 months for hilar duct obstruction, 8-mm diameter Wallstents (*arrows*) were deployed simultaneously in both hilar ducts. The percutaneous catheters (*arrowheads*) were removed after demonstration of patency of the stents.

The common complications of endoprostheses are occlusion, migration, and cholangitis. The occlusion is usually caused by either tumor overgrowth or ingrowth or clogging of the stent by sludge or debris. [103] Plastic-covered Wallstents may reduce the rate of tumor ingrowth in patients with malignant biliary obstruction, but their application should be limited to the common bile duct to avoid obstruction of the hepatic ducts. [104]

Combined therapy with stent placement and brachytherapy with iridium-192 wire in patients with malignant biliary obstruction appears to extend stent patency to a mean of 19.5 months for cholangiocarcinoma and 4.8 months for metastatic disease. [105] The combination of arterial chemoembolization and brachytherapy after stent placement may result in additional palliation for biliary obstruction. Covered Gianturco stents have been used for malignant biliary obstruction, achieving a longer patency rate without increased complication rates. [106]

In patients with a Hutson loop (afferent limb of a Roux-en-Y choledochojejunostomy or hepaticojejunostomy sutured to the anterior abdominal wall), repeat access to the bile duct can be done for biliary drainage, cholangioplasty, or placement of biliary endoprostheses. [107], [108] and [109]

Percutaneous Cholecystostomy

Percutaneous cholecystostomy (PC) has become an effective technique in the management of acute cholecystitis. The indications for PC include (1) suspected cholecystitis in severely ill patients unlikely to tolerate cholecystectomy, (2) sepsis of unknown cause and a distended gallbladder in critically ill patients, [110] (3) acalculous cholecystitis, [111] (4) obstructive jaundice because of distal common bile duct obstruction when PTBD and endoscopic drainage are unsuccessful, [112] (5) diagnostic cholecystocholangiography in patients without dilated intrahepatic ducts or in whom PTC and ERCP are unsuccessful, and (6) gallstones requiring percutaneous removal or dissolution, in selected patients. The relative contraindications for PC include the visualization of a necrotic or perforated gallbladder wall on US examination and an uncorrectable bleeding diathesis.

Once the PC tract is matured, percutaneous techniques—including contact dissolution using methyl-tert-butyl ether or monoctanoin, mechanical lithotripsy, electrohydraulic lithotripsy, and laser lithotripsy—can be used to remove gallstones. Aside from the cost and multiple sittings required for many of these procedures, the main failing is that the gallbladder remains in situ to reform stones in 20% to 50% of patients, [113] with an increased risk for gallbladder carcinoma. [114] The rapid evolution of laparoscopic cholecystectomy has supplanted these percutaneous techniques in most circumstances because laparoscopic cholecystectomy does not leave the gallbladder in place. PC should be performed in severely ill patients who may not tolerate laparoscopic cholecystectomy.

Technique Intravenous antibiotics are given and coagulopathies are corrected before the procedure. Ideally, the procedure is performed in the angiography suite with a combination of US guidance for gallbladder puncture and fluoroscopy for guidewire and catheter placement. Extremely ill patients may be treated at their bedside with the entire procedure guided by US. The procedure is performed under local anesthesia. PC initially was performed by means of a transhepatic approach in an attempt to puncture the gallbladder through the bare area of the liver and avoid the possible complication of bile peritonitis. [115] Transhepatic puncture does not ensure puncture through the bare area, however, and transhepatic transperitoneal punctures are common. [116] Subhepatic puncture has been shown to be safe and avoids the risk for bleeding from hepatic injury. [117], [118] and [119] A variety of techniques are used for PC, including the standard Seldinger technique with needle puncture, guidewire placement, removal of the needle, tract dilation, and advancement of a drainage catheter over the guidewire into the gallbladder. Another technique more suitable for use at the bedside involves the use of a trocar. A tapered catheter with an inner stiffener and a central mandril with a sharp point are advanced into the gallbladder under US guidance. Another technique appropriate for bedside use involves a long, 22-gauge needle with a 6-Fr Teflon catheter loaded on the back of the needle. The needle is placed into the gallbladder under US guidance, and its mandril is removed. Injection of a small volume of saline and observation with US can be used to confirm the intralumenal position of the needle tip if the bile is too viscous to be aspirated through the long 22-gauge needle. A 0.046-cm guidewire is advanced through the needle, and the needle tip is positioned in the center of the gallbladder. The catheter is advanced over the needle-wire unit into the gallbladder. The needle and guidewire are removed, and the monofilament suture present within the catheter is tightened to accordion the catheter into a Z-shaped self-retaining configuration. Bile is obtained for aerobic and anaerobic bacterial cultures, and the catheter is secured to the skin. Although a small amount of contrast medium may be injected to confirm catheter position, if the PC is being performed for cholecystitis, a cholecystogram should not be performed at this time to reduce the risk for gallbladder distention and bacteremia. The catheter then is connected to gravity drainage. The use of a self-retaining catheter is essential to reduce the risk for catheter dislodgment and bile leakage. A diagnostic cholecystocholangiogram can be performed to evaluate cystic duct patency and cholelithiasis after 48 hours and after the patient's condition stabilizes. Options for definitive therapy include cholecystectomy, percutaneous stone removal, or, if the patient had acalculous cholecystitis and cystic duct patency is confirmed, eventual removal of the catheter with no further treatment. The catheter cannot be removed until the tract is mature or bile leakage can occur. Patients with transhepatic PC catheters have mature tracts at 20 days. [119] If a question exists about the maturity of the tract, it can be evaluated under fluoroscopy with injection of contrast medium. For patients with severe nonbiliary problems, the catheter frequently is left in place until other medical problems resolve.

Complications The complication rate is 5% to 8%; complications includes bile leakage, vasovagal reaction, catheter dislodgment, hemorrhage, and a 0.5% procedure-related mortality rate. [120] In comparison, emergency surgical cholecystostomy has a mortality rate of 8%. [121]

Results PC for presumed cholecystitis in critically ill patients is useful for diagnosis and treatment. Although initially it was thought that Gram stain and culture of aspirated gallbladder contents would be useful to diagnose cholecystitis, many of these patients are already on broad-spectrum antibiotics. The 48% sensitivity rate of Gram stain and 38% sensitivity rate of bile culture are sufficiently low to make gallbladder aspiration a procedure of limited value. [120] However, PC is useful as a clinical diagnostic test. Essentially all patients who have cholecystitis without a necrotic gallbladder wall will defervesce and normalize their leukocyte count after drainage. [111], [122] Severely ill patients who have ultrasonographic evidence of a necrotic gallbladder wall are less likely to respond to PC and should undergo immediate operation or a trial of PC with operation to follow if no clinical improvement is seen in 24 hours, depending on the patient's risk for surgery. [123] In patients without a necrotic gallbladder wall and no response to PC, cholecystitis is excluded, and the search for a nongallbladder source of sepsis should continue.

Biliary Duct Biopsy

The most difficult diagnostic problem of bile duct lesions is differentiating between malignancy and inflammatory disease in the patient with biliary strictures. Bile aspiration yields only 35% positive cytology. Brush biopsy, clamshell forceps biopsy, and shave biopsy are somewhat more sensitive, with sensitivities of 44% to 67% reported. [124], [125] and [126] Endoscopically, a combination of tissue sampling techniques, such as direct forceps biopsy, brush cytology, and aspiration cytology, has the highest yield. [127] An advantage of endoscopic over percutaneous tissue sampling is that it can all be performed during the initial procedure.

For the percutaneous route, in the absence of bacteremia or hemobilia following drainage, biopsy can be performed 1 to 2 days after the procedure. [128] Broad-spectrum antibiotics are administered before the procedure. The transhepatic drainage catheter is exchanged over a guidewire for an introducer, which is advanced distal to the stricture or to the duodenum, and a second safety guidewire is placed into the duodenum. A 3-mm bronchoscopy brush or a removable ureteral biopsy brush is advanced through the sheath or through an introducing catheter beyond the lesion. After brushing of the lesion has been performed, the brush is pulled into the introducing catheter or the sheath before withdrawal. The brush is cut from the wire and submitted for cytologic examination.

Another technique for biliary biopsy involves the use of forceps. After placing a safety wire in the duodenum, a 7-Fr, peel-away sheath is placed immediately proximal to the lesion, a 5.2-Fr or a 7-Fr flexible clamshell forceps is advanced to the lesion, and biopsy is performed. Clamshell forceps biopsies can also be performed through a choledochofiberscope.

Laparoscopic Injuries to the Biliary System

Both endoscopic and interventional radiologic management techniques play an important role in the treatment of patients with bile duct injuries from laparoscopic cholecystectomy. The injuries include biliary obstruction from bile duct transection or stricture, biliary leakage with formation of bilomas, and retained stones. US or CT is the initial imaging method used for the diagnosis of the biliary complications. ERCP is then performed to obtain the necessary anatomic information for therapy. If ERCP is unsuccessful or unable to cross the obstruction secondary to inadvertent ligation of the bile duct, a drainage catheter must be placed above the obstruction.

Biliary strictures that are not amenable to surgical intervention may be treated with percutaneous or endoscopic balloon dilation. Before the procedure, the patient is given broad-spectrum antibiotics. The procedure can be done on an outpatient basis with conscious sedation and local anesthetic. After placing a 0.035-inch guidewire across the stricture, a balloon catheter (usually 8 to 10 mm in diameter) is placed over the guidewire and inflated two to three times for 3 to 5 minutes. A

drainage catheter, such as an 8.5-Fr Cope-loop catheter, is left across the stricture for external drainage, and the treatment effectiveness is then assessed in 1 to 2 weeks. If a satisfactory response is demonstrated by a follow-up cholangiogram, a catheter is placed above the stricture and capped to allow internal drainage for 1 to 2 weeks before withdrawal of the catheter. Metallic stents should be reserved for patients with a recurrent biliary stricture following multiple balloon dilations who are not candidates for surgery.

Bile leak is treated with temporary diversion of bile through endoscopic biliary intubation or transhepatic stent placement. After 3 to 4 weeks of bile diversion, the plastic stent is removed over a guidewire, and a cholangiogram is performed through a sheath to show healing of the leak. If no leak is demonstrated, a drainage catheter is placed above the area of leakage and capped for 1 to 2 weeks to reassess bile duct leak before removal of the catheter. If the leak is associated with significant bile collection, percutaneous drainage is performed under CT or US guidance.

Retained common bile stones may be found after laparoscopic cholecystectomy. Endoscopic extraction after sphincterotomy is the preferred method in such patients. If an endoscopic approach is unsuccessful, a percutaneous transhepatic approach may be used. Stone extraction should be deferred 4 to 6 weeks to allow the tract to mature after placement of a transhepatic catheter. Alternatively, combined ERCP and PTC, with the PTC wire facilitating endoscopic access, may be used.

Biliary Manometry

Biliary manometry is used to assess bile pressure and flow dynamics. This is different from the sphincter of Oddi manometry performed at ERCP, which measures sphincter muscle function. Measurement of bile pressure at PTC has been shown to be useful in predicting long-term success after treatment of biliary strictures with balloon cholangioplasty. [129]

The patient is treated with prophylactic antibiotics before the examination. In patients with transhepatic biliary intubation, the indwelling tube is removed over a guidewire and an end-hole catheter is placed above the treated stricture and connected to a manometer. Pressure is measured at the level of the midaxillary line. Continuous pressure measurements are obtained before and during perfusion of 30% contrast medium at rates of 5 and 10 mL/minute for 5 minutes and at rates of 15 and 20 mL/minute for 2 minutes. The perfusion should be discontinued if the patient experiences right upper abdominal pain or chills, or if the biliary pressure increases to more than 30 cm H_2O. In the absence of a significant stricture, the biliary pressure will remain less than 20 cm H_2O during the perfusion.

Percutaneous Biliary Stone Extraction

Endoscopic sphincterotomy with stone extraction is the primary mode of treatment for choledocholithiasis. However, if a T-tube tract or transhepatic access is available, radiologically guided stone extraction may be performed. Intrahepatic stones occasionally are inaccessible at ERCP and require the percutaneous transhepatic route. Choledoscopy facilitates stone extraction. [130] Percutaneous stone extraction is a radiologically guided procedure for the treatment of biliary stones not amenable to surgical, endoscopic, or extracorporeal shock wave therapy. [131], [132] Stone removal can be done through the preexisting mature transhepatic biliary drain tracts, T-tube tracts, cholecystostomy tube tracts, and hepaticocutaneous enterostomy.

Basket removal of retained stones through the T-tube tract is a safe and simple method of removing retained stones. With the advent of the steerable catheter system, stone extraction has become a technically easy procedure. The Dormia-type basket is most commonly used for stone extraction. The steps for stone extraction are (1) removal of the T-tube over a guidewire, (2) insertion of a steerable catheter through the T-tube tract, and (3) extraction of the stone using a wire basket. After the stone has been extracted, a drainage catheter is placed in the common bile duct. When no residual stones are present, the catheter is capped for 1 to 2 weeks of “clinical trial” before withdrawal of the catheter. Large stones must be fragmented using crushing baskets or electrohydraulic lithotriptor before extraction. [133] Extracorporeal shock wave lithotripsy is effective in fragmenting bile duct stones but often requires extraction of fragments. [134], [135] Percutaneous techniques may be used for removal of gallstones in patients with high surgical or general anesthetic risk. [136] Because the percutaneous method is a gallbladder-sparing procedure, it carries a risk for recurrence of stone (40%) and symptoms (12%).

Percutaneous Management of Biliary Fistula

Biliary fistulae that originate in the liver may result from trauma, surgery (cholecystectomy, resection of hepatic tumor, and liver transplantation), or local infection, such as hydatid disease. Small biliary fistulae may close spontaneously, and no specific treatment is required. When a biliary fistula is associated with distal biliary obstruction, however, biliary decompression is usually required by using endoscopic or percutaneous transhepatic intervention. [137], [138], [139] and [140]

The nonoperative methods for managing biliary fistulae include external biliary drainage, nasobiliary catheter drainage, bile duct stent placement, and sphincterotomy. Selective embolization through a percutaneous transhepatic or endoscopic approach may be used for the treatment of biliary fistulae unresponsive to biliary decompression. [141]

PERCUTANEOUS BIOPSY

Percutaneous image-guided sampling of abdominal lesions is a safe and effective method of obtaining material for cytologic or histological analysis and for microbiologic and chemical analysis of fluid collections. Advances in CT and US have allowed accurate localization of smaller and more subtle lesions, and experience has demonstrated the safety of percutaneous biopsy through windows previously thought to be unsafe.

Technique

The optimal imaging modality for guiding a needle biopsy depends on the position and visualization of the lesion, the patient’s body habitus, the ability to introduce radiopaque contrast medium adjacent to the lesion, and the experience of the radiologist. Patients undergoing biopsy have their prothrombin time, activated partial thromboplastin time, and platelet count checked and corrected if necessary. Patients who are to receive intravenous contrast medium are hydrated and have their blood urea nitrogen and creatinine levels checked. Most patients do not require a sedative, but those who are unusually anxious or find it painful to lie in the required position are given midazolam, fentanyl, or both.

Fluoroscopy in multiple planes, most frequently with a C-arm, provides easy and efficient guidance for biopsy of large, superficially located lesions. Fluoroscopic landmarks, such as distance from a particular bony structure or position adjacent to a radiopaque stent, can be used to position the needle. If an indwelling biliary catheter is present, contrast medium can be introduced to allow fluoroscopically guided biopsy of biliary duct lesions. Fluoroscopy also is useful for biopsy of abnormal lymph nodes identified at lymphangiography that still contain lymphangiographic contrast medium.

Real-time US has many advantages for intra-abdominal biopsy. Perhaps its greatest advantage is that, unlike CT, it allows continuous monitoring of the course of the needle while it is being advanced, allowing instant readjustment of the needle path as necessary. US guidance may be applied when the lesion is ultrasonographically visible and a needle path that avoids gas-filled bowel exists because the soft tissue–gas interfaces reflect most of the sound waves and preclude visualization of the needle tip and the lesion. US also is advantageous when the ideal needle path is at a steep angle to the axial plane because such an angle makes CT guidance more difficult. However, US guidance is difficult in obese patients because fat degrades the US image.

CT is most frequently used to guide biopsies that cannot be performed reliably with fluoroscopy or US. CT usually is the imaging modality of choice for small, deep-seated lesions. Oral, intravenous, and rectal contrast medium is administered as needed for lesion visualization. To perform CT-guided biopsies, a localizing radiopaque grid is placed on the skin covering the region of the skin entry site as estimated from prior scans, and a scan at the level of the lesion is repeated. A needle path is chosen, preferably in the axial plane, and the skin puncture site is marked on the skin. The depth of the lesion and the angle between the needle path and a vertical line through the lesion are measured.

The types of needles available for percutaneous biopsy are nearly as numerous as the types of diseases for which biopsy is performed. Needles can be classified into those that obtain material for cytologic analysis and those that obtain tissue for histological analysis. Needles from 25-gauge to 14-gauge are used: the smaller sizes predominantly for aspiration cytologic study and the larger ones for obtaining a core of tissue. Aspiration cytologic study with a skinny needle (20 to 25 gauge) is the most frequently performed percutaneous biopsy. When a tissue core is desirable, the spring-loaded, mechanically triggered biopsy needles (guns) are used. These needles have a Tru-Cut–type design, and once in position, the inner or outer parts (depending on the manufacturer) of the needle are advanced rapidly forward by a

preloaded spring mechanism. These guns offer the benefit of producing less pain than the Tru Cut needle, and some 18-gauge guns produce a specimen as good as that obtained with a 14-gauge Tru Cut needle. [142]

A needle path is chosen that avoids lung, gallbladder, and spleen and, if possible, bowel and vascular structures. Passing 21-gauge needles through the stomach and small and large bowel is safe. [143] Some institutions are routinely placing 18-gauge needles through bowel without complication. It appears judicious to avoid puncturing bowel in immunocompromised patients and those with ascites.

Local anesthetic and a small skin nick precede needle placement. The needle may then be advanced directly into position. If a larger needle is being used, a skinny needle may be first positioned within the lesion, then the larger needle may be placed parallel to the smaller needle. This allows the needle repositioning common with CT guidance to take place with the smaller needle and allows the larger needle to be properly positioned on the first pass. A coaxial needle technique also is useful for small or difficult lesions. The technique involves placement of a larger needle up to the lesion with the biopsy performed through a smaller inner needle. This allows simple, repetitive sampling by removing only the smaller inner needle, assessing its yield, and if necessary, replacing the inner needle and repeating the biopsy.

Indications

In most cases, an aspiration biopsy is adequate to make the diagnosis of malignancy, although specific tumor characterization may require a core of tissue. Aspiration biopsy is useful in diagnosing acute liver transplant rejection, but core biopsy is more useful in diagnosing chronic rejection. [144] Core soft tissue should be obtained routinely whenever the cellular architecture is important for microscopic diagnosis (e.g., diffuse liver disease, likely benign focal liver lesions, lymphoma).

Contraindications and Risks

A patient who will not lie still is an absolute contraindication for image-guided needle biopsy. It is impossible to target a moving lesion, and there is the risk for visceral injury. For biopsy of abdominal lesions, patients must be capable of holding their breath for a minimum of 10 seconds so that respiratory excursion of the lesion is suspended during needle placement. A bleeding diathesis is a relative contraindication depending on the severity of the diathesis, the location of the lesion, lesion vascularity, and the size of the needle required. If a coagulopathy would otherwise contraindicate biopsy and the lesion is intrahepatic, transvenous biopsy or biopsy with embolization of the needle tract (plugged biopsy) can be performed. Ascites does not affect the major or minor complication rate of image-guided hepatic biopsy. [145]

Suspected hemangiomas have been listed as a contraindication for needle biopsy; however, after unintended aspirations of such lesions were reported, several authors reported series of safe biopsy of these two entities. [146], [147] With use of a 20- gauge cutting needle, a percutaneous hepatic biopsy can be safely performed for histological diagnosis of hemangioma. [147] A needle path traversing normal liver before reaching the lesion is recommended to reduce the possibility of hemorrhage.

Percutaneous needle biopsy is a relatively safe, invasive procedure with low morbidity and mortality. Severe pancreatitis can occur after pancreatic biopsy, and the incidence of pancreatitis increases when biopsy is performed on a normal pancreas. Needle tract tumor seeding after intra-abdominal biopsy is a rare occurrence. Traversing normal parenchyma before entering a lesion may reduce the risk for seeding. Hemorrhage is the most common complication of liver biopsy. Hemorrhage may occur as intra-abdominal bleeding or hemobilia after creation of an arteriobiliary fistula. Severe hemobilia after needle biopsy is best managed with selective embolization of the bleeding artery. Severe intra-abdominal bleeding may be more common if the needle does not initially traverse normal parenchyma.

Results

Image-guided hepatic biopsy using skinny needles is accurate in the diagnosis of malignancy in more than 90% of patients. [148] Accurate diagnosis of hemangioma can be made 100% of the time using a 20-gauge coring needle. [147] Skinny needle biopsy of the pancreas has been reported to be accurate 60% to 90% of the time. The coexistence of pancreatic carcinoma and pancreatitis may result in biopsy of the inflammatory area, which frequently cannot be distinguished by CT or US from the neoplastic area. The possibility of sampling error suggests that an initial negative result from percutaneous pancreatic biopsy should not be accepted, and either a repeat percutaneous biopsy or an operative biopsy should be performed as warranted by clinical circumstances.

Percutaneous image-guided aspiration biopsy of lymph nodes has been performed more often than large-core biopsy for evaluation of lymphadenopathy. Fine-needle aspiration of lymph nodes using cytologic examination for detection of metastatic carcinoma is highly accurate. [149] The accuracy of detecting lymphoma is about 80%. [149] Accurate typing of lymphoma by fine-needle aspiration remains problematic, but advances in immunocytochemistry [150] and flow cytometry may prove helpful. The accuracy of percutaneous core biopsies for classifying lymphomas remains to be determined.

Alternative Techniques to Biopsy

A number of catheter-based techniques have evolved that are useful in specific situations when percutaneous needle biopsy is difficult or contraindicated.

Transjugular Liver Biopsy If coagulopathy or marked ascites is present, transjugular liver biopsy provides an alternative to percutaneous biopsy because the needle does not transverse the liver capsule, avoiding hemorrhage. [151] An 18-gauge, 60-cm long automated biopsy device has been designed for obtaining liver histological samples through a jugular venous approach. The technique is similar to that used for the TIPS procedure. The right internal jugular vein is punctured using a 21-gauge, single wall access needle under US guidance. A 7-Fr, 49-cm long, curved catheter is advanced into the right hepatic vein, and contrast medium is injected to confirm the catheter position in the right hepatic vein. Through this sheath, a 14-gauge stiffening cannula is advanced into the right hepatic vein and directed anteriorly against the wall of the vein. Liver biopsy is performed near the IVC (Fig. 160-13). Biopsy from a peripheral hepatic vein may result in perforation of the hepatic capsule and increases the possibility of bleeding. This technique is successful in more than 90% of patients. [151], [152] Major complications occur in 2% of patients and include cardiac arrhythmias and intraperitoneal hemorrhage from inadvertent capsular puncture.

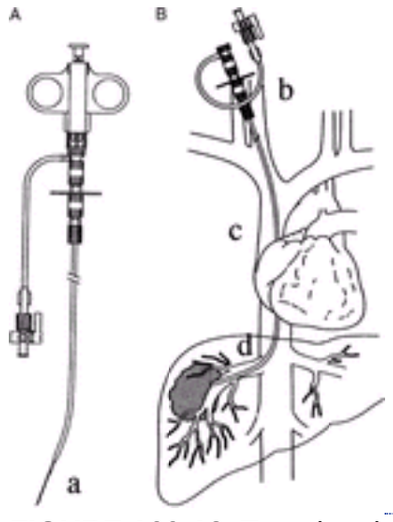

FIGURE 160-13. Transjugular liver biopsy. **A:** Liver access set assembled with Quick-Core biopsy needle. **B:** The preassembled liver access set has been introduced into the right hepatic vein over the guidewire from the internal jugular vein. The directional arrow on the stiffening cannula's hub is used to direct the needle anteriorly, and gentle pressure is applied to the wall of the central hepatic vein. The Quick-Core biopsy needle is advanced through the sheath into the liver tissue. The stylet is then advanced to expose the specimen notch (*a*), and the cutting cannula is fired to obtain tissue within the specimen notch. The biopsy needle is withdrawn, and the tissue specimen is removed from the notch and placed in formalin. *b,* Right internal jugular vein; *c,* superior vena cava; *d,* right hepatic vein.

Transhepatic Liver Biopsy with Tract Embolization When a histological core of liver tissue is needed and coagulopathy or marked ascites preclude standard percutaneous liver biopsy, embolization of the needle tract within the liver can prevent bleeding from the liver capsule puncture site. Embolization of the tract is

performed with a Gianturco coil [153] or with gelatin sponge plugs. The occluding materials may be introduced through the outer part of a Tru Cut–type needle after the inner obturator and specimen have been removed, or through a 4-Fr (1.3 mm diameter) vascular sheath fitted over the needle before biopsy. [154] Introducing the embolus through the vascular sheath is useful because the sheath is much more flexible than the needle cannula and is less likely to cause injury while the patient breathes and the liver moves. The potential disadvantage of using the sheath is that a larger hole is made in the liver capsule than would be made by the needle alone. Plugged biopsy is faster and usually less costly, and it does not require the same level of technical skill and experience required for transvenous biopsy. Plugged biopsy can be performed with imaging guidance to obtain a core sample of a focal lesion. Transvenous biopsy is not useful for most focal hepatic lesions because of the inability to steer the transvenous needle precisely. The published experience with plugged liver biopsy is too small to allow an accurate comparison of the risks of plugged liver biopsy with transvenous biopsy. Transvenous biopsy is considered safer for patients with severe coagulation disorders.

PERCUTANEOUS ABSCESS AND FLUID COLLECTION DRAINAGE

Percutaneous abscess drainage (PAD) is effective in treating abdominal abscesses and fluid collections. [155] Percutaneous needle aspiration is helpful in determining the nature of any intra-abdominal fluid collections, including abscess, biloma, lymphocele, seroma, loculated ascites, hematoma, and urinoma. Percutaneous catheter drainage is indicated for the treatment of infected fluid collections (e.g., hepatic and diverticular abscesses) and symptomatic fluid collections (e.g., pancreatic pseudocyst and lymphocele). Contraindications include absence of a safe access route to the fluid collection and coagulopathy.

Technique

Percutaneous needle aspiration and catheter drainage usually require CT or US guidance. Real-time US is most useful if the fluid collection is easily seen and a safe access route can be found, such as retroperitoneal, hepatic, or splenic drainage. C-arm–supported CT fluoroscopy is useful in PAD procedures. [156] CT guidance is preferred for drainage of deep fluid collections and is helpful in differentiating bowel loops from abscess. All patients undergoing abscess drainage receive intravenous broad-spectrum antibiotics before the catheter placement, and in anticipation of possible drain placement, bleeding diatheses are corrected.

The methods in general use for percutaneous drainage of the intra-abdominal abscesses include the Seldinger method, using guidewires, dilators, and a drainage catheter, and the trocar method, using a drainage catheter with an inner stiffener and central pointed trocar. The trocar catheter is advanced in a single pass, parallel to the initial needle, and to the same depth. The trocar technique obviates guidewire exchange and tract dilation and also theoretically reduces the risk for leakage of pus into a contaminated space during guidewire exchange. When the acceptable window of access is narrow, the Seldinger technique may be preferred, to avoid unintentional passage of the trocar catheter into a vital structure.

Single- or double-lumen (sump) catheters (8 to 16 Fr) may be used. Single-lumen catheters are connected to gravity drainage. Sump catheters may be left to gravity or low suction. The catheter is flushed with 10 mL of saline every 4 to 6 hours for the first day and once daily after the first day. The effectiveness of the drainage should be assessed with a repeat scan. The determination of successful therapy is made on the basis of abatement of symptoms and signs of infection and less than 10 mL/day of drainage, radiographic evidence of cavity closure with contrast injection, and absence of fluid collection by a repeat scan.

Hepatic Cysts and Abscess

Congenital cysts may be solitary or multiple and may be associated with polycystic kidney disease. Cysts that cause symptoms such as pain or jaundice may require treatment. Percutaneous drainage and injection of sclerosing agent into the cyst is an effective alternative to surgical treatment. [157], [158] The technique consists of percutaneous puncture of the cyst under US guidance and insertion of a 5-Fr pigtail catheter into the cyst using the Seldinger technique. After complete aspiration of the cyst, the cyst is filled with 95% ethanol in a volume of 30% of the cystic fluid aspirated. After 20 minutes of sclerosis with changes of the patient's position, the residual cystic fluid is aspirated.

Hepatic abscesses may be bacterial, echinococcal, or amebic in origin. When the diagnosis of pyogenic abscess is established, parenteral broad-spectrum antibiotic coverage is required 1 hour before percutaneous aspiration or catheter drainage. Sedation and use of analgesia with appropriate monitoring of vital signs are required during the procedure. Percutaneous drainage is safe and succeeds in about 90% of patients. [155] Effective drainage can be achieved in a loculated hepatic abscess. CT or US is required for accurate puncture of the lesion. The pleural reflection extends to the 10th intercostal space laterally. To avoid transgression of the pleural space, an angled approach, guided by US and CT, should be used for drainage of high lesions.

The traditional treatment of hydatid cysts has been surgical because of the risk for percutaneous puncture (e.g., peritoneal seeding and anaphylaxis). Although hydatid cysts were previously considered a contraindication for percutaneous aspiration, safe and successful drainage has been achieved with the use of transhepatic puncture and injection of alcohol or hypertonic saline into the cyst after aspiration. [159], [160]

The role of percutaneous aspiration or catheter drainage for the treatment of hepatic amebic abscess remains controversial. Nearly all hepatic amebic abscesses can be cured by antimicrobial drugs alone, although percutaneous drainage may be useful for patients with abscesses larger than 6 cm and for those who have failed one course of medical therapy. After a drainage catheter is placed, the catheter is irrigated with normal saline every 8 hours. The volume of irrigating saline is about 25% of the volume of the original cavity. Excessive amounts of fluid should be avoided to prevent rupture of the cavity and leakage of the fluid. Follow-up imaging of the abscess is performed at 5 to 7 days to evaluate for the effectiveness of the drainage and communication with bile ducts or bowel. When the patient is afebrile with normal white blood cell count, the 24-hour drainage volume is less than 10 mL, and a cavity has no communication with a bile duct, the tube is removed. The patients should receive antibiotics for 2 to 6 weeks.

Pancreatic Abscess and Fluid Collections

Pseudocysts, whether infected or not, are cured by percutaneous drainage in 70% to 90% of patients. [161], [162], [163] and [164] The response rate may be higher in infected than in noninfected pseudocysts. [163] Indications for percutaneous drainage include pseudocyst infection, pain associated with a pseudocyst greater than 4 to 5 cm, and a pseudocyst causing bile duct or gastric outlet obstruction. An asymptomatic pseudocyst larger than 10 cm also warrants percutaneous drainage to avoid serious complications. Somatostatin analogs reduce output from pseudocyst drainage catheters and may prove useful in reducing the duration of catheter drainage. The technique for percutaneous drainage of pancreatic pseudocysts is the same as that for other intra-abdominal fluid collections. Various access routes to pseudocysts have been used, including transgastric, transhepatic, transsplenic, and transhepatic-transduodenal approaches.

Long-term external drainage is often required for percutaneous transgastric decompression of large pancreatic pseudocysts. The initial external catheter can be converted to internal drainage by placing an internal double-mushroom stent after 14 days, eliminating the need for an external catheter. [165] When early catheter occlusion occurs, replacement or insertion of a second internal stent is done through the gastrostomy tract. When the cyst has resolved, the internal stent is retrieved by endoscopic snare.

The technique for the percutaneous cystogastrostomy involves insertion of a nasogastric tube, percutaneous transgastric puncture of the pancreatic fluid collection under CT guidance, and placement of a 10-Fr, percutaneous, transgastric catheter through an 11-Fr, peel-away sheath into the cyst. The percutaneous gastrostomy is left to gravity drainage for 2 to 3 days and, when no leakage is seen with injection of contrast medium, the tube is capped. After 14 days of external-internal drainage, the percutaneous drainage is converted to an internal drainage with placement of a stent between the cyst and the stomach under lateral fluoroscopy. Initial results in 19 patients showed a low complication and recurrence rate. [165]

Diverticular Abscess

PAD plays an important role in treating certain patients with complications of diverticulitis. [166], [167] Patients with phlegmonous changes around the colon can be managed medically. Patients with small pericolic abscesses can be treated with en bloc resection at the time of their colectomy, and patients with peritonitis require a two-stage operation. Patients who have larger pericolic, pelvic, or retroperitoneal abscesses may benefit from PAD. This subset of patients would require staged operations if PAD were not available. PAD provides for resolution of septic complications and healing of the abscess such that a delayed single-stage operation can be performed. As with all cases of PAD, if signs of sepsis do not improve within 24 to 48 hours of PAD and intravenous antibiotics, immediate operation should be undertaken unless catheter repositioning or replacement has a high likelihood of effecting improvement.

Abscesses with Fistulae

The identification of fistulae associated with an abdominal or pelvic abscess frequently is not made on imaging studies before drainage or even at the time of drainage. [168] After several days, if the quantity of drainage remains more than 50 mL/day or if the character of the drainage changes and visually or chemically resembles stool, small bowel secretions, pancreatic juice, bile, or urine, then identification of the fistula can be attempted by injecting contrast medium into the abscess cavity under fluoroscopic observation. If this is unsuccessful, an attempt can be made to identify the fistula from its other end by filling the suspected organ of origin with contrast medium; for example, a barium enema is performed if a colonic origin is suspected, or a PTC or ERCP if biliary communication is present.

The presence of a fistula does not preclude definitive PAD in most circumstances. If a downstream stenosis is present in the hollow viscus or if a foreign body or neoplasm is present at the site of perforation, then closure of the fistula will not occur without surgical intervention. [169] Low-output fistulae (less than 200 mL/day) appear to be more likely to heal than high-output fistulae. High-output fistulae may be treated more effectively by converting them to low-output fistulae with nasoenteric intubation and suction, total parenteral nutrition, and histamine H_2 blocker therapy. Catheterization of the fistula itself and advancement of a drainage catheter into the viscus is extremely useful in diverting drainage from the fistulous tract and allowing resolution. [170]

When a fistula is present in association with a percutaneously drained abscess, the duration of catheter drainage usually is longer than if no fistula is present. Drainage for several months may be necessary; however, most of these patients can be managed as outpatients. If a patient's social situation precludes outpatient treatment, operative treatment should be considered to avoid the costs and risks associated with prolonged hospitalization.

Abscesses and Crohn's Disease

The role of PAD in Crohn's disease has been debated, [171] but several points are clear. Postoperative abscesses with or without fistulae and hepatic abscesses in patients with Crohn's disease respond well to PAD. [172], [173] Abscesses in association with transmural disease of the bowel but without visible fistulae also appear to respond. [174] It is unclear what the response rate is for abscesses with fistulae from transmural disease. Nevertheless, these patients may benefit from palliation with PAD before definitive operation. PAD may control septic complications and allow improvement of nutritional status with a course of parenteral nutrition before operation. As in treatment of diverticular disease, PAD may allow conversion of a two-stage operation into a single-stage operation.

PERCUTANEOUS GASTROINTESTINAL INTERVENTION

Both endoscopic and interventional radiology techniques are currently used for gastrostomy, gastrojejunostomy, and direct jejunostomy placement. Morbidity is low, and the success rate is high for both approaches; hence, the choice between techniques depends on local expertise and availability.

Percutaneous, radiologically guided ostomy formation is performed in both adults and children with use of conscious sedation and local anesthesia. General anesthesia is required in uncooperative patients. The procedure is performed on a C-arm fluoroscopic table. Before gastrostomy tube placement, US may be used to identify the liver and spleen.

Percutaneous Gastrostomy and Gastrojejunostomy

Indications for percutaneous radiologic gastrostomy (Fig. 160-14) and gastrojejunostomy (Fig. 160-15) include (1) inadequate oral intake due to esophageal obstruction or neurologic disorders, (2) decreased gastric motility (for gastrojejunostomy), and (c) decompression in chronic small bowel obstruction.

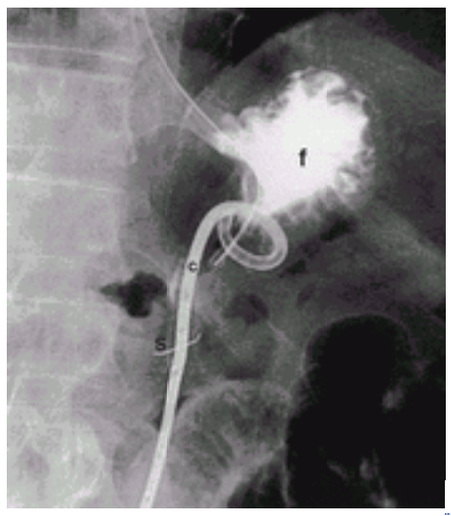

FIGURE 160-14. Percutaneous gastrostomy. A 12-Fr Cope loop gastrostomy tube (*c*) was placed after placement of a Cope suture anchor (*s*), and injection of contrast medium confirms the catheter loop in the fundus of the stomach (*f*). The nasogastric tube has been introduced into the stomach for air insufflation during puncture of the stomach.

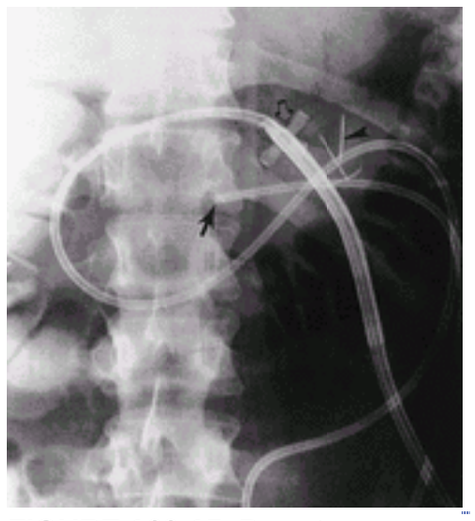

FIGURE 160-15. Percutaneous gastrojejunostomy. After gastrostomy, the pylorus was crossed using a guidewire and catheter. The tract was dilated, and a 16.5-Fr Carey-Alzate-Coons gastrojejunostomy catheter was introduced through a peel-away sheath. The distal catheter tip is positioned in the jejunum (*arrow*) beyond the ligament of Treitz, allowing enteral feeding immediately following tube placement. Three anchor sutures (*arrowhead*) have been placed in the stomach before tract dilation. The friction-lock Malecot tip (*open arrow*) prevents tube dislodgment.

The contraindications for gastrostomy or gastrojejunostomy tube placement include (1) uncorrectable bleeding diathesis; (2) inaccessible stomach from prior gastric pull-up, total gastrectomy, or partial gastrectomy; (3) clinical instability; (4) limited life expectancy; and (5) presence of a ventriculoperitoneal shunt. Ascites has been

considered a contraindication for gastrostomy, although successful placement in patients with ascites has been reported. [175] Pericatheter ascitic leak may be avoided with preprocedural paracentesis and, if necessary, postprocedural paracentesis to promote skin healing. Gastropexy sutures are used in patients with marked ascites to prevent catheter dislodgment by preventing increasing amounts of ascites from displacing the stomach from the anterior abdominal wall. Two to three suture anchors may be placed before tract dilation. The suture may be left in place for 1 to 2 weeks, or the suture may be cut after placement of a gastrostomy tube. Bacterial seeding of the ascitic fluid remains a potential problem.

Technique A nasogastric tube is placed the evening before the procedure, or, if a nasoenteric feeding tube is present, it is left in place. The patient is given nothing by mouth or through the nasogastric tube except for medications beginning at midnight before the procedure. Glucagon is administered immediately before the needle puncture of the stomach to reduce the egress of air from the stomach. Distention of the stomach brings its anterior wall closer to the anterior abdominal wall, displaces the small and large bowel, and brings the stomach out from under the costal margin to facilitate puncture. Inflation also allows fluoroscopic visualization of the stomach. If no nasoenteric tube can be passed blindly because of esophageal obstruction, in nearly all cases, a small-bore tube or catheter can be placed through the obstruction using standard angiographic techniques. For patients who cannot be transported to the angiography suite or who are unable to remain in supine position, percutaneous gastrostomy can be performed at the bedside under portable real-time US guidance. [176] The radiologic technique in general use for ostomy formation is the Seldinger method, using a guidewire, needle, dilators, and catheters. The puncture site is chosen fluoroscopically so that the needle enters the body of the stomach away from the greater curvature, avoiding the gastroepiploic vessels, epigastric vessels, the colon, and the left lobe of the liver. Oblique fluoroscopy is useful to confirm that the stomach abuts the anterior abdominal wall without intervening structures at the puncture site. The chosen puncture site is anesthetized with lidocaine, and a skin incision, large enough to admit the selected tube, is made. Gastropexy sutures may be placed with a modified 18-gauge needle. [177] Under fluoroscopic guidance, an 18-gauge needle attached to a 10-mL syringe half-filled with water-soluble contrast medium is advanced into the stomach with a brisk motion during aspiration with the syringe. Entry into the stomach is observed by free aspiration of air and is confirmed by injection of contrast medium and visualization of rugal folds. A 0.038-inch (0.97-mm) guidewire is advanced into the stomach, and the tract is dilated. If a gastrojejunostomy tube is to be placed, the catheter and a long, torqueable guidewire are used to traverse the pylorus and advance the guidewire through the duodenum into the proximal jejunum. The gastrojejunostomy catheter then is advanced over the guidewire into the jejunum through a peel-away sheath. Catheters from 2.64 to 8.58 mm (8 to 26 Fr) are used for gastrostomy, with the smallest catheters used in the pediatric population for feeding and the largest catheters used in adults for gastric decompression. Retention devices include balloons, Cope loops, and Malecot tips. Injection of contrast medium confirms the final position of the gastrostomy or gastrojejunostomy tube.

Large-bore gastrostomy tubes and endoscopic-type gastrostomy tubes may be safely placed using the same radiologic technique. [178] The gastrostomy or gastrojejunostomy tube is secured at the skin with a Molnar disk or friction fitting to stoma adhesive. If for any reason there is a high risk for catheter dislodgment, the tube may be sutured to the skin. The patient is observed for 6 hours for signs of bleeding or peritoneal irritation. If a gastrostomy tube has been placed, it is left open to gravity drainage overnight, and tube feedings begin the following morning. If a gastrojejunostomy has been placed, tube feedings may begin immediately. The stitches (and gastropexy fasteners, if used) are removed after 10 days. The tract usually is mature enough by 7 to 10 days that, if the tube is accidentally dislodged, the tract can be recatheterized and a de novo gastrostomy avoided if replacement is performed within 24 hours.

Feeding Gastrostomy versus Feeding Gastrojejunostomy Because adequate data are not available, radiologists remain divided into two camps: those who place gastrostomy tubes in most patients and gastrojejunostomy tubes only when gastroesophageal reflux is proved, and those who place gastrojejunostomy tubes in all patients. The most serious complication of tube feedings is aspiration pneumonia. Some evidence exists that surgical gastrostomies induce reflux; however, percutaneous radiologic gastrostomy does not induce reflux. No study has demonstrated that endoscopic or radiologic percutaneous gastrojejunostomy results in less aspiration than percutaneous gastrostomy. Gastrostomy tubes are superior for most patients. Most of the aspiration in these patients is due to oropharyngeal aspiration. Gastrojejunostomy tubes require greater maintenance than do gastrostomy tubes (see Fig. 160-15). Gastrojejunostomy tubes have occluded more frequently than gastrostomy tubes because the jejunostomy portion of the tubes has been limited in size to 3.3 to 3.96 mm (10 to 12 Fr). Poorly crushed pill fragments or concretions of tube feedings may block the smaller tube and necessitate tube replacement. The greater length of gastrojejunostomy tubes may also contribute to this problem. Gastrojejunostomy tubes are harder to manage at home or at chronic care facilities because they require mechanical pump infusion to achieve controlled infusion rates in the small intestine. In contrast, gastrostomy tubes can be infused with intermittent boluses or by gravity drips. If gastroesophageal reflux and aspiration occur in a patient with a gastrojejunostomy tube or in a patient with intractable gastroparesis, a better result may be achieved with two tubes: one placed into the jejunum for feeding and one placed into the gastric fundus for decompression.

Complications and Results A compilation of four major published series of radiologic gastrostomy and gastrojejunostomy tube placement [179] in a total of 635 patients revealed a procedure-related mortality rate of 1% and a major complication rate of 5%. Major complications included peritonitis requiring laparotomy, bleeding requiring transfusion, external leakage, aspiration, gastric or duodenal perforation, and deep abdominal wall infection. Minor complications occur in 5% of patients. A comparison of radiologic with endoscopic gastrostomy and surgical gastrostomy revealed that radiologic gastrostomy is associated with a higher success rate than is percutaneous endoscopic gastrostomy and less morbidity than either percutaneous endoscopic gastrostomy or surgery. [180] Patients were not randomized in this study, however, making comparisons difficult. Percutaneous radiologic gastrostomy or gastrojejunostomy can be performed in essentially all patients in whom the procedure is not contraindicated. Large-bore 20- to 24-Fr gastrostomy and gastrojejunostomy tubes can be placed under fluoroscopy. The technical success, morbidity, and mortality rates are similar to those of tubes placed surgically or endoscopically. [181] In pediatric patients with neurologic or oropharyngeal impairment, fluoroscopically guided gastrostomy provides a safe and effective means for enteral nutrition and gastric decompression. Colonic interposition, microgastria, and hepatosplenomegaly are the cause of access failure of 1.2%. [182] The procedure can be performed with use of sedation and local anesthesia in nearly 90% of children.

Percutaneous Jejunostomy

When percutaneous gastrostomy is not possible because of previous gastrectomy or an abnormal stomach position, direct percutaneous jejunostomy can be performed for enteral feeding. [183], [184] Under fluoroscopic guidance, a nasogastric tube is passed into the stomach and through the pylorus. One milligram of glucagon is administered intravenously to decrease peristalsis. The small bowel is then filled with room air. Using C-arm fluoroscopy, a loop of bowel adjacent to the anterior abdominal wall is identified, a 21-gauge needle is inserted into the jejunal lumen, and injection of contrast medium confirms the needle position within the jejunal lumen. A 0.018-inch (0.046-cm) guidewire is inserted, and a 6.3-Fr introducer catheter is advanced into the jejunum. Over a 0.038-inch (0.097-cm) guidewire, the tract is dilated, and an 8-Fr Cope-loop nephrostomy catheter is placed in the jejunal loop. Pericatheter leakage is the main complication. The use of Cope suture anchors facilitates a feeding tube insertion by securing the jejunal loop to the anterior abdominal wall.

In the absence of a previous surgical jejunostomy scar, this procedure is considered risky and is not widely performed. In patients who have undergone esophagectomy and a previous surgical jejunostomy, the jejunal loop that has been surgically fixed to the anterior abdominal wall can be punctured using the metal clips as a guide. [185] The skin mark or a dimple at the site of the previous surgical jejunostomy is used to guide the needle puncture into the bowel loop.

Percutaneous Cecostomy

Percutaneous cecostomy is an alternative to surgical and endoscopic decompression of the cecum in cases of colonic obstruction and pseudoobstruction (Ogilvie syndrome). [186], [187] Small 2.31- to 2.97-mm (7- to 9-Fr) catheters can be placed through the peritoneum with a Seldinger or trocar technique for decompression of the colon, and large 7.92- to 9.9-mm (24- to 30-Fr) catheters are placed for drainage of liquid stool after placement of anchoring sutures, as used for gastrostomy. This technique is applicable to patients with Ogilvie syndrome in whom endoscopic decompression fails and to patients with colonic obstruction whose medical condition precludes operation.

Balloon Dilation and Stent Placement for Gastrointestinal Obstruction

Balloon dilation or metallic stents may be used as alternatives to surgery for malignant and benign strictures in the esophagus and GI tract (stomach, pylorus, duodenum, colon, and rectum) using radiologic or endoscopic techniques. [188] Generally, balloon dilation is used for benign strictures, whereas stents are reserved for patients with malignant strictures.

The radiology-guided technique is similar to that used for PTA. It can be performed on outpatients under sedation and local anesthetic. The strictured site is identified by injection of contrast medium or endoscopy. After placing a 0.035-inch (0.89-mm) guidewire across the stricture, an angioplasty balloon catheter is advanced over the guidewire, placed across the stricture, and inflated two to three times for 3 to 5 minutes. Water-soluble contrast medium should be injected after dilation to rule out any perforation.

Metallic stents have been used for treatment of esophageal obstruction, gastric outlet stenosis, duodenal stenosis, and malignant colorectal stricture. [189], [190], [191], [192], [193], [194] and [195] The technique for stent placement is similar to that used for angioplasty. Use of metallic stents in patients with colonic obstruction caused by malignant neoplasms eliminates the need for emergency surgical intervention on unprepared bowel, reducing mortality and morbidity. [196] The procedure can be performed on an outpatient basis or requires minimal hospitalization, permitting a single-stage surgery. The procedural steps for colonic stent placement are as follows: the patient is

placed in the supine position on a fluoroscopic table, and the combination of a 0.038-inch (0.97-mm), stiff-angled hydrophilic guidewire and a catheter is advanced through the rectosigmoid colon under fluoroscopy to the area of obstruction. After identification of the obstruction by injecting water-soluble contrast material, the catheter and guidewire are advanced through the lesion. The length of the obstruction is measured, and a self-expanding Wallstent is deployed over a guidewire or through an endoscope if desired. The correct position of the stent and its patency is assessed by a barium examination. Complications occur in 10% of patients, including perforation, migration, hemorrhage, and sepsis.

Malignant Tracheoesophageal Fistula

A fistula may develop between the esophagus and the tracheobronchial tree from invasion of mediastinal structures by esophageal carcinoma. This may lead to pneumonia, lung abscess, and death. Covered esophageal stents can provide effective palliation of symptoms caused by the tracheoesophageal fistula. Simultaneous placement of a tracheal stent may be required for tracheal compression by the stent and tumor invasion. [197], [198] Although radiologic placement has been reported, most of these stents are placed endoscopically.

CHAPTER 161

Nathaniel J. Soper

LAPAROSCOPY AND LAPAROTOMY

Although laparoscopy for examination of the peritoneal surfaces and diagnosis of intra-abdominal pathology has been used since the turn of the 20th century, its popularity has waxed and waned over the years. Application of laparoscopic technology and techniques has recently been stimulated by the introduction of many therapeutic laparoscopic operations. [1] This resurgence of therapeutic laparoscopy has stimulated a renewed interest in the possibilities of diagnostic laparoscopy. For decades, this modality had been largely neglected as major advances were made in diagnostic imaging techniques; well-controlled comparison studies are now proving that diagnostic laparoscopy holds many potential advantages over these imaging techniques. [2]

Similarly, the enthusiasm with which the surgical community greeted laparoscopic cholecystectomy led to a plethora of other therapeutic procedures being performed using laparoscopic guidance. The unbridled zeal of some of the laparoscopic enthusiasts has occasionally led surgeons to perform laparoscopic operations that may be better performed with a standard laparotomy. [1] The results of outcome studies will show the proper role of many of these therapeutic laparoscopic procedures with regard to morbidity, mortality, and cost. Although laparoscopy and other “minimally invasive” technologies will likely continue to expand, a number of patients will still require laparotomy for diagnosis and therapy. This chapter summarizes the current status of diagnostic laparoscopy, therapeutic laparoscopy, and laparotomy.

HISTORY OF LAPAROSCOPY

The technique of accessing the abdomen through small incisions to diagnose and treat abdominal disease is today commonly referred to as laparoscopy (Greek *lapara,* the flank; *skopein,* to view). In 1901, G. Kelling performed the first minimally invasive examination of the abdomen using a cystoscope in a dog. [3], [4] A decade later, H. Jacobaeus reported the safe utilization of laparoscopy in patients to diagnose syphilis, tuberculosis, cirrhosis, and malignancy. [5] The German hepatologist H. Kalk introduced the oblique-viewing laparoscope for diagnosis of liver diseases and the concept of using accessory ports for biopsy. [6] Laparoscopic access was simplified by the introduction of the Veress spring-loaded needle in 1938, which was used to insufflate the abdomen with air. [7] Subsequently, carbon dioxide (CO_2) was used to create the pneumoperitoneum necessary to have a working space. Fiberoptics brightly illuminated the abdominal cavity with superior lighting, and as instruments for grasping, cutting, and cauterization became available, simple therapeutic procedures were possible.

The modern era of video laparoscopy began with the development of the computer-chip television in the 1980s. With the laparoscope attached to a television camera, the resulting images could be transmitted to a video monitor, and the whole operating team could visualize the operative field. No longer was the surgeon restricted to “scope holder.” With an assistant delegated as camera holder, the surgeon was free to operate with both hands and perform more difficult procedures. P. Mouret

performed the first laparoscopic cholecystectomy in France in 1987, [8] followed by Reddick and Olsen [9] and McKernan and Saye [10] in the United States in 1988.

The appeal of small incisions and claims of less pain, shorter hospitalization, and speedier recuperation after laparoscopy were portrayed by the media as "bellybutton," "Band-Aid," "Nintendo," and "minimally invasive" surgery. [11] Before randomized prospective studies could verify the proposed benefits of laparoscopy, general surgeons embraced the new methods, and other operations were performed using laparoscopic guidance. Hospitals invested in costly laparoscopes, monitors, and instruments. Surgical societies, journals, and even postgraduate fellowships were established to teach, validate, and credential surgeons in emerging laparoscopic procedures. Today, detailed outcome studies are being performed and reported to justify the outcomes and costs of these new procedures relative to alternative treatment strategies. Thus far, only laparoscopic cholecystectomy has succeeded in becoming the gold standard approach, [12] but many other laparoscopic abdominal procedures are rapidly gaining acceptance (Table 161-1).

Accepted
Diagnostic laparoscopy
Laparoscopic cholecystectomy
Operations for gastroesophageal reflux
Splenectomy
Adrenalectomy
Nephrectomy
Gaining Acceptance
Exploration of common bile duct
Appendectomy
Repair of inguinal hernia
Operations for peptic ulcer disease
Resection of colon
Esophagomyotomy
Operations for morbid obesity
Anecdotal Experience
Biliary bypass procedures
Pancreatic resection
Esophageal resection
Ablation of hepatic tumors

TABLE 161-1 Current Status of Laparoscopic Procedures

DIAGNOSTIC LAPAROSCOPY

Advantages

Diagnostic laparoscopy has many potential advantages over other diagnostic studies and traditional open laparotomy. Compared with other imaging modalities, diagnostic laparoscopy more realistically characterizes a lesion's color and contour; and enhanced resolution and magnification may detect lesions smaller than 1 mm, a size below the resolution of both computed tomography (CT) scan and magnetic resonance imaging (MRI). In addition to improving diagnostic accuracy, laparoscopy also allows directed biopsy with a reduced risk for bleeding. Furthermore, overall cost of the procedure may be less than that of multiple noninvasive tests.

Compared with exploratory laparotomy, diagnostic laparoscopy leads to less postoperative pain and intestinal ileus. Small trocar puncture sites are also cosmetically more appealing than large laparotomy incisions. By avoiding the morbidity of a laparotomy, otherwise healthy patients can usually be discharged from the hospital within 24 hours of a diagnostic laparoscopy and return to normal activity within a few days.

Disadvantages

Diagnostic laparoscopy also has several disadvantages. Patients should be acceptable candidates for general anesthesia. Even if laparoscopy is performed under local anesthesia, inadvertent perforation of a viscus or uncontrolled hemorrhage may occur and require formal laparotomy. Two-dimensional video systems lack depth perception, distort anatomic relationships, and hinder task performance. Elongated laparoscopic instruments allow the transfer of only minimal haptic information, and structures in the abdomen and retroperitoneum may not be palpated. Instead, the laparoscopist relies on visualizing the surfaces within the abdominal cavity. Some patients are not suitable candidates for laparoscopy because of intra-abdominal adhesions that are too extensive to allow visual exploration using a laparoscope. Adequate pneumoperitoneum and exposure of the operative field may be difficult to maintain because of continuous gas leaks, unrecognized perforated viscera, or excessive irrigation. Intraoperative complications are also more challenging to manage laparoscopically than during open surgery, especially control of brisk hemorrhage, and the laparoscopy suite should be equipped to deal with these rare emergencies. Still, the major concern with diagnostic laparoscopy is whether pathology is being overlooked. To minimize this problem, just as with traditional laparotomy, the laparoscopist needs to develop a systematic approach to examining the entire abdomen.

Technological advances may solve many of the current limitations of laparoscopy. Three-dimensional video systems restore depth perception, perhaps enhancing the safety and accuracy of laparoscopic examination and biopsies compared with two-dimensional systems. Intraoperative laparoscopic ultrasonography permits directed evaluation of organ parenchyma beyond the visible surface. Mechanical and robotic camera holders free the hands of the surgical team members to perform other tasks. [13] Alternatively, the pneumoperitoneum with its potential risks can be avoided using various abdominal wall retractors. [14], [15] and [16]

TECHNIQUE OF LAPAROSCOPIC ABDOMINAL EXPLORATION

Preoperative Care and Anesthesia

Ideally, patients are fasted from midnight before the operation. Patients without other major medical problems are admitted to the hospital the morning of the operation and given preoperative sedatives. If the possibility of intraoperative contamination exists, a single dose of intravenous antibiotics is administered. Gastric distention is diminished by administering both intravenous metoclopramide and a histamine H_2 receptor antagonist. Sequential compression stockings are placed on both legs to avoid pooling of blood in the lower extremities. In patients with known malignancy and in those at risk for venous thromboembolism, minidose subcutaneous heparin may be used. After induction of anesthesia, a bladder catheter and orogastric tube may be placed to decompress these hollow organs before inserting laparoscopic trocars. For more emergent exploration, an orogastric tube is placed and the stomach drained before induction to prevent aspiration. The abdomen is prepared and draped sterilely.

Local Anesthesia

Bupivacaine (0.5%) is injected at the initial port site and is used to a maximum dose of about 2.5 mg/kg. The skin and peritoneum surrounding the site of incision should be adequately infiltrated with anesthetic before inserting the laparoscopic trocar. All patients receive oxygen by nasal cannula or mask. As an adjunct, intravenous sedation or inhaled nitrous oxide may be added. Intravenous agents for sedation and amnesia may include a benzodiazepine, commonly midazolam, and a short-acting opioid such as fentanyl. Nitrous oxide also has analgesic properties, but inhalational agents are contraindicated if the patient has eaten within 6 hours of operation because of the high risk for aspiration with pneumoperitoneum. Routine patient monitoring would include blood pressure, pulse oximetry, and electrocardiography. Nord and Boyd [17] reported 357 patients examined by diagnostic laparoscopy under local anesthesia. None required intubation, general anesthesia, or ventilatory support. Transient vasovagal reactions occurred in 3% of patients, but hypotension generally responded promptly to atropine. When performing diagnostic laparoscopy under local anesthesia, one should consider using nitrous oxide, rather than CO_2, for creation of the pneumoperitoneum. This agent has anesthetic properties and is less irritating to the peritoneum. Because local anesthesia is safe for most patients, cost-containment issues will probably encourage more procedures to be performed under local anesthesia as an outpatient rather than under general anesthesia in the operating room.

General Anesthesia

General anesthesia allows pain-free probing of inflamed tissues and biopsy of peritoneal lesions, and when necessary, it facilitates rapid conversion to open laparotomy. Adequate depth of anesthesia, complete muscle relaxation, and administration of antiemetics are important considerations for optimal anesthetic management. Postoperative pain is lessened by preincisional subcutaneous injection at the port sites with a long-acting local anesthetic, such as 0.5% bupivacaine. [18]

Instrumentation

The laparoscopes may be 2 to 10 mm in diameter with a forward-viewing (0-degree) or obliquely angled lens. Smaller laparoscopes are more commonly used in the emergency room or office setting. Larger laparoscopes have the advantage of supplying more light and a wider visual field. The 30- to 45-degree angled lenses diminish illumination but permit a more thorough examination of the extremes of the peritoneal cavity, whereas a straight scope only views objects straight ahead. Other standard instruments for diagnostic laparoscopy include scissors, grasping devices, liver retractor, blunt probe, Babcock clamp, hook cautery, cupped forceps, biopsy forceps, uterine retractor, and a hollow suction-irrigator probe. The patient lies supine or in the lithotomy position on a table that has multiplanar movement to maximize gravitational retraction of intra-abdominal organs.

Access and Pneumoperitoneum

A working space (pneumoperitoneum) in the abdominal cavity is established by insufflating gas using a high-flow insufflator. The pneumoperitoneum is established by either a closed or an open technique. [19]

Closed Technique of Establishing Pneumoperitoneum The patient is placed in a 10- to 15-degree Trendelenburg position, and a small skin incision is made into the subcutaneous tissue of the infraumbilical skin fold. In patients who have had previous abdominal surgery, an alternative site distant from previous incisions is chosen for initial access. With an upper midline scar, a right or left lower quadrant insertion site is chosen two thirds of the distance from the umbilicus to the iliac crest lateral to the rectus sheath. Adhesions from a lower midline scar may be avoided by an initial puncture in the right or left upper abdomen at the lateral edge of the rectus muscle. The positions of the liver, spleen, and bladder relative to the port site must be ascertained before needle insertion to avoid iatrogenic injury. The lower abdominal wall is grasped to elevate the fascia safely away from the intra-abdominal organs before needle puncture. The Veress needle is then inserted at a right angle to the abdominal wall, usually at a 45-degree angle off the vertical axis toward the pelvis but away from the aortic bifurcation and iliac arteries (Fig. 161-1). Two or three clicks of the spring-loaded obturator may be heard as the needle passes through the fascia and peritoneum into the peritoneal cavity. Absence of blood, urine, or stool on aspiration and rapid flow of sterile saline through the needle by gravity (a positive drop test) corroborate the correct needle position. Elevating the lower abdominal wall during the drop test will decrease intra-abdominal pressure and enhance free flow. The abdominal cavity is then insufflated with the appropriate gas to a pressure of 8 to 15 mm Hg, beginning at a flow rate of 1 L/minute.

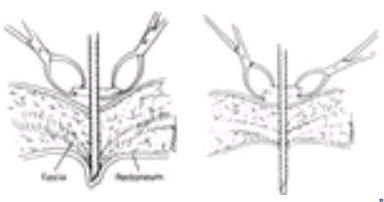

FIGURE 161-1. In the closed insertion technique, a Veress needle is blindly inserted at the umbilicus through the fascial layers of the anterior abdominal wall. (From ref. [19].)

After the abdominal cavity is distended, the Veress needle is removed, and a trocar is inserted carefully into the abdominal cavity while manually exerting anterior countertraction on the abdominal wall. The resistance of the fascia and peritoneum is apparent as the trocar slowly penetrates the abdominal wall. The sharp inner trocar is removed, and the sheath may be secured at the skin level with adhesive patches, screw threads, internal balloons, or suture. Blood-stained fluid and frank blood after trocar insertion are ominous signs. If trocar insertion is followed by brisk return of blood and hemodynamic compromise, a laparotomy should be performed immediately while leaving the trocar in place. Delay in converting to formal laparotomy has resulted in mortality from injury to a major blood vessel.

Open Technique of Establishing Pneumoperitoneum The closed technique is applicable in most patients; for patients who have undergone previous abdominal surgery, however, and for patients who are pregnant or have distended bowel, we generally use the open technique. Open port insertion is similar to the cut-down procedure used for catheter insertion during diagnostic peritoneal lavage (Fig. 161-2). A vertical or horizontal 1.5-cm skin incision is made in the infraumbilical skin fold. Blunt dissection of the subcutaneous tissue is performed deep to the skin until the umbilical raphe's insertion into the fascia is clearly visible. A clamp is applied to the fascia, which is elevated, and a small vertical incision is made into the peritoneal cavity. A finger or curved Kelly clamp is carefully introduced into the incision, and any loose adhesions may be swept away. A blunt-tipped (Hasson) port is then placed under direct vision through the fascial incision into the peritoneal cavity. The pneumoperitoneum is established only after ensuring safe access. The Hasson port is secured with sutures on both sides of the fascial incision.

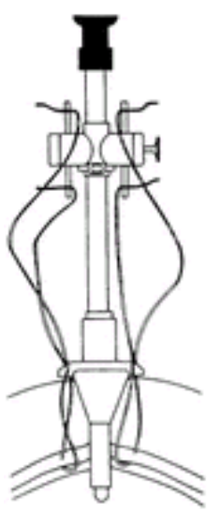

FIGURE 161-2. In the open technique, a wedge-shaped Hasson trocar is placed after peritonotomy and secured with sutures prior to insufflation with CO_2. (From ref. [19].)

Open techniques take a few minutes longer than the closed technique for initial port insertion; however, open insertion is especially advantageous in patients with previous abdominal incisions and in situations in which the Veress needle position is in doubt. At the conclusion of the operation, all trocar entry sites larger than 5 mm should be closed to avoid the risk for postoperative herniation. [20]

Gases Used for the Pneumoperitoneum For diagnostic laparoscopy, several gases may be used to insufflate the pneumoperitoneum, which creates the space for viewing and working (Fig. 161-3). Many laparoscopists use nitrous oxide during short cases and during cases performed with local anesthesia because it is inexpensive and associated with a lower incidence of cardiac arrhythmias than CO_2. Nitrous oxide also does not irritate the peritoneum (as does CO_2) and, when absorbed, does not cause metabolic abnormalities. However, nitrous oxide will support combustion and is therefore contraindicated when the use of electrocautery is anticipated. [21] Nitrous oxide is also less soluble in blood than CO_2 and may be more likely to cause gas embolism. CO_2, on the other hand, is commonly used during therapeutic laparoscopy because it is noncombustible. CO_2 is eliminated rapidly from the systemic circulation and will not form gas emboli under experimental conditions unless infused into a systemic vein at a rate greater than 1 L/minute. [22] However, CO_2 absorption may lead to hypercarbia and respiratory acidosis in patients with chronic obstructive pulmonary disease. [23] CO_2 also may cause postoperative discomfort because of referred diaphragmatic pain as it is converted on the moist peritoneal surfaces to carbonic acid.

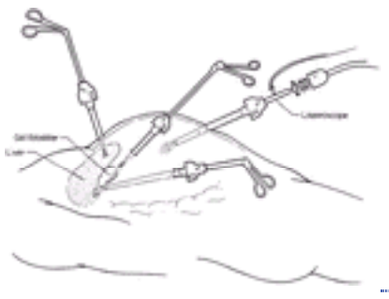

FIGURE 161-3. Cross section of abdomen after insufflating the pneumoperitoneum. Laparoscopic instruments are inserted through accessory ports. (From ref. [19].)

Gas embolism may cause right ventricular outflow obstruction signaled by a decrease in end-tidal CO_2, hypotension, or a "millwheel" heart murmur. When this life-threatening complication is suspected, the patient is placed immediately in the Trendelenburg (head-down) position with the left side down, and the gas is promptly aspirated through a central venous catheter. [24] Other problems encountered during laparoscopy include hypotension because of decreased venous return and diminished cardiac output, bradycardia due to vagal reactions, and acidosis secondary to hypercarbia. Fortunately, most of these adverse conditions improve or resolve by deflating the pneumoperitoneum. They also may be circumvented altogether by external retraction devices, which create working space by lifting the abdominal wall without pneumoperitoneum. [14], [15] and [16]

Intraoperative Ultrasonography

In the past, a criticism of diagnostic laparoscopy was that only the surfaces of organs could be visualized, and parenchymal disease was overlooked. Intraoperative laparoscopic ultrasonography improves the sensitivity of abdominal exploration when performed by laparoscopists skilled in ultrasonographic interpretation. [25] This technology has proved particularly useful in the staging of malignancy. [25], [26], [27], [28] and [29] With experience, laparoscopists have become quite facile with this technology, and we are using ultrasonography for more and more applications. [2]

Endoscopic Transillumination

Laparoscopically assisted panenteroscopy has been performed in select patients. Patients with obscure gastrointestinal bleeding or inaccessible small bowel lesions, who otherwise would require open laparotomy, may benefit from this novel approach. With the help of the laparoscopist, the endoscopist can quickly advance an enteroscope for intralumenal examination. In an animal model, Bleau and colleagues [30] used laparoscopically assisted panenteroscopy to reach the ileocecal valve in about 30 minutes without perforation. Moreover, distention and endoscopic transillumination of the bladder, stomach, and colon can sometimes aid in diagnosis during laparoscopy. [31] Transillumination of the duodenum and small bowel delineates tumors, vascular malformations, and other lesions that may be present.

Tissue Sampling

Laparoscopically directed biopsy of lesions is more accurate than blind percutaneous biopsy. In a review of several studies, Nord [32] found a false-negative rate of 24% (range, 1% to 67%) for blind percutaneous biopsy of the liver and an average false-negative rate of only 9% (range, 4% to 18%) for laparoscopically guided biopsy. Directed transabdominal ultrasonographically guided biopsy is comparable to laparoscopy in focal and diffuse disease of the liver; however, ultrasonography and CT scan are relatively insensitive to metastatic disease. [17]

For most solid hepatic tumors, a Tru-Cut biopsy is sufficient to make the diagnosis. Several biopsy instruments are available that can be passed under laparoscopic guidance through the abdominal wall or introduced through an accessory port. Bleeding is usually controlled by direct pressure. Most small exophytic lesions are ideally suited for the punch forceps. This instrument has a cup-shaped blade that may be used to remove a small tissue sample without tearing adjacent structures.

If larger tissue samples are required, an incisional biopsy is made, and the specimen is retrieved in an entrapment sac. Control of hemostasis should be considered before biopsy. Good exposure should be achieved, and hemostatic agents (e.g., cellulose, collagen, or thrombin) should be readily available. Most surface bleeding is controlled by monopolar electrocautery. Laparoscopic suturing may be necessary, and the laparoscopist should develop expertise in both intracorporeal and extracorporeal suturing techniques.

Advanced laparoscopic procedures may be indicated during diagnostic laparoscopy. For large tissue specimens, morcellation of an organ may be performed to retrieve the tissue through a small skin incision. The spleen, for example, after laparoscopic splenectomy may be placed in a sac and divided into smaller fragments until the contents can be retrieved through a 10-mm incision. Morcellation destroys tissue margins; hence, its use for malignancy is limited.

Cysts may be needle aspirated, but at the risk of determining that the lesion is in fact a hemangioma. These lesions are notorious for uncontrolled hemorrhage after biopsy of any kind. Needle aspiration also may be used to confirm gallbladder cancer by cytologic examination of bile. One method to prevent contamination of the peritoneal cavity is to introduce the needle through the liver rather than by direct puncture of the gallbladder.

The laparoscopic suction-irrigator is designed to aspirate fluid. Large quantities of ascitic fluid are easily collected by this means. Similarly, peritoneal washing may be done by injecting 20 to 30 mL of sterile saline and then aspirating the contents into a collection container.

Postoperative Care

Patients are either observed in the hospital overnight or discharged later the same day after diagnostic laparoscopy. Common problems encountered in the immediate postoperative period include urinary retention and nausea. Antiemetics and analgesics are given as needed. Most patients tolerate clear liquids in the immediate postoperative period and resume a regular diet the next day. Nausea and mild shoulder pain due to diaphragmatic irritation may occur in the early postoperative period and may be diminished by the routine administration of ketorolac. [33] Patient activity is not restricted, and abdominal tenderness usually subsides by the second or third postoperative day. Patients discharged home the same day should be advised about these problems and should live relatively near the hospital, preferably with another person. Within 1 week, patients are usually ready to resume their normal level of activity.

ABDOMINAL INSPECTION

Whenever a laparoscope is inserted into the abdomen, the entire abdominal cavity and pelvis should be explored systematically and thoroughly. For diagnostic exploration, most laparoscopists recommend a 5-mm laparoscope, whereas for therapeutic laparoscopy, a 10-mm laparoscope is usually used. A second trocar placed in the flank may be used to divide adhesions if necessary to facilitate a thorough exploration. A third port may be necessary to allow a second working instrument to help retract, "run" the bowel, or obtain biopsy samples. After accessing the abdomen, the abdominal viscera and retroperitoneum immediately posterior to the initial port are first viewed to ensure that no injury has resulted from inserting the trocar. If access is uneventful, the abdomen is examined systematically. The following discussion highlights just a few of the more common findings that the laparoscopist encounters during abdominal inspection.

Pelvis

The pelvic viscera are examined for pathological abnormalities before evaluating the upper abdomen. The patient is placed in the Trendelenburg position. In women, the ovaries, fallopian tubes, and uterus should be inspected. If pelvic pathology is expected, a uterine manipulator is used to elevate the uterus and increase access to the adnexa, cul de sac, and bladder. Mature ovaries are white and almond shaped and usually measure about 2 × 3 × 3 cm. Benign functional cysts have a characteristic appearance and may be left alone because they will resolve spontaneously, whereas other cysts are neoplastic and may require oophorectomy. If an ovarian malignancy is suspected, peritoneal washings are generally required. The fallopian tubes may be red and inflamed from salpingitis or an early ectopic pregnancy. During the first 2 to 6 weeks of an ectopic pregnancy, the tubes are dilated to 3 to 4 cm and may later rupture, causing life-threatening hemorrhage. Uterine leiomyomas are usually gray, firm masses that may be microscopic in size or fill the abdominal cavity. If the ovary, fallopian tube, or uterus is abnormal at laparoscopy, we generally request the presence of a gynecologist to assist in diagnosis. Whenever gynecologic disorders are suspected as the primary problem by history and physical examination, diagnostic laparoscopy is preferably performed by a gynecologist.

The pelvic floor should be inspected for inguinal or femoral hernias as well as tumors of the bladder and colon. Bowel or bladder attached to the pelvic floor may represent an incarcerated hernia, adhesions, or tumor extension. The sigmoid colon may reveal diverticular disease, abscess, or tumor. Typically, diverticula are herniations 1 mm to several centimeters in diameter and are located between the mesenteric and antimesenteric teniae of the colon.

Midabdomen

The anterior surfaces of the intestines, omentum, and stomach are examined for abnormalities. Following the teniae of the cecum proximally will locate the appendix. In the early stages of inflammation, the appendix is erythematous with engorged surface vessels or covered by a fibrinopurulent material; later, green-black foci of necrosis typify gangrenous appendicitis and herald impending perforation. Crohn's disease generally occurs in sharply demarcated segments of bowel that have a rubber-hose consistency surrounded by creeping fat. The duodenum may have a sealed patch of omentum covering a perforated ulcer, which can be missed altogether by cursory examination. If portal hypertension is present, the veins of the omentum and abdominal wall will be dilated. The intestine may be ischemic and appear blue because of volvulus or vascular infarction. With intestinal obstruction, the proximal bowel is generally distended and the bowel distal to the obstructive lesion decompressed, especially with a complete obstruction secondary to an adhesive band from a previous operation.

Right Upper Quadrant

To examine the right upper abdomen, the patient is placed in a reverse Trendelenburg position of 30 to 40 degrees while the table is rotated to the patient's left by 15 to 20 degrees. This maneuver allows the colon and duodenum to fall away from the liver's edge. Normal liver is reddish-brown and has a smooth surface. The falciform ligament and both lobes of the liver are closely examined for pathology. Adhesions on the anterior liver surface may be due to inflammation from Fitz-Hugh-Curtis syndrome. Primary carcinoma of the liver may appear as small nodular lesions with widespread peritoneal metastases. Fatty degeneration imparts a yellow color to the liver, whereas nodularity of the liver suggests cirrhosis. Extrahepatic biliary obstruction from periampullary cancer may cause cholestasis, and the liver will generally be tense and appear green hued owing to bile discoloration. Most metastatic liver lesions appear as yellow, gray, or white nodules that feel solid. Metastatic melanoma appears as brownish-black spots. Solid masses should be examined by biopsy using either a cutting needle, cupped forceps, or cautery scissors, or such masses may be sampled by needle aspiration to determine histology and cytology. Bluish cystic hepatic lesions, however, should never be examined by biopsy because hemangiomas can cause severe bleeding, which may be difficult to control laparoscopically. Hepatic, pancreatic, and other suspicious lesions may be further evaluated by laparoscopic ultrasonography.

Usually, the gallbladder can be seen protruding beyond the inferior edge of the liver, but sometimes, it is not visible without carefully elevating the liver or taking down adhesions. The normal gallbladder has a shiny bluish-green color. In acute cholecystitis, the gallbladder may be tense, edematous, fiery red, and covered with a fibrinosuppurative exudate. Extensive adhesions surrounding a thickened, gray-white, tough gallbladder wall are usually due to chronic inflammation. Distal extrahepatic obstruction may cause a distended (Courvoisier) gallbladder. Transcholecystic cholangiography or laparoscopic ultrasono- graphy [34] may be used to diagnose stones in the gallbladder or bile ducts. A pale or opaque gallbladder may represent chronic cholecystis or tumor.

Left Upper Quadrant

The normal spleen is usually not seen in the left upper quadrant; when visible, splenomegaly is often apparent. Further inspection of the spleen is best achieved by rotating the patient to the right in the head-up position. Although splenic biopsy has been performed, the risk for severe hemorrhage usually warrants caution. The left hemidiaphragm can be inspected for hiatal hernia and esophageal varices. If the diaphragm bows inward, a pneumothorax should be suspected.

INDICATIONS FOR DIAGNOSTIC LAPAROSCOPY

Diagnostic laparoscopy may be used to optimize the workup of abdominal pain and masses, triage trauma, and stage malignancy. Some of the current indications for diagnostic laparoscopy are listed in Table 161-2.

Accepted
Assessment of liver
Acute abdominal pain
Ascites of unknown etiology
Gaining Acceptance
Staging of malignancy
Blunt and penetrating trauma
Chronic abdominal pain
Anecdotal Experience
Intensive care unit setting
Fever of unknown origin
Second-look procedures

TABLE 161-2 Common Indications for Diagnostic Laparoscopy

Evaluation of Abdominal Pain

Acute Pain Acute right lower quadrant pain that may be due to acute appendicitis is ideally evaluated by laparoscopy. Traditionally, appendicitis was a clinical diagnosis, for which a 20% error rate with a normal appendix was considered acceptable because of the morbidity and mortality caused by appendiceal perforation from a delay in operation. With the use of laparoscopy, several studies have shown a markedly decreased rate of negative laparotomy results for questionable appendicitis. [35] Especially in young women, who experience gynecologic problems that may mimic appendicitis, diagnostic laparoscopy has reduced the unnecessary laparotomy rate by one third. [36], [37], [38] and [39] In a prospective randomized trial of 100 patients with the clinical diagnosis of appendicitis, 50 underwent open laparotomy, and 50 underwent diagnostic laparoscopy. In the latter group, 19 patients (38%) did not require appendectomy; moreover, there were no complications from laparoscopy. [40] When appendicitis is present, the appendix may be removed laparoscopically. If the appendix is perforated, laparoscopy allows thorough irrigation of the abdominal cavity. Several randomized prospective studies have suggested that laparoscopic appendectomy decreases postoperative pain and accelerates return to full activity compared with conventional appendectomy. [40], [41], [42] and [43] Other causes of right lower quadrant pain also may be better evaluated by a laparoscope. Laparoscopic treatment of tubal pregnancy is as safe as treatment with laparotomy and has the benefit of decreased length of hospital stay, lower cost, and earlier return to full activity. [44], [45] Laparoscopy has also been suggested as the definitive diagnostic modality for "pelvic inflammatory disease" because no reliable clinical methods exist that accurately establish such a diagnosis. [46] Children, newborn to 15 years of age, with ill-defined abdominal pain have been evaluated by laparoscopy and found to have problems including appendicitis, adhesions, cysts, Meckel diverticula, or unappreciated hernias. [47] Many of these problems can be treated laparoscopically. In the intensive care unit setting, diagnostic laparoscopy has been used to assess the critically ill patients with suspected abdominal catastrophe. In a study of 25 such patients, 13 (52%) laparoscopies yielded negative findings, and nontherapeutic operations were avoided. [48]
Chronic Pain The cause of chronic abdominal pain may be unclear even after extensive preoperative diagnostic evaluation. Diagnostic lap- aroscopy yielded positive findings in 47% of chronic abdominal pain cases. [49] Laparoscopy has the advantage of adding therapeutic possibilities to its diagnostic value; for example, when adhesions are detected, laparoscopic adhesiolysis may relieve the patient's symptoms.

Trauma

Laparoscopy may have a role in evaluating blunt and penetrating abdominal trauma. After trauma, a surgical dictum has been to explore all penetrating wounds of the abdomen. This practice results in many negative laparotomies when operation is based on clinical impression alone. Hemodynamically stable patients with significant abdominal trauma are traditionally evaluated by peritoneal lavage or CT scan. With a 5-mm laparoscope inserted under local anesthesia in the emergency room, in 150 blunt abdominal trauma cases, diagnostic laparoscopy predicted or excluded the need for laparotomy in more than 90% of patients. [50] Sosa and colleagues [51] used laparoscopy in six patients with tangential gunshot wounds to the abdomen to exclude fascial penetration and avoid laparotomy. Diagnostic laparoscopy is also efficacious as an adjunct in patient selection after CT scan has demonstrated solid organ injury; in 15 patients with splenic and liver lacerations, 8 (53%) were managed conservatively without laparotomy. [52] Diagnostic laparoscopy in 33 stable patients with penetrating trauma and no clinical evidence of intraperitoneal injury identified peritoneal penetration in 10 patients, of whom 9 had intraperitoneal injury at laparotomy; 23 patients were spared a negative exploratory laparotomy. [53]

Laparoscopy in 182 hemodynamically stable patients after abdominal trauma averted laparotomy in 44% after penetrating trauma and in 47% after blunt trauma. [54]

Diagnostic laparoscopy for trauma remains controversial despite its potential to avoid negative laparotomy because retroperitoneal wounds and hollow-organ perforations may not be recognized and go untreated. Diagnostic laparoscopy was better than peritoneal lavage in predicting the need for laparotomy for stab wounds but not after blunt trauma in a prospective study of 75 patients. [55] After penetrating abdominal trauma in a series of 100 patients, diagnostic laparoscopy was accurate in assessing for hemoperitoneum, solid-organ injuries, diaphragmatic lacerations, and retroperitoneal hematomas. For injuries to the hollow viscera, laparoscopy was 100% specific but only 18% sensitive. Injuries to the flank and epigastric region were frequently missed, thereby limiting its usefulness. [56] Laparoscopic findings in 32 patients before laparotomy correlated (97%) with the need for laparotomy, but injuries to the liver, pancreas, stomach, duodenum, small bowel, intestinal mesentery, ureter, and urinary bladder were missed by laparoscopy. [57] In the future, perhaps a combined approach using laparoscopy to examine the peritoneum and CT scan to image the retroperitoneum may increase diagnostic accuracy after abdominal trauma.

Liver Lesions and Ascites

Inspection of the liver may be the most common indication for diagnostic laparoscopy. Blind percutaneous biopsy of the liver may cause inapparent injury and will miss focal disease such as small metastases, whereas laparoscopy improves the accuracy of biopsy. [32] In addition, laparoscopic criteria may be predictive of outcome. In cirrhosis, although the interpretation of laparoscopic findings is largely subjective, the size and pattern of regenerative nodules, formation of lymphatic vesicles, and presence of an enlarged spleen all predict a poor prognosis. [58] Laparoscopy is indicated in the evaluation of ascites after transabdominal ultrasonography, CT scan, and paracentesis fail to determine its etiology. [59] Because of the 12- to 15-fold magnification and excellent ability to view the entire peritoneal surface, laparoscopy is particularly sensitive for small peritoneal implants. If the size of the miliary nodules is uniform, the nodules are more likely to be benign because malignant nodules usually are of varying sizes. [60] Biopsy for histological confirmation is essential to the diagnosis, and ascitic fluid should be sent routinely for cytology and microbiology. In a study of 129 patients with ascites of unknown origin, laparoscopy in combination with biopsy established the etiology of ascites in 86%. [61]

Staging of Malignancy

When performing laparoscopy to stage abdominal malignancy, preoperative consideration should be given to the accessibility to specific viscera, tissue samples required for adequate staging, and range of palliative interventions possible endoscopically and laparoscopically if the lesion proves unsuitable for curative operation. After initial port placement and primary visual survey of the abdomen, accessory ports are placed under direct vision in appropriate locations. Of 25 patients referred for evaluation, laparoscopy was 100% accurate in the diagnosis or exclusion of various intra-abdominal malignant neoplasms. [62]

Liver Cancer

Of patients thought to have resectable disease by preoperative transabdominal ultrasonography or CT scan, 40% to 70% of patients with primary or metastatic hepatic malignancy are found to have unresectable disease at operation. [63] Therefore, diagnostic laparoscopy before laparotomy is recommended to evaluate the extent of cancer and degree of cirrhosis.

Laparoscopy accurately diagnoses metastatic tumors to the liver. Lightdale and colleagues, [64] in a study of 65 metastatic lesions, obtained tissue samples in 60. Histology was 92% sensitive and 100% specific. However, 40% to 50% of hepatomas less than 3 cm in diameter are not visible on the surface of the liver. For these small tumors, laparoscopic ultrasonography improves the sensitivity to 88%, whereas for tumors larger than 3 cm, the sensitivity by laparoscopic ultrasonography is 100%. [26] Small hepatic cysts may be confused with metastases by surface imaging, whereas cysts usually appear as round, echo-free lesions with posterior enhancement by laparoscopic ultrasonography. [28]

Ovarian Cancer

Diagnostic laparoscopy has been used extensively to evaluate gynecologic malignancy. [65], [66] Laparoscopic evaluation of 819 adnexal masses had a sensitivity for the detection of malignancy of 100%, specificity of 97%, and negative predictive value of 100%. [66] However, the positive predictive value was only 41% because 27 benign tumors were incorrectly thought to be malignant. Ovarian cancer metastatic to the diaphragm is best identified by laparoscopy, [67], [68] and in one study, 11 of 14 patients were upstaged by diagnostic laparoscopy. [67]

Gastric Cancer

With cancer of the stomach, laparoscopic examination can prevent 40% to 50% of unnecessary laparotomies. [27], [69], [70] Laparoscopy determines serosal infiltration, tumor fixation, and metastases to the liver and peritoneum. Laparoscopy in 40 patients with gastric carcinoma detected distant metastases in 5 patients and locally advanced unresectable cancer in 11 patients (27%). [69] The overall diagnostic accuracy was 92%. Similarly, laparoscopy in 360 patients with gastric cancer was 89% accurate in detecting peritoneal spread and 97% accurate in identifying liver metastases. [70] Intraoperative ultrasonography is complementary, identifying small lymph nodes, gastric wall involvement, and deep hepatic metastases. [25], [27]

Gallbladder Cancer

If gallbladder cancer is suspected, diagnostic laparoscopy can confirm local or distant spread, precluding resection in 85% of patients. [71], [72] Fortunately, gallbladder cancer is rare. In the author's personal series of more than 1700 laparoscopic cholecystectomies, only 3 patients were initially diagnosed intraoperatively with cancer of the gallbladder, none of whom were resectable for cure.

Cancer of the Pancreas

Diagnostic laparoscopy was recognized as early as 1911 by Bernheim [73] as a valuable procedure to exclude pancreatic cancer metastases; however, Meyer-Burg [74] reported the first series using diagnostic laparoscopy for the staging of cancer of the pancreas. Since then, several different approaches have been proposed. Cuschieri and associates [75] examined the pancreas through an infragastric opening into the lesser sac and was able to see the entire gland in 60% of patients. Ishida, [76] using a supragastric approach, visualized only 32% of tumors in the head of the pancreas but accurately identified 85% of cancers in the body of the pancreas. Diagnostic laparoscopy is particularly helpful in patients who have no evidence of metastatic disease on preoperative imaging studies. In these patients, staging laparoscopy has identified metastases in more than 40% of cases. [73], [77] More recently, laparoscopic contact ultrasonography has enhanced the ability to stage cancer of the pancreas laparo- scopically. John and colleagues [29] reported that of 40 patients with suspected carcinoma of the head of the pancreas considered preoperatively to have resectable disease, 35% had advanced disease at laparoscopy. The addition of intraoperative laparoscopic ultrasonography identified another 10 patients (25%) with unresectable cancer. In addition to hepatic metastases, ultrasonography reveals lymphadenopathy, local tumor infiltration, portal vein or mesenteric arterial invasion, and anomalous anatomy.

At our institution, staging laparoscopy with laparoscopic ultrasonography is routinely used to stage cancer of the liver, biliary tree, and pancreas before laparotomy. We have shown that more than 40% of patients with tumors thought to be resectable by conventional imaging tests are proved unresectable using these studies. [2] Patients unresectable at laparoscopy are considered for laparoscopic biliary bypass or gastrojejunostomy, maintaining the goal of minimal invasion. Patients without evidence of metastases or vascular invasion by tumor are converted to a laparotomy for curative resection.

Lymphoma

Laparoscopy completely stages lymphoma by liver biopsy, nodal sampling, and complete visualization of the abdominal cavity. [78] During diagnostic laparoscopy, Salky [49] obtained adequate tissue samples in 12 of 12 patients after percutaneous biopsy was unsuccessful. Childers and Surwit [79] have reported laparoscopic paraaortic lymph node biopsy for non-Hodgkin lymphoma. Whether laparoscopic splenectomy is necessary for full staging remains controversial.

Esophageal Cancer

Diagnostic laparoscopy has been advocated for staging esophageal cancer in those patients considered suitable for resection by CT scan. Laparoscopy before laparotomy identified 14% of patients with metastases to the liver, peritoneum, omentum, and lymph nodes, precluding resection. [80]

Second-Look Procedures

After initial treatment of abdominal malignancy, assessment of response by second look may be better done laparoscopically than by a laparotomy. If early tumor recurrence is suggested by history, physical examination, or rising tumor markers, but imaging studies are negative, laparoscopy may be indicated. Imaging studies may be equivocal because of scar formation, altered anatomy from a previous operation, or reactive lymphadenopathy. Although abdominal exploration by laparoscopy also may be limited by adhesions, the finding of histologically confirmed distant metastases or peritoneal carcinomatosis may obviate further evaluation. In the future, radionuclide probes that detect tumors may improve the accuracy of diagnostic laparoscopy for this purpose.

Absolute and Relative Contraindications

Preoperative evaluation should determine the presence of confounding medical problems that may adversely affect the outcome of laparoscopy. Absolute contraindications to laparoscopy include the inability to tolerate general anesthesia or lap- arotomy, uncorrectable coagulopathy, a “frozen” abdomen (obliteration of the celomic cavity, usually caused by multiple prior operations), or a hemodynamically unstable patient (Table 161-3). Relative contraindications are as dependent on the experience of the laparoscopist as on any particular attribute of the patient.

Absolute
Poor risk for general anesthesia
Inability to tolerate a laparotomy
Uncorrected coagulopathy
"Frozen" abdomen
Hemodynamic instability
Relative
Prior abdominal surgery
Peritonitis; previous or acute
Obesity
Pregnancy
Unreducible abdominal/inguinal hernia
Severe pulmonary disease
Intestinal obstruction

TABLE 161-3 Contraindications to Laparoscopy

With experience, most of these conditions can be successfully managed. For example, morbidly obese patients may require longer trocars to traverse the anterior abdominal wall and higher insufflation pressures to obtain an adequate working space. Appendicitis and cholecystitis may occur during pregnancy, and laparoscopy is often helpful for diagnosing and treating this subset of patients with abdominal pain in whom additional radiologic studies are undesirable. Although laparoscopic cholecystectomies have been performed safely during pregnancy, [81] the prolonged exposure to CO_2 pneumoperitoneum may have untoward effects on the fetus. Hyperventilation and monitoring of end-tidal CO_2 minimize maternal hypercarbia and fetal acidosis. Insufflation pressures are kept low, preferably below 12 mm Hg, to obviate respiratory problems, and monitoring of fetal heart sounds should be done in consultation with an obstetrician. [82], [83]

Conclusions

Diagnostic laparoscopy has rapidly been embraced by clinicians around the world. With minimal morbidity, lesions too small to be seen by CT scan, MRI, and abdominal ultrasonography can be accurately described and examined by biopsy using laparoscopic techniques. Malignancy can be staged, and vague abdominal complaints may be elucidated. Certainly, many unnecessary and morbid laparotomies will be avoided. For these reasons, diagnostic laparoscopy is being incorporated into modern diagnostic and therapeutic algorithms for more and more disease processes. Occasionally, anatomic or physiological considerations will preclude the laparoscopic approach, and conversion to an open operation reflects sound surgical judgment and should not be considered a complication. The exact role for diagnostic laparoscopy in the elective and emergent situation is still evolving as laparoscopists become more technically facile and as newer “competing” technology improves.

THERAPEUTIC LAPAROSCOPY

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy has rapidly become the gold standard for removing the gallbladder. [12] In addition to reports from multiple large clinical series, several randomized studies have clearly demonstrated the benefits of laparoscopic cholecystectomy compared with open cholecystectomy. [83], [84] Laparoscopic cholecystectomy is indicated for symptomatic cholelithiasis, biliary dyskinesia (acalculous cholecystitis), and select patients with asymptomatic gallstones (e.g., immunosuppressed status, *Salmonella typhi* carriers, porcelain gallbladder [85], [86]). At our institution, more than 95% of elective cholecystectomies are performed laparoscopically. Although the operation was originally reserved for young thin patients, today elderly [87] and obese [88] patients also benefit from surgery through small incisions.

Several variations of the operation have been proposed; we favor the “American” technique. The 5- or 10-mm viewing port is placed at the umbilicus. Two 5-mm working ports are right subcostal, and one working port is epigastric. With the gallbladder retracted over the liver by the assistant, the gallbladder infundibulum and porta hepatis become accessible to the operating surgeon (Fig. 161-4). Antegrade dissection beginning on the gallbladder facilitates isolation of the cystic artery and cystic duct within the hepatocystic triangle (bounded by the gallbladder, liver, and cystic duct). This critical view must be clearly demonstrated before clipping or dividing any structure to avoid inadvertent injury to the common bile duct or right hepatic artery [89] (Fig. 161-5).

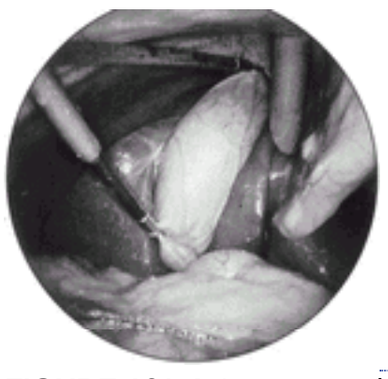

FIGURE 161-4. Laparoscopic view of the gallbladder during cholecystectomy.

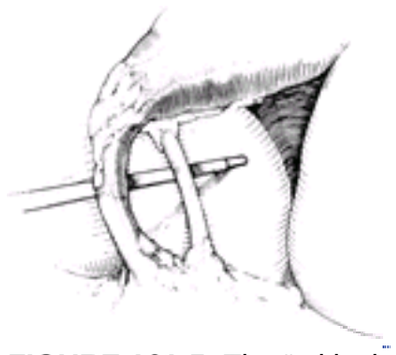

FIGURE 161-5. The “critical view” of safety during laparoscopic cholecystectomy after dissection of the neck of the gallbladder away from its bed. The cystic duct is seen on the left, and the cystic artery is on the right. This dissection should prevent bile duct injuries during laparoscopic cholecystectomy. (From ref. [89].)

Before dividing the cystic duct, a clip is placed across the junction of the cystic duct and gallbladder, and a small ductotomy is made distal to the clip. An atraumatic dissecting forceps is then used to palpate the cystic duct for stones and to milk potential stones out of the cystic duct. Cystic duct stones should be sought in all patients. Their presence predicts choledocholithiasis [90] and could lead to retained stones or the postcholecystectomy syndrome if left untreated.

Intraoperative cholangiography should be considered whenever there is a suspicion of choledocholithiasis (Fig. 161-6) or bile duct injury or when the anatomy is unclear intraoperatively. Fluoroscopic cholangiography may be performed more rapidly than static cholangiography. [90], [91] Using fluoroscopy, the surgeon can interact with findings (stones, air bubbles, aberrant anatomy) in real time. Although selective application of cholangiography will detect more than 90% of common bile duct stones, advocates for routine cholangiography argue that the best preoperative indicators of common bile duct stones are not adequately sensitive to detect all stones. [91] In the era of cost containment, however, a policy of routine cholangiography is difficult to justify. In the future, new technologies such as laparoscopic ultrasonography may delineate biliary anatomy and discover common bile duct stones less invasively and expensively.

FIGURE 161-6. Common bile duct stones identified by intraoperative digital fluorocholangiography during laparoscopic cholecystectomy. The stones can be viewed as filling defects in the contrast within the distal common bile duct (*arrows*).

After the critical view is clearly demonstrated and the common bile duct is cleared, the cystic duct and artery are clipped and divided. As dissection is continued, tension is maintained on the gallbladder wall to help define the plane between the gallbladder and liver bed. Electrocautery is usually used to dissect the gallbladder from the hepatic fossa. The gallbladder is removed through the umbilical port incision.

Laparoscopic cholecystectomy decreases postoperative pain, shortens hospital stay from 1 week to less than 24 hours, and returns the patient to full activity within 1 week compared with 1 month after open cholecystectomy. [12], [83], [84] In addition to lower morbidity and mortality, laparoscopic cholecystectomy also may be less expensive than open cholecystectomy. [92]

During the learning curve for laparoscopic cholecystectomy, however, bile duct injuries increased to about 0.5% or greater; one state-wide survey estimated the frequency of this potentially devastating complication to be seven or eight times higher than with open cholecystectomy. [93] Certain anatomic situations also have been found to predispose to bile duct injury: with absent or extremely short cystic ducts, the common bile duct may be mistaken for the cystic duct; clips of insufficient length may not occlude the dilated cystic duct and lead to a cystic duct stump leak; and aberrant origin of the right hepatic duct may not be recognized and result in biliary injury. Insult is added to injury whenever ductal injuries are not determined until days later; a straightforward repair is converted into a very complex repair of a high-grade injury. [89] With incomplete dissection, the right hepatic artery also may be mistaken for the cystic artery, and the divided right hepatic artery may cause hepatic or bile duct ischemia. Over time, the technical complications of Laparoscopic cholecystectomy, especially bile duct injuries, seem to have decreased. [94] When injuries occur, the gastroenterologist plays an important role in diagnostic evaluation and patient management. [90], [95]

Laparoscopic Appendectomy

Gynecologist K. Semm was the first to perform laparoscopic appendectomy in 1981. [96] A decade later, Attwood and colleagues [40] reported a randomized prospective study from the United Kingdom showing laparoscopic appendectomy to decrease pain, expedite hospital discharge, and cause fewer infections compared with open appendectomy. Other theoretical advantages include fewer postoperative adhesions and a lower frequency of subsequent intestinal obstruction. [97] When compared with the view afforded by a small right lower quadrant incision, a more thorough abdominal exploration is also possible laparoscopically. In women, for example, the adnexae are inspected, and many gynecologic problems that may account for pain in the right lower quadrant can be excluded. During laparoscopic appendectomy, the appendiceal stump may be isolated and closed with a preformed loop ligature or alternatively ligated and divided with a stapler. The appendix is usually placed in a plastic pouch to prevent contamination before it is removed through a port. Despite the shorter hospital stay, laparoscopic appendectomy appears to offer no overall medical cost savings. [98] Several prospective randomized trials of laparoscopic versus open appendectomy have been performed, with varying results. [40], [41], [42] and [43] Because of these discrepancies and because many appendectomies are performed at times of day when operating room staffing may not include individuals who are comfortable handling laparoscopic equipment, laparoscopic appendectomy has not been embraced for routine use.

Advanced Procedures

Advanced laparoscopic procedures rely on more complex techniques, such as using variable endoscopic viewpoints and suturing. These operations have not been used as frequently as the “basic” procedures mentioned earlier, and additional clinical experience is needed to clarify their role.

Laparoscopic Management of Choledocholithiasis

The optimal treatment of common bile duct stones is controversial. Although many methods for treating choledocholithiasis have been reported, the appropriate therapy depends on the patient’s condition and the relative local expertise in laparoscopy, endoscopy, and interventional radiology. [99] Management strategies depend not only on the patient’s medical condition but also on whether the stones are detected before, during, or after cholecystectomy. The algorithm we propose assumes that the surgeon has advanced laparoscopic biliary experience and excellent endoscopic and radiologic support (Fig. 161-7). The common goal of therapy must be to achieve ductal clearance with the fewest number of interventions, lowest cost, and least morbidity [91], [100], [101], [102], [103], [104], [105], [106], [107], [108], [109] and [110] (Table 161-4).

FIGURE 161-7. Algorithm for the management of common bile duct stones. (From ref. [100].)

METHOD	SUCCESS (%)	POSTOPERATIVE HOSPITALIZATION (days)	RTW (days)
Transcystic duct extraction	80–95	1–2	7–10
Laparoscopic CBDE	85–100	4–7	4–30
Open CBDE	90–100	5–10	20–42
ERC/ES	85–95	0–3	1–10

CBDE, common bile duct exploration; ERC, endoscopic retrograde cholangiography; ES, endoscopic sphincterotomy; RTW, return to work.

TABLE 161-4 Results of Therapy for Choledocholithiasis [91], [99], [100], [101], [102], [103], [104], [105], [106], [107], [108], [109] and [110]

Preoperative endoscopic retrograde cholangiography (ERC) with sphincterotomy and stone extraction should be performed in those patients with deep jaundice, cholangitis, severe pancreatitis, or an indication for biliary drainage. [106], [107], [108] and [109] In patients with frank jaundice and a dilated common bile duct by ultrasonography, ERC is performed to exclude malignancy or other conditions requiring therapy. If patients cannot be successfully managed endoscopically, transhepatic biliary decompression or operative therapy may become necessary. After stone extraction for acute gallstone pancreatitis, laparoscopic cholecystectomy is usually performed during the index admission. [111]

During laparoscopic cholecystectomy, 5% to 10% of patients are found to have unsuspected common bile duct stones. [99], [101], [102] and [103] When discovered by intraoperative cholangiography or ultrasonography, most stones in the common bile duct may be removed laparoscopically. Small stones can be cleared from the common bile duct by advancing the cholangiocatheter and irrigating forcefully with saline solution after relaxing the ampullary sphincter with 1 to 2 mg of intravenous glucagon. If irrigation is unsuccessful, baskets with soft, radiopaque, filiform tips may be passed under fluoroscopic guidance and used to extract stones. [101] If these attempts fail to retrieve the stones, the guidewire should be left in place to facilitate insertion of the choledochoscope.

Transcystic choledochoscopy directly visualizes the biliary tract and therefore is highly effective at clearing the common bile duct of stones [102], [103] and [104] (Fig. 161-8). A 7- to 10-French choledochoscope may be passed over the guidewire into the common bile duct after cystic duct dilation using balloon dilators. The endoscope is equipped with a biopsy channel for introducing a 3-French stone basket. Under visual guidance, the basket is advanced beyond the stone and opened. As the basket is pulled backward and rotated, the stone is ensnared. The stone and scope are removed under direct vision through the ductotomy. Multiple passes are made until the duct is clear. After stone removal, completion cholangiogram should be performed to demonstrate conclusively the clearance of the duct at the end of the procedure. [112] Ideal candidates for transcystic extraction are patients with relatively few, small (less than 8 mm) stones located in the distal common duct.

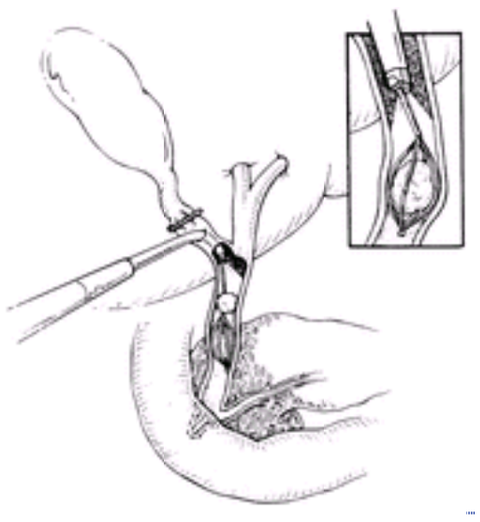

FIGURE 161-8. A flexible choledochoscope is passed through the cystic duct, and a basket is used to extract the stone from the common bile duct (From ref. [100].)

Larger or impacted stones and those located in the proximal bile ducts may require a choledochotomy and placement of a T tube. Laparoscopic choledochotomy has been performed safely and effectively in experienced hands with shorter hospitalization and disability when compared historically with open common bile duct exploration. [104], [105] If choledochotomy is reserved for failures of the transcystic technique, laparoscopic choledochotomy is needed only infrequently.

The major disadvantages of laparoscopic common bile duct exploration are that it is technically difficult, is time consuming, and requires special equipment. Because many surgeons have not yet acquired these skills, they either convert to open laparotomy or rely on ERC with sphincterotomy and stone extraction. [113] Open choledochotomy may be performed to clear the common duct in a single operation if the surgeon lacks the expertise needed to manipulate the choledochoscope and suture the choledochotomy closed.

Stones intentionally left for postoperative endoscopic clearance should be small and considered unlikely to obstruct the bile duct completely. Relying on postoperative ERC subjects the patient to at least two procedures with their additive morbidity, and possibly a second operation if ERC and stone extraction fail to clear the duct. Even in experienced hands, stone extraction has a 5% to 10% chance of failure. [106] Relative contraindications to leaving ductal stones to be managed by postoperative ERC and stone extraction include a distal common duct stricture, duodenal diverticulum, previous Billroth II reconstruction, and stones greater than 1 cm in size, and these patients may be best managed at the time of surgery. The surgeon also can leave a cholangiocatheter in the common bile duct to facilitate subsequent ERC and stone extraction. [114] Intraoperative ERC also may be considered, but this approach is difficult because of patient positioning, personnel coordination, and the tendency toward intestinal distention by endoscopic insufflation. Postoperative ERC with stone extraction is the procedure of choice for retained stones in the absence of a T tube; however, it is unwise to rely on postcholecystectomy ERC and stone extraction at centers with less than a 90% endoscopic duct clearance rate.

Laparoscopic Management of Gastroesophageal Reflux Disease

A recent randomized prospective study showed that conventional open Nissen fundoplication resulted in more effective treatment of complicated gastroesophageal reflux disease (GERD) than did medical management with histamine H_2 receptor antagonists. [115] However, few patients were treated operatively owing to the perceived morbidity of surgery until the first report of laparoscopic Nissen fundoplication was published in 1991. [116] The preoperative evaluation may include radiographic imaging, endoscopy, pH monitoring, and esophageal manometry. [117] A markedly shortened esophagus is a contraindication to standard Nissen repair and necessitates an esophageal lengthening procedure. If the propulsive force of the esophagus is diminished, a partial, rather than a total, wrap (200- to 270-degree

partial fundoplication) is preferred by many surgeons. [118], [119]

Laparoscopic Nissen fundoplication is usually performed through five ports with the patient in the reverse Trendelenburg (head-up) position. The laparoscope is placed through a port in the left midrectus 12 to 15 cm inferior to the xiphoid. The remaining ports are typically placed in an arc across the upper abdomen. This port arrangement allows access to the hiatus and permits comfortable suturing.

The Nissen fundoplication is performed by wrapping the gastric fundus 360 degrees around the distal esophagus. [120] A retractor placed through the right subcostal port elevates the left lobe of the liver, and a Babcock forceps, through the right midrectus port, pulls the stomach and epiphrenic fat pad inferiorly. After dividing the phrenoesophageal ligament, both crura and the anterior vagus nerve may be clearly identified. If a hiatal hernia is present, it is reduced into the abdominal cavity with gentle traction after cutting all adhesions to the hernia sac. By retracting the right crus laterally, the right side of the esophagus is dissected to expose the aortoesophageal groove and posterior vagus nerve. Similarly, the left crus is dissected from the esophagus and fundus to its point of origin from the right crural leaflet.

The fundus is fully mobilized by dividing the proximal gastrosplenic ligament (Fig. 161-9). Dissection begins about 8 to 10 cm distal to the esophageal junction on the greater curve. The short gastric vessels are placed on traction, and a window is created into the lesser sac. The short gastric vessels are then serially divided by clipping and cutting them or by serial application of ultrasonic coagulating shears. Division of the short gastric vessels may diminish early postoperative dysphagia. [121] All posterior retroperitoneal adhesions to the fundus are divided to mobilize the proximal stomach completely.

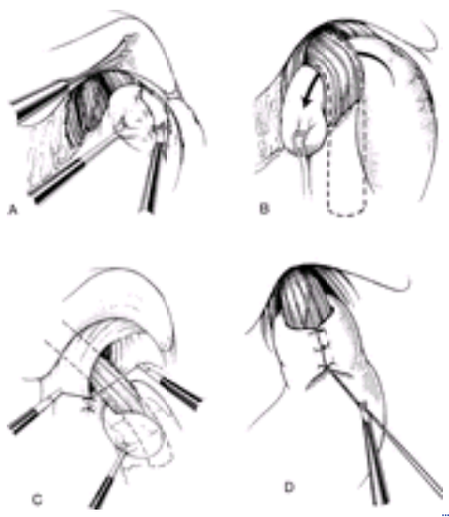

FIGURE 161-9. Laparoscopic Nissen fundoplication. **A:** Mobilization of fundus and division of short gastric vessels. **B:** Fundus of stomach is wrapped posterior to the esophagus around a 60-French bougie. **C:** The hiatus may be closed posteriorly. **D:** Appearance of completed fundoplication as viewed by the laparoscope. (From ref. [120].)

The fundus near the insertion of the short gastric vessels is pulled from left to right posterior to the esophagus (see Fig. 161-9). After serially dilating the esophagus to a 50- to 60-French Maloney bougie, the wrap can be formed without excessively narrowing the esophagus. The hiatus should be closed in most patients because of the hiatal dissection. Several sutures are placed to reapproximate the right and left crura.

The goal is a “short, floppy” Nissen fundoplication. Generous seromuscular bites of fundus to the left of the esophagus, the anterior esophageal wall away from the anterior vagus nerve, and the fundus to the right are all incorporated in sutures securing the 360-degree fundoplication. The esophageal wall is incorporated to prevent slippage of the wrap around the body of the stomach or into the thoracic cavity. The wrap should be only 1.5 to 2 cm in length because longer wraps may cause a higher incidence of postoperative dysphagia. [122]

Laparoscopic Nissen fundoplication has demonstrated excellent results in several large clinical series. [118], [119], [123], [124] The patient is usually discharged within 2 days, and more than 90% of patients report complete relief of symptoms up to 5 years after surgery. Long-term outcome data will be necessary to demonstrate the effectiveness of laparoscopic antireflux operations.

Laparoscopic and Thoracoscopic Esophagocardiomyotomy for Achalasia

Recent application of minimally invasive techniques to myotomy have stimulated a reemergence of esophageal myotomy in the treatment of this disease. Despite a previously published prospective, randomized trial demonstrating that esophageal myotomy yielded better results than balloon dilation, [125] the morbidity attendant on the necessary thoracotomy or laparotomy dampened enthusiasm for the operation. The incisional trauma related to the operation has been substantially decreased by minimally invasive procedures. The first technique reported was a thoracoscopic myotomy without an antireflux procedure. [126] This operation is performed using four or five trocars arranged in a diamond-shaped pattern around the lower portion of the left chest. A long myotomy can be performed using the thoracoscopic approach. Short-term postoperative results have been excellent, although 24-hour pH monitoring suggests that abnormal gastroesophageal reflux occurs in 60% of these patients postoperatively. [126]

Laparoscopic esophagomyotomy has been described more recently, subsequent to the extensive experience with the laparoscopic approach to the esophageal hiatus. Using the laparoscopic approach, a partial fundoplication can be added to help prevent postoperative gastroesophageal reflux. [127], [128] This may take the form of an anterior 180-degree (Dor) fundoplication [128] or a posterior 180-degree (Toupet) fundoplication. [127] A 360-degree Nissen fundoplication should not be added to the esophagomyotomy because it would likely cause postoperative dysphagia.

All laparoscopic approaches facilitate extending the myotomy onto the stomach and thus may prevent recurrence of postoperative dysphagia. [127], [128] However, it is more difficult to extend the myotomy as high cephalad as can be done using the thoracoscopic approach. Thus, the laparoscopic approach should probably not be used in the rare patients who require proximal extension of the myotomy to the midesophagus. As is typical of minimally invasive surgery, the hospital stay and recovery time are shortened by at least 50% compared with the standard open myotomies. Long-term follow-up results of the minimally invasive procedures are not yet available, but the initial outcomes are sufficiently promising to recommend this form of treatment by experienced surgeons in uncomplicated cases.

Laparoscopic Inguinal Herniorrhaphy

The initial laparoscopic inguinal herniorrhaphies simply plugged the fascial defect of the groin floor with a wad of prosthetic mesh or directly closed the defect under tension. Consequently, these approaches had higher recurrence rates than standard methods and are no longer performed. Many surgeons then adapted laparoscopic techniques to perform a tension-free Stoppa repair using prosthetic material. [129] Using a transabdominal approach, the peritoneal cavity is entered using three trocars placed at the level of the umbilicus. The peritoneum overlying the hernia is incised, and the inguinal floor defect is covered with mesh that is secured with staples to the Cooper ligament, the iliopubic tract, and the transverse arch (Fig. 161-10). The peritoneum is then closed to diminish formation of adhesions between the mesh and bowel. By resurfacing the inguinal floor with prosthetic mesh, good preliminary results were achieved. Large reports with short-term follow-up have shown an acceptable recurrence rate and an earlier return to full physical activity with this technique. [130], [131] Several randomized prospective studies comparing early results of open and laparoscopic herniorrhaphy confirmed these proposed advantages. [132], [133], [134] and [135] The major disadvantage of this approach compared with an inguinal incision is that the laparoscopic repair is more costly and nearly always requires general anesthesia, adding to the risks of the procedure and limiting its indications.

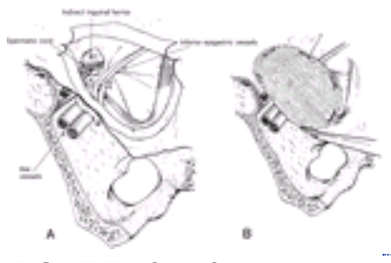

FIGURE 161-10. Laparoscopic inguinal herniorrhaphy. **A:** The peritoneum is incised to identify clearly the hernia and anatomy. **B:** Mesh is secured with staples to the Cooper ligament, iliopubic ligament, and transverse arch. (From ref. [1].)

More recently, many surgeons have begun performing a totally extraperitoneal laparoscopic hernia repair. [136] With the patient in the Trendelenburg position, the operation is begun with a 1.5-cm incision placed just below the umbilicus. An inflatable balloon is inserted into the properitoneal space and filled with saline to dissect the peritoneum from the posterior surface of the abdominal wall and create a working space in the groin. The working space is maintained by CO_2 insufflation, and two additional 5- and 10-mm ports are inserted. Mesh is laid between the fascial defect and peritoneum and may be fixed in place with staples. The advantage of the totally extraperitoneal approach is that the peritoneum is never violated. Therefore, the patient should avoid any complications of the transperitoneal herniorrhaphy related to adhesions and subsequent obstruction, intra-abdominal abscesses, or iatrogenic perforation injuries. The hernia repair also may be performed under regional anesthesia, thereby avoiding a general anesthetic.

Laparoscopic hernia repairs seem appropriate in certain settings. Many surgeons feel that laparoscopic herniorrhaphies are most beneficial for healthy patients with bilateral defects who would be incapacitated with bilateral groin incisions. Recurrent hernias previously repaired conventionally may be better repaired the second time laparoscopically from behind through “virgin” tissue rather than scar. Other patients who need to return to 100% physical activity with minimal delay are also suitable for a laparoscopic repair, which does not rely on suture strength to hold the repair together in the early postoperative period. Before laparoscopic herniorrhaphy gains full acceptance, the repair will need to become less costly, and long-term follow-up will need to prove its relative benefit.

Laparoscopic Management of Peptic Ulcer Disease

Ulcer surgery is rarely required in the current era because of the recent advances in medical therapy. The rare ulcer that is refractory to medical therapy and perforated ulcers have been treated laparoscopically with good results. Most commonly, perforations are closed primarily and then patched with omentum. [137] Laparoscopic truncal vagotomy with pyloric dilation or variations of proximal gastric vagotomy also boast nearly complete ulcer healing and few complications. [138] To date, most reports of laparoscopic ulcer surgery are anecdotal and have minimal follow-up data.

Laparoscopic Colectomy

Laparoscopic small and large bowel resections have been performed to treat benign and malignant disease. Using laparoscopic techniques, the colon is mobilized and the mesentery divided. The segment of colon may be exteriorized through a small incision, resected, and anastomosed before being dropped back into the abdominal cavity (coined *laparoscopy-assisted colectomies*). Alternatively, resection and anastomosis may be performed totally intracorporeally with transanal removal of the specimen. The extent of tissue margins and the number of lymph nodes included in the resection specimen suggest that laparoscopic techniques do not compromise an en bloc cancer operation, [139] although long-term follow-up will be necessary for confirmation. Patients usually are discharged from the hospital within 4 days, rather than the 5 to 7 days required after open operation. However, potential savings resulting from shorter hospitalization are offset by longer operative times and expensive laparoscopic equipment. [140], [141]

Laparoscopic resection of potentially curable colorectal malignancy is very controversial. A number of case reports of tumor metastases to trocar sites after laparoscopy-assisted surgery have raised concern that this approach may spread tumor mechanically. [142], [143], [144] and [145] In an animal model, pneumoperitoneum of 10 mm Hg for 10 minutes more than doubled tumor cell implantation at trocar sites. [146] Several multiinstitutional randomized trials comparing laparoscopic with open colectomy for resectable colon cancers are underway. For these reasons, laparoscopic colonic resection for cancer should be performed only on protocol.

Newer Procedures

Minimally invasive techniques may hold promise for many other procedures. We and others have had laboratory and clinical experience with adrenalectomy, nephrectomy, splenectomy, pancreatectomy, gastrectomy, and biliary bypass. Other surgeons have performed esophagectomy [147] and pancreaticoduodenectomy in humans. [148] However, just because an operation can be performed with a laparoscope does not mean that it should be. In our hands, laparoscopic performance of pancreaticoduodenectomy (the Whipple procedure) may have a higher complication rate and does not seem justified. [149] Randomized prospective outcome studies with longer periods of postoperative follow-up, as well as cost-benefit analyses, will be needed to settle the issues in an era of fiscal responsibility.

Emerging Technology

State-of-the art technology from the National Aeronautics and Space Administration and the defense industry is being redirected to solve many of the current limitations of laparoscopy. Several types of three-dimensional color video systems have been developed to restore the surgeon’s visual depth of field and possibly improve laparoscopic task performance for complex maneuvers such as suturing. [150] Flexible-tipped scopes and articulating instruments compensate for ports fixed to the abdominal wall. Biologic adhesives and new technology such as fibrin glue [151] and laser welding [152] are being investigated as alternatives to time-consuming suturing or costly stapling for anastomoses. The harmonic scalpel uses ultrasonic energy to coagulate vessels without desiccation and without obscuring vision with smoke. Dissecting balloons are creating small spaces in which to operate in the neck, axilla, and retroperitoneum. [136], [153] External retractors are used to lift the abdominal wall [14], [15] and avoid the potentially harmful local and systemic effects of a CO_2 pneumoperitoneum. Mechanical camera holders steady the camera and free the assistant to perform other tasks. Advances in simulation technology for pilot training are being applied to realistic laparoscopic surgical simulators to train surgeons, who may otherwise have limited laboratory and clinical experience with laparoscopy.

Laparoscopy has expanded the vision of general surgery, and the application of new technology is advancing rapidly. Robotic arms can precisely guide the laparoscope in response to the surgeon’s eye movements or voice commands. [12] Furthermore, slave robotic operating systems are being used, which can eliminate the surgeon’s tremor and allow ultraprecise surgical movements. [154] Interactive tactile feedback may be programmed into graphics to allow surgeons to “feel” what they are seeing on video. Three-dimensional images may be projected, not on a video monitor, but in the operating suite directly over the patient or superimposed on the patient to color-paint abnormalities for better identification during dissection. In time, applications of virtual reality may have surgeons wear Datasuits (Greenleaf Medical, Palo Alto, CA) and “fly” within the patient’s simulated abdomen to probe organs, just as architects today walk through simulated buildings testing structural properties. Teleproctoring may allow expert laparoscopic surgeons to guide novice surgeons safely along their learning curve as well as to establish a mode for credentialing and recertifying laparoscopic skills. Telepresence technology may even enable military surgeons safe behind-the-lines access to operate on patients on the battlefield. [155]

Compared with open operation, laparoscopy seems to offer most patients less postoperative pain, more rapid recovery, and better cosmesis. Patients are often discharged from the hospital earlier and return to active employment sooner. As the costs of technology decrease and the value of each health dollar is scrutinized, abdominal surgery will undoubtedly continue the evolution toward minimally invasive therapy.

LAPAROTOMY

The term laparotomy (Greek *lapara,* the flank; *otomy,* to cut into) is used loosely to indicate any operation in which the abdomen is cut open widely. An exploratory laparotomy is a surgical procedure performed through an abdominal incision for the diagnosis of intra-abdominal pathology. This exploration also forms a part of most

therapeutic abdominal operations, in which the primary objective is surgical correction of a previously defined problem. The number of exploratory laparotomies performed solely for the purpose of diagnosis is impossible to ascertain, but such procedures are relatively rare today. Medical advances, including improvements in diagnostic laparoscopy, flexible intralumenal endoscopy, imaging, and interventional treatment techniques, have reduced the necessity for laparotomy, but an appropriately directed abdominal exploration remains the most reliable method for diagnosing and treating obscure or acute catastrophic intra-abdominal illness. Particularly with the rapid acceptance of diagnostic laparoscopy by general surgeons, laparotomy has gained an increasingly worse reputation as being among the most costly, invasive, and morbid of diagnostic techniques available. In weighing the value of exploratory laparotomy as a diagnostic procedure, the accuracy and cost efficiency of diagnosis, corollary therapeutic benefit, and an accurate estimate of risk in the individual patient must all be assessed. Unfortunately, most of these end points are difficult to ascertain prospectively in the individual patient.

Surgical Stress Response

Laparotomy, with its surgical trauma, is always associated with an acute injury response. The degree of response is loosely associated with duration of anesthetic, degree of tissue injury, and metabolic derangements. Recovery after laparotomy occurs in stages similar to recovery from other types of traumatic injury. [156] Multiple abnormalities are seen in the perioperative interval in the hormonal milieu, [157] and cellular [158] and humoral [159] immunity are impaired. Furthermore, postoperative ileus is another reliable physiological consequence of laparotomy; although small bowel motility may be largely unaffected, the stomach and colon usually exhibit an ileus pattern of varying duration. [160] Recent research has suggested that virtually all of these aforementioned derangements occur to a lesser degree after laparoscopic procedures than after similar operations performed by laparotomy. [161], [162], [163], [164] and [165]

Laparotomy also increases myocardial oxygen demand while inducing physiological changes that potentially decrease oxygen supply to the heart. These alterations increase the risk for myocardial injury and arrhythmias for a period of up to 1 week postoperatively. [166] Laparotomy alone, particularly with incisions extending into the upper abdomen, remains an independent risk factor associated with a 15- to 25-fold increase in cardiac morbidity. [167] Upper abdominal incisions likewise cause major decreases in pulmonary function, particularly in functional residual capacity and lung compliance. [168] The diminution in abdominal wall trauma reduces the cardiopulmonary risks in patients undergoing laparoscopic procedures [169], [170] compared with the larger incisions used for operations performed by laparotomy.

PROCEDURE

Most exploratory laparotomies are performed using general endotracheal anesthesia with adequate muscle relaxation. The type of incision is dictated by patient factors such as prior incisions, intestinal stomas or wounds, and the indication for operation. Oblique or transverse incisions may work well for access to specific discrete lesions or organs (e.g., the right upper quadrant) while minimizing postoperative pain and pulmonary problems. [171] However, in the patient with unclear pathology or diffuse symptoms, as is the case with most patients undergoing true exploratory laparotomy, a midline incision has the greatest versatility for a complete abdominal exploration.

During exploratory laparotomy, all peritoneal and retroperitoneal organs are assessed in a systematic fashion. All available peritoneal surfaces are visually inspected with manual palpation of retroperitoneal structures. It is the use of the surgeon's hand with its trained haptic sensation that enhances the diagnostic capabilities of laparotomy above those of exploratory laparoscopy. The other primary advantage of laparotomy over laparoscopy is the ability to staunch the flow of major hemorrhage in a timely fashion. Laparoscopy is hindered by inadequate visualization when blood splashes on the lens or aggressive suctioning of blood evacuates the CO_2 pneumoperitoneum. It is also easier to control hemorrhage by direct pressure using one's hand placed through a laparotomy incision. Biopsy samples of abnormal tissues and aspirates of peritoneal fluid are sent for histology and, where necessary, cytology, bacterial culture, or chemical analysis. A systematic approach to exploration of the peritoneum is important to attain the full value of the procedure.

After the diagnostic phase, therapeutic maneuvers should be performed to achieve the goal set out preoperatively, as modified by the exploratory findings. In all patients, care must be taken to maintain normal temperature and hemostasis and to protect the tissues from drying or contamination. Upon completion of the procedure, the abdominal fascia must be closed in a secure fashion to prevent postoperative dehiscence or evisceration.

Indications for Laparotomy

Laparotomy is indicated for diagnostic purposes when a calculation has been made that the benefits of surgical intervention in a given patient outweigh the potential risk, complications, and costs of the procedure, when no other technique provides equal safety and accuracy of diagnosis, and when there is a reasonable likelihood that effective surgical treatment for the condition is possible. Exploratory laparotomy is the gold standard with which all other, less direct diagnostic techniques for abdominal pathology, including laparoscopy, must be compared. The range of specific diagnoses and procedures performed in or through the peritoneal space numbers in the hundreds. However, surgical pathology of the abdomen can be organized into several common categories (Table 161-5).

INDICATION	OBJECTIVES OF SURGICAL MANAGEMENT
Acute abdomen	Diagnosis and treatment
Visceral abdominal trauma	Diagnosis and treatment
Acute hemorrhage	Control intra-abdominal hemorrhage Define and control gastrointestinal source
Infection	Diagnosis Drainage or debridement
Inflammation	Diagnosis Ulcer disease: vagotomy and gastric drainage, repair perforation Cholecystitis/biliary colic: cholecystectomy Inflammatory bowel disease: resection or bypass Intestinal ischemia: revascularization, resection
Intestinal obstruction	Mechanical: repair Dysmotility syndrome: diagnosis, intestinal resection
Neoplasm	Diagnosis, staging Palliative bypass Resection

TABLE 161-5 Indications for Laparotomy

Medical and surgical advances, including laparoscopy and conventional imaging techniques, have reduced the necessity for laparotomy, and many of the indications for laparotomy listed in Table 161-5 may be performed using laparoscopic techniques. Several studies have emphasized the diagnostic value of laparotomy when there is a significant risk for missed or incorrect diagnoses of abdominal pathology, which can result in increased mortality. [172], [173] In contrast, blind abdominal exploration in the septic, gravely ill intensive care unit patient without specific evidence for an abdominal process has not been shown to influence survival. [174] Patients presenting with an "acute abdomen" (physical signs of peritonitis) are among those who benefit most from concomitant surgical treatment of their condition. Laparotomy is often the first and only diagnostic procedure for these patients other than physical examination. Although most patients who traditionally were thought to have indications for laparotomy may now be approached using laparoscopic techniques, in some cases initial laparotomy without consideration of laparoscopy is mandated. These situations would include patients with diffuse peritonitis of unclear etiology in whom there is a sense of urgency for diagnosis and treatment, those patients with an uncorrectable coagulopathy, those with hypotension and hemodynamic instability (in whom the pneumoperitoneum may cause vascular collapse), [175] and those with a "frozen" abdomen who have no true celomic cavity because of multiple prior operations with dense adhesions.

Conversion from Laparoscopy to Laparotomy

In many surgeons' practices, the aforementioned conditions are relatively rare, and most exploratory laparotomies occur as a result of conversion from an attempted laparoscopic procedure. The act of electively converting from a laparoscopic to an open operation should not be considered a complication but sound surgical judgment. Conversion generally occurs when the laparoscopic approach does not allow the surgeon to complete the objectives of the operation. These shortcomings would include the following: (1) inability to access the involved area, (2) inadequate laparoscopic visualization of the operative field, (3) inability to manipulate or intervene in a satisfactory manner, (4) lack of timely progression of the operation, (5) inability to treat a recognized complication by laparoscopic means.

Contraindications and Risks of Laparotomy

The contraindications to a laparotomy are, for the most part, relative rather than absolute. They primarily reflect the inherent risks of anesthesia, the surgical stress response, and the surgical wound. It is rare that the underlying health of a patient is so severely compromised or the risks of the procedure so prohibitive that he or she is absolutely ruled out as a candidate for laparotomy. If the indication for laparotomy is compelling and no good alternative treatment exists, the combination of preoperative resuscitation, modern anesthesia, expedient surgery, and postoperative intensive care can bring most patients through the stress of an operation. On the other hand, improvements in medical, endoscopic, laparoscopic, and interventional radiologic treatment now offer many alternatives that can achieve the same goals and may obviate the necessity for laparotomy, at least until the patient's status has improved.

Complications of Laparotomy

Numerous perioperative and postoperative complications may accompany laparotomy. These include cardiopulmonary complications, [176] complications of anesthesia and analgesia, [177] abnormal wound healing with wound infections or dehiscence, [178] venous thromboembolism, [179] and bowel obstruction. Abdominal surgery inevitably results in an injury to the peritoneal membrane. Exuberant healing of injured, ischemic peritoneum after surgery is the most common (80%) cause of abdominal adhesions in humans. [180] Adhesive small bowel obstruction occurs after 3% of all laparotomies, 20% of these within 1 month of operation, and a further 10% within the first year. Unfortunately, the risk for obstruction is lifelong. [181] Procedures centered inferior to the transverse mesocolon, such as colonic, small bowel, appendiceal, or pelvic procedures, have a higher risk for small bowel obstruction than upper abdominal operations. [182] There is a possibility of specific pharmacotherapy for adhesions in the future. [181], [183] Some early data suggest that laparoscopic procedures result in fewer adhesions than do their open counterparts. [97]

Results of Laparotomy

Conventional measures of efficacy for any procedure include morbidity, mortality, and long-term outcome from the disease process requiring laparotomy. More recently, other, less traditional measures of outcomes have assumed greater importance, including cost of therapy, length of stay, duration of disability, and quality of life. The very act of measuring cost and outcomes data has led to changes in the way physicians practice. These changes in physicians' habits have occurred simultaneous to the introduction of laparoscopy, rendering most retrospective comparisons between laparoscopic and open operations to be factitious. Surgery is a technical art, and the results of surgical therapy depend on skillful technique. Operator-dependent factors, such as excessive tension on tissues, inadequate hemostasis, technically poor anastomosis, excessive manipulation or inadequate margins in cancer surgery, and prolonged operative time, increase the risks for cancer recurrence, [184] complications, and death. [185] The skill and experience of the individual surgeon and the ancillary resources of the institution are crucial factors in patient outcome.

Conclusions

Exploratory laparotomy has been used for decades in patients with obscure or acute catastrophic intra-abdominal illness. Medical advancements, including improvements in flexible intralumenal endoscopy and radiologic imaging, have reduced the frequency with which direct or endoscopic imaging of the peritoneal cavity is necessary to establish a diagnosis. A number of studies suggest that when laparoscopy can be performed, it results in lower morbidity and probably less cost than laparotomy. Combined with the ability to perform diagnostic laparoscopy is the burgeoning field of therapeutic laparoscopic surgery, an area that remains in evolution today. A limited number of patients, however, because of acuity of illness or various confounding factors, are best served by a timely laparotomy performed in a skillful fashion. The choice between these techniques in the individual patient remains inherent to the art and craft of surgery.

EXPERIMENTAL THERAPIES: HEPATOCYTE TRANSPLANTATION, GENE THERAPY, AND LIVER ASSIST DEVICES

Hepatocyte transplantation, liver-directed gene therapy, and artificial liver-assist devices are being developed in a parallel but interdependent manner. For example, hepatocyte transplantation can be used as a vehicle for liver-directed gene therapy. On the other hand, gene transfer can be used to expand hepatocytes in culture for transplantation and abrogation of immune response. This chapter provides a short overview of advances and the remaining hurdles in these areas.

HEPATOCYTE TRANSPLANTATION

Orthotopic liver transplantation has significantly improved the prognosis for patients with acute or end-stage liver failure or potentially lethal inherited metabolic disorders. Because of the expense, complexity, and associated morbidity and mortality of this procedure, hepatocyte transplantation is being explored as an alternative. Hepatocyte transplantation is performed by percutaneous or transjugular injection into the portal vein, spleen, or peritoneal cavity and therefore is less invasive than liver transplantation. As the host liver remains intact, the loss of graft function should not worsen liver function. Although intact livers must be transplanted shortly after procurement, isolated liver cells may be cryopreserved for later use. [1] The success of hepatocyte transplantation in experimental animals has encouraged the clinical trial of this procedure at several institutions. Potential indications for hepatocyte transplantation include acute or chronic liver failure and inherited metabolic disorders. Hepatocytes could be used as a vehicle for ex vivo gene therapy of inherited metabolic disorders. Hepatocyte transplantation is also being considered for rescuing patients from radiation-induced liver damage after radiotherapy for liver tumors.

Liver-Based Metabolic Diseases

Hepatocyte transplantation has been shown to correct several liver-based metabolic disorders in animals. The Gunn rat, an animal model of Crigler-Najjar syndrome type 1, lacks bilirubin-UDP-glucuronosyltransferase (UGT1A1) activity and consequently exhibits toxic levels of hyperbilirubinemia. [2] Gunn rats and Nagase genetically analbuminemic (NAR) rats have been studied extensively in hepatocyte transplantation experiments. Transplantation of normal donor hepatocytes has ameliorated the metabolic abnormality in both animal models. [3] In the absence of cirrhosis, hepatocytes injected into the splenic pulp or infused into the portal vein engraft in the liver, where they integrate into the hepatic cords and function throughout life. [4], [5] Hepatocyte transplantation has resulted in partial correction of metabolic disorders in low-density lipoprotein receptor-deficient [6] Watanabe heritable hyperlipidemic rabbits (an animal model of familial hypercholesterolemia) and in the Long-Evans Cinnamon rat (an animal model for Wilson disease). [7]

Although many biologically active liver proteins are present in excess, the expectation that liver-based metabolic deficiencies could be corrected by the transplantation of a very small number of hepatocytes did not materialize. Repeated hepatocyte infusions can improve the response to transplantation, [8] but more dramatic results have been obtained by progressive repopulation of the host liver with engrafted hepatocytes.

Massive Repopulation of the Liver Studies in fumarylacetoacetate hydrolase (FAH) mutant mice (a model of hereditary tyrosinemia type I) showed that transplanted normal hepatocytes can spontaneously repopulate the liver of animals in which hepatocytes are dying because of a metabolic disorder. [9] A small number of hepatocytes from normal mice, engrafted into the liver of FAH mutant mice, almost completely replace the native liver cells. [9] However, the transplant recipients remain susceptible to the development of hepatocellular carcinomas, despite extensive repopulation of their livers with normal hepatocytes. Therefore, risk for cancer or recurrent disease should be an important consideration in the clinical application of hepatocyte transplantation for a given disease. For metabolic diseases, in which host hepatocytes do not die spontaneously, strategies are being developed to inhibit host hepatocyte regeneration while providing a proliferative stimulus to the transplanted cells by partial hepatectomy, induction of Fas-mediated apoptosis of host hepatocytes, or administration of pharmacological doses of thyroid hormone. [10], [11] The plant alkaloid retrorsine blocks the hepatocyte cell cycle and has been used for this purpose. [12] Because retrorsine is potentially carcinogenic, X-irradiation of the liver has been used as a part of the preparative regimen. [13], [14] Transplantation of normal hepatocytes from congeneic donor rats into Gunn rats that had undergone partial hepatectomy and hepatic irradiation resulted in complete normalization of serum bilirubin levels.

Inherited Metabolic Disorders Patients with ornithine transcarbamylase (OTC) deficiency, a $_1$-antitrypsin deficiency, and Crigler-Najjar syndrome type I have been transplanted with allogeneic hepatocytes. Although one child with OTC deficiency showed some evidence of enzyme activity on a liver biopsy, she ultimately died shortly thereafter from hyperammonemia. Unequivocal evidence of function of transplanted human hepatocytes was obtained in one patient with Crigler-Najjar syndrome type I (UGT1A1 deficiency). [15], [16] After transplantation, the serum bilirubin level decreased by 50%, hepatic bilirubin glucuronidating activity increased from essentially unmeasurable pretransplantation levels to about 5% of normal, and bilirubin glucuronides were excreted in bile. Allograft rejection was prevented with standard tacrolimus therapy. The procedure was not associated with any significant complications, but the extent of replacement of hepatic UGT1A1 activity was not sufficient to eliminate the need for phototherapy.

Acute Liver Failure

Conceptually, hepatocyte transplantation should be particularly suitable for treating acute liver failure because the liver remains architecturally normal and retains considerable restorative potential. Hepatocyte transplantation can rescue rodents with acute liver failure induced by hepatotoxins, liver ischemia, or 90% hepatectomy [17], [18] and prevent the development of intracranial hypertension in pigs with acute, ischemic liver failure. [19] However, the outcome of hepatocyte transplantation in patients with acute liver failure has been disappointing, except, when used as a bridge to liver transplantation.

In the first clinical study, seven patients with fulminant liver failure were injected with human fetal hepatocytes into the peritoneal cavity. Some of the recipients recovered from encephalopathy, [20] and survival of patients with grade III hepatic encephalopathy was superior to that observed in the untransplanted control group. Because long-term survival of hepatocytes following direct injection into the peritoneum has not been shown, investigators in the United States have used other sites. Because of ethical concerns, adult hepatocytes, rather than fetal cells, have been used. In one study, seven transplantation candidates received hepatocyte infusion through the splenic artery; five of these survived to undergo orthotopic liver transplantation. [21] In other studies, patients who were not candidates for organ transplantation were transplanted with hepatocytes by infusion into the portal vein for engraftment in the liver. [22], [23] Engrafted hepatocytes were found in the spleen and liver of some of the transplant recipients, and there are anecdotal reports of improvement in ammonia, prothrombin time, encephalopathy, cerebral perfusion pressure, and cardiovascular stability. Complications have been few but include transient hemodynamic instability during intraportal hepatocyte infusion, sepsis, and

embolization of hepatocytes into the pulmonary circulation. [24] Portal hypertension as a result of transplantation through the portal vein has been generally transient. Although the results suggested that the transplanted hepatocytes provided some benefit, convincing evidence for engraftment and function of the transplanted cells has not been obtained. Part of the problem could be that relatively small numbers of hepatocytes were ransplanted in many of the patients.

In contrast to the situation in animal models of acute liver failure, liver regeneration is significantly inhibited in patients with acute liver failure. [25] Because injection of bone marrow cells and hepatocyte lysates have also been shown to affect animal survival, hepatocyte transplantation in the animal models might have helped by enhancing the regeneration of the host liver rather than through functional engrafted cells. Based on studies on a recently developed mouse model of acute liver failure that more closely parallels the clinical situation, [26] it is likely that multiple hepatocyte infusions over time may be required for improved patient survival.

Chronic Liver Failure

Studies in Experimental Animals Because of the difficulty in generating animal models of stable and irreversible liver cirrhosis causing hepatic failure, most studies on evaluating hepatocyte transplantation in treating chronic liver failure have been performed in other animal models of hepatic encephalopathy. Intrasplenic transplantation of hepatocytes in rats with end-to-side portacaval shunt resulted in improvement of behavioral score, partial correction of the amino acid imbalance, [27] and prevention of hepatic coma induced by ammonium chloride administration. [28] The engrafted hepatocytes proliferated in the spleen, organizing into structures resembling hepatic chords. More recently, hepatocyte transplantation has been shown to improve many of the physiological abnormalities associated with decompensated liver failure in rats with end-stage liver cirrhosis, induced by chronic administration of phenobarbital and carbon tetrachloride. Hepatocyte transplantation also prolonged the survival of these animals. [29] Transplantation of hepatocytes into cirrhotic liver results in a severe and prolonged increase in portal pressure. [30] Although some transplanted hepatocytes migrate into cirrhotic nodules after intraportal infusion, it is unlikely that enough cells can engraft in the cirrhotic liver to affect liver function significantly. Moreover, it is unclear whether the transplanted cells could function within the cirrhotic nodules. For these reasons, in the studies on cirrhotic rats, hepatocytes were engrafted in the spleen.
Clinical Experience The initial clinical trial was performed on 10 Japanese patients with liver cirrhosis to test the hypothesis that the functional failure of hepatocytes within the cirrhotic liver is due to the deranged architecture of the organ. Ten million to six hundred million hepatocytes harvested from their own left lateral liver segments were injected directly into the spleen, or infused into the splenic artery or the portal vein. In one patient, ascites and encephalopathy eventually resolved, and engrafted hepatocytes in the spleen were detected by ^{99m}TC (technetium-9mm)- radioisotope uptake 11 months after transplantation. [31] Subsequently, in the United States, infusion of up to 10 [10] allogeneic donor hepatocytes into the splenic artery in patients with decompensated chronic liver disease was shown to be well tolerated and associated with improvement in encephalopathy, hepatic protein synthesis, and renal function. [24] Nuclear scanning demonstrated the presence of engrafted hepatocytes in the spleen. If extrahepatic hepatocyte transplantation proves to be effective in improving liver function, it could be performed in combination with transjugular intrahepatic portosystemic shunt (TIPS) to relieve portal hypertension. However, the risk for hepatocellular carcinoma would persist, and routine surveillance would still be needed. Unfortunately, the improvement of liver function after hepatocyte transplantation in chronic liver failure patients has been relatively poor, compared with that observed in animal models. The discrepancy may have resulted from the fact that hepatocytes were transplanted by injection into the splenic pulp in rats, whereas they were infused in the splenic artery of the patients. [24] In fact, hepatocytes infused in the arterial bed of rats are lost rapidly. [32] Similarly, in patients, only a few hepatocytes were found in the spleen after infusion into the splenic artery.

Ongoing Issues

Technically, the number of hepatocytes that can be transplanted at any one time is limited. Using present techniques, less than 30% of transplanted cells engraft in the liver. A better understanding of the factors that allow hepatocyte engraftment might reduce the need for repeated cell infusions and multiple donors. The most important issue limiting the application of hepatocyte transplantation is the availability of donor livers, which is reduced by competition for use in whole-organ transplantation. The ability to cryopreserve and bank hepatocytes might allow pooling of cells from multiple donors, increasing cell availability for transplantation. Unfortunately, cryopreserved liver cells have not yet been shown to engraft as well as fresh hepatocytes, [33] and viability of human hepatocyte cryopreserved by current methods is variable.

Despite some progress in growing primary hepatocytes in culture, [34] currently, only the hepatocytes that have been immortalized by gene transfer are capable of long-term growth and correcting metabolic abnormalities in liver failure after transplantation. [28], [35] An alternative solution for the scarcity of human donor cells is the transplantation of xenogeneic hepatocytes. [36] However, xenogeneic hepatocytes are susceptible to immunologic processes that are not active after allotransplantation. [36], [37] Xenograft survival in humans has been of such short duration that whether organs or tissues from another species will function adequately to replace human organ function remains uncertain. [38] It is also a concern that xenogeneic liver cells could transfer infectious agents to the recipient and, potentially, beyond. [39] It is possible, however, that transplanted nonhuman hepatocytes could be resistant to recurrence of infection by human-specific viruses.

Finally, it is difficult to detect early rejection of the transplanted hepatocytes, and new noninvasive approaches to the detection of donor hepatocytes are needed.

LIVER-DIRECTED GENE THERAPY

Goals

Targets of liver-directed gene therapy include both inherited metabolic disorders and acquired conditions, such as infectious and neoplastic diseases, cirrhosis of the liver, and immune rejection of transplants. Liver-directed gene therapy could be used for diverse purposes. Gene products that are missing in inherited disorders could be replaced by transferring transcription units expressing those proteins. In other cases, certain genes could be overexpressed for specific therapeutic benefits, such as treatment of cirrhosis by expression of metalloproteases. The large size of liver and its capability to secrete proteins to the plasma could be exploited to generate extrahepatic proteins, such as coagulation factors or hormones. Proteins that are normally expressed at extrahepatic sites could be expressed in the liver for specific purposes. For example, the catalytic subunit of the apolipoprotein B messenger RNA editing enzyme (APOBEC-1), which is expressed in the intestinal epithelial cells, could be expressed ectopically in the liver to switch the hepatic apolipoprotein production from apo B100 to apo B48, thereby reducing the generation of low-density lipoproteins. [40] Similarly, PDX, a homeobox protein that is responsible for pancreatic differentiation, could be expressed in the liver, to switch the hepatocyte phenotype to an insulin-generating phenotype. [41] Gene transfer to the liver could be used to generate pharmacological gene products, such as vaccines, single-chain antibodies, dominant negative proteins, immunomodulatory substances, and proapoptotic or antiapoptotic proteins. On the other hand, nucleic acids may be used to inhibit the expression of deleterious proteins, such as viral proteins or mutant a $_1$-antitrypsin. This could be accomplished by transferring synthetic antisense RNAs or ribozymes. Genes could be transferred to express antisense RNAs, [42] ribozymes, or dominant negative proteins. [43] Finally, technologies are being developed to correct mutations within the endogenous genes in intact organisms. This could be accomplished by targeted replacement of the defective gene [44] or by site-directed correction of a target genomic sequence. [45] These newer strategies permit the repaired gene to remain under the control of the endogenous promoter, whereby physiological regulation is retained. A partial list of inherited and acquired disorders targeted for liver-directed gene therapy is provided in Table 162-1.

I. Inherited Liver Disorders
Crigler-Najjar syndrome type I
Familial hypercholesterolemia and other lipid metabolic disorders
Maple syrup urine disease
Progressive familial intrahepatic cholestasis
Phenylketonuria
Tyrosinemia
Mucopolysaccharidosis VII
α_1-Antitrypsin deficiency
Ornithine transcarbamylase deficiency
Wilson disease
Glycogen storage diseases, e.g., von Gierke disease and Pompe disease
II. Inherited Systemic Disorders
Hemophilia A and B
Oxalosis
III. Acquired Disorders
Infectious diseases, e.g., hepatitis B and C
Malignant neoplasms: hepatomas, cholangiocarcinomas, metastatic tumors
Extrahepatic tumors (inhibition of neovascularization)
Cirrhosis of the liver
Allograft or xenograft rejection

TABLE 162-1 Some Hepatic Disorders that are Currently Targeted for Gene Therapy

Cancer Like other therapeutic approaches, the target is to eliminate the tumor cells while minimizing the damage to normal cells. Gene transfer could be used to kill the tumor cells or inhibit their growth, reduce the vascular supply to tumors, generate immune response against tumor cells, or augment the effect of chemotherapy and radiotherapy. Enhancement of apoptosis of the tumor cells could be promoted by expressing *p53,* a sentinel gene of the cell cycle. [46] Tumor killing is attempted by transferring "suicide genes," such as the herpes simplex virus thymidine kinase (*HSV-TK*), which converts a prodrug, ganciclovir, to its active phosphate derivative, [47] or cytosine deaminase and purine nucleoside phosphorylase (which converts fludarabine to a diffusible toxic metabolite). [48] The activated toxin, such as ganciclovir phosphate, may diffuse to neighboring cells, killing them by "by-stander effect." Toxicity to normal cells could be reduced by tumor-specific delivery by tagging the DNA to a monoclonal antibody, such as that directed against AF-20, a 180-kd tumor-specific cell-surface glycoprotein, expressed in hepatoma cell lines, [49] and by using tumor-specific promoters (e.g., alpha-fetoprotein or carcinoembryonic antigen) to drive the expression of transgene. In an alternative approach, E1B-mutant adenoviruses that are capable of replicating in tumor cells deficient in functional *p53* have been used in an attempt to kill tumor cells, [50] although the replication of these mutant adenoviruses may not necessarily depend on the absence of *p53*. Direct killing of the tumor cells by topical expression of toxic gene products does not eliminate those at metastatic sites. Because tumor requires neovascularization, inhibition of new blood vessel formation by the expression of angiostatin or endostatin may retard the growth of both primary and metastatic tumors. [51], [52] Permanent elimination of the tumor cells may require host immune response against tumor-specific "neoantigens" that are not expressed by normal cells. Specific tumor antigens, such as those from melanoma cells, may permit DNA-based tumor vaccination. Host immune response against the neoantigens may be feeble because of inadequate presentation of the antigens by antigen-presenting cells (APCs). Genetic manipulation of APCs may augment the host immune response against tumor cells. Secretion of cytokines, such as transforming growth factor-ß or interleukin-10, by large tumors may suppress immune response. [53] "Debulking" the tumor by surgery, radiotherapy, chemotherapy, or gene therapy may enhance the immune response. Currently, gene therapy for cancer has the greatest potential as an adjunct to chemotherapy or radiotherapy. Irradiation enhances the number of tumor cells transducible by recombinant viruses. Transgene expression could be driven by promoters that are stimulated by irradiation. [54] On the other hand, inhibition of the expression in the tumor cells of radioprotective proteins, such as ATM (mutated in ataxia telangiectasia), could increase their radiosensitivity.

Infectious Diseases Nucleic acid–based approaches are being explored both for prophylaxis and treatment of hepatic viral infections. DNA vaccination [55] eliminates the possibility of contamination of the vaccines by microbes or other organic material. The injected DNA itself serves as an adjuvant, enhancing the immune response. For viral antigens that are presented poorly, the antigenic peptides may be expressed directly in APCs by gene transfer. Gene transfer may also be used to express cytokines that promote the APC proliferation and maturation of T cells to helper T cells. In a different approach, termed *intracellular vaccination,* single-chain antibodies or antibody fragments may be expressed within the cells to make them resistant to viral infections. [56] Gene therapy can also be used to interfere with the viral life cycle by introducing synthetic antisense RNAs, ribozymes, or DNA ribonucleases (see later). Ribozymes, antisense RNA, or dominant negative proteins [57] can also be expressed within the target cells by gene transfer.

Inherited Disorders Because many inherited disorders are caused by the abnormality of a single gene, the effect of gene therapy can be evaluated directly and precisely in these conditions. For this reason, although the inherited disorders are much less common than acquired diseases, single gene abnormalities continue to be important targets of liver-directed gene therapy. Table 162-1 contains a partial list of inherited disorders that are currently targets of gene therapy.

Methods of Gene Transfer to the Liver

Genes may be delivered to the liver through isolated hepatocytes, termed ex vivo gene therapy, or by delivery of the gene into the intact liver. Hepatocyte transplantation-based methods were discussed previously. In this section, we consider available methods of delivering genes to the intact organism, using replication-deficient recombinant viruses, or nonviral vectors. For gene transfer to hepatocytes, important considerations include the attainable infectious titer, ability of the virus to infect nondividing cells, integration into the host genome, repeatability of administration, and safety of the vector system. Frequently used methods of gene transfer to the liver are listed in Table 162-2. Some commonly used recombinant viral vectors are described below.

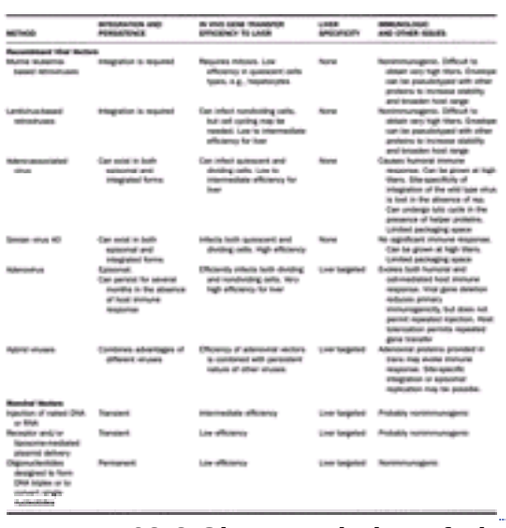

TABLE 162-2 Characteristics of Liver-directed Gene Therapy Methods

Vectors Based on Recombinant Viruses

Retrovirus-based vectors. Complementary DNA generated from the RNA genome of retroviruses are integrated into the host genome and are transmitted to the progeny of the transduced cells. [58] Murine leukemia viruses, particularly Moloney murine leukemia virus (MoMuLV), are used commonly for generating recombinant vectors (Fig. 162-1). The viral genes are replaced by target transgenes, but the packaging signal (*?*) is retained. [59] The viral proteins are provided in *trans* by "packaging cell lines," generating a replication-deficient recombinant virus (Fig. 162-2). The range of species that recombinant retroviruses can infect is determined by the envelope protein. The host range can be expanded by engineering the viral envelope to contain proteins, such as the G protein of the vesicular stomatitis virus (VSV). Inside the cell, the RNA genome is reverse-transcribed into double-stranded DNA, which is transported to the nucleus and is integrated into the host genome. This process requires mitosis of the host cell, which is infrequent in hepatocytes of the adult liver. To overcome this obstacle, retroviruses of the lentivirus group, which form preintegration complexes that can be translocated into nondividing nuclei, are being explored for liver-directed gene therapy. However, lentivirus-based gene transfer *in vivo* may also require the hepatocytes to be in cell cycle. [60]

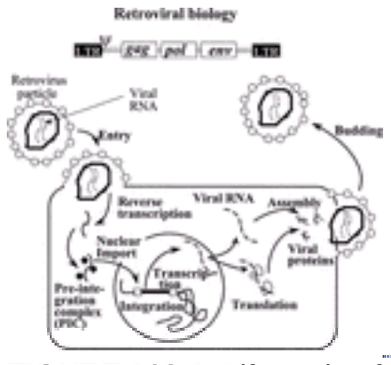

FIGURE 162-1. Life cycle of wild-type Moloney murine leukemia virus. The RNA genome of the virus consists of the retroviral genes, *gag, pol,* and *env,* flanked on the 5' and 3' ends by the long terminal repeats (LTRs), consisting of a promoter, enhancers, and polyadenylation signals. Sequences upstream to the 5' LTR contain the packaging signal (*?*) that is needed for packaging of the viral RNA genome into viral particles. After entry into the infected cell, the RNA genome undergoes reverse transcription, and the DNA transcript is incorporated into a preintegration complex (PIC), which is imported into the nucleus. Dissolution of the nuclear envelope, which occurs during mitosis, may be needed for this step. The proviral DNA is then integrated into the host genome. The entire unspliced transcript provides the new viral genome, which is packaged with the viral proteins expressed from the integrated proviral DNA. The assembled virus buds out and is ready to infect another cell.

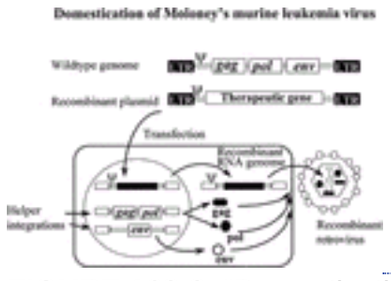

FIGURE 162-2. "Domestication" of the Moloney murine leukemia virus. The packaging cell is stably transfected with multiple DNA segments expressing different viral proteins (gag, pol, and env). A DNA version of the viral genome is cloned into a plasmid. All viral genes are replaced by target transgene, but the packaging signal (') is left intact. The recombinant plasmid is transfected into the packaging cell, which provides the viral proteins in *trans*. The viral RNA genome can be assembled with the viral proteins because of the presence of the packaging signal, '. The assembled recombinant virus buds out of the packaging cell into the culture medium. The recombinant virus can infect other cells but is replication incompetent owing to the lack of the viral genes.

Recombinant adenovirus. Adenoviruses are large linear double-stranded DNA viruses. Adenovirus types 5 and 2 are commonly used for preparing gene transfer vectors. Recombinant adenoviruses can be generated at high titers, can infect both dividing and quiescent cells, and upon intravenous administration in rodents, can localize preferentially to the liver. [61] The adenoviral receptor, CAR, is highly concentrated in rodent liver, but less so in the human liver. Thus, it is unclear whether the high gene transfer efficiency observed in the rodent liver will be replicated in human liver. Adenovirus vectors are generated by inserting the transgene into the early region-1 (*E1*) gene, which encodes transcription factors required for the expression of adenoviral genes. The recombinant virus is generated in packaging cells that provide the *E1* gene products in *trans*. All adenoviral genes may be deleted to increase the "stuffing space" and to prevent any possibility of expression of viral proteins. [62] These "gene-deleted" vectors require replication competent helper adenoviruses to provide the structural proteins. The helper virus is removed during purification. Strong immunogenicity of the viral antigens limits the clinical application of adenovectors. Neutralizing antibodies generated after the first injection block gene transfer following subsequent administrations of the vector. Cytotoxic lymphocytes against adenoviral antigens attack the adenovirally infected host cells, causing liver damage and rapid loss of the transgene after secondary gene transfer. [63] The helper-dependent, gene-deleted ("gutless") adenovectors, in which all viral genes are deleted, retain their immunogenicity, [64] thereby frustrating the attempts at repeated gene transfer. Immunosuppressive genes have been incorporated into adenovectors to inhibit host immune response to adenoviral proteins. [65] Development of effective immune response requires costimulatory interaction between antigen-presenting cells and cytotoxic lymphocytes by the B7-CD28 and CD40-CD40 ligand interactions. Injection of CTLA4-Ig, a soluble inhibitor of B7-CD28 costimulation, prolongs the expression of transgenes introduced by adenoviral vectors but, used alone, does not permit repeated administration of adenovectors. [66] However, coexpression of CTLA4-Ig and the target transgene permits multiple administration of the recombinant adenovirus. [67] Alternatively, host tolerance toward adenoviral proteins can be induced by injecting recombinant adenoviruses in utero into newborn rats, [61] inoculating adenoviral proteins into the thymus of young adult rats, [68] or orally administering small doses of adenoviral proteins. [69] However, safety concerns persist regarding tolerization of humans to adenoviral antigens because wild-type adenoviruses are pathogenic to humans.

Herpes simplex virus type 1. Herpes simplex virus type 1 (HSV-1) is a 150-kb double-stranded DNA virus with a broad host range [70] and ability to infect nondividing cells. However, long-term gene expression in the liver has not been achieved with the available HSV vectors.

Recombinant baculovirus. The *Autographa californica* nuclear polyhedrosis virus (AcNPV) is usually employed for generating recombinant proteins in insect cells. [71] Interestingly, among mammalian cells, hepatocytes can be infected by baculovirus vectors, and the transgene expression can be driven by mammalian promoters. Hybrid viruses, consisting partly of baculoviral sequences, are being evaluated for in vivo application.

Recombinant adeno-associated virus. Adeno-associated virus type 2 (AAV-2) is a small (4.7-kb) single-stranded DNA virus of the parvovirus family. The wild-type virus integrates preferentially on the q13.4-ter arm of human chromosome 19. [72] The AAV remains latent in the cell genome for long periods but can cause lytic infection following infection with a "helper virus," such as adenovirus or herpes simplex virus, or by genotoxic stimuli, such as ultraviolet light or irradiation. [73] Binding of AAV-2 to a heparin sulfate proteoglycan at the cell surface is required for its internalization. The AAV genome is flanked by 145-bp inverted terminal repeats (ITRs) that are needed for integration into the host genome. After introduction into cells, AAV vectors may persist as episomes or integrate into the host genome over several weeks. The viral Rep protein directs the site specificity of AAV integration into chromosome 19. Recombinant vectors lacking this gene lose site specificity of integration and in fact may remain in the nucleus as episomes [74] (Fig. 162-3).

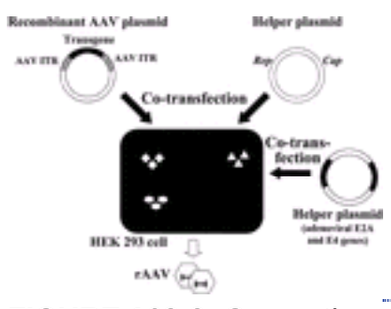

FIGURE 162-3. Generation of recombinant adeno-associated viruses (AAVs). To generate AAV vectors, two plasmids, one containing the transgene, flanked by the inverted terminal repeats (ITRs) and the other encoding rep, cap, and adenoviral proteins are cotransfected into 293 cells, which provide adenoviral E1A in *trans*. The recombinant virus is "rescued" by infection with a helper adenovirus (E1A-deleted) or, more commonly, by transfecting a plasmid that expresses adenoviral proteins.

Initial studies of intramuscular administration of AAV-based vectors for delivering coagulation factor IX in patients with hemophilia B resulted in low levels of protein production, [75] but infusion of high doses of the recombinant virus into the portal vein of factor IX–deficient dogs resulted in the appearance of 5% of normal levels of factor IX activity in plasma. [76] Efficiency of AAV-mediated cancer gene therapy could be augmented when used in combination with conventional tumor therapies, such as irradiation or chemotherapy. [77] Recombinant AAV causes a humoral immune response, which may be a problem if the vector needs to be readministered.

Simian virus 40–based vectors. Simian virus 40 (SV40) is a nonenveloped virus of the papova family with a 5.2-kb double-stranded DNA genome. The large (Tag) and small (tag) T antigens are transcription factors required for the expression of the viral structural genes, *VP1, VP2,* and *VP3.* The recombinant vector is generated by replacing the *Tag* genes of the viral genome by the target transgene. Various lengths of the structural genes can also be deleted to make additional stuffing space. The recombinant viral genome is transfected into a helper cell line (e.g., COS cells that provide Tag in *trans*). Absence of the *Tag* gene makes the recombinant virus replication deficient and markedly reduces its immunogenicity. Up to 4.7 kb of exogenous DNA can be inserted into SV40 vectors, which can be generated at 10^{9} infectious units (IU)/mL and concentrated to 10^{12} IU/mL. [78], [79] Recombinant SV40 integrates into the genome of both dividing and nondividing cells. The range of target cells is broad and includes hepatocytes and bone marrow cells. [78], [79]

Nonviral Vectors

Liposomes, lipoplexes, and polyplexes. Nonviral vectors comprise (1) lipid-based delivery systems, such as lipid microcapsules (liposomes) or lipid-nucleic acid complexes (lipoplex); (2) polycations, such as poly-L-lysine (PLL), polyethylenimine (PEI), polyglucosamines, lipopolyamines, and cationic peptides; and (3) polycation-lipid hybrids (lipopolyplex). DNAs are usually compacted with polycations before lipid encapsulation into liposomes or forming complexes with lipids. Lipopolyplex particles are smaller than are the liposomes or lipoplexes and provide greater protection of the nucleic acids from degradation by nucleases. Cationic lipid transfecting agents (e.g., lipofectamine, DOTAP), and cationic polymers, (e.g., PLL and PEI), provide relatively effective transfection [80] but are inefficient in the presence of plasma and too toxic for use in vivo. For targeting the gene delivery to hepatocytes, the gene transfer vehicles have been modified to include ligands that are endocytosed by hepatocyte-specific receptors, such as the asialoglycoprotein receptor (ASGPr). Galactose-terminated peptides (e.g., asialoorosomucoid) or galactose can be conjugated to polylysine or PEI for hepatocyte-specific gene delivery. [81] Similarly, liposomes composed of galactocerebrosides serve as ligands for the ASGPr through the galactose residues. [82] Incorporation of nuclear localization signal peptide motifs on plasmid constructs enhances their translocation to the nucleus. [83] Nucleic acid transfection generally results in transient effect in vivo, which may be sufficient when using synthetic antisense RNAs or ribosymes. Long-term effect is possible if the DNA integration can be enhanced by some mechanism, such as using the transposon-transposase system, or if the transfected nucleic acid triggers a permanent change, such as site-directed gene repair. Some specific applications of nonviral gene transfer methods are discussed below.

Ribozymes, antisense RNA, and DNA ribonucleases. Ribozymes are RNA enzymes that hybridize to complementary RNA sequences and catalyze endoribonucleolytic cleavage, causing rapid degradation of the RNA molecule. [84] For hairpin ribozymes, the presence of a guanosine residue immediately downstream to the cleavage site is essential, but the effect is enhanced by a GUC sequence. Hammerhead ribozymes require only a UA, UC, or UU dinucleotide for cleavage. Ribozymes can be synthesized and packaged for cellular uptake or expressed in cells from transfected DNA. Hammerhead [84] and hairpin [85] ribozymes have been shown to inhibit the production of hepatitis B and hepatitis C viruses in cells. Antisense oligonucleotides targeted to 5'-untranslated region of hepatitis C virus were transferred to a differentiated human hepatoma cell line HuH7 using ASGPr-polylysine complexes, resulting in specific inhibition of the hepatitis C–directed protein synthesis in the cells. [86] Multiple sites within the hepatitis C RNA genome may be targeted simultaneously using a series of ribozymes expressed from a single vector, thereby inhibiting the development of drug-resistant mutants. [87] Hepatitis B virus, a partially double-stranded DNA virus, replicates through a pregenomic RNA intermediate, which could also be a target for ribozyme-based RNA cleavage. [85] DNA ribonucleases are synthetic single-stranded DNAs comprising a 15-nucleotide catalytic domain, flanked by two RNA-binding domains, that catalyze RNA cleavage with a greater efficiency than ribozymes. [88] DNA ribonucleases against the hepatitis C viral genome can specifically cleave the viral RNA. DNA ribonucleases designed to cleave hepatitis B RNA transcript substantially inhibit viral gene expression. [89]

Homologous recombination. Site-specific recombination of DNA could be a precise means of repairing mutated or damaged DNA. Several proteins, including homologs of yeast recombination proteins rad51 or rad52, are important in homologous recombination in higher eukaryotes. [90] Although used extensively in cultured cells, the process is inefficient and has been rarely successful in vivo. [91] As homologous recombination is cell cycle–regulated, it occurs extremely infrequently in quiescent cells, such as hepatocytes. [92]

Triplex DNA. This method is based on the formation of a triple DNA by the binding of an exogenous single-stranded nucleic acid to the major grove of a homopurine region of the double-stranded genomic DNA. [93] The polypurine regions must be guanine rich and 12 to 14 nucleotides in length for adequate triplex formation to occur. Conventionally, cross-linking agents, such as psoralen or other mutagens, are covalently attached to the triplex forming oligonucleotide. [93] After intercalation of the psoralen at the target 5'ApT3' site, ultraviolet irradiation causes cross-linking of the thymines in the two strands. This substrate is then repaired by endogenous cellular DNA repair mechanisms, producing the characteristic T:A to A:T transversions. Single-strand DNAs with cross-linking agents can also be used to promote insertions and deletions at target through the excision repair pathway. [94] The target sequence constraints currently limit the application of this method in vivo. Bifunctional oligonucleotides comprising regions that form triple-helical structures as well as conventional Watson and Crick base pairs have partly overcome this hurdle in cultured cells. [95]

Single nucleotide modification. A method that uses the cells' mismatch repair machinery to correct single base mutations has been introduced recently. A synthetic oligonucleotide is generated that is complementary to the targeted genomic DNA, except at a single mismatched base. Most of the successful studies have used a DNA/RNA chimera. The RNA component, consisting of 2'-O-methyl ribonucleic acid residues, is included to increase the strength of hybridization with the targeted DNA sequence. The mismatch between the oligonucleotide and the genomic DNA triggers the mismatch repair system of the cell, so that the genomic mutation is permanently corrected. In *Escherichia coli* strains deficient in specific repair proteins, [96] this approach was shown to require RecA and MutS, proteins involved in DNA pairing and mismatch repair, respectively, suggesting the involvement of both the homologous recombination and mismatch repair pathways. Both recombination and mismatch repair pathways are evolutionarily conserved. Extracts of human hepatoma cells (HuH-7) containing the mismatch repair protein hMSH2 can complement MutS-deficient *E. coli* in converting the mutant aminoglycoside resistance gene. Wild-type *p53* may inhibit the initial pairing step in this repair process by inhibiting the pairing activity of RecA and its human homolog Rad51. [97] In intact rats, RNA-DNA chimeric oligonucleotides were delivered to the liver by receptor-mediated endocytosis, using lactosylated PEI or galactocerebroside-containing liposomes. In initial studies, a Ser365Arg conversion of the rat factor IX gene was achieved with significant frequency. [98] Subsequently, the guanosine base deletion in the bilirubin-UDP-glucuronosyltransferase (*UGT1A1*) gene in jaundiced Gunn rats was repaired at a frequency that was sufficient to express detectable enzyme activity in the liver and reduce serum bilirubin levels significantly. [99] Nucleotide insertion was verified by differential hybridization, Southern blot, and Western blot analysis. Tagalakis and associates [100] have demonstrated a high level of conversion of the gene-expressing human apolipoprotein E2 in a transgenic mouse to apolipoprotein E3 after intraperitoneal injection of a RNA-DNA chimeric oligonucleotide. In addition to hepatocytes, the RNA-DNA chimera has been used successfully for site-directed gene conversion of the apolipoprotein *A2* gene in human lymphocytes, [100] carbonic anhydrase II in nude mouse primary kidney tubular cells, [101] the missense mutation in the tyrosinase gene in albino mouse melanocytes, [102] and the dystrophin gene of myocytes. [103]

Transposon-based gene delivery. Transposable genetic elements (transposons) are ubiquitous in eukaryotic genomes and are capable of moving from one chromosomal location to another by a "cut-and-paste" mechanism. Radice and associates [104] characterized five transposable elements from fish, which were similar in structure to the Tc1 transposon of the nematode *Caenorhabditis elegans*. These transposons of the Tc1/*mariner* superfamily consist of short inverted repeats that flank an open reading frame, encoding a transposase. Ivics and associates [105] generated a synthetic transposable element from defective copies of an ancestral Tc1-like fish transposon. This transposon was termed "Sleeping Beauty" because it had remained dormant for millions of years during evolution and became functional only after correcting mutations that had accumulated over many generations. It is a 1.6-kb element, flanked by 250-bp terminal inverted repeats. DNA sequences, flanked by the terminal inverted repeats, can efficiently integrate into mammalian cellular genome, provided the transposase is expressed in the same cell. The integration occurs at TA dinucleotide sites, which are duplicated upon insertion of the transposable element. [105] The coding region of human factor IX has been inserted into the genome of hepatocytes of factor IX–deficient hemophilic mice by cotransfection of one plasmid containing the factor IX transcription unit flanked by the inverted repeats and another plasmid expressing the Sleeping Beauty transposase. [106]

EXTRACORPOREAL LIVER ASSIST DEVICES

The fact that some patients with acute liver failure recover spontaneously led to the idea that patient survival could be improved by providing metabolic support until the liver had time to regenerate. During the 1960s and early 1970s, ex vivo and in situ cross-circulation with animal and human livers was shown to improve clinical and biochemical parameters in animal models of liver failure and in uncontrolled human trials. [107] However, without the option of transplantation, there was no evidence of increased survival. In the 1980s, the life-saving effects of liver transplantation in fulminant hepatic failure was shown, resulting in expanding demand for a finite number of donor organs, increasing the difficulty of obtaining suitable organs in a timely manner. Thus, the concept of temporary liver support as a bridge to successful liver transplantation emerged. Because coagulopathy, renal failure, encephalopathy, and cerebral edema negatively affect the prognosis after liver transplantation, survival could improve if these complications could be held at bay while waiting for a suitable organ. Liver-assist devices have been considered also for use in acute exacerbation of chronic liver failure to alleviate encephalopathy following gastrointestinal bleeding or to prevent hepatorenal syndrome. Because many of these patients are not transplantation candidates, the potential for liver-assist devices in improving survival is limited.

Although many liver support systems are in the development stage, only a few have been tested in animal models. Although the survival benefit of these devices in patients with acute liver failure is yet to be shown in controlled, randomized trials, much progress has been made in the bioengineering of artificial liver support systems. Hepatic support systems comprise three basic groups, namely (1) cell-free liver assist devices; (2) entirely biologic systems, such as extracorporeal liver perfusion; and (3) hybrid bioartificial devices that include both nonbiologic and biologic components. A brief discussion of these devices follows.

Cell-free Liver Assist Devices

To substitute for the detoxification and excretion functions, hemodialysis, [108] exchange transfusion, [109] and hemoperfusion [110] through charcoal or resins have been attempted during the past 40 years, without consistent beneficial outcomes. Currently, two such systems are available for clinical use. In the BioLogic-DT plasma filter system, patient plasma comes in contact with a powdered charcoal suspension. [111] Many putative toxins that are thought to contribute to the complications of hepatic failure bind to these columns in vitro. Clinical trials have suggested improvement in patients with decompensated chronic liver disease, but studies in acute hepatic

failure did not show any benefit over standard clinical management.

The second system, named the *molecular absorbent recirculating system* (MARS), is a cell-free system for selective removal of albumin-bound substances (Fig. 162-4). As standard dialysis is included in the circuitry, some water-soluble substances are also removed. [112] An albumin-enriched dialysate is passed through an anion exchange resin column and a charcoal column and recirculated through the dialysis unit. This system effectively reduces plasma bilirubin and bile acid concentrations in patients with cholestasis. Use in more than 200 patients has suggested that treatment with this system may improve encephalopathy scores and the hemodynamic status, thereby increasing urine output in hepatorenal syndrome reducing ascites. Significant improvement in cases of acute-on-chronic decompensation was documented in controlled trials. [112] Patients with fulminant hepatic failure have been bridged to transplantation, and four cases of primary graft hypofunction have been supported until recovery with the MARS system. [113] Although these results are encouraging, the cell-free plasma detoxification systems cannot substitute for the metabolic and synthetic functions of the liver. Therefore, other liver support systems, including liver tissues or liver-derived cells, are being developed.

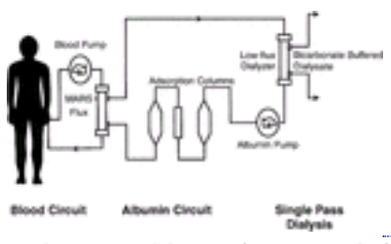

FIGURE 162-4. The MARS (molecular adsorbent recirculating system) unit, a cell-free liver assist device. An albumin-enriched dialysate is passed through a series of adsorption columns, including an anion exchange resin column and a charcoal column, and recirculated through the dialysis unit.

Extracorporeal Liver Perfusion

Otto and colleagues [114] in 1958 demonstrated that allogeneic extracorporeal liver perfusion could reduce plasma ammonia in hyperammonemic dogs. Eiseman and associates [115] applied this concept in patients in the 1960s using both human and xenogeneic livers. By 1994, 87 cases treated with extracorporeal perfusion using porcine liver or human cadaver livers were reported. [116] More recently, at the University of Nebraska, 14 patients received extracorporeal liver perfusion using eight human and eight pig livers. Of the 10 patients who were considered suitable for transplantation, 9 were “bridged” to liver transplantation. [117] In one study, livers from transgenic pigs expressing human CD55 and CD59 to limit hyperacute rejection were used for the management of two patients with fulminant hepatic failure. [118] Although controlled trials of extracorporeal liver perfusion have not been carried out, the complete recovery of three patients and the prolonged survival of some patients suggest improvement over conventional treatment. [118] However, even the best results using extracorporeal liver perfusion are not equal to that of liver transplantation. Membranes, filters, and tubing included in the circuitry may activate leukocytes, leading to cytokine release. Because immunosuppression is avoided to reduce the risk for sepsis, humoral and cellular rejection can occur. Finally, perfusion of the extracorporeal organ with systemic, rather than the portal, blood may reduce hepatic function. Logistic hurdles to extracorporeal perfusion include the limited availability of human donor organs and difficulty of procuring porcine livers, unless an institution maintains its own colony. Concerns over safety and efficacy of porcine organs persist.

Hybrid Bioartificial Liver Support Devices

Standardized machinery, including bioreactors containing metabolically active hepatocytes, have been in development in recent years. Initially, Matsumara and colleagues [119] used a device containing liver cell suspension to treat one patient, but it is now recognized that hepatocytes function more effectively when anchored to a surface. In a clinical trial on patients with acute liver failure, perfusion of patient plasma over porcine hepatocytes attached to Biosilon microcarriers, 37 of the 59 patients recovered, but only 25% of those with grades 3 and 4 encephalopathy survived. [120] The hepatocytes lost function after a few hours of application. Other systems that use hepatocytes cultured onto stacked flat surfaces [121] or three-dimensional structures [122] have been designed but not yet tested in clinical studies. The largest clinical experience is with systems consisting of a large number of cellulose-acetate hollow fibers packaged into plastic cartridges. The intralumenal and the extralumenal compartments can be perfused independently. In all devices presently undergoing clinical trial, the intralumenal compartment is used for perfusion of blood or plasma, and the hepatocytes are inoculated into the extralumenal compartment, although Nyburg and associates [123] have designed an experimental system in which gel-entrapped hepatocytes are packed within the intralumenal compartment.

Sussman and co-workers employed C3A cells, a human hepatoblastoma derived cell line, grown to confluence in the extralumenal compartment of hollow fiber cartridges in their Extracorporeal Liver-Assist Device (ELAD). [124] Whole blood from patients was perfused through the intralumenal compartment. Although initial uncontrolled observations in 11 patients with acute hepatic necrosis were encouraging, a pilot control trial demonstrated no difference in outcome compared with a control group receiving conventional supportive therapy. [125] In this study, the survival rate was surprisingly high in both the treatment (78%) and the control group (75%), probably because of the inclusion of patients with very early stages of acute liver failure.

Rozga and associates [126] used cryopreserved primary pig hepatocytes, attached to collagen-coated microcarriers in a device, named HepatAssist (Fig. 162-5). In this device, hepatocytes are introduced into the extralumenal compartment of hollow fiber cartridges, and the intralumenal compartment is perfused with patient plasma, which has been previously circulated through a charcoal column to remove toxins in the “hepatic failure” plasma. Each cartridge functions for 6 hours only, but the course may be repeated several times. The ongoing controlled trial of HepatAssist has not been published at the time of this writing.

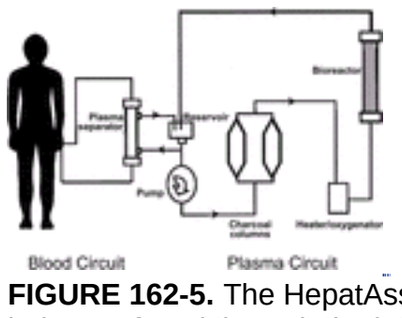

FIGURE 162-5. The HepatAssist device, an example of a hybrid liver assist device. Plasma is separated from blood cells and passed through a charcoal column being perfused through the intralumenal compartment of a hollow-fiber bioreactor. The extralumenal space of the bioreactor is packed with cryopreserved primary pig hepatocytes, attached to collagen-coated microcarriers.

A third hybrid hollow fiber system, Modular Extracorporeal Liver Support (MELS), uses woven polyether-sulphone capillaries that exit from the bioreactor in discrete bundles, so that different bundles can serve separate functions such as plasma flow and oxygenation. [127] The three-dimensional structure is claimed to improve the function of the cultured hepatocytes. CellModule bioreactors containing primary porcine hepatocytes were used to treat eight patients with liver failure, all of whom were carried through to successful transplantation. More recently, primary human hepatocytes obtained from cadaver donor organs were used, leading to encouraging results in six patients with acute failure (I.M. Sauer and J.C. Gerlach, personal communication, 2001).

Hurdles that Need to be Overcome for the Development of Extracorporeal Liver Support

Currently, porcine livers are the main source of the biologic component of artificial liver devices. Limitations of using xenogeneic sources include hyperacute or

delayed immune response to the cells or their products and concerns regarding the presence of infectious organisms, such as the porcine endogenous retrovirus. The use of human hepatocytes would be logical but is limited by donor organ shortage. Therefore, more progress is needed for generating human hepatocytes that can be expanded in vitro. The potential sources, including embryonic stem cells, hepatocyte progenitors, fetal hepatocytes, and genetically engineered immortalized hepatocytes are being explored actively.

Preclinical evaluation of extracorporeal liver-assist devices has been limited by the lack of animal models of fulminant hepatic failure that fully represent the clinical course of acute liver failure in patients. The relatively low incidence of acute liver failure makes it difficult to perform a detailed clinical evaluation of a hepatic support system at any one center, on the other hand, multicenter trials add to the variables to be considered in the trial design. The wide spectra of etiology, severity at presentation, and rapidity of progression of acute liver failure complicate the standardization of entry criteria and randomization. The level of encephalopathy in patients is difficult to quantify. Because liver transplantation is known to improve survival after fulminant hepatic failure, the extracorporeal hepatic support may be applied only until a donor organ becomes available, making the data analysis difficult. However, even if the present generations of devices do not prove sufficiently efficacious, the experience gained will undoubtedly help in the future development of an effective extracorporeal liver support.

Acknowledgment

We acknowledge the important contributions of many investigators in the fields of hepatocyte transplantation, liver-directed gene therapy, and extracorporeal liver-assist devices that were not cited because of limited space.

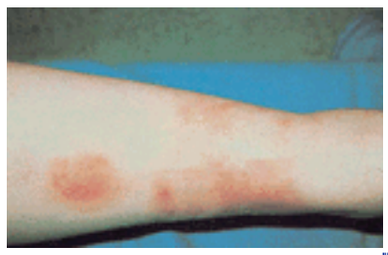
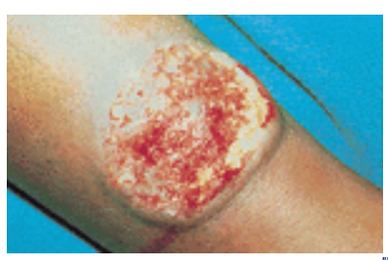
Color Plates



COLOR FIGURE 49-1. The tender nodules of erythema nodosum occurred in association with ulcerative colitis. (This figure is printed in black and white as Figure 49-1.)

COLOR FIGURE 49-2. Typical lesions over joints in a patient with erythema elevatum diutinum. (This figure is printed in black and white as Figure 49-2.)



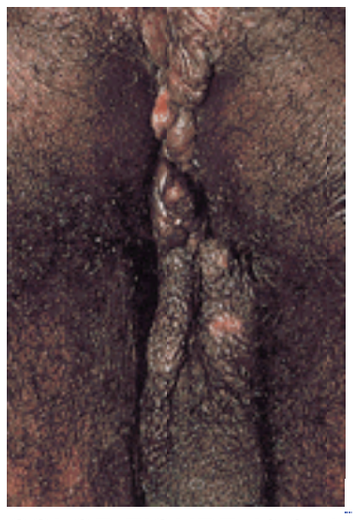
COLOR FIGURE 49-3. Pyoderma gangrenosum in a patient with Crohn's disease. (This figure is printed in black and white as Figure 49-3.)

COLOR FIGURE 49-4. Tender erythematous papules and plaques on the upper extremities in a patient with Sweet syndrome. (This figure is printed in black and white as Figure 49-4.)

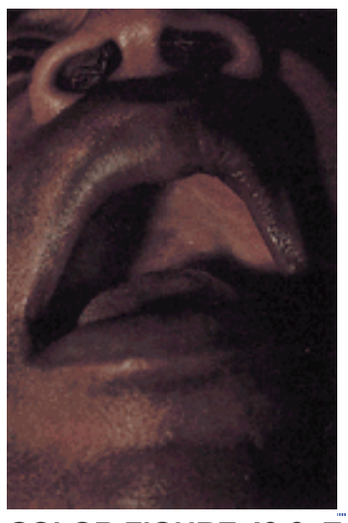
COLOR FIGURE 49-5. Aphthous ulcer involving the tongue in a patient with Behçet disease. (This figure is printed in black and white as Figure 49-5.)

COLOR FIGURE 49-6. Early genital aphtha showing features of pustular vasculitis in a patient with Behçet disease. (This figure is printed in black and white as Figure 49-6.)

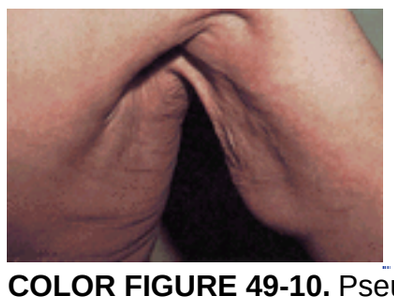
COLOR FIGURE 49-7. Bowel-associated dermatosis-arthritis syndrome. Pustular vasculitis lesions occurred in a patient with a blind loop after Billroth II surgery. (This figure is printed in black and white as Figure 49-7.)



COLOR FIGURE 49-8. Amyloidosis. Note the perirectal amyloid nodules in this patient with multiple myeloma. (This figure is printed in black and white as Figure 49-8.)



COLOR FIGURE 49-9. Typical telangiectasia of Osler-Weber-Rendu disease. (This figure is printed in black and white as Figure 49-9.)



COLOR FIGURE 49-10. Pseudoxanthoma elasticum. Note the chicken skin–like appearance of the axillary skin. (This figure is printed in black and white as Figure

49-10.)

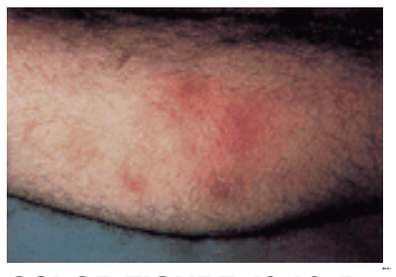
COLOR FIGURE 49-11. Typical epidermal inclusion cyst of Gardner syndrome. This patient had many other cystic nodules, particularly on the scalp. (This figure is printed in black and white as Figure 49-11.)

COLOR FIGURE 49-12. Acanthosis nigricans in a nonobese adult patient. (This figure is printed in black and white as Figure 49-12.)

COLOR FIGURE 49-13. Characteristic telangiectasias, acneiform papules, and rhinophyma in a patient with rosacea. (This figure is printed in black and white as Figure 49-13.)

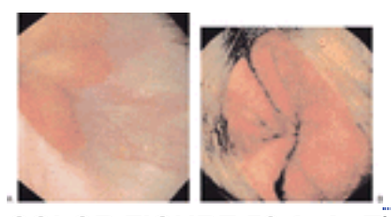
COLOR FIGURE 49-14. Polyarteritis nodosa with characteristic livedo reticularis and tender nodules. (This figure is printed in black and white as Figure 49-14.)

COLOR FIGURE 49-15. Cryoglobulinemia often results in acral vasculitic infarcts. (This figure is printed in black and white as Figure 49-15.)

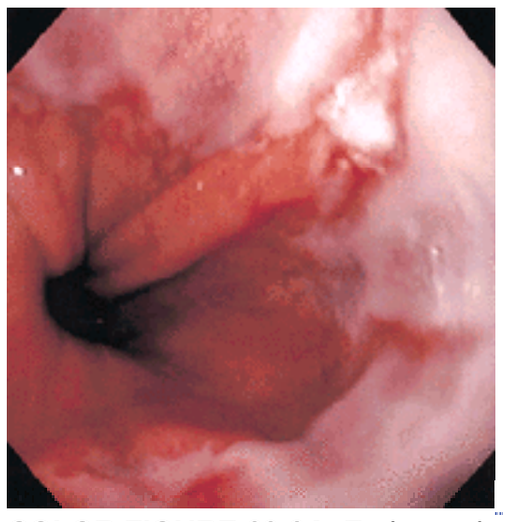


COLOR FIGURE 49-16. Panniculitis presented as tender erythematous nodules in a patient with pancreatitis. (This figure is printed in black and white as Figure 49-16.)

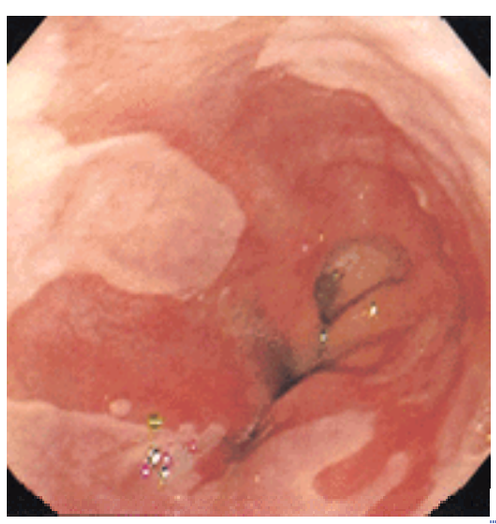
COLOR FIGURE 49-17. Dermatitis herpetiformis. Both elbows are involved. Note the intact vesicles and multiple crusted (i.e., excoriated) lesions. (This figure is printed in black and white as Figure 49-17.)



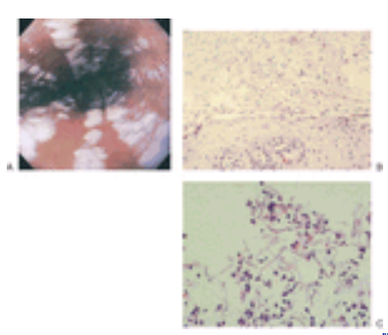
COLOR FIGURE 58-1. A: This view of the normal squamocolumnar junction reveals a slightly serrated contour, a distinct color difference between the two types of mucosa, and linear esophageal vessels that disappear at the mucosal junction. The slightly elevated gastric mucosal folds contact the squamous margin. **B:** The squamocolumnar junction has been better defined by dark Lugol iodine staining of the glycogen-containing squamous cells. This normal junction is located just below the diaphragmatic hiatus. (This figure is printed in black and white as Figure 58-1.)



COLOR FIGURE 60-9A. Endoscopic signs of esophagitis. Two linear erosions extend proximally from the squamocolumnar junction at the proximal border of a hiatal hernia. This would be classified as grade II esophagitis by the Savary-Miller and Hetzel systems and as grade B by the Los Angeles scale. (This figure is printed in black and white as Figure 60-9.)

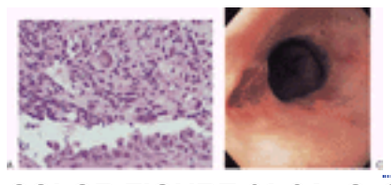


COLOR FIGURE 60-12A. Barrett esophagus. Reddish pink columnar mucosa with tonguelike projections 3 to 4 cm into the tubular esophagus. (This figure is printed in black and white as Figure 60-12.)

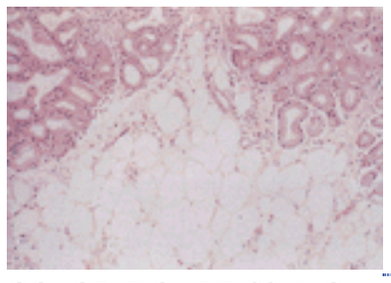


COLOR FIGURE 61-1. *Candida* esophagitis. **A:** Endoscopic photograph shows multiple raised plaques involving the esophagus with normal intervening mucosa. **B:** Desquamated squamous epithelial cells admixed with fungi and inflammatory cells adherent to the mucosa. The underlying squamous epithilium appears normal. **C:**.

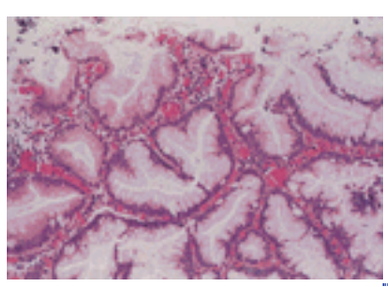
Close-up view of the plaque material demonstrates mycelia and spores typical of *Candida.* (This figure is printed in black and white as Figure 61-1.)



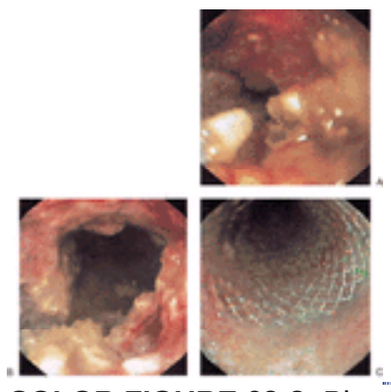
COLOR FIGURE 61-3A, C. Cytomegalovirus esophagitis. **A:** Biopsies from an ulcer base demonstrate granulation tissue with one large cell with intranuclear and intracytoplasmic inclusions diagnostic for cytomegalovirus. **C:** Endoscopic photograph shows the two ulcers, which are well circumscribed and have some depth, and the surrounding mucosa is normal. (This figure is printed in black and white as Figure 61-3.)



COLOR FIGURE 62-4. Specialized-type Barrett esophagus. The epithelium shows intestinal-type absorptive cells, goblet cells, and mucinous cells in a villiform pattern. (Courtesy of Robert Odze, MD.) (This figure is printed in black and white as Figure 62-4.)

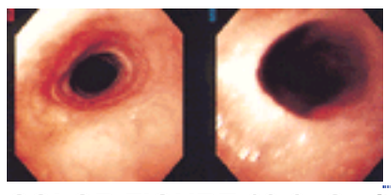


COLOR FIGURE 62-5. High-grade dysplasia in Barrett esophagus. The epithelium shows architectural complexity, atypia, pleomorphism, and nuclear stratification. (Courtesy of Robert Odze, MD.) (This figure is printed in black and white as Figure 62-5.)



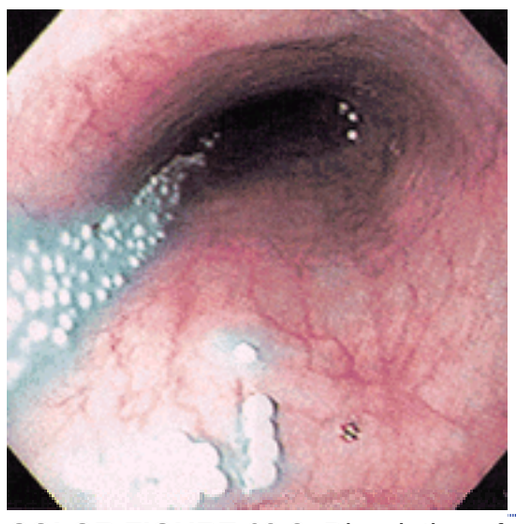
COLOR FIGURE 62-8. Photodynamic therapy of esophageal cancer with laser after administration of porfimer sodium, a photosensitizer. Light of 630 nm from a laser acts on cells that accumulate the photosensitizer (**A**). After 6 days, there is some decrease in the mass size (**B**). After 12 days, the mass is diminished in size significantly, and a metallic endoprosthesis is endoscopically inserted (**C**). (Courtesy of Norman Nishioka, MD.) (This figure is printed in black and white as Figure 62-8.)

COLOR FIGURE 63-1. Food impaction in the distal esophagus (**A**). When cleared by advancing the bolus into the stomach (**B**), a Schatzki ring is evident (**C**). (This figure is printed in black and white as Figure 63-1.)

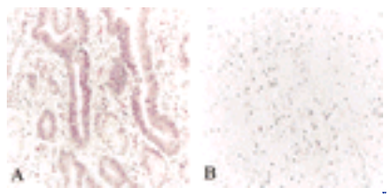


COLOR FIGURE 63-3. Graft-versus-host disease. Multiple fine mucosal webs are present in the esophagus. (This figure is printed in black and white as Figure 63-3.)

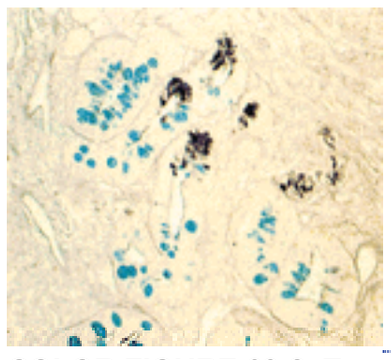
COLOR FIGURE 63-5. Benign mucous membrane pemphigoid. Also known as cicatricial pemphigoid, this endoscopic photograph depicts a tight esophageal stricture. (This figure is printed in black and white as Figure 63-5.)



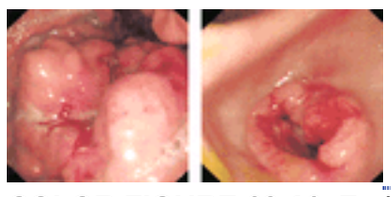
COLOR FIGURE 63-8. Dissolution of a medication in the midesophagus. (This figure is printed in black and white as Figure 63-8.)



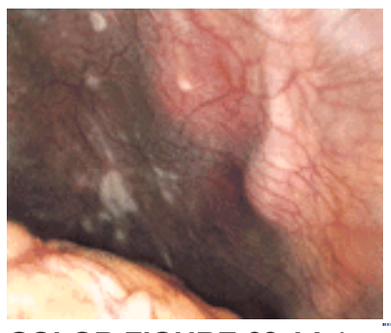
COLOR FIGURE 69-6. Lauren classification of gastric adenocarcinoma. **A:** Well-differentiated intestinal-type gastric cancer. **B:** Diffuse-type cancer with infiltrative and discohesive tumor cells. (Courtesy of Dr. K. F. To, Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong.) (This figure is printed in black and white as Figure 69-6.)



COLOR FIGURE 69-8. Type III intestinal metaplasia of stomach. The presence of sulfomucin in type III intestinal metaplasia is illustrated by the high iron diamine (*HID*)/Alcian blue staining. (This figure is printed in black and white as Figure 69-8.)

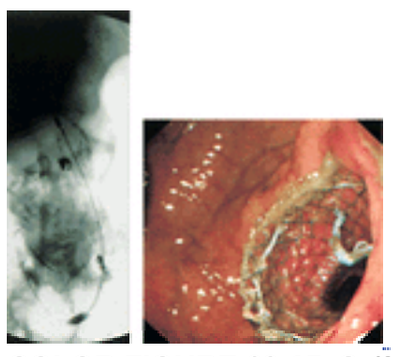


COLOR FIGURE 69-10. Endoscopic appearance of gastric cancer. (This figure is printed in black and white as Figure 69-10.)

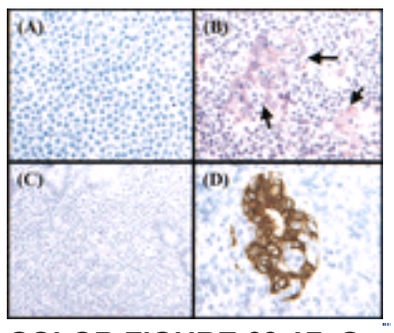


COLOR FIGURE 69-14. Laparoscopic view of a patient with gastric carcinoma with peritoneal metastasis (whitish nodule). (This figure is printed in black and white as

Figure 69-14.)

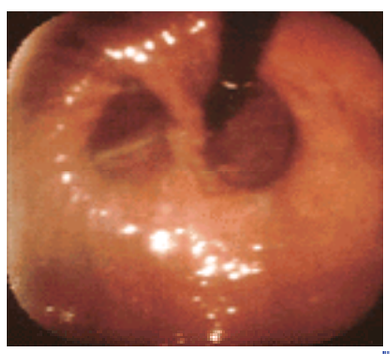


COLOR FIGURE 69-15. Self-expandable metal stent in patient with recurrent gastric carcinoma causing gastric outlet obstruction after subtotal gastrectomy. (This figure is printed in black and white as Figure 69-15.)

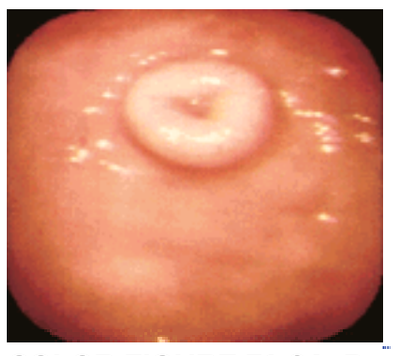


COLOR FIGURE 69-17. Gastric mucosa-associated lymphoid tissue (MALT) lymphoma: characteristics features of low-grade MALT lymphoma. (**A**) Centrocyte-like cells (hematoxylin and eosin, ×200). (**B**) Lymphoepithelial lesions (marked by *arrows*) (hematoxylin and eosin, ×200). (**C**) Plasmacytic differentiation (hematoxylin and eosin, ×100). (**D**) Lymphoepithelial lesions (immunostain for cytokeratin, ×200). (Courtesy of Dr. Wing Y. Chan, Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong.) (This figure is printed in black and white as Figure 69-17.)

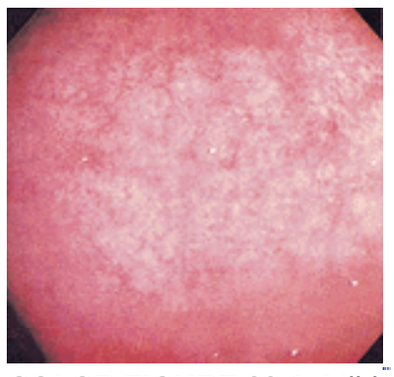
COLOR FIGURE 71-1A. Endoscopic view of a type I hiatal hernia while in gastric retroflexion. (This figure is printed in black and white as Figure 71-1.)



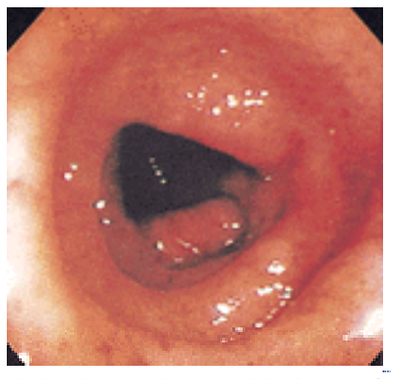
COLOR FIGURE 71-2. Endoscopic view of a paraesophageal hernia while in gastric retroflexion. The fundus is herniating into the thoracic cavity alongside a concomitant type I hernia. (This figure is printed in black and white as Figure 71-2.)



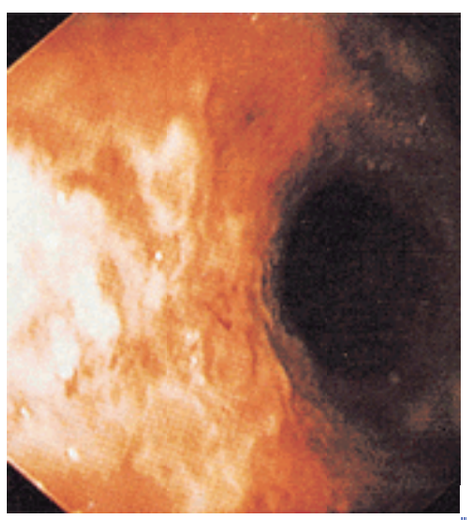
COLOR FIGURE 71-8A. Pancreatic rest identified in the antrum during upper endoscopy. (This figure is printed in black and white as Figure 71-8.)



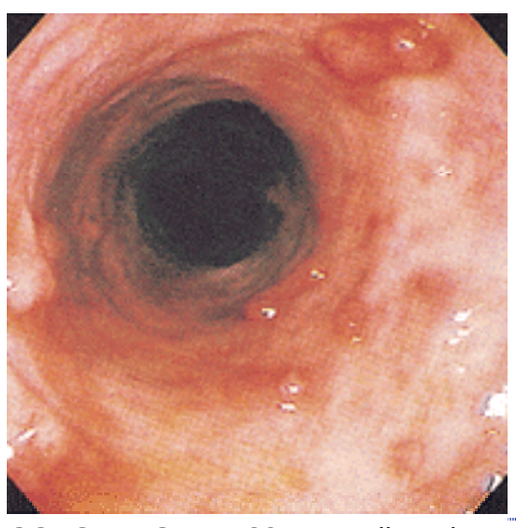
COLOR FIGURE 83-1. Mild ulcerative colitis with erythema, blurring of the vascular pattern, and granularity. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-1.)



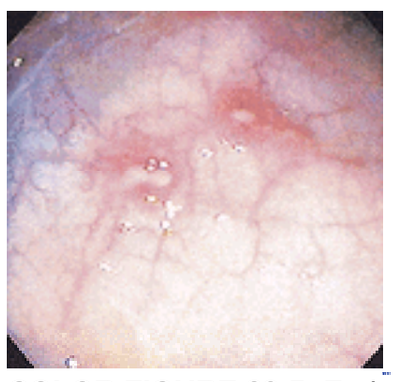
COLOR FIGURE 83-2. Moderate ulcerative colitis with prominent edema, blunting of the haustral pattern, diffuse granularity, and loss of the vascular pattern. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-2.)



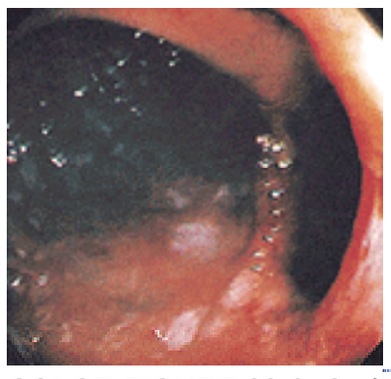
COLOR FIGURE 83-3. Moderate-to-severe ulcerative colitis with coarse granularity, marked edema with early nodule formation, and superficial ulcerations. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-3.)



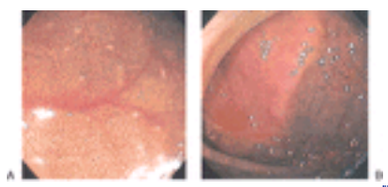
COLOR FIGURE 83-4. Healing ulcerative colitis with residual edema, absent vasculature, and postinflammatory polyps in a tubular, ahaustral lumen. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-4.)



COLOR FIGURE 83-5. Early Crohn's disease with aphthoid ulcers. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-5.)



COLOR FIGURE 83-6. Crohn's ileocolitis with rounded, punched-out ulcers around the ileocecal valve. (Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.) (This figure is printed in black and white as Figure 83-6.)

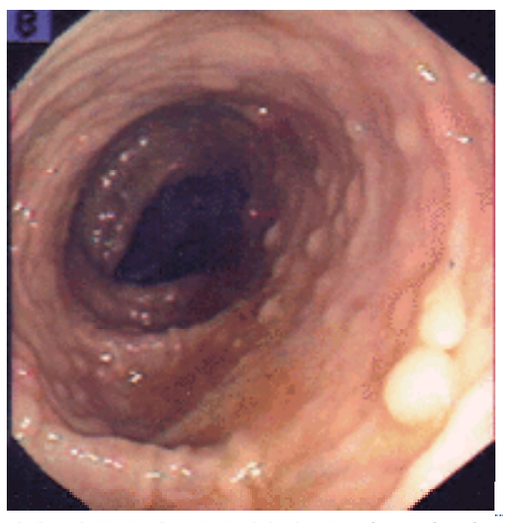


COLOR FIGURE 85-3. Endoscopic photographs of melanosis coli. **A:** The reticulated, alligator-skin appearance is characteristic of this condition. **B:** Melanosis coli with a sharp line of demarcation at the small bowel–colonic anastomosis. (This figure is printed in black and white as Figure 85-3.)

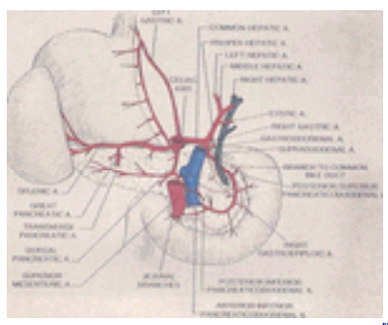
COLOR FIGURE 89-2. Macroscopic appearance of a pedunculated tubular adenoma. The forceps mark the base and the neck of the stalk. (This figure is printed in black and white as Figure 89-2.)

COLOR FIGURE 89-3. A synchronous, pedunculated, tubular adenoma adjacent to a sessile, tubulovillous adenoma. Synchronous adenomas not infrequently are found adjacent to each other. In this instance, a 1-cm, pedunculated, tubular adenoma is found about 5 cm from a 3-cm, sessile, tubulovillous adenoma. Note the smooth surface of the tubular adenoma and the smooth, lobulated surface of the tubulovillous adenoma. (This figure is printed in black and white as Figure 89-3.)

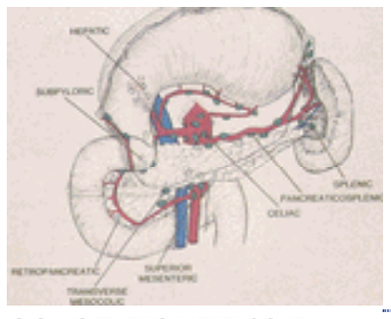
COLOR FIGURE 89-7. This cecal villous adenoma is virtually circumferential, with submucosal carcinomatous invasion. The lesion is sessile in nature and has a cauliflower appearance with a shaggy, frondlike, friable surface that contrasts with the smoother, lobulated surface seen in Color Figure 89-2. (This figure is printed in black and white as Figure 89-7.)



COLOR FIGURE 90-2. Early colonic polyposis in familial adenomatous polyposis. (This figure is printed in black and white as Figure 90-2.)

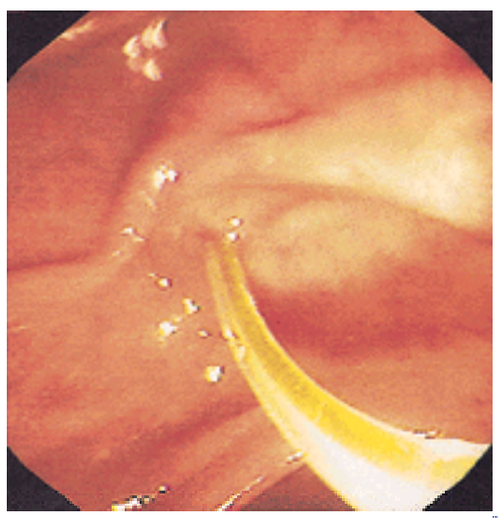


COLOR FIGURE 93-3. Blood supply of the pancreas. The pancreas, duodenum, stomach, and spleen are viewed from their posterior aspects. (This figure is printed in black and white as Figure 93-3.)

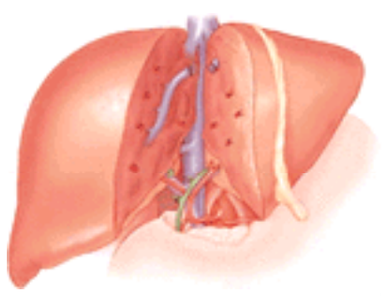


COLOR FIGURE 93-5. Lymphatic drainage of the pancreas. The pancreas is viewed from its anterior aspect. The gastrocolic ligament has been divided along the greater curvature of the stomach, which has been retracted anterosuperiorly. The transverse mesocolon has been detached from the peritoneum of the posterior abdominal wall. Labels indicate representative lymph nodes in the major regional nodal groups. (This figure is printed in black and white as Figure 93-5.)

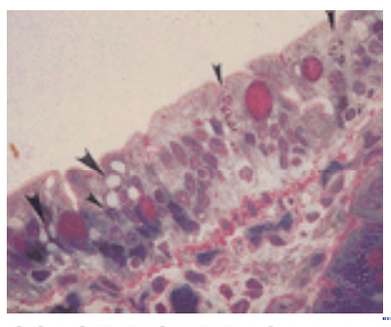
COLOR FIGURE 97-2. Migratory necrolytic erythema involving the face in a patient with metastatic glucagonoma. These typical skin lesions usually start on the extremities or intertriginous or periorificial sites. The lesions initially are erythematous and scaly, later become raised and bullous, and finally become crusty as is evident in this patient. Healing results in hyperpigmentation. Angular cheilitis, a common feature in patients with glucagonoma, is also present in a mild form in this patient. The patient also demonstrates loss of the buccal fat pad and temporal muscle wasting indicative of the generalized wasting these patients characteristically develop. (This figure is printed in black and white as Figure 97-2.)



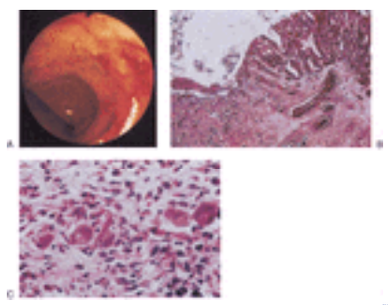
COLOR FIGURE 104-2. The duct entered during sphincter of Oddi manometry can be identified by aspirating the catheter. Dark-colored fluid (*top right*) signifies entry into the bile duct, whereas clear fluid indicates pancreatic duct entry. (This figure is printed in black and white as Figure 104-2.)



COLOR FIGURE 117-2. Illustration of technique of living donor right hepatic lobectomy. (Courtesy John P. Roberts, M.D., Department of Surgery, University of California, San Francisco.) (This figure is printed in black and white as Figure 117-2.)



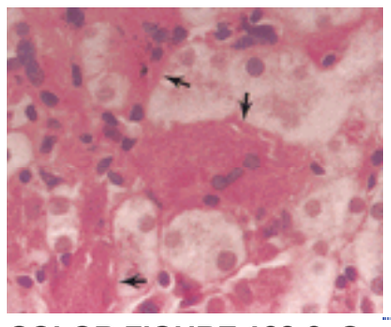
COLOR FIGURE 124-1. A: Densely stained microsporidial spores are detected in the cytoplasm of several epithelial cells by light microscopic examination of an intestinal biopsy from a patient with microsporidiosis (semi-thin plastic section; methylene blue–azure II and basic fuchsin stain, original magnification × 630). (Courtesy of Dr. Jan M. Orenstein.) (This figure is printed in black and white as Figure 124-1.)



COLOR FIGURE 124-2. A: Endoscopic visualization of mucosal ulceration and inflammation in a patient with cytomegalovirus colitis. **B:** Light microscopic view of a colon biopsy from the same patient shows ulceration and hemorrhage. **C:** A higher magnification shows infiltration by inflammatory cells, many containing cytomegalic inclusions. (**B, C,** hematoxylin and eosin; **B,** original magnification × 30; **C,** original magnification × 62). (From ref. [211].) (This figure is printed in black and white as Figure 124-2.)

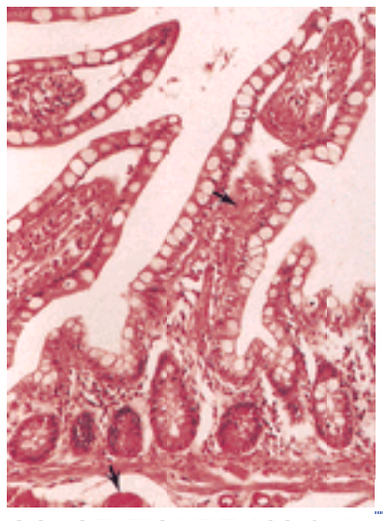
COLOR FIGURE 126-2. *Trichuris trichiura* associated with rectal prolapse in a child. Adult *T trichiura* are seen as white threads on the mucosal surface. (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.) (This figure is printed in black and white as Figure 126-2.)

COLOR FIGURE 126-4. Intestinal obstruction caused by a mass of adult *Ascaris lumbricoides* is seen in this autopsy specimen. Intestinal obstruction is an unusual complication of heavy *Ascaris* infection. (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.) (This figure is printed in black and white as Figure 126-4.)



COLOR FIGURE 128-2. Gaucher disease of the liver. Multinucleated Gaucher cells (*arrows*) are present. (Hematoxylin and eosin stain; original magnification × 400.) (This figure is printed in black and white as Figure 128-2.)

COLOR FIGURE 128-4. Hyperkeratosis of the palm and leg may be indicative of tylosis. (This figure is printed in black and white as Figure 128-4.)

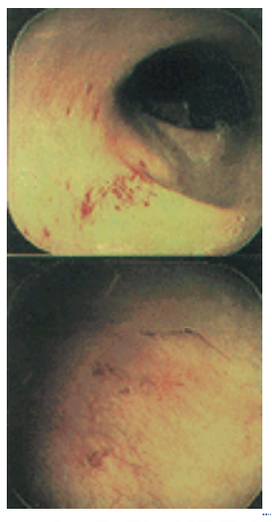


COLOR FIGURE 128-6. Amyloid infiltration of the small intestine (*arrows*). (Congo red stain; original magnification ×200.) (This figure is printed in black and white as Figure 128-6.)

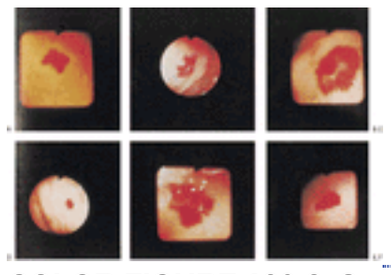
COLOR FIGURE 128-10. Kaposi sarcoma of the lower extremities. (This figure is printed in black and white as Figure 128-10.)

COLOR FIGURE 128-12. Duodenal biopsy specimen from a patient with pseudomelanosis duodeni shows the deposition of pigment within lamina propria macrophages. (This figure is printed in black and white as Figure 128-12.)

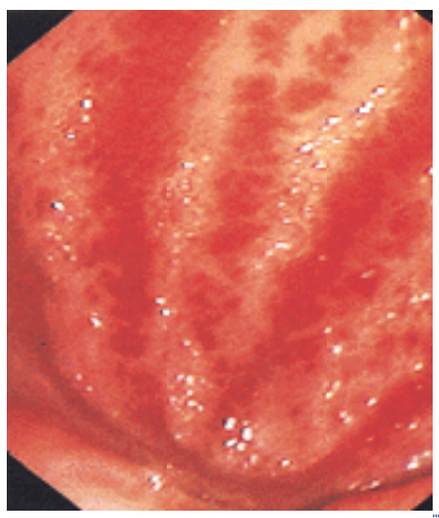
COLOR FIGURE 130-2. Endoscopic appearance of Dieulafoy lesion. Videophotograph shows a gastric cardial Dieulafoy lesion as a small, pigmented protuberance, which represents the vessel stump, with minimal surrounding erosion and no ulceration. (From: Lee JG, Leung JWC. Stigmata of recent hemorrhage in Dieulafoy's lesion. Gastrointest Endosc 2000;51:191.) (This figure is printed in black and white as Figure 130-2.)



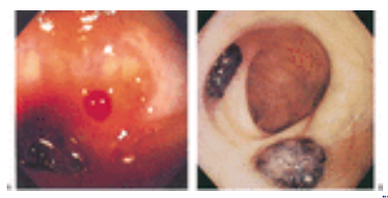
COLOR FIGURE 130-5. Endoscopic photo of cluster of angiodysplasia. **A:** Colonoscopic videophotography demonstrates two adjunct clusters of angiodysplasia in the descending colon in an elderly female with iron deficiency anemia; colonoscopy revealed no other angiodysplasia in the rest of the colon. **B:** Close-up views demonstrate the characteristic endoscopic appearance of angiodysplasia: an intensely red color, an intricate reticulonodular structure, and communication with prominent feeding or draining vessels. (From ref. [69].) (This figure is printed in black and white as Figure 130-5.)



COLOR FIGURE 130-8. Spectrum of endoscopic appearance of upper gastrointestinal angiodysplasia. The characteristic endoscopic findings of angiodysplasia are intense erythema, well-demarcated margin, irregular stellate (fern-like) margin, fine internal reticular (fern-like) structure, and macular mucosal location. Lesions range from 2 × 3 mm to 5 × 7 mm in size. All angiodysplasia are from the stomach, except for **A,** which is from the duodenum. (From ref. [80].) (This figure is printed in black and white as Figure 130-8.)

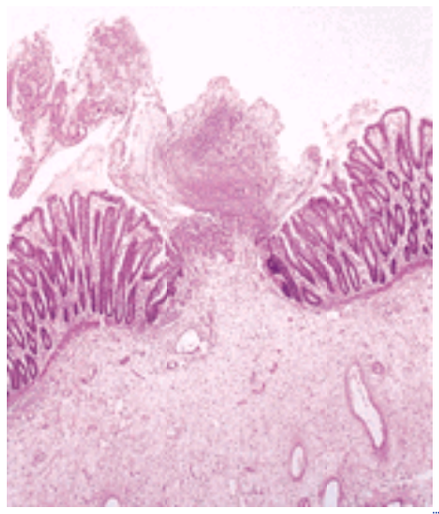


COLOR FIGURE 130-10. Videophotograph shows the characteristic endoscopic finding in gastric antral vascular ectasia (GAVE) of linear, intensely erythematous lesions at the apices of longitudinal antral folds radiating to the pylorus. The alternative lesion name of *watermelon stomach* derives from the resemblance of these erythematous linear streaks to the stripes on a watermelon rind. (From Clouse RE. Vascular ectasias, tumors, and malformations. In: Yamada T, Alpers DH, Laine L, Owyang C, Powell DW, eds. Atlas of gastroenterology. 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 1999:550.) (This figure is printed in black and white as Figure 130-10.)

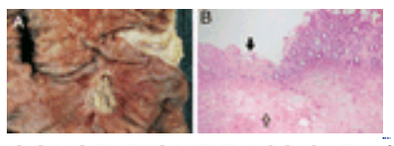


COLOR FIGURE 130-12. Endoscopic appearance of colonic hemangiomas. **A:** Videophotograph of a 3-mm colonic capillary hemangioma (bottom left) adjacent to a

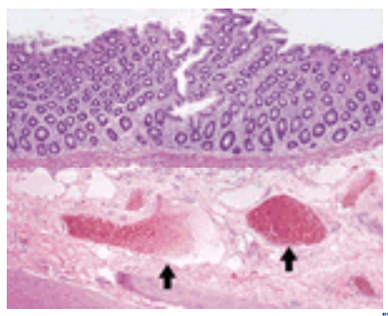
mid-sigmoid diverticulum (center). **B:** Videophotograph from the colon shows the characteristic endoscopic appearance of a cavernous hemangioma as a bluish, round, smooth, and well-circumscribed sessile polypoid lesion. (**A,** Courtesy of T.G. Tietjen, M.D., Petoskey, Michigan; **B,** From ref. [206] .) (This figure is printed in black and white as Figure 130-12.)



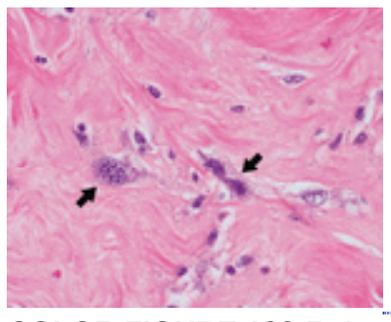
COLOR FIGURE 131-7. Intestinal ischemic damage. Well-delimited ulceration of the mucosa, with formation of a pseudomembrane. The remaining mucosa is normal. The submucosa has a marked edema and discrete infiltration by inflammatory cells. (This figure is printed in black and white as Figure 131-7.)



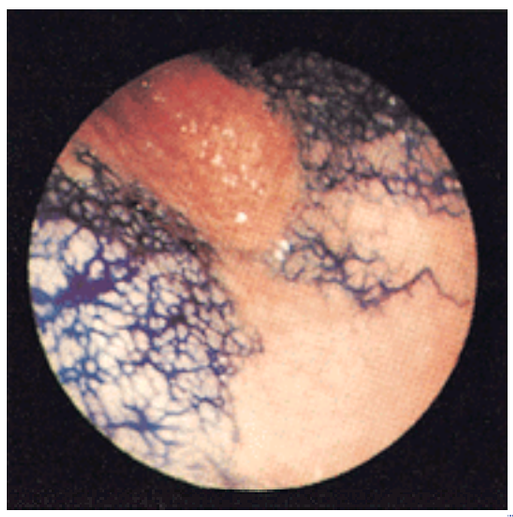
COLOR FIGURE 132-2. Radiation-induced ulceration in the colon. **A:** Gross appearance of a well-demarcated ulcer present in the rectum years after external radiation for an adjacent neoplasm. **B:** Histological appearance with chronic ulceration, mucosal necrosis (*solid arrow*), and dense submucosal fibrosis (*open arrow*) similar to that seen in ischemic injury. The lesion is notable for the absence of a prominent inflammatory infiltrate. (H&E, original magnification × 20.) (Courtesy of Dr. Christopher Moskaluk.) (This figure is printed in black and white as Figure 132-2.)



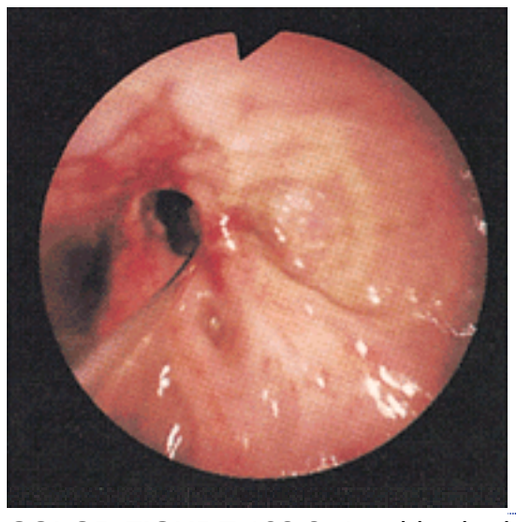
COLOR FIGURE 132-4. Submucosal telangiectasias (*arrows*) are seen in delayed radiation injury. Dilated venules and lymphatic channels are seen in the submucosa underlying relatively normal-appearing colonic epithelium. (H&E, original magnification × 40.) (Courtesy of Dr. Christopher Moskaluk.) (This figure is printed in black and white as Figure 132-4.)



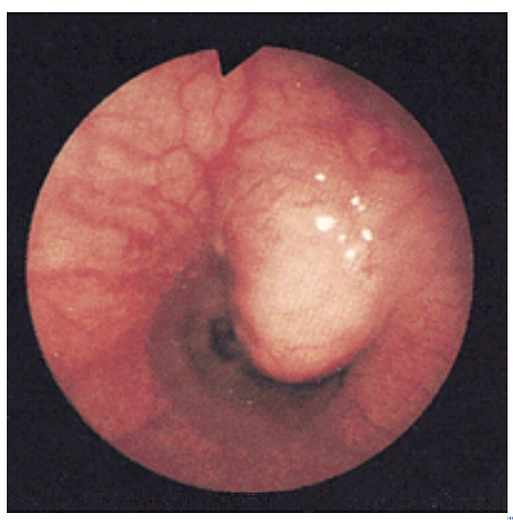
COLOR FIGURE 132-5. Atypical fibroblasts in radiation injury (*arrows*). Bizarre-appearing, pyknotic fibroblasts are frequently seen in the delayed phase of radiation injury in the alimentary tract. Although these atypical fibroblasts are frequently observed, their presence is not specific for radiation injury. (H&E, original magnification × 4000.) (Courtesy of Dr. Christopher Moskaluk.) (This figure is printed in black and white as Figure 132-5.)



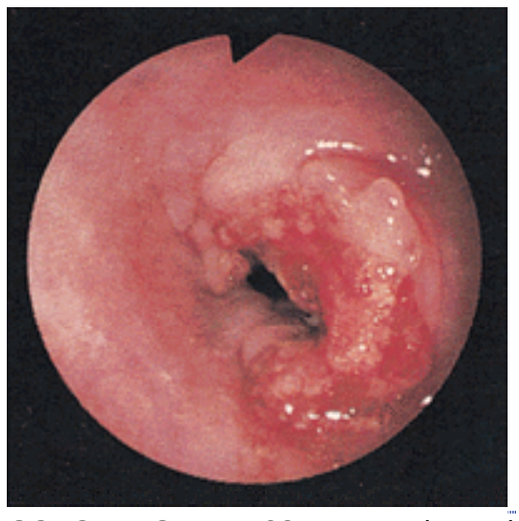
COLOR FIGURE 138-4. Gluten enteropathy with total villous atrophy. Mosaic appearance of the mucosal lining, accentuated by methylene blue entering deep mucosal crevices. (This figure is printed in black and white as Figure 138-4.)



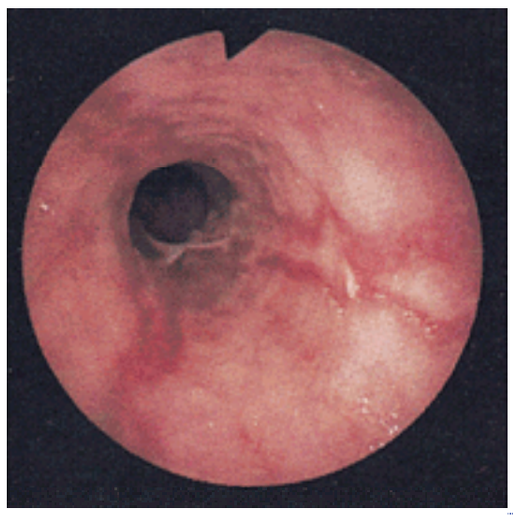
COLOR FIGURE 138-8. A guidewire has been passed through this eccentric, reflux-induced stricture. (This figure is printed in black and white as Figure 138-8.)



COLOR FIGURE 138-10. Esophageal leiomyoma. (This figure is printed in black and white as Figure 138-10.)

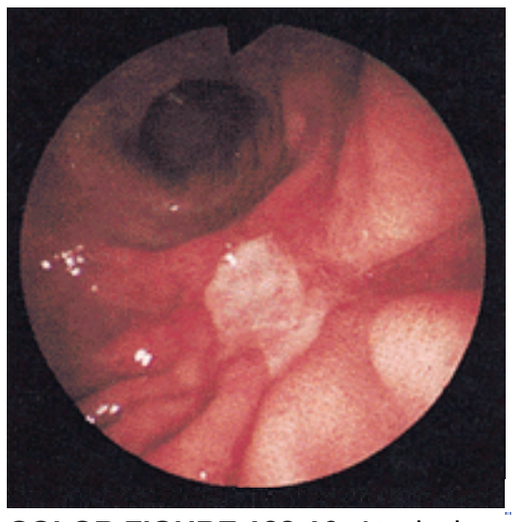


COLOR FIGURE 138-11. Esophageal carcinoma obstructs the esophagus. (This figure is printed in black and white as Figure 138-11.)

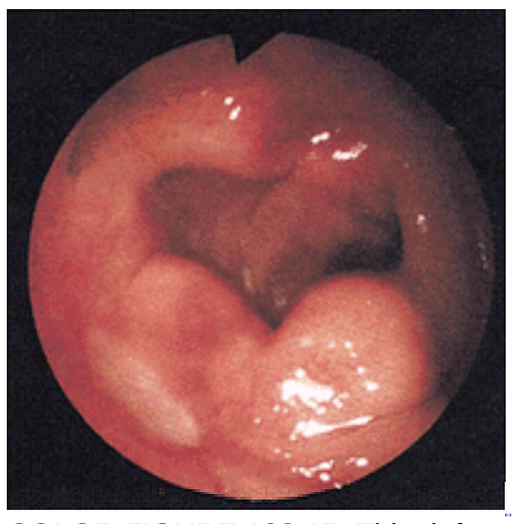


COLOR FIGURE 138-12. Reflux esophagitis with confluent but noncircumferential breaks or erosions. (This figure is printed in black and white as Figure 138-12.)

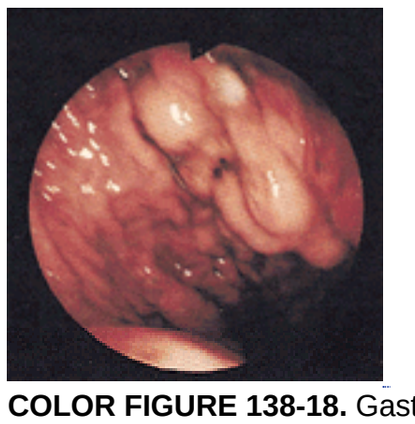
COLOR FIGURE 138-13. A columnar mucosa–lined esophagus, also known as Barrett esophagus. (This figure is printed in black and white as Figure 138-13.)



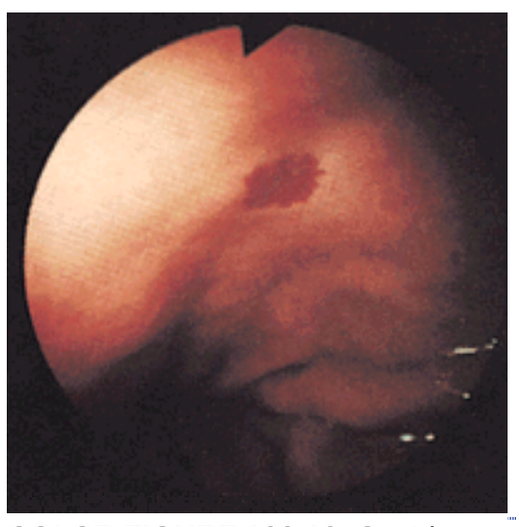
COLOR FIGURE 138-16. Atypical gastric ulceration along the greater curvature was presumably induced by nonsteroidal antiinflammatory drugs. (This figure is printed in black and white as Figure 138-16.)



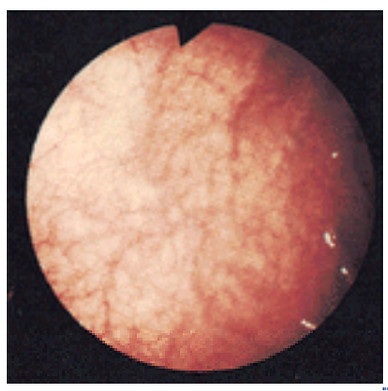
COLOR FIGURE 138-17. This deformed bulb was caused by scarring after prior ulceration and recurrent duodenal ulcer. (This figure is printed in black and white as Figure 138-17.)



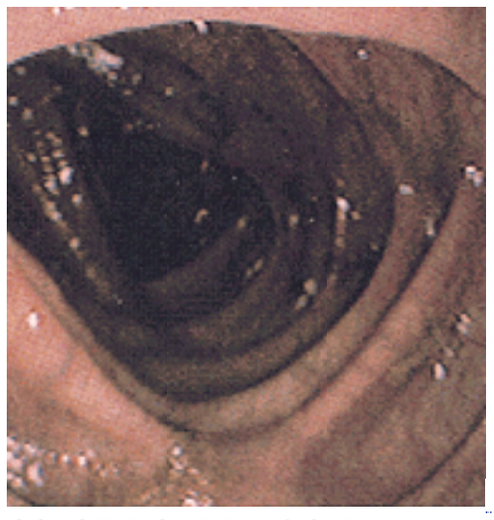
COLOR FIGURE 138-18. Gastric fundus varices. (This figure is printed in black and white as Figure 138-18.)



COLOR FIGURE 138-19. Gastric mucosal vascular ectasia. (This figure is printed in black and white as Figure 138-19.)



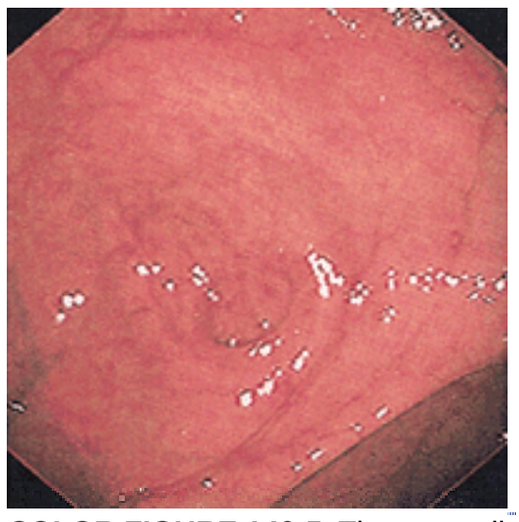
COLOR FIGURE 138-21. Atrophic gastritis. (This figure is printed in black and white as Figure 138-21.)



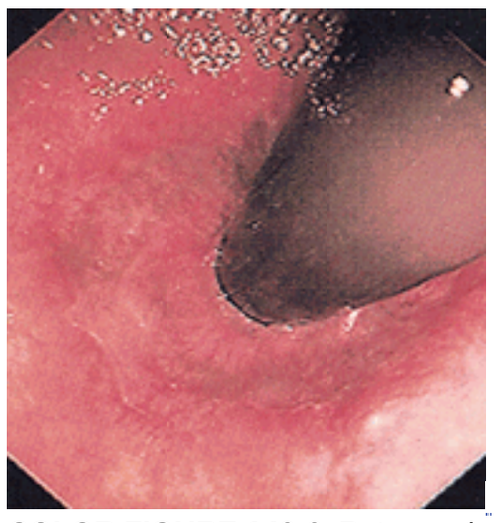
COLOR FIGURE 140-2. Transverse colon shows the characteristic triangular outline resulting from the relative thickness of the three longitudinal teniae coli. The circular muscle is much thinner. (This figure is printed in black and white as Figure 140-2.)

COLOR FIGURE 140-3. Hepatic flexure shows the dark impression of the liver. Similar discoloration can be caused by other extracolonic viscera at the splenic flexure or in the distal colon. Note the longitudinal impression of a tenia and the transverse haustral folds. (This figure is printed in black and white as Figure 140-3.)

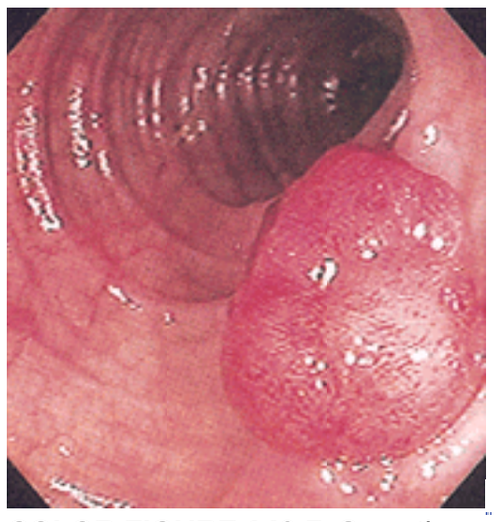
COLOR FIGURE 140-4. Ileocecal fold shows the characteristic notch on a flattened fold. The notch denotes the superior lip of the ileocecal valve. The opening is just proximal to and below the notch, and cannot be seen without marked angulation of the instrument tip. (This figure is printed in black and white as Figure 140-4.)



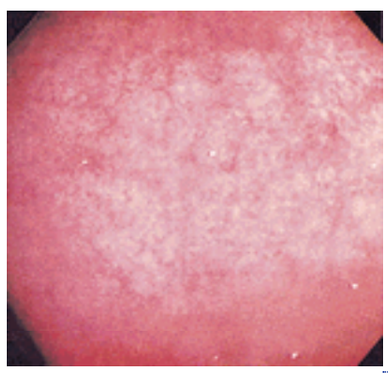
COLOR FIGURE 140-5. The appendix orifice is variable in configuration. Here, the orifice is round, but it may also be seen as a crescent-shaped slit. It is usually rather insignificant in appearance. The internal aspect remains the same after appendectomy. (This figure is printed in black and white as Figure 140-5.)



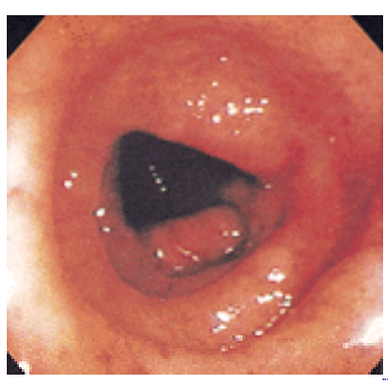
COLOR FIGURE 140-6. Retroversion of the endoscope in the rectum is a useful maneuver to find or remove small polyps in the distal part of the rectal ampulla. The dentate (pectinate) line is serpiginous at the junction of the squamous mucosa of the anal canal and the columnar rectal mucosa. (This figure is printed in black and white as Figure 140-6.)



COLOR FIGURE 140-7. Smooth sessile adenoma is located in the descending colon. (This figure is printed in black and white as Figure 140-7.)

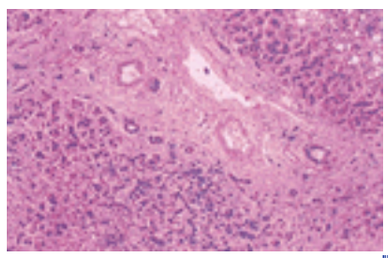


COLOR FIGURE 143-1. Cirrhosis of liver with fibrous septa and regenerative nodules. (Masson stain; original magnification ×40.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-1.)

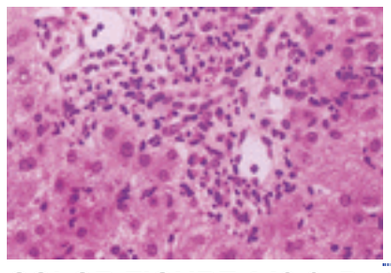


COLOR FIGURE 143-2. a $_1$-Antitrypsin globules in the periportal hepatocytes-diastase resistant PAS-positive. (Di-PAS stain; original magnification ×200.) (From

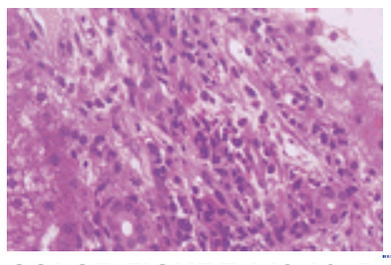
Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-2.)



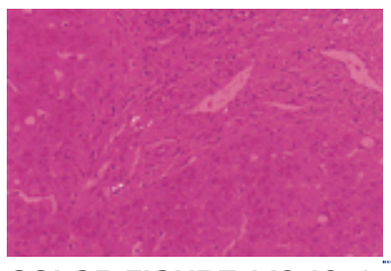
COLOR FIGURE 143-3. Perls iron stain demonstrating bright blue granules in hepatocytes and duct epithelial cells in hemochromatosis. (Original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-3.)



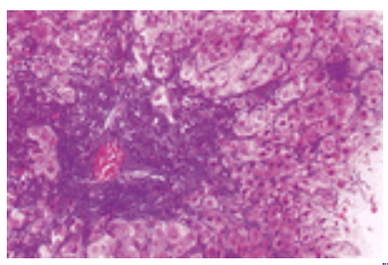
COLOR FIGURE 143-9. Portal area with prominent eosinophils among the inflammatory infiltrates in a case of Dilantin-induced hepatotoxicity. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-9.)



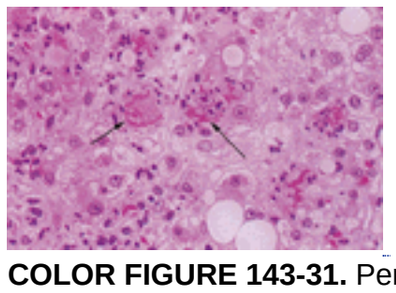
COLOR FIGURE 143-10. Portal area with increased number of eosinophils in a case of early rejection of orthotopic liver transplantation. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-10.)



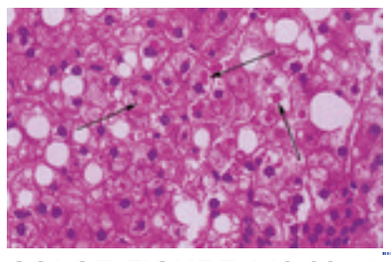
COLOR FIGURE 143-12. A portal area under polarizing light to demonstrate polarizable crystals in an intravenous drug user. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-12.)



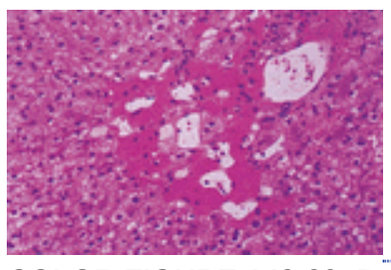
COLOR FIGURE 143-14. Arachnoid portal fibrosis with periportal extension of collagen in chronic alcoholic liver disease. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-14.)



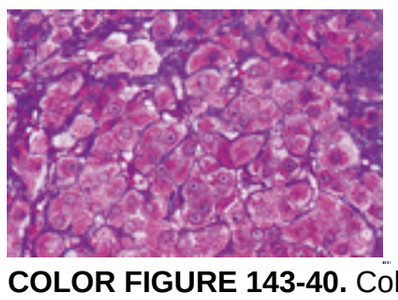
COLOR FIGURE 143-31. Perivenular hepatocytes containing Mallory hyaline (*arrows*) with neutrophilic reaction around them. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-31.)



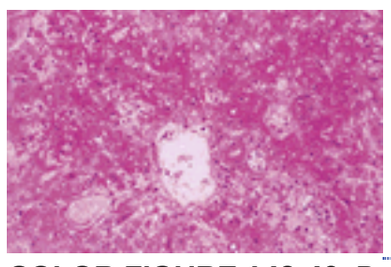
COLOR FIGURE 143-33. Hepatocytes containing spherical megamitochondria (*arrows*) in alcoholic liver disease. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-33.)



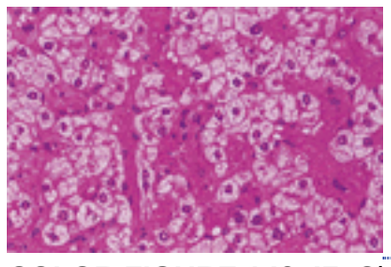
COLOR FIGURE 143-39. Perivenular hepatic parenchyma with dilated sinusoids and the presence of red blood cells within the hepatic cords in left-sided heart failure. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-39.)



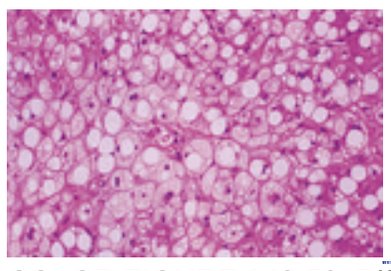
COLOR FIGURE 143-40. Collagen fibers along the sinusoids in the space of Disse in alcoholic liver disease. (Masson stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-40.)



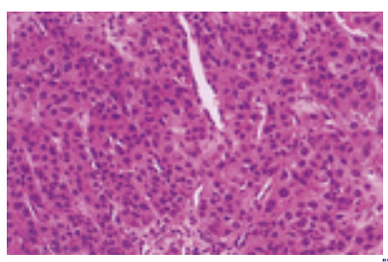
COLOR FIGURE 143-46. Periportal sinusoidal space filled with fibrin thrombi in toxemia of pregnancy. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-46.)



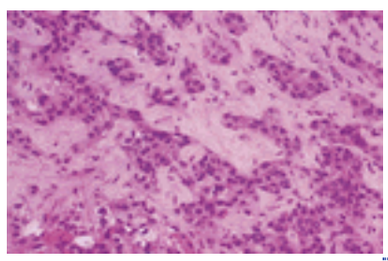
COLOR FIGURE 143-47. Clumps of sickled red blood cells packed in the sinusoidal spaces. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-47.)



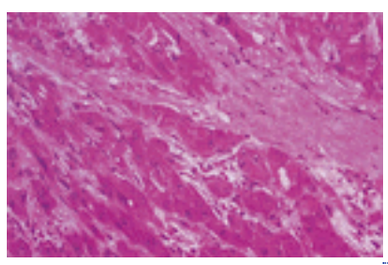
COLOR FIGURE 143-50. Diffusely enlarged hepatocytes with foamy fatty change in acute alcoholic liver disease. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-50.)



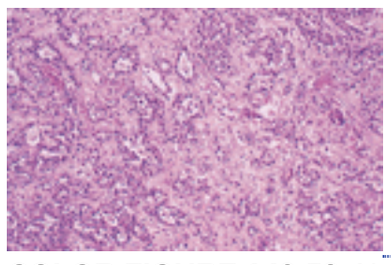
COLOR FIGURE 143-55. Well-differentiated trabecular hepatocellular carcinoma with endothelial lining. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-55.)



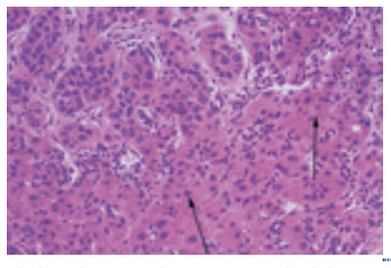
COLOR FIGURE 143-56. Sclerosing hepatic carcinoma with dense fibrous stroma. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-56.)



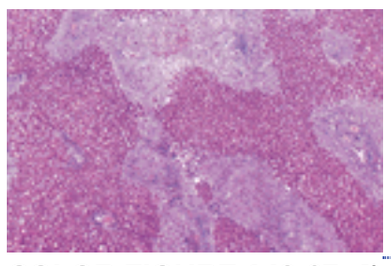
COLOR FIGURE 143-57. Eosinophilic neoplastic hepatocytes with lamellar fibrous stroma in fibrolamellar hepatocellular carcinoma. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-57.)



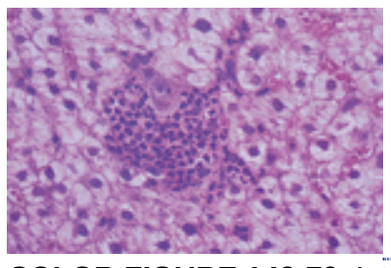
COLOR FIGURE 143-58. Neoplastic ductal structures with fibrous stroma in cholangiocarcinoma. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-58.)



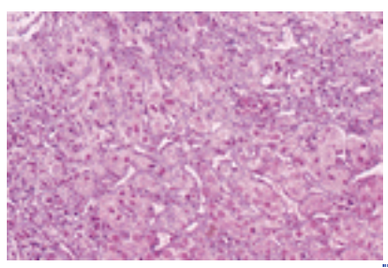
COLOR FIGURE 143-60. Junction of tumor and nontumor liver in hepatocellular carcinoma. The tumor cells grow into the hepatic cords (*arrows*). (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-60.)



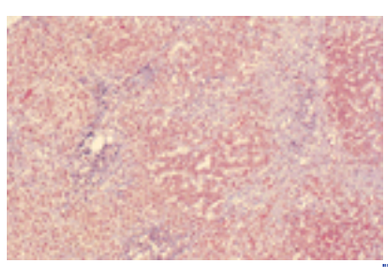
COLOR FIGURE 143-67. Jigsaw-puzzle appearance of biliary cirrhosis. (Masson stain; original magnification ×40.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-67.)



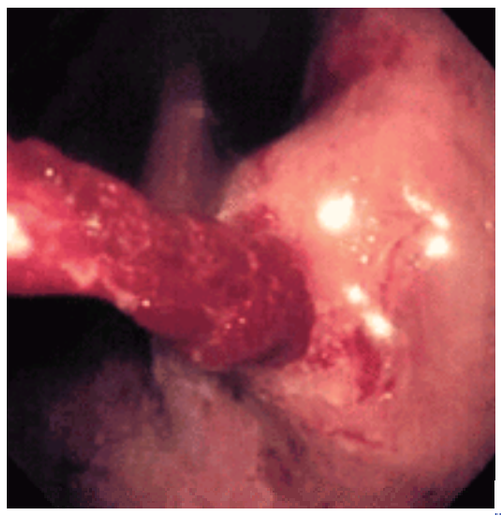
COLOR FIGURE 143-79. Intranuclear and cytoplasmic inclusions of cytomegalovirus (CMV) in a hepatocyte surrounded by polymorphonuclear leukocytes in an orthotopic liver transplant infected with CMV. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-79.)



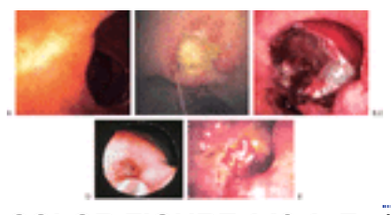
COLOR FIGURE 143-81. Diffuse interstitial fibrosis in chronic alcoholic liver disease. (Masson stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-81.)



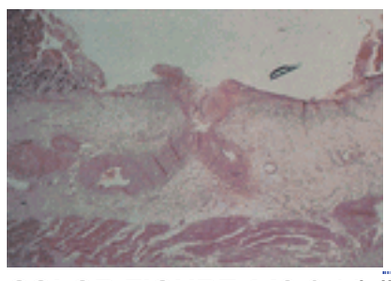
COLOR FIGURE 143-82. Marked perivenular fibrous scarring with mild portal fibrosis and lack of regenerative nodules in progressive perivenular fibrosis of alcoholic etiology. (Masson stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.) (This figure is printed in black and white as Figure 143-82.)



COLOR FIGURE 147-2A. Cyanoacrylate injection for gastric varices. The injected cyanoacrylate stops bleeding from a fundal varix instanteously. (This figure is printed in black and white as Figure 147-2.)



COLOR FIGURE 148-1. Endoscopic photos of stigmata of recent hemorrhage. **A:** Clean base. Duodenal ulcer with a clean base. No evidence of protruding or pigmented areas is present. The rebleeding rate in this lesion is near zero. **B:** Flat spot. Pyloric channel ulcer with a flat, black spot in the center. The risk for rebleeding in this lesion is less than 10%. **C:** Adherent clot. Duodenal ulcer with a large adherent clot in the base that could not be removed with vigorous irrigation. The nature of the lesion beneath the clot is unknown. The risk for rebleeding in this lesion is intermediate (up to 25%). **D:** Nonbleeding visible vessel. A prominent protruding visible vessel with a bipolar probe in the foreground. This lesion has a high risk for recurrent bleeding (40% to 50%) without endoscopic therapy. **E:** Active bleeding. A duodenal ulcer with blood vigorously flowing. This is the lesion with the highest risk for continued or recurrent bleeding (approaching 60%). Endoscopic hemostasis can control active bleeding in most patients and can reduce the risk for rebleeding. (This figure is printed in black and white as Figure 148-1.)



COLOR FIGURE 148-6. Visible vessel. This classic image demonstrates the histology of a bleeding vessel in the base of an ulcer. The submucosal vessel is seen

extending to the ulcer surface, with a thrombus present in the “hole” in the arterial wall. (Courtesy of C. Paul Swain, M.D.) (This figure is printed in black and white as Figure 148-6.)
