At present two basic approaches are used. These are called exhaustive inspections and selective inspections. The first approach involves inspection and assessment of all of the elements in a given area. The order of the inspections does not have to be fixed. Monitoring is carried out in chosen areas, e.g. A district of a city. Due to the number of elements involved, such inspections tend to take a very long time. Thus, inspections are more often carried out according to a specified plan, which defines the order in which the inspections are made (elements whose failure would lead to the largest costs). A possible scheme for choosing the order in which inspections are made is shown in figure 4.

This scheme chooses the order of inspections according to the seriouness of the consequences associated with leaks in channels. However, it should be stressed that this should not be the only criterion. An analysis of the consequences of a fault in an element may result in improved criteria for choosing the ordering. The scheme illustrated above is thus an illustration of a scheme that can be practically implemented. Such a scheme should be adapted to the characteristics of the local sewage network.

Good results can be obtained by highlighting critical channels and treating such channels as the core of the system. These channels should have priority treatment, with respect to both inspections and planning renovation work. A method for choosing these critical channels was proposed by WRC (1990).

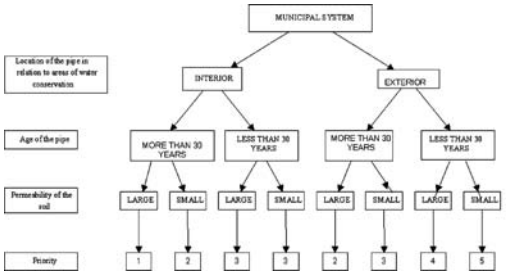

Figure 4. Determining the order for assessing the state of pipes (Schaaf, 1997).

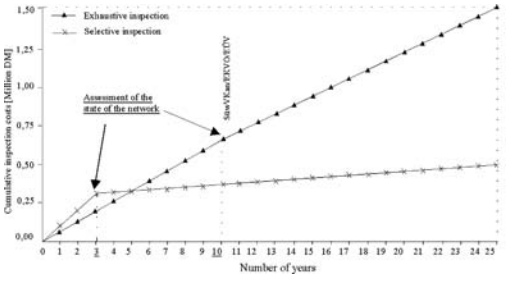

Figure 5. A comparison of the costs of selective inspection and exhaustive inspection for a 100 km network (Hertwig & Krug, 1999).

Ascribing priority to certain channels obviously does not undermine the assumptions of exhaustive control that over a given period of time all the pipes from a given class will be inspected and only then will the appropriate conclusions regarding the state of the network be taken (in order to specify the future course of inspections).

4.2 *Selective inspection*

Selective inspection is an alternative to exhaustive inspection. Information regarding the state of the network as a whole is obtained by generalising the assessments of a sample of elements chosen from each class using appropriate statistical techniques. According to the EN 752-5:1997 norm, both methods are equally acceptable.

Figure 5 presents a comparison of the costs of using selective selection for the first and following inspections and the analogical costs when exhaustive inspection covering the same fraction of the network at each stage is used (Hertwig & Krug, 1999). To begin with the costs of selective control are higher than the costs of exhaustive inspection. After carrying out a general appraisal of the state of the network (this can be done at an earlier stage if selective inspection is used), the costs of using selective inspection are decidly lower.

In Poland, when assessing the state of a network there is often an additional problem associated with an incomplete inventory of its elements. Hence, inspections are used as an element in creating a full inventory. Adopting selective control seems particularly appropriate in this case, since costs can be significantly lowered. In order to make accurate general conclusions regarding the state of a network, it is necessary to inspect about 20% of the elements.

The selective control of pipes embraces the following stages:

– a classification of the elements in the network, elements in a class have similar characteristics (e.g. age),
– selection of a random sample from each each class that is to be inspected,
– inspection and assessment of these random samples,
– statistical analysis of these assessments and then generalising, firstly for each class and then at the level of the network as a whole.

One may define various criteria to be used in defining classes. Among other things, these may be:

– the load carried by a pipe,
– the type of material the pipe is made from,
– the diameter and the cross-section type,
– the sewage system to which a pipe belongs,
– the corrosiveness of waste waters carried,
– other…

In situations where there are a large number of categories of varying importance, such a procedure may lead to an excessive number of classes. This is a result of the number of criteria (which directly depends on the classification used) and the characteristics of a given network. It seems useful in this case to resign from the use of certain criteria and group similar classes together. In cases where such a classification is still too rich, classes which contain too few elements to carry out the appropriate statistical analysis (there should be at least 30 elements in a class) should be subject to exhaustive inspection.

Another question regards the choice of the number of pipes (a random sample) to be inspected in a given class. Muller and Krug 2001 argued that at least 12–15 pipes in a class should be inspected. Also, in order for the random sample to be representative of a given class, a random sample should contain at least 10–20% of the elements in the class.

According to the results of an inspection, the pipes from these random samples are graded with respect to their state. Various aspects of changes in pipes may be used to grade the state of a pipe (e.g. the technical state of the pipe, aspects regarding possible ecological consequences resulting from a fault, the social costs resulting from renovating a pipe). If one has observed

the distribution of the states of the pipes in the random samples from each class, one may generalise these results to each class and then to the network as a whole. The mean grade of pipes in a given class can be characterised by a confidence interval, which gives bounds which are very likely to contain the mean grade of the pipes in the whole of a class given the grades of the pipes in the random sample from that class.

A fundamental question when using selective inspection is the verification of the results obtained. The random samples taken may give a false picture of the network as a whole due to: inappropriate choice of classes, small size of random samples, poor quality of assessments, differences between assessments carried out at different times, lack of consistency in the assessments (despite using the same assessment scheme) and inappropriate statistical analysis.

In order to verify the results of inspections, according to standard practice a water supply company commissions additional inspections. The results obtained in these inspections are compared with the results of the original inspections.

5 SUMMARY

- Monitoring is crucial in ensuring a reliable sewage network and protect areas surrounding the network (road surfaces, buildings and other urban infrastructure).
- The need to optimise the process of renovating sewage networks implies the need to constantly find improved monitoring systems, methods of diagnosis and formal procedures. Considering the techniques available at present, renovation strategies based on prognosing the future state of the network seem to be the most appropriate strategies.
- Due to the size of sewage networks and associated costs of inspection, exhaustive inspections in a short period of time are impractical.
- Due to the size of sewage networks and associated costs of inspection, selective inspections are a more practical solution, especially when carrying out an inventory of the system.
- Inspection of the system is a fundamental element of its reliability and is necessary in order to adapt a sewage network to the needs of a modern city.

Investigation behavior of vertical shaft under loadings of intake tower at first filling of Doosti Dam

Daliri-Massoud
TOOSSAB Consulting Engineers Co, Dams & Hydropower Department

ABSTRACT: Intake Tower of Doosti Dam is constructed on the left bank of Dam body with 54 m height. Regarding to the concept of Intake Tower's Load conditions and Mechanical Parameters of rock foundation (soft Rock), Evaluation of Foundation and effects on Behavior of Shaft's Lining under Tower are important. In this Studies considering to Monitoring of foundation with extensometers' and Modeling with Numerical Method, effect of Static Loads at duration of construction and first filling on Shaft's behavior are investigated and compared Results with Monitoring Data. Finally Intake Tower's Foundation with Shaft under Static Loads conditions is evaluated.

1 INTRODUCTION

Doosti Dam is located at 260 km from the north-East of Mashhad city on the border of Iran and Turkmenistan. This dam is constructed by two countries at 2004 on Harirrud River and supplied agricultural water of two countries and drinkable water of Mashhad city. Doosti Earth fill Dam has 78 m height and 700 m crest length. water intake system of dam has 50 m^3/s capacities and is included Intake Tower with 54 m height, Vertical Shaft with 24 m depth and transmission galleries. Doosti Dam and Intake Tower are shown in figure 1. [1].

Intake Tower is constructed on the left bank of dam body on the Argillite bed rock that it is one of the soft rocks type and Shaft as part of transmission section was constructed under Intake Tower.

Vertical Shaft under Tower is affected by Tower loadings and acts as a part of tower foundation, Therefore investigation behavior of shaft and safety control of Tower foundation is important. For monitoring of tower and foundation, some extensometers after finishing of tower were installed on tower foundation. After installation of instruments, left side of dam body extended on tower foundation and 26 m of tower height were buried by embankment. Then reservoir elevation increased after finishing of dam construction. During stage construction of dam body and first filling, instruments were monitored. In this study, regarding to form of loading, shaft and tower rock foundation with numerical method, are modeled and analyzed. Then results checked and comparing with instruments data. In figure 2 section of Tower, Shaft and Dam body are shown.

Geomechanical parameter	
Module of elasticity (Gpa)	2.6
Module of deformation (Gpa)	1.1∼1.9
Friction angle ϕ (Deg)	27°
Cohesion C (Mpa)	0.1
Poisson's ratio υ	0.3
Density (ton/m^3)	2.32

2 GEOTECHNICAL CHARACTERCTIC

According to the results of explorations program at Feasibility study stage, foundation rock of Intake Tower and Shaft located in the "Koape_Dagh" formation, that consisted of argillite with small spacing and are slightly jointed filled with clay and gypsum. Rock at surface is very weathered and degree of weathering to the depth decreases and apparent strength of intak rock are weak. Regarding to the type of rock, after excavation of Shaft, some field and laboratory tests were performed and properties of rock measured. For determination module of deformation were used Dilatometery test method. In this method expanding of borehole diameter derived of cell pressure are measured directly. This test is reasonable for some weak rock like Argillite. In this stage six vertical boreholes and two horizontal borehole of the Shaft wall were tested. Summery Result of in-situ and laboratory tests of rock's periphery of the shaft is shown in table 1.[1].

Considering to the physical and mechanical parameters of rock, especially in the vicinity of water, consolidation grouting of foundation were performed. Furthermore, according to result of analysis for stability of Intake Tower in extreme load conditions numbers of 32 bar anchors were installed on the foundation of Tower. Length of anchor in the rock is 16m that 6 m end of them are restraint with grout and then prestressed up to 80 kpa, next fully grouted. These conditions are affected on the mechanical parameters of foundation rock that is considered on modeling with back Analysis, which is explained later.

3 MONITORING

One of the important methods for monitoring of rock for controlling of safety is regular measurement of deflection and displacements. With this method regarding to the rate of variations, behavior of system are predicted. On the Intake Tower of Doosti Dam besides some surveying points on tower body, numbers of 4 Extensometers on the foundations were installed. Every extensometer has four fixed points, that it monitored four level of rock around the Shaft. Length of

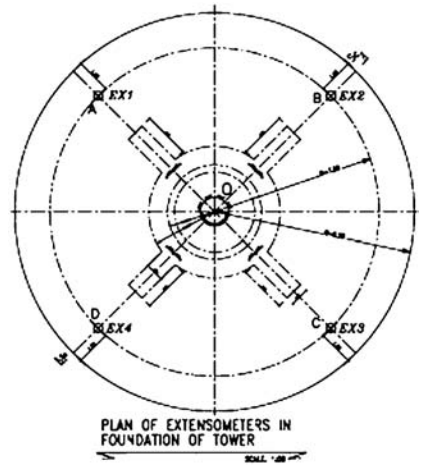

Figure 3. Position of extensometers on foundation of tower.

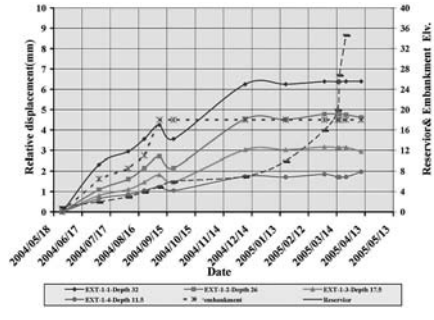

Figure 4. Variation of foundation relative displacement No. 1 with embankment and water level from March 2004 to 2005.

restraint of extensometer is performed in 11.5, 20, 28 and 32 m from top of tower foundation. Thickness of tower foundation is 8 m. Positions of extensometeres in figure 3 are shown.

Extensometers were installed after completion main part of Tower, foundation treatment with consolidation grouting and anchors bars installation. Therefore effect of dead load of tower and prestressed force of anchor bars weren't considered. But effects of stage construction of embankment were monitored by extensometers. In figure 4 variation of deflection on the tower foundation at the duration of dam body construction and the impounding of reservoir from 2004 to 2005 are shown. [2]. Horizontal axis is date and vertical axis at left side is relative displacement of extensometer No. 1 in millimeter. Furthermore, variation of embankment on foundation and depth of reservoir water are shown at right side of graph in meter from Bed River.

Like it is shown in figure 4, large proportion of displacement is related to the effect of loading's embankment and trend of increasing on graphs is

similar. But effect of water rising in reservoir on deflection of extensometer is low that the main reason is unloading due to buoyancy effects on weight of tower and embankment's materials. In this graph sensible short term effects of water on physical and mechanical parameters of rock not observed too.

4 MODELING AND ANALYSIS

Modeling of Shaft-Rock and Tower system was made using with Flac3D software. This software is an explicit finite difference program to study numerically the behavior of a continuous three dimensional medium as it reaches equilibrium or steady plastic flow. [3]. Modeling in this software are performed by making of 3D meshed model with brick elements that they behave according to the mechanical properties and model of materials under external or internal loading and boundary conditions and are developed to the yield state. In this software regarding to method of analysis and solution of equations (Explicit Lagrangian method), calculation time and solution problems is less than other FEM soft wares.

In the first stage of modeling, limitation of model is recognized and rock in dimension of 100 m by 100 m and 50 m depth were modeled. Then shaft are excavated and lined. In the Next, Intake Tower on the shaft is constructed. According to the stage of construction, modeling was performed in program. In the modeling procedure, has been made an attempt real conditions of model was considered. In figure 5 models of Rock, Shaft and Tower is shown.

4.1 *Material model*

In the second stage regarding to material properties, behavior of materials are determined. For rock foundation materials around the shaft Mohr-Coulomb plasticity model was used. This model is one of the most applicable for Geoengineering studies. Mohr-Coulomb model is used for materials that yield when subjected to shear loading, but the yield stress depends on the major and minor principal stresses only. Main Parameters for model is cohesion and friction angle that the initial amounts of them in table 1 are available. Final parameters for rock after back analysis were determined and are used for calibrated model. Material model for the Shaft lining and Intake Tower are considered elastic. These materials are assumed homogeneous, isotropic and continuous that exhibit linear stress – strain behavior.

4.2 *Boundary conditions*

In the next stage boundary conditions of model should be recognize. The boundary conditions in a numerical model consist of the value of the field variables that are prescribed at boundary of the numerical grid. Boundary can be either real or artificial. The model boundary must be far enough away from the region of study so that response is not adversely affected, that appropriate distance depends on the purpose of analysis. Generally boundary should be 3 to 5 time the size of the cavern. In this model distance of boundaries in x and y directions 50 m are considered that enough for this type of analysis. Roller Displacement boundary has been applied on all five sides that causes the stress and displacement to be underestimated. This fact has to be considered while interpreting the result.[4].

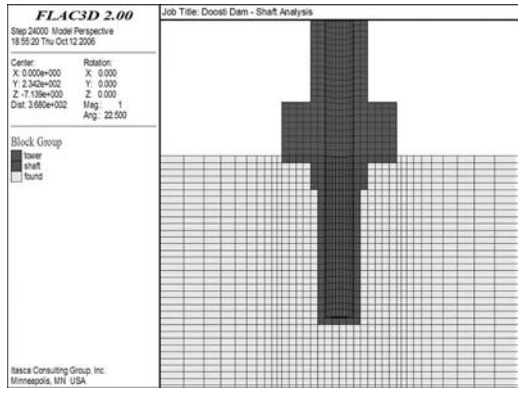

Figure 5. Modeling of Rock-Shaft-Tower in Flac3D.

4.3 *Stage analysis*

As it explained at the last parts, three stages for analyzing of model before loading are considered. At the First stage, model before excavation was analyzed to equilibrium of model that initial stresses in model generated. Displacements at end of this stage reset to zero. Second, shaft is excavated and lined with Thickness and geometry In the real state, consolidation grouting in the shaft's rock was performed in this stage and effect of them as increasing module of deformation in the back analysis are considered. Third, in this stage Intake Tower was modeled. Weight of tower is about 7800 tons that is considerable for determination of initial stresses in the shaft rock before instrumentation. The number of anchor bars is 32 with post tension forces about 80 kpa per anchors, that loading as uniform load on model was considered. At end of this stage, reset displacement to zero. In the last three stages, for material parameters of rock and concrete in model, initial parameters of the field and laboratory test of the studies stage are used. In the next stage, considering to the installation of instruments, model were calibrated after back analysis and determination of final parameters. Result of stress analysis of model and relative displacements before installation of extensometers in figure 6 are shown.

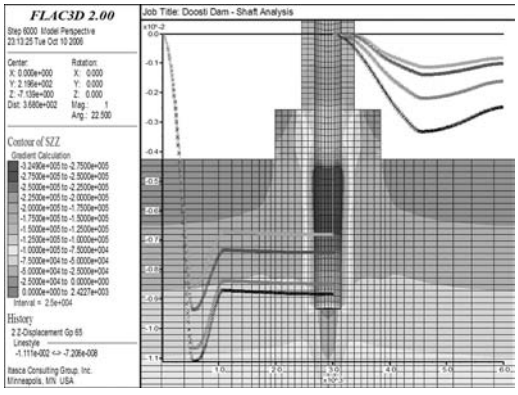

Figure 6. Results of stresses and relative displacements before installation of instruments.

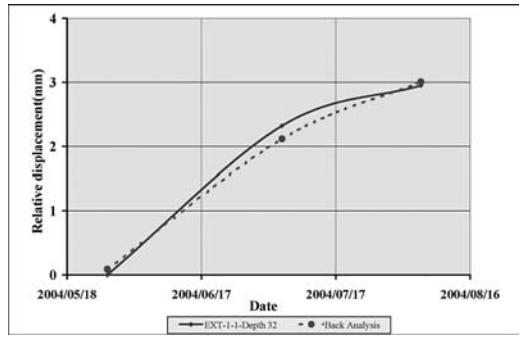

Figure 7. Compare displacement of extensometer and analyzing with final parameters.

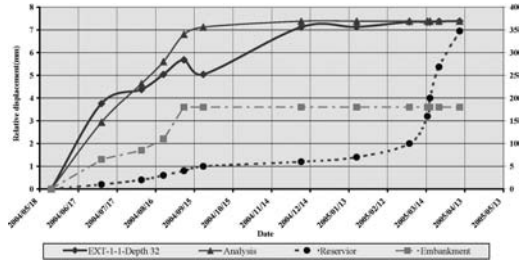

Figure 8. Displacements variation during of loading.

4.4 *Back analysis*

Considering to the variation of mechanical rock parameters at during of construction of Shaft and Tower and effect of foundation treatments, it is necessary that the main parameters of rock are determined. In this stage regarding to data of extensometers, Back Analysis was carried out. Before back analysis, for determination of main parameters, sensitive analysis on friction angle, cohesion and module of deformation are done and module of deformation according to the effect on displacements of model was defined for back analysis. Initial amounts of friction angle and cohesion regarding to the range of variation and effect on results are selected. For module of deformation, Back Analysis with direct method was performed [5]. In this method with minimizing of deference's square of displacement for extensometers and displacement of analyzed model, as equation (1), reasonable amount for module of deformation are determined.

$$\sum (U_m - U_p)^2 = Min \qquad (1)$$

In this equation U_m is amount of measured displacement from extensometers and U_p is predicting displacements of model after analyzing. This equation is used for 16 points that extensometers have had data. Regarding to the range of modules 1.1 Gpa to 2.6 Gpa from reports and site investigations, during 18 analysis minimum of error for 1.5 Gp is determined. As it explained, the first stage of embankment's loads for back analysis was applied, because in this stage, loading are uniform. In figure 7 Data's extensometer compared with displacement of analyzed model using final parameter of back Analysis.

After determination parameters of analyze, model are calibrated for applying loads with final parameters. In this stage, loading are included effects of embankment and reservoir elevation that were applied gradually. Maximum elevation of embankment on the shaft's rock is 26 m with density 2.0 ton/m^3. Loading of embankment was applied to model as uniform load that increased to 26 m in three stages.

Effect of water as pressure was applied to the model. Because this load acts after embankment, sequence of loading was considered. In this stage weight of intake Tower and embankment's materials reduced caused effect of buoyancy and Reservoir elevation rose up to the normal water level. In this study, notwithstanding, reservoir elevation haven't rose to this elevation yet, but for control safety of Tower and Shaft, up to normal water level in reservoir, model was analyzed and stresses and deflections were checked. Variation of displacements during the whole of loading is shown if figure 8. As it is shown, parting of loads stages in excavation of shaft, construction of shaft lining, Tower and embankment are cleared and coincidence of results with instrument's data is acceptable.

Stresses in Shaft are shown in figure 9. As it has shown, increasing of vertical stresses in Shaft lining regarding to the weak parameters of around rock is important. Structural function of shaft's lining in distribution of loads effect on the rock is reasonable.

Regarding to the maximum deflection of foundation and stresses in the shaft lining (8.6 Mpa), Intake Tower and shaft under maximum static loads in normal condition of loadings is safe.

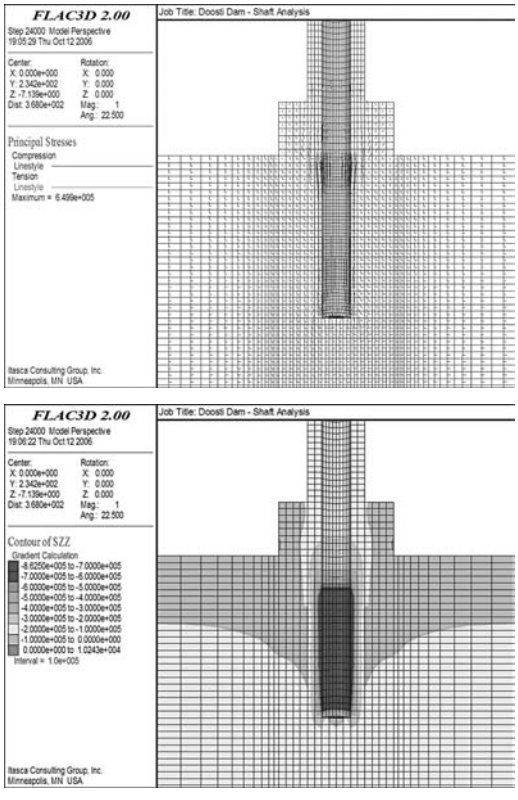

Figure 9. Distribution vertical and horizontal stress in shaft and rock.

5 CONCLUSIONS

1. contrary to the result of some laboratory tests, effect of water on physical and mechanical quality of shaft's rock in the short term is low.
2. considering to the weak rock around the shaft, effect of geometry and structural parameters of lining for reasonable distribution of tower loads on rock is more important.
3. comparing results of dilatometery tests after excavation of shaft and final parameters of back analysis indicate positive effect of foundation treatments.
4. regarding to the analysis results, condition of Shaft and Intake Tower at end of first filling is acceptable.

Membrane waterproofing – Activation of the grouting system and its re-sealing ability

R. Matzner
Matteo spol. s r.o., České Budějovice, The Czech Republic

M. Grossmann
Minova Bohemia s.r.o., Ostrava, The Czech Republic

ABSTRACT: For new tunnel structures and underground line structures, then in existing practice the lining of these constructions is designed for waterproof class 0. However, the lining of these structures contain many activities where human factor plays an important role. This presents many risks to the waterproof layer which is the most problematic and the worst repaired element of the lining – in fact after production of the secondary lining, this layer is not accessible, i.e. it cannot be repaired in a standard manner. Therefore, in the case of tunnel structures it is purposeful to apply a safety system for the waterproof insulation which enables effective action in the case of problems with the waterproof insulation. If such a system is correctly designed, performed and used, it is possible, if necessary, to be used again and this system will maintain its functionality in the long term.

1 INTRODUCTION

Waterproof insulation of the lining of tunnel structures is currently made of special waterproof foils. This mostly concerns a sophisticated system of products which, in addition to the waterproof foil, contains sealing strips for the expansion joints, various shaped units and anchoring elements, protection geotextiles and special glues. Foil insulation systems function very reliably but their 100% functionality is characterized by several aspects. First of all they are very demanding for the quality of the base, for maintaining the placement technology and, in particular, for the exact performing of all joints and other details. Protection of the placed insulation is also important in order to prevent damage during subsequent work starting from the placement of the reinforcement through to the placement of the form of boarding up to the concreting of the secondary lining. Within such a complicated construction process influenced by many inputs it is very difficult to prevent errors which can have a negative influence on the efficiency of the waterproof insulation. It is necessary to take these problems into consideration in advance and to prepare conditions for fast and effective action. Therefore, it is recommended to complete the injection protection system in the design phase where it can be easily activated if necessary, i.e. in the case of the occurrence of leakages and to remove these leakages. This is mainly valid in the case of intermediate foil insulations performed along the whole perimeter of the structure (the so-called "submarine" type) where the underground structure is submerged into the underground water and no its drainage effect is reflected.

Such an injection protection system was used in 2004 for prolongation of northern line C of the Prague Metro in the operating system indicated IV.C1 and in the same year it was also used in the Mrázovka road tunnel which is the part of the Prague inner city ring road.

2 UNDERGROUND IV.C1

2.1 *Tunnel design*

The tunnel was excavated using the NRTM method in the areas of rock with the rock clay and sand stone types. The work was reinforced depending on the stability of the rock by hydraulically expandable beams of the BOLTEX type and by boring R type anchor bars in combination with injection by cement suspension. The primary lining is from sprayed concrete and the secondary lining is made of cast concrete. The intermediate insulation is made of strips from Sikaplan V Tunnel transparent TR 30 softened PVC with a thickness of 3 mm, joined by welding by hot drift or hot air. In the cross-lateral and longitudinal working and expansion joints there are Sika Fugenband joint sealing strips to which the Sikaplan foil is connected.

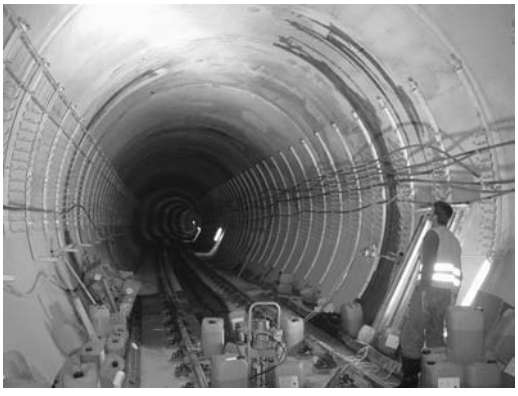

Figure 1. Metro IV.C1 – grouting in the single-track running tunnel.

Waterproof insulation is completed with the injection protection system consisting of two parts. In the expansion and working gaps are injection hoses and in individual sectors throughout the whole area there are injection and aeration hoses fixed to the foil insulation which terminates in the boxes of the central outlet in the secondary lining. The length of the individual sectors is 10 m for the two-rail tunnel and 7.0 m or 7.5 m for single-rail tunnels according to the type of the boarding. The length of the construction joint on the perimeter of the tunnel tube is 29 m. The area of one sector is about 290 m^2. The division of the tunnels into sectors enables to rehabilitate only those sectors which were damaged and had leakages. In Kobyliská station the protection injection system is designed as a floor type with two collection boxes on each side of the section.

2.2 *Defects*

The underground line in the section between Holešovice railway station and the new Kobylisy station has a height difference of 112 m and runs through a territory containing complicated hydro-geological conditions. The Kobylisy station is very unique by its design and it is the largest single-aisle bored station to ever have been constructed in the Prague Metro. In the final stage of the final (secondary) lining, leakages were reflected. The most frequent symptoms were:

- leakages in construction and expansion joints,
- leakages in the area of sectors which were reflected by leaks from the lining,
- local leakages, in particular in the places of the control points of the concreting in the top points of the arc (working name “spy”),
- escapes in complicated construction areas (e.g. connection of the station to escalator tunnels and the contact of the cable shaft with the railway tunnels).

Figure 2. Metro IV.C1 – grout injection into a joint in the vault of the Kobylisy station.

These leakages were removed with the use of the injection protection system, but because there was no experience with the activation in such a scope in the Czech Republic, it was necessary to look for the optimal solution. In particular, it was necessary to find suitable injection material which would fulfil the stated criteria. The common requirement of the general designer, the general supplier and the supplier of the waterproof foil system was to perform the rehabilitation of penetration through such injection material which would fulfil the following requirements – high flexibility, excellent sealing properties, ability to permanently ensure the sealing function, resistance to aggressive influences and, at the same time without any damage to the intermediate waterproof foil by any chemical composition.

2.3 *Activation of the backup grouting system*

The company CarboTech – Bohemia s.r.o. (now Minova Bohemia s.r.o.) was requested to prepare a technical proposal for the rehabilitation of individual types of defects with the aim to prevent penetration into the tunnel tube. For injection work both protection systems were used – injection hoses and local injection. Penetration on construction joints with inserted injection hoses was proposed to be stopped by

Figure 3. Metro IV.C1 – grouting in the double-track running tunnel.

Figure 4. The Mrázovka tunnel – testing of the passableness and continuity of the grouting system.

using CarboCryl T methacrylate gel, developed specially for this case. For stopping the penetration in the area of individual sectors it was proposed, due to the impossibility of precisely localising the defect in such large area, the complete filling by CarboCryl Hv, or CarboCryl Wv methacrylate gel. Prior to this step each section was "separated" by injection into joint strips. Injection work was performed by low-pressure injection with the use of a WIWA pneumatic pump followed by the Booster 10A pump which has a higher output. The consumption of injection material in individual sections was different depending on the scope and the manner of the defect of the intermediate insulation. On the basis of knowledge achieved during the activation of the protection system, on regular control days the further procedure was stated. Immediately after termination of injection, the filling hoses of the injection system were cleaned in order to endure their throughput for the next injection in the case of an occurrence of penetration.

Stronger local escapes in the top points of the arch were pre-sealed by high-pressure injection with Bevedan – Bevedol WF and Bevedan – Bevedol WFA polyurethane resin (currently the delivered modified CarboPur WF and CarboPur WFA types). The injection was performed through packets mounted into the holes in the concrete secondary lining. A DV 97 electric pump was used to do the work. Consumption in these cases did not exceed the volume of 10 litres per one sealing area.

In the Kobylisy station the situation was more complicated. After commissioning, the access to the face of the inside walling was disabled due to the additional mounted lower ceiling tiling from enamelled metal sheet. Therefore, it was decided to perform a whole surface injection of the station. Moreover, it is not possible to design the insulation of the arch as a sector due to technical reasons. Using the whole surface injection a similar effect was achieved with lower financial costs. Local penetration and leakages were removed and in fact, the waterproof insulation was doubled. The average consumption of the CarboCryl Hv injection gel during the whole surface injection did not exceed 5 litres/m^2 of the sealed area.

Costs for activation of the injection system did not exceed the values of similar constructions which were confirmed by expert opinions.

The injection work was performed by MATTEO s.r.o., and CarboTech – Bohemia s.r.o. delivered the injection materials and performed the technical consultancy, in particular during the preparation of the technical proposal for rehabilitation and during the commencement of the injection work.

After commissioning of a new underground section, one additional sealing of five newly created escapes was performed. In none of these places had any sealing injections been performed by that time. These additionally created defects were evidently caused by additional firming of the upper layers or an increase in the level of underground water. These latest activities were performed during night closures between 01:00 and 03:00 in the morning during the common operation of the Metro. During this time-restricted work the accessibility and functionality of the injection system was positively evaluated. When using another system than the used injection system, during the 45–60 minutes reserved for the injection, it would not be practical to perform the sealing within the necessary scope. Last but not least, the success of these actions was supported by the experience and the organisation of the work of the injection teams. Consumption of material during this action varied by only approximately 200 kg gel per penetration.

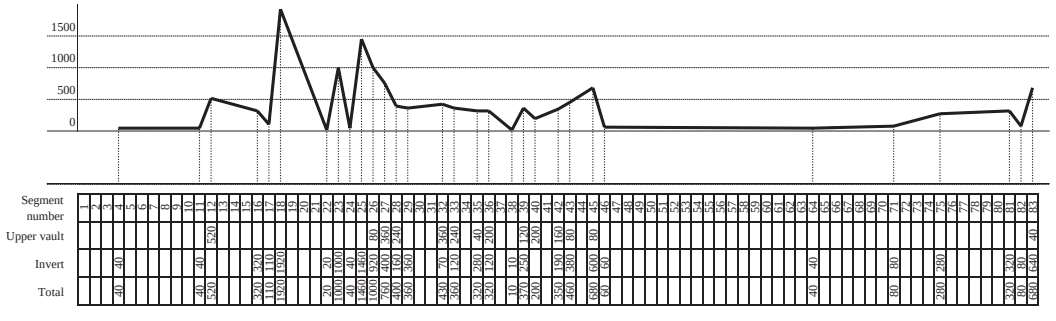

Diagram 3. The Mrázovka tunnel – the eastern tunnel tube – the time story of the injection gel consumption (lt.).

3 MRÁZOVKA

The second completed tunnel for which part of the waterproof system was the protection system of injection hoses was the Mrázovka road tunnel.

3.1 *Tunnel design*

The tunnel was excavated by the NRTM method in the rock environment of slate with the occurrence of quartz rock. In the case of the Mrázovka tunnel in the mentioned locality there are very complicated hydro-geologic conditions which led to a similar proposal of waterproof insulation as in the case of the Metro tunnel – whole surface closed foil insulation located between the primary and secondary lining. For the Mrázovka tunnel, a SARNAFIL MP 915-30 B2 polyethylene waterproof foil was used with a thickness of 3.2 mm with a signal layer. Geotextile NETEX 800 B2 was used as the protective layer. In the place of the working joints between the construction of a calotte, bridge deck and supports located in parallel to the longitudinal axis of the tunnel tube, the waterproof insulation is equipped with a reinforcing strip of insulation with a width of 500 mm. In the whole area of the lower arch is a waterproof layer which is protected against damage by N8-25 protective foil with a thickness of 2.5 mm. Welding of the foil was performed by semi-automated welding machines on the principle of hot drift, details were performed manually by hot-air electric welding devices.

The insulation system is based on the creation of individual cross-lateral sectors which are mutually separated by Fugenband AFI 600/35 MP joint strips located in the cross-lateral joints. In addition to the cross-lateral joints the same joint strips are used for horizontal construction joints between the lower and upper arch. In both cases the strips are welded on their perimeter to the insulation foil. This construction divides the whole tunnel tube into segments with average lengths of 7.5 m. The mutual connection of horizontal and vertical strips was performed by manual welding. As cross joints were not permitted, the lower strips are continuous and the cross-lateral strips are shifted at the upper and lower arch by approximately half of the segment.

The protection system consists of two separate circles. The first circle is represented by injection hoses located in the upper arch of the secondary lining. These are used for filling of the wall cavity and holes which may originate in the top part of the upper arch during the concreting of secondary lining. In these cases, cement plaster is used for injection.

The second circle of the protection system is used for additional sealing injection in the case of the occurrence of defects in the waterproof layer. The principle of the solution is similar to that used in the Metro IV.C1 tunnel. In segments specified by horizontal and vertical joint strips, injection and aerating hoses are spread out which are fixed to the insulation foil and directed to the central outlet in boxes. These are mounted at about 10 m in the support of the tunnel. In the place of the joint strips it is not necessary to mount injection hoses because the joint strips contain channels which fulfil the same function as the injection hoses. It was only necessary to perform the connection of the filling hoses to the channels and perform their termination in the boxes on the central outlet.

3.2 *Activation of the backup grouting system*

In the case of the activation of the protection system in the Mrázovka tunnel, the situation was significantly simplified by the acquired experience from the Metro IV.C1 tunnel. Due to the fact that the system for both tunnels was very similar, it was possible to perform the sealing injection in a similar manner with the use of the same substances – CarboCryl Hv and CarboCryl T methacrylate gels. This work was performed by MATTEO s.r.o. in cooperation with CarboTech - Bohemia s.r.o. as the supplier of injection substances.

Very small resistance of the protection injection system and channels in joint strips against outside pressure was a big problem. This caused blocking of the system during the filling injection by cement and low tightness and leakage during the activation of the protective injection system by gels.

Additional sealing of newly originated escapes ascertained during revision inspections after the commissioning of the tunnel was performed during three regular closures of the tunnel. This concerned very minor escapes or penetration into the collection boxes and in most cases it concerned areas in which the activation of the protection inspection system was not performed. Similarly as in the case of the metro tunnel there was effecting by underground water increased to the stable level.

4 CONCLUSION

It is possible to demonstrate with the examples of the prolongation of the Metro in section IV.C1 and the Mrázovka road tunnel that the completion of waterproof insulation systems of constructions by injection protection systems has its importance mainly for intermediate foil insulations performed along the whole perimeter of the underground structure (“submarine” type). It uniquely contributes to the achievement of the full functionality of the insulation which, due to the scope of the described structures, the complicated hydro-geological conditions and other limited requirements would mean in the case of a standard manner of performing injection work a significantly higher time and price demand. The important aspect for selection of the technical solution submitted by CarboTech – Bohemia s.r.o. was the fulfilment of the requirement to keep the throughput of the protection system after the performed injection. This requirement could be fulfilled due to the application of CarboCryl methycrylate gels and the experience of MATTEO s.r.o.

The main idea of the combination of waterproof insulation and a protection injection system is not only the simplification of the injection work in the time of the completion of the construction of the work and before commissioning. If such a solution is applied which keeps the functionality of the protection system in the future, it is possible to use this system at anytime. It is possible to rehabilitate leakages which can be reflected later and are adapted to the final completion of the work, change of outside conditions, etc.

Geomechanical studies for a road tunnel in volcanic formations

A.T. Menezes, F.M. Varela & L. Ribeiro e Sousa
University of Porto, Porto, Portugal

F. Moura
University of Minho, Guimarães, Portugal

ABSTRACT: The extremely mountainous and the heterogeneous volcanic rock formations of the Madeira Island led to the construction of an important road network where the tunnels are dominants, representing about 14% of the total network. In this paper the analysis of a road tunnel between Caniço and Camacha is presented, along with the description of the construction and of the geotechnical information. The evaluation of the geomechanical rock mass properties using empiric systems and 2D and 3D numerical analysis of sections of a tunnel are presented. Finally an empirical system that was developed for tunnels in volcanic rocks common at Madeira Island is also presented.

1 ROAD TUNNELS AT MADEIRA ISLAND

The road tunnels of new transport system of Madeira Island were strongly affected by the heterogeneous and complex volcanic formations, by the topography and by the land occupation. All these factors originate the design of a large spectrum of innovative structural solutions that permit to achieve economic solutions more adequate to the topographic and geological conditions.

The new road transport network, with high radii curves and more reduced longitudinal inclinations permitted easy and comfortable accesses to the whole island. The regional road system length is about 546 km, with about 78 km in tunnels. In the new highways the relation is about 43% in tunnels, in total of 173 km. More important works are still planned, mainly in the Northern part of the island, also with an important of these being tunnels (Moura and Sousa 2006).

The geology of Madeira Island comprise five volcanic complexes (Figure 1): $\beta 1$ – mio-pliocenic volcanic complex of Curral das Freiras, Serra de Água, Vale de São Vicente and Vale da Boaventura, in west part of the island and Ruivo e Areeiro mountains, São Roque, Porto da Cruz, Machico and Ponta de São Lourenço; $\beta 2$ – pos-miocenic volcanic complex at Ribeira da Janela, Porto Moniz, Ponta do Pargo, Ribeira Brava and Câmara de Lobos, in the west part, and Funchal, Camacha, Santa Cruz and Santana, including tuffs at Arco de São Jorge; $\beta 3$ – pos-miocenic volcanic complex of Paúl da Serra, Achada da Pinta and Lombada das Vacas, at west part, and Lombada do Meio, Cabeços de Fajã dos Vinháticos and Terreiro da Luta, in the east part of the island; $\beta 4$ – Superior basaltic complex of Paúl da Serra, Chão dos Balcões, Poiso and Achada do Teixeira; $\beta 5$ – Modern basaltic lava of Porto Moniz and the valleys of São Vicente and Seixal.

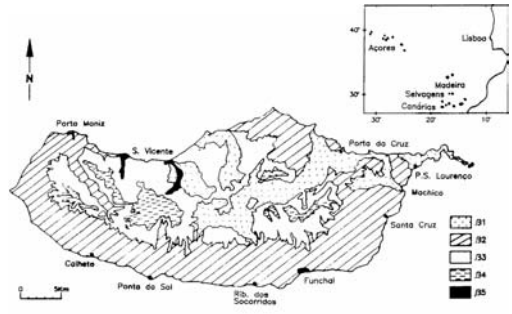

Figure 1. Identification of the geological-geotechnical formations at Madeira Island.

The transversal section of the road tunnels at Madeira Island Region have a horse-shoe (semi-circulat arch) cross section with a span of 9.0 m, for tunnels with one directional of traffic and 9.6 m for tunnels with two directions of traffic. Both types of tunnels consist of two lanes with a width of 3.5 m. In some older tunnels a semi-elliptic arch was adopted (João Gomes and Jardim Botânico tunnels). Some tunnels may have up to three (Pestana Júnior tunnel) or

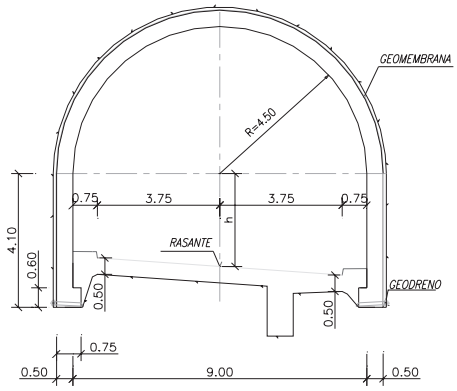

Figure 2. One traffic directional tunnel with two lanes.

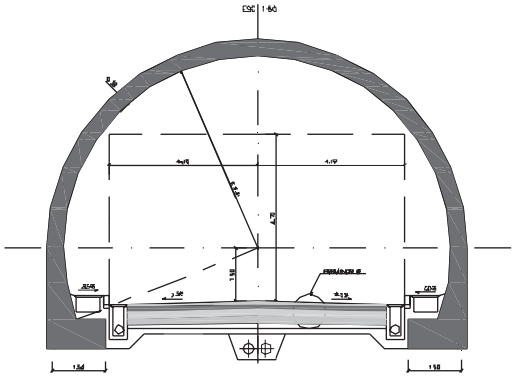

Figure 3. One traffic directional tunnel with two lanes.

four lanes (Santa Cruz West and East tunnels). Here the width is 18.5 m, in order to allow 2 lanes in each direction, separated by a central separator.

Figures 2 to 4 presents examples of geometric characteristics of road tunnels constructed at Madeira Island.

2 CANIÇO-CAMACHA TUNNELS

In order to establish a road liaison between Cancela and Nogueira located in the towns of Caniço and Camacha, respectively, important viaducts and tunnels were constructed in a mountainous region of Madeira in an extension of about 3.9 km. Of these an extension of 2.44 km (63% of the total) consisted of four tunnels. They have two directional of traffic with a lane in each direction (until km 0+725 including Tunnel 1) and with two lanes in the North direction (since km 0+725) for heavy traffic (trucks).

This paper is focus in Tunnel 2. Two sections are being considered, A (km 1+167) and B (km 1+256). Section A crosses a zone of disaggregated to moderate

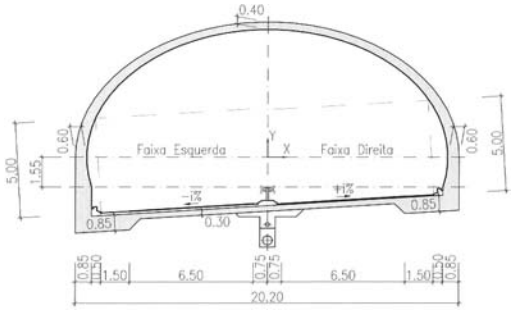

Figure 4. Two traffic directions tunnel with four lanes.

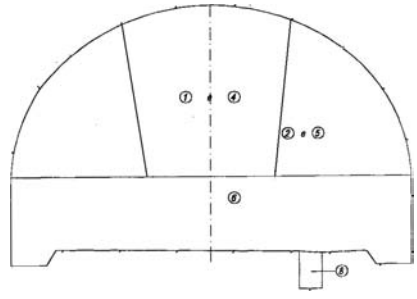

Figure 5. Construction sequence for section A.

compacted breccias. Section B corresponds to a zone of disaggregated and compact breccias, and compact basalts.

The design of supports adopted for the different types of rock formations were based on empirical methodologies (Viés 2001). In this tunnel supports used on both sections A and B were the following: bolts – length of 4 m, 20 mm in diameter and a capacity of 177 kN, 1.5 m spacing in the ceiling and 2.0 m in the walls for section A and 1.0 m for section B; shotcrete −10 cm in thickness for section A and 5 cm for section B; steel linings – only for section A, a profile HEB 160 spacing of 0.8 in upper part of the section. As usually done at Madeira Island a final concrete support was adopted with a thickness of 30 cm was adopted.

The construction process adopted is the Sequential Excavation Method (SEM). Due to the strong heterogeneity of the volcanic formations the construction was versatile in order to consider the adaptability to the different geotechnical conditions. Section A of Tunnel 2 has an overburden of about 3.9 m, composed by rock material of weak geomechanical quality. The construction sequence is illustrated in Figure 5. Section B has an overburden of 26 m composed of basalt of good geomechanical. The construction sequence is presented in Figure 6.

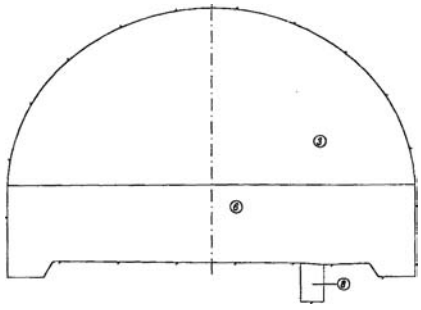

Figure 6. Construction sequence for section B.

Table 1. Results of uniaxial tests.

Samples		E	σ_c
Borehole	Depth(m)	(GPa)	(MPa)
S2	19.8–20.25	–	117.5
S5	8.55–8.85	–	1.55
S12	12.6–12.97	14.7	63.8
S13	31.4–31.7	–	316.0
S14	9.2–9.55	37.0	63.3
S38	20.3–20.95	–	2.2

3 EVALUATION OF THE GEOMECHANICAL PARAMETERS

Tunnel 2 is located in the volcanic complex β^2, that is composed by basalts and by piroclastic materials with variable dimensions like tuffs, breccias and scoria. The geotechnical survey of the tunnel consisted of boreholes and laboratory tests. The deformability and strength properties were estimated based on laboratory tests results. Table 1 shows some results of the Young modulus (E) and uniaxial strength (σ_c). The results from the survey show highly complex heterogeneous formations from complex β^2 with different types of formations apart the surface soil formations with about 3 m thickness:

Compact basalt – predominant lithology with a weathering degree between W3 to W1-2; RQD between 60–100; E = [17–46]GPa and σ_c = [35–100]MPa.

Volcanic breccias – with the basalts is also an important lithology with a matrix highly variable, being more or less compact. The weathering degree varies between W4 to W3; RQD is in average 50, being null in the disaggregated breccias; E = [0.1–33]GPa and σ_c = [1–35]MPa.

Volcanic tuffs – the less important lithology appearing in the upper part of the rock mass. The weathering degree varies between W4-5 to W3; RQD is in average 60, with a wide spectrum; E = [0.1–5]GPa and σ_c = [0.9–18]MPa.

Table 2. Geomechanical parameters.

Parameter	Disaggregated breccia	Moderate compact breccia	
Section A			
γ(kN/m^3)	25	25	
E (GPa)	1.5	3.6	
σ_c (MPa)	10.3	10.3	
m_b (HB crit.)	0.154	0.682	
s (HB crit.)	5.44×10^{-6}	0.0002	
Parameter	Disaggregated breccia	Compact breccia	Compact basalt
Section B			
γ(kN/m^3)	25	25	29
E (GPa)	1.6	5.6	19.5
σ_c (MPa)	10.3	10.3	170
m_b (HB crit.)	0.154	0.605	1.572
s (HB crit.)	5.44×10^{-6}	0.0002	0.0023

The geomechanical parameters were determined through the RMR empirical system. Relevant average geomechanical parameter values are presented in Table 2. Probabilistic approaches and a software developed for underground construction designated GEOPAT were used to obtain a probabilistic distribution and average values (Costa et al. 2002; Miranda et al. 2005).

4 STRUCTURAL BEHAVIOR OF CANIÇO-CAMACHA TUNNEL

The structural analysis of Tunnel 2 was performed using the software Phases2 from Rockscience for 2D analysis and FLAC 3D from Itasca, for the 3D analysis. The two referred sections A (portal section) and B.(inside the rock mass) were considered. The in situ state of stress adopted considered a ratio of 0.8 between in situ state horizontal and vertical. Section A analysis required a 3D model using 93527 nodal points and 2464 shell elements (Figures 7 and 8). For section A and using 2D approaches Figures 9 and 10 reveals the initial and final meshes.

The maximum settlement at the tunnel crown was about 5.8 mm and maximum convergences measured were equal to 10,0 mm. Settlements at surface were also evaluated in order to assess any possible damage on the buildings. The yielded zones were evaluated. They are mainly located at the disaggregated breccia that exhibited low strength.

Some results of the 2D analysis of section A are presented in Figures 11 and 12.

As a result two situations for the reinforcement of the crown tunnel were analyzed. One considered the

use of forepoling and other the use of bolts. The use of forepoling led clearly to the reducing of the yielded zones of the rock mass.

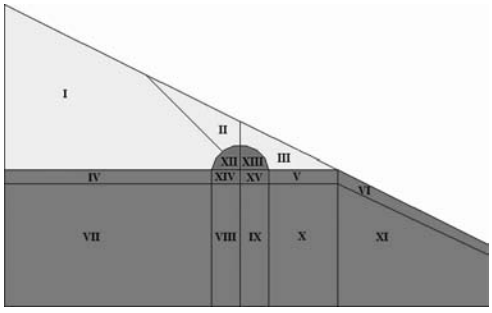

Figure 7. Detail of the 3D mesh near the tunnel.

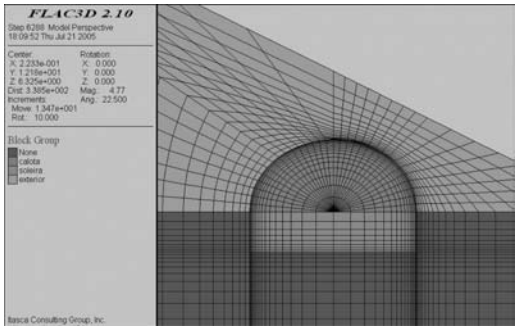

Figure 8. Detail of the 3D mesh near the tunnel.

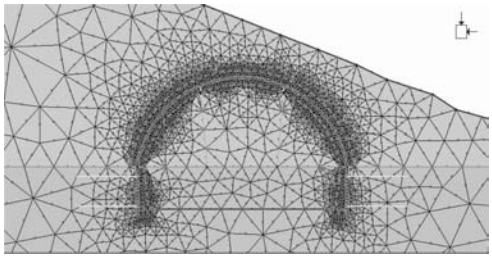

Figure 9. Initial 2D mesh for section A.

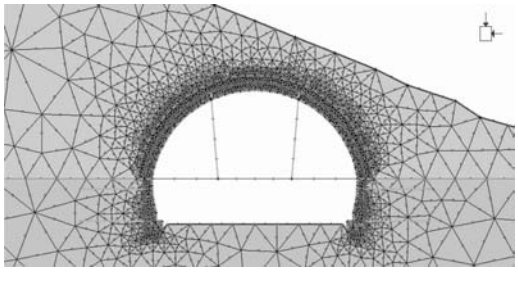

Figure 10. Final 2D mesh for section A.

In the portal 3D analysis were performed considering a 5 step excavation sequence following as proxy as possible the construction procedure. Table 3 indicates the geomechanical properties adopted at FLAC 3D.

Figures 13 to 15 present some obtained results at the last excavation stage. A comparison with 2D results shows that the displacements obtained with the 3D

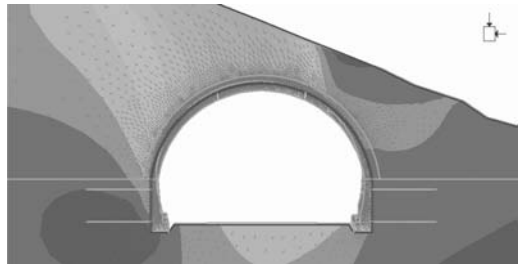

Figure 11. Displacements in the last stage.

model were higher. The maximum displacement is in this case of about 1.7 cm, in the left side of the crown. The maximum stresses are registered in the vicinity of the excavation e mainly in the walls.

5 EMPRICAL SYSTEM FOR VOLCANIC ROCK FORMATIONS

An empiric system was developed specifically for volcanic rock formations. It was adapted by the RMR system and by a classification developed at IPT, São Paulo, for the design of several tunnels in basaltic formations (Ojima 1981).

The geomechanical characterization developed at Tunnel 2 revealed that the volcanic formations were mainly composed by breccias and basalts from the volcanic complex β^2 existing regions with a high level of weathering and crashed.

The following parameters were considered for this empirical system:

- Uniaxial compression strength
- Rock characteristics

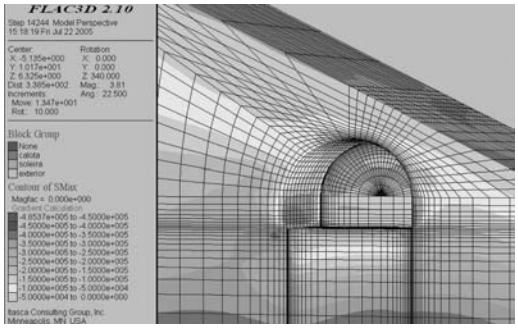

Figure 14. Principal stresses at final stage

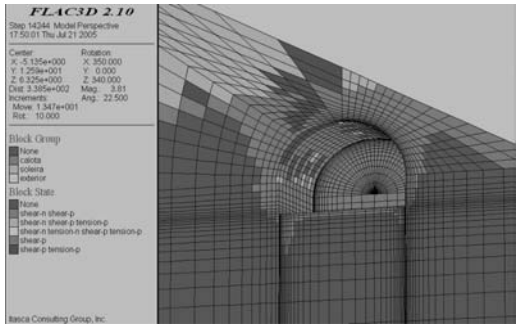

Figure 15. Yielded elements in the last stage

Table 4. Application of the proposed classification for volcanic rocks.

Parameters	Rock Mass classification and weights				
P_1	Uniaxial strength	R_1	R_2	R_3	R_4	R_5
		>120 MPa	60–120 MPa	30–60 MPa	15–30 MPa	<15 MPa
	Weight	15	9	6	3	1
P_2	Rock weathering	A_1		A_2		A_3
	Weight	20		12		4
P_3	Joint frequency	F_1	F_2	F_3	F_4	F_5
	Weight	25	20	15	10	5
P_4	Joint surface conditions	B_1	B_2	B_3	B_4	B_5
	Weight	30	25	17	10	0
P_5	Presence of water	C_1	C_2	C_3		C_4
	Weight	10	7	4		0
P_6	Block position	Very favorable	Reasonable	Acceptable		Not favorable
	Weight	0	−2	−5		−10

Classification of the rock mass

Final indexes	Rock mass class	Description of the class
100–91	I	Excellent
90–76	II	Good
75–61	III	Reasonable
60–41	IV	Regular
40–21	V	Poor
20–0	VI	Very poor

Table 5. Parameters for rock weathering.

Parameter	Description
A1	Sound or practically sound
A2	Median weathered
A3	Highly or very highly weathered

Table 6. Parameters for joint frequency.

Parameter	Description
F1	Joint spacing >1 m
F2	Joint spacing 0.25–1 m
F3	Joint spacing 0.1–0.25 m
F4	Joint spacing 0.06–0.1 m
F5	Joint spacing <0.06 m

Table 7. Parameters for joint surface conditions.

Parameter	Description
B1	Rough joints without continuity, closed and hard walls
B2	Slight rough joints with an aperture <1 mm and hard walls
B3	Slight rough joints with and aperture >1 mm and soft walls
B4	Joints with soft walls with filling material and aperture <5 mm
B5	Joints with filling material, continuous and aperture >5 mm

– Intensity of jointing
– Discontinuity conditions
– Presence of water
– Disposition of blocks.

In the proposed empirical system different weights were attributed for the different conditions of each parameter. Table 4 represents the used methodology and the classification proposed. The meaning of the different parameters is referred in Tables 5 to 8. The new system was applied to the several volcanic formations with the results shown at Table 9.

A rock mass formation designated by VI has a behavior conditioned by the rock characteristics in terms of deformability and strength; while a formation designated by class I behave in accordance with the characteristics of discontinuities. In relation to the remaining classes their behavior is determined by the conjugation of both types of characteristics.

Other parameters were not taken into consideration in the proposed classification as is the case of discontinuity orientation and the operational parameters. The evaluation of the discontinuity orientation is a complex process since the identification of discontinuity

Table 8. Parameters for presence of water.

Parameter	Description
C1	Dry
C2	Wet
C3	Dripping
C4	Flowing

Table 9. Application of the new empirical system to the different formations of Tunnel 2.

Formation	Weight		Classification	
	Min.	Max.	Min.	Max.
Disaggregated breccia	20	53	VI	IV
Median compact breccia	43	63	IV	III
Compact breccia	48	58	IV	IV
Compact basalt	62	93	III	I

sets in volcanic rocks is extremely difficult. The attitude of a discontinuity set is not only conditioning the block falls since to create instability it is necessary the occurrence of the discontinuity intersection. Thus it was judged more important to consider as a criterion the disposal of rock blocks.

This classification has the disadvantage of being basically based in the survey of the rock masses. Due to this fact certain parameters can not be evaluated directly. It is necessary, therefore, to perform visits to the works in order to have a detailed knowledge of the properties of the rock masses.

6 CONCLUSIONS

A reference is made for the important highway network at Madeira Island recently built. The percentage of tunnel length is perhaps unique.

A behavior analysis was performed of a road tunnel recently constructed in Madeira Island. It is part of the connection Caniço-Camacha and it was constructed in volcanic formations.

In this work special emphasis is made to an empirical system developed for volcanic formations. The system needs to be calibrated and correlated with other systems mainly developed for other formations. A study is initialized using Data Mining techniques or the so-called pattern recognition in order to the check the system and the parameters used for the evaluation, as well as the evaluation of deformability and strength parameters.

Finally the importance of the numerical studies is emphasized for two sections following 2D and 3D approaches. It was not possible to compare the obtained numerical results with the observed ones,

since only convergences were measured in a certain distance of the front of excavation.

ACKNOWLEDGEMENTS

The authors are greatly indebted to Road Regional Direction of the Autonomic Region of Madeira for authorizing the publication of this paper. They also wish to thank Mr Tiago Miranda from the University of Minho for his help in the 3D modeling.

Large-scale model tests for the verification of Braced Rib Arch Method for shallow overburden tunnel

S.M. Na, S.H. Moon, S.P. Lee & S.H. Cho
Technical Division, GS E&C Corp., Seoul, Korea

S.D. Lee
Professor, Ajou University, Suwon, Korea

ABSTRACT: The large-scale model tests are conducted to verify BRAM (Braced Rib Arch Method). The BRAM is developed to excavate the shallow overburden tunnel. This method uses the rib arch structure that consists of H-beams and braced walls. The rib arch structure takes a role to distribute the load to the ground. To verify mechanical behavior of the proposed rib arch structure, the large-scale model tests were performed to reduce the scale effect. The large-scale model tests are carried out backfill process and tunnel excavation process. To simulate displacement of the ground with tunnel excavation process, the fulcrums are able to move downward manually. Some experimental results of the behavior of the rib arch structure and the backfill ground are introduced. The reaction force of fulcrums, grid reinforced effects, displacements of surface and in-ground and earth pressure are monitored to investigate the stability of the method. From the results, it can be concluded that the effect of the displacement with tunnel excavation is not serious to the stability of the rib arch structure. And verified using grid is an effective method to lesson the load when the ground has not sufficient bearing capacity.

1 INTRODUCTION

1.1 *BRAM*

In concept of NATM, tunnel stability is based on the ground arching effect. Shallow overburden tunnel is the weakest section of the tunnel construction because of the arching effect is hardly showed up in this section. Therefore several assistance methods are applied for the stability of the shallow overburden tunnel. These methods are generally expensive and take a long time.

So the BRAM is developed to excavate shallow overburden tunnel. This method is a kind of the arch slab method. Conventional arch slab methods have concrete arch slab. However it is not easy to make arch shape surface for pouring concrete. And concrete arch slab is a weak structure in vibration of blasting. So we replace the concrete arch slab with the rib arch structure that consist of H-beams and braced walls. This structure is not requiring arch shape surface and it is easy to assemble. Fig. 1 shows the rib arch structure.

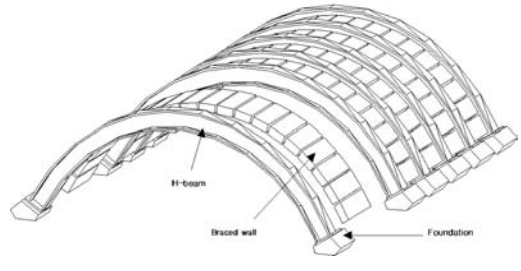

Figure 1. Diagram of the rib arch structure.

1.2 *Construction sequence of the BRAM*

The construction sequences of the suggested method are as follows:

(i) Excavating from surface to tunnel arch (Fig. 2(a)),
(ii) Installing the rib arch structure (Fig. 2(b)),

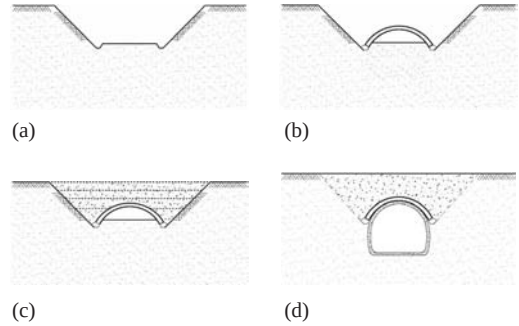

Figure 2. Construction sequences of the BRAM.

Table 1. The properties of the model ground.

Property	Value
Max. unit weight (kN/m^3)	16.86
Min. unit weight (kN/m^3)	13.82
Dryness unit weight (kN/m^3)	15.57
Relative density (%)	62
Specific gravity	2.63
Water content (%)	7∼7.59
Internal friction angle (°)	38
Cohesion (kN/m^2)	11

(iii) Backfilling with hardening (Fig. 2(c)),
(iv) Excavating tunnel section with conventional tunneling method, drilling and blasting or mechanical method (Fig. 2(d)).

The rib arch structure that is used in the suggested method consists of H-beams, braced walls and foundations (Fig. 2). The H-beams are installed at intervals of 1∼2 m longitudinally depend on the ground condition. The braced walls are installed between H-beams. The foundations take a role of load transfer to the ground. The type of foundation can be varied with ground.

2 LARGE-SCALE MODEL TESTS

2.1 *Preparing the tests*

Soil chamber, 4 m (width) × 3.3 m (height) × 3 m (length), is prepared for large-scale model tests. The front and rear walls are attached 10 mm steel plate with double anointment, bentonite and grease, for the minimum friction between soil and walls. The both slope sides are attached steel mesh to simulate real ground friction.

The model ground is tested particle distribution test, KS F2301, specific gravity test, KS F2343, and max./min. dryness unit weight test, KS F2345 for physical properties and direct shear test, KS F2348, for mechanical properties. The particle distribution of model ground is SP according to the unified soil classification system. The properties of model ground are summarized in Table 1.

For the rib arch structure, five H-beams, H-100×100×6×8, are prepare in bending. The wood is used as braced wall for convenience. Its size is 5 cm (width) × 3.5 cm (height) × 95 cm (length).

The fulcrums are hinge condition and horizontal and vertical forces are measured with load cells (Fig. 3).

2.2 *Measuring instruments*

Total five H-beams are used. To measure the stresses on the H-beams, 64 strain gages are used (Fig. 4). To measure the displacement of the H-beams and braced walls, 18 LVDTs are installed (Fig. 5).

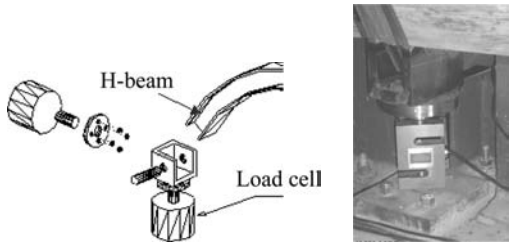

Figure 3. Diagram and picture of the fulcrum.

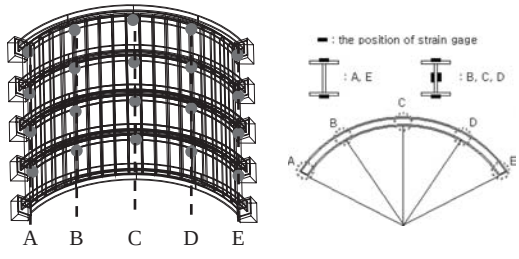

Figure 4. Diagram of the positions of strain gages.

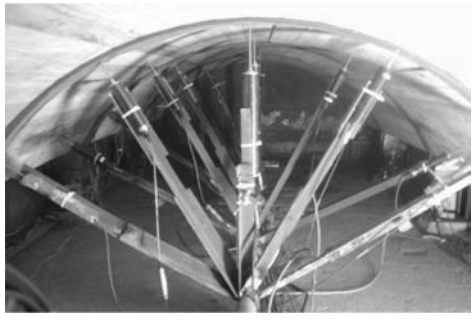

Figure 5. Picture of installed LVDTs.

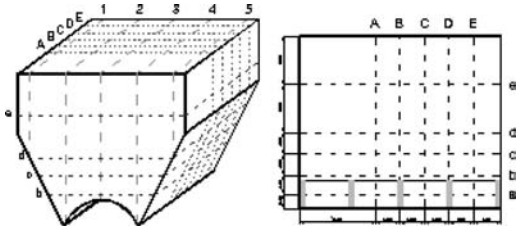
To measure the reaction forces of fulcrums, 20 load cells are installed. Figure 3 shows vertical load cell.

To measure the ground pressure, the pressure meters are installed in ground. The whole measurements of surface and in-ground displacement and ground pressure are designed to get the 3-dimensional effects of the fulcrum subsidence. Figure 6 shows 3-D diagram of measurement points of the surface and in-ground displacement and ground pressure.

2.3 *Cases of the model tests*

The large-scale model tests have two main objects. First, verifying the ground load on the arch structure with backfill process. Second, investigating the amount of load transfer in neighboring fulcrum with tunnel excavation process. In the tests, two slope angles are used; the slope angel of 60° for general ground condition and 90° for special site condition such as



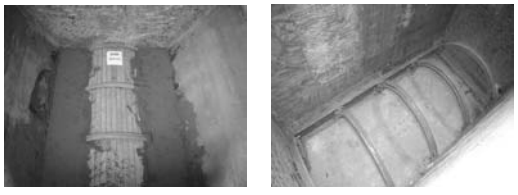


Figure 6. Diagram of the positions of LVDTs and pressure meters.

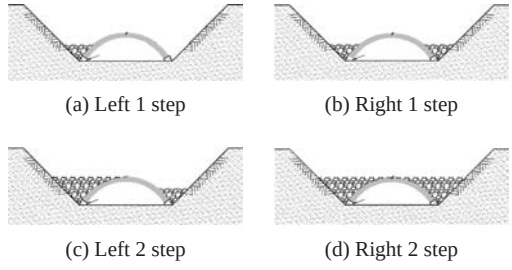
(a) 60° (b) 90°

Figure 7. Pictures of 60° and 90° slope angle cases.

existing adjacency building. Figure 7 shows the 60° and 90° slope angel models.

The tests have two sequences, backfill and fulcrum displacement process. Backfill process has several stages. To investigate the effect of the unequal backfill, left and right sides are backfilled take turns. Figure 8 shows the sequences of the backfill process up to the top of the rib arch structure.

The fulcrum displacement process is simulating the tunnel excavation process. The circumference ground moves with the tunnel face advancing. Therefore this is simulated fulcrum displacement in the large-scale model test. The third fulcrums of both sides are able to move vertical downward maximum 10 mm (Fig. 9).



If the ground bearing capacity is low, there are necessary to reduce the load on the rib arch structure. Therefore the grid is tested to reduce that load. The total test cases are summarized in Table 2.

2.4 *Test results*

The large-scale model tests are carried out in two stages. In this paper, the results of the fulcrum displacement process are showed only.

2.4.1 *Reaction force*

The load on the rib arch structure is concentrate on the fulcrums. During the fulcrum displacement process, the loads on the third fulcrums are decreased. These loads transfer to the neighbor fulcrums or side slopes. Figure 10 shows the loads transfer to the neighbor fulcrums. The amount of the loads transfer is increasing according to the slope angle is steeper. However the absolute amount of that is not serious on the stability of the rib arch structure.

(a) Left 1 step (b) Right 1 step

(c) Left 2 step (d) Right 2 step

Figure 8. Backfilling sequences.

Table 2. The cases of the model test.

Case	Slope angle	Backfill height	Reinforcement
Case 1	60°	1.5D∗	No
Case 2	60°	0.5D	No
Case 3	60°	1.5D	Grid
Case 4	90°	1.5D	No

∗ Tunnel diameter.

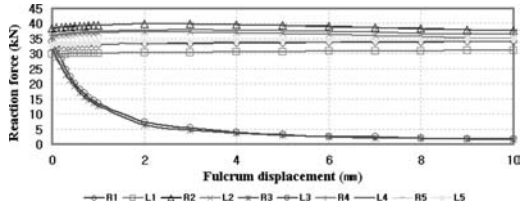

Figure 10. Graph of the load change with fulcrum displacement.

2.4.2 *Earth pressure*

The earth pressure is changed with fulcrum displacement process. Figure 11 shows vertical pressure in section B.

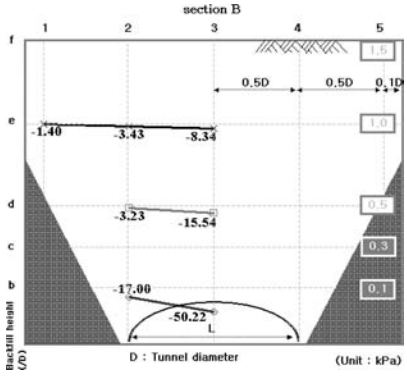

Figure 11. The variation of vertical earth pressure in section B.

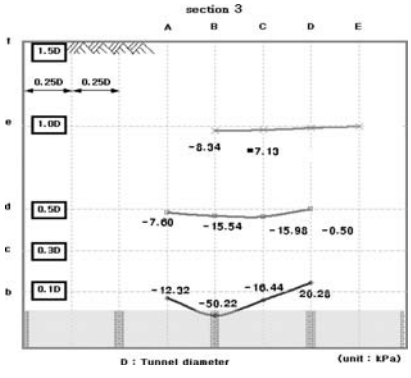

Figure 12. The variation of vertical earth pressure in section 3.

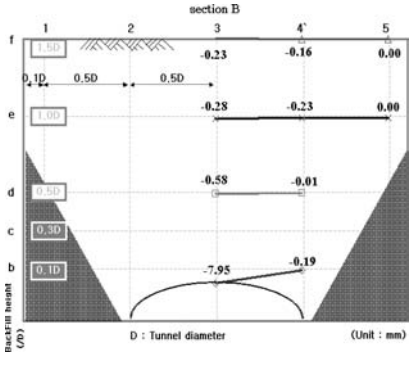

Figure 13. Surface and in-ground displacement at transversal section.

The variation of vertical earth pressure above the top arch is pretty much. And the absolute amount is decreased very rapidly with backfill height. The effect of fulcrum displacement on the earth pressure is decreasing with go away from the center. The variation

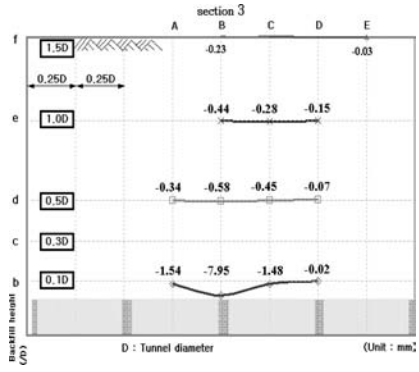

Figure 14. Surface and in-ground displacements at longitudinal section.

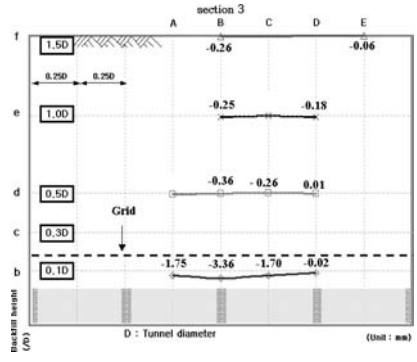

Figure 15. Surface and in-ground displacements at longitudinal section in Case 3.

of vertical earth pressure in longitudinal section is shown in figure 12. It can be seen that longitudinal arching effect is appeared with fulcrum displacement.

2.5 *Surface and in-ground displacement*

The maximum in-ground displacement is 7.95 mm at 3b (Fig. 13) above the top arch. However the in-ground displacement at Ab and Cb (Fig. 14) (in longitudinal section, the distance between 3b and Ab or Cb is 0.25D) is occurred only 20% compare with that of 3b. Also the in-ground displacement at 4b (Fig. 13) (in transversal section, the distance between 3b and 4b is 0.5D) is very small.

Therefore it is explained that the small form of soil above the top arch is subsided by the effect of fulcrum displacement. The surface settlement is started at 6mm fulcrum displacement. The maximum surface settlement is 0.23 mm at 3f (Fig. 13).

2.6 *Reinforcement effect of the grid*

The position of the grid is 0.2D from the top arch. In the reinforced case, the displacement at Bb is decreased

about 58% compare with the Case 1 (Fig. 15). The displacements at Bd and Be are also decreased about 40%. However it does not appear that reducing effect of the load on the fulcrum in backfill process with grid reinforcement.

3 CONCLUSION

The developed method, BRAM, is a kind of the arch slab method. It improves the construction efficiency and vibration resistance compare with conventional arch slab methods. It was carried out the large-scale model test because of it reduces the scale effect of the model test. And another object of this test is to find any problem to apply the BRAM to the construction site. Hence, we obtained some practical results to apply this method. The following conclusions can be drawn from this study.

- The load on specified fulcrum is transferring to the neighborhood fulcrums with displacement of that. However the amount of load transfer with fulcrum displacement is not serious effect to the stability of the rib arch structure.
- The arching effect of ground is appeared with fulcrum displacement. This phenomenon advantages to the stability of the rib arch structure.
- The grid reinforcement method is not effective to reduce the load on fulcrum in backfill process. However it is effective to reduce the in-ground displacement during the fulcrum displacement process.

An investigation into the effects of Shiraz metro tunnels on the stability of Ghadir bridge

I. Namazi, R. Rahmannejad & M.A. Ebrahimi Farsangi
Mining Engineering Department, Shahid Bahonar University of Kerman, Kerman, Iran

H. Jamshidi
Industrial advisor, Shiraz Metro, Shiraz, Iran

ABSTRACT: Tunneling in the shallow area, through the soft ground and under the water level is a difficult job. In such an environment, the associated effects of tunnel driving on the surface structures is one of the main concerns. Generally, the appropriate selection of tunneling method as well as the type of support prevent surface settlements and having less effect on the surface structures.

In the constructing plan of Shiraz metro, two parallel tunnels, in an alluvial, clay and siltstone environment with a diameter of 6.88 m and length of 14 Km are excavating. These two tunnels pass under heavy structures, such as Ghadir bridge for which EPB machines are being used. In this paper, by a three-dimensional analysis, using Plaxis 3D, the effects of excavating such tunnels on the stability of Ghadir bridge and the effects of the bridge piles on the pressure at the tunnel faces are investigated. Furthermore, a settlement profile prediction was carried out, considering the effects of piles.

1 INTRODUCTION

In the Shiraz metro, which is under construction, in some part twin tunnels with a diameter of 6.88 m, length of 14 Km and an axial distance of 10.88 m are driving. These tunnels are located at the depth of 16 m for which the water level is 5 m from the surface.

For tunneling in such a ground two EPB machines were designed by WirthNFM company. Supporting is being carried out using concrete segments with a thickness of 30 cm and external diameter of 6.6 m. The gap of 14 cm between the segments and the soil is filled by grouting.

These two tunnels are driving under heavy structures such as Ghadir bridge. The loads accounted in the numerical modeling including dead and traffic transfer through the side and middle pillars to the foundations with a length of 16.4 m, width of 6 m and a thickness of 1.5 m. The middle pillars have a pattern of two rows and 8 pillars in each row. The foundations are supported by 40 friction piles with a length of 24 m and a diameter of 1.2 m. As it can be seen in Figure 1, the twin tunnels are driven through the middle piles with a distance of 4 m and 3.4 m to the piles in the left and right sides respectively.

In the present paper, using Plaxis 3D software, the load-bearing of friction piles as well as the effects of tunnel driving on the load-bearing were studied.

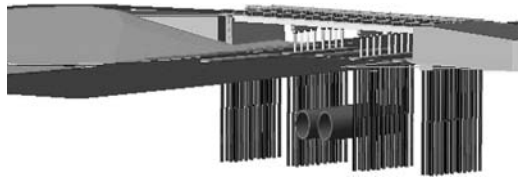

Figure 1. A schematic view of Ghadir bridge and associated twin tunnels (Bamrah, 2005).

Furthermore, the effects of loaded friction piles on the tunnel face pressure as well as possible settlement were investigated.

2 THREE-DIMENSIONAL MODELLING

In the three-dimensional modeling carried out, all process involved in mechanized excavation were considered. The model with a length of 80 m, a height of 40 m and width of 40 m including 26 segments were taken into account. Due to long distance between the side piles and the tunnels, the effects of such piles were ignored and only the middle piles were considered.

The amount of total loading, 300 tones on each pillar, was determined based on the bridge weight and

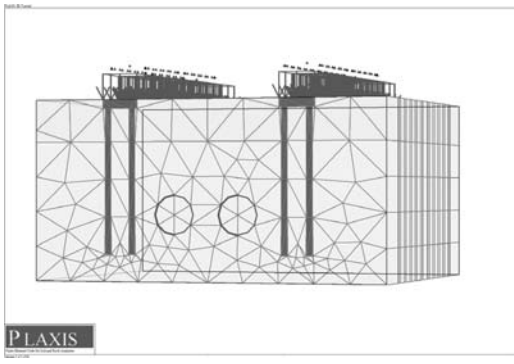

Figure 2. The three-dimensional numerical model of Ghadir bridge.

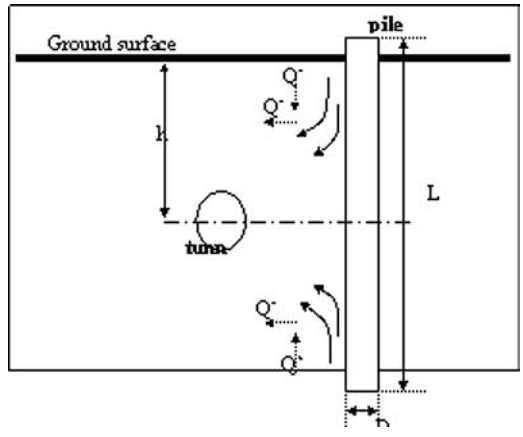
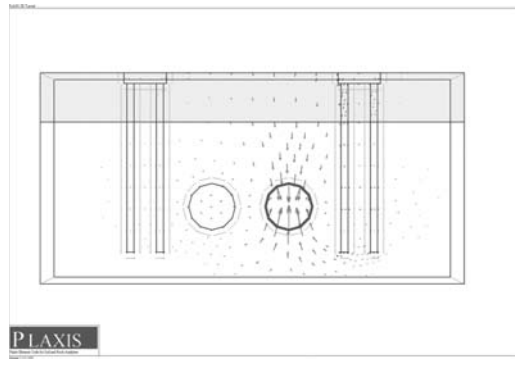
traffic loads, which is transferred to foundations in a distributed form (Figure 2) (Shiraz metro, 2002).

The Mohr-Columb and linear elastic models were considered for soil and piles respectively. The modeling of contact zone between the tunnels supports and soil, and also, piles and soil was carried out using contact interfaces. In this case, the amount of internal friction angle and cohesion are 0.6 of the nearby soil (Shiraz metro, 2002). Boundary conditions with fixed nodes were applied on the model.



3 THE MECHANISM OF THE EFFECT OF TUNNELING ON THE LOAD-BEARING OF PILES

In practice, in construction engineering, if the hard rock formation is located in deep ground, the piles construction carries out without reaching hard rock. The stability of such piles can be achieved by the friction between the soil and pile. If the pile is constructed in the soil-claystone formation, load-bearing of such a pile extremely depends upon the cohesion between the pile and the clay. In the case of Ghadir bridge, having the top layers of clay and the hard rock formation is located in deep ground, the friction piles were used. In clays, the load-bearing of such piles can be determined using Equation 1 (Tahooni, 2001):



$$Q=Qp+Qs \quad (1)$$

Where Q = the permitted load-bearing of pile (N); Qp = the permitted load-bearing of the top part of pile (N); and Qs = the permitted load-bearing of the body of pile (N).

In the first step of modeling, prior to tunnel driving, the displacement of soil-mass due to the weight of the bridge as well as traffic loads was calculated. The results revealed that piles settled 20 mm, which is accounted as zero at the next step of modeling.

(a)

(b)

Figure 3. The mechanism of effects of tunnel excavation on a: the load-bearing of piles (Ghazavi, 2001); b: soil-mass displacement.

While the tunneling is carried out close to the piles, the soil near to the piles is dislocated causing changing in the load-bearing of piles, which depends on the soil type, the distance between piles and tunnel, the tunnel geometry, pile geometry and the amount of load on the pile (Ghazavi, 2001).

The soil displacement close to the piles has two horizontal and vertical components. Horizontal displacement around piles and toward tunnels causing weakness at the intersection between soil and piles, which results in reducing load-bearing capacity of friction piles. Furthermore, vertical movement of soil in the crown area of tunnel also decreases the load-bearing capacity (Q^-).

With an upward movement of soil, located below the horizontal symmetry axis of tunnel, the friction force at the intersection between soil and pile will be increased resulting in increasing load-bearing capacity of piles (Q^+) (Figure 3) (Ghazavi, 2001).

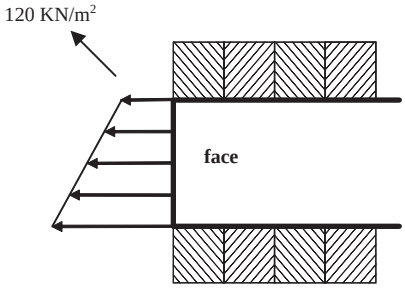


Figure 4. Applied pressure on the tunnel face (Namazi 2006).

4 EARTH PRESSURE BALANCE MODELING

Usually Earth Pressure Balance (EPB) TBM uses in the soft ground tunneling in the urban area to minimize the ground deformation during and post-tunneling. Also, in presence of water, it is used to prevent water flow toward tunnel.

The amount of real face pressure depends on: soil properties, water level, method of tunneling, tunnel geometry, overburden and surface loads (Broere 2001). Finding the optimum pressure at the tunnel face while using EPB machine was carried out by many researchers based on the mechanism of failure (Broere 2001). In these models, the effects of piles on the face pressure were not taken into account. In this research, such an effect is investigated using Plaxis 3D software.

In the first step, neglecting piles effects, using wedge method, the face pressure at the level of tunnel crown was calculated (120 KN/m^2) (Namazi 2006), which is increased with a gradient of 12 KN/m^2 downward from the tunnel crown. In the next step, using Plaxis 3D software, applying the above mentioned pressure, the operation of driving for a round and installation of supporting system was modeled.

But, by applying such a condition, while tunneling under the Ghadir bridge, the soil in the tunnel face centre was displaced 45 mm and failure occurred at the face. With a try and error base, the pressure at the face was increased, reaching to a pressure for which no failure at the tunnel occurred. The final amount of pressure obtained at the face on the crown part is 120 KN/m^2 with a gradient of 16 KN/m^2 downward (Figure 4).

5 THE EFFECTS OF PILES ON THE SUBSIDENCE PROFILE

Usually, prediction and control of subsidence due to underground excavation in the urban area is an active field of research (Peck 1969). In the excavation by

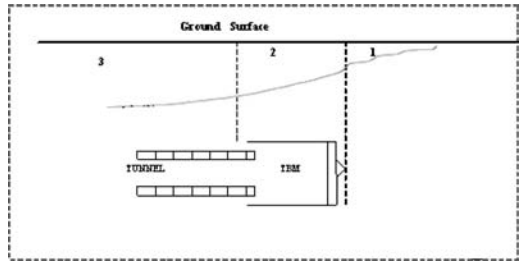

Figure 5. Different stages associated with subsidence due to EPB tunneling (Cording 1975).

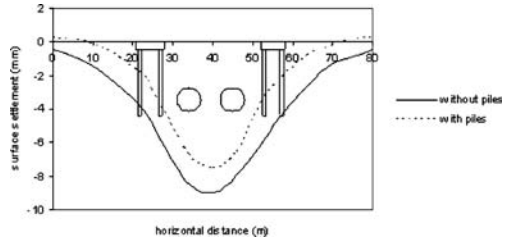

Figure 6. The profile of subsidence.

EPB machine, subsidence occurs in different stages as follows (Figure 5) (Cording et al 1975):

Stage 1: Front zone,
Stage 2: On the shield,
Stage 3: After excavation and grouting.

In stage 1, the amount of subsidence is depended upon the EPB pressure on the face-wall, which sometimes in the case of unbalancing reaches to 50 m front of machine (Mari et al 1997). While the pressure is balanced, the amount of subsidence goes to zero.

In stage 2, as shown in Figure 5 the shield is in contact with soil-mass for which a little amount of subsidence is observed.

In stage 3, due to gap between segments and soil-mass or grouting material, more subsidence is expected.

In the case of Ghadir project, also, the effects of existing friction piles on the subsidence is investigated for which two models were taken into account.

In the first model, it was assumed that there is no pile present. In the second model, the effects of piles were considered. In this case, the presence of axial force (weight) on the piles causing increasing in the stresses around the piles for which more stresses on the top and the base of piles were observed (Broere 2001). Since the tunnels are located in the lower part of piles, such stresses causing upward movement which in return results in less subsidence on the ground surface. Figure 6 shows the subsidence profile in two cases, without piles and with piles using numerical analysis.

Considering the effects of piles, the subsidence profile is squeezed causing reducing in maximum subsidence and the width of surface subsidence profile.

6 CONCLUSIONS

Studies reveal that the interaction between piles and tunnels is depended upon: the distance between piles and tunnel, geometry of piles and the amount of load on piles.

An investigation into the interaction of system of pile-soil-mass and tunnel showed that the presence of piles affects the face pressure during excavation, which results in increasing of this pressure. Also, it causes decreasing of maximum settlement and the width of settlement curve.

ABSTRACT: This paper presents the use of an Underground Space Information Management System (USIMS) for road tunnel maintenance. The USIMS is a three-dimensional representation of an underground structure and the surrounding rockmass, coupled to a database which holds all data gathered during planning, construction, inspections and repairs. Data can be accessed interactively and some of it directly visualized in the three-dimensional virtual underground structure. A number of applications are presented in this paper including a USIMS model developed for road tunnel maintenance. Instant access to all data, the ability to investigate three-dimensional relations as well as the ability to track development of specific locations over time are important advantages for optimizing planning, executing and controlling maintenance and inspections.

1 INTRODUCTION

Economic, political and societal changes in Japan have forced the construction industry to shift the focus from building new, to maintaining existing infrastructure. Good maintenance can extend the life of an engineering structure considerably. Overlooked defects can have devastating results. This is especially true for tunnels and other underground structures. However, to reach the goal of extending the life time of a tunnel while maintaining safety, a well carried out maintenance program needs to be implemented.

For this purpose we have developed new extensions to our Underground Space Information Management System or USIMS (Ohnishi et al., 2006; Bruines et al., 2006). USIMS is a system that can improve the way data is managed by providing a system that:

- Allows for examining 3-D relationships between data
- Stores data in a systematical way, and
- Is easily extendible to include additional data and data sets.

This is achieved by sorting data by location and making the data available in a 3-D virtual representation of the underground structures. The user can navigate through this virtual version of an underground structure and access all available data at each particular location. By using one data management system for all datasets, the user can access all data even after many years, which means that no datasets are lost or forgotten.

In the following chapter we will discuss the USIMS in more detail. We will tell why we have adopted the USIMS, explain the advantages and illustrate some of the concepts by presenting some of the previous USIMS models we have developed. In the next chapter the road maintenance USIMS is presented. We will conclude this paper with a discussion of the results and the next steps of our research.

2 THE UNDERGROUND SPACE INFORMATION MANAGEMENT SYSTEM

In this chapter we will first explain why we have developed an Underground Space Information Management

System. In the following section some of the advantages of the USIMS will be presented. The last section will present our previously developed USIMS models.

2.1 *Why an Underground Space Information Management System?*

Underground engineering structures need to be evaluated in the context of the geology surrounding the underground space. This geology is three-dimensional and by its nature largely unknown.

The geology is usually revealed only during construction. It is therefore important to collect geologic and construction related data and store it for future use. After the completion and commissioning of the underground space, inspections have to be carried out, and repairs made if defects are found. At each of these steps large amounts of data are gathered that have to be stored and retrieved at a later stage.

At first sight the data collected seems to be only relevant for its particular phase or for the first steps of the next phase. However, for a number of tasks a complete database can be of great help. Some examples are:

- Performance evaluations of different methods, materials and crews,
- Support for past and future decisions,
- Research of deterioration mechanisms, or
- For the purpose of asset management.

Nowadays most information can be made available in an electronic format. For instance, construction drawings are made using a Computer Aided Design program; during construction digital photographs will be taken of each excavation stage; inspection reports are written using a word-processing program; repairs might be documented using a spreadsheet program on a handheld device.

For regulatory, administrative or contractual reasons most of these data have to be stored. Very often this means that the data is printed out as a hard copy and archived as such. Although there are some efforts on the way to store information digitally, more often electronic data tends to disappear over time.

Data in general will be stored with different people and organizations, and datasets are organized by type of data. The construction drawings might be at the planning department of the general constructor, the rock mechanical analysis with an external consulting firm, the construction records with a subcontractor and inspection records with the regulatory agency.

The way in which the data is collected is usually different from one project to the other, even if the same file format is used.

With the USIMS we have developed we hope to address most of the before mentioned problems.

2.2 *Advantages of adopting a USIMS*

We are of the opinion that using a USIMS has a number of advantages. The USIMS is a three dimensional virtual representation of the underground structure that can be used both for navigation and display of information, where all data at a location is available by the click of the mouse, and data in the database is sorted by location. The USIMS is also a platform for storing data generated at every stage of the underground structure, from conception to decommissioning, preferably for the entire lifetime of the structure. It is readily extendable and very flexible with regards to the data types that can be included. Data is readily accessible, and the individual databases can be easily updated or imported, yet, if required, different levels of access can be created. Adopting a USIMS will standardize the data gathering effort. It can be extended with modules for analyzing data, exporting findings and generating checklists and forms.

The current version of the USIMS is developed using freely available software that allows the system to be accessible to everybody with a web browser, a VRML plug-in and standard office software.

2.3 *Examples of previous USIMS models*

The USIMS can be seen as being built up of three main components which will be discussed in the following sections. The components are:

- The three-dimensional virtual representation
- The data exploration
- The database

2.3.1 *Three-dimensional virtual representation*

The main feature that distinguishes the USIMS from a regular database system is the ability to explore data in a three-dimensional virtual representation.

Almost any level of detail can be included. In Figure 1 for instance all installed bolts have been included. For the walls a color code has been used to identify the different construction steps.

In Figure 2 additional ground class measurements are visualized. This approach allow for a very quick visual evaluation of the ground classes of a tunnel.

Photographic material can be incorporated into the model. It can be projected onto the wall or on a movable screen as shown in Figure 3. At regular intervals during the construction of the tunnel the excavation face has been photographed and described in detail. The image of the excavation face can be pushed backward or pulled forward. At each location the correct photograph is displayed. Comparing the excavation face at different stages in three-dimensions can yield additional information.

There is no limit to the amount of detail that can be incorporated. Photogrammetry data have been used to visualize details of 3-D rock surfaces. By taking

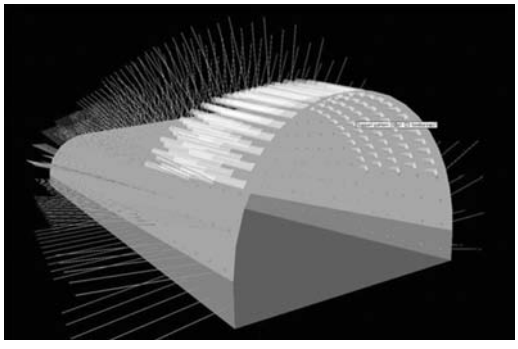

Figure 1. Three-dimensional virtual representation of the entrance section of a tunnel showing the different support patterns used. The tunnel is constructed in two steps by using a bench. The second excavation step is indicated by a different color.

Figure 2. Gradual coloring is used to visualize a dataset of ground class measurements. The view is into the tunnel with generally higher quality rockmass values towards the deeper end of the tunnel.

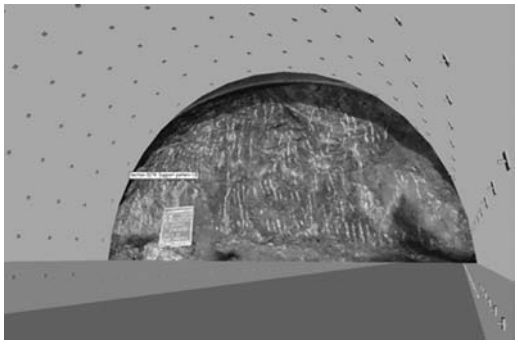

Figure 3. The three-dimensional model of a tunnel located in Kyoto prefecture, Japan. Digital photographs of the excavation face at each stage are included.

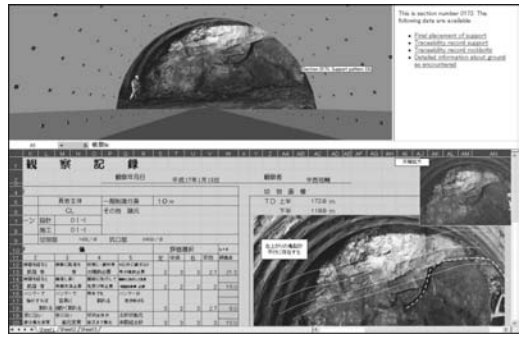

Figure 4. By incorporating the virtual representation in a set of frames additional data can be accessed. Concise data of each tunnel section is available using the mouse over event. A mouse click event will open links to all data available at the particular location in the upper right frame. When a link is clicked the data opens in the lower frame. In this case the detailed engineering geological description is displayed.

photographs from different perspectives of the same surface, the three-dimensional coordinates can be reconstructed. The photographs can than be projected on the three-dimensional frame work. In a tunnel environment this could be used for key block analysis.

2.3.2 *Data exploration*

The different locations in the model can include links to the data. To enhance the navigation of the data, the 3-D model is integrated in a set of frames. A summary of the data can be included in a small pop-up that moves with the mouse. When clicking the mouse, a file is opened in an adjacent frame that shows links to all available information at that particular location. Activating one of these links will open the detailed data in a separate frame. This could be a detailed investigation of the excavation face at that location (Fig. 4) or data of the location, time of installation and description of materials used (Fig. 5).

2.3.3 *Database management*

To generate the three-dimensional model, and all the links, a small program has been made using a scripting language that goes through all the directories and files in the database and automatically generates the entire USIMS. This does mean that the database needs to be structured. However once the computer program has been made and the user strictly respects the database structure, the USIMS can be updated on-the-fly when new data becomes available.

It will be beneficial in the long run to invest time to agree on a good database structure, because the data of an underground construction project in a USIMS should be preferably stored and updated until decommissioning.

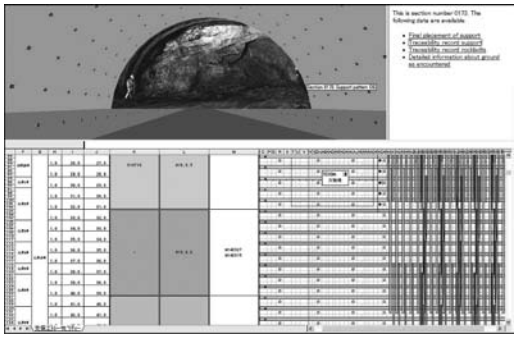

Figure 5. In this data frame the traceability record of installed support is opened. It shows the exact location of each rockbolt, the date of installation as well as a reference to the batch of materials used.

3 ROAD TUNNEL MAINTENANCE INFORMATION MANAGEMENT SYSTEM

If during an inspection a problem is encountered it will be at a location within a tunnel. For the analysis of the observed defect the inspector is not interested in the entire inspection report of last year, but only in the information from last year's inspection at that particular location. However, it would be more helpful if all relevant data of that location would be available: all the previous inspection findings at that particular location as well as a complete repair history. If the inspection and repair data indicates that deterioration is particularly fast additional data would be useful to perform a more detailed analysis. "What was the ground-class classification?"; "Was there excessive groundwater inflow recorded?"; "Has the correct support been installed?" are just a few of the questions that might come up. If a likely scenario for accelerated deterioration is formulated, locations with similar conditions could be identified by the Information Management System for more detailed inspection or for preventive maintenance measures.

In the next part we would like to show the development of a USIMS for an actual tunnel located in Kinki district.

The data available are:

- location maps, construction drawings and other general information about the tunnel,
- sketches of the tunnel lining from inspection,
- database with a detailed description of each observed defect, and
- photographs of defects.

All available information has been incorporated into the USIMS. A three-dimensional representation of the tunnel has been modeled. Since the entire lining of the tunnel has been mapped, the sketches with the observed defects are projected on the walls and floor of the tunnel. Clicking on each of the sections opens links to all available data of that section. This additional data can than be investigated by a click of the mouse.

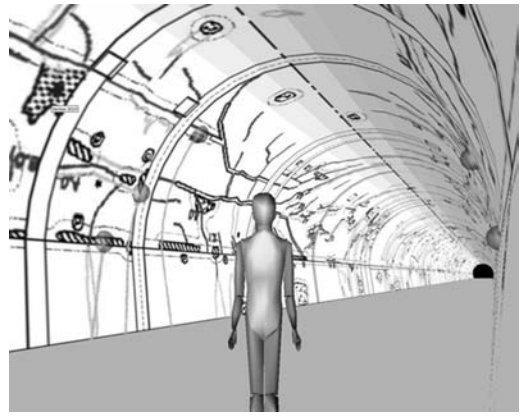

Figure 6. Sketches made during an inspection are projected on the walls. Blue spheres link to additional information about individual trouble spots.

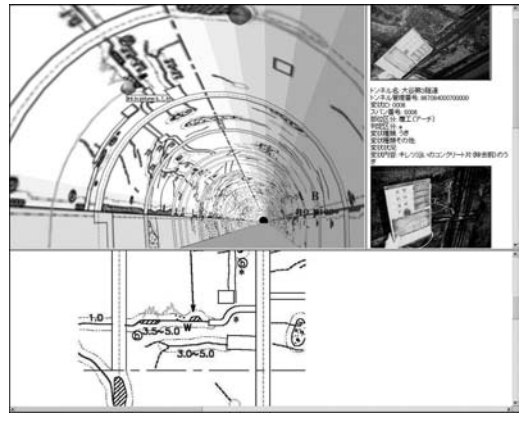

Figure 7. Clicking on the wall or one of the blue spheres opens a frame with a short summary of available data on the right. Photos, sketches and data can be closer examined in the data frame on the bottom.

Apart from the tunnel section, detailed descriptions of each of the observed defects are available. They are marked in the three-dimensional representation with a blue sphere so that the information is available from the inside and from outside the tunnel. Clicking the sphere will open a small picture together with a description of the defect. The small picture can be clicked to investigate the problem area in detail. The generation of the HTML code necessary to visualize all the data is automatically extracted from the database using a scripting language.

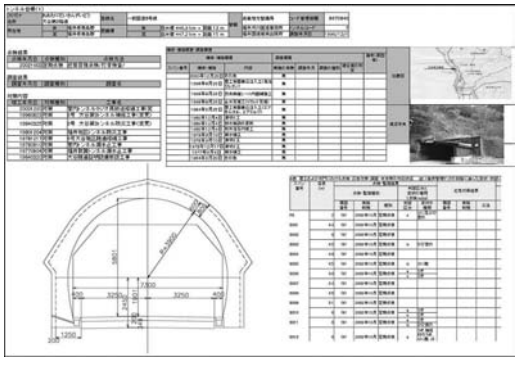

Figure 8. A small selection of non-location specific data available in the USIMS.

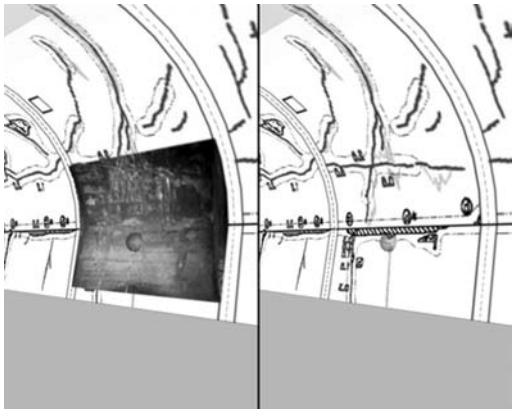

Figure 9. The user can switch between different projections at any time. In this case a projection of the sketches only or of a projection with integrated photographic information.

Data that is not directly related to a particular location can be accessed at anytime. A navigation menu will be available at all times in the lower right corner of the USIMS. The navigation menu links to files on the construction history, the technical details, the location, a cross-section of the tunnel as well as information on the history and the costs of inspection and maintenance.

The pictures taken of the defects have been added as an overlay to the sketches. The user can switch between the sketches with and without pictures at any moment using the navigation menu.

A few other applications which fit in the frame work of inspection and maintenance have been developed. Especially in the early stages after construction of the tunnel the geology has to readjust which can lead to convergence. Although a slight movement can help to stabilize the tunnel, excessive movements can lead to disaster. It is for that reason movements of control

Figure 10. Reflective targets in a tunnel. Reflective targets are ideal reference points to be used for three-dimensional photogrammetric measurements.

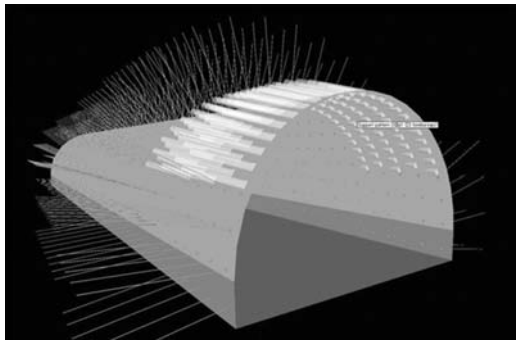

Figure 11. Visualization of the displacements from photogrammetric measurements.

points have to be measured. Nakai et al., (2002) have developed a new method that can calculate these movements using digital photography. When many photographs are taken of the same object from different angles the 3-D position of this object can be determined. The methodology developed is unique because it doesn't have any constraints on the location and direction of photographs taken. It gives the photographer the maximum freedom to take pictures. This means that pictures can be taken faster, outside of dangerous areas and of unreachable locations. Figure 10 shows a picture of the inside of tunnel where reflective targets are used.

By comparing the 3-D measurements over time the movements can be determined. The precision of the method used is less than 1.0mm. The USIMS is an ideal platform to visualize these results.

Further development of this method is ongoing, which might lead to other applications that can be incorporated in the USIMS, such as for instance 3-D analysis of excavation faces for real time key block analysis.

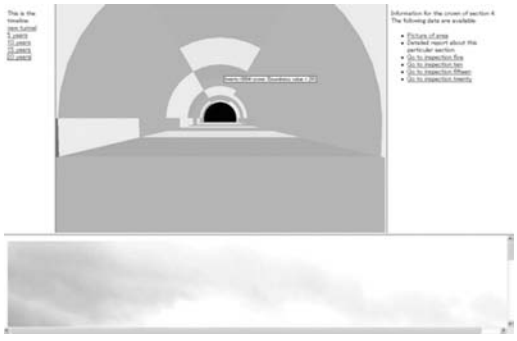

Figure 12. In this example for maintenance purposes an additional timeline frame is included that lets the user investigate the condition of the tunnel at different times. This shows the same three-dimensional model after 20 years. Different colors indicate that certain parts of the tunnel have deteriorated. Different colors relate to suggested actions to be taken such as e.g. “special attention during next inspection”, “preventive maintenance suggested”, “immediate repair required”.

In another application a visualization of the results from deterioration analysis has been developed. Using a questionnaire a soundness rating can be assigned to different sections of a tunnel . The analysis is performed at different times and using a deterioration model, predictions for the future are made. Figure 12 shows a USIMS that includes an additional frame for the time line, which lets the user jump between the different soundness values over time. It shows the soundness value of the tunnel lining as determined after 20 years of operation. Different colors correspond to different suggested responses.

4 DISCUSSION

The models presented in this paper have to be regarded as preliminary explorations of the possibilities of what could offer a fully developed USIMS. The USIMS models that have been developed nevertheless are fully functional.

We have not yet encountered data that can not incorporated. The size of the database has proven to be not a big issue. As long as some care is taken to the design of the database, building the USIMS can be easily automated.

The system is very flexible as to what can be displayed. Three-dimensional shapes, textures, colors indicating values, pictures of the geology during excavation, pictures of observed defects, location of boreholes, borehole scan pictures, three-dimensional rock surfaces for the interpretation of discontinuities are just some of the features that have already been implemented.

A number of ideas are currently being worked out. These include the development of an inspection system. Before the inspector goes to a tunnel for an inspection a questionnaire is generated. This module is downloaded to a tablet computer or handheld device. In the tunnel the inspector is guided by the questionnaire that has been generated from the previous inspection results. His questionnaire would attend the inspector to recent repairs, or to locations that during a previous inspection was a border case. If the inspector has identified a certain problem the questionnaire opens a special set of detailed questions that are relevant for this type of problems. When the inspector comes back from the inspection the results are uploaded to the USIMS that automatically updates the database, perform a number of analyses and updates the three-dimensional model.

Another idea is to incorporate modules into the USIMS to make it an asset management tool. Some research has already been carried out to come up with the best strategies for scheduling inspections and maintenance. A full-fledged USIMS with a complete set of data would have the possibility to do many more analyses. It could be a tool to compare the efficiency of different contractors, materials, construction methods or maintenance schedules.

Performance of pile due to tunneling-induced soil movements

C.W. Ong, C.F. Leung, K.Y. Yong & Y.K. Chow
Centre for Soft Ground Engineering, Department of Civil Engineering, National University of Singapore

ABSTRACT: Tunneling would inevitably induce vertical and lateral soil movements on piles supporting adjacent buildings. In the present study, centrifuge model tests were conducted to evaluate the free-field soil movements due to tunneling and the effects of soil movements on a free-head single pile located nearby. Three-dimensional finite element analysis was also performed to back-analyze the centrifuge test data. The measured and predicted pile responses due to tunneling show fair agreement in both short-term (immediately after tunnel excavation) and long-term.

1 INTRODUCTION

In many large heavily populated cities, tunnel excavations very close to adjacent buildings. In view of this, an assessment on the performance of piles due to tunneling is important to ensure that the structural integrity of the piles can be maintained. In the present study, centrifuge model studies were carried out at the National University of Singapore (NUS) to examine the pile behavior due to tunneling-induced soil movement.

As tunnelling is an unloading process, it will cause stress relief and redistribution in the ground and induce soil movement. In such scenario, piles will be subjected to simultaneous vertical and lateral soil movements. Different modes of tunnelling deformations in centrifuge were evaluated by a good number of early researchers (Feng, 2003; Ghahremannejad et al. 2006; Grant and Taylor, 2000; Jacobsz et al. 2005; Lee et al.2006; Loganathan et al. 2000; Ran, 2004; Sharma et al. 2001).

In the present study, inward tunnel deformation at the tunnel springline is simulated using both centrifuge and finite element models. Free-field soil movements and tunneling-induced pile lateral and axial responses in both short-term (immediately after tunnel excavation) and long-term are evaluated. The study is limited to a single free head pile only.

2 CENTRIFUGE MODEL SETUP

Two centrifuge tests were conducted at an acceleration field of 100 g on the NUS centrifuge. Unless otherwise stated, the test configuration and results are presented in this paper. The first test was conducted without the presence of pile to solely study the free-field soil movements due to tunneling. During this test, high resolution photographs were taken at regular intervals and the soil displacement trajectory was derived using particle image velocimetry (White et al. (2003), an advanced image processing technique. The second test was conducted to study the tunneling-induced responses of a pile located at 6 m away from the tunnel axis. Figure 1 shows a photograph of the centrifuge model setup in the present study.

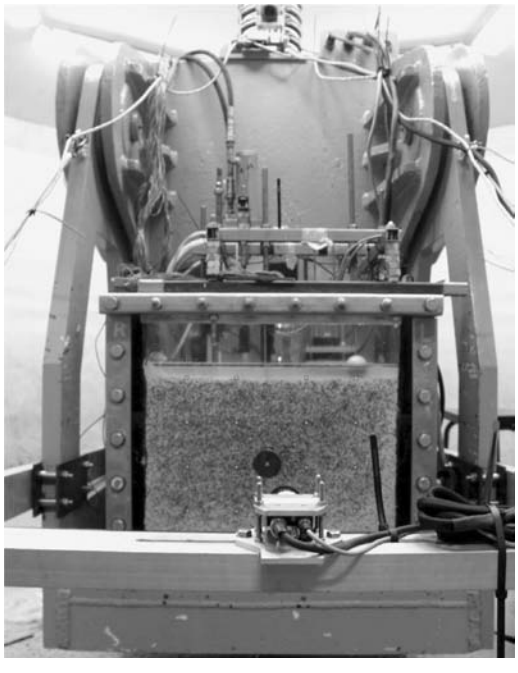

Figure 1. Centrifuge model setup.

Table 1. Test parameters (prototype scale).

Parameter	Value
Volume loss	6.6%
Tunnel diameter (D)	6 m
Tunnel depth (Z)	15 m
Tunnel cover (C)	12 m
Pile cross-section	1.26 m × 1.26 m
Pile length	23.5 m
Pile bending rigidity	3.97×10^6 kNm^2
Pile axial rigidity	3.64×10^7 kN
Pile distance from tunnel axis	6 m

The strong box soil container used is made of stainless steel alloy and has internal model dimensions of 525 mm × 200 mm × 490 mm (length × width × height). One sidewall of the container is made of transparent Perspex plate and all sides of the container were heavily greased to minimize the soil/container side friction.

In both tests, the elevation of the crown of the 6 m diameter tunnel was at 12 m beneath the ground surface. In the second test, a long free head single pile with its tip beneath the tunnel was investigated. In this test, two instrumented piles (one for measuring axial pile responses and the other for lateral responses) were placed at equidistance from the tunnel. The test parameters are given in table 1.

The model piles were fabricated using square aluminium tubes. Ten pairs of strain gauges were attached along the pile shafts to measure the bending moment along one pile (termed 'bending' pile) and axial forces along the other pile (termed 'axial pile'), as shown in Figure 2. The strain gauges were protected by a thin layer of epoxy resin for waterproofing. The 'bending' and 'axial' piles were connected to the strain meter (placed on the centrifuge arm) with half-bridge mode and full-bridge mode, respectively. The prototype pile configurations are also listed in table 1.

Figure 3(a) shows the cross-section of the model tunnel. The tunnel was made of stainless steel of 6 m diameter. A technique has been developed to simulate the inward tunnel deformation at the tunnel springline by dissolving the over-shaped high density polystyrene foam placed outside a model tunnel lining using an organic solvent, acetone, while the centrifuge was in-flight at 100 g. A discharge outlet has been made to allow the drainage of acetone into the tunnel cavity. This technique was initiated by Sharma et al. (2001). In this paper, the gap parameter GAP as proposed by Lee et al. (1992) has been adopted to quantify the degree of over-cut of tunnel. The simulated tunnel opening for this model has a GAP of 200 mm in prototype scale with an equivalent imposed volume loss of 6.6%.

The model ground was prepared from slurry of kaolin clay at a water content of 120% preconsolidated under a pressure of 20 kPa before accelerated to

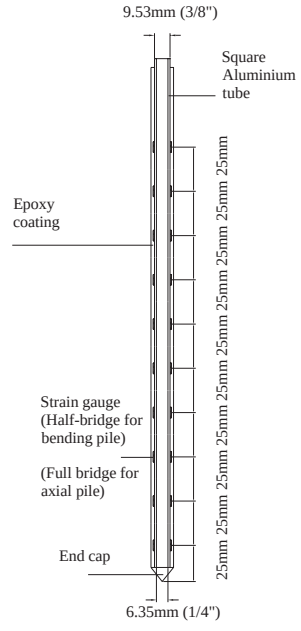

Figure 2. Instrumented model pile.

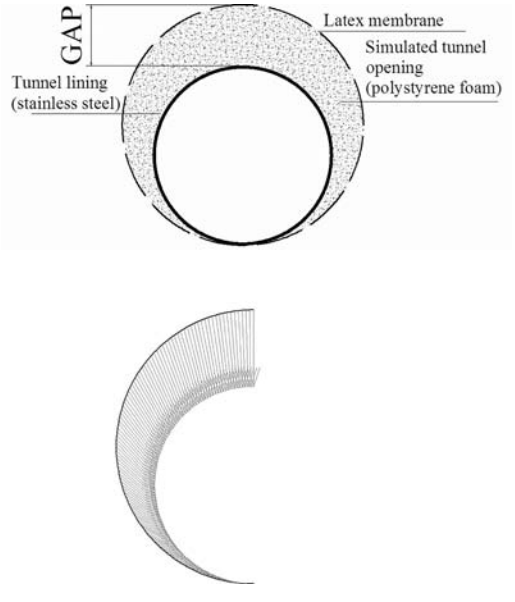

Figure 3. (a) Cross-section of model tunnel in centrifuge. (b) Simulation of tunnel over-cut in numerical analysis.

100 g. After the ground settlement and pore water pressure readings stabilized, the centrifuge was stopped and the front and back walls of the container was removed to install the model tunnel, transducers and to place marker beads onto the soil behind the perspex front wall.

The model piles were then installed and two non-contact laser displacement transducers were used to measure the lateral deflection and rotation of the pile head. The pile settlement was measured by one transducer resting on the pile head. The model setup was then subject to reconsolidation at 100 g until the pore water pressure reached a steady state. The test began by draining Acetone to dissolve the high density polystyrene foam. All instruments were monitored regularly throughout the test. In order to study the post-excavation effects, the centrifuge would be kept at 100 g for 2.3 years (i.e. 2 hours in model scale) after the completion of tunnel excavation.

3 NUMERICAL ANALYSIS

The 3-dimensional numerical back analysis was performed using the PLAXIS 3D Tunnel program (version 2). Similar to the centrifuge model tests, the tunnel excavation was simulated under plane strain condition. The Hardening Soil model, which is a general second-order and an elasto-plastic type hyperbolic model, was adopted for the clay. In contrast to an elastic perfectly-plastic soil model, the yield surface of a hardening plasticity model is not fixed in the principal stress space and can expand due to plastic straining.

Due to symmetry, only one-half of the centrifuge setup was modeled. Simulation of tunnel over-cut in numerical analysis is shown in Figure 3(b). The finite element mesh shown in Figure 4 has an overall dimension similar to the centrifuge container size, i.e. width = 26 m, depth = 28 m and width = 20 m. It is assumed that no horizontal or vertical displacement takes places at the bottom boundary as it is beyond the influence of tunnel excavation. The mesh sides were restrained from moving laterally but free to settle. The right-hand boundary was the line of symmetry. The ground water level was at the ground surface.

The same geometry and pile parameters given in table 1 were adopted in the numerical simulation. The model tunnel lining was modeled such that it was rigid having nil deformation. The soil parameters are given in table 2.

Undrained analysis was performed to evaluate the short-term pile behavior whereas drained analysis was conducted to examine the pile responses at 720 days after tunnel excavation.

4 TUNNELING-INDUCED SOIL MOVEMENT

In the present study, a centrifuge model test has been conducted without the presence of pile to study the green-field soil movements due to tunneling. The measured soil movements are computed by comparing the bead locations from high resolution photographs

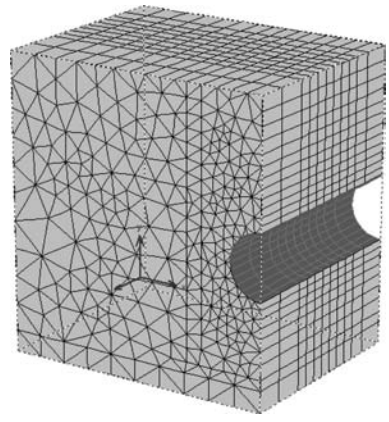

Figure 4. Finite element mesh.

Table 2. Soil properties (After Goh, 2003).

Parameter	Value
Saturated unit weight, γ_w	16.39 kN/m^3
Permeability k_x	2.0×10^{-8} m/s
Permeability, k_y	6.0×10^{-8} m/s
Angle of friction, Φ	23°
Angle of dilation, Ψ	0°
Cohesion, c	0.001
E_{oed}^{ref}	1520 kPa
E_{ur}^{ref}	8500 kPa
E_{50}^{ref}	1900 kPa

before and after tunnel excavation using particle image velocimetry (PIV) (White et al. 2003).

It is observed that the soil movement wedge above the tunnel crown behaves as an active zone and it moves towards the tunnel lining to fill the gap above the tunnel crown created by tunneling. The soil beyond the wedge acts like a passive zone, with the soil in the wedge gradually deforms by arching.

Figure 5 shows the comparison of the tunneling induced surface settlement troughs between the centrifuge test results and the numerical calculations. The volume loss immediately after tunneling (short-term) was 6.6% with a maximum ground surface settlement of 91.5 mm. This corresponds to the imposed volume loss with simulated tunnel opening of GAP = 200 mm. The measured value of the surface trough is similar to the volume loss imposed at the tunnel depth; hence confirming the modeling method is appropriate.

The horizontal distance from the tunnel axis to the point of inflection, i, of the settlement trough is determined to be 7.50 m. This value is close to the prediction of 7.5 m by Peck (1969), in which the trough width parameter k is 0.5 for tunnels in clay, as suggested by Mair et al. (1993). Thus it can be established that the

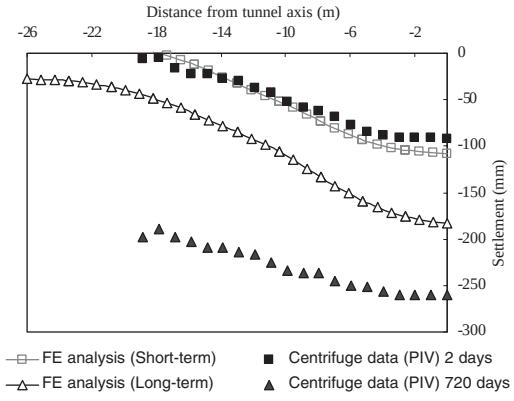

Figure 5. Comparison of surface settlement troughs.

observed settlement trough in the short-term can be reasonably predicted by the finite element analysis.

It is noted that in the long-term, the observed ground settlement continued to increase with time, as shown in Figure 5. This can be attributed to the reconsolidation of the clay, with the dissipation of pore water pressure caused by tunneling. As a result, the settlement trough becomes wider with time after tunnel excavation. Shirlaw (1993) presented examples of long-term settlements and reported that the ground settlement due to tunneling and the extent of settlement trough can increase significantly in the long term in some cases. Figure 5 also shows that the calculated ground settlements also increase with time after tunnel excavation, but the magnitude of increase is smaller than that observed in the centrifuge test.

5 TUNNELING-INDUCED PILE RESPONSES

Piles adjacent to tunneling are subjected to simultaneous vertical and lateral soil movements, which in turn induce axial (pile axial force and settlement) and lateral responses (pile bending moment and deflection) on the piles. It should be noted that the induced bending moment and axial load are additional loads over and above the design working moment/load of the pile.

This additional loading caused by soil movement must be taken into account in order to avoid excessive pile settlement or exceeding pile structural capacity.

5.1 *Induced pile axial force*

In general, the soil settlement due to tunneling would induce negative skin friction along the shaft of an adjacent shaft. This response is evident from the observation shown in Figure 6. Owing to large soil settlement above the tunnel springline, the settling soil drags the pile down. In addition, the magnitude of negative skin friction increases significantly with time. The neutral plane, below which positive shaft friction occurs,

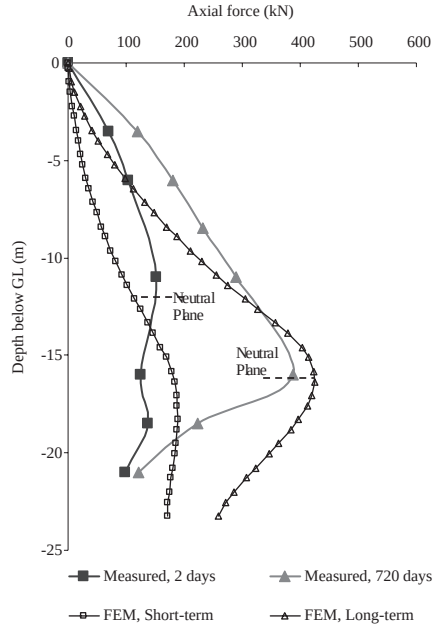

Figure 6. Induced pile axial force (Test 2).

moves downward with time with the final neutral plane located around the tunnel springline elevation.

Figure 6 reveals that the observed short and long-term pile axial force profile can be reasonably predicted by the finite element analysis. As an example, the magnitude of observed negative skin friction increase from 151 kN at the end of excavation (short term) to 387 kN at 720 days after excavation (long term), an increment of 156%. For the numerical calculations, the negative skin friction increases from 188 kN in the short term to 424 kN in the long term. Although the FE analysis over predicts the peak axial force, but the difference is relatively small.

Considering the ultimate axial force capacity of the model pile of 1800 kN, the negative skin friction induced by tunneling reveal that the factor of safety of the pile against pile material failure has been considerably reduced.

5.2 *Induced pile settlement*

Figure 7 shows the observed short and long term green field vertical soil movement profile at the pile location and the corresponding pile settlement. It is evident that the pile has suffered large settlement which increased significantly over time. The high axial stiffness of the pile is evident as the pile body compression is very small.

By comparing the pile settlement with the free field soil movement, the elevation of the neutral plane, where there is no relative movement between the soil

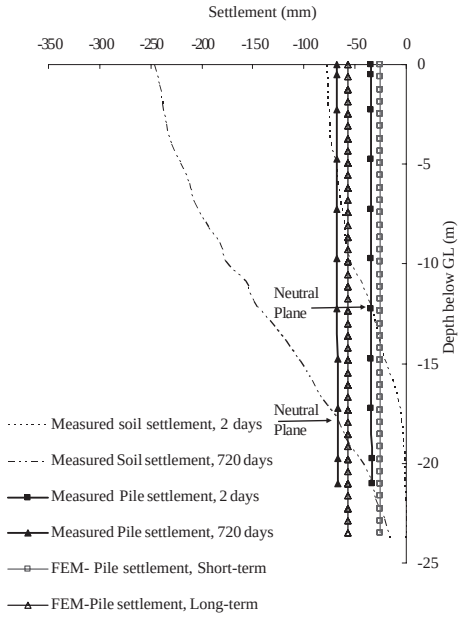

Figure 7. Induced pile settlement (Test 2).

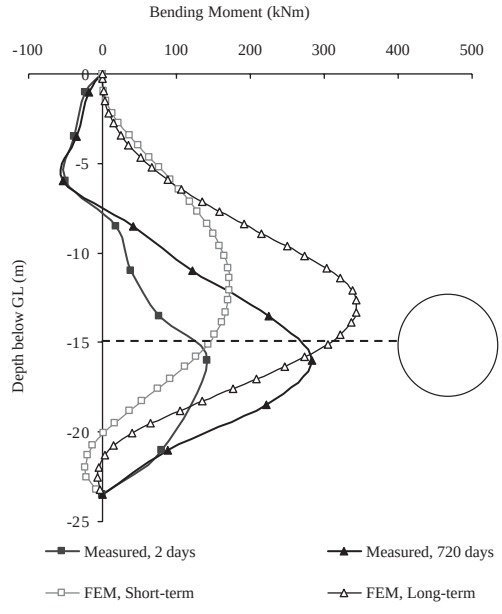

Figure 8. Induced pile bending moment (Test 2).

and pile, can be obtained. The elevation of the neutral plane is consistent with that observed in Figure 6.

5.3 *Induced pile bending moment*

Tunneling-induced soil movement would impose additional bending moment on adjacent piles. As the tunneling process is modeled as plane strain, the bending moment in the transverse direction is much higher than that in the longitudinal direction. Pang (2006) reported that during a tunnel excavation in, Singapore, it was observed that the bending moment in the longitudinal direction was consistently either equal to or smaller (up to 5 times) than the bending moment in the transverse direction. Hence, the modeling technique adopted in the present study is justified.

Figure 8 shows the tunneling-induced pile bending moment profiles at different times. The induced bending moment profile has a double curvature with the moment increasing with depth and time. The bending moment at the pile head and tip is zero because the pile head is free while the pile tip behaves as a hinge. The shape of bending moment profile remains fairly constant over time with the maximum induced bending moment occurs approximately at the tunnel springline. Owing to tunnel over-cut, the soil moves towards the tunnel spring elevation due to volume loss and therefore pushes the pile towards the tunnel.

The induced pile bending moment obtained from the centrifuge test and numerical analysis has a similar profile but the maximum bending moment back analyzed by numerical analysis is located at a higher elevation. This is because the largest negative horizontal soil movement occurs at the tunnel crown elevation, rather than at the tunnel spring line elevation.

In the present study, the ultimate bending moment capacity of the model pile used in centrifuge is estimated to be 3000 kNm. In the short-term, soil movements due to tunneling cause the soil to flow past the pile and induce a maximum bending moment of 141 kNm on the pile and increases to 283 kNm after 720 days. In the numerical analysis, the maximum induced pile bending moment is 172 kNm in short-term and increases by about 100% to 343 kNm in long-term. The percentage of increment of pile bending movement in both centrifuge test and numerical analysis are the same in long-term although the finite element analysis slightly over predict the peak bending moment.

5.4 *Induced pile horizontal displacement*

The horizontal displacement of the pile is related to the free-field horizontal soil movements, pile bending stiffness and the horizontal pile-soil interaction. A comparison of pile and free-field horizontal displacements is shown in Figure 9.

The free-field horizontal soil displacements are obtained in test 1 where as the pile horizontal displacement profile is obtained by integrating the spline function for the bending moment profiles twice with two specified boundary conditions in the double integration, i.e. the measured pile head displacement and assume no pile toe rotation.

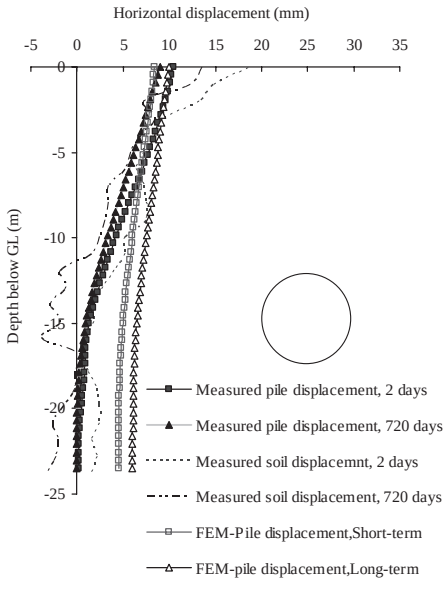

Figure 9. Induced pile lateral deflection (Test 2).

Generally, the pile and soil are moving in the same direction, i.e. toward the tunnel. In this case, the pile head moves laterally more than pile tip because the upper portion of the model tunnel has a higher magnitude of over-cut than that of the lower portion. Both results from centrifuge and numerical analysis exhibit a similar profile. However, the pile horizontal displacement profile obtained from the numerical analysis shows a stiffer pile behavior in which it has a larger toe movement compared with the negligible displacement of pile toe in centrifuge test.

6 CONCLUSIONS

Two plane strain centrifuge model tests have been conducted at NUS to study the tunnel-pile interaction in clay. A technique has been developed to simulate the inward tunnel deformation at the tunnel springline in centrifuge model tests. Besides, 3D numerical analysis has been performed to back analyze the centrifuge test results.

The results reveal that the observed and calculated surface settlement trough in clay generally agreed well in the short-term. The trough extends much wider in the long-term. Tunneling induces both vertical and horizontal soil movements simultaneously and hence affects the axial and lateral behavior of adjacent piles. Back analysis of centrifuges studies has demonstrated the ability of the 3D finite element analysis in predicting the soil movement and pile responses, although the numerical method predicts somewhat slightly over-estimated the pile responses.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Mr Eddie Hu and the laboratory officers in the NUS Geotechnical Centrifuge Laboratory for their assistance in carrying out the centrifuge model experiments.

The continual load development measurement of the central concrete pillar in the Valík tunnels

J. Pacovský, J. Svoboda & R. Vašíček
Centre of Experimental Geotechnics, Faculty of Civil Engineering, Czech Technical University in Prague, The Czech Republic

ABSTRACT: The safe and cost-effective construction of tunnels employing modern technologies requires that systematic geo-monitoring be carried out. It is often necessary to supplement basic monitoring with further measurements and observations. In the case of complicated geological conditions or in the case of the use of complicated, atypical construction methods, stress measurements are required. The continual measurement of stress on the contact between the rock and the primary tunnel lining and between the rock and the central concrete supporting pillar was carried out during the construction of the Valík tunnels. The measurement results provided information on the development of loading by rock pressure over the course of time.

1 INTRODUCTION

The present-day construction of underground structures requires constant geo-monitoring. The amount of monitoring needed is open to debate and, despite professional advice, it is often the case that underground structures are either subjected to unnecessary and costly over-monitoring or, at the opposite end of the spectrum, insufficient monitoring. The cost of geo-monitoring can make up a considerable portion of the overall construction budget, therefore the investor would be well advised, in cooperation with the designer, to approach the issue in a responsible manner and to take full advantage of the professional advice on offer.

Continual stress measurements are not usually considered an integral part of geo-monitoring and are only utilised when tunnels are constructed in areas with complicated geological conditions, or at sites where non-traditional tunnelling technologies are employed. Stress measuring, as well as being costly, requires a high level of professional knowledge. It is advisable therefore to employ specialised, experienced companies with a proven track record in the taking of such measurements. Only a limited number of geo-monitoring companies are able to provide such services and the employment of unskilled companies in the past who have provided unsatisfactory stress measurement data has led to a general lack of trust in the field.

2 PRINCIPLE OF CONTINUAL STRESS MEASUREMENT

The principal advantage of stress measurement at the contact of the rock mass with the tunnel lining is that it may provide information on changes in the load acting on the lining before such changes cause any real damage. Since measuring is carried out on a continual basis, a decision can be made, based on load change development in the risk area, to increase the frequency of basic deformation measurements thus preventing, well in advance, any dangerous deformation of the lining.

Since these measurements are fully automated, any measurement interval can be selected allowing practically any number of gauges to be connected to the datalogger.

Contact stress measurement is performed by means of hydraulic pressure cells (Fig. 1) and the continual recording of measurement results is provided by an ADSYS-ASOFT datalogger which is tough enough to withstand the demanding environment of an underground site (Fig. 2).

3 VALÍK TUNNELS

3.1 *Basic information*

The Valík Tunnels are located on the D5 highway, which runs from Prague to Rozvadov (on the German

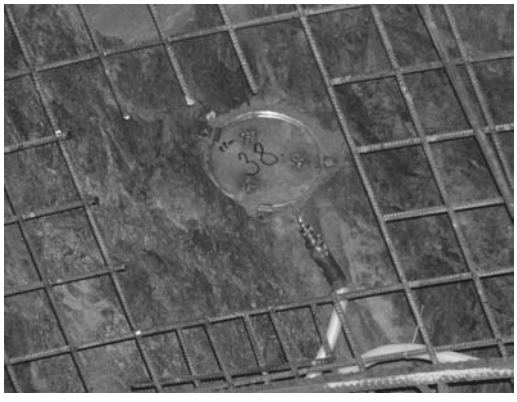

Figure 1. Hydraulic pressure cell (HPC).

Figure 2. Data transport from the ADSYS – ASOFT datalogger.

border). The construction investor is Ředitelství silnic a dálnic ČR Praha, i.e. Road and Highway Management for the Czech Republic, Prague, and the construction contractor Metrostav a.s., SG-Geotechnika a.s., responsible for comprehensive geotechnical monitoring during the construction of the tunnel. The driven tunnel section is 330 m in length and is made up of two separate tunnel tubes, 12 m wide and 8.2 m high. Two traffic lanes each with a width of 3.75 m were designed in each direction plus one emergency lane with a width of 3.25 m. There is no rock pillar between the tunnel tubes, the tubes being separated by a central reinforced concrete pillar built in advance. The construction of the driven tunnel sections is of the double-jacket design with intermediate insulation.

3.2 *Geological conditions*

The geological conditions along the whole length of the highway tunnel were verified in 2002 using a driven prospecting drift. Both the tunnel construction

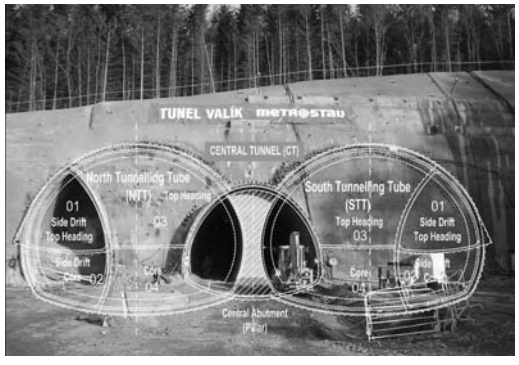

Figure 3. Tunnel cross section – excavation sequence.

technology and the level of geotechnical monitoring were subsequently designed according to the exploration results.

The tunnels were driven into weathered, tectonically highly affected Proterozoic shales. In terms of hydrogeology, the prevailing rock mass was dry.

3.3 *Tunnel technology and construction procedure*

The basic partial excavation procedure can be seen in Figure 3. Combined zoning (vertical and horizontal) was chosen because of the complex geological conditions, the minimum roof thickness above the tunnels and the considerable width and height of the breakings.

The primary lining consists of shotcrete, truss arches (BTX), a lattice grid and anchoring elements. The final lining is designed to be of in-situ reinforced concrete cast in 10 m lengths in monolithic form.

In terms of technology and structural design, the most complicated problem was the construction of the central reinforced concrete pillar which bears a considerable part of the rock load above the tunnels. The pillar was built in advance in the central tunnel.

Excavations, performed to 70% without blasting, commenced in March 2004 with the excavation of the central tunnel, which was completed one month ahead of schedule at the end of July 2004. In September 2004, the concreting of the central pillar commenced so that the excavation of the main tunnels could be in full swing by the beginning of October. The concreting of the central pillar was completed in January 2005; the excavation of the main tunnels was completed in May 2005. The tunnel was put into operation in early October 2006 (Bernard, 2004).

3.4 *Geotechnical monitoring system*

Geotechnical monitoring (GTM) is a component part of the New Austrian Tunnelling Method (NATM), used in the construction of the majority of tunnels in the Czech Republic.

Basic geo-monitoring in this case included: the geological observation of the faces, the measurement of settlement on the surface of the area observed, extenzometric measurements in vertical drills from the surface of the terrain, the measurement of horizontal deformations in the surrounding massif using inclinometers, the measurement of primary lining deformations (measurement of convergence), stress measurement in the primary lining as well as on the rock - lining contact (Bernard, 2004).

4 CONTINUAL CONTACT STRESS MEASUREMENT

Based on the results of geological prospecting, 3 driving sections along the tunnel length were selected in which geo-monitoring was extended to include automated continual contact stress measurements carried out in the vicinity of the central concrete pillar at the rock-lining – lining-pillar contact. Such measurements performed hourly provided immediate information on the on-going redistribution of stresses in the surrounding rock continuum and in the central concrete pillar itself. Stress redistribution in a complex rock continuum is a long-term process (Pacovský, 2002). The measurement results allowed predictions to be made concerning future changes in lining deformation due to changes in loading (stress-state).

In these 3 difficult driving sections, 3 joint measurement profiles were instrumented. In all, 36 hydraulic pressure cells (HPC) were installed at various stages of the excavation work. As the result of long-term experience, continual temperature measurements at the stress measurement points were carried out simultaneously. The measurement of temperature is relatively both simple and cheap and is able to provide some very useful information.

Gauges were installed in stages with respect to the stope subdivision. The mounting process was designed to keep as many gauges in operable condition as excavation progressed.

4.1 *Installations and measurements in the central tunnel*

The driving process of both Valík tunnels commenced by driving the central tunnel in which a central supporting pillar for both tunnel tubes was concreted (Fig. 3). Since the main task of continual stress measurement was to monitor the development of the load acting on the central concrete pillar, installation of the HPC gauges was concentrated in the area immediately above and below the future concrete pillar. The gauges were first mounted in the upper vault area and, subsequently, below the lower vault, at the contact point with the rock or at the contact point of the pillar with the primary lining of the central tunnel. Due to the long distances between the measuring profiles, 3 collecting dataloggers were installed along the tunnel.

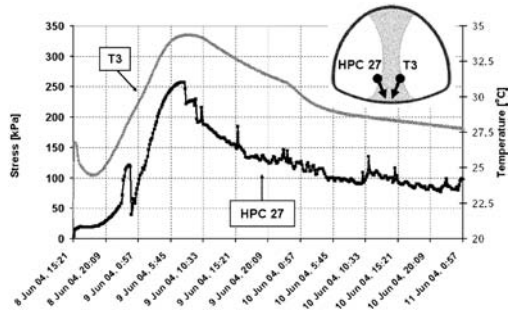

Figure 4. Stress-temperature time distribution at rock – primary lining contact – joint profile 2.

Each stress measuring gauge (HPC) installed on the surface of the stope was covered with a layer of shotcrete during the spraying of the primary lining. During the shotcrete hydration process, there is an increase in temperature and hydration pressure, which loads the stope surface. When the concrete cools, the falling hydration pressure can, for a certain time, locally load the contact with the rock with tensile stress and, eventually, the lining starts to take over the load from the rock continuum.

In cases where shotcrete is not applied into the formwork in the shotcrete lining, hydration pressure values are relatively low (max. x*100 kPa) while, conversely, in the lining which is concreted into the formwork, values increase to several MPa. The difference in the hydration stresses is the result of permitting or eliminating volume changes in the concrete during hydration. A typical example of a hydration phase time pattern is shown in Figure 4.

In 2002, as part of the prospecting stage, an exploration gallery was driven along the whole length of the future tunnel. The gallery subsequently caved in as work commenced on driving the central tunnel in 2004. During driving operations on the central tunnel this gallery was reopened which increased the amount of natural ventilation, which in turn led to a slight temperature drop in the central tunnel. Subsequently, a slight temperature drop was observed at the primary lining-rock contact which caused a change in the load acting on the lining (Fig. 5). Although the change in loading was insignificant, it proved the usefulness of the monitoring of temperature together with the development of stress.

4.2 *Installation and measurement during concreting of the central concrete pillar*

An important part of the continual measurement process was the monitoring of temperature development

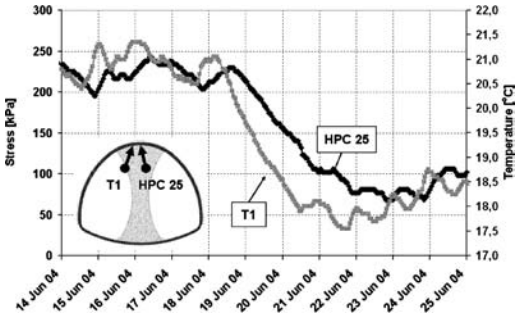

Figure 5. The effect of temperature change in the tunnel on the change in the load on the lining – joint profile 1.

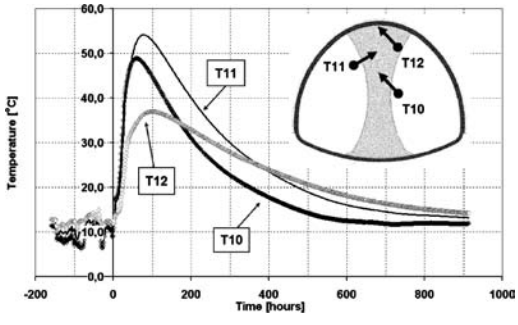

Figure 6. Time pattern of concrete hydration in the central pillar – joint profile 1.

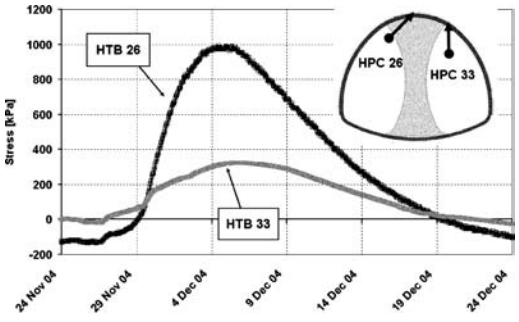

Figure 7. The effect of the concrete hydration of the central pillar on increased load at the rock-primary lining contact in the central tunnel – joint profile 2.

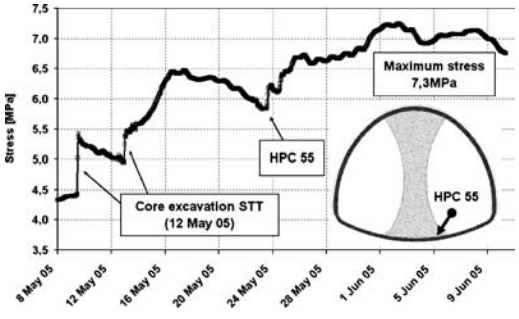

Figure 8. Load changes on the pillar footing bottom – joint profile 3.

during the hydration of the concrete of the central supporting pillar. Exceeding the maximum temperature could have resulted in a reduction in the quality of the concrete thus reducing the load-bearing capacity of the pillar (Fig. 6).

Hydration stress developed along with temperature. The development of hydration stress in the concrete of the pillar was initiated by the time-limited increase in the load at the rock-primary lining contact of the central tunnel. At the end of the hydration process, contact stresses (load) in some places above the pillar became tensile stresses which in turn, due to rock stress state redistribution, became compressive stresses (Fig. 7). More significant changes in the pillar load, however, occurred only with the approaching partial stopes of the south and north tunnel tubes as construction progressed.

4.3 *Measurement of the development of pillar loading due to the advance in partial driving*

The main reason for extending the range of geomonitoring to include continual stress measurement was the need to verify that the load on the central concrete pillar would not exceed the values determined in the dimensioning stage, in any of the various construction phases.

After the pillar in the central tunnel (CT) was concreted, the primary lining assumed practically all the load exerted by the rock massif. The pillar started to assume the load as partial driving operations in the north and south tunnel tubes (NTT and STT) approached. In some places, the load change was very fast. Figure 8 shows the rapid increase in the load on the footing bottom due to the excavation of the STT core. These rapid changes in loading justified the automated reading of measured data at 1 hour intervals.

A gradual increase in the load on the pillar was recorded at all the measuring profiles. The discontinuous, non-homogenous rock continuum exerted a considerable influence on non-uniform pillar loading. Stress concentration values locally reached 11 MPa (Fig. 9). During partial driving operations on the STT and NTT load acting on the pillar increased many times over several days (Fig. 10).

Approximately one month after the driving operations came to an end, the load on the pillar stabilised within a range of 4–8 MPa.

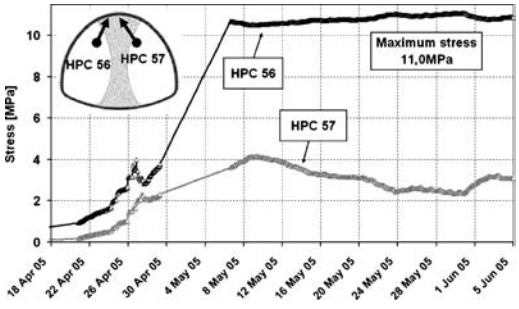

Figure 9. Maximum load on the central pillar – joint profile 3.

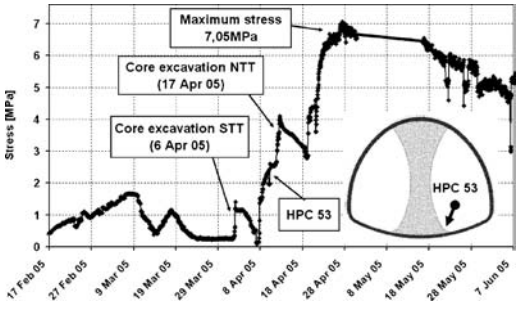

Figure 10. The effect of partial driving operations on load on the central pillar.

5 CONCLUSION

The measurement of changes in stress is one of the most difficult geotechnical measurements to perform. The continual measurement of contact stress is a method whose results depend upon the quality of each step of the installation and monitoring process. The greater the non-homogeneity and discontinuity of the rock continuum, the more difficult such measurement becomes. Any slight imperfection in the mounting of the gauges can drastically affect the usefulness of the results. It is, therefore, essential that the company chosen to do this work is able to prove its suitability for the task in terms both of qualifications and previous experience. A common underestimation of the complexity of such measurements has tended to drive commercial clients to distrust the results and to question the usefulness and relevance of this method.

The information obtained through continual stress measurement during the construction of the Valík tunnels has contributed to the safety and cost-effectiveness of the project. It is clear that the use of this method, in combination with other geo-monitoring methods, has an important part to play in the driving of tunnels in complicated geological conditions and/or where non-traditional tunnelling technology is employed.

The Josef underground educational facility project

J. Pacovský, J. Svoboda & R. Vašíček
Centre of Experimental Geotechnics, Faculty of Civil Engineering, Czech Technical University in Prague, The Czech Republic

ABSTRACT: The Faculty of Civil Engineering, CTU in Prague, is in the process of establishing a new, modern experimental facility to be used for both educational and research purposes – the Josef Underground Educational Facility (UEF). The reason for the establishment of this underground workplace arose from the need for a facility which would contribute towards providing an increased amount of practical education for students in the fields of underground structures, rock mechanics, material testing, engineering-geological surveying, geodesy and mapping, blasting, ventilation and safety training. It is envisaged that this facility will contribute towards closer collaboration between universities and outside institutions, allow the performance of national and foreign experimental projects and will be available for use as a training facility for experts in the practical application of new technologies etc.

1 INTRODUCTION

The reasons for establishing a new, modern underground educational facility as part of the Faculty of Civil Engineering, CTU in Prague, resulted from the following:

- the need for further development of experimental research at universities, particularly with regard to material engineering, environmental geotechnics, geology and hydrogeology in a natural, "in-situ" environment
- the present lack of facilities (at a convenient distance from Prague) for the practical training of students in the fields of engineering-geological and geotechnical investigation and mapping in underground spaces
- the establishment of this workplace will contribute towards closer collaboration between universities and outside institutions
- there are a number of closed, unexploited minor underground workings currently available in the Czech Republic the utilization of which for such purposes is self-explanatory.

2 LOCATION SELECTION

The basic requirements for the selection of a suitable underground site were defined as follows:

- financial feasibility (purchase price, operating and closure costs)
- varied geological conditions (occurrence of non-monotonous geological formations)
- the site's potential for future expansion (short insets for individual experiments)
- distance of up to 60 km from Prague.

Selection of a suitable location was based on the precondition that the facility should be sited in a horizontal gallery, rather than a vertical pit the operation of which would be considerably more expensive.

Economic considerations dictated that the most favorable of the various alternatives was clearly the purchase of an unexploited underground gallery. From the very beginning of the selection process it was evident that the most suitable of all the locations which fulfilled the basic site requirements and had a good local infrastructure and the potential for future expansion (reconstruction of the existing structure) was the Josef Gallery situated in the Mokrsko-Čelina area.

3 BASIC DESCRIPTION OF THE JOSEF GALLERY

The Mokrsko-Čelina area in which the Josef Gallery is located belongs to the Jílové gold bearing zone (Morávek, 1996). The Josef exploration gallery was excavated as part of renewed prospecting activities which commenced in 1981 (Fig.1). It was decided, however, that mining operations would be discontinued since ore extraction and dressing would result in the devastation of an area of natural and recreational potential and consequently, in 1991,

Figure 1. Josef exploration gallery construction yard in 1981.

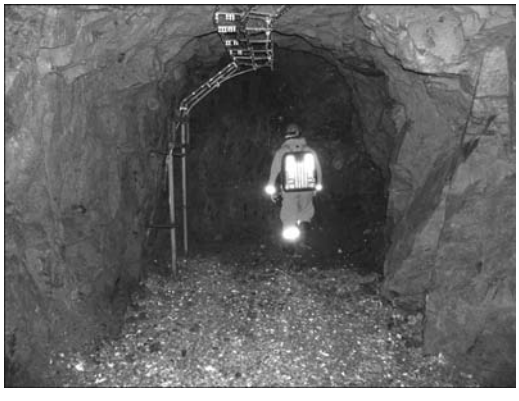

Figure 2. Typical prospecting drift profile.

prospecting activity in the Josef Gallery finally came to an end. In 2000, the entrance portals were plugged with concrete to prevent access to the underground areas.

The Josef exploration gallery is cut into the Mokrsko Hill rock massif. The total length of the main drift is 1700 m, with a cross-section of 14–16 m^2. The overlying rock thickness is 90–110 m.

The main exploration gallery is connected to various other exploration workings by numerous insets (total length of 8.6 km) which follow ore formations and provide access to two further levels. Approximately 90% of the breakings are not fitted with linings (Fig. 2).

The end of the main gallery is connected to the ground surface by means of an unsupported 90 m vent.

The geological continuum is made up of Jílové zone volcanic (basalts, andesites, rhyolites) and sedimentary (hornfels) rock types and their combinations (tuffs, tuffites) characterized by younger intrusive rock types (granodiorites, albitic granites).

4 THE PLAN TO EXPLOIT THE JOSEF UNDERGROUND GALLERY

The idea of exploiting the Josef underground gallery originated as early as 2003. Following extensive discussions and consideration of the information available, the management of the Czech Technical University in Prague gave its support to the Faculty of Civil Engineering's scheme to establish the Josef Underground Educational Facility (UEF) as a CTU multidisciplinary workplace. Unlike a number of foreign underground laboratories, the CTU workplace will not be single topic-oriented; the size of the Josef underground gallery and its geological diversity allow the participation of a wide spectrum of those interested in experimental research.

Since Josef is to be a university workplace, its primary mission is the education of young scientists – specialists in their respective branches; it is envisaged that the Josef facility will significantly improve the level of practical instruction provided by the Faculty of Civil Engineering.

One of the facility's most important areas of activity will be collaboration with outside institutions in solving topical problems concerning construction engineering, ecological engineering, verification of new building technologies and materials etc. The underground educational facility will provide space for specialized instruction and training of staff of building companies (shotcrete technology, bolt lining and anchorage, operation of modern building machinery and devices, health and safety training etc.).

A further use for Josef will be in providing facilities for domestic and international single- as well as multi-disciplinary research projects (grants); the Josef underground exploration gallery allows the performance of extensive experiments.

The organizers of the project have gained extensive experience in the exploitation of underground workplaces as part of their research participation in a number of international projects assigned by the European Union. Such experience has shown that performing experimental projects in underground facilities sets high financial demands and that without EU grant support such projects would not be practically feasible in the Czech context. It is envisaged that the Josef Facility will allow a wide range of interested parties to work on their research projects in ideal underground conditions and, moreover, that good value for money will attract academic institutions from other EU member states.

5 PROJECT IMPLEMENTATION

In 2004, the Faculty of Civil Engineering, CTU in Prague, signed a contract of cooperation with the company Metrostav a.s. in which both parties agreed to build a joint workplace, UEF Josef. At the same time,

Figure 3. Survey of the newly opened Josef underground gallery.

Figure 4. UEF Josef 's commissioning kick off.

Metrostav a.s. undertook to put the Josef gallery into operation at its own expense.

In March 2005, a loan agreement, the subject of which was the Josef underground exploration gallery, was concluded between the Faculty of Civil Engineering, CTU in Prague, and the owner of the Josef gallery, the Ministry of the Environment of the Czech Republic (MŽP). In August 2005, Metrostav a.s. removed the concrete plug blocking the entrance to the main gallery.

In September 2005, the Prague Mining Rescue Service carried out a detailed survey of the Josef complex concluding that: "The condition of the Josef underground complex allows its use as an underground educational facility" (Fig. 3).

In February 2006, the Faculty of Civil Engineering, CTU in Prague, concluded a lease contract with the owners (Lesy ČR s.p.) of the land concerned (15,000 m^2). At the same time, negotiations on their purchase were started. Based on the results of the above-mentioned survey, Metrostav a.s. ordered a project concerning the commissioning of the underground facility.

In April 2006, the Faculty of Civil Engineering won a grant from European Structural Funds JPD3, which will cover the funding of the first two years of trial instruction of students specialized in geotechnics and geodesy.

The building permit for the start of work was granted on 21st July 2006, and the commissioning of the underground was begun by Metrostav a.s. – Division 5 on 21st August 2006 (Figs 4, 5).

Discussions with the designer of the underground part of UEF Josef, IKP Consulting Engineers s.r.o., and the experts from Metrostav a.s. resulted in a decision to cater for the needs of student instruction in the first phase of the Josef Underground Facility commissioning (total length of 8.6 km of drifts) by putting into operation a section of the main gallery and the west part of the Èelina zone (Fig. 6).

Figure 5. Removal of concrete portal plugs.

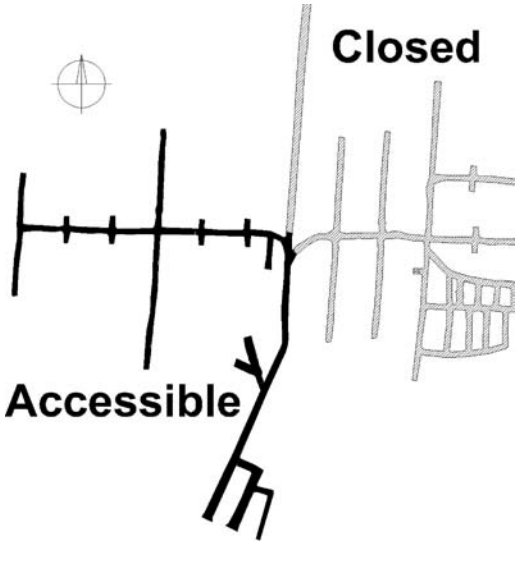

Figure 6. The size of underground spaces put into operation.

Figure 7. Current condition of Josef underground work.

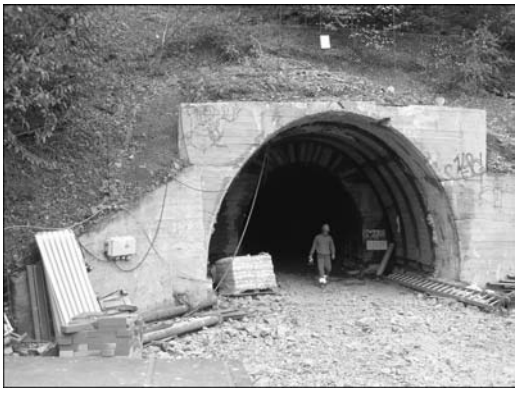

Figure 8. Adaptations of Josef gallery.

Although the Josef underground work was found in very good condition (Fig. 7), in accordance with the IKP project Metrostav a.s. started works necessary for ensuring the safety of the underground facility for student instruction (Fig. 8).

All activity within the commissioning of the underground will be completed by the end of 2006 when, following the approval of construction, Metrostav a.s. will hand the underground work over to the Faculty of Civil Engineering, CTU for further use. The following process is set by the time schedule of the JPD3 project. January 2007 is the start of the implementation of a pilot (trial) project of instruction, June 2007 is the month of presumed festive opening of UEF Josef, and from September 2007 the underground part put into operation will be used for regular instruction following newly designed study plans of the Faculty of Civil Engineering, CTU. It is envisaged that over 300 students will use the Josef facility in the first year of teaching, mainly in teaching blocks covering several days (Pacovský, 2006).

6 CONCLUSION

The exploitation of a part of the unused underground work Josef for practical educational purposes will be the first step towards the use of the total volume of the underground spaces available. Step by step, the galleries are presumed to be used for research on domestic and international experimental projects, for specialized training and instruction of staff members of building companies, and for the presentation of modern building technologies and products by both Czech and foreign construction companies.

The disused two-storey building at the Josef site, which was donated to the Faculty of Civil Engineering by its owner (MŽP) in 2005, will be converted into surface premises to serve the underground educational facility. If the underground area is to be exploited to its full extent, good quality surface premises will be required for use as offices, laboratories, accommodation, storerooms, workshops etc.; therefore plans have been made for the building's complete reconstruction.

The UEF Josef complex is situated in a beautiful natural locality. Based on an agreement with Chotilsko Municipality, UEF Josef will become part of an existing instructive foot trail with public access to the exploited part of the underground.

ACKNOWLEDGEMENT

This project would not be feasible without funding obtained from European Structural Funds – project CZ.04.3.07/3.1.01.3/3148, and financial and professional support provided by the joint-stock company Metrostav. We would also like to thank the Ministry of the Environment of the Czech Republic and Chotilsko Municipality.

Displacements estimate due twin tunnel excavation under low overburden

E.A. Palma Filho, A.C. Zingano, J.C. Koppe & J.F.C.L. Costa
Federal University of Rio Grande do Sul, Porto Alegre, Brazil

ABSTRACT: The study of the stresses and strains caused by an underground excavation can currently be modeled with better precision and much faster than a few years ago. However, the tools which allow numerical analysis in two or three dimensions, for any geometry of excavation, need data for input into the system. In the Reversion tunnel project, the contractor measured a series of displacements of the walls of the tunnels. This was done in conjunction with the mechanical characterization of the rock and the geomechanical classification of the tunnel workmanship. Using these three parameters, it was possible in this study to calculate the stress in the rock mass, by means of backward-analysis, and the ratio between the horizontal stress and vertical stress, K_0. This was accomplished using finite element software. With parameterized geomechanical data, it was possible to calculate the stresses acting on the support system for each phase of excavation.

1 INTRODUCTION

1.1 *General view*

The opening of an underground excavation, for civil, military or mining use, is an activity that has for thousands of years followed the development of civilization. Beside the diversification of use, over the years excavation techniques have developed the stage that today involves the modern technology in all the stage of an underground excavation.

1.2 *Objectives*

In this work the objective was to estimate by means of numerical simulation the displacements resulting from the excavation of twin road tunnels constructed in an area of low overburden (depth varying from 0.5 to 4 tunnel diameter), and of in the side of a hillside. For this, the software Plaxis® Tunnel 3D (Brinkgreve & Broere, 2004), that allows the three-dimensional simulation of the excavation process using the Finite Element Method, was used.

1.3 *Methodology*

The necessary data for input into the Plaxis® software (Deformability Modulus – E, Cohesion – c, Friction Angle – Ø, Stress ratio – K_0) was obtained from three sets of information: (i) the instrumentation of the tunnel; (ii) geomechanical classification carried out during the excavation; (iii) laboratory assays for characterization of the rock. Whit this information, Roclab software (Rocscience, 2006) was used to estimate the parameters, as show in Figure 1.

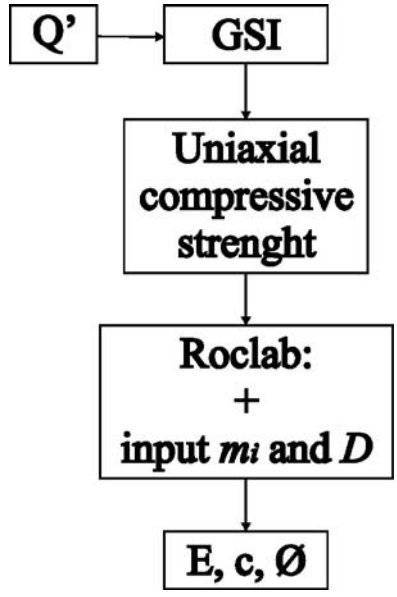

Figure 1. Sequence to estimation of the parameters.

From the information of deformability modulus, cohesion and friction angle obtained from the Roclab software, and with the displacements of the walls of the tunnels already known from the instrumentation, a

backward-analysis with the Plaxis® software was carried out, in order to get estimates of the stress ratio K_0.

2 CASE STUDY

A case study involving the stress distribution was carried out during the construction of twin road tunnels in the RS-486 road, the "Route of the Sun", that is located in Rio Grande do Sul State, in the southern region of Brazil. The double tunnels of Km 10, the so called "Reversion Tunnels", are being executed with the New Austrian Tunneling Method (NATM), along with technique of drilling and blasting. They possess an arched passage way, with 7% inclination and they are being excavated with a partialized section (Figures 2 and 3).

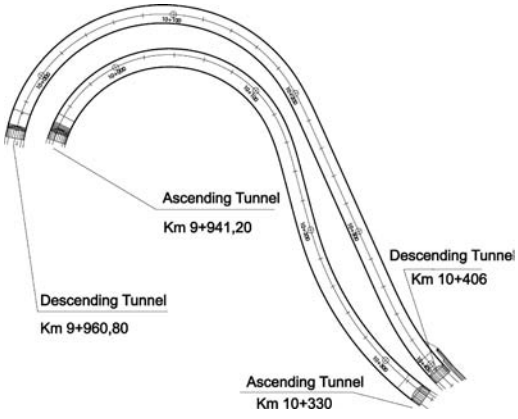

Figure 2. Road tunnel way.

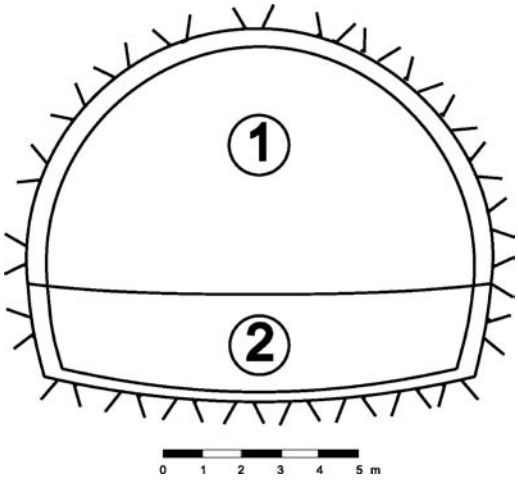

Figure 3. Typical section of the tunnels, with excavation sequence.

2.1 *Local geology*

The "Três Forquilhas" river valley cuts through a sequence of acid and basic volcanic rocks (lava flows) of the Serra Geral Formation (Cretceous period). In the base of this sequence, occurs lenses of sandstones of the Botucatu Formation. In the lowest areas of the valley Quaternary fluvial sediments of the Três Forquilhas river basin are found and, above these, sediments of the Coastal Plain (Nummer, 2003).

2.2 *Backward-analysis*

From the information of the instrumentation of the tunnel, where the measures of displacement carried out by the contractor of the project gave a divergence between the walls of the order of 3 mm, a parameterized backward-analysis was made, in order to estimate the stress ratio K_0. The parameterized values used in the analysis are described in Table 1, and lead to a stress ratio of the order of $K_0 \approx 0.2$.

2.3 *Geomechanical classification*

Since the beginning of the execution of the tunnel a geologic-geotechnical classification of the rock mass was made, by means of the Q System. Three maps were generated with this information: (i) description of the rock mass; (ii) commercial classification; and (iii) geomechanical classification.

This work classification gave values of Q between section $10+075$ and $10+149$, in the ascending tunnel, and between $10+110$ and $10+180$, in the descending tunnel. The summarized information is presented in Table 2.

Table 1. Geomechanical data for backward-analysis.

N° of simulation	Defomability modulus (GPa)	Coesion (MPa)	Friction angle (°)
1	14.60	1.011	64.04
2	14.60	1.011	64.04
3	8.51	0.565	63.02
4	3.25	0.466	60.59
5	2.40	0.467	60.37
6	2.56	0.510	60.51

Table 2. Q′ value, in the section $10+075$ to $10+149$ (ascending), and $10+110$ to $10+180$ (descending).

Information	Value
Number of data	120
Minimum value	0.10
Maximum value	35
Standard deviation	8.02
Mean	8.64

2.4 *Laboratory assays*

Concerning the quality of the rock, values from laboratory assays are summarized in Table 3.

From the value of known resistance of uniaxial compression, and the value of Q′ obtained from the classification, RocLab software was used in order to estimate the Mohr-Coulomb parameters to input into the software. Table 4 shows the average values obtained using the RocLab software. The Disturbance Factor *D* used was 0.5.

2.5 *Numerical simulation*

With the geometry known; the geomechanical parameters estimated; and with the excavation sequence also already known, a numerical simulation of the excavation was made. The resulting mesh was as shown in Figure 4.

Table 3. Rock quality, from laboratory assays.

Litology	Riolite
Rock parameter	mean – standard deviation – number of samples
UCS (MPa)	79.91 – 14.91–11
Point load (MPa)	101.87 – 33.45–9
c (MPa)	19.80

* estimated in accordance with Hoek *et al.* 2002.

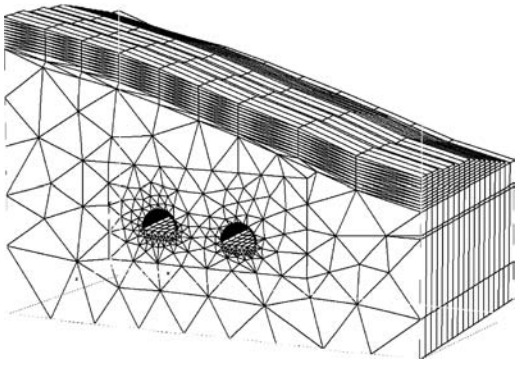

Figure 4. Mesh for the numerical simulation.

For the simulation in the Plaxis®, the sequence of the work was:

- the general configurations had been defined (file name, model declivity, dimensions of the work area, grid spacement, and units);
- extension and geometry mesh was defined;
- in the tunnel designer auxiliar command was draw the geometry of twin tunnels;
- the restrictions of the mesh had been defined; the properties of the material, and the K_0 ratio had been input;
- was defined the support system (shotcrete and bolts);
- the Finite Element mash was generated;
- the eighteen slices of four meters each had been inserted (three-dimensional);
- the excavation sequence was defined.

3 RESULTS

A 72 meters section of excavation was simulated three-dimensionally, split into 4 meters slices, for the section between stations $10 + 075$ and $10 + 146$ of the ascending tunnel. In the excavation, in this stretch, there are sections of instrumentation at stations $10 + 075$, $10 + 110$ and $10 + 146$, from where the data for the comparison with the simulation was obtained. The results of the estimated displacements between the walls of the tunnels are given in Tables 5 and 6, as a function of each stage of excavation.

Other information was also obtained by means of the numerical simulation software an the forces acting

Table 5. Estimated displacements, for half section.

Section	Horizontal displacements, ascending tunnel, in mm	Horizontal displacements, descending tunnel, in mm
01	2.35	2.60
02	2.05	2.10
03	1.90	1.60

Section	Horizontal displacements, ascending tunnel, in mm	Horizontal displacements, descending tunnel, in mm
01	1.84	2.00
02	1.56	1.50
03	1.24	1.10

Table 7. Forces acting on the support system.

Full section excavation – maximum value	
Axial force	1.80×10^3 kN/m
Shear force	62.38 kN/m
Bending moment	19.15 kNm · m

on the support system of the excavation, as presented in Table 7.

4 CONCLUSIONS

It was possible to carry out, by means of numerical methods, the three-dimensional simulation of the excavation of double twin tunnels.

The value estimated from parameterized backward-analysis for the stress ratio K_0 was of the order of 0.2 and is consistant with the topographical situation of the project, having little overburden and in the side of a hillside.

The estimated values of total displacements of the excavation for the full section stage are slightly lower than the displacements estimated for the half section stage of excavation.

Parametric study of displacements on sequential and full-face tunnel excavation

S. Papakonstantinou & W. Schubert
Institut of Rock Mechanics and Tunnelling, Graz, Styria, Austria

ABSTRACT: When constructing tunnels with low overburden in built-up areas face stability and in the unsupported span, as well as displacements of ground and subsidence are major issues. Presently two different concepts to deal with such tunnels can be observed. One concept is to subdivide the face into several excavation steps, like top heading bench and invert excavation with a certain distance between the single steps. The other concept is a full-face excavation with a quick ring closure and heavy support of the face to account for the face stability problem. The different concepts have been compared in a parametric study, using the code FLAC3D.

1 INTRODUCTION

According to the Austrian Guideline for Geomechanical Design of Underground Structures, the system behaviour is defined as the behaviour of the compound system resulting from rock mass and selected construction measures (excavation and support method, auxiliary measures). In tunnels with low overburden, the stress redistribution, combined with poor quality of the ground can lead to instability of the face and the crown. Shear failures can develop progressively without significant sign (Schubert & Vavrovsky 1994). This can lead to serious overbreak of the crown or even to a chimney type failure in case of poor ground and low confining stress (Feder 1981). Therefore, deformations should be carefully controlled to minimize the risk and scale of collapses, as well as surface settlements.

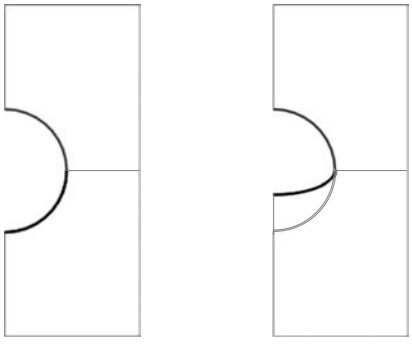
The advocates of the full face method claim that the increase of the rigidity of the core ahead of the face is the main medium of controlling pre-convergence and convergence in the cavity (Lunardi 2000). In cases of low face stability extensive face reinforcement is applied, ranging from a number of 50–60 anchors in shallow tunnels, up to 200 in tunnels with higher overburden (100–200 m) or even 400 in extremely poor ground.

Quick final ring closure was also demanded by some protagonists of the NATM (Müller 1978). Over the decades in poor ground, sequential excavation with the installation of a temporary invert in the top heading however has become common practice. In very weak ground, the face usually is supported by shotcrete and a small and adequate amount of anchors.

An unbiased evaluation of the advantages and disadvantages of the different construction methods so far has not been attempted. To allow an objective comparison of the two approaches, a parametric study has been conducted. The emphasis in this work was put on the evaluation of displacements of the tunnel, the ground ahead of the face, and the surface settlement.

2 3D NUMERICAL MODEL

The Flac3D code was used for the simulation of the tunnel excavation.



2.1 *Model geometry*

The length of the model was chosen with 150 m and the width with 60 m and 80 m respectively for the weaker ground. The tunnel diameter was chosen with 10 m, while the overburden was 20 m. For the sequential excavation, the top heading height in the model is 5 m with a depth of the temporary invert of 2 m. The thickness of the slices in longitudinal direction was chosen with 2 m. The two construction methods simulated are shown in Figure 1a, b.

2.2 *Material parameters*

The Mohr-Coulomb failure criterion was used for the soil, while the shotcrete was modelled elastically. The parametric study included variations of cohesion, friction and K_0 (Table 1).

The shotcrete was modelled with elastic behaviour, considering the effects of time dependent hardening,

(a) Full-face excavation method.

(b) Sequential excavation method (top heading stage)

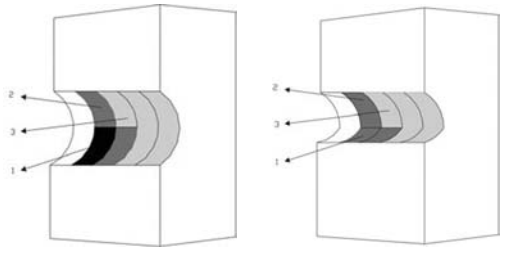
Figure 1. Excavation methods.

Table 1. Ground parameters used in the study

Model	Cohesion (kPa)	Friction angle (degrees)	E (MPa)	ν (–)	k_0 (–)
1	10–100	25	40	0.3	1.0
2	20	15–25	40	0.3	1.0
3	30	25	40	0.3	0.5–1.0

Table 2. Development of effective Young's modulus of shotcrete.

Input parameter Ec,eff	1 (MPa)	2 (MPa)	3 (MPa)
	500	1000	2000



shrink and creep by using an effective Young's modulus with a maximum value of 2000 MPa (Wittke et al. 2003, Schubert 2001, Leitner 2005). Three stages of hardening were considered (see Table 2).

For all simulations a shotcrete thickness of 20 cm was chosen.

2.3 *Sequence of excavation and support installation*

Excavation of 80 m in the longitudinal direction was simulated step by step with round lengths of 2 m. The installation of the support is done 2 m behind the face. The process of installing the support in both construction methods is illustrated in Figure 2a, b. Numbers 1, 2, and 3 in the diagrams correspond to the table 2 values above.

For the top heading – bench excavation sequence it showed, that due to the invert in the top heading and the immediate invert closure after bench and invert excavation only negligible displacements occurred. Hence,

(b) Installation of support for full-face excavation.

(b) Installation of support for top heading excavation.

Figure 2. Installation of support behind the face for both methods.

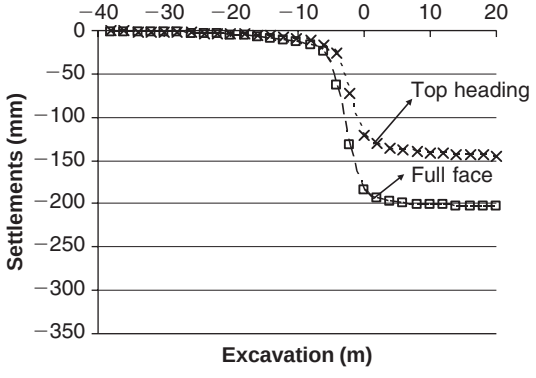


Figure 3. History plot of crown settlements for station 40, $\varphi = 25°$, $K_0 = 1.0$, $c = 10$ kPa.

the results of the bench excavation are not shown in this paper.

2.4 *Face support*

The face support was simulated with a uniformly distributed pressure on the face. The influence of the face pressure on the displacements was studied for both excavation methods. The support was simulated in cases, which would not stabilize without it. To evaluate the equivalent number of face bolts, the average load taken by each bolt was chosen at 100 kN. Some authors use the ultimate load of bolts (Peila 1994) to evaluate the equivalent face support pressure. Other studies show, that the load taken by a bolt is in the range of maximally 100 kN, regardless of its strength (Dias 1999, Trompille 2003, Leitner 2005).

3 RESULTS

3.1 *Terminology*

In this study, pre-settlement refers to the settlement, which takes place ahead of the face.

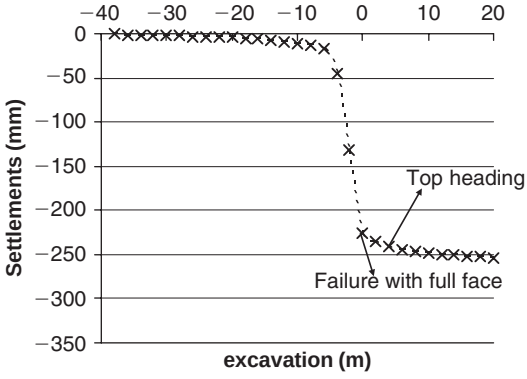

Figure 4. History plot of crown settlements for station 40, $\varphi = 25°$, $K_0 = 1.0$, for c = 15 kPa.

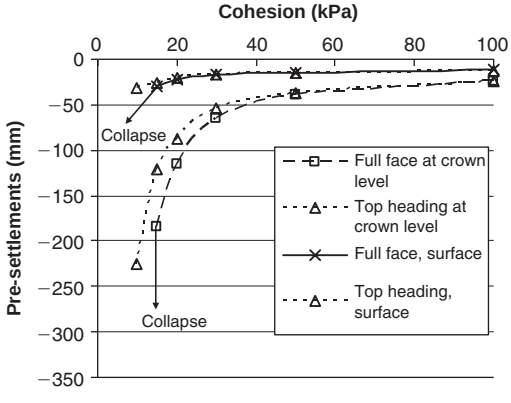

Figure 5. Pre-settlements at crown level and surface, $\varphi = 25°$, $K_0 = 1.0$, cohesion varied.

3.2 *Influence of cohesion*

For a cohesion below 50 kPa, pre-settlements (at the crown as well as at the surface level) caused by sequential excavation are smaller than those with full -face excavation, even if they both increase with decrease of cohesion (See Fig. 5). Disturbance of ground ahead of the face increases with full-face excavation. This soon leads to larger final crown settlements as well as slightly larger surface settlements (Fig. 6). The main difference is that with the full-face excavation the pre-displacements are considerably higher. Face displacements in the case of full-face excavation are much larger (Fig. 7) than those with sequential excavation. Higher displacements of the face increase the hazard for the labour force and lead to the requirement of face support.

A critical cohesion of 30 kPa was detected for which final crown settlements with staged construction are lower than the ones with full-face (Fig. 6).

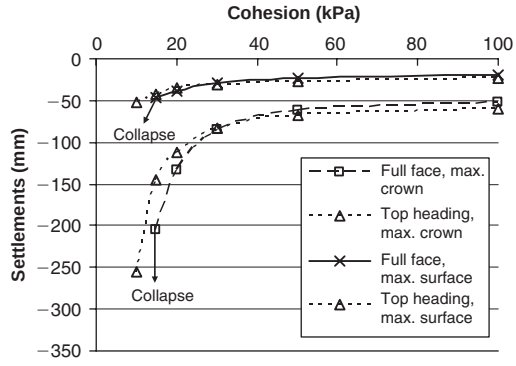

Figure 6. Settlements at crown level and surface, $\varphi = 25°$, $K_0 = 1.0$, cohesion varied.

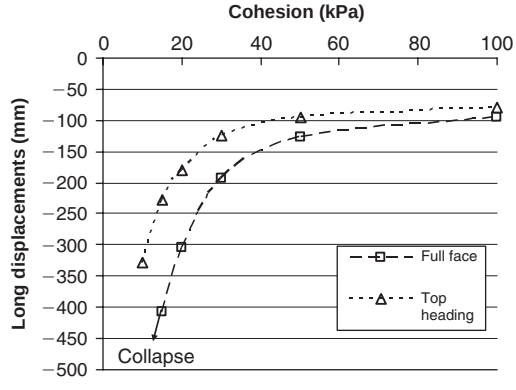

Figure 7. Face displacements, $\varphi = 25°$, $K_0 = 1.0$, cohesion varied.

With a further decrease of cohesion below 20 kPa the final crown settlements increase with the full-face excavation more than those with the staged excavation.

When the cohesion is reduced to 10 kPa the tunnel excavated full face collapses while the top heading remains stable.

3.3 *Influence of coefficient of stresses* K_0

A variation of the coefficient of stresses was investigated for cohesion of 30 kPa. It showed that this parameter had a minimal influence on the development of displacements with different construction methods.

3.4 *Influence of friction angle*

A high sensitivity of displacements to this strength parameter was revealed even with small changes of its value, keeping the cohesion at 20 kPa and K_0 at 1.0. Crown and surface settlements increase significantly

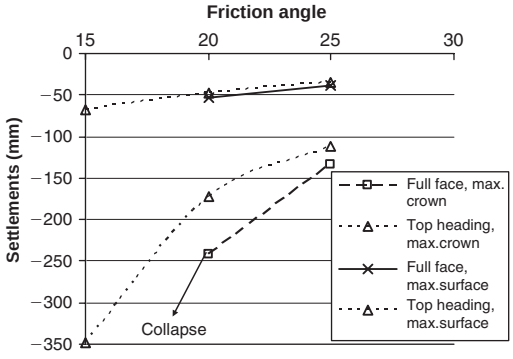

Figure 8. Crown and surface maximal settlements, $c = 20$ kPa, $K_0 = 1.0$, friction varied.

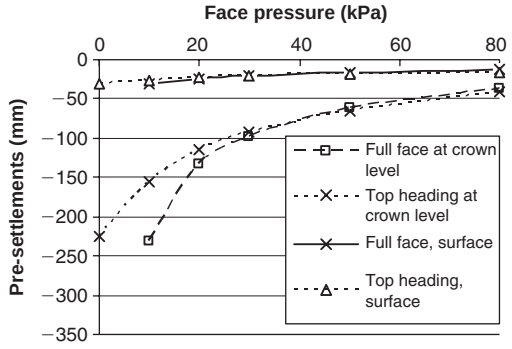

Figure 9. Pre-settlements at crown level and surface, $\varphi = 25°$, $K_0 = 1.0$, $c = 10$ kPa, face pressure varied.

for a lowering of 5 degrees in the friction angle, from 25° to 20° (see Fig. 8).

When the friction angle is reduced to 15°, the tunnel excavated full-face collapses.

In case of a pronounced variation of the friction of the ground, tunnelling with full-face excavation appears to be risky, because displacements escalate rather fast and can not easily be controlled on site.

3.5 *Variation of face pressure*

In cases, where the full-face excavation would lead to failure (in this case $c = 10$ kPa) a pressure was applied on the face at each excavation step. A parametric study for top heading stage was also made to find with what pressure same level of crown settlement, surface settlement or facial displacement occurs. As pointed out before, only a small amount of the face bolts' strength in shallow tunnels is activated, approximately 100 kN. This still is an optimistic estimation, as the activated force in each anchor depends on the position and overlapping length (Leitner 2005). Assuming such a load mobilised in each anchor, we found that full-face excavation demands 24 face bolts and top heading excavation 12 face bolts to achieve nearly the same crown and surface settlements. If the design criterion is only face displacement the full face excavation would require 16 bolts more than the face of the top heading.

Additionally, one can observe that an increase of the bolt density beyond a critical value decreases the displacements only in an insignificant way. Such an effect has been already proved, but only for deep tunnels. A critical bolt density of 0.5 b/m^2 and 0.2 b/m^2, up to which there is a significant influence of the bolts on the displacements was found for full face excavation by Cosciotti (2001). In our study, an optimum face pressure of 30 kPa for both methods and for each examined displacement was found (see Figs. 9–10), meaning 0.3 b/m^2 for top heading stage and 0.6 b/m^2

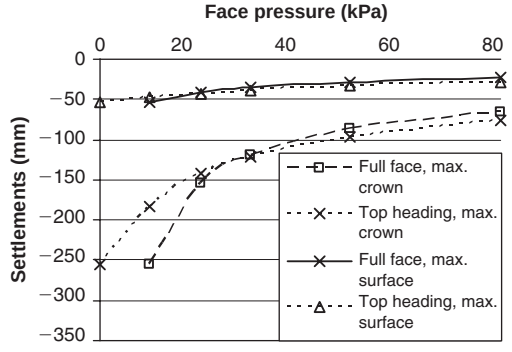

Figure 10. Settlements at crown level and surface, $\varphi = 25°$, $K_0 = 1.0$, $c = 10$ kPa, face pressure varied.

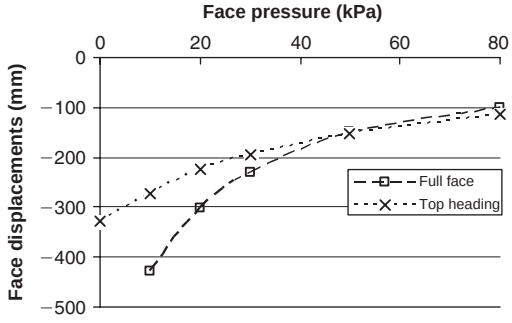

Figure 11. Face displacements, $\varphi = 25°$, $K_0 = 1.0$, $c = 10$ kPa, face pressure varied.

for full face excavation, which is close to the findings of Cosciotti (2001). Face pressure more than 50 kPa makes full-face excavation slightly better than the staged excavation with respect to roof settlements (Fig. 9). However, in such a case the number of bolts is large (40 bolts).

4 CONCLUSIONS

The results of this parametric study demonstrated that for a crucial value of cohesion, the sequential excavation leads to smaller pre-displacements and total displacements than with the full-face approach. The portion of predisplacements dominantly controls the rate and final value of crown and surface settlements.

Collapse occurred at a cohesion value equal to 10 kPa with full face driving, while the top heading remained stable. Full-face tunnel excavation also led to collapse for a soil with cohesion of 20 kPa and friction angle of 15°. This means that for very poor ground the most safe tunnel construction method is sequential excavation. The friction angle proved to be more influential parameter on evolution of displacements than the cohesion. Consequently, in a geological environment with low or frequently changing of friction angle, staged construction of a tunnel reduces the risk of abrupt and uncontrollable propagation of displacements as well as a collapse.

As recent research has shown, forces mobilized in the face bolts are rather low. When using the bolt strength for the estimation of the equivalent face pressure, the effect of the bolts is overestimated.

The study also showed that with the sequential excavation a considerably lower amount of face support is required than with the full-face method to achieve the same deformation magnitudes. It has shown, that with sequential excavation support of the bench face is not required, providing a sufficient distance between top heading and bench excavation is maintained.

The effectiveness of face bolting progressively decreases beyond a density of 0.3 bolts/m^2 and 0.6 bolts/m^2 for the top heading and full-face excavation respectively.

The study shows, that in very poor ground sequential excavation is preferable in terms of crown, face, and surface displacements and risk of collapse of the face. To achieve an equivalent level of safety, the full-face excavation would require a considerable number of face bolts.

The final decision on which construction method is preferable for specific soil conditions has to be based on an analysis of time, costs, and risk associated with each method.

ABSTRACT: Recently, interest has increased in the underground storage of cryogenic materials such as LNG. When designing and constructing underground storage for LNG, it is very important to evaluate the characteristics of the rock mass under cryogenic conditions. The formation mechanism and extent of the ice-ring, which is a key factor in the new concept for storing LNG and is the frozen zone including ice in several joints within the rock mass, should be studied especially when considering the stability of underground storage for LNG. However, little research exists on ice-ring formation and the thermo-mechanical behavior of rocks exposed to cryogenic conditions. In this study, in order to investigate the characteristics of the ice-ring caused by cooling, we measured the swelling pressure within the joints caused by the phase change of water to ice. We also performed the cryo-suction test to investigate the flow characteristic after ice formation. The results of tests show that the swelling pressure was approximately 2.43 MPa at the phase change temperature, 0°C, and the swelling pressure increased about 11.66 MPa/°C as cooling took place. In the cryo-suction test, the growth rate of the ice in the joints was 1.0 mm/day to 1.1 mm/day and varied minimally in joint apertures.

1 INTRODUCTION

The demand for liquefied petroleum gas (LPG) and liquefied natural gas (LNG) is increasing rapidly, and there are plans to build new liquefied gas storage facilities in Korea. To construct underground storage for cryogenic temperature materials such as LNG, the thermal effects on structural stability underground should be considered.

A number of unsuccessful attempts to store LNG in unlined rock caverns have been tried (Kim, Amantini & Chanfreau, 2003). Those failures were mainly caused by the opening and generation of cracks by a cryogenic thermal load (−162°C) on the cavern wall. In order to overcome this problem, a new concept for storing LNG in a lined rock cavern (LRC) has since been developed and tested for several years (KIGAM, 2004). In this concept, a containment system with a gas-tight steel liner and insulation protect the host rock against the extremely low temperature. In addition, a new groundwater control system was introduced to create an ice-ring (ice barrier) around the LRC cavern to protect it from groundwater intrusion into the containment system. The ice-ring is supposed to play an important part as a secondary barrier against leakage of the stored material. In the case of groundwater intrusion into the containment system, the integrity of the containment system can be destroyed because of the volume expansion of the groundwater during the freezing process. Therefore, the location and thickness of the ice-ring and the characteristics of the ice-ring are important factors for the stable storage of LNG in a lined rock cavern.

To validate this new concept of storing LNG in a lined rock cavern, a pilot plant has been constructed and operated in an existing research cavern in KIGAM since 2003 by storing LN_2 (−196°C) instead of LNG for safety and practical reasons.

In this research, in order to investigate the characteristics of the ice-ring caused by cooling, we measured

the swelling pressure within the joints caused by the phase change of water to ice. And we performed the cryo-suction test to investigate the flow characteristic after ice formation. We also measured the propagation of the ice-ring with joint apertures.

2 ICE-RING FORMATION IN PILOT CAVERN

The schematic construction sequences are outlined in Figure 1. In this new concept of LNG storage, groundwater near the cavern must be drained in order to avoid the freezing of groundwater that causes instability of the rock cavern and the concrete lining. After completing the drainage around the cavern, the cavern was filled with LN_2. Then a heat transfer occurred from the cavern to the rock mass due to the temperature gradient. After checking the spread of an 0°C isotherm location by temperature monitoring, the drainage system stopped, and the groundwater table returned to the original state. Consequently, an ice-ring formed around the 0°C isotherm.

The pilot underground cavern is located at Daejeon, Korea, and the depth from the surface to the cavern roof is about 20 m. Detailed information about this cavern has been described in KIGAM research reports (KIGAM, 2004). A comprehensive geotechnical monitoring system was applied to measure the temperature and the thermo-mechanical responses of the rock mass and concrete during the construction and operation of the LNG storage. Temperature and displacement were monitored from 6 borehole extensometers, which have 6 measuring points, respectively. After several commissioning tests, operation began on 10 January 2004 with a 2.6 m level of LN_2; the drainage rate was reduced gradually from 10 June 2004 to 8 July 2004. Filling of LN_2 was completely stopped on 5 July 2004. The cavern was completely emptied on 12 August 2004. In addition, through groundwater level monitoring, it was found that the groundwater level rose to the roof of the cavern on 1 July 2004.

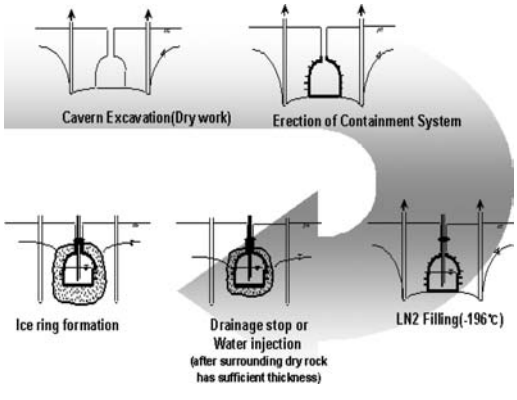

Figure 1. Schematic construction of the Daejeon pilot LNG cavern.

The cavern and containment system were dismantled after the completion of the scheduled operations in order to judge the validity and safety of the proposed concept. The decision criterion was based on the occurrence of thermal cracks in the rock mass and concrete lining. No remarkable thermal cracks were detected in the rock mass and concrete lining; thus, the experiment was considered a success.

3 ROCK SPECIMENS

The rock specimens used in the experiment were biotitic granite, which were sampled by the LNG pilot plant. The basic properties of the tested rocks are as follows.

3.1 *Mechanical properties*

The mechanical properties of the tested rocks are summarized in Table 1.

3.2 *Thermal properties*

The thermal properties of the granite were measured by Korea Research Institute of Standard and Science. Thermal conductivity, specific heat, and the linear thermal expansion coefficient are listed in Table 2.

Table 1. Mechanical properties of the tested rocks.

Properties	Values
Bulk specific gravity	2.66
Absorption ratio (%)	0.32
P-wave velocity (m/s)	3,740
S-wave velocity (m/s)	2,010
UCS (MPa)	129
Young's modulus (GPa)	43.2
Poisson's ratio	0.22

Table 2. Thermal properties of the tested rocks.

Properties	Values
Specific heat (J/g °C)	0.7282
Thermal conductivity (W/mK)	2.382
Linear thermal expansion coefficient ($\times 10^{-6}$/°C)	7.411

These properties vary with temperature. Table 2 shows the numerical value at room temperature.

4 LABORATORY TESTS

4.1 *Swelling pressure test by phase change*

To measure the swelling pressure during the phase change of water to ice, a new testing system was manufactured as shown in Figure 2. The vessel is made with 10 mm thick circular steel to prevent deformation with phase change. The environmental chamber (Fig. 3) supplied by the Interlaken rock testing system was used to obtain a cold environment. The swelling pressure was measured using a PG-1TH (Kyowa) pressure transducer, which has a capacity of 100 MPa and thermal correction to −10°C. As shown in Figure 2, the inner space was filled with water and silicon oil. The swelling pressure by the phase change was transmitted to the pressure transducer through the silicon oil.

The tests were performed from room temperature to −3°C, from −3°C to −6°C and again −6°C to −8°C. The temperature was lowered at the rate of 1°C/min to minimize the thermal stress buildup during refrigeration. The test sampling rate was 0.1 Hz for consideration of test time.

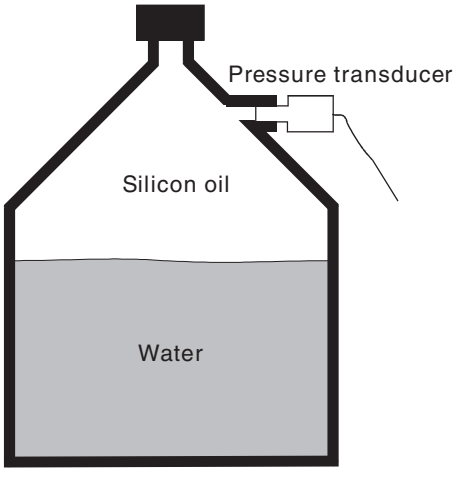

Figure 2. Schematic diagram of test equipment.

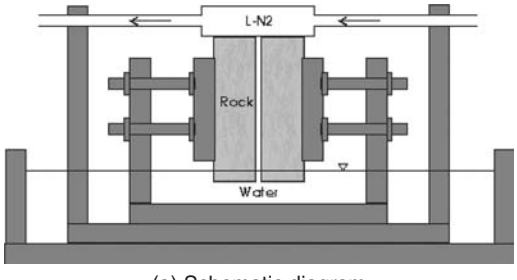

Figure 3. A view of environmental chamber for cryogenic test.

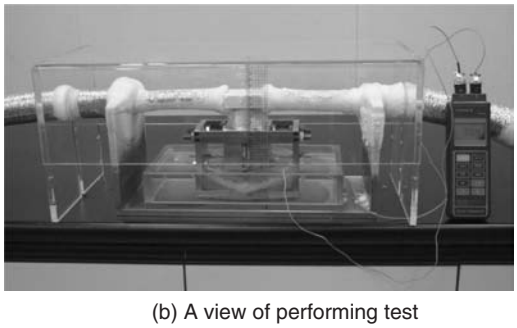

4.2 *Cryo-suction test*

For the cryo-suction test, new test apparatus also was manufactured (Fig. 4). The purpose of this cryo-suction test was to identify the possibility of progressive ice-ring movement to the LNG cavern. For this test, we measured the progress length of ice within the joints. To reproduce the joints, a rock specimen with a 150-mm height was separated into two parts. The tested apertures between the two rock specimens were 1.5 mm and 3.0 mm.

As shown in Figure 4(a), cryogen was conducted to the specimens through the LN_2 pipe located at the upper end of the specimens. The lower end of the specimens was under water. After the water within the joint changed to ice, the progress length of the ice was measured with visual observation for 12 hours. From these measurements, the growth rate was calculated.

Figure 4. Cryo-suction test.

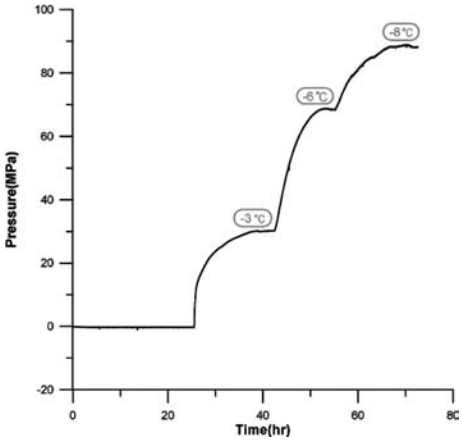

Figure 5. Results of swelling pressure test.

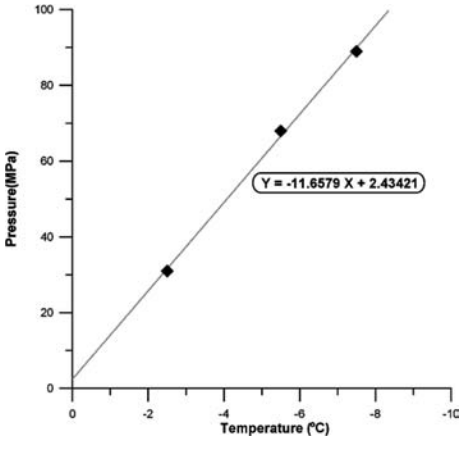

Figure 6. Swelling pressure as a function of temperature.

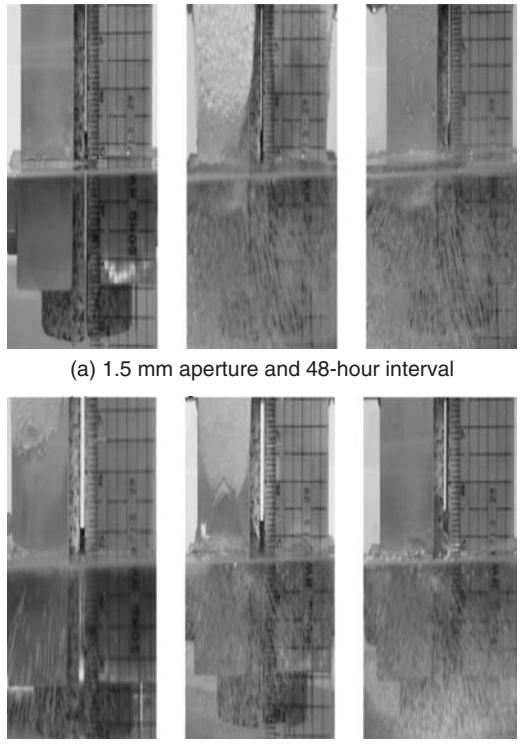

5 TEST RESULTS

5.1 *Swelling pressure test*

The test results show that swelling pressure by the phase change of water to ice was about 31 MPa when the temperature was lowered from room temperature to −3°C. The swelling pressures were 68 MPa from −3°C to −6°C and 89 MPa from −6°C to −8°C (Fig. 5).

From the linear regression on the temperature, swelling pressure was 2.43 MPa at 0°C and increased at a rate of 11.66 MPa°C (Fig. 6).

According to previous research, the swelling pressure occurring within the pore or joint was about 14 MPa (Blyth et al., 1984), and when the water was completely confined, the swelling pressure was 25 MPa (Andersland et al., 1978). Compared to the previous research, the different swelling pressure observed in our study was due to the effect of the state of the water confinement and test temperatures.

Elapsed time (day)	Cryo-suction (mm)	
	1.5 mm aperture	3.0 mm aperture
0.5	0	0
1.0	0.5	0.5
1.5	0.5	1.0
2.0	0.5	1.5
2.5	1.0	2.0
3.0	1.5	2.5
3.5	2.0	3.0
4.0	2.0	3.5
4.5	2.5	4.5
5.0	3.5	5.0
5.5	4.0	6.0
6.0	4.5	6.0

5.2 *Cryo-suction test*

From the observation of the progress length of ice, ice growth rates were measured. Figure 7 shows the test

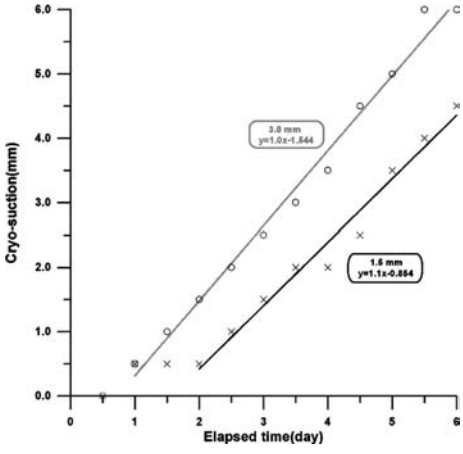

Figure 8. Cryo-suction with elapsed time.

results at the 1.5 mm aperture and 3.0 mm aperture. The numerical values with reading visual observation are listed in Table 3.

As shown in Figure 8, the ice growth rate was 1.0 mm/day at the 1.5 mm aperture, and the ice growth rate was 1.1 mm/day at the 3.0 mm aperture. There is no significant difference with variation of apertures.

6 CONCLUSION

To investigate the characteristics of the ice-ring caused by cooling, we manufactured new test apparatus and measured the swelling pressure and growth rate of ice within joints caused by the phase change of water to ice. From this study, the following results were obtained:

- The Swelling pressure by the phase change of water to ice was about 31 MPa, 68 MPa, and 89 MPa when the temperature was lowered from room temperature to −3°C, from −3°C to −6°C and from −6°C to −8°C, respectively.
- From linear regression on temperature, the swelling pressure was approximately 2.43 MPa at the phase change temperature, 0°C. The swelling pressure increased about 11.66 MPa/°C.
- The growth rate of ice within the joint was 1.0 mm/day to 1.1 mm/day and varied minimally in the joint apertures.

Underground exploitation of a granite mine by large voids: stability aspects

D. Peila, S. Pelizza, & C. Guardini
Tunnelling and Underground Space Center Dept. of Land, Environment and Geoengineering, Politenconco di Torino, Torino, Italy

ABSTRACT: This paper describes the geomechanical and stability aspects of an underground granite mine located in Canal San Bovo (Trento district, North – East Italy). The exploitation of the granite, which is used in the ceramic industry, is carried out the by room and diaphragm method. The rooms are 12 m wide and they cross the main discontinuity set of the rock mass in the perpendicular direction. This work presents the analyses that were performed to verify the local and global underground void stability.

1 INTRODUCTION

Industrial mineral exploitations are usually carried out in open pit mines, since they are characterized by lower production costs than the underground exploitation of the same ore. The underground option is however unavoidable when environmental preservation is necessary and when the topography of the area does not allow the creation of an open pit mine.

An interesting example of these conditions is the underground granite mine in Canal San Bovo (Trento District, Italy) (Fig. 1), which is exploited to obtain feldspar for the ceramic industry. The exploitation method consists of the excavation of long rooms separated by diaphragms, which are excavated starting from a main tunnel sub-parallel to the mountain slope. The choice of the exploitation method was influenced by the geomechanical parameters of the good quality rock mass, which therefore, allows the rooms to be excavated with an annual production of about 30000 m^3 of granite. It is important to point out that the chosen geometry is very interesting since it does not require large infrastructural works, can be selective and allows a large flexibility in terms of production quantities (if necessary, more rooms can be exploited simultaneously).

2 GEOLOGICAL AND GEOMECHANICAL ENVIRONMENT

2.1 *Geological conditions*

The exploitable granite rock mass is located on the left side of Vanoi stream valley, between Canal San Bovo and Caoria (Trento District), and enters inside the Col Tondo mountain for about 500 m. It is a coarse

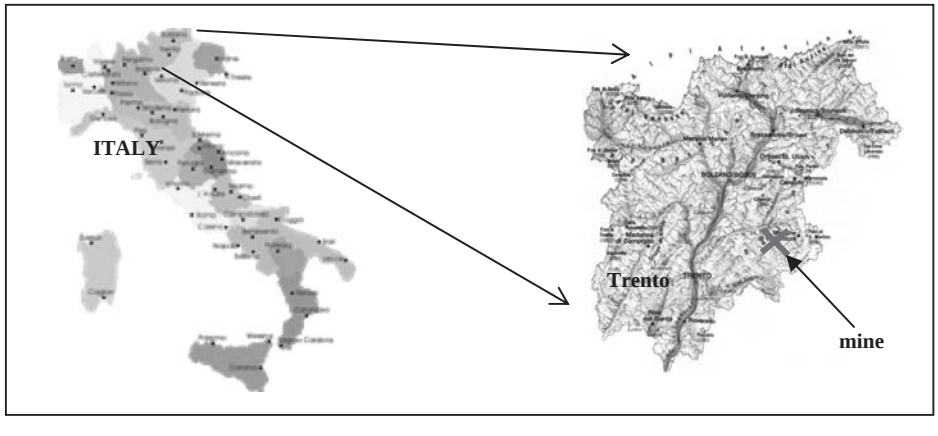

Figure 1. The position of the mine inside the Trento district.

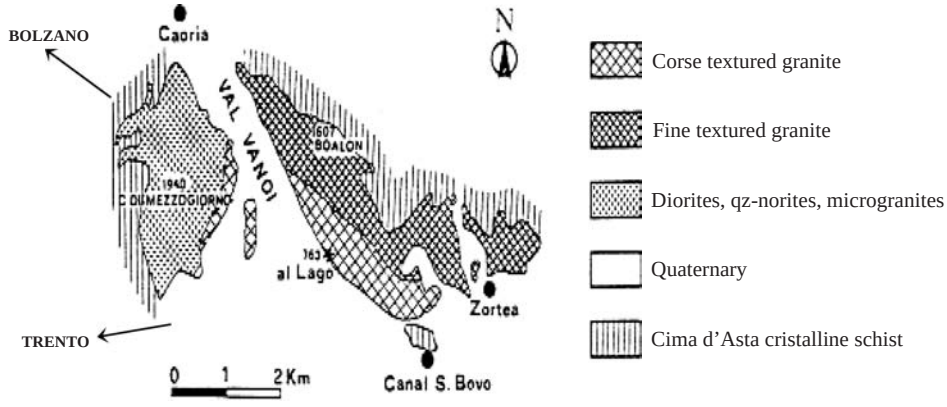

Figure 2. Simplified geological map of the area where the mine is located (Siena, 1977).

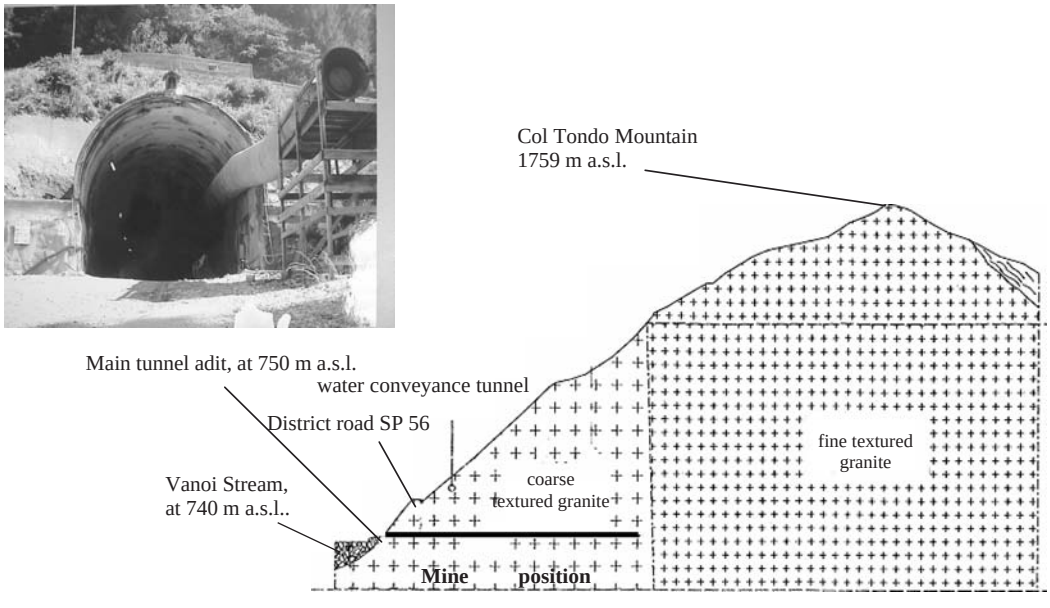

Figure 3. Rock mass geological section.

textured granite, with medium grains size (ranging between 1 mm and 3 mm), mainly composed of quartz, k-feldspar, plagioclase, biotite and muscovite.

The excavated ore is subject to a crushing treatment in order to separate the biotite from the other minerals, which are the useful products for the ceramic industry.

2.2 *Geomechanical investigations*

Detailed investigations, both in the laboratory and in situ, with a geotechnical survey in the first exploration tunnel, were carried out to provide reliable geotechnical data for the stability analyses of the mine voids. The results of the in situ survey were processed using the Dips code (Ver. 5.2, Rocscience) (Figs. 4–5). Four main discontinuity sets are present in the rock mass (Tab. 1), the most important is the A set, which has a 233° dip direction and a dip of 77°, and is therefore sub-parallel to the mountain slope. The discontinuity set indicated as C is also noticeable since it has a high persistence and if coupled to the previous one may cause block collapses in the rooms. The B and D sub-horizontal and the sub-vertical discontinuity sets are less important since they are less persistent than the A and C ones (Fig. 6). Globally speaking, the geomechanical conditions of the rock mass are generally good and, according to the Bieniawski rock mass classification, the calculated RMR

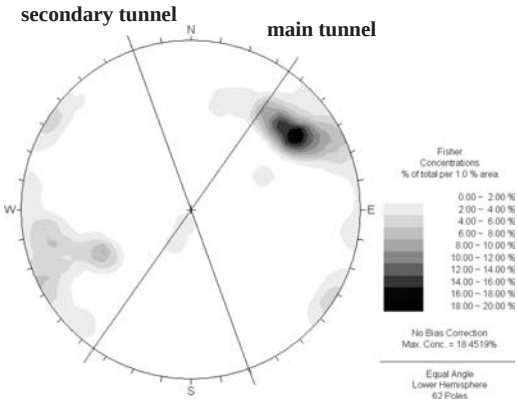

Figure 4. Stereoplot of joint poles.

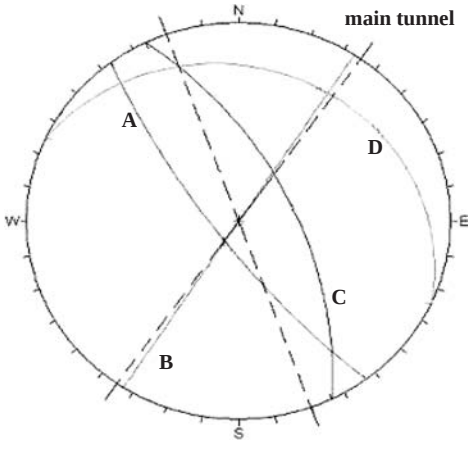

Figure 5. Representation of the main discontinuity sets.

Table 1. Orientation of the discontinuity sets.

Discontinuity sets	Dip	Dip direction
A	77°	233°
B	90°	123°
C	61°	64°
D	15°	25°

values are between 59 and 74 (class II) (Bieniawski, 1989; Hoek et al., 2002). The most important geomechanical parameters of the intact rock, evaluated by laboratory tests, are summarized in Table 2.

3 LAYOUT OF THE MINE

The mine consists of sub-parallel rooms separated by rock diaphragms, as shown in Figure 7. The slopes

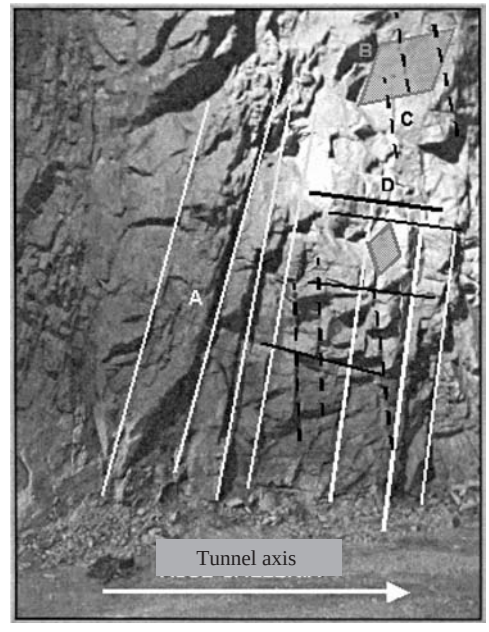

Figure 6. Photograph of the main tunnel wall and indication of the main discontinuity sets.

Table 2. Geomechanical parameters of the rock mass.

Rock mass Young's modulus	$E_M = 2RMR - 10$ [GPa]	40
Rock mass Poisson's ratio	ν	0.3
Uniaxial compressive strength of the intact rock	σ_c [MPa]	170
Rock mass m (peak) and s (peak)	m_p, s_p	8.595–0.0205
Rock mass m (residual) and s (residual)	m_r, s_r	1.000–0.0100

overhanging the adit are very steep and they have therefore made it necessary to place the mine adit at 750 m a.s.l. and pass under the local SP 56 road with forepoling (Fig. 3). The main tunnel axis orientation is N35°E, with a section of about 53 m^2. A secondary tunnel was driven from the main tunnel and the exploitation rooms are excavated from this secondary tunnel. The rooms are 12 m wide and 18.5 m high and their axis is almost parallel to the main entrance and is perpendicular to the main discontinuity set (A), in this way it was possible to obtain more favorable stability conditions.

The sequence of operations used to exploit each room is as follows:

– driving the top gate from the secondary tunnel to the end of the room;
– exploitation of the room by blasting with a bench height of 10 m.

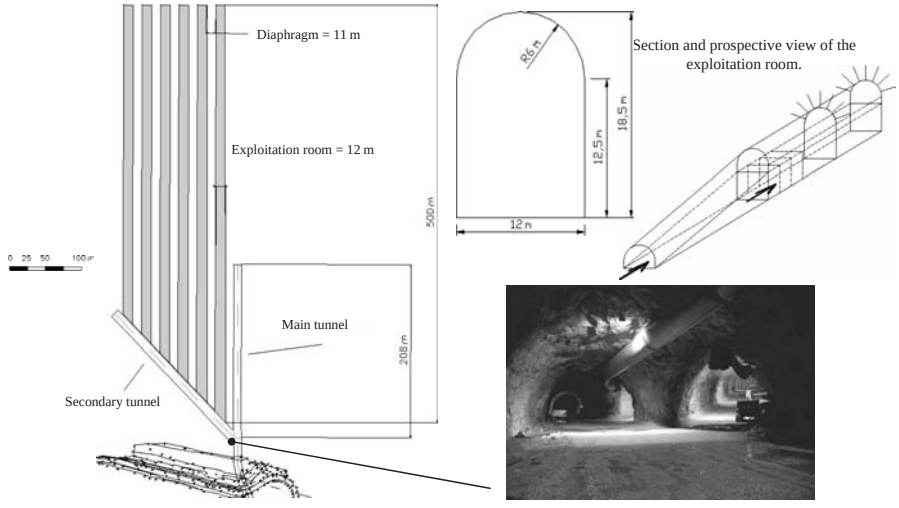

Figure 7. Plan of the mine, prospective view and transversal section of an exploitation room.

Table 3. Results of the Unwedge calculation . In order to improve the quality of the results, three different orientations were assumed for joint set A, corresponding to medium and extreme values of the distribution (A (medium): dip = 77°, dip dir = 233°; A1: dip = 71°, dip dir = 211°; A2: dip = 77°, dip dir = 248°). SF = safety factor.

Analysis number	Joint sets	Cohesion of the joints [kg/cm^2]	Total number of expected wedges	% of wedges with SF < 1.5	% of wedges with SF < 1
1	A (medium), B, C, D	0.1	18	11.1%	5.5%
2	A1, B, C, D	0.1	19	15.8%	5.3%
3	A2, B, C, D	0.1	17	5.9%	5.9%
4	A (medium), B, C, D	0.05	18	27.8%	11.1%
5	A1, B, C, D	0.05	19	21.1%	10.5%
6	A2, B, C, D	0.05	17	29.4%	11.8%

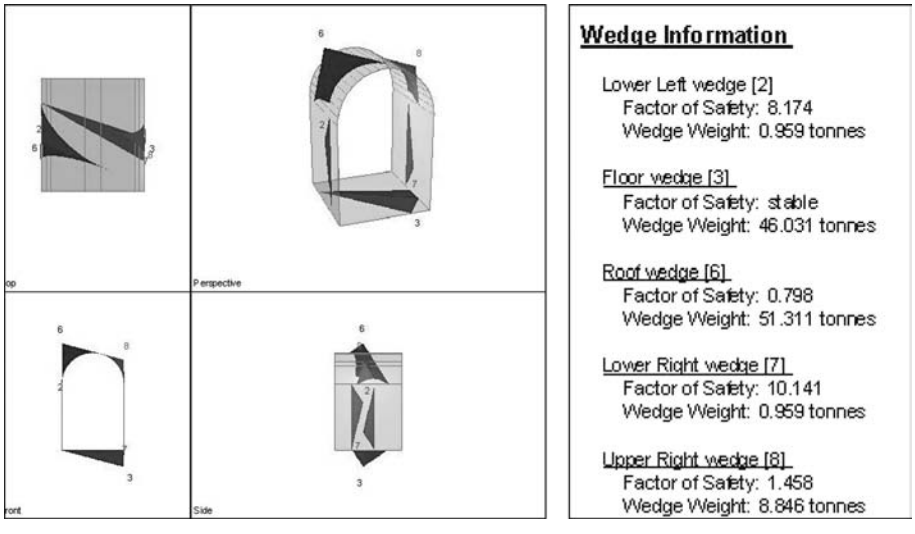

Figure 8. Graphical and analytical results of analysis n.1 using the Unwedge code.

Spot bolting is foreseen for the areas where the geo-structural survey and jobsite observations have detected unstable rock wedges. Systematic rock bolting, wire mesh and shotcreting is also used when crossing fault zones.

4 NUMERICAL MODELS

The study of the stability conditions of the exploitation rooms was carried out using two numerical analyses. The first one was carried out to evaluate the possible presence of unstable rock wedges, due to discontinuities, using the Unwedge code (ver. 3.0, Rocscience) (Guardini, 2005). The second one had the aim of analyzing the global stress and deformation conditions of the rock mass during the exploitation, which depend on the height of the overburden, in a transversal section of the mine. These numerical models were developed using the FEM Phase^2 code (ver. 6.0, Rocscience).

4.1 *Wedges stability analysis*

The used code allows the maximum wedges, which are present on the room walls and roof, to be simulated, and their volume and the safety factor (defined by the ratio between the stabilizing and destabilizing forces acting on the wedge) to be calculated, based on the geometry of the joint sets and the geomechanical properties.

The results of the calculation are summarized in Table 3 and an example of calculation output is shown in Figure 8.

The study of the stability of the wedges was carried out focusing on the cohesion of the joints and the influence of the persistence on the safety factor value. In the first set of analyses, the joint persistence was assumed equal to 100% in order to highlight only the cohesion effect. The results showed that the most critical area in the room is the roof, where local wedge falls could occur. However, it is possible to observe that a reduced increase of the cohesion ensures the stability of all the computed rock wedges. The second set of analyses was carried out to analyse the influence of the joint persistence on the safety factor values. The comparison between the obtained results showed that a small decrease in joint persistence leads to a large increase in the value of the safety factors (Fig. 9). This analysis was repeated for all the possible values of joint persistence and the final results are summarized in the graphics shown in Figure 10. From the study of the results of analysis 1, 2 and 3 (assumed cohesion value = 0.1 kg/cm^2), with 100% joint persistence, 11% of all the possible wedges have a SF < 1.5; this value increases to 26% when analyses 4,

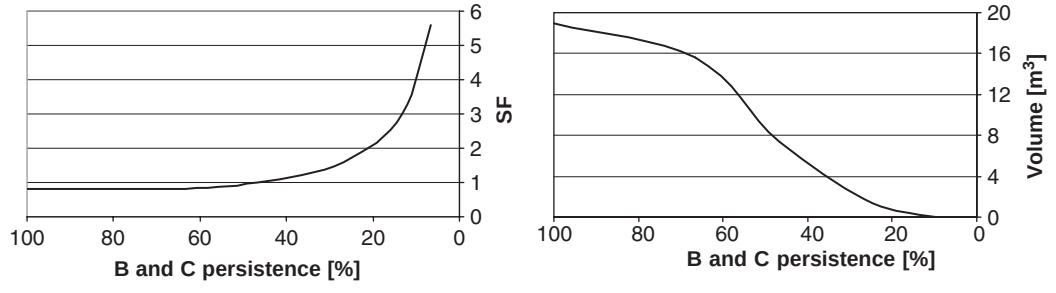

Figure 9. Examples of parametrical analysis of the persistence of the discontinuities. In the left graph it is possible to observe that with a decrease in the persistence value to 30%, SF shows a higher value than 1,5. The decrease in the wedges volume is shown in the right graph in function of the decrease in discontinuity persistence.

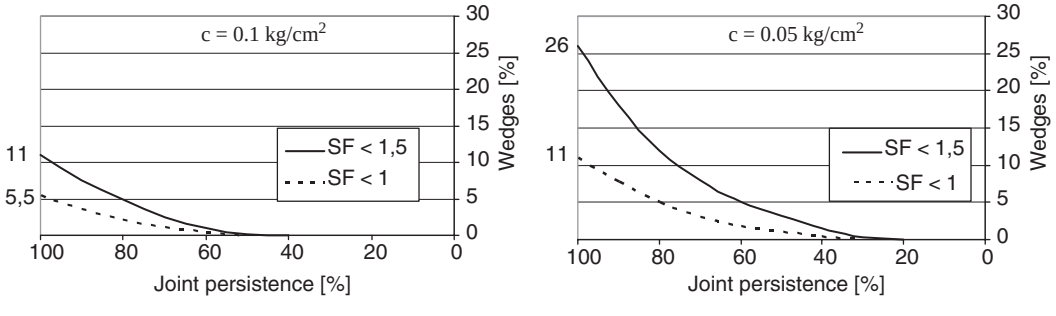

Figure 10. Discontinuity persistence effect on the safety factor of the wedges.

5, and 6 (assumed cohesion value = 0.05 kg/cm^2) are considered. The reduction in joint persistence to 50% leads to the reduction in the wedges with a SF < 1.5 at about 0%, with c = 0.1 kg/cm^2, and at 3%, with c = 0.05 kg/cm^2. The discussed results highlight that the presence of some rock bridges along the discontinuities could ensure a consistent increase in the safety factor of the wedges and therefore it is possible to state that the technical choice of spot rock bolting would guarantee roof stability for most of the possible joint geometries.

4.2 *Rock mass stress condition analysis*

The study of stress and deformation around the mine rooms was carried out by applying both the two-dimensional Phase^2 FEM code (ver. 6.0, Rocscience) and the tributary area analytical method. The use of a two-dimensional model is suitable for the analysis of this problem because the exploited rooms are developed mainly in the longitudinal direction and it is therefore possible to disregard the three-dimensional effect due to the excavation face when the rooms have been excavated. The developed numerical models, which simulate the excavation of six rooms at different depths, allowed the rock diaphragm stability to be verified. The model is 607 m wide and its height ranges between 318.5 m and 718.5 m, in function of the overburden (Tab. 4 and Fig. 10); two different K_0 (σ_o/σ_v) were considered: $K_0 = 0.5$ and 1.

Table 4. Main parameters assumed in the Phase^2 numerical analysis.

		Overburden height [m]	Exploitation room advancement [m]	k
Analysis 1	1a	100	50	1
	1b	200	180	
	1c	300	300	
	1d	400	450	
Analysis 2	2a	100	50	0.5
	2b	200	180	
	2c	300	300	
	2d	400	450	

The following stages were considered in the model:

1. application of the original stress field;
2. simulation of the excavation of the upper part of the first room;
3. simulation of the room exploitation with 10m vertical benching;
4. repetition of stages two and three till the end of the mine exploitation (i.e. excavation of 6 rooms).

The stresses (Figs 12 and 13), the horizontal and vertical displacements after the exploitation of each room (Fig. 14) and the plastic zones (Fig. 15) were analysed from each simulation.

From these calculations, it was possible to evaluate the underground stability conditions during and at the end of the mine exploitation: the vertical stress inside the diaphragms never overcame 24 MPa and the displacement maximum value was 6 mm (Fig. 13).

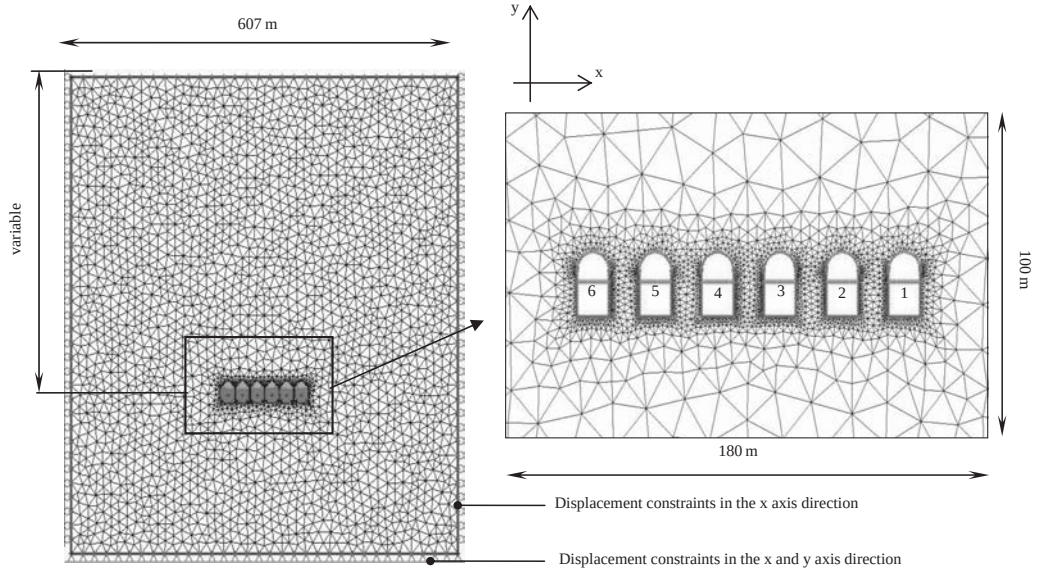

Figure 11. Numerical model section and zoom of the excavation boundaries.

The plastic zones around the room walls had a maximum thickness of 2 m, where the overburden height is 400 m, however this plastic zones do not compromise the global underground stability, though they could cause the local detachment of rock wedges from the room walls, therefore a particular attention is required during the vertical benches exploitation.

Yielding phenomena on the crowns of the rooms is almost absent.

The results obtained from the numerical models were verified by applying the tributary area method. The analytical equations used for the calculation of the vertical stress acting on the diaphragms are defined in technical literature (Brady & Bown, 1985) and allow the safety factor to be defined by comparing the computed stress value to the rock mass uniaxial compressive strength (σ_{cRM}), which in this case was assumed equal to 60 MPa. The results of the tributary area calculations are summarized in Table 5, while Figures 16 and 17 report the stresses acting on the diaphragms and the computed safety factors.

From the results of the analytical and numerical calculations it is possible to point out that average vertical stress values, calculated according to the analytic method, are usually very close to the maximum value obtained with the numerical model, while the safety factor, evaluated according to the analytic method, usually shows higher values than the ones obtained with the numerical model.

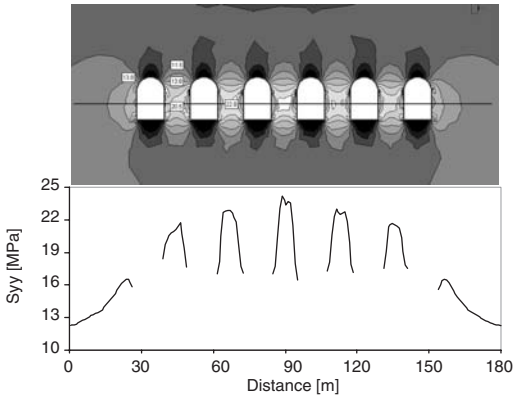

Figure 12. Vertical stress (σ_{yy}) distribution in the numerical analysis n. 2d (overburden height = 400 m, k = 0.5). The σ_{yy} value along the horizontal section in the middle of the diaphragms is shown. The maximum σ_{yy} value is 24 MPa in the central diaphragm (stress values increase from black to white).

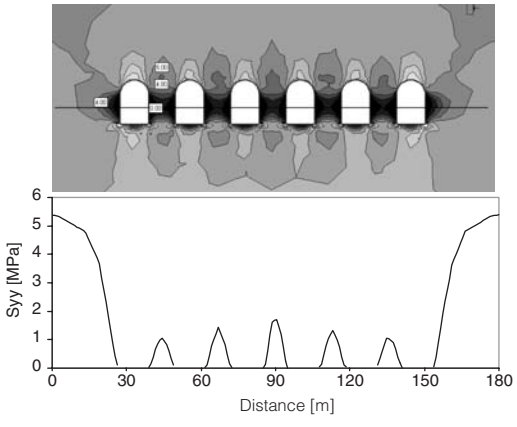

Figure 13. Horizontal stress (σ_{yy}) distribution in the numerical analysis n. 2d (overburden height = 400 m, k = 0.5). The σ_{xx} value along the horizontal section in the middle of the diaphragms is shown. The maximum σ_{xx} value is 1.7 MPa (stress values increase from black to white).

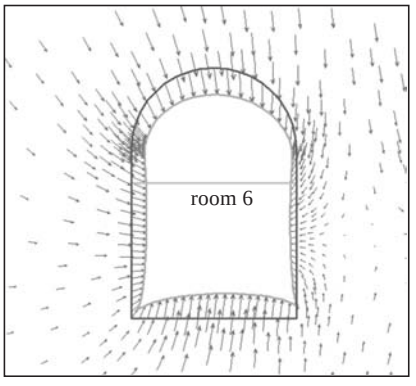

Figure 14. Displacements of the walls of room 6 obtained from the analysis n. 2d, the maximum displacement value is 5.5 mm (scale factor = 500).

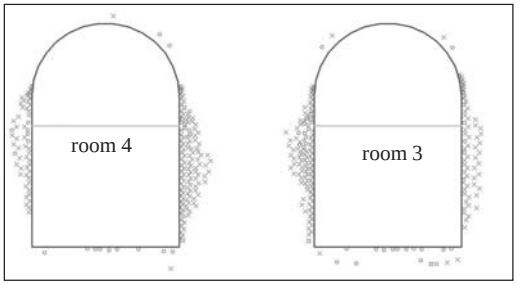

Figure 15. Plastic zones (maximum value = 2 m) in the central diaphragm, obtained from the analysis n. 2d, at the end of mine exploitation.

Table 5. Vertical stress and safety factor values of the diaphragms obtained using the tributary area method.

Overburden height [m]	100	200	300	400
σ_p [MPa]	5.6	11.3	16.9	22.6
SF	10.6	5.3	3.5	2.7

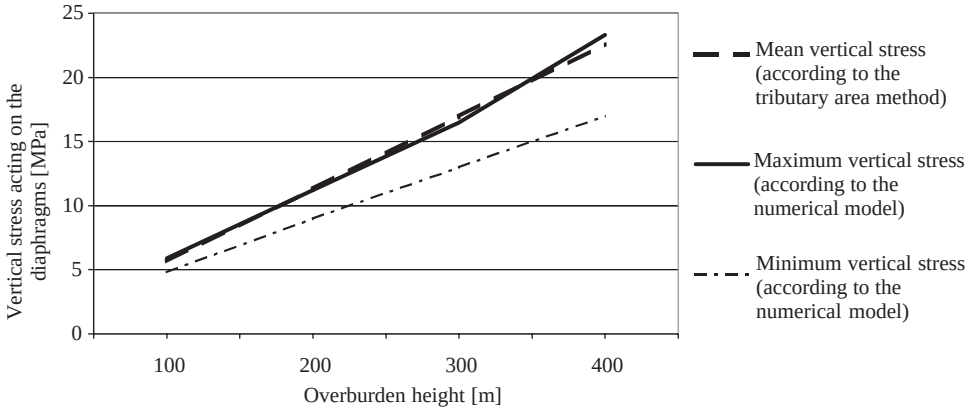

Figure 16. Vertical stress acting on the diaphragms for increasing overburden heights computed with the analytical and numerical approaches.

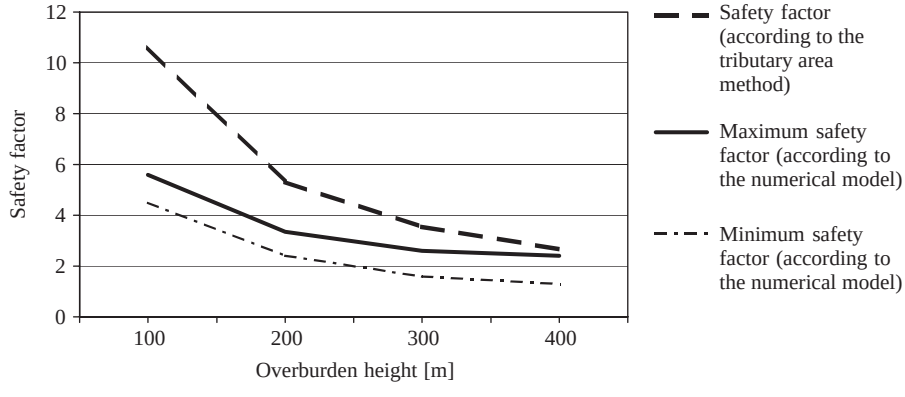

Figure 17. Safety factor of the diaphragms computed with the numerical and analytical approaches. Analytical safety factor values correspond to the ratio between rock mass uniaxial compressive strength and mean vertical stress acting on the diaphragm: while, for the numerical model, the safety factor is defined by $SF = [\sigma_3 + \sqrt{m\sigma_c\sigma_3 + s\sigma_c^2}]/\sigma_1$.

In the last part of the analysis, the tributary area method was applied again, in order to verify the stress condition which would be induced in the diaphragms if the plasticized zones detached from the room, thus reducing the width of the diaphragm itself. The results make it possible to affirm that, also in this case, global stability of the diaphragms would not be compromised because the safety factor never has a value lower than 1.5.

5 CONCLUSIONS

In order to verify the "near field" and the "far from field" (Brady & Brown, 1985) stability condition of an underground room and pillar mine, it is necessary to carry out computations that are able to check both the rock wedge stability, which can form around the rooms, and the stress redistribution around the room and in the pillars. The computation carried out for the study of an underground granite exploitation, in Canal San Bovo (Trento district, Italy), is a good example of how this analysis should be carried out. In this specific case, it can be pointed out that the underground exploitation of a good geomechanical quality granite rock mass to obtain feldspar to be used in the ceramic industry, is an interesting application of how surface constraints can prevent exploitation from being carried out in a open pit mine.

Analysis of input parameters of the rock mass

J. Pruška
CTU in Prague, Faculty of Civil Engineering, Prague, The Czech Republic

ABSTRACT: The main goal of the paper is focused on the effect of the input parameters to the suitable mathematical models of the underground structures. Within the introduction of the paper the inaccuracy in the geotechnical tasks modelling is performed. In the following part the Fuzzy techniques are summarized and the Fuzzy arithmetic using on the Index Q rock mass classification is mentioned. The next part of the paper is focused on the stochastic simulation – Monte Carlo Simulation is shortly described while Latin Hypercubes method is described in detailed. At the end the application of the statistical analysis of the input parameters on the numerical modelling of Prague tunnels Mrázovka and Špejchar – Pelc Tyrolka is shown.

1 INTRODUCTION

The inherent variability of rock mass is difficult to take into account and for this reason engineers very often solve the question "What value should be used in analyses?". The answer on such question requires a probabilistic approach in the evaluating the uncertainty in the input parameters in geologic media. In the recent time specialists encounter problems of the input parameters in using uncertainty modelling based on the Fuzzy set theory, Monte Carlo Simulation, Latin Hypercube Sampling etc.

To illustrate this concept, the variability in the strength R and stress S (given by their probability density functions) is shown in Figure 1. The overlap between the strength and stress distributions indicates the zone that contributes to the probability of failure P_f. The probability of failure can vary from a very low value to nearly unity (depending of the degree of overlay).

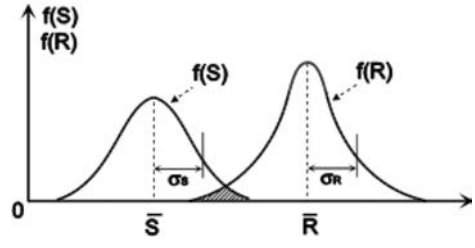

Figure 1. Probability of failure (Pauli 1991).

2 FUZZY METHODS

In underground structures design is very difficult to take into account inherent variability of rock mass using the current rock mass classification. One of the main methods in improving rock mass classification is by accounting for variations in the individual parameters using fuzzy mathematics (Hudson 1998).

The fuzzy set was first introduced in 1965 by Lofti A. Zadeh (Zadeh 1965) as a mathematical way to represent linguistic vagueness. In a classical set, an element belongs to or does not to a set. The concepts and definitions of the fuzzy set theory are mentioned in many publications. Dubois and Pride (Dubois & Pride 2000) provide the following definition: "Fuzzy set is a generalization of ordinary or classical set theory it consists of mathematical tools developed to model and process incomplete and/or gradual information, ranging from interval – valued numerical data to symbolic and linguistic expressions".

Contrary to crisp (or ordinary) set, fuzzy set have no sharp or precise boundaries. In crisp set, element x belongs to or does not to a set A and membership function (or degree of membership) $\mu_A(x)$ is a unique. Fuzzy set assigns membership function $\mu_A(x)$ for each element x to range over the interval (0,1). This type of membership function is characteristic by smooth transition from "belong to a set" (1) to "not belong to a set" (0) and gives fuzzy sets flexibility in modeling used linguistic expressions of engineering practice (such as "Fairly rough surface"). Membership functions can be represented by analytical method too.

Two types of variables are used in the fuzzy model: fuzzy variables and fuzzy numbers. Fuzzy variables are defined directly as fuzzy sets on the set of reference

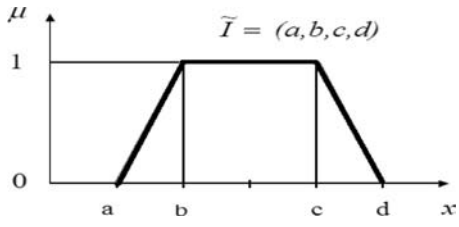

Figure 2. Trapezoidal fuzzy number.

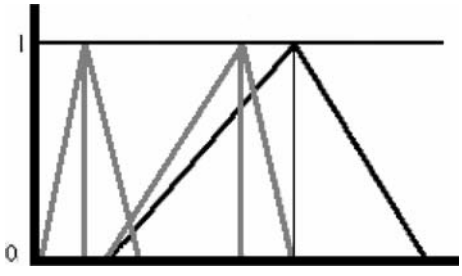

Figure 3. Fuzzy addition.

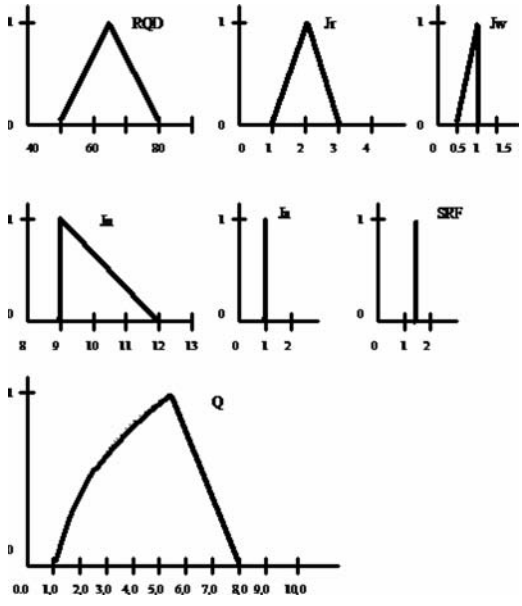

Figure 4. Applying fuzzy arithmetic to the Q-system (Hudson 1998).

linguistic terms. Generally, a fuzzy variable x_j can acquire any value expressing various shades between the reference terms. For the linguistic terms the fuzzy variables are fuzzy singletons. Fuzzy variables need not to be associated with any numerical universe. This can be because their values are qualitative in nature, or are respected as qualitative for the sake of convenience. Fuzzy numbers are defined over a continuous domain – triangular or trapezoidal membership functions (or numbers). Trapezoidal number is defined by the height and four distinct elements of the fuzzy set interval – Figure 2. Taking $b = c$ reduce the trapezoidal number to those of triangular.

Fuzzy Logic provides a number of functions for performing fuzzy arithmetic. The fuzzy arithmetic functions are a little different than the rest of Fuzzy Logic's functions in that they operate on lists of above mentioned fuzzy numbers. In the Figure 3 is fuzzy addition of two triangular fuzzy numbers.

The application of fuzzy arithmetic in the rock mass classification is direct and generate a fuzzy number representing the classification value. Fuzzy mathematics even introduce the uncertainty in the evaluating of parameters to the rock mass classification. Let us have for example Index Q rock mass classification. This classification was established in 1974 in Norway (by Barton, Lien, Lunde and Loset) and is based on six parameters (Bieniawski 1989):

$$Q = \frac{RQD}{J_n} \cdot \frac{J_r}{J_a} \cdot \frac{J_w}{SRF} \qquad (1)$$

where $RQD =$ rock quality designation, $J_n =$ joint set number, $J_a =$ joint alteration number, $J_w =$ joint water reduction number, $SRF =$ stress reduction factor.

By applying the fuzzy logic to the equations for Index Q (Equation 1) we obtain results in the fuzzy classification value (Figure 4) with non-linear distributions. The convex nature of the flanks has the effect of increasing the possibility that the conditions will be worse than a single computed index Q.

3 MONTE CARLO SIMULATION

Monte Carlo simulation is a well-known toll that is used to analyze random phenomena. In Monte Carlo simulation is the random problem transformed into several deterministic problems that are much easier to solve – sample inputs are used to generate sample outputs with statistical or probabilistic information about random output quantity. Monte Carlo simulation is simple to use and therefore has found much favor in geomechanics, particularly in stability analysis of rock slopes (McMahon 1971).

The simplest sampling scheme of a Monte Carlo simulation approach is to use a pseudorandom number generator to select random numbers between 0 and 1 and swap them with randomly generate values for each variable which will be input to the calculation. However, this simple (and best-known) random sampling scheme required for good accuracy and repeatability

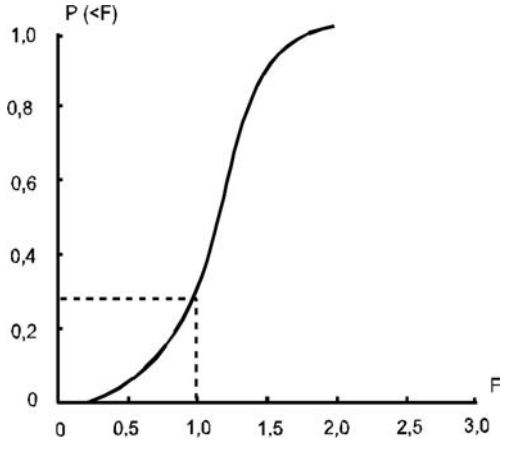

Figure 5. Cumulative distribution of Monte Carlo results (Mahtab 1992).

many samples – in practice for generating a probability distribution of the safety factor of rock slopes is the minimum number of selection between 200 up to 2000 (depending on the desired accuracy).

The simulation output (random variable which depends upon random input variables, fields and processes) may be in several approaches. One way is to define the probability that safety factor F is less than a prescribed value Fp:

$$P\left(F < F_0\right) = \frac{n}{N} \tag{2}$$

where $n =$ number of trials in which $F < F_n, N =$ number of selections.

Another approach (Mahtab 1992) is to plot a cumulative distribution of random F, which can be used to define the probability of F being less than a given value (Figure 5).

4 LATIN HYPERCUBES

To reduce the number of samples required for good accuracy in Monte Carlo simulation have been developed other sampling methods. One of the best is Latin hypercube sampling (Bažant 1987). Latin hypercube sampling preserves marginal probability distributions for each simulated variables. To fulfilled this aim, Latin hypercube sampling constructs a highly depend joint probability density function for the random variables in the problem, which allows good accuracy in the response parameter using only a small number of samples.

In Latin hypercube sampling is the bounded interval $<0, 1>$ uniformly divided into N non-overlaying intervals (with the same probability of accuracy). Than is one value per interval generated. This can be performed by initially generating N random numbers within range $<0, 1>$. These values are linearly transformed to the random numbers in the non-overlaying intervals for each random variable:

$$u_i = \frac{u}{N} + \frac{(i-1)}{N} \tag{3}$$

where $i = 1,2\ldots.n$ (n number of values), $u =$ a random number ($u \in <0,1>$), $u_i =$ random numbers in the ith interval, $N =$ number of the non-overlaying intervals.

From the above equation follows that we generated only one value for each random variable (this value is randomly selected within each of N intervals):

$$\frac{(i-1)}{N} < u_i < \frac{1}{N} \tag{4}$$

where $i = 1, 2 \ldots .n$ (n number of values), $u_i = a$ random numbers in the ith interval, $N =$ number of the non-overlaying.

The n values obtained fir the first random variable x_1 are paired in a random manner with the values of the second random variable. These n pairs of (x_1, x_2) are combined in a random manner with n values of the third random variable. This combination results in the n triads (x_1, x_2, x_3) which are combined in a with n values of the 4th random variable and so on until (K-2) triads are formed (K is a number of random variables). Thus we can assembled N^*K matrix. It can be seen that a certain statistical correlations among columns of the matrix may have a significant influence on the results of simulation (Spolehlivost 2001).

5 APPLICATION OF LATIN HYPERCUBE SAMPLING

The north-western sector of the City Circular Road in Prague contains three major road tunnels of large cross section area. While the Strahov and Mrázovka tunnels are already open for traffic, the Špejchar – Pelc Tyrolka tunnel is still in the planning phase. The very difficult Prague Ordovician geological conditions make it necessary to apply NATM. Stabilization of the deformations was always achieved only after closure of the whole primary lining, but the following supporting technical measures were performed: anchoring, widening of the top heading legs, micropile support under the top heading legs, reinforcing grouting performed in advance from the exploratory gallery (Fig. 6), and closing the top heading by a temporary invert. Due to increased deformations occurring at the excavation with a horizontally divided face, a vertical pattern of the sequence was used in the further course of excavating the Mrázovka tunnel.

The outputs of two tunnel Mrázovka models were verified by Latin Hypercubes method (Barták at al. 2002). The numerical analysis was carried out by means of the PLAXIS program system. 3D behaviour of the excavation face area, and correct description of the influence on the deformations and the state of the massif were simulated by means of the frequently used procedure of loading the excavation and lining using the so-called β-method. The modelled area of the profile covers an area of about 200 m wide and 110 m high and was divided into eight basic sub-areas according to the types of rock encountered. The rock mass behaviour was approximated by means of the Mohr-Coulomb model. The intervals of input parameters of the rock mass (E_{def}, ν, c, φ, γ) were determined on the basis of the engineering-geological investigation results (Hudek 1999). The modulus of deformation of the tectonic zone was determined according to the results of plate bearing tests. A comparison of theoretically determined deformations with the values obtained by monitoring (Kolečkář 2000) was used verifying the applicability of the mathematical model.

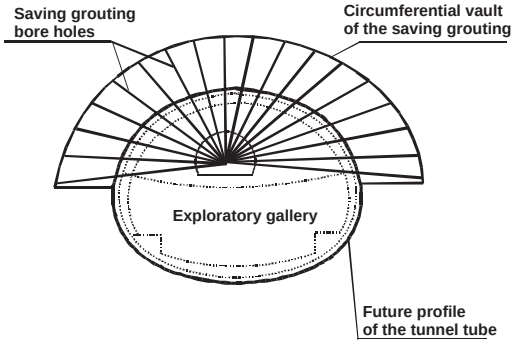

Figure 6. Scheme of the execution of the saving grouting.

The results of statistical study of West Tunnel Tube (WTT) in profile km 5.160 are shown in Table 1. They show that final settlements will be with probability 95% between values 71 mm and 213 mm. The interval of settlement without deformations caused by excavation of pilot adit is from 65 mm to 198 mm. The recognised range was in coincidence with measured value 194 mm (value does not include effect of pilot adit).

The construction package Špejchar – Pelc-Tyrolka is 4,320 m long – the length of the tunnelled section amounts to 3,438 m. The construction package also contains underground garages in Letná, four underground Technology Centres and the Trója Bridge. According to the design, the excavation will be carried out using the New Austrian Tunnelling Method (NATM). Due to the given conditions, a vertical excavation sequence will be applied to the three-lane tunnel excavation. Regarding the two-lane tunnels, a horizontal sequence is expected.

The position of the exploratory drift is selected with respect to complicated sections so that the vertical sequence can be applied to the top heading, or the vertical sequence can be used for the entire cross section. Mechanical rock breaking is expected, or also in combination with the drill-and-blast when passing through the Quartzites. A transition zone between the Quartzites exists at the foot of the slope falling from the Letná Plain. Due to the gradient parameters, the tunnels run at a close vicinity of fully saturated Quaternary sediments. A multicriteria analysis resulted into selection of the variant of pre-excavation grouting (Dvořák at al. 2004).

The outputs of the exploratory drift near the transition zone (km 5,900 ETT) were verified by Latin Hypercubes method with coperation with design and consulting company SATRA (Louženský 2006). The 2D and 3D numerical analysis was carried out by means of the CESAR – LCPC program system. The

rock mass behaviour was approximated by means of the Mohr-Coulomb model. The intervals of input parameters of the rock mass were determined on the basis of the engineering-geological investigation results (Butovič 2004). The results of statistical study of South Tunnel Tube (SWTT) in profile km 5,900 is shown in Table 2. They show that final settlements of the tunnel lining will be with probability 95% between values 13 mm and 347 mm. The interval of surface settlement above excavated tunnels is from 7 mm to 26 mm.

6 CONCLUSION

The results of analysis show the effect of variation of input parameters of rock mass behaviour on results of FEM. It can be seen, how different can be this influence. Difference of outputs is given by disparity of geological layout. However it can be clearly seen, how important is at least basic study of input parameters variation for determination of final structure behaviour. Latin Hypercubes method is advantageous procedure for qualified statistical evaluation of FE calculation. These methods make possible radical time saving in regards to common statistical methods (Monte Carlo method, estimations of probability moments etc.). Latin Hypercubes method is also not bonded with concrete rock mass classification with respect to fuzzy technique.

ACKNOWLEDGEMENT

The authors wish to express their gratitude to Ministry of Education of the Czech Republic for research project *MSM 6840770003* "Developments of the Algorithms of Computational Mechanics and their Application in Engineering" for allowing to develop this article. Thanks also to Ing. A. Butovič of the SATRA company for their supporting in the analysis of the Spejchar – Pelc Tyrolka tunnel.

Study on neighboring construction of three parallel shield tunnels in soft ground by centrifugal model test

Wenge Qiu, Yuchao Zheng*, Shufeng Li, Ruiguo Wu & Hongbo Guo
School of Civil Engineering, Southwest Jiaotong University, Chengdu, Sichuan, China

ABSTRACT: Based on the prototype of three-tube parallel shield tunnel of R413 bid segment of the ninth route in Shanghai track traffic, stratum loss of shield tunnel was simulated by the control of injecting and releasing water quantitative of pockets around tunnel model, centrifugal model test study was carried out on ground face settlement of three-tube parallel shield tunnel. There were two group of centrifugal model test in all, one group with stratum reinforcement and another not, and the construction of three-tube tunnel was divided into two stages. The comparison was carried out between the result in site and in model test. The result shows that this method, injecting and releasing water quantitative of pockets around tunnel model, could simulate stratum loss effectively. The settler would create superposition with the construction of tunnel one by one, ground face settlement could be controlled effectively through the method of stratum reinforcement, the Max ground face settlement value would not ultralimit in each stages of construction, but the Max accumulated settlement would ultralimit, so it needed the cooperation of railway department and could deal with combining the railway maintenance.

1 INTRODUCTION

In the prevision of surface settlement induced by shield driving for the time being, the routine methods are empirical formula, numerical simulation and model test. With help of centrifugal machine in high speed, centrifugal model test can impose more than n times centrifugal force, and compensate weight loss caused by 1/n shrinkage rule. Which also can maintain the same stress, strain, fracture mechanism and similar deformation between the proto and model. So studying geotechnics problem on which the most important load is gravity by the way of centrifugal model test is a perfect way[1]. However, because it difficult to simulate drilling of shield machine in earth. Model test faces large difficulty in studying shield tunneling. Some scholar like Zhou has made a lot of model test in tunnel engineering of South-to-North Water TransferProject by control of injecting and releasing air quantitative of pockets around tunnel model, and studied the relationship between support stress and stratum displacement, influence of construction space, and mechanism about the stability and destruction[2][3]. Wu, Liu and other scholars simulated drilling tunneling by the way of melting paraffin with coupling between stress field and filtration[4][5].

A large number of study and engineering experience have indicated that in shield tunneling surface, settlement is in relation to stratum loss. A lot of empirical formulas for forecasting surface settlement are in relation to stratum loss, for example, Peck advanced Gaussian distribution curve in 1969[6], Loganathan and Poulos advanced an empirical formula[7]. Demestic TongJI University advanced correction Peck formula considering cross settlement value based on construction space and consolidation[8], Academician Liu advanced correction Peck formula for forecasting portrait settlement[9]. Author got an idea from it, considering that the centrifugal test equipment of author's work station can't compressed air and water, author decided to simulate the stratum loss of shield tunneling driving by injecting and release water. So the model test of three-tube parallel shield tunnel can be implemented.

2 ENGINEERING GENERAL SITUATION

Based on the prototype of three-tube parallel shield tunnel of R413 bid segment of the ninth route in Shanghai track traffic, the tunnel segment between east and west slip road DK20 + 664 (= L2DKO + 220) across under NanXin circle railway (railway mileage DK31 + 820). NanXin circle railway is double-track

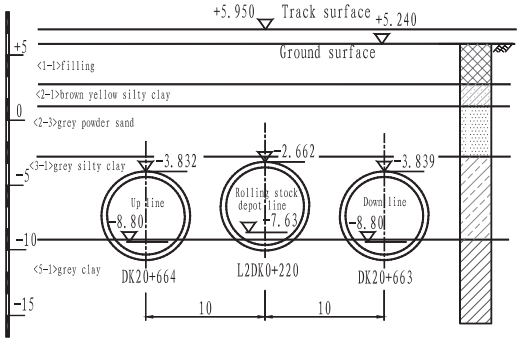

Figure 1. Cross section of three-tube parallel shield tunnel underthrough railway.

main way(the width of subgrade is 13 m), it lay over the tunnel, it is orthogonal to the tunnel (the angle of intersection is 88), the cross segment is in the north of HuSong highway, the distance from eastside to westside of slip-road delve is 60 m.

There are three parallel line, that is up-line, down-line and east rolling stock depot line, are all straight line, the distance between rolling stock depot line and down-line is 20 m, and east rolling stock depot line is in the middle of up-line and down-line. The clear distance between the three line is only 3.8 m, the longitudinal gradients from east to west of cross segment are as following: the degree of slop of up-line is 16.427‰ falling gradient, the degree of slop of down-line is 16.263‰ ascending gradient and the degree of slop of east rolling stock depot line is 3‰ ascending gradient. The depth of embedment of up-line and down-line is 9.1 m, the depth of embedment of rolling stock depot line is 7.8 m.

According to the detailed engineering geology survey report of ninth track traffic between JiuTing station and QiBao station, the stratum situation of parallel and overpass segment is as following: filling, brown yellow silty clay, grey powder sand, grey silty clay, grey clay and so on.

Most of study and construction are based on the driving of one-tube tunnel, there are less study on surface settlement cased by three-tube parallel tunnel driving. Considering that the tunnel goes under crowed railway main line, safety is quite important, so forecasting the surface settlement and regular cased by three-tube shield tunnel driving by centrifugal modest test is useful.

3 TEST WAY AND TEST MODEL

3.1 *Test equipment*

Test was made on centrifugal machine of Southwest Jiaotong University. The major parameter of the equipment are as following: (1) 100 g·t; (2)effective radius: 2.7 m; (3)effective size of model is 0.8 m × 0.8 m × l m, 06 m × 0.6 m × 0.8 m; (4)working range of centrifugal machine is 10∼200 g; (5)the longest working time is 12; (6)survey pattern: sensor + amplifier + intellectual survey macheng + data digitization parallel transmination(computer); (7)monitoring and recording test procedure by camera system.

3.2 *Model test field and similarity rate*

06 m × 0.6 m × 0.8 m model case is used, considering the size and space position of the three tunnel, influence of boundary effect and size of model case, we used 100 as the similarity rate in this test, geometry size of test field is shown as Table 1. Double-skin plastic film is used in boundary to remove boundary constraint effect, according to basic principle of centrifugal model test and π theoren of Buckingham, the similarity rate of physical quantity is shown as Table 2.

3.3 *Test material*

Substratum soil is allocated by people in testing laboratory, matching rate is controlling nonconfined compressive strength, the we tamped the soil field stratal soil is adopted as padding of the rest strate. Because most of stratum is made of soft clay. It is remolded according to the moisture content offered by geologic examination report, and it is consolidated on centrifugal machine, the index c and ϕ is controlled by shear test[10]. For lining structure of shield tunnel, if we use material index as prototype, structure will be too thin as concrete, it can't meet the need, so we choose steady LYZ aluminium product as similar material, which has similar density and Poisson ratio with concrete, we can get the aluminium product of similarity criterion can be got from documentation[3].

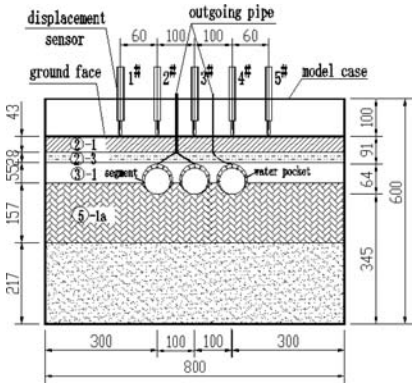

Figure 2. Layout figure of tunnel, stratum and sense organ.

3.4 *Stratum loss and model way*

Stratum loss of shield tunnel by the control of inject and releasing water quantitive of pockets around tunnel model, the pocket is made of rubber, the single width is 1 mm, the external is 64 mm, the inner diameter is 62 mm, the length of one sector is 60 mm, long conduct pipe of 1000 is located on one sector, a value is located in the outside. According to document[11], the stratum loss rate of Shanghai subway shield construction is 0.3%∼0.6% generally, considering the fact situation, we choose 0.5%, we can get the value of stratum loss per mater 0.158 m^3 from the diameter of shield machine, we can get the water discharge value 0.95 ml, we choose the value 1ml,according to equation of state of ideal gas, if compression force increases to 100 times, air will be compressed to 1%, so injecting water to fill the pocket will be nice, and the influence of air compression can be ignored, put the pocket full of water on the outside of tunnel lining model, injecting and releasing can be realized by injector.

3.5 *Displacement test original production and layout of measuring point*

Displacement sensors used in test are MDA-5 series line displacement sensor. Survey rod is controlled by spring, the measuring range is 10 mm, the measurement accuracy is 0.1%F · S, the current source ±12VDC, the output rate 0∼5VDC. Other cross-section lays in center, five sensors are located in it, the locating point is shown as Picture 2.

3.6 *Experiment process*

There were two groups of test in all, one group with stratum reinforcement and another not. The reinforcement scope was a cuboid with one time diameter apart from the tunnel. The Portland cement with grade 425 was adopted to mix with the ground, and the content of the cement was 10%. The various soils and the tunnel with 3 holes was enclosed into the model box following the Figure 3, the enclosing height of each layer soil should be strictly controlled and be symmetrically tamped. The wire and water pocket pipe were put out of the model box.

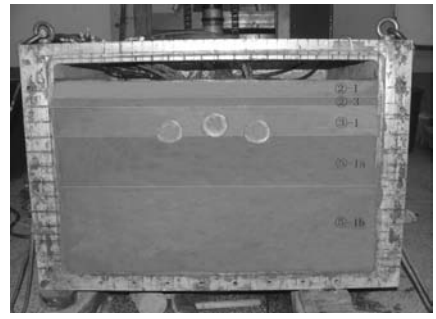

Figure 3. Model obverse figure.

The basic construction sequence of the three tunnels is following: firstly the tunnel(the first tunnel in the experiment) on the down line and the tunnel(the third tunnel in the experiment) on the up line were excavated face to face at the same time, the tunnel on the down line advanced from east to west (from inside to outside in the experiment), the tunnel on the up line advanced from west to east (from outside to inside in the experiment), finally the tunnel on the rolling stock depot line advanced from east to rolling stock depot (from inside to outside in the experiment). The water pockets were gradually released one by one (or by twos), in order to simulate the gradual advance of stratum loss. The idiographic process of the experiment simulation is as follows:

(1) Clean up the scene, close the centrifugal room armor door, then start to carry out the experiment. Gradually increases the centrifuge rotational speed to cause the acceleration to 100 g, and continue revolving for 1 hour (to be equal to 417 days in the prototype), in order to simulate the solidifying of the soil layer, observe the reading of each sensor for displacement measurement, if the reading is out of the measuring range, readjust the position of the sensor for displacement measurement after the engine is off.
(2) Slow down until stop, open the armor door, extract 1 milliliter of water in the first and second water pocket of the third tunnel and in the ninth water pocket of the first tunnel through the conductor pipe and the injector, after cleaning up the scene, close the armor door, gradually speed up to cause the acceleration up to 100 g and continue revolving for 10 seconds (to be equal to 27.8 h in the prototype), and gather displacement data dynamically, the sampling frequency is set to 0.03 k.

(3)∼(6) The operating procedure is similar to that of the step (2), Slow down until stop, open the armor door, gradually extract 1 milliliter of water in the other water pockets through the conductor pipe and the injector, after cleaning up the scene, close the armor door, gradually speed up to cause the acceleration up to 100 g and continue revolving for 10 seconds, and gather displacement data dynamically.

(7) Slow down until stop, open the armor door, extract 1 milliliter of water in the ninth water pocket of the third tunnel and in the first and second water pocket of the first tunnel through the conductor pipe and the injector, after cleaning up the scene, close the armor door, gradually speed up to cause the acceleration up to 100 g and record the reading and continue revolving for 10 minutes (to be equal to 69 days in the prototype), finally complete the simulation of the stratum loss in the third and first tunnel.

(8)∼(12) The step (8)∼(12) are similar to that of the step (2)∼(6), gradually complete the simulation of the stratum loss in the second tunnel and gather data.

(13) Slow down until stop, open the armor door, extract 1 milliliter of water in the first and second water pocket of the second tunnel and through the conductor pipe and the injector, after cleaning up the scene, close the armor door, gradually speed up to cause the acceleration up to 100 g and continue revolving for 1 hour (to be equal to 417 days in the prototype), gather displacement data dynamically.

4 THE ANALYSIS OF THE EXPERIMENTAL RESULT ABOUT SRUFACE DISPLACEMENT

According to the obtained data, the writer draws ground surface settlement curve of cross section under different construction simulation steps, as well as ground surface settlement curve of various measuring points along with the position of the water pocket (stratum loss driving distance). See Figures 4 to 7. In the chart, the frontal 0 to 60 of the position of releasing water pocket (prototype: m model: cm) is the driving distances of the first and the third tunnel, and 60∼120 (prototype: m model: cm) is the driving distances of the second tunnel.

As a result of the insufficient measuring points, the experiment does not obtain the entire settler scope, but

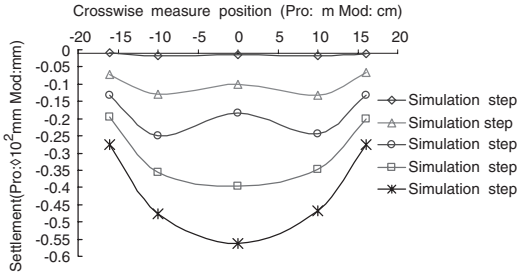

Figure 4. Settlement curve of each stage with non reinforcement of ground.

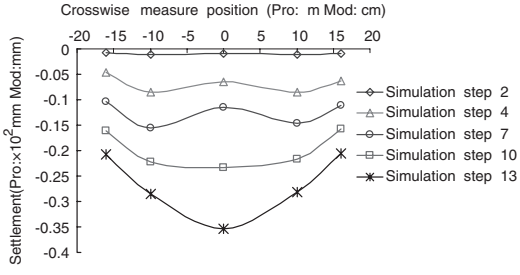

Figure 5. Settlement curve of each stage with reinforcement of ground.

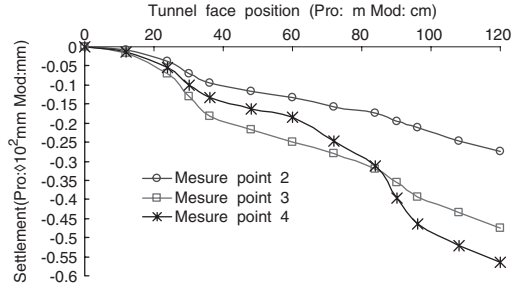

Figure 6. Relationship of measuring point settlement with position of releasing water pocket with non reinforcement of ground.

it is still seen from chart 4 to 7 that the surface displacement has the following characteristics (the following analyzing values are all prototype values):

(1) When the first and third tunnel are tunneling, the settlement value of the measuring point 2 (above the first tunnel) and the measuring point 4 (above the third tunnel) is bigger than that of the measuring point 3 (above the second tunnel), after the construction of the first and third tunnel is finished, the surface settler assumes shape of W, which is crosswise settlers' superposition of

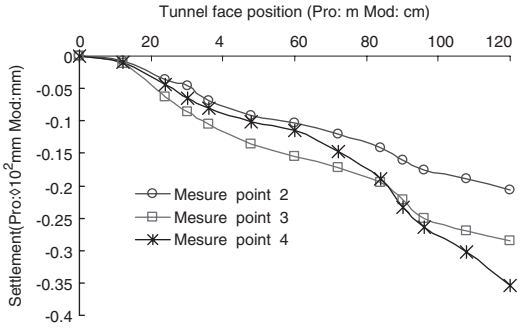

Figure 7. Relationship of measuring point settlement with position of releasing water pocket with reinforcement of ground.

the first and third tunnel. After the second tunnel's construction, the measuring point 4 subsides quicker, and the settlement value of the measuring point 4 surpasses that of the measuring point 3 and the measuring point 5, then forms a settler of U shape.

(2) When the stratum is not reinforced, the biggest surface settlement value is 25.0 mm the latter 69 days after the first and third tunnel are completed, and the accumulative biggest surface settlement value is 56.4 mm (prototype) the latter 417 days after the three tunnels are completed; when the stratum is reinforced, the biggest surface settlement value is 19.5 mm the latter 69 days after the first and third tunnel are completed, and the accumulative biggest surface settlement value is 39.4 mm (prototype) the latter 417 days after the three tunnels are completed. The accumulative biggest surface settlement value with reinforcement of ground is 30% less than without reinforcement of ground, so it indicates that the stratum reinforcement may effectively reduce the surface settlement.

(3) If dividing the construction of the first and third tunnel and the construction of the second tunnel into two stages, thus the biggest settlement value without reinforcement of ground which is caused in the first stage is 25 mm and 19.5 mm with reinforcement of ground, and the corresponding value is respectively 38 mm and 23 mm, the settlement value in the second stage is remarkably bigger than in the first stage, so it indicates that the later period consolidation settlement of shield driving is bigger in the clay stratum.

The permitted settlement value which is proposed by the railway department is 10∼30 mm, so looking from the single stage, the surface settlement overruns the permission without reinforcement of ground, while the surface settlement satisfies the requirement with

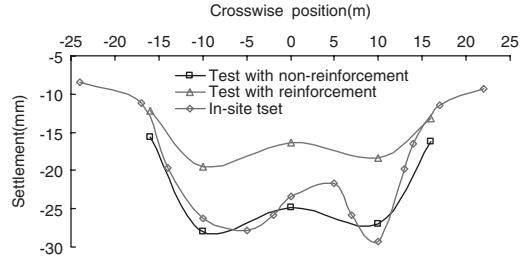

Figure 8. Model test and actual measurement settlement curve after up and down line tunnel completed.

reinforcement of ground, but looking from the accumulative biggest surface settlement after three tunnels' construction, the both experiment values overrun the permission, especially considering that the stratum needs experience a long-term consolidation and secondary consolidation process in the clay, hence besides requiring strictly control the construction measure and strengthening monitor in the construction as well as the forward monitor, and it is needed that we cooperate with the railroad department closely, if necessary, we would unite maintaining job of the railway to adjust plane and vertical parameter of the line through track lifting.

5 THE COMPARISON BETWEEN THE MEASURED VALUE IN THE FIELD AND THE EXPERIMENTAL VALUE

Before the construction of shield passing the railroad, the stratum among 6m scope around the tunnels is reinforced through compaction grouting. At present, the shields in the up and down lines have passed through the railroad smoothly, thereamong, the down line passed ahead, after 20 days, the up line also passed successfully. Thus we have obtained ground surface settlement curve after 2 months when the down line passed, and the article draws ground surface settlement curve during around 2 months after the up and down line passed from the experiment, see Figure 8. From Figure 8, it can be seen that measured ground surface settlement curve with reinforcement of ground is consistent with experimental settlement curve without reinforcement of ground, and it is obviously bigger than experimental settlement curve with reinforcement of ground, through analyzing reason preliminary, it is thought that the effect of adopting compaction grouting in the soft clay is difficultly to meet the design requirement, while the experiment adopts mixing method which is similar to churning up, thus the effect is better. The measured ground surface settlement curve assumes the remarkable asymmetry; it has something to do with the two

tunnels' asynchronous construction and the soft clay's obvious upper settlement.

6 CONCLUSIONS

(1) Stratum loss of shield tunneling was effectively simulated through the method of injecting and releasing water by water pockets, sequentially the ground surface settlement in the shield construction would be researched.
(2) Crosswise settler which is aroused by near various tunnels' construction would create superposition, and the ground surface settlement is effectively controlled by stratum reinforcement.
(3) Looking from the single stage, ground surface settlement without reinforcement of ground overruns the permission, and ground surface settlement with reinforcement of ground meets the requirement, but looking from the accumulative biggest surface settlement after the construction of three tunnels, the both experiment values overrun the permission, hence, besides requiring to strictly control the construction measure and strengthen monitor, and it is needed that we cooperate with the railroad department closely, if necessary, we would unite maintaining job of the railway to adjust plane and vertical parameter of the line through track lifting.
(4) The comparison between the measured ground surface settlement in the field and the experimental settlement shows that the effect is better to adopt mixing method in the soft clay.

The effect of advance rate on shield loading in squeezing ground

M. Ramoni & G. Anagnostou
ETH Zurich, Switzerland

ABSTRACT: Squeezing ground may slow down or even obstruct TBM operation and, if occurring over frequent tunnel intervals or persisting over longer portions of a tunnel, may be decisive for the economic viability and the feasibility of a TBM drive. Among other problems, a low strength or high deformability ground may cause jamming of the shield. From tunnelling practice, it is well known that squeezing is a time-dependent process, which may take place over a period of days, weeks or months. The risk of shield jamming therefore essentially depends on the TBM advance rate. This paper investigates the complex problem of the interaction between the advancing machine and the creeping or consolidating ground. Numerical analyses highlight the effect of advance rate, ground permeability, shield length and installed thrust.

1 INTRODUCTION

Squeezing refers to the phenomenon of large time-dependent deformations during tunnel excavation. It occurs mostly in weak rocks with a high deformability and a low strength, often in combination with a high overburden (Kovári 1998). It is also known that a high pore water pressure promotes the development of squeezing. If suitable preventive measures are not implemented, squeezing may even lead to complete closure of the tunnel cross section. In the presence of a lining, the ground exerts a gradually increasing pressure which can lead to it becoming damaged or even completely destroyed.

Squeezing ground may slow down or even obstruct TBM advance and – if occurring over frequent tunnel intervals or persisting over longer portions of a tunnel – may be decisive for the economic viability and the feasibility of a TBM drive (Lombardi & Panciera 1997). An overview of the specific problems of mechanized tunnelling in squeezing ground can be found elsewhere (Ramoni & Anagnostou 2006). Depending on the TBM type (thrusting system, type of support, existence or not of a shield etc.) a series of potential hazards must be considered concerning the machine (sticking of the cutter head, jamming of the shield) or the back-up area (inadmissible convergences of the bored profile, damage to the support).

The present paper deals with the risk of shield jamming, with particular emphasis placed on the time-dependency of squeezing, on understanding the mechanisms governing the ground response to tunnelling operations and on some of the practical questions of mechanized tunnelling through water bearing squeezing ground.

2 TIME-DEPENDENCY OF DEFORMATIONS

2.1 *Observations*

Experience shows that squeezing may take place over a period of days, weeks or months. Usually it is a slow process, although there have also been cases of intense and rapid development of ground deformations close to the working face.

As an example, the "Strada"–section of the headrace tunnel Tavanasa-Ilanz in Switzerland may be mentioned. This tunnel crosses a phyllitic verrucano and was bored in the period 1985–1988 by a gripper TBM ($Ø = 5.20$ m). During the drive in an overthrust zone, measurements revealed that within just a half day the convergence was greater than 25 cm, i.e. 5% of the diameter (Marty 1989).

Another interesting example is the water tunnel Evinos-Mornos in Greece. This tunnel crosses mainly Flysch and it was constructed in the years 1993–1994 by two gripper TBMs ($Ø = 4.20$ m) and two double shielded TBMs ($Ø = 4.04$ m). During the gripper TBM drives through some thrust zones, the ground squeezed so rapidly that the radial displacements amounted 3–5 cm right at the cutter head and 5–8 cm at the location of support installation (Vigl & Jäger 1997). The double shielded TBMs encountered squeezing conditions in an overthrust zone more than 650 m long. Within less than one hour after the excavation, at a distance of only 2 m from the working face, the convergences reached 15 cm, i.e. 4% of the diameter (Grandori & Antonini 1994, Grandori et al. 1995).

The New Viola water tunnel (Italy) was constructed in the years 1999–2004 by a double shielded TBM ($Ø = 3.60$ m). The machine was trapped first during

excavation in a phyllitic rock. The ground deformation was fast enough to close the gap (8 cm) between the double shield (L = 9 m) and the rock mass within a time period of six to ten hours (Höfle 2001). The same machine was later stopped again because of squeezing ground, although this was after a one 1-week holiday stop.

2.2 *Mechanisms*

The gradual increase of the ground deformation or pressure is first of all a consequence of the *spatial stress redistribution* associated with progressive excavation (Lombardi 1973). The stress redistribution is completed within a relatively short distance from the face (about two tunnel diameters), and cannot therefore explain long-term phenomena but is, nevertheless, essential for the convergence close to the working face and, consequently, for the loads acting upon the shield.

Long-term deformations can be traced back to the *creep* and *consolidation* processes taking place in the ground surrounding the tunnel (Gioda & Cividini 1996). In the vicinity of the working face, creep and consolidation are in general superimposed on the spatial stress redistribution associated with the advancing excavation. Consolidation comes into play when tunnelling through a water-bearing, low-permeability ground. Creeping depends on the rheological properties of the ground and becomes evident especially when the ground is highly stressed as the state of failure is approached. It is therefore of great importance in the case of squeezing ground (Fritz 1981). In order to reduce complexity, creeping will not be considered further in this paper. Instead, attention will be paid to the consolidation processes around the advancing face.

2.3 *Pore water pressure generation and dissipation*

Squeezing is in general accompanied by a volume increase of the ground. In theory one speaks of "plastic dilatancy", in tunnelling practice of "loosening". The water content of a saturated ground increases during squeezing. This occurs more or less rapidly depending on the permeability of the ground. In a low-permeability ground, the water content remains constant in the short term. Since the pore water hinders dilatancy, excess pore water pressures develop, which dissipate over the course of time. Tunnel excavation in a saturated squeezing ground thus triggers a transient seepage flow process. Seepage flow and ground deformation are coupled to each other. The pore water pressures and the effective stresses change with time, the latter leading to additional deformations or, in the presence of a lining, to increasing loading (Anagnostou & Kovári 2005).

Two important limiting states of the transient process are: the state at time $t = 0^+$ ("short-term behavior") and the state at $t = \infty$ ("long-term behavior"). The first is characterized by the condition of a constant water content (so-called "undrained conditions"), while the second is governed by the steady state pore water pressure distribution (so-called "drained conditions"). According to theoretical and experimental investigations (Vogelhuber 2006), the negative excess pore pressures developing under undrained conditions strengthen the ground (so-called "dilatancy hardening"). The short-term behavior is therefore more favorable than the long-term behavior.

During tunnel excavation, consolidation takes place in general simultaneously with the stress redistribution caused by the advancing tunnel heading. In the case of rapid excavation through a low-permeability ground, the favourable "undrained conditions" prevail in the vicinity of the advancing face. If the excavation proceeds slowly or the permeability of the ground is high, the unfavourable "drained conditions" prevail practically right from the start. A simple dimensional analysis shows that the time development of deformations is governed by the ratio of advance rate v to permeability k.

Subsequently, the role of pore water pressure dissipation will be illustrated by means of numerical results concerning a 500 m deep, Ø 10 m tunnel which crosses weak ground at a depth of 100 m beneath the water table. Information on the modelling assumptions and numerical procedures can be found in the Appendix. For simplicity, the hypothetical case of an unsupported tunnel will be considered first.

Figure 1 shows, for different v/k-ratios, the contour lines of pore water pressure, the distribution of volumetric strain ε_v (in the radial direction and along the tunnel axis ahead of the face) as well as the radial displacement u of the tunnel wall (after subtracting the deformations taking place ahead of the face). With increasing permeability (or an equivalent decreasing advance rate), dissipation of the excess pore water pressures accelerates, i.e. it takes place more and more closely to the tunnel heading. The higher the permeability of the ground (or, in equivalent terms, the slower the tunnel excavation), the quicker the consolidation process develops and the larger are the deformations occurring at a fixed distance from the face.

3 THRUST FORCE

When tunnelling with a shielded TBM, some limited convergence may occur because the gap which exists between the shield and the rock provides space for deformations. In the case of intense and rapid squeezing, the ground closes the gap at a short distance from the tunnel face and starts to develop a pressure upon the shield. Figure 2 shows, for the example discussed before, the distribution of the ground pressure p alongside the tunnel assuming a normal gap

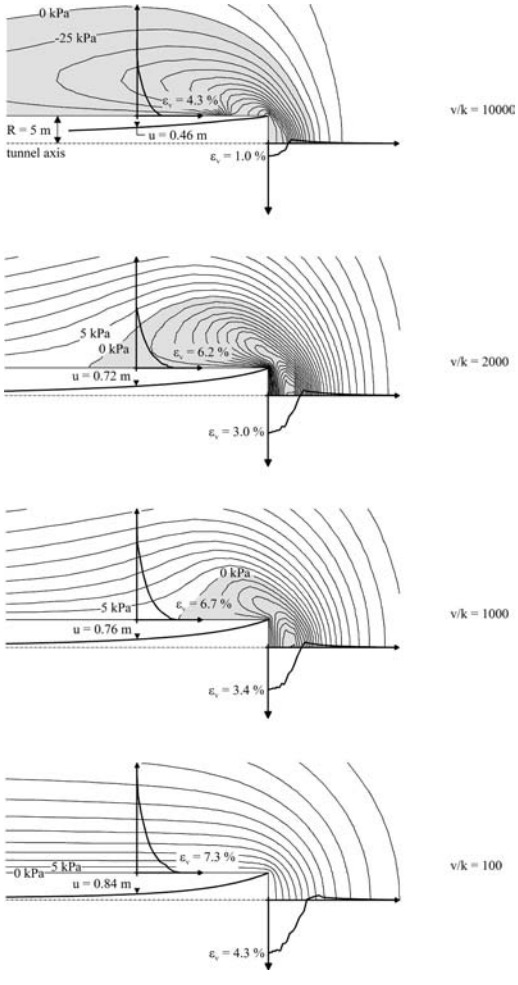

Figure 1. Contour lines of the pore water pressure, convergence of tunnel wall u and distribution of volumetric strain ε_v for different values of the ratio of advance rate v to permeability k (other parameters: see Table 1).

ΔR of 5 cm. Again, the ratio of advance rate v to ground permeability k governs the pressure development. If the permeability is low and the advance rate high ($v/k \geq 10^6$), the gap remains open for the first 6 m. Consequently, the pressure acting upon, e.g., a 10 m long shield would be very low, while a gripper TBM with a short canopy ($L \leq 3$ m) would not experience any squeezing pressure at all. In the case of high permeability, a low advance rate or a standstill ($v/k \leq 10^2$), however, the ground will close the gap in a distance of 2 m from the face and exert a considerable pressure on the shield, possibly endangering its structural stability and also posing the question of the thrust force needed to keep the TBM advancing.

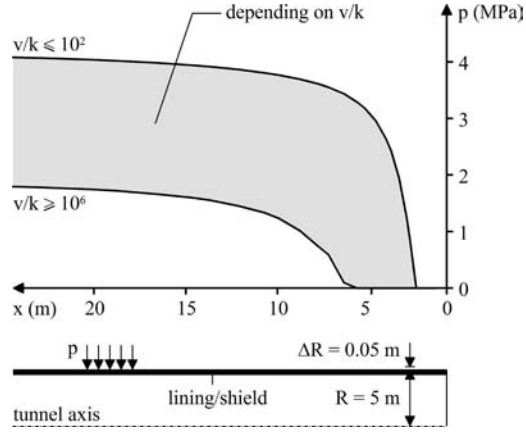

Figure 2. Radial pressure p acting upon the shield or lining for different values of the ratio of advance rate v to permeability k (gap between shield and ground $\Delta R = 0.05$ m; other parameters: see Table 1).

Figure 3 shows the thrust needed to overcome the friction of a 10 m long shield as a function of the advance rate v in a low permeability ground ($k = 10^{-9}$ m/s). The curves have been calculated by integrating the ground pressure p (Fig. 2) over the shield length L and taking into account additionally the thrust needed for the boring process (15 MN). The skin friction coefficient was taken equal to $\mu = 0.25$. In the case of a normal gap ($\Delta R = 5$ cm, upper curve), a continuous excavation rate of $v = 10$ m/cd in combination with a high but still feasible thrust of 90 MN would be necessary to overcome squeezing. The lower curve applies to a gap of $\Delta R = 15$ cm. Accordingly, the thrust requirements can be reduced considerably by overboring – this comes, however, at the cost of possible steering difficulties and reduced production rates.

The permeability of the ground governs the rate of the consolidation process and thus the intensity of the deformations close to the advancing face. Figure 4 shows the effect of permeability k on the thrust needed to overcome friction. The curves apply to different advance rates v and gap sizes ΔR. The lowest curve is rather theoretical as it presupposes a high advance rate inspire of the extreme overboring. Figure 4 shows that for feasible production rates the consolidation process is practically irrelevant if the permeability is higher than about $10^{-7}-10^{-8}$ m/s. The unfavorable steady state conditions apply immediately after excavation, i.e. in the vicinity of the tunnel face. High ground pressures and, consequently, also high thrust forces characterize the steady state. The thrust requirements reach, in the present example, the limits of feasibility. On the other hand, for a practically impermeable ground ($k < 10^{-10}-10^{-11}$ m/s) and even moderate advance rates ($v = 1-10$ m/cd),

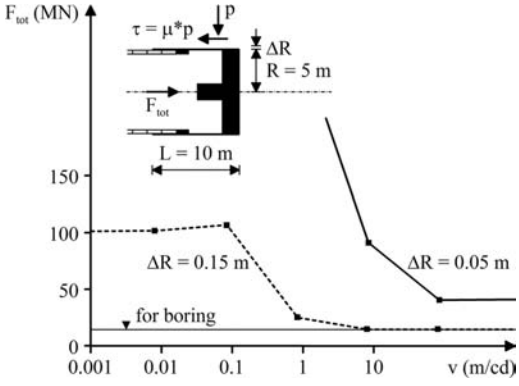

Figure 3. Needed total thrust force F_{tot} as a function of the advance rate v (permeability $k = 10^{-9}$ m/s, gap between shield and ground $\Delta R = 0.05$ or 0.15 m, shield length L = 10 m, skin friction coefficient $\mu = 0.25$; other parameters: see Table 1).

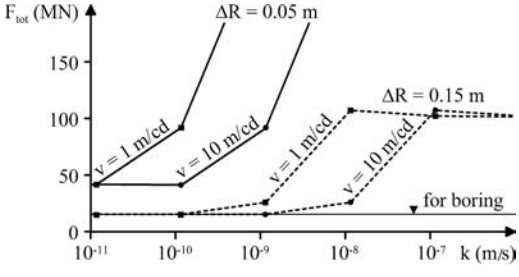

Figure 4. Needed total thrust force F_{tot} as a function of the permeability k (advance rate $v = 1$ or 10 m/cd, gap between shield and ground $\Delta R = 0.05$ or 0.15 m, shield length L = 10 m, skin friction coefficient $\mu = 0.25$; other parameters: see Table 1).

the favorable undrained conditions prevail. The thrust needed to overcome friction is considerably lower.

In the permeability range of $k = 10^{-10} - 10^{-8}$ m/s, a large sensitivity of the results can be observed. This permeability range is thoroughly relevant in practice. For example, the extensive laboratory testing program carried out for investigating the kakiritic rocks of the Gotthard Base Tunnel (Lot Sedrun) revealed permeabilities between 1.1×10^{-10} and 1.5×10^{-9} m/s (Vogelhuber 2006). The large sensitivity in the results indicates a major source of prediction uncertainty, as permeability cannot be estimated reliably. This is particular true for heterogeneous ground (Anagnostou & Kovári 2005).

4 CLOSING REMARKS

The thrust force *needed* to overcome shield friction in given ground conditions depends on the length of the shield, the amount of overboring, the skin friction coefficient and the advance rate. A reduction in the advance rate leads as a rule to an increase in the ground pressure, and thus to further deceleration or even standstill of the machine.

The *available* thrust force depends on the installed thrust and on the capacity of the thrusting system. In a single shielded TBM, for example, the possible thrust force is limited by the bearing capacity of the segmental lining and depends, therefore, on the structural design of the segments and on the quality of the annulus grouting. A quick, proper installation and backfilling of the segmental lining may be impeded by poor ground conditions or water inflows. These difficulties lead to a reduction of the advance rate with the result that the ground pressure acting upon the shield, the required thrust force and the force to be introduced into the lining all increase. Similar feedback effects exist also for gripper TBMs. The time needed for support installation in a poor quality ground reduces machine utilization and may lead to a higher ground pressure on the cutter head shield, to a higher thrust force in order to avoid jamming and therefore to problems with the bracing of the grippers.

In conclusion, on the one hand, the ground-machine–support interaction is decisive for the advance rate, but on the other hand the advance rate influences this interaction too. Besides adverse ground conditions, undesirable events such as electric power stoppages, mechanical breakdowns of the TBM or problems in the back-up system may slow-down excavation progress unpredictably. Maintaining a high production rate is of course a main goal of any TBM drive. For tunnelling through squeezing ground, it may also help avoiding trapping of the machine. Nevertheless, a high advance rate cannot be seen as a panacea for coping with squeezing, as several uncertainties exist with respect both to ground and the machine.

APPENDIX. COMPUTATIONAL MODEL

The numerical investigations are based on an axial symmetric model. The ground is modelled as a saturated porous medium according to the principle of effective stresses. Seepage flow is taken into account using Darcy's law. The mechanical behaviour is modelled as an isotropic, linear elastic, perfectly plastic material obeying the Mohr-Coulomb yield criterion and a non-associated flow rule. The material constants (Table 1) are typical for kakiritic rocks from the Gotthard Base Tunnel (Vogelhuber 2006). For simplicity, both the lining and the shield are assumed to be rigid and only the simplified case of a constant gap size ΔR is considered.

At the far-field boundary the radial stress is kept constant and equal to the initial value σ_0. The respective hydraulic potential Φ is fixed to 78 m. This value is slightly lower than the initial value of $\Phi_o = 100$ m. It

Table 1. Parameter Values.

Tunnel radius R	5 m

Permeability coefficient k	variable

takes into account the deviation from axial symmetry and it was estimated based upon a preliminary two-dimensional seepage flow analysis. At the excavation boundary the initial stress is reduced to zero. In order to avoid water inflow from the excavation boundary, a mixed seepage flow boundary condition is prescribed (no flow condition in the case of negative pore water pressures, atmospheric boundary pressure in the case of positive pore water pressures).

The pore water pressure dissipation takes place in general simultaneously with the spatial stress redistribution in the vicinity of the advancing face. Consequently the analysis of an advancing tunnel heading is inherently a time-dependent, three-dimensional problem with a moving boundary. Usually, the tunnel excavation is simulated by a step-by-step excavation and support installation procedure. Since high deformation- and pore water pressure- gradients prevail in the vicinity of the tunnel face and the latter moves during the step-by-step simulation, the finite element mesh has to be fine everywhere. Such an analysis is, therefore, extremely time-consuming even in the case of linear material behavior. The calculations of this paper are based upon a new numerical solution method, which solves the advancing tunnel heading problem in just one single computational step (Anagnostou 2007). This is possible (i) by re-formulating and solving the underlying transient equations in a reference frame which is fixed to the moving face (Anagnostou 1995), and (ii) by applying a special stress-point algorithm to the integration of the incremental, elasto-plastic stress-strain equations which takes into account appropriately the stress path dependency of the material's behavior. The numerical solution was accomplished with the finite element program HYDMEC (Anagnostou 1992).

Benefits and life-cycle costs of underground projects

John Reilly
John Reilly Associates International, Framingham, Massachusetts, USA

Harvey Parker
President, International Tunneling Association; Harvey Parker & Associates, Bellevue, WA USA

ABSTRACT: Prior to 2002, ITA's Working Group (WG) 13 addressed the "Direct and Indirect Benefits of Underground Structures. In 2002 WG20 continued this theme with the topic "Urban Problems – Underground Solutions" (the principal author was an Animateur of both groups). Much progress has been made in understanding the issues, however in many parts of the world it is very difficult to obtain funding and approval for underground projects, even if the benefits are positive, because the higher initial capital cost of underground projects means that a cheaper elevated or above ground project is frequently chosen. However, selection of an alternative only on the basis of initial capital cost is misleading and in many cases precludes the realization of very substantial long-term benefits. Underground projects have long-term (life cycle) benefits that are, in many cases, much greater than those for above ground projects. These and other benefits mean that the tunnel alternative can return more benefits if long range benefits and costs are considered.

1 INTRODUCTION

There are many complex political and technical issues and decisions in the planning and financing of any infrastructure project. Perceived high cost is an assumption that prematurely eliminates consideration of tunnels in many cases. These premature decisions are usually made only on the basis of initial capital cost since there is a general misconception that tunnels cost too much and therefore need not be considered at all. In fact the true long-term cost of a tunnel may or may not be more expensive than surface or elevated schemes. When evaluated from the standpoint of Life Cycle Cost and Benefits there are examples of tunnels having benefits that outweigh their higher initial capital cost and many examples of tunnels being "in the competitive range".

Therefore, the true cost of a tunnel should be evaluated, not in terms of initial capital cost which is often the only factor considered, but in terms of life cycle costs and benefits considering the generally much longer useful service life of tunnels and their contribution to the environment and sustainability.

The underground industry has been remiss in not developing methodologies and databases that can allow evaluation of projects using life cycle costs and benefits. In 2001, in Seattle, USA the authors organized an American Underground Association Regional conference which discussed these issues (see also, Hess 2001). It is noted that life cycle cost methodology is used routinely for selection of highway pavement alternatives and by private businesses but is seldom used for a complete evaluation of major infrastructure projects.

Fortunately, new tools have been developed to better identify cost, risk and value (*Reilly, 2003 et. seq.*). These tools can include life-cycle costs and benefits as well as funding and revenue projections. An outline of this is presented later in this paper.

1.1 *Overview – The decision to build underground*

More cities are deciding to construct urban transportation projects underground for several reasons.

- They are often the shortest route between two points.
- Tunnels are a way to maintain mobility, using space that is not in conflict with surface functions.
- Tunnels allow multiple use of real estate, essentially doubling the potential use of any parcel of land.
- They provide significant environmental benefits (reduction of noise and visual impacts) and social opportunities (better public use for the surface space).
- They allow movement of people, goods and services, without having to change modes of conveyance.
- Tunnels operate in, and can provide shelter from, adverse weather conditions – safety is improved by the absence of glare, distractions, rain and snow.

- They allow movement under or through obstacles (preserving the obstacles if necessary).
- They conserve energy and are inherently energy efficient.
- They are ideal for preservation of the environment and sustainability.

Examples of international cities building transportation tunnels include: Amsterdam, Hamburg, Stuttgart, Melbourne, Moscow, Oslo, Paris, Shanghai, Stockholm, Sydney and Tokyo. In these cities, there is a relationship between sustainable development and tunnel demand. These tunnels have environmental and social benefits that are recognized by decision makers and voters.

Population, and urban concentration are major factors to consider. In Japan, the lack of available land for infrastructure is driving demand for tunnel construction, and the country builds more tunnels than any country with over 1200 km of tunnels. Switzerland builds mostly through mountains in rock tunnels. Sweden has a policy to first consider underground solutions. All of these factors are relevant, many quantified specifically for a particular city, region or country – however, we need a process to allow this quantification to be more reliable in the determination and political environment of the jurisdiction.

2 COST OF UNDERGROUND PROJECTS & LIFE-CYCLE BENEFITS/COSTS

It is generally true that the initial capital cost of underground construction is significantly greater than elevated or surface facilities. This was documented in the ITA WG 13 Report "Underground or Aboveground", Making the Choice for Urban Mass Transit Systems. (ITA, 2004). The cost factors for underground were reported, in general, to be around 4.5 times that of surface and 2.25 times elevated. These are very significant cost factors in the choice of an underground facility.

Significant conclusions of the WG13 report follow (only some of the findings are given):

1. The decision on whether to place an urban mass transit system underground or aboveground is a complex planning, engineering, construction, urban design, economic and political decision.
2. In many cases – for example in the center areas of older cities – there is no alternative to the choice of an underground alignment for new mass transit systems because of for functional, social, historic environmental and economic reasons.
3. In newer cities, cities without extensive historical districts, and cities with wide streets, elevated alignments can offer full grade separation typically at substantially lower initial construction cost than underground alignments, with certain exceptions usually related to right-of-way costs.
4. The initial capital cost is only a part of the total long-term financial commitment. Costs include capital (including financing), operations, maintenance, security and rehabilitation. A rational and quantified consideration of all costs and benefits (direct and indirect) is necessary.
5. Many aspects of the long-term cost-benefit relationships are hard to quantify. Reference analyses and reports with the experience of other cities are very useful – particularly in the early stages of planning and design – however such quantification must be considered.

2.1 *Long-range cost-benefit analysis*

Cost-benefit analysis should include capital, operating and maintenance costs, road user time savings, public transport user time savings, travel time variability, pedestrian time savings, vehicle operating cost savings, accident reduction, etc. The benefits accrued to underground projects should include the time value of the use of the surface over the tunnel (a value can be assigned even if it is a park), right of way advantages, increased property values and employment in the general vicinity, and overall energy savings that might result from shorter travel times, flatter grades, etc. Moreover, an equivalent accrued value should applied for the less tangible environmental and sustainability benefits such as noise impacts, air quality impacts, and greenhouse gases which are significant over the life cycle (Parker, 2004, Hess, 2001). The following examples include many of these elements and this issue is developed further later in this paper.

2.2 *Maintenance and operating costs – underground vs. above-ground*

Increased maintenance and operational costs for underground facilities may or may not be greater than surface or elevated facilities. Operating costs for light, ventilation, communications and safety systems will cost more for a tunnel. Maintenance costs however may be the same or could be less than for an elevated structure. For example a study for the Newfoundland and Labrador Fixed-Link project, 18 km long, which compared the estimated capital, maintenance and operating costs for several alternatives including bridges compared to immersed tube, drill and blast and TBM tunnels, found significantly lower maintenance and operational costs for the tunnel configurations in the order of $CA16.9 million/year for the bridge and between $CA 6.8 and $CA7.6 million for the tunnel (Newfoundland and Labrador Fixed-Link project).

In Sydney (see following) the projected Net Present Value (NPV) of operating and maintenance costs

Table 1. Estimated Long-Term Savings, Sydney.

Element	Estimated benefit ($A m)
Time savings – road	738.15
Time savings, public	83.48
Time savings, pedestrian	67.15
Vehicle cost savings	211.27
Accident reduction	10.17
Reduction in noise	10.94
Reduction in pollution	0.13
Greenhouse gases	50.58
Increased property	3.41
Total	1,175.28

were projected at about 8% of the cost of construction. These costs were included in the cost-benefit analysis which showed a positive investment return. Hess (2001) reported a similar very comprehensive life-cycle evaluation of the Prague Metro in which he concluded that over the life cycle, a subway project brings a profit to public budgets in spite of increased operational costs compared with the surface transport.

3 EXAMPLES – BENEFITS OF URBAN UNDERGROUND TRANSPORTATION PROJECTS

The following examples outline major transportation projects in dense urban environments where an underground solution has been chosen or preferred over a surface or elevated solution. These are road projects, but the same considerations would apply to rail or transit projects. In a few cases the cost-benefit of the underground solution has been quantified and is reported here.

3.1 *Cross-City Tunnel, Sydney, Australia*

Sydney, Australia examined the costs and benefits of the construction of the Cross-City Tunnel which occupies a critical location in relation to the flow of traffic in the inner metropolitan area. It is the crossing point for major road and public transport flows in both north–south and east–west directions. The economic assessment of the Cross-City Tunnel (NSW Roads and Traffic Authority Working Paper 2000) found a very positive benefit for the underground facility. The project had an estimated a capital cost of $A330 m and a delivered capital cost of $A680 m (see other papers for cost growth of major infrastructure projects e.g. Reilly, 2005a) but was estimated to deliver total benefits of some $A1,175 m as shown following. The net present value of the benefits was $A448 m.

3.2 *Rheinufertunnel (Rhine embankment tunnel), Düsseldorf, Germany*

As in many old cities, which are situated along rivers, the road along the embankment of the Rhine in Düsseldorf was frequented by 55,000 cars per day until the early 90s. This road separated Düsseldorf's "Altstadt", the famous historic part of the town, which is also frequented by many tourists, from the river Rhine, preventing the public from enjoying the special urban quality of living next to a river. In 1993 a 4-lane road tunnel under the previous embankment road was opened, also opening the chance for an immense improvement of the urban quality in this part of Düsseldorf. The tunnel partly is under the water line of the Rhine and therefore was built using compressed air under a lid with the help of diaphragm walls. The area today has proved to be one of the most beautiful parts of the city and its recreational value, esp. on weekends, is inviting thousands of citizens. The case history is being evaluated by ITA Working Group 20, Urban Problems, Underground Solutions.

The tunnel provided the following benefits:

- Valuable surface space made available again
- Additional traffic capacities provided for individual transport
- Relief from traffic congestion achieved
- Time savings in transport achieved
- Noise levels brought to acceptable levels
- Pollution (especially air pollution) reduced
- Architectural quality of urban environment improved
- Service quality of the urban environment improved
- Safety and security in urban environment improved
- The project was completed on time and within the original 300 million Euro budget.

3.3 *Alaska Way Viaduct and Seawall Replacement, Seattle, USA*

The Washington State Department of Transportation (WSDOT), the City of Seattle and the U.S. Federal Highway Administration are working to replace the old Alaskan Way Viaduct and Seawall, considering two basic alternatives – a tunnel along the waterfront or an elevated highway structure. These two alternatives were carried forward in 2004, following three years of environmental and engineering review, 76 initial concepts, over 200 community meetings and over 4,500 public comments.

The viaduct plays a major role in sustaining the regional and city economy and maintaining mobility throughout Seattle. One quarter of all north-south traffic through Seattle (103,000 vehicles) use the viaduct every day. When the project was closed temporarily after the 2001 Nisqually Earthquake there was extreme congestion on adjacent freeways and the downtown

city grid. The earthquake also damaged the seawall and subsequent investigations revealed that the seawall also needs to be replaced. Options considered for the Alaska Way Viaduct replacement were:

- Boulevard Along Alaskan Way (Multi-Modal Transportation)
- Elevated Roadway Along Alaskan Way
- Cut & Cover Tunnel Along Alaskan Way
- Deep Bored Tunnels
  - Along Alaskan Way
  - Along 1st & 2nd Aves.
  - Along 5th Avenue
  - Under Interstate – 5
- Sunken Tube Under Elliott Bay
- Deep Bored Tunnel Under Elliott Bay
- Submerged Floating Tube Under Elliott Bay
- Elliot Bay Signature Bridge

As of this writing, the City of Seattle believes the Cut & Cover Tunnel along Alaskan Way using the outboard wall of the tunnel to replace the seawall is the preferred project and the State is working with the City to find funding for the extra capital cost of this alternative. The additional funding is not yet assured.

4 BENEFITS OF UNDERGROUND FACILITIES – WITH REFERENCE TO SEATTLE

One of the primary findings from the Seattle review is that relevant tunnels and underground structures last a significantly longer time than the equivalent above-ground structures. Tunnels constructed over one hundred years ago in the U.S. and elsewhere are still in useful service today.

For example, the Seattle Alaskan Way (elevated) Viaduct is 52 years old but needs to be urgently replaced. The West Side Highway in New York City was taken out of service after 42 years. The Embarcadero Freeway in San Francisco was demolished after approximately 30 years.

A review of transportation corridors shows that underground structures last much longer, often over a century and more. The Burlington Northern (BN) Rail Tunnel beneath Seattle is over 100 years old – it was opened in November 1904 and is now on its second century of low-maintenance service. The Seattle Battery Street Tunnel, now 53 years old, will continue to take traffic well into the future.

A significantly longer service life means that the present value (worth) of that structure (the tunnel) can be less than a shorter-life structure (elevated viaduct) although the initial capital cost of the elevated structure is usually less than that of the tunnel.

Table 2. Benefits associated with the tunnel option, seattle.

Element	Benefit
Increased values associated with the waterfront:	\$0.7–\$1 billion over 25 years
New visitor spending:	\$1 billion for each 1% increase in visitors
Increased property values:	\$280–\$960 million.

5 ECONOMIC STUDIES

An economic case for the tunnel was outlined recently to the Downtown Seattle Association (Pascall, 2006). This study reported that, by funding the tunnel option (at an additional cost of over \$1 billion more than the elevated viaduct replacement), property values could increase by \$450 million, as much as \$2 billion in additional property development could occur and \$325 million a year could be generated by tourism.

A previous (but limited) had review indicated that the following potential benefits for the tunnel might be realized in addition to the environmental improvements:

In total these numbers indicate that the present worth value of the tunnel could exceed the extra initial capital cost by a factor of between 1 and 3. However, because it is hard to quantify these numbers sufficiently or accurately in the context of current practice this is an area for further study and development by ITA.

6 NEW TOOLS TO QUANTIFY COSTS AND BENEFITS

There are new tools that can better address cost, probable cost, risk identification, risk management, value engineering, life-cycle costs and benefits and probable funding. An example of one of these is the U.S. Washington State Department of Transportation's Cost Estimate Validation Process CEVP® which is a process to identify ranges of probable costs by identifying and combining "base costs" and risks plus opportunities to produce a "range of probable cost and schedule" for the explicit and implicit conditions of the evaluation. The process has been described previously (Reilly, 2005a, 2004b & c, 2003c).

Current thought is to extend this process to include life-cycle and value-engineering components. An outline has been drafted for the value engineering process and one could be readily developed for life-cycle costs. This Life Cycle Cost Estimation Process (LCCEP) would allow us to tie together cost validation, ranges of probable costs and benefits and value-added returns in order to better assist determination of alternatives considering long-range costs and benefits.

7 CONCLUSIONS

1. There is rising skepticism toward the underground design and construction industry, particularly for large expensive projects in cities. This is due to many major cost over-runs and sometimes mismanagement – which need to be addressed. We also need to improve design standards for safety, security, environmental soundness and user friendly tunnels and to and communicate this effectively to the public and political decision makers.
2. We cannot do this unless we develop reliable methodologies to systematically estimate and manage costs and risk, and to use those methodologies to reduce the out-turn costs of tunnels and underground space. Adding value engineering and life-cycle costs and benefits will enable better total cost comparisons for alternatives if the environmental and political decision processes are also aligned.
3. The concepts outlined in this paper, including the proposed Life Cycle Cost Estimation Process (LCCEP) if developed and applied, would allow, practical and more reliable comparisons on the basis of cost and benefits to select a preferred project alternative from significantly different alternatives such as elevated, surface, cut-and-cover, various bored tunnel and other underground schemes and alignments.
4. This can be done because of the comprehensive nature of the proposed process, which could fully take into account relevant factors and could provide the equivalent monetary value of all the environmental benefits the proposed project provides. It is anticipated that underground projects would become more economically attractive as a result.
5. The referenced CEVP process (Reilly, 2005) has improved our ability to predict a project's probable cost and schedule in ways that incorporate the effects of risks, technical and non-technical. The same concepts and attitudes necessary to be successful with CEVP are also those that are needed to quantify for life cycle costs and benefits.
6. When fully developed, LCCEP will allow engineers, planners, decision makers, politicians, the general public, and the media to better understand the compromises and tradeoff choices that are made in planning a given infrastructure project.
7. When this methodology becomes mature, the authors believe that tunnels and underground space will be found to be more competitive with other alternatives and many decisions regarding alternates can be made on the basis of issues such as the environment and quality of life. It is likely that the underground alternative will be selected more often – provided funding can be found.
8. The concept of life cycle costs is not new as it has been applied to pavement replacement for decades. The approach regards cost as an investment to be managed prudently. The same is true for major transportation projects, but the methodology has not been applied similarly and, as a result, engineers and planners do not commonly apply it to major infrastructure projects.
9. The underground industry should have already developed this acutely needed methodology. We must be proactive to develop these concepts and to get them to be understood and accepted by the decision makers. We must continue to explain that tunnels and underground facilities are "investments and not costs".
10. Much needs to be done to develop and simplify practical methodology to accomplish the goals of a complete Life Cycle Cost Process. If this initiative is successful, the result will be benefits to urban communities in the form of more value and improved environmental quality and sustainability. And, there will be more underground facilities designed and constructed.

8 SUMMARY

To make a more equitable case for appropriate selection of underground alternatives, the following actions must be considered:

1. Planning and public policies must consider long-term life-cycle costs and benefits
2. The long-term life-cycle costs and benefits need to be quantified through an accepted methodology
3. Benefits must be communicated to the public and political decision-makers
4. The political process must recognize that this is an appropriate planning and selection process
5. A funding mechanism that will support the higher initial capital cost must be found
6. Revenue to support the funding mechanism needs to be collected
7. The credibility of this process must be demonstrated.

New York Second Avenue Subway – Initial support design of shallow rock caverns

K. Rossler & C. Stone
DMJM Harris, New York, USA.

ABSTRACT: New York Metropolitan Transportation Authority Capital Construction (MTACC) has authorized the DMJM+HARRIS•Arup Joint Venture team with preliminary engineering of the $16 billion 2nd Avenue Subway project consisting of 14 km of twin tunnels and sixteen underground stations. The project will include large, shallow caverns for stations and crossovers mined in rock, which will be featured in this paper. Clear span openings up to 30 m, low rock cover ranging from 6 m to 12 m, and non-circular shapes below groundwater level presented many design challenges and dictated unique design considerations to assure prudent solutions. Confronting the caverns' design intricacies, a robust design procedure was developed to increase the design safety margin and to assure economic feasibility. The core of the design procedure was the adoption of ground behavior rules identifying support types, and verification by a simultaneous deployment of the best-known tunnel design methods.

1 INTRODUCTION

The Second Avenue Subway (SAS) project alignment (Fig. 1) is planned for the east side of Manhattan Island in New York City. The project includes six underground mined station caverns and five mined crossover caverns.

2 GEOLOGY

Manhattan Schist along the alignment typically has three joint sets with scattered shear zones. Joint spacing ranges from moderate to close within the top 9 m of bedrock. Top of rock elevation is variable, and typical soil overburden is about 6 m.

The design intact rock parameters are shown in Table 1. With respect to the compressive strength, the intact rock cores measured higher tensile strength (Brazilian test), and lower Young's modulus (uniaxial compression test) likely influenced by the mica schist content.

The direct shear test results revealed an elasto-plastic behavior of joints with zero displacement weakening, and peak friction angle equal to residual friction. The joint parameters are provided in Tables 2–3.

Base friction angle of Set 2 in conditions I, II, and III was increased to account for effect of joint waviness by 5 deg. Cohesion was zero.

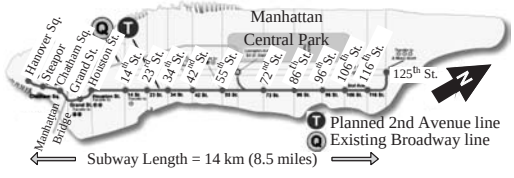

Figure 1. Plan of second avenue subway.

3 DESIGN METHODOLOGY

The design methodology relied on three design concepts:

1. Initial support design chart structured by ground behavior rules.
2. Four verification methods with fundamentally different design approaches.
3. Rock load as a parameter of ground behavior.

Table 1. Design intact rock parameters.

Unit weight (kN/m^3)	27.5
Secant modulus (GPa)	20.7
Poisson's ratio	0.15
Compressive strength (MPa)	48
Tensile strength (MPa)	14

Table 2. Measured rock joint shear strength parameters (Snee & Rocha 2005).

	Joint sets∗			
	Set 1, and Set 3,		Set 2,	
Base friction, and dilation angles	ϕ_b deg	ϕ_d deg	ϕ_b deg	ϕ_d deg
I Fresh to slightly weathered with iron-oxide staining	30–40	5–10	42	5–10
II As condition I with heavy iron-oxide staining	30	5–10	35	5–10
III Slightly to moderately weathered with mineralization, chlorite, kaolinite, sericite	20–35	2–10	40	5–10
IV As condition III with heavy iron-oxide staining and clay coating	20–30	0–5	20–36	5
V Condition I–III with slickensides	25	3	25	3

Table 3. Design rock joint parameters.

Shear displacement for zero dilation (mm)	4
Joint normal stiffness (kN/m^3)	1.6E+07
Joint shear stiffness (kN/m^3)	6.0E+06

3.1 *Initial support design chart*

The design chart in Table 4 includes:

- Five support types (Types I thru V), and their support quantities.
- Ground behavior rules defining design ranges of the five support types.

The five ground support types have been developed to cope with anticipated changes in ground conditions. The ground behavior rules, which recognize the impacts of both rock quality and excavation geometry, were used to arrange the five support types in hierarchy from bolt-reinforced rock to structural shotcrete arch in recognition of a boundary between "good" and "bad" ground behavior.

3.2 *Methods with fundamentally different design approaches*

Four methods with fundamentally different design approaches were utilized in verification and optimization of initial support quantities to comply with design criteria, and performance requirements for given geotechnical parameters:

1. Empirical methods (Q, RMR).
2. Stress-strain method of discontinuum (UDEC).
3. Stress-strain method of continuum (STAAD).
4. Force-equilibrium method (UNWEDGE, Closed-form).

The four methods allow accounting for a broad range of the tunnel design aspects to assure safe and economic construction. The methodology recognized the strengths of each method, and maintained a premise of the methods equal importance for the design. Neither method was considered an inferior or superior analytical tool in making design decisions. The key, however, was to distinguish the method's range of applicability. An engineer with tunnel design experience and familiar with the methods would make design decisions based on understanding the features that impact the design and which methods include the features.

Table 5 describes the methods, their strengths and weaknesses, and their range of applicability. Table 6 provides selection guidelines of verification methods appropriate for given ground conditions.

3.3 *Rock load parameter*

Rock load is required input for structural design of the final concrete lining, and the initial shotcrete structural arch. In the design chart, rock load was also recognized as a parameter to measure ground behavior, and to identify the support types because it accounts for all the impacts including the rock quality and the excavation geometry, and is directly proportional to the amount of support required.

4 FUNDAMENTAL CAVERN DESIGN CONSIDERATIONS

Loading considerations and dimensional elements relating to the transit station and crossover cavern design were discussed and agreed upon with the client, MTACC, early in the design phase. These included the following:

- Station and crossover geometries,
- Two-pass lining system, in which initial lining does not contribute to the final support.

4.1 *Performance requirements*

The mined cavern linings were designed to ensure stability of the rock mass and to protect the existing structures. The design was required to comply with the following requirements:

- Maximum permissible vertical movement in crown, and at street level = 0.020 m.
- Maximum permissible differential settlement for a historic structure near cavern = 1/1000.
- Maximum permissible differential settlement for a modern structure near cavern = 1/750.

Table 4. Initial support design chart.

Good ground behavior. Reinforced rock arch. ⟷ Bad ground behavior. Structural arch required

4.2 *Design criteria*

Initial support was designed as a temporary structure over the time period prior to installation of the final liner; this involved:

1. Non-factored loads.
2. Strength reduction factors applied in structural verifications of shotcrete arch and steel sets.
3. Safety factors applied in bolt design and wedge stability.

Design criteria were summarized in Table 7.

5 DESIGN ISSUES

This paper focuses on issues that have generated controversial points of view. The adopted solutions shall not be taken as definitive statements, rather as project-specific design approaches that are offered for discussion.

5.1 *Rock load magnitudes*

The rock load ranges of the design chart were defined by the minimum rock load of 3 m of NYCT design guidelines (NYCT 2003), and by empirical data from previously constructed mined station caverns in Washington, D.C. and New York, which were correlated with geological data and cavern geometry using the Q value and scaled crown span (Fig. 2).

The rock loads are generally in compliance with the U.S. Army Corps of Engineers guidelines, and were confirmed by UDEC analyses (Fig. 3).

Rock loads of shallow caverns are limited by the low rock cover, however due to proximity of the top of rock, the loads may approach full overburden loads by adding the pressures of soil overburden, as shown in Figure 3.

Force equilibrium methods (Closed form solutions or UNWEDGE) cannot fully account for the impact of low rock cover, and were utilized to verify wedge loads for Types I thru III.

5.2 *Low rock cover*

Various design methods define shallow tunnels differently. The Q tunneling index considers the impact of low rock cover when it is less than the excavation span. Low cover of soil tunnels is defined by three excavation spans by considering the impact of gravity gradient on ground load distribution.

In the design of the SAS caverns, the adverse impact of low rock cover was defined by the rule of minimum rock cover thickness equal to 1/3 and 1/4 of

Table 7. Design criteria of initial support.

* Elastic modulus reduced by 35% to account for plastic deformation, and microcracking.
** Structural shotcrete arch defined as a curved structural member with thickness >15 cm, which relies on rock support along the walls and under the footings to generate axial thrust, enhancing the arch flexural strength. Fiber content of 0.6, 0.9, 1.2% (by volume) may account for 20, 35, and 40% shear strength increases, respectively, (ACI 544.4R-88).
*** The design tensile strength of shotcrete arch enhanced by lattice girder shall be determined from moment-thrust diagram in correspondence to the steel bar reinforcement per foot. The compressive strength of shotcrete shall be considered without contribution of lattice girder.

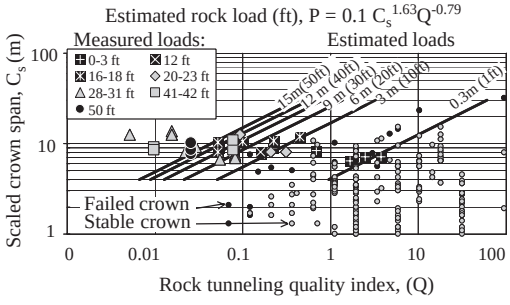

Figure 2. Estimation of rock loads for shallow caverns via the scaled crown span.

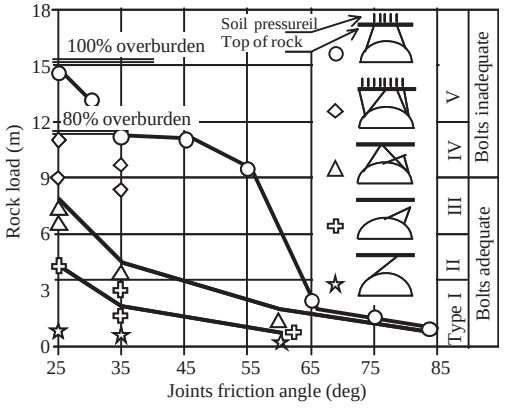

Figure 3. UDEC rock loads on 30.5 m wide cavern liner, under 5 m of soil, 12 m of rock cover with various joint dips.

excavation span in support Types IV, and V, respectively. It was assumed that a rock mass reinforced by bolts would be capable of supporting the excavation in compliance with the definition of good ground behavior with rock cover more than the defined minimum. Bad ground behavior or excavation with rock cover thickness less than the minimum would require support via a structural shotcrete arch.

The minimum rock cover thickness is less restrictive than the Q or the soft ground tunnel rules, and therefore it was verified by the numerical method UDEC, (Fig. 3), including the adverse impacts of low rock cover, as follows:

1. Overstressing and limited rock arching in the roof.
2. Tensile stresses and joint opening due to bending of the roof under the soil overburden.
3. Failure mechanism defined by steep discontinuities and by the top of rock surface.
4. Limited roof thickness for productive drill and blast operation.
5. Limited rock thickness for proper bolting lengths.

5.3 *Verification of structural shotcrete arch*

Design aspects of the shotcrete arch for support of Types IV, and V are described in the following sections.

5.3.1 *Rock load distribution diagrams*

The uniform rock load distribution (Fig. 4), and unbalanced rock load distribution (Fig. 5) were utilized in STAAD analyses to obtain shotcrete design forces.

Figure 4. Uniform rock load diagrams; RL = rock load magnitude in Table 4.

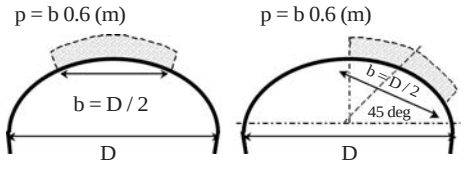

Figure 5. Unbalanced rock load diagrams.

Table 8. Rock mass modulus and spring stiffness magnitudes.

Rock quality classification	Q ≥ 4, or RMR ≥ 60	Q < 4, or RMR < 60
Rock mass modulus, E_m (GPa)	16.5	4.1
Radial spring stiffness, k_r(kN/m^3)	9.4E+05	3.1E+05
Vertical spring stiffness under footings, k_v (kN/m^3)	9.4E+06	3.1E+06
Horizontal spring reaction under footings, k_h (kN)*	<N_u tan(15 deg)	

* N_u = vertical thrust force exerted by the footing.

5.3.2 *Springs*

Rock mass modulus estimated from correlations of RQD (Bieniawski 1984), and Q (Barton 2002) with derived spring stiffness are shown in Table 8.

Convergence of UDEC and STAAD results was utilized in the calculation of spring stiffness, which represented passive resistance of the rock mass. Figure 6 shows agreement between axial thrust, moments, and shear forces calculated by UDEC, and STAAD in the shotcrete arch, which confirmed similar boundary conditions in both models, and yielded the spring stiffness equivalent to the rock mass behavior.

5.3.3 *Comparison to Q*

The Q support chart (Grimstad 2002) defines structural arch support by shotcrete ribs reinforced with steel bars, while the SAS design chart recommended a structural arch of uniformly thick shotcrete liner reinforced by lattice girders. For comparison purposes, Figure 7 converted the Q reinforced shotcrete ribs into equivalent support of the uniform shotcrete liner reinforced by lattice girders. The comparison showed, that the SAS subway design chart prescribed smaller shotcrete thickness, and less reinforcement than the Q design, which demonstrated the effect of support optimization of the robust design methodology. Note that the SAS shotcrete lining is to be followed by a concrete final lining.

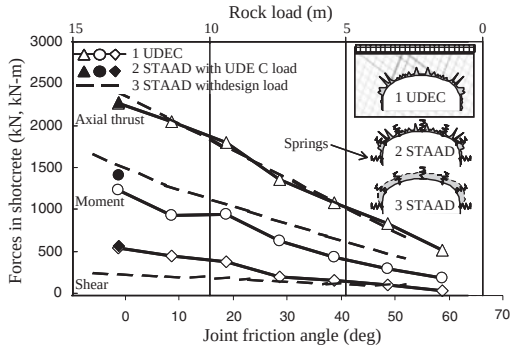

Figure 6. Forces in shotcrete arch (30.5 m wide cavern, under 6 m of soil, 10 m of rock cover, joint dips +50 × −50 deg.)

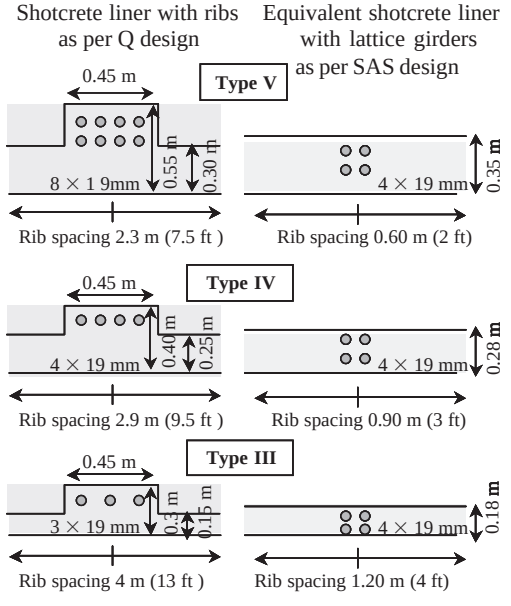

Figure 7. Shotcrete liners reinforced by lattice girders equivalent to the Q design requirements.

5.4 *In situ stress and Ko*

With respect to the low stress environment of shallow caverns, overstressing of intact rock blocks is unlikely, and the planes of weakness of joints, faults, and shear zones will control the excavation stability.

In preliminary engineering, the design of shallow caverns adopted a design value of Ko = 0.75, with lithostatic vertical stress equal to the weight of overburden. However, later in the project, the hydrofracture field tests measured high in situ stresses in the range of 1724 to 2758 kPa within the depths of 18 m, which would lead to Ko values of more than 10.

UDEC analysis demonstrated that before any excavation, the rock joints with the known design strengths would not support the high in situ stresses and failed, which led to a hypothesis that the measured stresses, would not transfer across the joints. The in situ measurements are to be re-examined.

5.5 *Groundwater*

Monitored groundwater levels indicated that the cavern construction would take place below the ground water table. Nevertheless the initial support design assumed zero groundwater pressures. In faulted areas the pressures are expected to be zero due to the recharge being less than the joints conductivity, while in tight rock mass areas the excavation is expected to be dry.

5.6 *Size of drill and blast drift*

The initial support design supported the excavation throughout all stages of excavation sequencing. General limitations that apply to drift size, round length, installation of support, and cut sequences were specified.

For cost estimating purposes, the SAS project adopted a round length of 2 m, which complied with the limited mucking capacity at the shafts, although, rock mechanics issues would allow larger round lengths of up to 6 m.

Applying the round length of 2 m, and considering vibration impacts on the surface structures yielded maximum drift size of 37 m^2. Drift height and span ranged from 4.5 to 8 m to accommodate mining equipment.

5.7 *Initial lining contribution*

Complying with the client's request and considering liability issues, the initial support, rock bolts and shotcrete liner were considered temporary support and would not contribute to the support capacity of the final lining during the 100-year design life. As a permanent support, the initial support would have to comply with strict quality assurance procedures, including inspection of lining thickness, shotcrete quality, steel cover, and corrosion protection.

Considering the shotcrete separation from the final liner by a waterproofing membrane, the analyses showed that the contribution of the 0.15 m thick shotcrete arch to the permanent support of a 0.9 m final liner would be only 15%.

ACKNOWLEDGEMENTS

The authors wish to thank Jeff Fosbrook, Project Manager of DMJM Harris•Arup Joint Venture, and Anil Parikh, Program Manager, of MTACC for permission to publish the project information. Our thanks also extend to Stanley Niemiec of Jenny Engineering for his mentoring, Sakir Selcuk, and Nils Pettersson of DMJM Harris who performed design analyses.

Laboratory and numerical investigation of tunnel reinforced with face bolts

K.W. Seo, T. Domon & K. Nishimura
Tokyo Metropolitan University, Japan

ABSTRACT: During the excavation of tunnel, to prevent the collapse of tunnel face and settlement of ground the face bolts have been being frequently used in the soft ground. In this study, the face bolts were installed near to excavation line upwardly and radially on purpose and their supporting effects according to the installation angles were examined. Based upon the results of the laboratory and numerical investigation, the following conclusions were obtained. The axial displacement of the tunnel face depends on the installation angel under the same construction condition. The upward installation of the face bolts is fairly effective on controlling the vertical settlement. Inclined installation of face bolts depending on the purpose of support may be required for effective control of axial displacement of the face and/or the vertical settlement of surface.

1 INSTRUCTION

Construction of a NATM tunnel in soft ground usually calls for a supplementary method or methods to secure the stability of its working face and minimize its effect on the structures on surface. Especially face bolts prevent collapse of the face and settlement of ground during excavation. Therefore, they are frequently used in soft ground. (Geofronte research Association, 2002). As the main characteristic, the face bolts are installed in the excavation area and cut off during excavation process. (Geofronte research Association, 2002). Geofronte research Association (2002) reported that the face bolts has been used with other supplementary methods in 84% tunnel construction sites out of 29 tunnels where the bolts are employed. The reason of this is thought that the vertical settlement, such as surface settlement, as well as the axial displacement of the face is needed to be controlled.

Although the current construction standard prescribes that boring for bolts should be done horizontally as possible, it often deviates from the designed boring line due to geological condition, working condition, etc. (Seo, 2006). In this study, we give the angle, upward and radial, to the face bolt being installed near to the excavation line and examine its support effect against the vertical settlement of surface.

2 LABORATORY TEST AND NUMERICAL ANALYSIS

2.1 *Laboratory test*

Face bolts, as described above, are cut during the excavation. To model this, the following test method is used employed.

2.1.1 *Material of the ground*

The artificial material used as soil here is the mixture of copper bead, Vaseline and zincous oxide in the weight ratio of 200:1:0.3 respectively. Although copper bead is not light enough to handle easily and required to be kept in the stable temperature because of using Vaseline, it could provide some adhesive power, and the properties are stable due to not using water and could be preserved for a long time.

2.1.2 *Test box*

The test box used in this study is a aluminum box of which the width is 0.88 m, the length is 1.08 m and the height is 0.6 m.

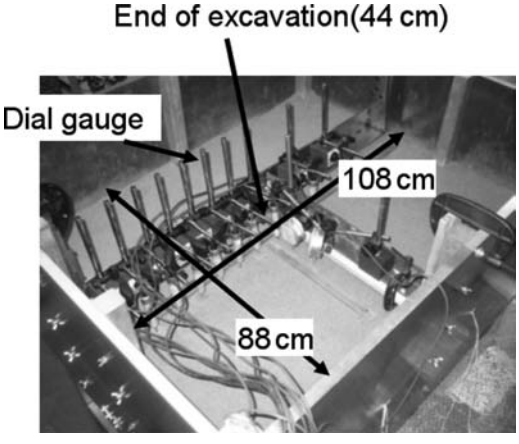
2.1.3 *Face bolt*

The face bolts used in this test, of which the section is a 2 mm wide square, is a 1D (160 mm) long acryl rod. On its surface, sand is attached with epoxy.

2.1.4 *Excavation method*

The model tunnel is advanced 2 cm sequentially to 2.8D (44 cm) by hand. This excavation method was successfully carried out by Ishimura (1998). Picture 1 shows the test box set with artificial ground and gauges.

2.2 *Numerical analysis*



The axial displacement is not easy to measure directly on the face. Therefore, it is analyzed by numerical analysis. The ground material is presumed as elasto-plastic material of Mohr-Coulomb.

Figure 1 represents the numerical model and its input properties are listed in Table 1.

2.3 *Test case*

To compare face bolts with angles to horizontally installed bolts, the test cases shown in Table 2 are analyzed. Figure 2 shows the layout of the <0°> model.

Here, <none> represents a model without a face bolt, and <0°> does that with horizontally installed bolts. <0°> model is compared with 4 models of which face bolts on line 1 in Figure 2 are installed with radially upward angles of 15° and 30° and the upward 15° and 30° in parallel to the tunnel axis. The bolts on line 2 are horizontally installed. Both the laboratory test

- overlap: 0.5D 8 cm
- excavation distance 2.8D 44 cm
- the number of excavation: 6 times

Figure 2. Layout of model <0°>.

and numerical analysis are conducted on <R30°> and <U30°> models and only the numerical analysis is carried out on <R15°> and <U15°>. The overlap length is 0.5D (8 cm) and the tunnel is excavated six times to 2.8D (44 cm).

Radially and upwardly installed face bolts are remained in ground after excavation although horizontally installed bolts are removed by excavation. Upward installed face bolts on Line 1 reach the outside of the tunnel face. The more angle the face bolts have, the bolts reach further, that is, in the order of <U15°>, <R15°>, <U30°>, <R30°>, the bolts are installed further out of the tunnel. As the tunnel progresses, horizontally installed face bolts on Line 2 are cut off and those installed upwardly and radially on Line 1 are remained in the ground.

3 TEST RESULT AND CONSIDERATION

Figure 3 shows the maximum axial displacement according to the installation angle by numerical analysis. As shown in the figure, the axial displacement with the face bolts of 0° installation angle is minimal and it is greater with greater installation angle. The displacement of <U15°> and that of <R30°> are 27% and 45% greater than that of <0°>, respectively. The reason that the displacement of <U30°> and that of <R30°> are so big is thought that the installation angle of bolts on Line 2 is 0° and only those on Line 1 have the angle. It is believed that this is because horizontally installed face bolts mainly have the effect on axial displacement prevention.

This explains that the face bolts should be installed horizontally as possible to prevent axial displacement.

The axial force after horizontal installation of face bolts on Line 2 (See Figure 2) is represented in Figure 4. In every step of excavation, ground behind the face has the maximal axial force and it is the maximum after 2 step excavation. Further behind location with the maximal axial force, the force decreases. This phenomenon matches to the real measurement data (Nishizaki, 2002; Shimizu, 2003) and, therefore, it can be said that the laboratory test is successfully done.

The axis-direction vertical settlement after 2.0D excavation is shown in Figure 5. The settlement with radial installation is bigger than that with horizontal one. The reason is thought that the face bolts are stretches out of the face area and, therefore, the displacement on the face is large. Also, the bolts left in the ground may not affect much on supporting. Figure 6 represents the vertical settlement in axial direction after 2.8D (44 cm) excavation. Comparing the effects of horizontal installation and upward installation of face bolts, the vertical settlement with upward installation is about 10% less than that with horizontal installation and 17% less than that at 1.9D of the

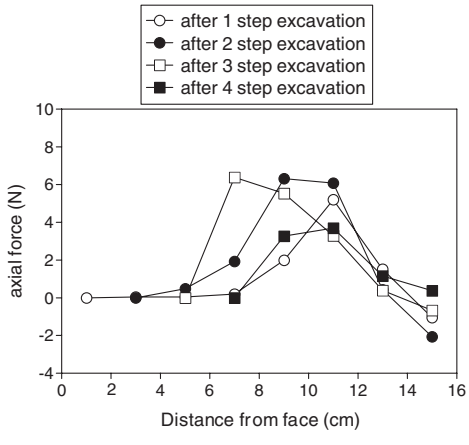

Figure 4. Axial force distribution on horizontally installed face bolts <0°> according to the excavation.

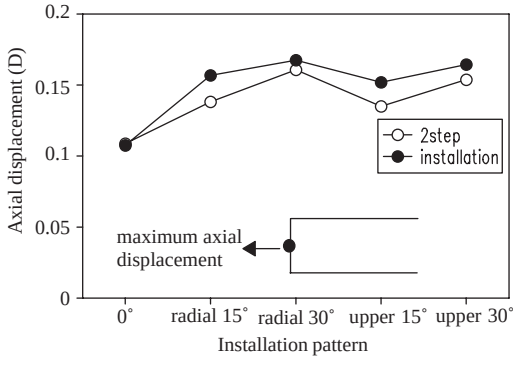

Figure 3. Maximum axial displacement according to the installation angle – numerical analysis.

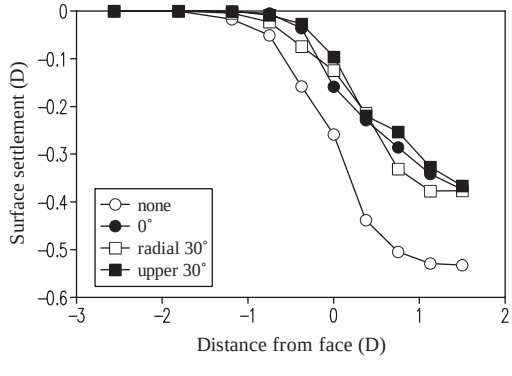

Figure 5. The vertical settlement according to the installation angle (after 2.0D excavation).

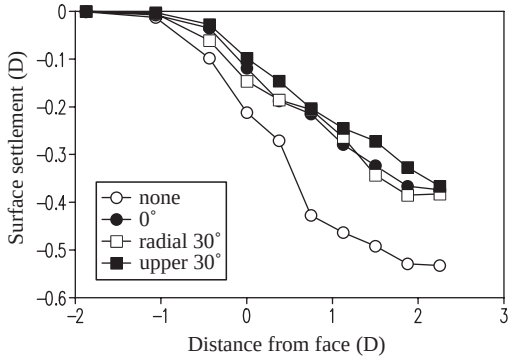

Figure 6. The vertical settlement according to the installation angle (after 2.8D excavation).

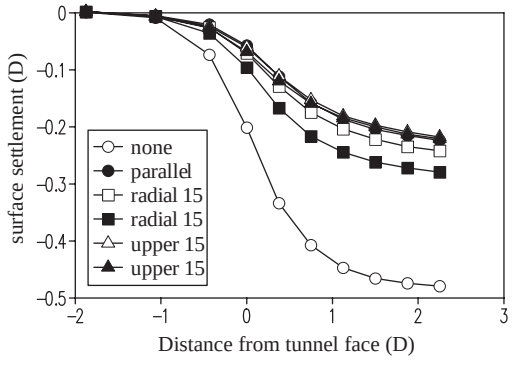

Figure 7. The vertical settlement according to the installation angle (after 2.0D excavation).

tunnel. The reason why the axial displacement with upward angle installation in Figure 3 is bigger and the vertical settlement is smaller than those with horizontal installation is believed that the bolts are installed in the opposite direction of surface settlements.

Figure 7 is the vertical settlement after 2.8D excavation calculated with numerical model. The settlement with radial installation is obviously larger than that with horizontal installation and that with upward installation is almost same as it. This may represent that the bolts left in ground become disjoined from the ground and then they don't affect on supporting.

According to the results shown above the following can be said: horizontal installation is effective on controlling the axial displacement of the tunnel face and the larger installation angle leads to the larger axial displacement. Also, the upward, not radial, is effective on controlling vertical settlement. Therefore, the installation design for face bolts proper to the support purpose may be required.

4 CONCLUSION

During the excavation of tunnel, to prevent the collapse of tunnel face and settlement of ground the face bolts have been being frequently used in the soft ground. Also, in the current construction standard for working the bolts prescribe that boring must be as horizontal as possible (in some cases, a slight inclination is given for the convenience of boring) , but in the field boring often deviates from the original boring line due to geological condition, working condition, etc. In this study, the face bolts were installed near to excavation line upwardly and radially on purpose and their supporting effects according to the installation angles were examined.

Based upon the results of the laboratory and numerical investigation, the following conclusions were obtained.

(1) The axial displacement of the tunnel face depends on the installation angel under the same construction condition.
(2) The upward installation of the face bolts is fairly effective on controlling the vertical settlement.
(3) Inclined installation of face bolts depending on the purpose of support may be required for effective control of axial displacement of the face and/or the vertical settlement of surface.

Non-linear FE analysis of a grouted pipe-roofing reinforcement applied to a tunnel portal area

H.S. Shin, G.J. Bae, D.G. Kim & S.W. Lee
Geotech. Eng. Res. Dept., Korea Institute of Construction Technology (KICT), Gyunggi-Do, South Korea

ABSTRACT: This paper deals with a grouted pipe-roofing reinforcement method (GPRRM) which is used in construction of tunnels on weak grounds. This reinforcement method has proven to be very efficient in reducing amount of tunnel convergence and water inflow taking place in tunneling on weak grounds. However, due to the geometrical and mechanical complexity of the reinforcement, existing finite element frameworks are very difficult to simulate the kind of reinforcements for tunneling. Therefore, a mathematical framework for modeling a grouted pipe-roofing reinforced ground (GPRRG) by introducing a homogenization technique and its implementation into a 3-D finite element program are presented. The constitutive model developed allows considering the main design parameters of the problem and only requires geometrical and mechanical properties of the constituents. Additionally, the use of a homogenization approach implies that the generation of the finite element mesh can be easily produced and that re-meshing is not required as basic geometrical parameters such as the orientation of the pipes are changed. The model developed is used to simulate tunneling with the UARS. From the analyses, the effects of the main design parameters on the elastic and the elastoplastic analyses are considered.

1 INTRODUCTION

The GPRRM for ground reinforcement has been commonly applied in tunnelling under difficult ground conditions, with satisfactory results. Previous experience on the use of the technique has shown effective reductions on potentially large tunnel convergence, ground settlement and water inflow (KICT, 1986; Societa Italiana Gallerie, 1991; Pelizza and Pelia, 1993; Pelia, 1994; Bae et al., 1997). However, due to the geometrical and mechanical complexity of the problem, there have been very few attempts to analyse this problem and no adequate method for determining the design parameters of the reinforcement system has been developed.

In this study, a mathematical framework based on a homogenization technique similar to the one used by Lee et al. (2000), but with a different geometrical definition of the reinforced ground is adopted to derive an anisotropic composite material representing the elastoplastic macroscopic behaviour of GPRRM. A new algorithm for nonlinear stress integration is also proposed. The constitutive model developed is then incorporated into a FE program, capable of considering stage construction, to produce a tool that allows considering the effect of the main design parameters of GPRRM.

2 HOMOGENISATION TECHNIQUE FOR GPRRM

The general idealised geometry of the system to simulate is shown in Figure 1. As shown, two sets of axes are defined, a global axis X-Y-Z associated with the geometry of the tunnel and a local axis x-y-z associated with the geometry of the reinforcement system. The latter coincides with the axis of orthotropy of the reinforcement system, z being parallel to the pipe and y perpendicular to the arch formed by the set of pipes. As shown in Figure 1, it is assumed that the injected grout produces a continuum in the x direction but a finite

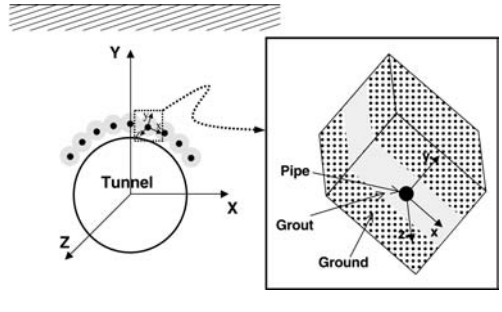

Figure 1. Geometrical description of GPRRM model.

depth band in the y direction. The use of the local axes allows defining the properties of the reinforced ground in its axis of orthotropy regardless of the orientation of the pipes with relation to the tunnel. The orientation of the reinforcement system at each location is included in the model by converting the properties of the reinforced ground into the global axes. For this, transformation matrices are composed by introducing angles θ and β, shown in Figure 2. This procedure allows defining the FE mesh independently from the orientation of each constituent of the GPRRM.

Then, a two-stage homogenisation procedure as shown in Figure 3 is employed to define the composite GPRRM, which contains three basic isotropic constituents, i.e. ground, pipes and grout (see Figure 1). The mathematical formation of the procedure in details can be found in a reference (Bae et al., 2003). The basic mathematical framework is similar to that given by Pietruszczak and Niu (1992) for the simulation of structural masonry. In the local axes of the GPRRM, the properties of the homogenised material at the end of each step, depends only on the volume fraction of each constituent and its constitutive law. The stress-strain relationship for each constituent can be described as shown in Equation (1), where [D] indicates either an isotropic elastic or an elastoplastic constitutive matrix. The same equation can be used to describe the constitutive behaviour of the stage 1 and stage 2 homogenised equivalent composite materials. In the first stage, the ground (constituent 1) and the pipes (constituent 2) are homogenised, leading to a homogenised material (composite I). In the second stage, composite I is homogenised with the grout (constituent 3) to obtain the final equivalent composite material (composite eq).

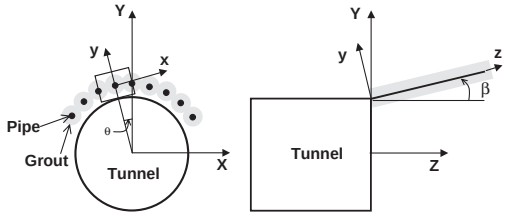

Figure 2. Typical arrangement of pipes.

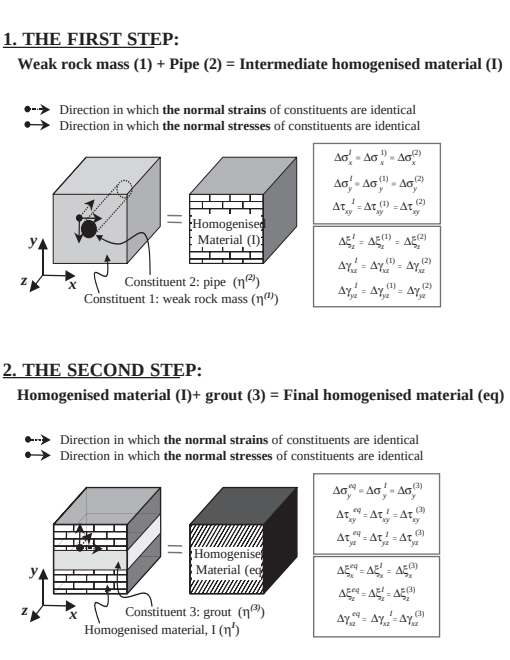

Figure 3. Schematic diagram of dual homogenisation procedure.

3 ELASTOPLASTIC SIMULATION IN HOMOGENISATION FRAMEWORK

The nonlinear behaviour of the GPRRG material is considered at a constituent level. As constituents undertake elastoplastic straining, their constitutive matrices [D] are modified according to the classic elastoplastic theory (Zienkiewicz and Taylor, 2000). A detail of the nonlinear stress integration algorithm developed can be found in a reference (Bae et al, 2003). At the end of each convergence iteration, within each load increment iteration, the basic homogenisation procedure described in the previous section is repeated, using the constituent elastoplastic matrix for the constituents that have yielded. From this procedure, the matrix for the homogenised material and the elastic or elastoplastic structural matrices for the constituents are obtained. The structural matrices and the stiffness matrix for the homogenised material used for the ith iteration are shown as follows.

$$\begin{aligned}\left[S_{k,ep}^{i-1}\right] &= S_{k,ep}^{i-1}\left(\nu_1,\nu_2,\nu_3,\left[D_{1,ep}^{i-1}\right],\left[D_{2,ep}^{i-1}\right],\left[D_{3,ep}^{i-1}\right]\right)\\ \left[D_{h,ep}^{i-1}\right] &= D_{h,ep}^{i-1}\left(\nu_1,\nu_2,\nu_3,\left[D_{1,ep}^{i-1}\right],\left[D_{2,ep}^{i-1}\right],\left[D_{3,ep}^{i-1}\right]\right)\end{aligned} \quad .(1)$$

At each iteration, the updated elastoplastic structural matrices are used to obtain the strain increment in each constituent from the increment in strain in the homogenised material (Equation (2)). Following the classic elastoplastic algorithm, the admissible stress increment in each constituent is computed. The admissible stress increment in the homogenised material is then obtained using the averaging rule and added to the stress state at the end of the previous iteration (Equation (3)). Following standard elastoplastic theory, the equivalent nodal forces are computed from

the stresses in the equivalent homogenised material and compared with applied load increment to check convergence.

$$\Delta\varepsilon_k^i = \left[S_{k,ep}^{i-1} \right] \cdot \Delta\varepsilon_h^i \tag{2}$$

$$\sigma_h^i = \sigma_h^{i-1} + \sum_{k=1}^{3} v_k \Delta\sigma_k^i \tag{3}$$

In the current version of the code, each constituent can be considered using either Mohr-Coulomb, Drucker-Prager, Tresca or Tension cut-off as a yield criterion, combined with either a linear or an exponential softening/hardening rule (Zienkiewicz and Taylor, 2000). The use of the elastoplastic structural matrices instead of the elastic ones ensures that the kinematic and equilibrium conditions of the homogenisation formulation are satisfied incrementally and therefore at all stages. As shown in Equation (3), the averaging rule is applied incrementally instead of being applied in total stresses due to the conditions of the construction procedure. Nevertheless, a certain approximation is introduced, since the elastoplastic structural matrices employed correspond to the previous iteration and, therefore, do not consider the changes in the [D] matrices of the constituents that will take place in the current iteration. This approximation induces an accumulation of error in the results. However, if the load increments considered are sufficiently small the errors accumulated are not significant. In order to avoid this accumulation of errors, the stresses and strains of constituents and homogenised material could be adjusted to satisfy fully the homogenisation conditions. However, this adjustment would be arbitrary and would not provide any benefit to the formulation.

A method of stress adjustment was used by Lee et al. (2000). In that approach, instead of updating the structural matrices and equivalent constitutive matrix, the stresses were adjusted. Although this approach had a much lower computational cost, the accuracy of the results was severely affected on the areas where yielding took place.

3.1 *Implementation in staged construction*

For simulating the staged construction, nodal forces are calculated at all the nodes on the excavated surfaces at every excavation stage, from the initial stresses around the tunnel. These initial stresses have been generated by considering the depth of the points under the ground surface and the ground specific weight. Similarly, as the GPRRG is applied, a series of elements within the FE model change from ground elements into homogenised GPRRG elements. In order to maintain global equilibrium within the model, the stress state in the ground element is transferred into the homogenised material. Internally, all the stress is transferred into the ground constituent (Equation (4)).

$$\begin{aligned} \sigma_h &= \sigma_{ground} \\ \sigma_{ground\ constituent} &= \sigma_{ground} \\ \sigma_{pipe\ constituent} &= 0 \\ \sigma_{grout\ constituent} &= 0 \end{aligned} \tag{4}$$

Stress is only absorbed by the grout and the pipes as more loads are introduced in system. As a result of this, however, the kinematic constraints and equilibrium conditions to be satisfied are only valid incrementally. Similarly, the averaging rule is also only valid incrementally.

4 STUDY ON THE REINFORCING EFFECT OF GPRRG

4.1 *Orthotropic elastic characteristics of GPRRG*

In this section, a series of parametric studies on the effects of the main design variables of the problem on the orthotropic elastic properties are presented. The isotropic elastic material properties and volume contributions of the constituents assumed in these studies are given in Table 1.

When considering the effects of modifying the volume fractions, the volume of the constituent considered is modified while the volume of the other two constituents is left unchanged. Since this results in a change on the total volume, the volume fractions of all constituents change. The volumes of the constituents not modified are shown on in Table 1.

Figure 4(a), (b) and (c) show the effects of changes in the volume of ground, pipe and grout, respectively, on the nine orthotropic elastic constants of GPRRG. The results have been normalised by the properties of plain ground material. Figure 4(a) represents the effect of increasing the zone affected by the reinforcement, while maintaining the level of reinforcement introduced. As expected, the Young's and shear moduli decrease as the volume of ground material increases, due to the lower stiffness of the ground material. The

Table 1. Elastic material properties of constituents of GPRRG.

Constituents	Young's modulus (MPa)	Poisson's ratio	Volume contribution (m^3)
Ground material	500	0.33	89.6
Grout material	5,000	0.17	10.0
Pipe	200,000	0.25	0.4

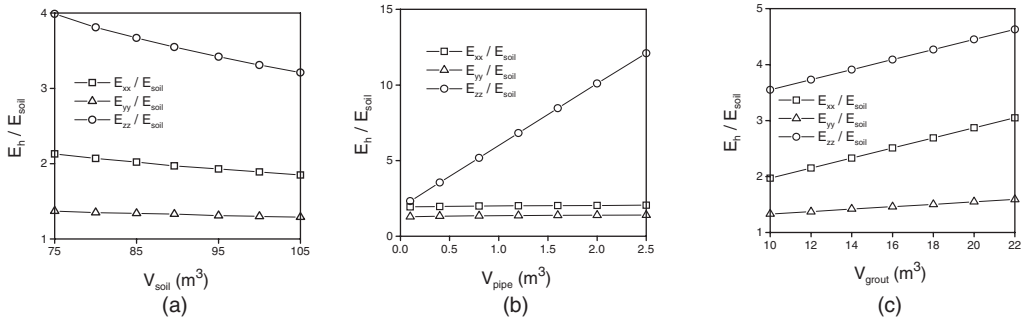

Figure 4. Evolution of orthotropic elastic constants.

effects are most significant in the z direction, i.e. parallel to the pipe, as a result of the kinematic conditions imposed. The effects of varying the degree of reinforcement are shown on Figure 4(b). The results show a very significant effect on all the properties, but particularly in the z direction. This suggests that the elastic characteristics of GPRRG are mainly governed by the contribution of pipes. Figure 4(c) illustrates the effect of modifying the extent of grouting on the properties of GPRRG. As a result of the geometric arrangement, i.e. grout is injected through the set of pipes, and the modelling assumptions, i.e. the grout is assumed to form a continuum in between the pipes, the most affected properties are the Young's moduli in x and z directions. Conversely, the Young's modulus in y direction is only slightly affected. This result is in disagreement with the prediction by Lee et al. (2000), as a result of the different geometrical hypotheses. The results obtained suggest that grouting enhances the arching effect in the circumferential direction but provides a small reinforcing effect on the ground stiffness in the radial direction.

4.2 *Direct tension test with elastoplastic medium of GPRRM*

In order to verify the results of the elastoplastic model proposed, a simple arrangement was first considered. The arrangement consists of a single GPRRG under direct tension at an angle with the reinforcement varying between 0 and 90˚ , as shown in Figure 5. The results are also compared with the case of plain ground material. In this model, the constituents have the material properties given in Table 2, a Mohr-Coulomb yield criterion with associated flow rule and perfect plasticity. The volume fractions considered are 63, 2 and 35% for the soil, pipe and grout, respectively.

As expected, the stiffness and yielding stress increase as the direction of loading becomes more parallel to the direction of the pipes. For the case of $\theta = 90°$, an elastic response of obtained due to the very high stiffness of the pipes in their axial direction.

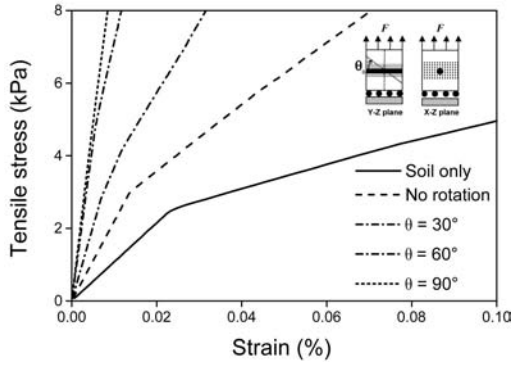

Figure 5. Elastoplastic response of GPRRG.

5 APPLICATIONS TO A TUNNEL PORTAL AREA

5.1 *Brief description of the site*

The tunnel site is OO twin road tunnels constructed at mountain area in Korea which are in 500 m long and 11.7 m width each. One of the tunnel gates is in quite weak ground condition which, therefore, requires a special auxiliary reinforcement system to be installed such as GPRRM. The analysis technique proposed in this study is used for determining the optimum major design variables of the reinforcement. The portal site of concern is described in Figure 6.

5.2 *Model set-up*

A FE model is set up for 3D FE analysis incorporating the GPRRM model developed in this study. The analysis is to determine a set of optimum values for three major design parameters which are overlapped length (4 m, 6 m, 8 m), angular range of reinforcements in tunnel section (120°, 150°, 180°) and CTC (centre to centre) of pipes (50 cm, 75 cm, 100 cm) chosen from other possible design variables. Three cases for

Table 2. Material properties of constituents of GPRRG used in FE analyses.

Material		Young's modulus (MPa)	Poisson's ratio	Volume fraction (%)	Cohesion (kPa)	Internal friction angle (°)
Soil		200	0.33	–	100	35
GPRR	Soil	200	0.33	89.6	100	35
G I	Pipe	200,000	0.25	0.4	–	–
	Grout	4,900	0.17	10	1500	30
GPRR	Soil	200	0.33	89.2	100	35
G II	Pipe	200,000	0.25	0.8	–	–
	Grout	4,900	0.17	10	1500	35

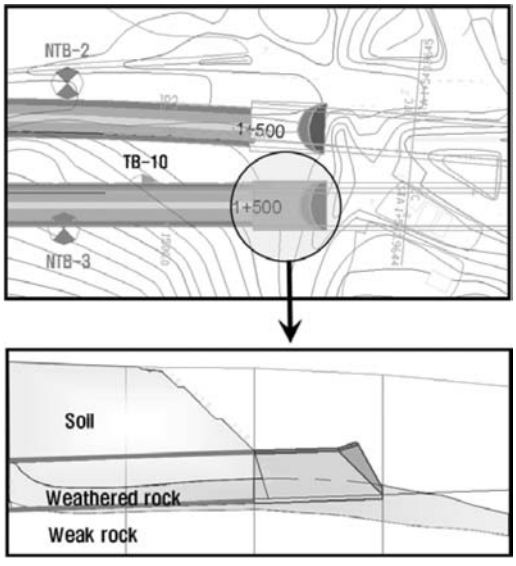

Figure 6. Description of the considered tunnel portal site.

each design parameters under consideration are set up. Therefore, total number of sets to be simulated is 27 sets. The optimum set chosen could confirm the safety as well as economical efficiency in construction.

Figure 7 shows the FE mesh and dimension of the model used. The mesh is generated by importing the exact geometry of the tunnel and ground levels. The colors in Figure 8 denote the ground conditions and different material properties.

Material properties of the grounds and reinforcements are given in Table 3. The properties have been determined by laboratory tests with the specimens from a number of borehole tests at NTB-2 & NTB-3 in Figure 8. It is noted that each material properties of pipe and grout material is given individually which are the same as in Table 2.

Young's modulus (Poisson's ratio) of shotcrete are 5 GPa (0.17), and 15 GPa (0.17) in soft and harden

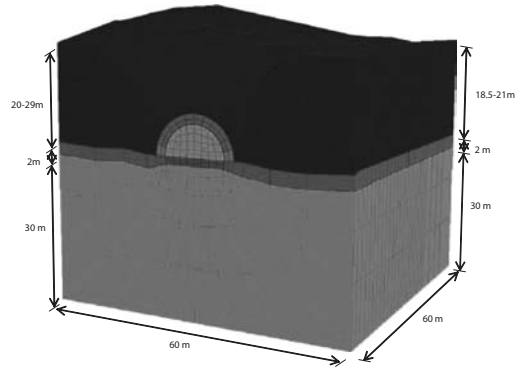

Figure 7. A FE mesh and dimensions.

condition, respectively. Elastic constants of rock bolt with section area of 5 cm^2 are the same as ones of the pipe in Table 2. In analysis, it is possible to involve one to three set(s) of pipes to be overlapped. The overlapped layers are simulated by changing the volume fractions of constituents which would be subjected by the volume of pipes occupied on unit volume of GPRRG. Excavation and installation stages of reinforcements are taken into account in the simulation.

5.3 *Results*

The orthotropic Young's modulus of GPRRG automatically calculated during the analysis are given in Table 4. In fact, twenty-one orthotropic elastic constants are calculated but only three Young's modulli (Ex, Ey, Ez) are given for comparison because of a lack of space.

As mentioned in Section 4.2, Young's module in longitudinal direction of pipe is sensitively increasing depending on the volume fraction of pipes while the one in horizontal direction changes insensitively. The Figure 9 shows total displacement distribution resulting from the analysis case without application of GPRRM, in which tunnel collapse with a localized large deformation at tunnel crown can be seen.

Table 3. Material properties used for FE analysis.

Material	Young's modulus (MPa)	Poisson's ratio	Cohesion (kPa)	Internal friction angle (°)	Unit Weight (kN/m^3)
Weathered soil	23	0.35	20	28	19.2
Weathered rock	500	0.33	70	29	23
Weak rock	5,000	0.25	1,320	38.3	25.1

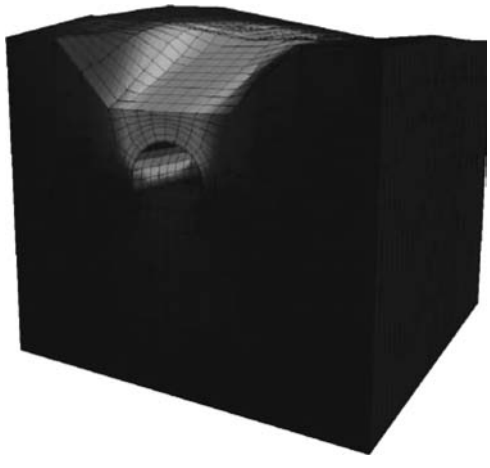

Figure 8. Displacement distribution on the analysis case without application of GPPRM (collapsed zone in green).

Table 4. Orthotropic Young's modulli of GPRRG with overlapped pipes.

Number of overlapping	Ex (MPa)	Ey (MPa)	Ez (MPa)	Volume fraction of pipes (%)	Volume fraction of grout (%)
1	889.9	363.4	1230.2	0.168	13.564
2	1089.5	392.7	1775.4	0.336	17.503
3	1191.1	408.0	2224.1	0.504	19.523

Then, an optimum set of design parameters has been determined from the case that contains no plastic strains at any elements and has minimum displacement at crown and side wall. Based on this, the final design parameters have been decided as the set of angular range of 180, CTC of 50 cm, overlapped length of 6 m. The case shows no plastic zone and maximum displacement of about 8 mm at crown. The details of the results from all the cases considered are omitted because of lack of space.

6 CONCLUSIONS

In this study, a new mathematical framework for modelling the ground reinforcement system known as GPRRM has been proposed using a homogenisation technique. This tunnelling method has been previously applied successfully in the construction of tunnels in weak ground conditions.

The framework developed provides the 12 independent orthotropic elastic constants of the reinforced ground material and the structural matrices that allow deriving the stresses/strains in each constituent from the stresses/strains in the homogenised ground material. The constitutive matrix of the equivalent material and the structural matrices are obtained as functions of the mechanical properties, volume contribution and internal geometrical arrangement of the three constituents of the reinforcement system, i.e. ground, steel pipes and grout.

This homogenisation framework is capable of considering the effect of the main parameters of the problem, i.e. amount of reinforcement and grout, the geometry of the pipe installation, the length of pipes, the extent of the grouted area, the length of excavation prior to the installation of additional reinforcement and the length of pipe overlapping. Additionally, the use of a homogenisation approach implies that the generation of the Finite Element mesh for the complex geometry of the problem can be simulated easily and that re-meshing is not required as basic geometrical parameters such as the orientation of the pipes are changed.

The use of a homogenisation approach also allows considering the elastoplastic behaviour of the composite material at a constituent level, using well-known constitutive models. This approach, therefore, only requires constituent parameters, instead of composite parameters, which would be very difficult to define and obtain. In order to satisfy the kinematic and the equilibrium constraints of the two stages of the homogenisation procedure during the non-linear computations, the homogenisation is applied incrementally. Then, the homogenisation procedure proposed has been implemented in a Finite Element model capable of considering stage construction situations.

The tool developed allows the effective simulation of tunnelling operations using the GPRRM and flexibility in the design stages.

The mathematical formulation proposed has been used to determine optimum design parameters in a tunnel portal area on a quite weak ground condition. Since this work was able to be undertaken in reasonable computing time by using the model proposed, it enables us to achieve optimum design of the GPRRM. It lead to achievement of economical efficiency with confirmation of the safety against tunnel collapses.

However, experimental data are required to fully validate the model proposed. A number of investigations are currently being undertaken in the authors' research groups to further understand the validity, range of applications and effectiveness of this homogenisation technique for tunnelling. Results of these studies will be reported shortly. The model proposed has also been used to undertake the elastoplastic analysis of a tunnelling operation. The results indicate that, in the example considered, the nonlinear effects have a limited effect on the results. It is expected, however, that the nonlinear effects will have a greater influence in weaker grounds.

An enhanced pre & post processing techniques for three dimensional tunnel analysis: Tunnel Modelling Wizard

J.H. Shin
Dept of Civil Eng., Konkuk University, Seoul, Korea

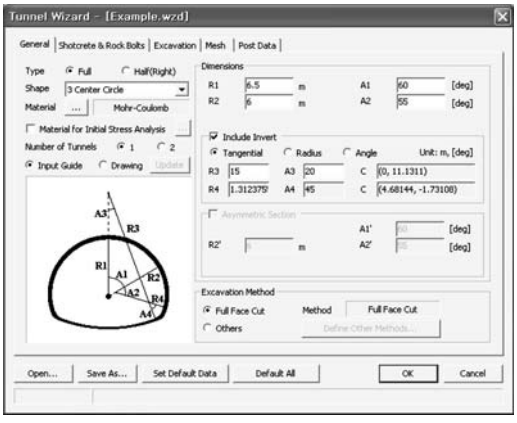
J.H. Moon & D.S., Shin
MIDAS Information Technology Co., Ltd., Seongnam, Korea

ABSTRACT: An enhancement to pre & post processing techniques, which is encapsulated in 'Tunnel Modelling Wizard (TMW)' for three dimensional tunnel analysis, is developed and described in this paper. The techniques include geometry modelling, mesh generation, virtual transformation, flying view and utilization and interpretation of analysis results. The TMW automatically generates full analysis data including mesh, loads, boundary conditions and construction stages from the user-defined parameters. The TMW also provides its own file I/O service to help users expedite modelling tasks for similar models and build their own tunnel templates. Implementation of the TMW into a FE Program is described, and applications of the TMW to practical tunnel problems will be demonstrated.

1 INTRODUCTION

Tunnel construction entails complex three dimensional operations. Consequently, any numerical modelling methods should, in principle, attempt to closely represent such characteristics. It has been a common practice, however, that two dimensional modelling methods have been used for convenience to perform parametric studies for the optimization of tunnel design and construction. The main limitation of such two dimensional modelling methods is that they do not provide any information on the behaviour of tunnel headings. A recent investigation on NATM tunnel collapses revealed that most failures occurred during or soon after excavation of tunnels before completing linings, which suggests that intermediate stages of construction are becoming more critical. A conclusion can be drawn that three dimensional analyses are required for the cases of tunnel headings.

Three dimensional analyses are becoming more and more practical with high performance computer systems. Engineering costs are nevertheless still remaining high as the preparation of input data and the interpretation of results require a significant amount of time.



In order to overcome these difficulties of three dimensional tunnelling analyses, an enhancement to pre & post processing techniques, which is called 'Tunnel Modelling Wizard (TMW)', is developed. TMW automates almost all time-consuming operations of three dimensional modelling and produces reports of output data for swift interpretation of analysis results. With respect to the enhancement to pre-processing, it provides various tunnel templates, NATM tunnelling method, advanced surface modelling tool for terrain and strata, and automatic hexahedral mesh generation. In addition, results of construction stage data are generated in an MS-Excel file, which is a most widely used data solution. This paper describes the implementation of the TMW into a FE Program, and applications of the TMW to practical tunnel problems are demonstrated.

2 TUNNEL MODELLING WIZARD

2.1 *Modelling procedures*

The general modelling procedure for TMW consists of 5 major steps; (a) configuration of a tunnel cross section and excavation type; (b) specification of shotcrete and rock bolts; (c) definition of excavation and construction stages; (d) configuration of mesh data with terrain and strata; and (e) preparation for reports with output data.

In the first step, TMW provides a template for various tunnel cross sections and excavation types. Most common tunnel cross sections can be chosen from TMW such as circular, 3-center circle and 5-center circle including their inverts. A tunnel cross section does not necessarily have to be symmetrical; unsymmetrical sections can be defined. Figure 1 (b) shows all the excavation types available in TMW.

Step 1: definition of tunnel cross section

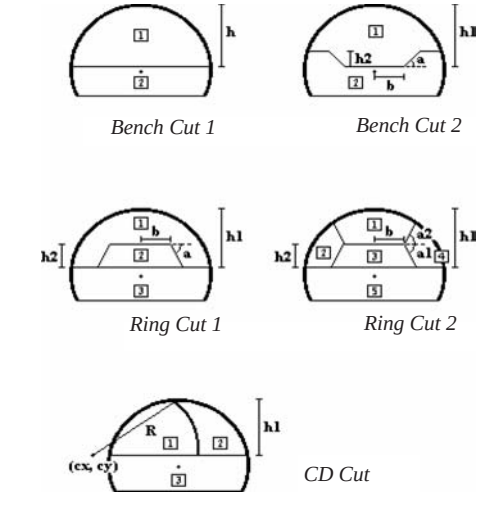


Figure 1. Templates of tunnel cross sections and excavation types.

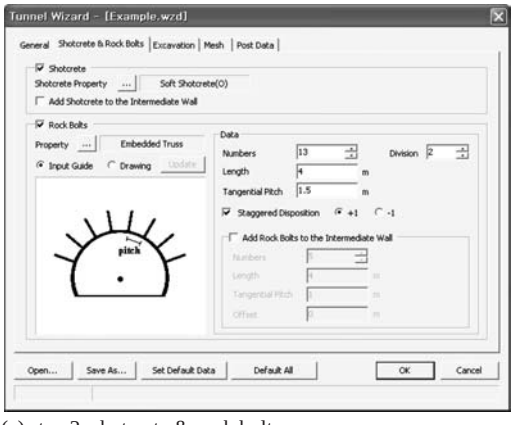
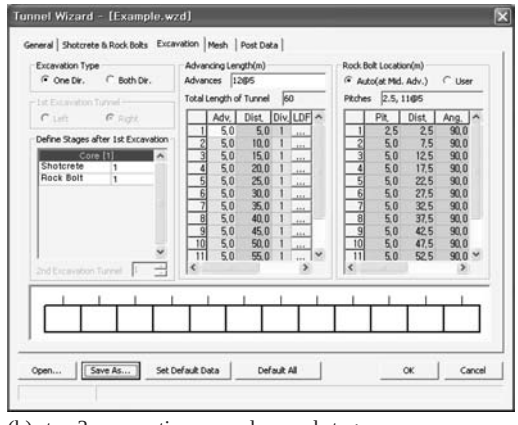
The ground material is also specified in this step. TMW provides 4 material models; an elastic model and three most popular non-linear material models used in geotechnical engineering, which are Mohr-Coulomb, Hoek-Brown and Drucker-Prager.

In the second step, the parameters for shotcrete and rock bolts, which are considered as general reinforcements in a NATM tunnel, are defined. If shotcrete is installed, it is configured for material, thickness and hardening property for the transition from the initial soft shotcrete. Similarly, rock bolt's material, section property and a position arrangement can be established herein. With the defined parameters, TGM models shotcrete with shell elements and rock bolts with embedded truss elements, which can retain element stiffness regardless of mesh connectivity (Figure 2(a)).



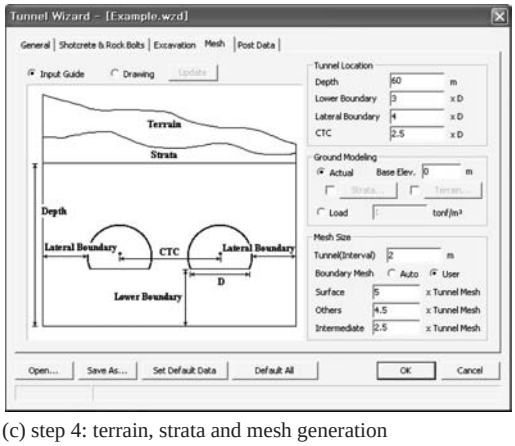
The third stage involves excavation sequence and construction stage definition. Advancing length, rock bolt locations and pattern, and the duration of shotcrete and rock bolt installation after excavation can be specified. Construction stages are arranged in a tabular format, and discrete options such as Load Distribution Factor can be defined for each stage (Figure 2(b)).

The fourth stage of TMW is used to define the location of tunnel(s), the boundaries of subsurface and pillar width in case of two tunnels. If the location of the tunnel is relatively close to the ground, it is crucial to consider the impact of the ground weight difference in the analysis. Consequently, TMW provides advanced surface modelling tools, which can generate an analysis model with actual terrain and strata. Having defined all the geometric parameters, information for mesh generation should be provided. The geometrical algorithms for terrain and strata surface modelling and the method of three dimensional mesh generation are explained in Section *2.2 Surface and mesh generation.*



Since not every project readily has the required elevation information for its terrain surface, TMW provides 'Terrain Geometry Maker (TGM)', which is a module of TMW. This module can automatically obtain the elevation data from a digital map. In order to create a terrain surface from a digital map, TMW goes through the following algorithm. As shown in Figure 4(a), the modelling area is first defined on a digital map, and contours that are included in or crosses through the region are uniformly divided for sampling. After performing Delaunay triangulation in the xy plane, they are mapped into three dimensional facets Figure 4(b). Then, it determines to which facet a sampling point belongs. Using the area coordinate system shown in Figure 4(c), it interpolates the elevation at each sampling point. Figure 4(d) shows an example of a terrain surface, which has been generated using a digital map.

Once it completes the construction stage analysis of an assembled NATM tunnel model, TMW autogenerates post processing data for the purpose of preparing reports and provides the related functions to arrange and generate graphs. The last step defines the range of post-processing and construction stages for desired output, which are automatically produced in MS-Excel files. The data file contains the displacements of crown, wall and invert, stresses of shotcrete and axial forces of rock bolts.



Upon completion of Steps 1 through 5, TMW automatically performs mesh generation, while applying loads and boundary conditions and generating construction stages. Subsequently, it performs a construction stage analysis based on stress-displacement using the finite element method. TMW generates MS-Excel files for the interpretation of output results, which are specified in Step 5.

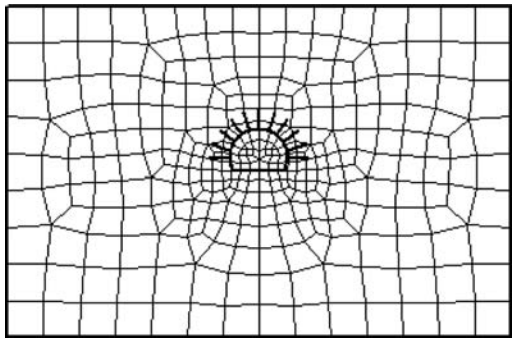
Using its own file I/O service, the user can generate similar models by simply updating the parameters. This enables the user to undertake comprehensive parametric studies of multiple analysis models without significant efforts.

2.2 *Surface and mesh generation*

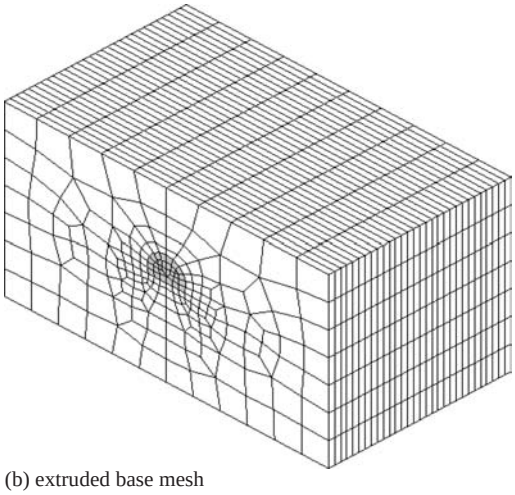
TMW internally creates surfaces from the input data for terrain and stratum generation. As shown in Figure 3(a), the terrain surface is a B-spline surface, which is generated using the elevations at each grid points of a virtual rectangular grid. The stratum surface, as shown in Figure 3(b), is created by Coons Patch, which is a bi-linear interpolation surface with defined coordinates and offsets of profiles in the x-z and y-z planes. All input data for the terrain and stratum are entered in a table. TMW can create up to five strata in a single model.

In order to obtain accurate analysis results, TMW generates an analysis model using a hexahedral mesh. First, a two dimensional quadrilateral mesh is created within the defined rectangular analysis area including the tunnel cross section by the looping mesh generation algorithm as shown in Figure 5(a).



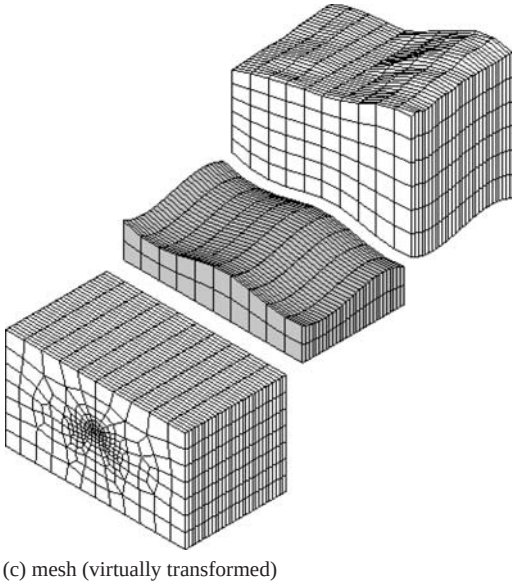
The quadrilateral mesh is then extruded based on the excavation stages to generate a box-shape hexahedral mesh for each stage Figure 5(b). After the extrusion, the top faces of the hexahedral meshes are projected onto the stratum and terrain respectively. This completes the final mesh, which appears in Figure 5(c).

TMW is exclusively implemented in the commercially available geotechnical analysis software, MIDAS/GTS, in the form of the NATM tunnel wizard.



3 EXAMPLES

3.1 *Mountain tunnels*



This example pertains to an analysis model of parallel mountain tunnels, which is generated by TMW in MIDAS/GTS. The overview of the analysis model is shown in Figure 6(a). It contains a single stratum above

the tunnels. Figure 6(b) represents the displacement contour after the analysis, and its interior results are checked using the 'Flying View' function. Figure 6(c) shows a graph of vertical displacements at the crown relative to advancing distances, which is captured from the automatically generated MS-Excel result file.

3.2 *Subway tunnels*

The second example of TMW, as shown in Figure 7(a), is the analysis model of a subway tunnel. The deformation and settlement of the ground surface are checked in Figure 7(b) using 'Settlement Profile', which is one of the post processing functions in MIDAS/GTS. Figure 7(c) displays a graph of maximum stresses of shotcrete for each excavation stage prepared by TMW.

4 CONCLUSIONS

This paper describes the implementation of TMW, which provides an automated pre & post-processing procedure for three dimensional NATM tunnel analyses. The templates provided in TMW enables the user to model various tunnel types and specify different excavation methods. TMW permits the user to simply enter necessary parametric variables in a simple five-step definition process in order to readily create a complex three dimensional model. Moreover, TMW provides advanced surface modelling and hexahedral mesh generation functions, which are ideal for modelling complex strata and terrains encountered in practice. Not only does TMW provide the capabilities of modelling complex geo-structures, but it also enables the user to readily interpret the analysis results to reflect in design by the automatic summary arrangement and graphic processing of the analysis results. For a reasonably complex tunnel problem, TMW enables the user to complete the overall tasks of pre & post processing and analysis within about two hours. Such dramatic reduction in engineering time provides the user much more time to undertake numerous preliminary analyses, carry out parametric studies for various patterns, and investigate for potential problems during construction.

TMW is intended to be further developed to support automatic repetitive analyses for self parametric studies and more complex geometric configurations such as tunnel intersections.

ABSTRACT: This paper suggests that a simple micro-scale approach combined with a macro-scale approach to determine equivalent design parameters provides effective numerical modeling of pre-reinforced zones in a tunnel. This new technique enables the determination of the equivalent stiffness of pre-reinforced zones with a series or parallel combination of ground, grout bulb, and steel pipe stiffness. For verification, the authors compared the 3D numerical results from the suggested approach with the results of a precisely-simulated model. The comparison suggests that two cases achieve the best approximation to the solution: one case is related to the series-parallel stiffness system (SPSS) in which a bulb and steel are coupled in parallel and then connected to the ground in series; the other case is related to the series stiffness system (SSS) in which only a bulb and steel are coupled in series. The SPSS suggested in this paper effectively represents the behavior mechanism of pre-reinforced zones when compared to a precisely-simulated model.

1 INTRODUCTION

The construction of a large underground space has many risk factors such as difficulties with predicting arching effects and determination of various uncertain underground properties. Researchers have suggested various techniques for auxiliary support systems such as the reinforced protective umbrella method (RPUM), which has the advantage of combining a modern fore-poling system with the grouting injection method (Barisone *et al*., 1982). This method is used for pre-reinforcement design before the underground excavation: not only for small section tunneling within weathered and crashed zones, but also for large underground spaces. In addition, to decrease the risk of a collapse or failure in large excavation caverns, researchers developed various techniques and construction methods: the tunneling method using an advanced reinforcing system, where a double steel pipe is used for water-proofing and a urethane injection is used for reinforcement; the Trevi jet method which involves constructing an arch-shell structure around a tunnel crown with cement grout; and steel pipe reinforced multistep grouting where a beam arch is constructed around the tunnel crown with large diameter steel pipes, and a multilayer cement grouting injection.

However, the design and analysis of pre-reinforcement techniques require design assumptions that are problematic at best resulting in the increase of uncertainty in tunnel design. The pre-reinforcement effect is typically modeled by simulating the construction sequence of setting the reinforced zone and then increasing the stiffness, thereby obviating the need for complex modeling of each bulb and steel pipe. However, this approach has been found unsuitable when the center-to-center between pipes is larger than the expansion of the grout bulb. This approach assumes that the stiffness of the pre-reinforced zone is the same as the stiffness of the grout bulb, which may be either completely hardened or arbitrary and that the pre-reinforced zone become two to four times stronger than before reinforcement. Therefore, this study presents a new technique of determining a reasonable equivalent parameter of a pre-reinforced zone.

2 PROPOSED APPROACH

The RPUM design procedure is based on a combination of theoretical and numerical methods: the micro-scale approach which uses equivalent design parameters; and the macro-scale approach which uses a mathematical model.

2.1 *The macro-scale approach*

A mathematical model of reinforced media is defined in terms of the geometrical and mechanical characteristics of the ground and each reinforcing

component. Using derived constitutive equations, various researchers have numerically modeled struc-tural response of tunnels. Zienkiewicz and Pande (1977) used a multilaminate model to derive a constitutive relation of the composite material. The multilaminate model subsequently became the foundation of the homogenization constitutive relation used by Bernaud *et al*. (1995) to derive mathematical models of rock-bolted ground. The mathematical model could simulate anisotropic elastic behavior of a grouted zone. In addition, Bae *et al*. (2005) used the homogenization technique to develop constitutive relations for elasto-plastic FEM codes. The macro-scale approach differs from realistic conditions where the relation between the ground, the steel pipes and the grouted zone needs to be assumed.

2.2 *The micro-scale approach*

The micro-scale approach uses predefined structural element with a commercial program to individually model each component of a reinforcing system. In recent years, this approach has been supported by the evolution of computers and the development of various finite element method (FEM) programs specific for underground applications. The modeling method for RPUM design assessment has been developed for many years. For example, Kotake *et al*. (1994) considered a reinforced zone as a shell element. Later, beam elements were used to simulate inserted pipes with shell elements to model the reinforced zone around the pipes. In addition, steel pipes were modeled as beam elements with a weighted Young's modulus, which is the series summation of Young's modulus of pipes weighted by an area ratio. The micro-scale approach, however, can be controlled and affected by the intuition and experience of a designer and the analytical results are sensitive to the size and shape of finite elements and boundary conditions. Moreover, the pre- and post-processing of the micro-scale approach are significantly more time-consuming than those of the macro-scale approach.

2.3 *A micro-scale approach based on a macro-scale approach*

The pre-reinforced zone can be considered as a composite of pipe, grout and in-situ formation material. For the proposed micro-scale approach of a pre-reinforced zone, orthotropic material properties such as the elastic modulus, Poisson's ratio and the shear modulus should be considered as the equivalence composite parameters of reinforced soil and/or rock obtained on the basis of mean field theory and strain energy theory. However, this approach is hard to apply for a field design. We therefore present a micro-scale approach which is based on a macro-scale concept that can be applied effectively in commercial FEM programs. The new

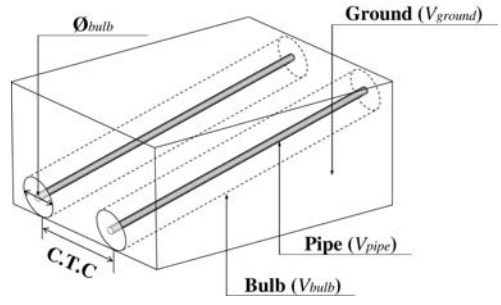

Figure 1. Diagram of simplified pre-reinforced zone.

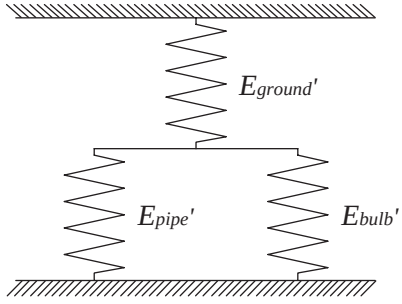
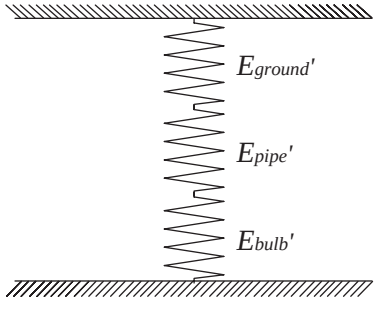
approach determines the equivalent system composite stiffness of pre-reinforced zones developed by combining ground, grout bulbs and steel pipes in series or in parallel formation. For verification of our approach, we compared the results of a 3D numerical analysis using this system composite with the results of a precisely-simulated model. In precisely-simulated model, all components such as ground, grout bulb and steel pipe were modeled in realistic condition. This model therefore has the best exactness. We now discuss a proposed approach and comparative assessment for analysis of pre-reinforced zone.



3 DETERMINATION OF EQUIVALENT DESIGN PARAMETER FOR PRE-REINFORCED ZONE

A pre-reinforced zone consists of ground, grout bulbs and steel pipes. It may be simplified, as shown in Fig. 1, to a condition of when the space between the pipes is wider than the grout expansion range. In weathered rock, the injected grout along the bore holes permeates into the gaps and joints; it also binds jointed rocks together and increases the stiffness of rock around the bore holes. In sandy soil and weathered soil, the bulb may be cylindrical. We assessed five cases of conditions to model the pre-reinforced zone.



3.1 *Case 1: grout bulbs and steel pipes only*

The equivalent design parameters that we obtained from a SSS(series stiffness system) of a bulb and steel pipes are based on the micro-macro scale approach. As shown in the following equation (1), the equivalent design parameters are the sum of the parameters of the pipe weighted by the volume ratio and the parameters of the grout bulb weighted by the volume ratio in series:

$$E_{eq} = \frac{V_{pipe}}{V_{bulb} + V_{pipe}} E_{pipe} + \frac{V_{bulb}}{V_{bulb} + V_{pipe}} E_{bulb} \qquad (1)$$

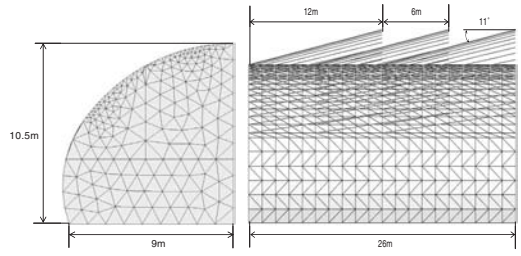
(a) Series-parallel stiffness system (SPSS)

(b) Series stiffness system (SSS)

Figure 2. Series and/or parallel stiffness system of pre-reinforced zone.

3.2 *Case 2: a series-parallel stiffness system for the ground, grout bulbs and steel pipes*

The fan-shaped pre-reinforced zone is comprised of the ground, grout bulbs and steel pipes. We obtained the equivalent parameters from a SPSS(series-parallel stiffness system) in which the stiffness of gout bulbs and steel pipes was coupled in parallel and then connected to the stiffness of the ground in series as shown in Fig. 2(a). Each stiffness value of the constitutive components was weighted with a volume fraction as follows:



$$E_{eq} = E_{ground}' + \frac{E_{pipe}' \cdot E_{bulb}'}{E_{pipe}' + E_{bulb}'} \tag{2-1}$$

$$\text{where,} \quad E_i' = \frac{V_i}{\sum V} E_i \tag{2-2}$$

3.3 *Case 3: the ground and gout bulbs only*

Equivalent design parameters, which were weighted by a volume fraction, are based on a SSS of grout bulbs and the ground.

$$E_{eq} = \frac{V_{bulb}}{V_{bulb} + V_{ground}} E_{bulb} + \frac{V_{ground}}{V_{bulb} + V_{ground}} E_{ground} \tag{3}$$

(a) Transversal section (b) Longitudinal section

Figure 3. Profile of four-lane tunnel and condition of pre-reinforcement.

3.4 *Case 4: a series stiffness system for the ground, grout bulbs and steel pipes*

As with Case 2, the pre-reinforced zone in Case 4 is comprised of the ground, grout bulbs and steel pipes.

The equivalent design parameters were calculated by a SSS in which the stiffness of the ground, grout bulbs and the steel pipes were connected in series as shown in Fig. 2(b).

$$E_{eq} = E_{bulb}' + E_{pipe}' + E_{ground}' \tag{4}$$

3.5 *Case 5: supposition of a pre-reinforced zone with a high level of stiffness*

Case 5 is the most general method for modeling the pre-reinforcement. In this case, the properties of the fan-shaped pre-reinforced domain are replaced by a level of stiffness that is twofold to tenfold the original level of stiffness. When a grout bulb is not connected to neighboring bulbs, this method does not represent the practical and real behavior of a pre-reinforced zone and causes wrong and biased results. The equivalent parameters are expressed as follows:

$$E_{eq} = E_{bulb} \tag{5}$$

4 NUMERICAL MODELLING

4.1 *Analytical model: a four-lane tunnel*

For a more practical and realistic simulation of the tunneling process for each case, we used the 3D FEM program MIDAS-GTS (MIDAS-IT, 2005), which enabled us to consider and model the construction sequences and boundary conditions in detail. We selected a four-lane tunnel to make our comparison. Fig. 3(a) show our simulated four-lane tunnel, constructed 50 m under the surface of the ground, a radius of 9 m, and a height of 10.5 m. This simulated tunnel is an actual section of a four-lane tunnel that was designed and constructed in weathered rock in Korea. We modeled four subsectional excavations with a length of 1.2 m per stage.

Table 1. Mohr-Coulomb material properties of ground and structure.

Properties	E (MPa)	C (kPa)	υ	γ (kN/m^3)	φ (°)	σ_t (kPa)
Weathered soil						
Ground	49.04	58.84	0.35	18.63	30	98.07
Grout bulb	490.35	588.42				
Weathered rock						
Ground	490.35	245.18	0.30	20.59	35	490.35
Grout bulb	2451.75	1225.9				
Double steel pipe	205947	78456	–	–	–	–

Where, E: Elastic modulus, C: Cohesion, υ: Poisson's ratio, γ: Unit weight, φ: Friction angle, σ_t: Tensile strength.

Table 2. Equivalent design properties used for numerical modeling.

Ground Type	Weathered Soil		Weathered Rock	
Equivalent design properties	E_{eq} (MPa)	C_{eq} (kPa)	E_{eq} (MPa)	C_{eq} (kPa)
Case 1	1748.21	1065.04	3697.61	1698.57
Case 2	107.35	91.21	569.3	260.87
Case 3	117.81	141.22	796.02	398.16
Case 4	315.22	216.73	992.78	472.7
Case 5	490.35	588.42	2451.75	1225.88

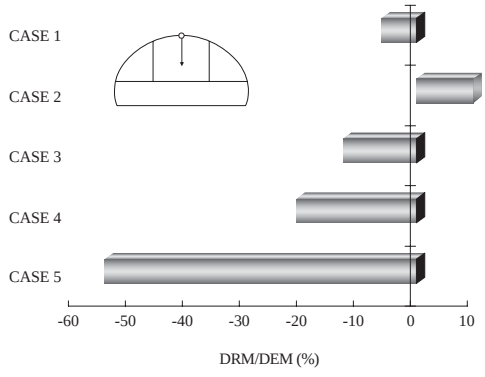
Fig. 3(b) shows the case of a double steel pipe being modeled as a beam element: a 12 m steel pipe is installed at an inclination of 11° with a 6 m overlap; there is a 0.7 m interval between the steel pipes that are installed along the tunnel crown 60° from the center; and the grout expansion range is 0.5 m.

Table 1 lists the material properties used in this analysis. For the strengthening of the grout bulb reinforcement, we followed the method of Kikuchi *et al*. (1995). The grout injection consequently produced a tenfold increase in the stiffness of the weathered soil and a fivefold increase in the stiffness of the weathered rock. Table 2 shows the equivalent design parameters for the various compositions.

5 COMPARATIVE ANALYSIS OF NUMERICAL RESULTS

We analyzed numerical models for the weathered rock and the weathered soil. First, we examined the effect of precisely-simulated models that were modeled with different sized finite elements. On the basis of these results, we constructed five equivalent models of the pre-reinforced zone and compared these models to the precisely-simulated model results in terms of the vertical displacement of the tunnel crown and the horizontal displacement of the springline.

5.1 *Effect of finite element size*



To deduce a reasonable reference for a comparison of a precisely-simulated model and an equivalent model, we completed a 3D FEM parametric analysis of a precisely-simulated model with respect to the size of the finite elements. As the number of elements of model increases, the displacement converges. Rather than the model that used the biggest finite elements, the model that used the smallest finite element shows a 4% to 5% increase in both the vertical displacement at the tunnel crown and the horizontal displacement at the springline, as well as a 13.4% increase in the ground surface settlement. The outcomes can be changed with respect to the size and shape of the finite element, which are inherent characteristics of FE analysis. Hence, to support a rational comparison between a precisely-simulated model and equivalent models, we used the small finite elements for the comparison models.

5.2 *Comparative analysis of equivalent models: vertical displacement at the tunnel crown*

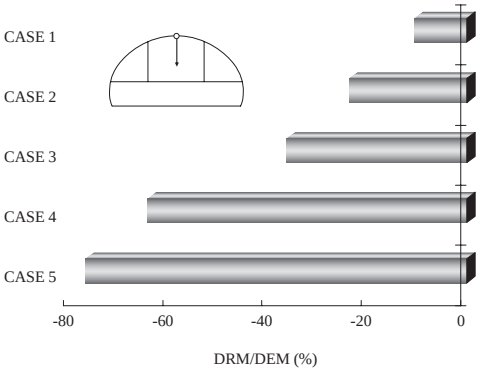


Fig. 4 shows the vertical displacement at the tunnel crown. To obtain this value, we averaged the five nodes located at the center and left areas of the tunnel crown at a depth of 4.5 m from the portal. The DRM/DEM parameter, as shown in the following equation (6), is the fraction of the displacement of the referential model (DRM) to the displacement of the equivalent model (DEM). A precisely-simulated model is represented by a value of 0%.

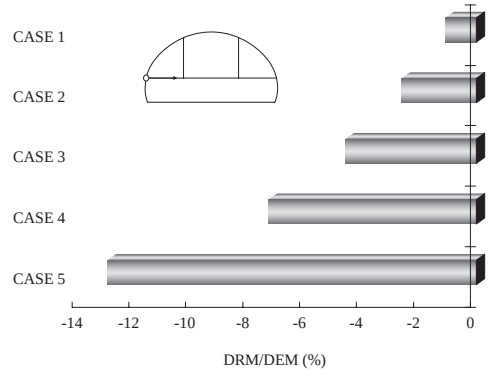
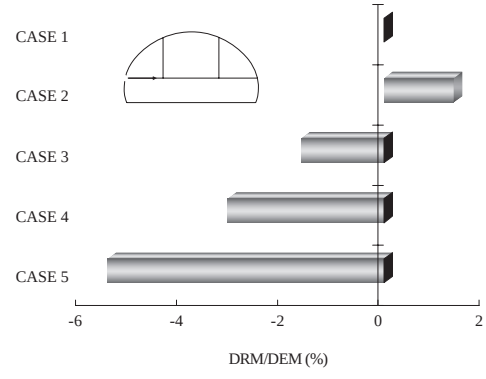
$$DRM / DEM = \left(\frac{Disp_{case}}{Disp_{real}} - 1 \right) \times 100(\%) \quad (6)$$

Case 1 gives the closest result to the precisely-simulated model in weathered rock and weathered



(a) Weathered soil



(b) Weathered rock

Figure 4. Comparison of the vertical displacement at tunnel crown.

(a) Weathered soil

(b) Weathered rock

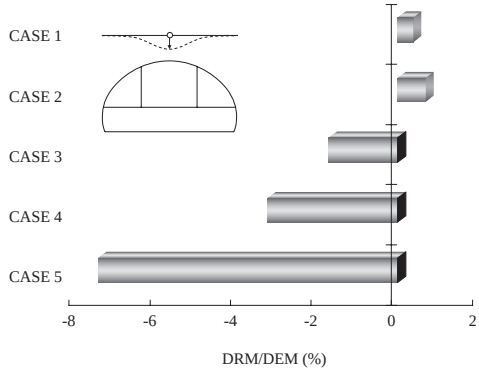


Figure 5. Comparison of the horizontal displacement at springline.

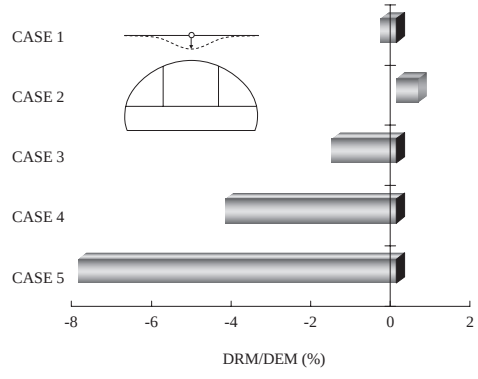
soil because of the similarity in the geometry and the finite element mesh of the equivalent model and the precisely-simulated model. Case 2 predicts an increase of around 10% for the DRM/DEM in weathered rock, though it provides a close prediction for the vertical displacement at the tunnel crown in the precisely-simulated model and ensures a safe design. As the equivalent elastic modulus and the equivalent cohesion increase, the vertical displacement at the crown decreases. In the general method (Case 5), the DRM/DEM value is 76% for the weathered soil and 54% for the weathered rock, indicating that general methods tend to overestimate the effect of pre-reinforcement. Moreover, the DRM/DEM decreases so significantly in soft ground that, in modeling the pre-reinforcement, we must simulate cylindrical bulbs rather than equivalent pre-reinforced zones.



5.3 *Comparative analysis of equivalent models: horizontal displacement at the springline*

To determine the horizontal displacement at the springline, we averaged the four nodes around the springline at a depth of 4.5 m from the portal. The results of each case are plotted in Fig. 5. From Fig. 4 and Fig. 5, we can see that for each ground condition the phase behavior of the horizontal displacement is very similar to the horizontal displacement at the tunnel crown. The DRM/DEM value of the horizontal displacement at the springline is smaller than that of the vertical displacement at the crown. Thus, depending on the location of the four-lane tunnel, the geometrical effect induces a displacement difference in the internal direction.

The DRM/DEM value increases as the ground properties change from weathered rock to weathered soil. For all weathered soil cases, the horizontal displacement of the equivalent model was smaller than that of the precisely-simulated model. On the other hand, the DRM/DEM value increased by 1.3% in Case 2 for weathered rock. Although there is only a slight difference between Case 2 and Case 3, Case 2 predicts a similar horizontal displacement at the springline for the precisely-simulated model and the design is rather safe.

(a) Weathered soil

(b) Weathered rock

Figure 6. Comparison of the ground surface settlement.

5.4 *Comparative analysis of equivalent models: ground surface settlement*

To determine the ground surface settlement, we averaged the two middle nodes of the four nodes at the top of the model immediately above the tunnel crown. Fig. 6 shows that the surface settlement characteristics were not greatly affected by the material properties of the ground. The ratio between the precisely-simulated model and the equivalent model in weathered rock and weathered soil is analogous even though the scale of the induced displacements differs in each case. The DRM/DEM value ranges from 0.55% to 0.7% in Case 1 and Case 2. Thus, the equivalent model offers a satisfactory prediction of the ground surface settlement.

5.5 *The Apprehension of behavior of a pipe-grout pre-reinforced zone*

Case 1 exemplifies a proper equivalent modeling technique for simulating the pre-reinforcing mechanism in sandy ground. Case 2, which is a SPSS in which the stiffness of the bulb and steel pipes are coupled in parallel and then connected to the stiffness of the ground in series, exemplifies a simple equivalent modeling technique that predicts the vertical displacement at the tunnel crown, the horizontal displacement at the springline, and the ground surface settlement.

When the ground, grout bulbs and the steel pipes are regarded as an individual support system, the pre-reinforced zone is not a series or parallel stiffness system but a series-parallel compound stiffness system. Thus, a small degree of stiffness support receives the biggest stress; moreover, the linear combination of big stiffness supports resists ground displacement. The SPSS explains the failure mechanism of the pre-reinforced zone: namely, the rupture of the steel pipes and the grout bulb follows the yielding of the ground. The SPSS should be used in various studies related to the analysis of pre-reinforced tunnels.

6 CONCLUSION

We conducted a comparative analysis in order to suggest a technique of determining the equivalent design parameters for effective numerical modeling of pre-reinforced zones in tunnels. We deduced the following conclusion after verifying the technique of determining the equivalent design parameters. The general method (Case 5) leads to an unconservative design for predicting vertical displacement at the tunnel crown. In contrast to other cases, Case 2, the SPSS model, predicts that the vertical displacement at the tunnel crown is likely to conservatively resemble the vertical displacement of a precisely-simulated model. In addition, we can use the SPSS a degree of horizontal displacement that is approximately the same as that of a precisely-simulated model. The DRM/DEM value of the horizontal displacement at the springline increases as the ground property changes from weathered rock to weathered soil. However, for each ground condition, the displacements behave similarly to the vertical displacement at the tunnel crown. In addition, the material property of the ground does not affect the DRM/DEM value of the surface settlement. Moreover, Case 1 and Case 2 produce similar results for predicting ground surface settlement in close agreement with the precisely-simulated model.

The pre-reinforced zone before the excavation tunnel can be simplified as a composite system of the ground, grout bulbs and steel pipes. The Case 1 of SSS, which relies on the stiffness of steel pipes and a grout bulb, is a reasonable simulation method for analysis under specific conditions. However, to model cylindrical grout bulbs, we need considerable time and manual labor to establish and run the model. We therefore recommend that another technique be used for determining the equivalent parameters with the SPSS; namely, by coupling the stiffness of grout bulbs and

the steel pipes in parallel and then connecting them to the stiffness of the ground in series. This alternative approach is simple and effective relation for numerical analysis of a pre-reinforcement with the RPUM. The failure mechanism of pre-reinforced zone can be explained by SPSS, where the yielding of the ground occurs before the failure of the steel pipes and the grout bulbs.

Computer aided hierarchical ground characterization for underground structures

A. Steiner & W. Schubert
Graz University of Technology, Institute for Rock Mechanics and Tunneling, Austria

ABSTRACT: The characterization of the ground comprises an integral part in the design of an underground structure. For this reason several classification systems have been developed in the past. They were derived from specific project conditions. The Austrian "Guideline for the Geomechanical Design of Underground Structures with Conventional Excavation" describes a consistent procedure for the characterization of the ground and determination of excavation and support. The software GEOCLASS has been developed in order to accelerate the calculation process following this guideline. GEOCLASS allows dealing with Ground Types, failure mechanisms, and ground behavior. The result of the calculation is a classification of identified ground behaviors into Ground Behavior Types. It allows the application of deterministic and probabilistic methods due to the automatic processing of the data. The results are used to determine excavation and support, as well as costs, time and risks of the construction works.

1 INTRODUCTION

The development of a tunnel project contains several investigations and design phases. Those start with a preliminary site assessment and typically end with a final design. The particular investigation and design steps are usually executed by various companies and/or working groups. Results from these subsequent steps lead to continuous increase of knowledge on the tunnel project and finally end with the final design.

The Austrian "Guideline for the Geomechanical Design of Underground Structures with Conventional Excavation" (ÖGG 2001) illustrates a coherent procedure for both the design- as well as the construction stage of a tunnel. The procedure for the design phase includes the following intermediate stages: definition of Ground Types (GT), assessment of ground behavior and classification into Ground Behavior Types (BT), evaluation of System Behavior (SB), and determination of excavation and support methods.

Reliable results require sufficient and representative data sets for input, which have to be processed by using predefined rules and definitions. Due to the large amount of data obtained from investigation campaigns, this analysis calls for an efficient, automated processing, accelerating the entire process. For this reason, the program GEOCLASS was created following the procedure illustrated in the previously mentioned Austrian Guideline. In this paper, the computer aided data processing is presented up to the determination of the Ground Behavior Types comprising the basic result of the ground characterization.

2 GUIDELINE FOR THE GEOMECHANICAL DESIGN OF UNDERGROUND STRUCTURES WITH CONVENTIONAL EXCAVATION

The guideline considers two main phases, the design phase the construction phase. The procedures described in the design phase lead to a coherent determination and characterization of support and excavation methods related to the expected ground conditions. The expected ground, excavation and support interaction is assessed (System Behavior) (ÖGG 2001, Goricki 2003). Additionally during the design process, the natural spread of the input parameters is considered.

During the construction phase, the observed System Behavior can be compared to the behavior that was determined for the associated Ground Type during the design phase. When all concepts, considerations, and decisions are documented during both phases, the systematic procedure described in the guideline allows a review of the decision making process, whenever new findings from the site are gained.

The design phase consists of five general steps: determination of Ground Types, assessment of ground behavior and classification into Ground Behavior Types, evaluation of System Behavior, Baseline Construction Plan, and determination of excavation classes

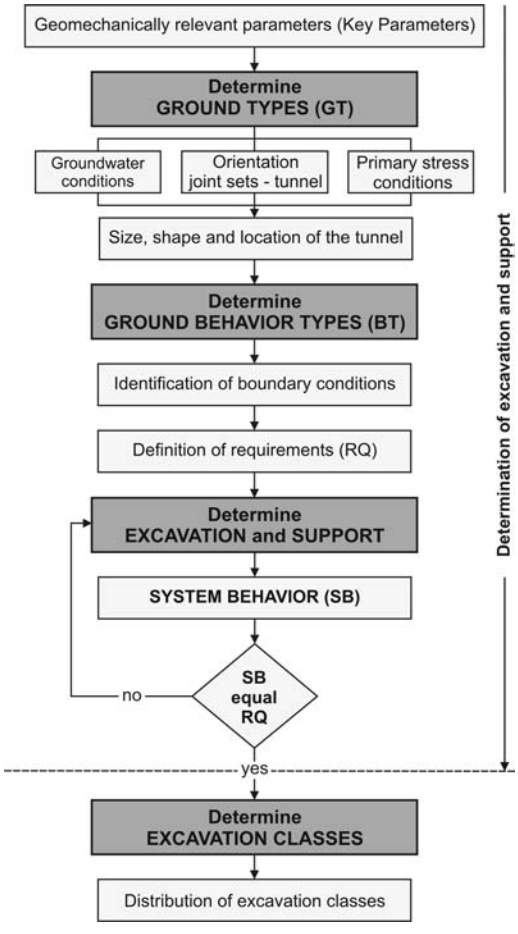

Figure 1. Fundamental design procedure based on ground characterization and classification according to the Austrian society for Geomechanics (ÖGG 2001, Goricki 2003) modified by Steiner (2005).

(Figure 1). In order to account for the variability of the input parameters they should be described with statistical values to enable the evaluation with probabilistic procedures later on.

The basis for the determination of the Ground Types is the geological model for the project area. The information about the geological architecture allows correlating geological units with geomechanically relevant parameters (key parameters). The key parameters describe the relevant properties of the ground within a geological unit. Ground Types are defined by similar material and properties. The number of necessary Ground Types for one geological unit is dominated by the variation of the key parameter values.

The ground behavior is the response of the ground to the excavation a tunnel without consideration of excavation and support methods as well as auxiliary measures. It considers the specific local influencing factors (primary stress situation, ground water conditions, discontinuity orientation relative to the excavation direction, etc.). These analyses evaluate only involved failure mechanisms. The observed mechanisms characterize the behavior caused by the excavation. Similar behavior is subsequently grouped into the Ground Behavior Types. The basic Ground Behavior Types, mentioned in the Guideline, are presented in Table 1.

Table 1. Eleven general Ground Behavior Types (ÖGG 2001), for a detail description (Goricki 2003).

Number	Ground behavior types
1	Stable
2	Discontinuity controlled block failure
3	Shallow stress induced failure
4	Deep seated stress induced failure
5	Rock burst
6	Buckling failure
7	Shear failure under low confining pressure
8	Raveling ground
9	Flowing ground
10	Swelling
11	Frequently changing behavior

The evaluated ground behaviors form the basis for the determination of excavation and support methods as well as auxiliary measures (Schubert et al. 2000). Several combinations of excavation and support methods may result in a stable excavation fulfilling all project requirements but only one regarding to economical and safety issues has to be chosen. Based on this result the Baseline Construction Plan is developed. The Baseline Construction Plan defines the excavation and support measures for each tunnel section.

The final step in the design phase includes the preparation of the tender documents as well as costs and construction times estimated for the entire project consistent with the determined amount of excavation and support measures.

Since the input parameters have a natural spread, the influence of varying key parameters on the ground and System Behavior has to be assessed for a realistic risk assessment in the design, the use of probabilistic methods is recommended and described in this paper.

3 COMPUTER AIDED DESIGN PROCEDURE

The Austrian guideline describes a consecutive approach for the design of an underground structure. Due to the consideration of the natural spread in the input parameters via statistical and probabilistic approaches, calculation and time efforts increase for the design process. To optimize these time consuming processes the program GEOCLASS was developed

for the evaluation of the first two steps in the design procedure.

The core of GEOCLASS is the determination of the response of the ground using empirical and closed-form solutions for 2D failure mechanisms under current boundary conditions.

3.1 *Basic procedure in GEOCLASS*

GEOCLASS requires for computation the definition of several input parameters, which are related to the implemented approaches, and the assignment of boundary conditions. The parameter values are simultaneously processed with all models resulting in specific output values for each model. Typical output categories are depth of the failure zone, rock burst potential, or displacement magnitudes. Each of the output categories is characteristic for a particular ground behavior. The output values of each category are used to classify the ground into a particular Ground Behavior Type. Due to the use of several calculation models, it is possible that for a particular ground several Ground Behavior Types apply. Therefore, it is necessary to assign the dominating Ground Behavior Type with a hierarchical sequence.

3.1.1 *Input*

At the beginning, the mechanical ground properties are assigned to the predefined Ground Types. Typical properties used in the program are uniaxial compressive strength, Hoek's constant, Young's modulus, Poisson's ratio, etc. These parameters describe the properties of the intact ground. They are usually determined by laboratory tests, and additionally by field tests, index tests, or from literature.

The influence of the ground structure has to be considered, in order to enable the determination of ground properties from the intact rock values. Presently the GSI model (Hoek et al. 1998, Marinos & Hoek 2001) is implemented in the software to account for fracturing, block interlocking, weathering, etc. of the ground. Appropriate GSI values are assigned for each Ground Type.

When the Ground Types have been determined, the project related geometry and other influencing factors have to be defined. The project geometry includes the geometry of the excavation (size, shape, and length), the corresponding overburden, and the assignment of the Ground Types along the tunnel axis according to the geological model. For the calculation, it is necessary to assign the Ground Types to discrete locations, so called calculation segments. One characteristic parameter set is assigned for each calculation segment. The length of the calculation segments is project specific and depends on the complexity of the geological architecture. Typical length values range between 10–50 m. Singular structures such as faults can be individually discredited. Other project dependent influencing factors are also assigned directly to the calculation segments, such as ground water conditions, the lateral confining coefficient, discontinuity orientation relative to the tunnel direction, etc.

In order to enable the software to classify automatically different Ground Behavior Types the input of delimiting criteria are necessary. The delimiting criteria are compared with the output parameters of the calculation models. Delimiting criteria are given, for instance, for rock burst potential, depth of the failure zone, overbreak, etc. Reasonable delimiting criteria should be based on a geotechnical model and take into account practical relevance.

Finally, a hierarchy of Ground Behavior Types has to be defined because the analysis can result in several Ground Behavior Types for each calculation segment. However, the following automated processing only considers one Ground Behavior Type per calculation segment. For this reason, the dominating Ground Behavior Type has to be defined for each particular calculation segment, though secondarily defined Ground Behavior Types have an impact on later steps of the design procedure (e.g. swelling).

3.1.2 *Data processing*

In the first step, the defined intact ground properties of the Ground Types are processed into ground properties. Presently GEOCLASS uses for the upscaling process of intact properties to ground properties the GSI system (Hoek et al. 2002).

Using the ground properties and the boundary conditions assigned to each calculation segment the response of the ground to the excavation is determined based on the analytical models implemented in the software. For example, GEOCLASS includes two models for the determination of the failure zone depth and the displacements (Carranza-Torres 2003, Feder & Arwanitakis 1976), one model for rock burst potential (Wang & Park 2001), as well as one model for determining dome and chimney type failures (Feder 1980). The models are simultaneously applied for each calculation segment.

The results of the analysis are compared to the defined delimiting criteria. For a particular parameter, whose magnitude complies with the range of the delimiting criteria, the corresponding Ground Behavior Type is assigned to the calculation segment. Several Ground Behavior Types can be assigned due to the simultaneous use of different calculation models. The relevant BT is determined according to the previously defined BT hierarchy (Figure 2).

3.1.3 *Results*

In order to judge the results of the ground characterization, several tables and visualizations can be created. The obtained BT for all calculation segments can be

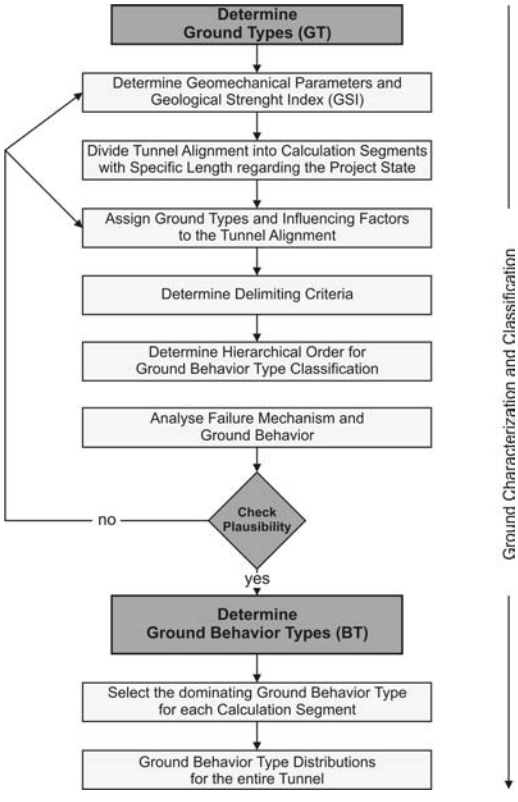

Figure 2. Deterministic procedure for the ground characterization and classification implemented in GEOCLASS.

visualized in a longitudinal tunnel section. This way of illustrating the results descriptively shows the different BT location, as well as their variation along the tunnel, and geotechnical units can be derived. Based on these units the conceptual layout of the excavation and support is established.

Diagrams, showing the displacement magnitudes and depth of failure zone can also be created. All diagrams are generated relative to the geometric project layout (Figure 3). All these visualizations allow the engineer a fast and clear judgment of the analysis and provide valuable input for the subsequent design of excavation and support.

3.2 *Exemplary calculation for Ground Behavior Type 7*

Practically input parameters are determined by laboratory tests and measurements during the geological investigations. In GEOCLASS the parameters UCS_{intact} and Hoek's constant (m_i) describe the intact ground and the GSI value is used to consider the discontinuity condition. These input parameters result in

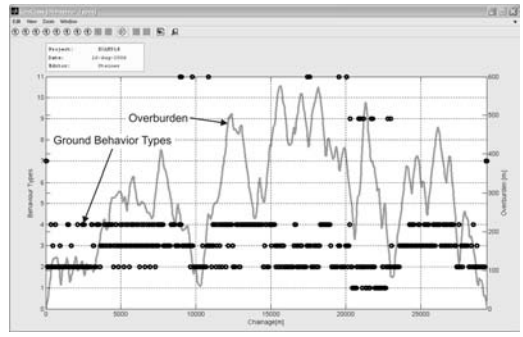

Figure 3. Distribution of the Ground Behavior Types in the longitudinal direction of a project; with the associated overburden.

the parameters describing the homogenized ground (UCS_{rm}, E_{rm}, c_{rm} and φ_{rm}).

These parameters can be used to classify the Ground Behavior Type 7. The analysis of the BT 7 (Formula 1-3) considers a failure criterion delimiting a chimney type failure from stable conditions (Feder 1980).

$$T_{shear} = \frac{h_{overburden}^{2} * \gamma_{rm}}{2} * K_0 * \tan(\varphi_{rm}) \quad (1)$$

$$G_{block} = h_{overburden} * \gamma_{rm} * D_{tunnel} \quad (2)$$

$$2 * T_{shear} \leq G_{block} \quad (3)$$

where T_{shear} = shear force in the sliding plane; $h_{overburden}$ = overburden; γ_{rm} = specific weight of the ground; K_0 = lateral confining coefficient; φ_{rm} = friction angle of the ground; G_{block} = weight of the block over the excavation; D_{tunnel} = excavation diameter.

3.3 *Exemplary calculation for Ground Behavior Type 1/3/4*

For the classification between Ground Behavior Type 1, 3, and 4, the UCS_{rm} is used in the calculation model from both Feder & Arwanetakis (1976) as well as Carranza-Torres (2003). The second one is limited to hydrostatic stress situations.

The result of this calculation is the size and shape of the failure zone (secondary stress condition > UCS_{rm}). The delimiting criterion between BT 3 and 4 is determined depending on project conditions and practical issues. In GEOCLASS an empirical formula (4), which is primarily based on the size of the excavation, is used for the classification (Figure 4).

$$DBZ_{\lim it} = 2.5 * \sqrt{R_{equivalent}} \quad (4)$$

where $DBZ_{\lim it}$ = delimiting depth of failure zone; $R_{equivalent}$ = equivalent radius of excavation.

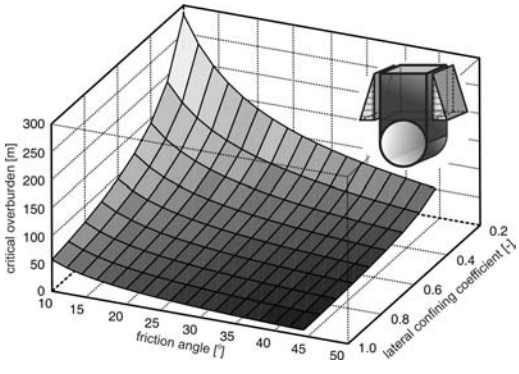

Figure 5. Delimiting criteria to determine the critical overburden depending on the friction angle and the lateral confining coefficient.

4 PROBABILISTIC APPROACH

In contrast to the deterministic calculation that proceeds with one representative parameter set during the entire calculation, the probabilistic approach uses a number of such calculations with varying input parameter sets. Those input parameter sets are determined by the natural spread of the values for each GT. The probabilistic approach results in a statistical distribution for the calculation results, hence also for the Ground Behavior Types after a sufficient high number of calculations (Figure 6).

At the ideal case, a number of laboratory results for each geotechnical unit can be used for the determination of the statistic distribution type and its characteristic values. If there is a lack of laboratory results, the determined input parameters can be used as average values. In this case, expert knowledge can

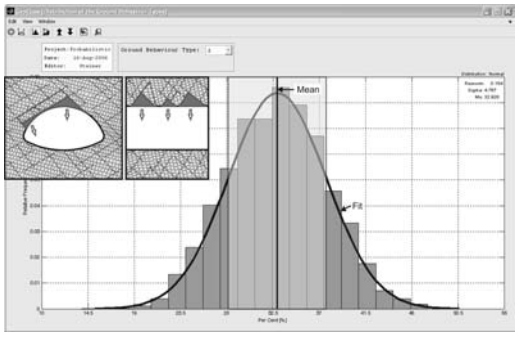

Figure 6. Histogram of the Ground Behavior Type 2 with a sketch of the appropriate failure mechanism.

be used to assume a realistic distribution. Now the random input values can be determined. In GEOCLASS this determination is done by using the Monte Carlo Simulation (Haldar & Mahadevan 2000).

The previously described deterministic calculation is executed with each of these random parameter sets, which represent the natural spread of the ground properties. The evaluation of the probabilistically determined results offers relevant conclusions (e.g. risk assessment, etc.).

During the following steps in the design procedure, each Ground Behavior Type is assigned with specific excavation and support measures. Those measures result in costs and time. The distribution, showing the expected length of each Ground Behavior Type, is later used for the determination of the costs and their possible spread.

Even when the natural spread of the input parameters is used for the calculation, some calculation segments can clearly be assigned to one expected Ground Behavior Type. Others may possibly be assigned to several Ground behavior types. In early stages of a project, these may indicate a lack of information about the ground conditions possibly resulting in further ground investigations. During final design these results represent the natural spread inherent in the explored data sets.

5 CONCLUSION

The estimation of costs and time requires rules for the determination of excavation and support during design stage. Both depend on the ground behavior. For this reason characterization systems were developed (GSI, RMR, RMi, RSR, Q-System, etc.). These systems are mostly based on measurable and/or observable values, which are used to classify the ground quality. The determined ground quality is then used to associate support methods without considering the ground behavior (Edelbro 2004, Goricki 2003).

The complexity of projects effort a lot of calculation works, so a program (GEOCLASS) was developed to accelerate the design procedure following the rules of the Austrian Guideline for the Geomechanical Design of Underground Structures with Conventional Excavation (ÖGG 2001). In the program, different approaches can be used to analyze the ground behavior. The simple illustrations of the results allow a continuous engineering judgment of the results during the first steps of the design process. Normally only deterministic procedures are used to analyze project conditions. The implementation of the Monte Carlo Simulation in GEOCLASS additionally provides the use of probabilistic procedures for the entire procedure.

The results of the probabilistic approach contain the natural spread and/or variability of the ground. When this statistic results are used for the determination of excavation and support, the variability of expected costs, and time can also be determined.

By the consideration of the natural spread inherent in the input parameters, the results for the design process are more significant in each project stage.

Developments of structural performance assessment for sewer liners

C. Madryas & A. Szot
Wrocław University of Technology, Poland

ABSTRACT: Wide application of strengthening and sealing CIPP and FFP liners in sewage sewers imposes taking into detailed consideration their structural performance. Some research has been conducted to capture and describe rules that govern their behaviour. The specificity and complexity of those constructions, as well as still insufficient long term experience in this subject has not allowed to work out fully relevant principles of structural design. Instead some approximate solutions based on different classic pipe approaches have been used. The behaviour of liners indicates significant degree of non-linearity, both geometrical and physical along with the unsteady boundary conditions, which is an outcome of the contact between liner and host-pipe. The results of latest research for verifying previous approaches and establishing relevant algorithm for structural design of liners have been presented in the paper.

1 INTRODUCTION

Renewal of gravity flow sewer pipeline with the use of continuous polymer liners is one of the most efficient methods for restoration of its former technical and functional condition. In general, the method consists in inserting and forming a polymer liner to make it close-fit to the pipeline. The purpose of the liner installing is to seal and strengthen the pipeline with minimum reduction of the pipeline cross-section. Among materials used for liner productions the most popular is so-called "prepreg" made of thermosetting polyester, epoxy or vinyl ester resins as well as HDPE or PVC. Liners may be inserted in loose form (prior to installation – resin prepreg; CIPP technology) or with the use of thermo-mechanical deformation (HDPE, PVC; FFP technology). In the manufacturers' specifications such constructions are commonly called "liner" or "sleeve".

Although liners have already been in use for over 30 years it seems that many theoretical aspects of this technology related to structural design and long-term liner exploitation under chemical load have not been thoroughly examined and identified. The chief questions refer to load pattern and its magnitude which hinge upon installation conditions, failure modes and relevant criteria of bearing capacity of liners.

The structural performance of sewage pipeline liners is known to be affected by the following factors:

- geometry of the ideal circular model – thickness and diameter
- geometrical imperfections – deviations of the ideal model that occur in the real model
- material physical properties of the liner with consideration of rheology
- structural condition of the host-pipe – the degree of deterioration, which might govern the loading pattern to which liner is subject
- loading pattern – mainly ground water pressure, sporadically soil pressure passed by the host-pipe
- altering boundary conditions – depending on the contact between liner and host-pipe

Vitally important in the case of liners is defining a relevant model for the structural design. There are two potential sources of failure, namely instability and exceeding material yield point. According to some research concerning that matter (Bakeer et al. 1996, Boot 1998, El Savy et al. 1998, Falter 1997), liners in sound but leaking host-pipe are reported to collapse mainly due to acting of ground water pressure and the failure usually takes form of one-lobe snap-through buckling.

Since there is no reliable bond between polymer liners and host-pipes after installation it is usually assumed that there is no obstructions for ground water to penetrate the gap and the pressure is acting along the circumference. The liner installed in a host-pipe is known to be subject to ground water pressure in most real-life cases, which is the main cause of failure. Although, in practice, the load pattern is non-uniform along the circumference of the liner the uniform distribution is accepted in publications presented to date (Bakeer et al. 1996, Boot 1998, El Savy et al. 1998, Falter 1997). In this research project, the non-uniform pressure is incorporated into FEM analysis as accurate

enough at this stage of problem examination. Moreover, there may be certain circumstances where liner is also subject to ground and overburden load. This occurs where the host-pipe is severely structurally deteriorated which results in transferring some part of loading on the liner by the local contact interaction. For liners installed in cracked host-pipes the failure mode is exceeding yield point.

2 GENERAL STABILITY FOR 2D MODEL

Performance of the shell subject to uniformly distributed ground water pressure is described in publications by several approaches. The analytical model by Glock (Glock 1977) apparently predominates and, in its evaluation by means of FEM, it was proven to comply very good with the results of laboratory tests of liners with no initial imperfections (Boot 1998, Szot 2002).

Glock's model embraces stability problem of thin, circular ring confined in rigid boundary, which corresponds with ideal conditions of liners application. The ring is subject to uniformly distributed pressure on its circumference. Since this approach is based on the potential energy balance calculation, the post-buckling form was assumed. The formula for critical water pressure resulting in instability, dependent on geometrical parameter and modulus of elasticity, takes the following form:

$$P_{cr} = \frac{2 \cdot E_L}{1 - \nu^2} \cdot \left(\frac{t}{2 \cdot R} \right)^{2.2} \tag{1}$$

where: R = liner radius (mean value of the inner and outer diameter), t = wall thickness of the liner, E_L = long-term modulus of elasticity as an equivalent of creep modulus, ν = Poisson ratio.

The formula is currently considered to be the base for further development of the load-bearing capacity assessment. Although it is relevant for ideal conditions that assume perfect circular geometry, the formula can be used as a point of reference for introduction of initial geometrical imperfections influence as a simplification of the real, highly complex model. The important topic is to combine all the kinds of imperfections into the design algorithm.

The simulations of liner performance in the natural-like conditions were performed with the use of Finite Element Method. Taking non-uniform distribution of ground water pressure into consideration, which exist in practice and may be an another relevant factor for large diameter liners. A wide range of calculations have been performed by the authors of this paper to describe dependencies between important geometrical or load factors and, relevant for structural design, critical pressure. The aim of this calculations was to identify the importance, compare and confirm the influence of initial geometrical imperfections and some other factors like buoyancy (non-uniform pressure distribution), interaction between the liner and the host-pipe and dead loads.

Results of the current analysis pertain only to the cases, where the host-pipe fully maintains ability of bearing loads, so the assumption of no traffic and ground dead loads passed to the liner was established. Such assumption covers most of the real cases of the liners' installations. Also no exact rheological behaviour was introduced into calculation. Instead, simple reduction of the modulus of elasticity as an equivalent of the creep modulus was set.

3 STABILITY AND DETERMINED GEOMETRICAL IMPERFECTIONS

The aim of the analysis was to establish the quantitative influence of imperfections combined in the model on the critical groundwater pressure. Some previous results have been used both as a point of reference and intermediate values, namely individual imperfection reduction charts. Formulae for individual reduction factors have been incorporated into a combined model, which was then calibrated with the use of FEM and regression analysis.

Three types of imperfections have been taken into account to examine the influence they produce on the critical pressure value. Geometrical imperfections have been set as follows:

- gap between the liner and the host-pipe,
- local imperfection (wave form).

Circumferential gap is a general measure of liner geometrical mismatch to the internal host-pipe surface caused by design errors, liner shrinkage and installation procedure quality. Local intrusion is a departure from the ideal circular liner cross-section resulting from installation inaccuracy, presence of bottom solidified sediment or local host-pipe surface irregularity. Local intrusions take forms of an inward bulge. Furthermore, ovalisation is often indicated to be another form of initial imperfection but in the author's opinion this form refers rather to the case of a liner installed in deteriorated host-pipe, which is a separate problem. The normalised size of a gap is often expressed as a percentage fraction as nominal gap to liner radius ratio Δ_g/R. The form of intrusion used by the author is adapted from displacement description presented in Glock's analytical solution and expressed by intrusion wave amplitude in relation to liner radius Δ_{wi}/R.

The impact of combined imperfections on the structural performance of sewer liners is of vital importance in the process of its structural design. Detailed study into this problem may allow the thickness of the liner

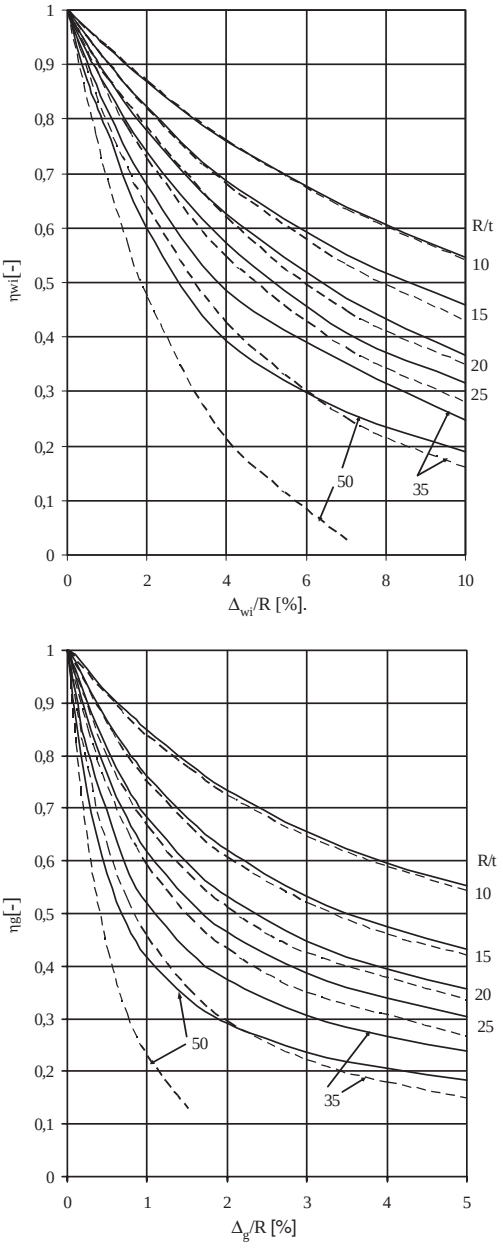

Figure 1. Diagrams of critical pressure reduction factors due to local imperfection and gap for uniform pressure distribution (solid line) and non-uniform (dashed line).

wall to be reduced, which when considering the economy of the technology, is highly desirable. Apart from rheological variation of the liner material, this issue is the main point of current discussion concerning liner performance.

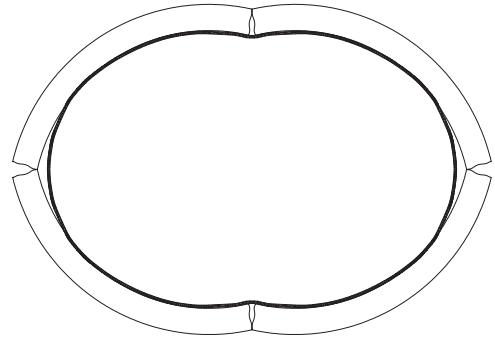

Figure 2. Mechanically deteriorated sewer and typical liner geometry.

As an intermediate parameter of the analysis there has been assumed the height of ground water pressure, being the cause of the liner instability. The parameters resulting from the analysis include reduction factors (Fig. 1), which express the ratio of pressure load in the model with imperfections to that of the corresponding, perfectly circular model. They express the influence produced by a simple-type geometrical imperfection. In the scope of the analysis combined imperfections were studied.

4 BEARING CAPACITY OF LINER IN CRACKED HOST-PIPE

The aim of the research subproject was the quantification of maximum stress in liner walls as well as the deflection of pipe-and-liner system for continuous polymer liners installed in sanitary sewers. Determination of functions of key parameters in relation to installation conditions was carried out with the use of finite element method, theory of similarity and dimensional analysis. The performed analysis enabled to work out universal formulae describing the wanted mechanical parameters for a variety of geometrical and soil conditions.

Results of the conducted analysis help assessing maximum stress and deformation of liners of all size with satisfactory accuracy. Range of geometrical and physical properties taken into account covered most practically existing cases.

Derived formulae (2) do (3) can completely describe limit states of bearing capacity and deformation. Following conclusions were drawn from the analysis:

– there are two limits of the liner stiffness envelope – upper limit depending on maximum stress and lower limit depending on maximum deformation,

– contrary the intuitive prediction setting higher stiffness does not lead to a safe solution. This effect leads to exceeding stress threshold due to increase of load on the liner,
– too low liner stiffness results in large deformation, which is unfavorable due to decreasing hydraulic performance.

In conclusion, it is recommended to use in structural design optimum magnitude of liner stiffness located within the limit envelope.

Analysis carried out with the use of finite element method and multivariable non-linear regression models led to formulae describing maximum stress and maximum deformation (ovalisation):

$$y_1 = 8{,}966 + 0{,}064 \cdot x_1 - 0{,}370 \cdot x_2 + 0{,}006 \cdot x_2^{\,2} - 0{,}002 \cdot x_1 \cdot x_2 \tag{2}$$

$$y_2 = 0{,}323 \cdot x_1^{\,1{,}017} \cdot x_2^{\,0{,}332} \approx \frac{1}{3} \cdot x_1 \cdot x_2^{\frac{1}{3}} \tag{3}$$

$$y_1 = \frac{\sigma_{\max}}{E_L} \cdot 10^3 \tag{4}$$

$$y_2 = \left(\frac{\Delta D}{D}\right) \cdot 10^3 \tag{5}$$

$$x_1 = \frac{\gamma_g \cdot h + p_k}{E_{gr}} \tag{6}$$

$$x_2 = \frac{R}{t} \tag{7}$$

where: $\sigma_{\max}$ = maximum existing stress in liner wall, D = liner diameter, γ_{gr} = ground density, E_{gr} = ground modulus of deformation, p_k = overburden pressure, h = host-pipe ground cover height.

5 STABILITY OF 3D LINER MODEL

Numerical analysis of the stability of sewer liner model was performed in the research project. The aim of the analysis was to compare results generated by plane and spatial solutions concerning stability of shell in rigid boundary subject to non-uniform circumferential pressure. Significant raise of the critical circumferential pressure was observed for the spatial model in comparison with the plane one. A linear multiplying factor for the critical pressure was determined and incorporated as a modification of the analytical plane model solution. The modification makes the analytical solution approach the laboratory test results and significantly improve accuracy of the entire solution.

The direct result of the performer simulation was water table height resulting in snap-trough instability. Only first level of critical pressure was taken into account, which complies with general stability consideration in structural design algorithms.

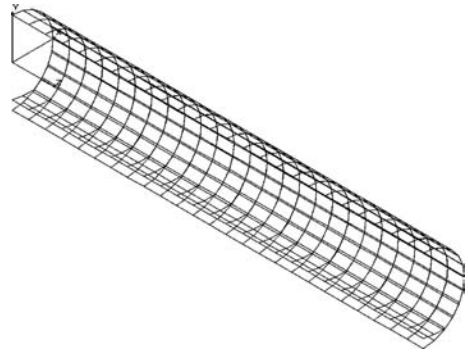

Figure 3. Typical post-critical snap-trough configuration according to FEM simulation for spatial model.

Observer results of FEM simulations for spatial liner model showed that deformations tend to be uniform along the liner axis (Fig. 3). This phenomenon does not comply with the laboratory test results (Aggarwal et al. 1984, Wagner 1992). In fact, these discrepancies can be attributed to specificity of laboratory models geometry, which were rather short. Also, boundary conditions applied in laboratory tests affects strongly the critical pressure and post-critical configuration.

Numerical critical pressure results showed that there is linear relation between spatial and plain strain model. As expected, results for spatial model showed higher magnitudes of critical pressure, which means that plain strain model is conservative and safe. This also complies with results of laboratory test, where generally linearly higher magnitudes of critical water pressure comparing to analytical ones can be observed.

Approximation of numerical results was carried out to derive modification to formula (1) in order to include spatial stability performance for liners. After linear modification the general formula for critical groundwater pressure took the following form:

$$p_{cr} = 1{,}255 \cdot \frac{E_L}{1-\nu^2} \cdot \left(\frac{t}{2R}\right)^{2{,}2} \tag{8}$$

Taking spatial performance into account leads to critical pressure higher by about 25% comparing to the 2D model. This means that current structural design algorithms are far conservative. Laboratory test results (Aggarwal et al. 1984, Wagner 1992) and the authors' solution showed good compatibility. However, in the range of low liner stiffness convergence slightly lower was observed. This could be attributed to local of liner to host-pipe adherence occurring in laboratory model, which affected boundary conditions.

6 CONCLUSIONS

Some basic results of bearing capacity analysis for continuous polymer liners used for sewer renewal have been presented in this paper. Identified valid structure load parameters and expected failure modes were shown. Circumferential ground water pressure was pointed out to be the dominant liner load. One-lobe snap-through instability localised at the liner bottom turned out to be both the predicted and observed failure mode. The model which appeared to comply best with FEM results was that proposed by Glock (Glock 1977). The assumptions and procedure proposed therein were used to work out the author's own improved approach which takes into account non-uniform water pressure. Further on, based on FEM simulations the influence of initial geometrical imperfections (circumferential gap and local intrusion) on critical pressure was analysed with taking into consideration uniform and non-uniform pressure distribution.

The impact of combined imperfections on the structural performance of sewer liners is of vital importance in the process of its structural design. A detailed study into this problem may allow the thickness of the liner wall to be reduced, which when considering the economy of the technology, is highly desirable. Apart from rheological variation of the liner material, this issue is the main point of current discussion concerning liner performance.

The problem of stability of the polymer non-circular sewer liner subject to the action of ground water pressure has been studied. In comparison with computational results the first approximate analytical solution by Glock turned out to be fairly accurate and useful for practical purposes. The magnitudes of the snap-through pressure calculated in this way were in good agreement with those obtained from FEM analysis.

Analysis of the liner installed in cracked host-pipe was performed. Formulae describing liner performance were determined with the use of FEM. General solution presented herein may be universally used for various geometries and installation conditions.

Numerical analysis of the stability of spatial model of sewer liner model was conducted. Significant raise of the critical circumferential pressure was observed for the spatial model in comparison with the plane one. A linear multiplying factor for the critical pressure was determined and incorporated as a modification of the analytical plane model solution. The modification made the analytical solution approach the laboratory test results and significantly improve accuracy of the entire solution.

All the examinations performed led to improving the general liner performance assessment.

ACKNOWLEDGEMENTS

The study presented in the paper was supported by The Polish Ministry of Science and Education within the project No. 4 T07E 023 27 and Fundation for Polish Science within the Professorial Grant.

Experimental verification of final tunnel lining performance

P. Šourek
SATRA, Prague, The Czech Republic

J.L. Vítek
METROSTAV, Prague, The Czech Republic

ABSTRACT: Design of final tunnel lining is influenced by many factors – rock/soil performance, concrete and geometry of the lining, technology of construction, etc. The input data for the analysis have usually a large statistical scatter. The design used to be conservative, in order to guarantee the safety of the tunnel. This paper deals with the experimental work carried out with the aim of monitoring the actual performance of the tunnel lining in selected tunnels. The measured values are recorded for a period 1 to 4 years.

1 INTRODUCTION

The progressive development of transport infrastructures in the Czech Republic resulted in design of many tunnels. The new trends of design and construction of underground structures came mostly from abroad. Tunnels represent very important parts of roads and railways, no limitations of traffic should be allowed, and therefore the tunnels must be safe, economical and they must serve the users without any restrictions during their entire service life. The experiences concerning the long term tunnel performance are sufficiently different in many countries, so that it was considered useful to verify the tunnel lining performance in the Czech conditions. The objective of this paper is to provide information on measurements carried out in selected tunnels, which should provide a basis for tunnel assessment and, later, for possible modification of the design methods.

2 CONSTRUCTION OF TUNNELS IN THE CZECH REPUBLIC

Geological conditions, tunnel alignment and but above all, the equipment of contractors resulted in the fact, that most of the new tunnels are built using the New Austrian Tunnelling Method (NATM). The principle of the NATM is based on the interaction of the rock massive with primary lining in the first phase. The temporary primary lining is made of sprayed concrete, reinforced by steel mats supplemented by rock nails and temporary anchors. In this phase, the deformations become stabilized and the stress in the rock massive is redistributed.

In the second phase, the definitive secondary lining is cast into the free space supported by primary lining. It forms a final structure, which should carry all the permanent loads during the entire service life of the tunnel. The secondary lining is usually made of reinforced concrete composed of the heading, side foundation blocks and, in some cases, also by an invert.

The reinforcement used to be assembled from mats at each surface which are supplemented by individual bars. The final lining made only of plain concrete was applied in very few tunnels. The individual sections of the lining are cast in sequence, the invert using a classical system formwork, and the top using a hydraulically operated formwork. The length of individual casting segments varies in dependence on the size of the tunnel cross-section; tunnel alignment and length of the formwork from 5 to 15 m. Individual segments are statically independent.

3 DESIGN ASSUMPTIONS OF THE FINAL LINING

The application of advanced numerical methods has become standard over recent years. Internal forces and deformations in the tunnel lining are analyzed using a method of finite elements. The complete rock/soil massive, including a secondary lining, is modelled together with its time development and important construction stages like installation of individual linings.

The structural analysis is focused on the most complex cross-sections regarding many loading stages and

their combinations. The most important loadings are as follows:

– self-weight of the lining,
– geostatic load of the rock/soil massive,
– hydrostatic pressure of underground water (if the waterproofing is applied),
– shrinkage of concrete,
– changes of the ambient temperature, etc.

The loading of classical structures, such as buildings and bridges can be relatively precisely defined. Above the ground structures may be also built with a high degree of accuracy and their deviations from the designed shape and dimensions are minor. The material parameters are given with an acceptable statistical scatter.

To the contrary, the underground driven tunnel forms a system which includes the tunnel lining and the rock/soil massive. Both parts interact and the response of the lining is highly dependent on the rock/soil massive performance. The determination of actual parameters of the system composed of a rock/soil massive and a tunnel lining is a rather complex task. Therefore, during the tunnel design, it is necessary to accept many simplifying assumptions. In addition, the safety reserves are subject to the code requirements as well as to the subjective considerations of the designer. This results in the design of the tunnel lining being significantly dependent on the experience of the designer and on the availability of the data describing the performance of the rock/soil massive. It can be expected that in this situation, the designs will be rather conservative. The non-existing unified methodology of the design in terms of loading stages consideration and the interaction of the rock/soil massive with the secondary lining including their deformation and strength characteristics variable in time contributes to the complexity of the design.

4 EXPERIMENTAL MEASUREMENTS

The uncertainties described above led to a decision to observe the actual tunnel performance, and to compare the measured values with those obtained from the design calculations. Within the research project of the Grant agency of the Czech Republic, the strain gauges were embedded into the secondary or primary linings of selected tunnels. The vibrating wire strain gauges produced by the Gauge Technique Company were used since they are rather robust and reliable, and the research team had had a long term experience with their application.

The vibrating wire strain gauges were installed in the final lining of some road tunnels, for example:

– Tunnel Valik, motorway D5, 4 measured sections
– Tunnel Panenska, motorway D8, 2 measured sections

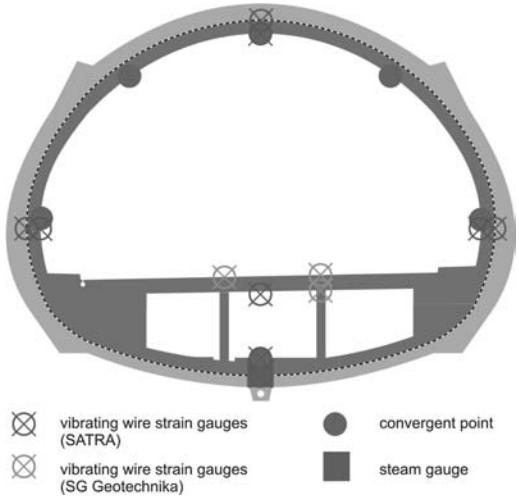

Figure 1. Cross-section of the tunnel Mrazovka including the position of vibrating wire strain gauges.

– Tunnel Libouchec, motorway D8, 2 measured sections.

Besides these tunnels, the results of the measurements that had begun earlier were used. Similar strain gauges were embedded in the secondary lining of the tunnel Mrazovka in Prague, where about 6 sections have been measured and in the surveying gallery of the tunnel Blanka, where the two sections are monitored.

Using the vibrating wire strain gauges, the strain and temperature developments in the secondary lining are recorded at regular time intervals. This method of measurement has been verified over the past 20 years when the same types of gauges were installed in different structures, and the strains are within many projects successfully recorded until now.

The changes in stress and strain in the secondary linings are assumed to be rather slow; therefore, the readings are taken only several times a year. The cross-sections, where the gauges are embedded, are supposed to be subjected to a significant loading. The locations deep in the rock/soil massive or the locations with a high hydrostatic pressure of underground water were given preference. The position of gauges within the cross-section was chosen according to the bending moment distributions. The locations in the top of the vault or above the abutments are typical for appearance of the large bending moments. The symmetry of the cross-section is used as an independent check of the recorded strains. It is assumed that if the loading is symmetrical, the recorded strains should also satisfy the condition of the symmetry. Figure 1 shows the positions of the vibration wire strain gauges in one of the sections of the tunnel Mrazovka. The section is not typical; therefore the strain gauges are also located in

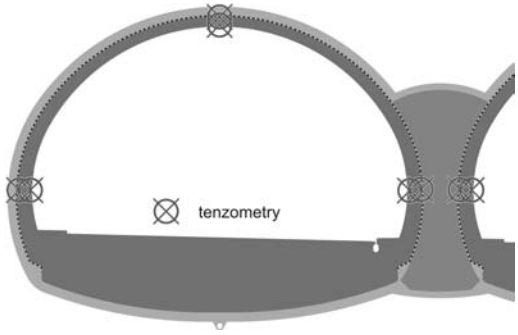

Figure 2. Cross-section of the tunnel Valik including the position of vibrating wire strain gauges.

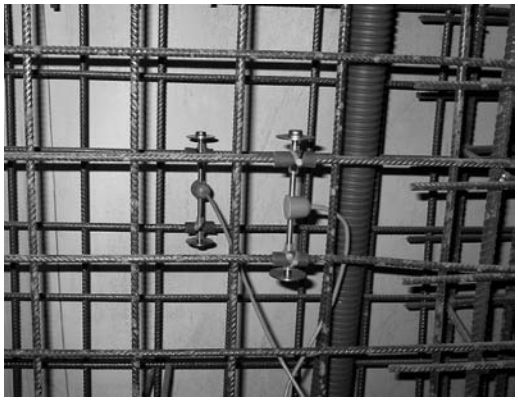

Figure 3. Vibrating wire strain gauges attached to the reinforcing bars prior to pouring of concrete.

a slab under the pavement (called bridge deck). This slab also works as a tie which stiffens the complete cross-section of the tunnel. In this tunnel two independent measurements are carried out by the SATRA and by the SG Geotechnika companies. The results are shared and the evaluation is based on the results of both measurements. Additionally, the deformations of the lining measured by surveying and measurements of the underground water pressure are taken into account as part of the evaluation of all the measured values.

The vibrating wire strain gauges are attached to the reinforcing bars (Fig. 3). The leads from the gauges are connected into the box which is installed at the surface of the tunnel lining. The boxes are also accessible during the operation of the tunnel, which allows for recording of the strains after the opening of the tunnel to the traffic as well. No calibration is necessary before taking the new readings, which is one of the advantages of this strain gauge. The electric impulse sent by the reading device starts the string in the gauge to vibrate and immediately its frequency is measured. The frequency varies with the strain, which is then calculated. The measuring length of the used gauges is 140 mm, which is suitable for measurements in heterogenic materials like concrete. The initial reading is taken just after the pouring of concrete and further readings are taken approximately 4 times a year. Fig. 2 shows the positions of the gauges in the tunnel Valik.

5 MEASURED VALUES

The measured strains are compared with the strains measured in other similar tunnels or with the strain values obtained from the structural analysis of the secondary lining. The measured strain is a result of many effects, including an elastic strain due to the applied stress, creep and shrinkage of concrete, temperature effects, and sometimes, increased strain due to cracking. Within the evaluation, it is necessary to measure the concrete properties in order to estimate the stress values in the instrumented locations. The bond between steel and concrete is assumed to be perfect since the stresses are rather low. It is necessary to note that the stress in steel reinforcement is also influenced by internal stresses induced by shrinkage and temperature changes of concrete. The smaller the reinforcement ratio, the higher the internal stress in steel.

The secondary lining of the tunnels Valik, Libouchec and Panenska was built mostly in 2005. The strains measured in these tunnels are therefore rather low. The stress in steel is in the order of the tens of MPa and the stress in concrete does not exceed 2 MPa. The strain development in time at the tunnel Valik is plotted in Fig. 4. The secondary lining (in this case without the closed waterproofing), is loaded by the self weight of concrete, shrinkage, and by temperature changes. The effect of the self-weight is not in the reading involved since the first reading was taken after demoulding. The load induced by the rock/soil pressure will be active later, at present it is transferred still by the primary lining. After its degradation, the secondary lining will be slowly loaded. The degradation of primary loading will be dependent on the design parameters and on the aggressiveness of the rock/soil environment.

The secondary lining of the tunnel Mrazovka was finished in 2003. The tunnel was open to traffic in 2004. The tunnel is completely protected by waterproofing which is located between the primary and the secondary lining. The measured strains also in this tunnel do not show that the secondary lining would be loaded up to the expected design level. The maximum measured stress in the reinforcing steel has reached about 12 MPa, while the compression on concrete does not exceed 1 MPa. The time development of strains proved the growth of the stress due to the growing pressure of underground water after the pumping

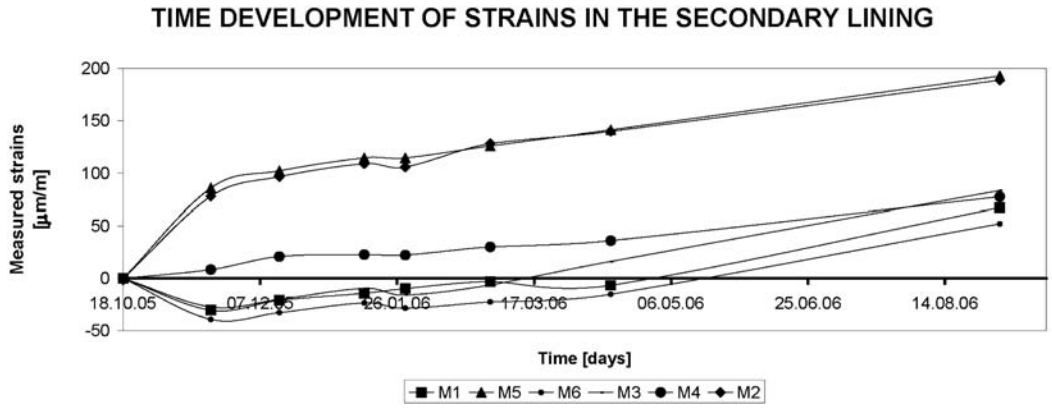

Figure 4. Time development of strains in the secondary lining – Valik tunnel.

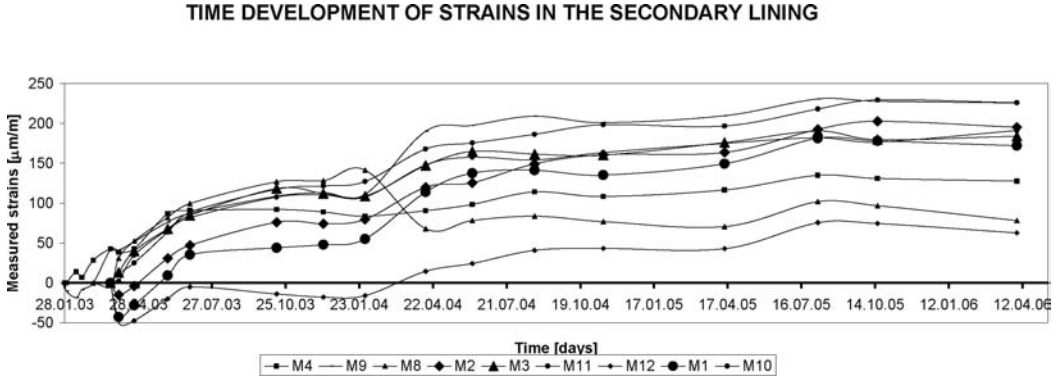

Figure 5. Time development of strains in the secondary lining – Mrazovka tunnel.

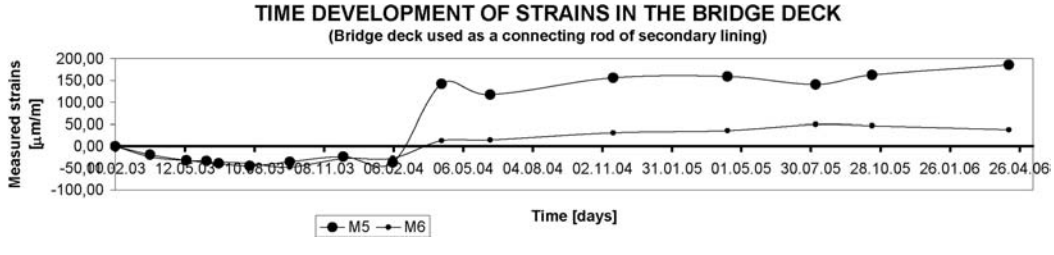

Figure 6. Time development of strains in the bridge deck – Mrazovka tunnel.

shafts had been closed. The water pressure stabilized after some period (see Fig. 5 and 6). The measured values also prove the functionality of the designed system, where the road slab works like a tie and stiffens the whole cross-section of the tunnel. The slab transfers the tensile force and the measured strain values correspond to the stress in the steel about 70 MPa (the effects of traffic excluded).

6 CONCLUSION

The primary lining initially carries the complete loading at all the instrumented tunnels, since they were built by the new Austrian tunnelling method (NATM). In the later stages, the secondary lining is cast. It is usually separated from the primary lining by a waterproofing. A structural analysis assumes that the

primary lining will disintegrate in time and the total loading will be carried by the secondary lining. If it happens, to what extent and when, is still rather uncertain. The measurement carried out under the mentioned research project should help to explain how the transfer of load will influence the measured strains. The instrumented tunnels are rather new, and the actual load of the secondary lining is small, which is in accordance with the design philosophy of the NATM. Even the shrinkage alone exhibits smaller strain than that measured on the small concrete specimens. It can be assumed that the actual shrinkage of the tunnel lining is rather small. The reason may be (a) the environment in tunnels is rather wet, the drying of concrete is slow, (b) the concrete lining is thicker than the usual dimensions of the standard laboratory specimens and (c) the surface of the lining is exposed to the environment only from one side.

The significance of the proposed measurements consists of long term observation of the actual performance of tunnel linings. The strains will be recorded for many years, and it is expected that there will be a possibility to register changes in strains, which could indicate the degree of loading carried by the secondary lining (it would also provide information about the degradation of the primary lining). When the secondary lining is exposed to the pressure of underground water, it is possible to trace this loading from the measured strains. This was evidenced in the case of the measured strains in the Mrazovka tunnel. One can assume that the measured strains in instrumented segments of selected tunnels will bring information on the behaviour of the system primary and secondary lining in the future. Such knowledge will hopefully be of interest in the design of the new tunnels, along with the evaluation, and possibly for modification, of the currently used design procedures.

ACKNOWLEDGEMENT

The research team gratefully appreciates the support of the Grant Agency of the Czech Republic, Project No.103/2005/2231.

Stability analysis and excavation schemes of large-span highway tunnel under complex geological conditions

J.S. Tang, S.Y. Liu & L.Y. Tong
Transportation College, Southeast University, Nanjing, jiangsu, P.R. China

C.H. Shen
Transportation College, Hohai University, Nanjing, jiangsu, P.R. China

ABSTRACT: More and more practice problems arise during the construction of the big-span highway tunnels due to the complexity of the geological conditions, such as geological disasters, failure of the shot and lining concrete, etc. Tunneling excavation is actually the process of stress redistribution and rock deformation, which are much influenced by different construction methods and sequences. A case study of the east Mao Mountain tunnel on the Ning-Chang highway, China, is carried out in this paper. The three dimensional numerical simulation is conducted on different excavation schemes in the condition of pre-designing support system using the FLAC^{3D} software. The displacement behavior and stress characteristics are analyzed to propose the reasonable tunneling scheme. Accordingly, the stability of selected scheme is predicted. Moreover, the simulation results are compared with field monitoring data. The pre-designing support parameters of the large-span highway tunnel are evaluated. The results of this study are expected to be useful for the successive design and construction control.

1 INTRODUCTION

The stress and deformation of the surrounding rock are influenced by different tunneling methods and sequences. Especially, for partial excavation methods, different construction sequences have different stress paths, which affect final stress and displacement fields of surrounding rock as well as support structures. Accordingly, tunneling methods and construction sequences are of importance for tunneling safety and are also key concerns for the engineers.

Numerical simulation is mostly applied to validate rationality of pre-designing schemes by theory and engineering analogy. However, most papers on simulation of construction schemes are two-dimensional and three-dimension analysis are rather few. Moreover, the single tunnel model based on symmetry theory is mostly used. The change of surrounding rock is not revealed using two-dimensional model, which doesn't consider space effect during tunneling process. The interaction of two separate tunnels isn't also considered by single tunnel model. So, it is more reasonable for two separate tunnels analysis using three-dimensional model.

In this paper, the three-dimensional model of east Mao Mountain tunnel, on the Ning-Chang highway, China, is founded. The construction schemes and sequences under Class III surrounding rock is simulated using FLAC^{3D} software. The reasonable construction scheme for large-span highway tunnel is recommended and the corresponding stability of the surrounding rock is evaluated.

2 BACKGROUND OF EAST MAO MOUNTAIN TUNNEL PROJECT

The east Mao Mountain tunnel is a typical large span tunnel under complex geological conditions. It locates the highway from Nanjing to Changzhou, China. The total length of the double-direction tunnel is 513 m. It has a shape of ellipse with the maximum values of 17.33 m in width and 11.89 m in height. Moreover, the shallow overburden mostly varies from a few meters up to approximately 45 m.

The excavation scheme of east Mao Mountain tunnel is designed based on NATM theory. It adopts compound lining structure. The initial support consists of rock bolts, steel arch girder, wire mesh and shotcrete. The grouted rock bolt has diameter of 25 mm and length of 3.5 m. The distribution of rock bolt is 1 m × 1 m. The type of steel arch girder is I20a and the space is 1 m in each round. The wire mesh has diameter of 8 mm and space of 20 cm. The shotcrete is

C25 polypropylene fibre concrete, which has thickness of 23 cm. The inner lining is C30 waterproof-self reinforced concrete, which has thickness of 45 cm. The EVA waterproofing membrance are in the gap between the initial support and the inner lining.

For rock mass of Class III, the CRD tunneling method is proposed in pre-designing based on engineering analogy method. However, the bench cut method is suggested on the basis of real surrounding rock conditions during construction. It needs to be verified whether the bench cut method is more feasible compared with the CRD method.

3 GENERAL GEOLOGICAL SITUATIONS

3.1 *Stratum and lithology*

There are complex stratums in region where the east Mao Mountain tunnel passes through from west portal to east exit. The surrounding rock consists of conglomerate of Pu-kou group, cretaceous and andesite of Long-wang-shan group, Jurassic. Especially, the species of andesite are rather complex, which include andesite, tuff and cracked gravel tuff. Granitic porphyry makes inroads into andesite at some sections. The uni-axial compressive strength of conglomerate is from 33.5 MPa to 82.6 Mpa. The andesite species has mostly disintegrated structure and the uni-axial compressive strength varies from 7.6 MPa to 37.3 Mpa.

3.2 *Geological structural features*

The tunnel locates in the active Mao Mountain fault zone. However, there are few major faults crossing the tunnel alignment. But many small faults are revealed during excavation.

3.3 *Hydrological geological conditions*

The groundwater is mainly porous phreatic water and bedrock fissure-water. The quantity of groundwater is small and controlled by rainfall mainly. However, in view of the characteristics of shallow overburden, particular area with weak structural plane combination is deserved to consider.

3.4 *Rock mass classification*

According to rock mass structure, rock mass integrality, RQD index and other influencing factors, the appropriate classification of the rock mass is proposed on the basis of Code for Design of Road Tunnel (JTG D70-2004, China).The percentage of Class III is 67.3% in uplink and 88.8% in downlink. It is obvious that the surrounding rock is weak and the stability is deserved to consider during excavation.

Table 1. Physic-mechanical parameters of rock mass.

Material name	Young's modulus (GPa)	Poisson ratio	Density ($kg \cdot m^{-3}$)	Cohesion (MPa)	Frictional angle (°)
Rock mass	0.5	0.35	2300	0.1	38

4 SIMULATION AND ANALYSIS OF CONSTRUCTION SCHEMES

4.1 *Calculation model of east Mao Mountain tunnel*

As theory analysis indicates, for circular cavern in infinity homogeneous elastic media, the change of stress and displacement is less than 1% outside 5 times of excavation diameter and less than 5% outside 3 times of excavation diameter on account of load release. The error may satisfy the needs of practical engineering. Considering calculation reliability and reasonable computing time, the range of the three-dimensional model is proposed as following: The transverse computing range, that is, the central line to the side boundary, is 3 times of the tunnel span, which is actually 60 m. The vertical range is 57 m from the tunnel bottom to the model bottom. The space between uplink and downlink is 50 m according to the central line. Taking into account the shallow overburden, the upper boundary of the model reaches to the ground plane surface and the depth from the top of the tunnel to the ground surface is approximately 17 m. Considering the space effect of construction process, the longitudinal length of the model is 60 m.

The boundary conditions of the model are described as: the side-face boundaries are respectively restricted by horizontal displacement of x-axial and z-axial direction. The bottom boundary is restricted by vertical displacement of y-axial direction. The ground surface is free boundary.

The surrounding rock is modeled using zone element. The shotcrete is simulated using shell structural element. The equivalent principle is introduced to simulate the effect of supporting system, which consists of small grouting pipe, steel arch girder and rock bolts.

4.2 *Determination of computational parameters*

The surrounding rock of class III is assumed as simplex homogeneous continuous media in this study. The physic-mechanical parameters of surrounding rock are obtained from the engineering geological exploration (showed in Table 1). The parameters of C25 and C30 concrete are showed in Table 2.

The pre-supporting effect of small grouting pipe, which is treated as assistant construction measurement, is simulated by increasing physic-mechanical parameters of rock mass. The reinforced effect of rock bolts is also treated with equivalent principle, that is, by increasing Young's modulus, cohesion and inner friction angle of surrounding rock. Here, the improvement of inner friction angle is less and doesn't take into account. The Young's modulus and cohesion of reinforced surrounding rock are respectively proposed by equation 1 and 2 as following:

$$E = E_0(1 + \frac{f}{e \cdot i}) \tag{1}$$

$$C = C_0 + \frac{f}{e \cdot i}\tau_b \tag{2}$$

where $E =$ Young's modulus of reinforced rock mass by rock bolts; $C =$ cohesion of reinforced rock mass by rock bolts; $E_0 =$ Young's modulus of rock mass not reinforced by rock bolts; $C_0 =$ cohesion of rock mass not reinforced by rock bolts; $\tau_b =$ maximal shearing strength; $f =$ area of cross section of rock-bolt; $e =$ longitudinal spacing of rock bolts; $i =$ transverse spacing of rock bolts.

The effect of steel arch girder is also simulated by increasing the Young's modulus of shotcrete (Wu B. et al. 2005). The calculation method is as following:

$$E = E_0 + S_g E_g / S_c \tag{3}$$

where $E =$ Young's modulus of reinforced shotcrete considering steel arch girder; $E_0 =$ Young's modulus of shotcrete; $E_g =$ Young's modulus of steel arch girder; $S_g =$ cross section area of steel arch support; $S_c =$ cross section area of shotcrete.

Owing to shallow depth of the east Mao Mountain tunnel, the initial stress field of the model is the self-gravitational stress field. The ideal elastic-plastic model is adopted for the constitute model of rock mass, which is submitted to Mohr-Coulomb yield rule. The initial support is simulated as ideal elastic material.

Table 2. Physic-mechanical parameters of support structure.

Material name	Grade	Young's modulus (GPa)	Poisson ratio	Density (kg · m^{-3})	Thickness (cm)
Shotcrete	C25	26*	0.25	2200	23
Reinforced concrete	C30	31	0.2	2500	45

* Young's modulus of C25 shotcrete in the Table is the Young's modulus considering the equivalent effect of steel arch girder in initial support.

4.3 *Simulation of construction schemes*

According to pre-designing scheme and practical geological conditions, the bench cut and CRD method are respectively simulated. Figure 1 is the sketch map of construction sequence of them.

The excavation sequences of bench cut method can be simplified as following: step 1, top-heading excavation; step 2: top-heading initial support; step 3: bench and invert excavation; step 4: bench and invert initial support.

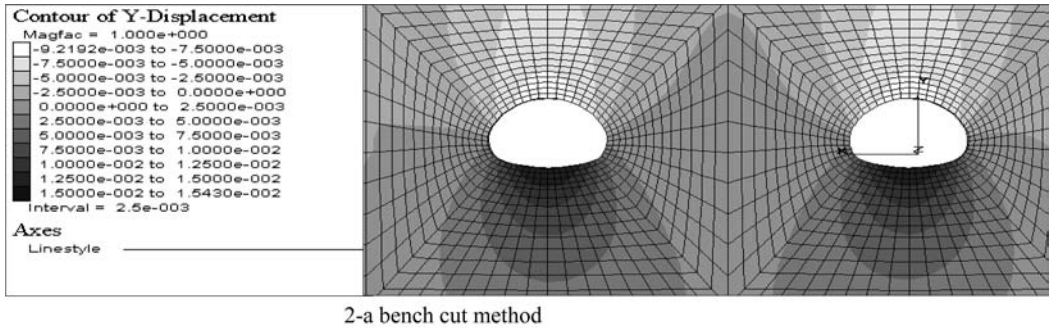
The excavation sequences of CRD method can be simplified as following: step 1: top-heading1 excavation; step 2: top-heading1 initial support and temporary support (including diaphragm wall and temporary invert arch); step 3: top-heading2 excavation; step 4: top-heading2 initial support and temporary support; step 5: bench and invert 3 excavation; step 6: bench and invert 3 initial support and temporary support; step 7: bench and invert 4 excavation; step 8: bench and invert 4 initial support.

Because of time limit for tunnel project, the uplink and downlink tunnel are usually excavated in turn in the same direction. In this study, each length of tunneling step is 3 m. The interval of each cutting face in one tunnel is 12 m. Moreover, left tunnel is excavated at first and the least interval of the advancing excavation face between left and right tunnel is 21 m. The excavation sequences with the same or reverse direction synchronously aren't simulated.

Considering the complexity of the problem, the step of removing temporary support in this study isn't simulated with CRD construction method. The inner lining is calculated by load-structure method according to the Code for Design of Road Tunnel (JTG D70-2004) and isn't simulated in this study.

4.4 *Analysis of calculation results and excavation scheme*

Considering influence of boundary conditions and space effect, the typical cross section of z = 21 m along tunnel alignment is selected. The analysis consist of stress distribution, displacement change, plastic area of surrounding rock and stress state of initial support structure. The final displacement and stress of the selected section are listed in Table 3 after excavation completed. The vertical displacement distribution of two schemes is showed as Figure 2. The minimal principle stress distribution of surrounding rock is showed



(a) bench cut method (b) CRD method

Figure 1. The sketch map of construction sequence.

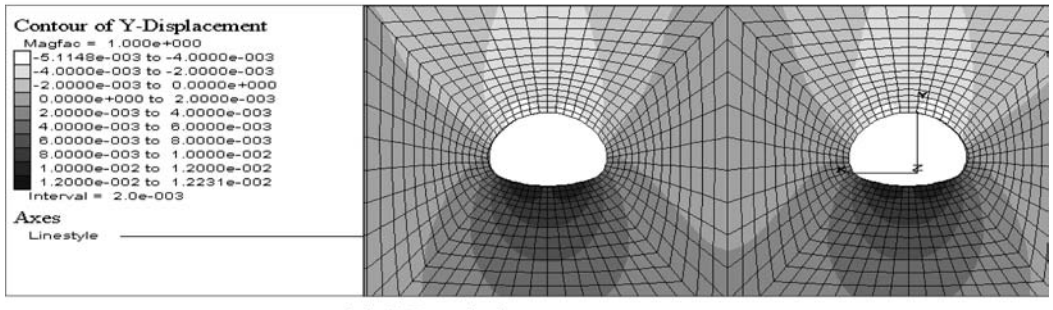


Table 3. The calculation results of two tunneling schemes.

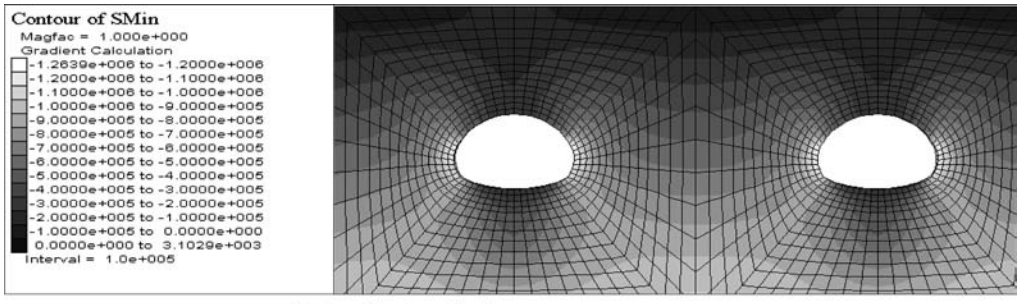
Tunneling method	The maximal settlement of arch crown (mm)	The maximal rise of invert (mm)	Principal stress of surrounding rock*		Principal stress of initial support*	
			(σ_1/MPa)	(σ_3/MPa)	(σ_1/MPa)	(σ_3/MPa)
Bench cut method	9.22	15.43	0.11	−1.26	2.42	−6.57
CRD method	5.11	12.23	0.06	−1.14	7.94	−14.75

* The rule of stress sign is that '+' denotes tensional stress and '−' denotes compressive stress.

2-a bench cut method

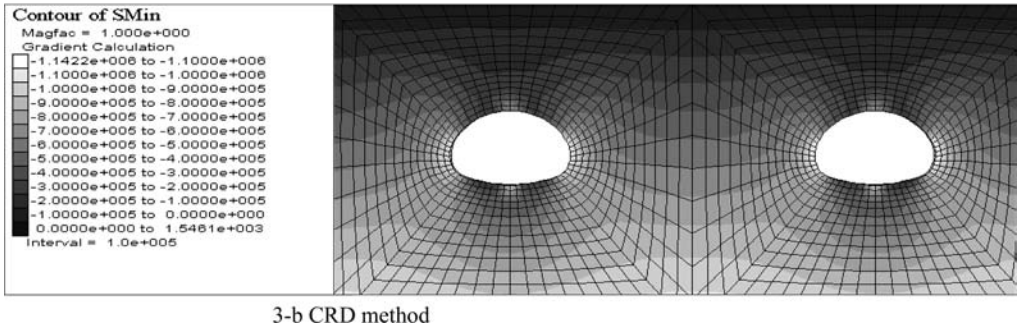
2-b CRD method

Figure 2. The vertical displacement sketch of surrounding rock.



as Figure 3. The minimal principle stress distribution of initial support structure is showed as Figure 4.

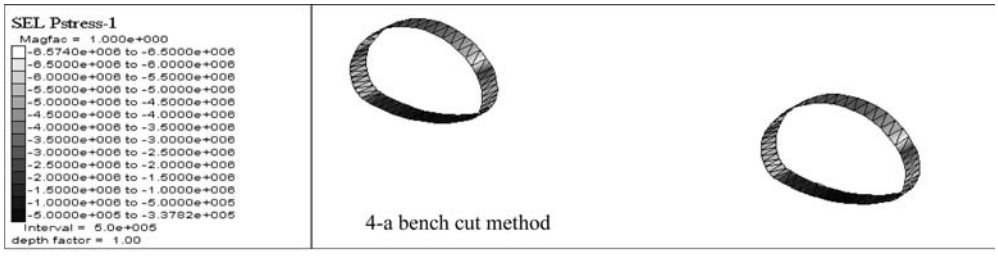
The vertical displacement of surrounding rock in Figure 2 shows that the maximal settlement of arch crown using CRD method is 55% of that using bench cut method. The maximal rise of invert arch using CRD method is 80% of that using bench cut method. It is obvious that CRD tunneling method may effectively lessen disturbance to surrounding rock and temporary support can control displacement of surrounding rock better.



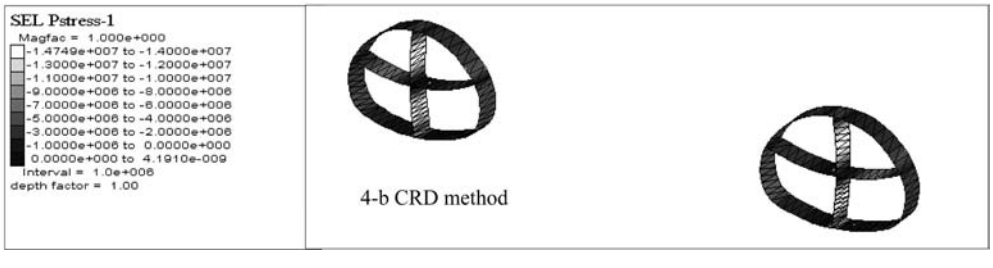
This is very important for subway construction in urban region. According to the safety of adjacent structures and residing living, the maximal subsidence of ground surface should be controlled to within 30 mm. So, the release of displacement of surrounding rock must be effectively restricted. The results of numerical simulation indicate that CRD method can do it well. But for mountain tunnel, the subsidence of ground surface isn't the primary controlling target. It is allowable that deformation of surrounding rock is tended to stability and doesn't exceed allowable deformation synchronously.

Figure 2 also indicates that the maximal settlement of arch crown using bench cut method occurs at the center of arch crown. However, the maximal settlement of arch crown using CRD method takes place at two side spandrels. This is because of the restriction of temporary support and the maximal settlement of arch crown transfers from the center of arch crown to two sides.

Shown as Figure 3, the minimal principal stress is mainly compressive stress, which is concentrated in the sidewall within 1m range. So, the surrounding rock on the sidewall should be reinforced especially to ensure safety in the process of construction.



3-a bench cut method



3-b CRD method

Figure 3. The minimal principal stress sketch of surrounding rock.

4-a bench cut method

4-b CRD method

Figure 4. The sketch for the minimal principal stress of initial support.

The minimal principal stress of bench cut method is greater 10% than that of CRD method. It is shown that the surrounding rock is lesser disturbed using CRD method because the excavating face of each round is smaller, which reduces stress concentration on both sidewall. However, the minimal principal stress of bench cut method is only 1.26 MPa, which can be endured by surrounding rock.

Figure 4 shows that the minimal principal stress of initial support structure is also compressive stress. The stress value using bench cut method isn't larger than 5.5 MPa except several parts, where the value reaches

6.57 MPa. The stress value using CRD method indicates that temporary support, especially diaphragm wall, endured biggish compressive stress, which reached 14.75 MPa. This is a baptism to initial support. However, the minimal principal stress of shotcrete doesn't exceed 5 MPa using CRD method. So we can say that displacement of surrounding rock is effectively controlled, which is obtained at the cost of biggish compression bearing by temporary support. Reinforced temporary support, especially diaphragm wall, is the primary task to ensure safety and stability.

All the analysis above indicate that the stability of surrounding rock itself is the primarily concern for bench cut method. The displacement of surrounding rock is biggish. But the stress of initial support structure is lesser. So, the initial support system can be properly decreased and cost can be saved. Comparatively, the stress of surrounding rock can't effectively be released using CRD method because initial support is in the wake of excavation and closed to ring at each stage. Although displacement of surrounding rock is lesser, biggish compression is acted on initial support. So cost of reinforcing initial support must be increased and it isn't economical for mountain tunnel.

Considering construction convenience and economic rationality, bench cut method is better appropriate construction method for big-span highway tunnel under Class III surrounding rock conditions, which can exert self-bearing capacity of surrounding rock. However, CRD method, which may effectively control surface subsidence, is more reasonable for city subway.

4.5 *Evaluation of selected excavation scheme*

According to the analysis mentioned above, the bench cut method is selected as the excavation scheme for east Mao Mountain tunnel. Moreover, the displacement, the maximal principal stress and plastic zone of surrounding rock are simulated as well as the former analysis.

The stress distribution and deformation characteristics of typical cross section can be summarized as following:

- The vertical displacement of surrounding rock using bench cut method for big-span tunnel primarily occurs at crown and invert area. The horizontal displacement on sidewall is very small.
- The maximal principal stress of surrounding rock is mainly compressive stress. The tension stress occurs at arch crown, invert area and near ground surface. But tension stress is small except near ground surface, where tension stress reaches 0.11 MPa.
- The plastic failure of surrounding rock is shear failure and no tension failure. Biggish plastic zone takes place at the intersection between invert and sidewall, sidewall and arch crown. The maximal depth of plastic zone is approximately 2.5 m. The length of rock bolts is 3.5 m for initial support. The plastic zone doesn't exceed the reinforced range of rock bolts, so the initial support design scheme is reasonable.

Above analysis indicate that surrounding rock is stable and the bench cut excavation is reasonable construction scheme for the east Mao mountain tunnel.

5 CONSTRUCTION TEST OF EXCAVATION SCHEME

During the process of excavation and support workings, the continuous field stress and deformation monitoring are conducted. The measurement data show that the maximal settlement of arch crown is approximately 5 mm, which is less than the simulation value. That is because of the installation of monitoring points was slightly delayed. Generally speaking, the monitoring data accord with the results of theoretical calculation. It indicates that the surrounding rock of east Mao Mountain tunnel is stable and the selected construction scheme is reasonable.

6 CONCLUSIONS

The three-dimensional numerical simulation shows that different excavation schemes have significant impact on tunnel stability and deformation. So the optimal construction scheme should be selected before construction, especially for poor rock conditions.

In the case studied for the east Mao Mountain tunnel, the bench cut method is a better scheme than CRD method, as the former takes a much shorter time to complete the opening and the initial support may be properly decreased. The numerical results also accord well with the field results. It is hoped that this case study will provide a good reference for the design and construction of similar tunnel engineering projects.

Introductory tunnel design – Lining types and selection: A case history of large span soft ground tunnel design

B.F. Townsend
Hatch Mott MacDonald, LLC

C.R. Speers
Arcus Gbb

ABSTRACT: This paper presents a general design methodology for linings. *Inter alia* it discusses typical lining types and functions and factors governing the selection of a lining, geometrical considerations, ground and groundwater considerations, loadings acting on linings, lining-ground strength-stiffness interaction, allowable working stresses, factors of safety, load factors, etc, and presents strength design and serviceability design approaches. A case study is presented in the form of the design of a final lining for a large diameter railway tunnels, excavated in extremely saturated weak ground using sequential excavation and support methods.

1 INTRODUCTION

This is the second in a series of papers addressing practical tunnel lining design. The format for this and future papers is to present a particular topic and support the presentation of the guidelines by the practical application of a case history. The primary intent is to provide guidelines for the geotechnical and structural design of tunnels where the tunnel size and/or ground conditions dictates that systematic support of the excavation is required following each increment of excavation. This method of tunneling is commonly referred to as Sequential Excavation and Support (SES) and is also commonly termed the New Austrian Tunneling Method (NATM).

The authors developed the design guidelines from experience gained over the past two decades during the design and construction of several major railway, highway and water-transfer tunnel projects in Africa and Asia. During this time it has been possible to compare the performance of the as-constructed structures to the predicted performance as given by the design process. Excavation was typically carried out in widely varying ground conditions (weak-bedded rock, jointed hard rock, and soil-like poorly cemented rock with groundwater). It is therefore intended that the design guidelines could be applied, in general terms at least, to any tunnel excavated in any ground mass condition with any ground material type (hard rock, soft rock, bedded rock, soft ground, and soil) with or without ground water.

This paper is a continuation of the introductory paper that defines the scope and a brief outline of the design issues that are required for lining selection and may be presented in detail in later papers.

A tunnel is a relatively long horizontal or near horizontal opening located below ground surface (underground), typically for the purpose of transportation of one form or another, for example, of water, sewerage, utilities, road or rail traffic. The construction of a tunnel is in most cases carried out by underground excavation that commences at one or more tunnel entrances termed portals. This type of tunnel is often referred to as a "mined tunnel". In some cases, normally in low cover areas such as less than 15 meters, and as an example close to the portals, the tunnel is constructed in open cut and then backfilled to restore the original ground line as close as possible. This type of tunnel is called a "cut-and-cover tunnel". The content of this paper is focused on mined tunnels and lining requirements.

2 GENERAL

The mining of an underground opening introduces a new stress boundary condition in the ground in that the ground stresses are significantly changed along and adjacent to the boundary of the opening. The normal and shear stresses on the boundary reduce from their original pre-construction *in-situ* values to zero. In the ground immediately inside from the excavation

boundary the stress at right angles to the excavation boundary is also reduced to zero but the stress tangential to excavation boundary increases considerably to a value that typically depends on the ratio of the original vertical and horizontal stresses at that point in the ground. For example, if the original vertical and horizontal stresses were equal, the induced tangential stress in the ground will be twice the original stress. However, if the original horizontal stress was twice that of the vertical stress (for example, in over-consolidated sediments), the induced tangential stress will be five times that of the original vertical stress. These stresses are given by equations originally derived by Kirsch (1858) and are based on the assumption that the ground material is perfectly homogeneous, isotropic, linearly elastic with an infinite strength in both compression and tension.

In most cases the ground material will not act in this manner due to the following two factors:

(1) the ground is not homogenous, isotropic and elastic but rather contains incipient planes of potential weakness, in the form of bedding planes and geologically-induced fractures caused by cooling of rock, shrinkage of soil, etc (normally called "joints"), fault zones, shear zones, etc; and
(2) the intact material itself (that is the material between the joints) has a limited strength.

Depending on the original stresses in the ground relative to the respective strengths of the intact material and joints, two typical types of failure of the ground can be expected:

(3) shear or tensile failure of the intact material; and
(4) shear or tensile failure on the joints.

The combined action of the intact material and the joints determines the ground mass behavior, which is typically non-linear, resulting in an inward displacement, commonly termed "convergence", of the tunnel boundary that will continue with time until a collapse of part or all of the ground around the opening will occur.

In order to prevent such potential failure the opening boundary requires that it be supported. The support, which can vary greatly, depending on the ground or rock mass strength relative to the induced ground stresses and other loads, from light support comprising for example nominal "spot" or "random" widely spaced ground bolts, to a medium lining comprising reinforced shotcrete, to heavy support comprising for example heavily reinforced concrete, prestressed concrete or steel. The applied support may be termed as "tunnel lining" or simply "lining". Notwithstanding its support function, a lining can often be used for non-structural reasons, for example for hydraulic reasons, etc.

3 LINING TYPES FUNCTION AND SELECTION

Tunnel linings may be classified in a number of ways, for example as follows:

- In terms of the lining function
- In terms of permanency (temporary or permanent)
- In terms of timing of their application in relation to excavation phase
- In terms of the lining material
- In terms of load bearing capacity
- In terms of durability

No matter how the lining is termed, each of all conditions must be evaluated in relation to not only each above mentioned requirement but in terms of cost, schedule and constructability.

Tunnel lining types usually considered are typically constructed from the following:

- Cast-in-Place Unreinforced Concrete
- Cast-in-Place Reinforced Concrete
- Spayed Shotcrete (w/ or w/o Steel Fibres)
- Precast Reinforced Concrete Segments
- Steel Liner Plate
- Spheroidal Graphite Iron Segments

Combinations of these types of linins are possible and sometimes required based on project design and in-situ conditions.

3.1 *Lining function*

The type of tunnel to be designed and constructed often defines the requirements. Generally there are five (5) types of tunnels and each category generally has its' own specific requirements for functionality. The most common types of civil works tunnels are:

- Road Tunnels
- Railway Tunnels (Mass Transit, Commuter, Freight, High Speed)
- Hydraulic Tunnels (Water, Wastewater, Storm Water, Head/Tail Race)
- Utility Tunnels
- Pedestrian Tunnels

Each of the above tunnels generally require a clear statement of performance requirements regarding but not limited to the following:

- Tunnel cross-section(s) (twin bores versus single bores)
- Tunnel Orientation
- Alignment (horizontal and vertical)
- Portal Locations
- Structure gauge/size
- Water Tightness / Leakage
- Ventilation/Purging
- Drainage

- Design Life
- Durability
- Lighting
- Power
- Aerodynamics
- Noise
- Vibration

As described above, a lining is normally required to provide support to the surrounding ground, i.e. it must carry the ground loadings and provide sufficient pressure to the ground to prevent ongoing convergence ultimately leading to rupture of the ground and fall of ground into the opening.

However, in many cases, the lining may be primarily required for reasons other than that of support of ground. For example, in water transfer tunnels, a final concrete lining is often specified for hydraulic reasons to reduce friction losses, for durability reasons (loss of the ground through the ongoing action of the water), or to prevent water leakage into the surrounding ground.

A careful definition of a lining's function/functions is required before a selection of the lining type is made.

3.2 *Geometry requirements*

Once the "User" defined requirements identified, there are always select issues which need to be accounted for in the design which will adequately allow sufficient space to construct the final tunnel structure following the excavation and support phase for SES/NATM type of tunnels.

There are several major design decisions which must be identified and resolved prior to the excavation phases such as:

- Pressure Design Requirements (if not environmentally required)
- Allowance for Outer lining Installation and Deformations
- User Requirements such as:
  - Ventilation Requirements
  - Alignment Constraints
  - Water Tightness Criteria
  - Emergency Egress & Niches/Laybys
- Constructability Requirements for Excavation and Lining Installation

It is extremely important that there is a complete and full understanding of how these issues relate to the determination of the tunnel excavation opening size. Once a tunnel excavation is underway, it is very difficult and costly to have to increase the size of the existing opening as a result of a design errors or omissions.

3.3 *Lining permanency*

A lining can be temporary or permanent depending on a number of factors such as the excavation method, lining type and timing of installation in relation to the excavation phase, costs, etc. For example, in a rock tunnel excavation using drill and blast or in soft ground tunnel excavation using sequential excavation-support methods, the largest cost of the completed tunnel is that of the excavation phase. In order to minimize this cost it is important that the tunneling advance rate be as fast as possible subject to proper effective stabilization of the tunnel being implemented. For this reason relatively rapidly applied lining methods that provide minimum initial support are used. These would vary from light bolting in strong rocks with widely spaced joints or highly cemented hard to stiff ground, to medium bolting with shotcrete in weaker rocks/round mass, to lattice girders or steel arches covered with thick mesh-reinforced shotcrete and closely spaced dowels in soft ground open face tunneling without a shield. Following completion of the excavation and installation of the initial support, which is often referred to as the "outer lining", typically a second lining is added for reasons of permanency in terms of durability, seepage, etc. In this case the outer lining is often designed using a lower factor of safety, subject to the correct use of monitoring to confirm ground stabilization and ensure tunnel safety and then the final lining is designed according to standard norms of structural practice. This method of tunnel lining construction is often referred to as a "two pass" lining system.

It is also possible to provide a permanent lining immediately following excavation, i.e. a "single pass" lining system is used, if a tunnel-boring machine ("TBM") is used or selection of precast elements are to be used for typical SES/NATM methods.

For a TBM excavated drive, this construction method consists of erecting rings of reinforced pre-cast concrete segments from within a double shield type machine. Provided the segments are properly backfilled with grout or pea gravel at a suitable distance behind the shield and provided with gaskets, if waterproofing is a design issue. The installed rings can serve the dual function of initial stabilization of the ground and final permanent lining.

The choice of this type of lining is dictated by the choice of the tunnel excavation method using a TBM, which in turn is often dictated by other factors. For example, the use a tunnel boring machines in relatively large size and short tunnels in good ground is not economical, but in relatively small and long tunnels in the same ground or in saturated soft ground, it could be a viable method of tunnel construction. Another example might be in urban tunneling where drill-blast may not be permitted or where the groundwater table may not be lowered. In these cases, a tunnel-boring machine may be the most desirable method of construction the tunnel. This is the extent of discussion on TBM driven tunnels as this is considered a separate topic.

However, precast segmental liners are not only used with TBM driven tunnels. These liners often constructed from Spheroidal Graphite Iron (SGI), steel liner plate or precast concrete segments may be used in smaller drives or complex arrangements where special openings or alignment curvatures are required.

3.4 *Lining application timing*

A lining applied at or close to the excavation face has been referred to in a number of ways, for example "initial support", "primary support", "outer lining", etc. The term "initial support" is the preferred terminology; as it leaves no uncertainty about its main role, initial stabilization of the opening. Depending on how effective this initial support proves in meeting its main requirement, there is an opportunity to add additional support further behind the excavation face. The term "primary support" is not recommended as it could be construed to mean that it is the most important part of the final completed tunnel lining and that may not be the case depending on the requirements of the tunnel and the permanency of the initial lining.

In two-pass linings systems the second lining is often referred to as a "secondary" lining, as it is placed as a second lining, or as an "inner lining", as it is placed inside the initial lining. If the initial lining is discarded as part of completed tunnel lining, the second lining is often referred to as a "final lining". Terminology is often project related, but it is important to understand the primary roles of each lining type and the following is recommended:

- The "initial lining" must stabilize the opening (limit all ground movements) and provide safety and security, which must be confirmed by ongoing tunnel convergence monitoring. Depending on the design of the initial lining with respect to stresses, deflections and durability, the initial lining may or may not form part of the completed tunnel final lining system.
- The "final lining", whether it incorporates the initial lining or not must provide the permanent support of the tunnel against all applied loads.

It is typically permitted to assume that the outer lining, unless located in an aggressive water environment, could support part of the ground load, depending on the relative stiffness. In the event that the initial lining is used as part of the final lining the following rule is a good starting point for the determination of load bearing capacity allocated to each lining type.

Shear interaction should not be considered unless special provisions have been made for shear transfer from the outer lining to the inner lining. However, generally the benefits of ground support from the outer lining are ignored in designs due to the small contribution to overall lining stiffness. The following is a recommended distribution of stiffness between the inner and outer linings if the outer lining is to be used to support part of the total ground load.

$$EI_{\text{shotcrete lining}} + EI_{\text{inner lining}} = EI_{\text{total}}$$

$$P_{\text{ground}} \times \left(EI_{\text{shotcrete lining}} / EI_{\text{total}}\right) = P_{\text{shotcrete lining}}$$

$$P_{\text{ground}} \times \left(EI_{\text{inner lining}} / EI_{\text{total}}\right) = P_{\text{inner lining}}$$

where:

- $EI_{\text{shotcrete lining}}$ is flexure stiffness of shotcrete lining
- $EI_{\text{inner lining}}$ is flexure stiffness of inner lining
- EI_{total} is flexure stiffness of shotcrete lining + inner lining
- P_{ground} is the total ground load
- $P_{\text{shotcrete lining}}$ is part of the ground load acting on the shotcrete lining
- $P_{\text{inner lining}}$ is part of the ground load acting on the inner lining.

3.5 *Lining materials*

Typically, when a two-pass lining system is used, initial linings comprise various combinations of support elements that can be installed rapidly, such as shotcrete, rock bolts, ground dowels, etc, so that the cycle time can be minimized and thus the tunneling advance rate maximized. In this case, final linings would be cast-in-place concrete, with or without steel reinforcement, depending on whether tensile strains are induced by the applied loads; post-stressed concrete; or steel linings.

Typically, when a one-pass lining system is used, the lining would comprise bolted pre-cast segmental linings placed within a shield near the tunnel face followed by grouting of the annulus at a short distance behind the erection area.

4 SELECTION OF FINAL PERMANENT TUNNEL LININGS

4.1 *Geometric considerations*

In terms of lining design and tunnel stability the best shape for a lining is circular as it is the best shape structurally and minimum, if any, bending moments and thus shear forces would be induced by the applied loads. However, in many tunnel cases, the final lining is not fully circular, often for reasons relating to the excavation phase and economy. For example in traditional drill-blast excavation of a rock tunnel or sequential-support excavation of a soft ground tunnel, the tunnel invert is often made flat or near flat to facilitate rapid mucking out of the excavated material and thus maximize the tunneling advance rate.

In these cases the final lining would be non-circular over the invert section of the lining and often, depending on the applied loads, steel reinforcement may be required in the cast-in-place concrete for strength.

For high loads the geometry may be used to limit bending moments in the liner and to increase axial thrust which would be considered beneficial to the liner design.

4.2 *Ground and groundwater considerations*

Fundamentally, as described earlier, the main reason for a lining is to provide long-term stabilization to the excavated perimeter. Thus, the weaker the ground relative to the stresses induced by the excavation, the higher the ground loadings acting on the lining will be. Conversely, in competent ground the structural demand on the installed lining would be lower than in weaker ground.

In cases where there is a high groundwater table, the final lining can be required to perform in one of two possible ways; firstly as an undrained tunnel whereby the lining must be able to resist the maximum possible groundwater that could act on the back face of the lining; and secondly as a drained tunnel whereby pressure relief is provided such that no adverse groundwater pressures can develop on the lining back face. The latter implies that a residual pressure may act on the tunnel lining even when designed as a drained tunnel.

The development of groundwater pressure with time is dependent on factors such as the rate of recharge of the ground and the permeability of the ground. For example, in poorly consolidated sand-like sediments such as in the western coastal plain of Taiwan, the void ratio of the sediments is typically 0.5 and thus the permeability of the ground is relatively high. With sequential-support excavations the driving of the tunnel typically requires that the groundwater table be lowered ahead of the tunnel face. After completion of the tunnel drive and final lining installation, the groundwater would tend to recover to its original elevation in the case of a fully undrained tunnel. On the other hand in highly consolidated hard mudstone in the Karoo Sequence in Southern Africa the ground permeability is so low that the tunneling may not materially affect the groundwater table. Nevertheless, with time after completion of the tunnel final lining, groundwater pressure may develop on the back face of the lining.

5 CONCLUSION

Further issues regarding individual lining types will be presented in later papers. However this paper is provided to present the basic issues and option related to tunnel lining selection and design. The are many issues regarding ground loading and groundwater drainage requirements that will influence how the liner is required to perform. Among issues to be discussed in future papers is the selection of appropriate load factors to e used in ultimate strength design of reinforced concrete liners as well as the liner stiffness and the development of tunnel liner load.

However, this paper has presented in introduction to liner selection and the factors and use of terminology that need to be considered in the tunnel design process.

Effectiveness of zonal ground mass pre-stressing round an opening at grouting

K. Vojtasik & J. Aldorf
VŠB–Technical University of Ostrava, Ostrava, The Czech Republic

ABSTRACT: The ground changes due grouting find out their impact not only on the area touched just by grouting material but go beyond penetrated area. The explanation of the outside impacts resides in the volumetric expansion getting on penetrated ground. Non penetrated ground is subdued to compaction and state strain-stress is altered too (pre-stressing). The article reports knowledge regarding the quantitative and qualitative state strain-stress changes beyond penetrated area and what next circumstances of grouting technology are working essentially upon these changes. The findings are benefited finally to boost ground stability round an opening.

1 INTRODUCTION

The modification of ground became a routine practice to pass over the unfavourable circumstances have been met in geotechnical constructions such as insufficient strength-strain properties of ground, permeability and so on.

The grouting of ground is classified as one of the major method that has branched out to many mutations to cope with the operative objectives and nature of the ground conditions.

The fundamental idea of grouting is in favour of ground which is mostly faulted and split in particles with free voids (pores, fissures) in the between of them. The voids are not just cause of ground weakens but a likely track of grouting medium to flow through. In this manner a grouting medium simply penetrates the ground, fills voids in. After mediums hardening ground gets for new qualities. A cohesionless soil aggregates and becomes cohesive, a low strength-strain properties of weak rock intensifies and a faulted rock mass turns up to a continuous unit. The water permeability of ground decreases in proportion to the degree of void saturation with grouting medium. The ground is penetrated with a grouting medium in first hand and this area and their changes in it noted above are usually taken into account as a tangible result we wish to achieve.

The grouting of the ground is very much complex process featured of a few phenomena such as flow progression of grouting medium through ground voids. The velocity, pressure, operating period, pumped volume of grouting medium as well as material transformation change from liquid to solid state of grouting material are significant constituents not being involved satisfyingly into account. They strike not only the penetrated area but they are essential on changes of condition round penetrated area.

The article pursues the grouting volume increase effect occurring in penetrated area on the adjoined non penetrated ground. There are also envisaged the ways to put to use the detected findings within the field of underground constructions.

2 PROBLEM ANALYSIS

2.1 *Fundamentals*

The pre-stressing of the ground by means of the grouting is executable only in grounds being apt to absorb uniformly grouting medium around a source of the grouting medium (grouting borehole). As representatives of these may be shown cohesionless porous soil, backfill, crushed hard rock. The component unit of these grounds may be found in softened state. The forces and stress-strains on boundary points and planes between the units of ground are relaxed. A ground in such state is prone to collapse as it comes on when circumstances are fit to. This unfavourable state of ground its low shear-strength and strain parameters are changeable. They all can be raised up and preserved in the end embodying measurements which are capable to bring about change in stress-strain state of the boundary points and planes between the units of ground. The ground units lock tightly in and compact those in also.

The grouting technology seems to be a tool to achieve the wanted change of a softened ground in its stress-strain state and compaction.

The pre-stressing of ground is based on grouting technology. It supposed to run grouting in several steps and on different grouting regimes.

The first grouting step has to set up the area of a regular circular shape penetrated by a grouting medium filling up voids around a grouting borehole. The units of ground should be glued partly within this area. After the first step there is made a new structure body in the ground. This body is bounded and detached sharply by the boundary line from the rest of ground. It differs from those part of ground non touched by grouting material in the manner it will act in the second grouting step.

The second grouting step is intended to star up increasing volume of grouted area. The pressure of grouting material fed in this step dilates cracks and the partly glued ground units shift in the flow direction of grouting medium.

The pre-stressing shift impulse comes into being on the boundary line and it goes from here over to the non penetrated units of ground. The ground units behind the boundary line close to this one are compacted. The ground units lying far-away the boundary line are only press together (pre-stressed) more intensively than they were before. The same effect of pre-stressing is in progress also in the compacted zone. The enhancement of stress-strain parameters of ground is due the compaction and the value increment of the normal stress on the contacts between the ground units. The pre-stressing is more significant than the compaction for being throughout the ground around penetrated area and spreading more deeply the ground than the compaction.

2.2 *Ground pre-stressing analysis*

A ground behavior under circumstances of pre-stressing has been neither investigate in detail yet nor sufficiently clarified and also it fails any quantitative findings at all.

The pre-stressing of ground is a complex process conditioned by many factors. Generally the factors split in two substantial groups regarding the possibilities to handle them.

The first group encompasses the conditions met in ground. They have to be identified and next evaluated reliably. Any lapse made in this group brings about the unavoidable failing in operation. The learned facts have to be taken into account and a it can't then change subjectively in any significant manner.

The second group takes the wide spectrum of grouting technology aspects in. Each of them can be modified to get the best outputs.

The following topics have a decisive signification for pre-stressing of ground.

– Grouting medium. Two various grouting mediums in each step of pre-stressing grouting operation are supposed to be used. In the first step the grouting medium has to penetrate uniformly the ground and fill all its voids in. A regular cylindrical or conic solid body should be made in ground. The volume of grouted area doesn't grow in this step. The second grouting step has to start before the first step grouting medium solidifies and cements a ground units together firmly. It has to cause a volume expansion and to hold grouting pressure till it hardens. It effects only the penetrated area at first step.
– Parameters of grouting procedure. Alike the grouting mediums there are two different regimes to put grouting medium to ground considering the medium's qualities and the performance they have to do. The grouting pressure for both grouting steps is governed by hydraulic features of ground and mediums. In the second step grouting pressure takes extra into the account the desired value of pre-stressing.
– Design of grouted area and attained value of pre-stressing. The design of pre-stressing compounds the above discussed factors within the context of looking for an accord between them with respect to intensify a ground quality. There are several issues to be thought out as the size of ground penetrated area the impact radius of efficacious pre-stressing in ground and the value of attained change at ground. Beaten track to start surveying such issues is mathematical modeling. The following paper section shows a few outputs detailing the last reported issues.

3 MATHEMATICAL MODEL

A survey on some essential pre-stressing phenomena was carried out by 2D FEM model (PHASE2D) see figure 1. The situation contains the basic objects taking part in pre-stressing. They are borehole, grouted area, plain ground, forked cracks put in the grouted area. Other necessary conditions are chosen the simplest. The zero primary strain state, isotropic elastic material represents both the ground and penetrated ground, values of elastic modulus are related by multiplier. The start value of ground elastic modulus equals 100 MPa. The pressure of grouting medium with inside the cracks is in keeping with real grouting pressure values and it equals 10 MPa. The grouted area extends from borehole to distance of 0.3 m deep into ground. The model calculates only the second step referring to the pre-stressing volume expansion.

4 MODEL CALCULATION RESULTS

The diagrams presented in figures below summarize results of the parametric calculation aimed to

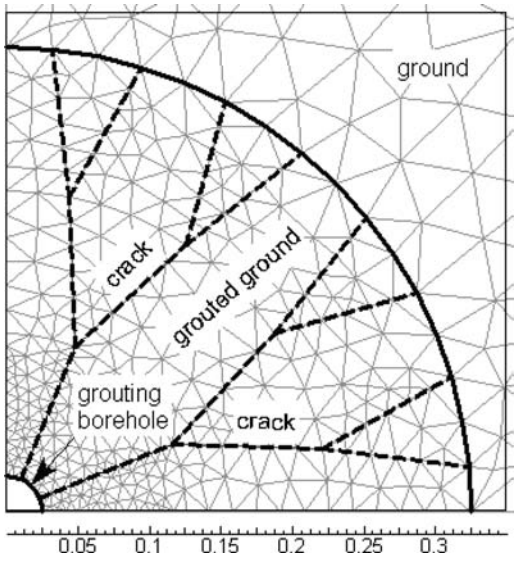

Figure 1. The analysis model – detail showing the concept of a mathematical simulation of a volume change at the grouted area.

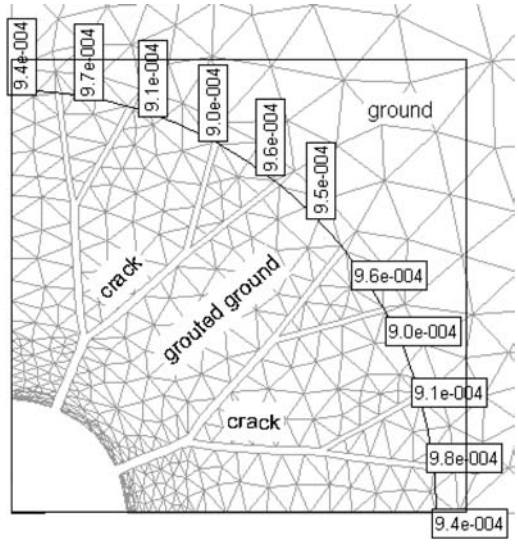

Figure 2. The displacements on boundary line between the grouted ground area and non grouted ground [m].

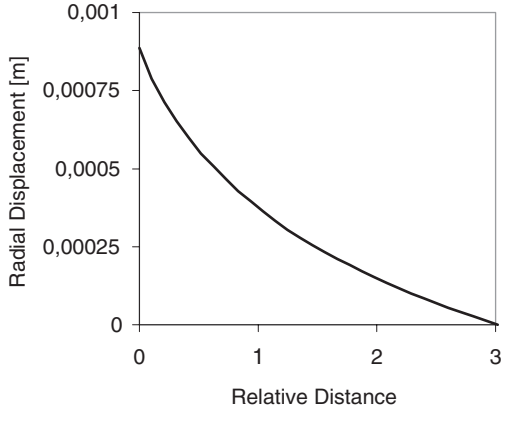

Figure 3. Radial displacement in non penetrated area. (Note: Relative Distance = Real Distance/Thickness of penetrated ground area; Thickness of penetrated ground area equals 0,3 m).

investigate the development of impacts of ground pre-stressing. Especially an accent is put on the ground movements at grouted area boundary line and on the dependence of ground movement off penetrated area. Analogously to ground movement attention is paid to ground stress changes on the identical areas. The insight into both dependencies is significant to pre-stressing feasibility evaluation.

The figure 2 displays the values of displacements on boundary line between the grouted ground area and non grouted ground.

Graph at figure 3 tracks development of displacement in non penetrated ground in radial direction starting at boundary line.

Development of radial and circumferential stresses on the identical line as previous dependency is brought in figure 4.

5 IMPLEMENTATION

The employment of ground pre-stressing in underground construction practice illustrates figure 5. The ground surrounding the underground opening is usually grouted continually to form a shall stabilizing the hanging wall. Implementation of the pre-stressing doesn't necessitate a continually grouted area to achieve the stabilizing effect. The ground is grouted in discrete areas and the space between them is pre-stressed. The stabilizing effect intensifies if the penetrated area is deeply fixed by the bolts or cables. The conical shape of penetrated area seems to be better than cylindrical as the pre-stressing effects are heading into the hanging wall opposite the destabilizing forces. The effects of cylindrical shape follow the tangential direction to the opening line.

6 CONCLUSION

The achieved appealing results allow to draw some principal conclusions.

– the softened ground seems to be capable to be pre-stressed by means of grouting technology

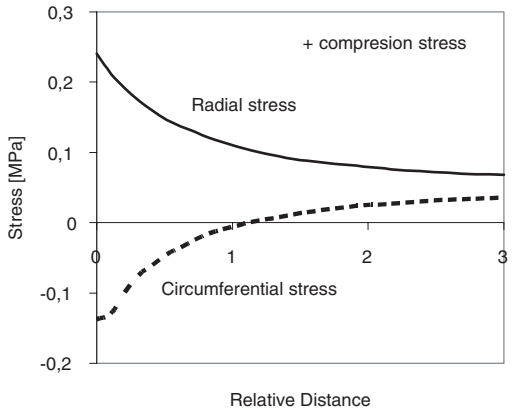

Figure 4. Radial and Circumferential stresses in non penetrated area.

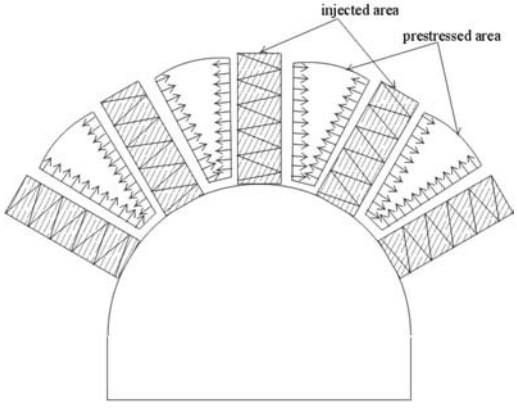

Figure 5. The implementation of ground pre-stressing to stabilizing the hanging wall of an excavation.

- the fundamental cause for pre-stressing of ground by means of grouting technology is volume expansion at grouted area.
- in non penetrated ground area the ground units may be compacted at section in which the circumferential stress causes tension (fig. 4).
- all over the non penetrated ground area the increment of radial stress causes the pre-stressing. Intensity of pre-stressing wanes gradually in dependency of distance form boundary line of penetrated ground (fig. 3).
- an intensity of ground pre-stressing depends on the value of the grouting pressure.
- an intensity of ground pre-stressing depends as well upon the ratio of elasticity modulus ($E_{grouted\ ground}/E_{ground}$). The higher it is this ratio the more intensive it is the pre-stressing of ground. The value of this ratio doesn't extend significantly the intensively pre-stressed area.
- an extend of intensively pre-stressed area is proportional just only to a value of thickness of penetrated ground area.
- an extend of intensively pre-stressed area intensifies due to conjunction effect when the pre-stressed areas overlap. There are three lay-outs to place the grouted areas each other in. A triangle, square and hexagon lay-out.
- tracking the curves on figures 3 and 4 showing the development of displacement a stresses it can be established the value of effective distance between the two neighboring grouted areas. The distance seems to be the double of the thickness of penetrated ground area. This distance guarantees the pre-stressing efficiency in the ground.
- a quantitative evaluation of ground pre-stressing isn't possible to achieve only on model calculation now owing to problem complexity.
- the ground pre-stressing is applicable in geotechnical practice. Its effects is necessary to assess first of all following the monitored values on real situation and subsequently to use them in model calculation as inputs data (back analysis).
- the pre-stressing was applied to stabilizing a mining drift traversing heavily faulted shift area.

ACKNOWLEDGEMENTS

This paper is part of a research program provided by Czech Grant Agency under No. GACR 105/05/2712 "Construction of shallow galleries in territories affected by mining activities". The authors greatly appreciated this support.

Geotechnical model for pipe roof supports in tunneling

G.M. Volkmann
ALWAG Tunnelausbau GesmbH, Austria

W. Schubert
Graz University of Technology, Institute for Rock Mechanics and Tunneling, Austria

ABSTRACT: Pipe Roof Support systems have increasingly been used in weak ground tunneling although the design is often based solely on experience. The results of an intensive measurement campaign, including settlement measurements ahead of the face, were used to determine a geotechnical model for this pre-support system. The measured ground-support interaction was reproduced utilizing three-dimensional numerical calculations with FLAC-3D. This study confirmed the model created by the in situ data and clarified the influence of the design parameters on both the support effect and the ability to control displacements. This enables a more informed decision in the design stage on whether a Pipe Roof System or more cost- and time-consuming support systems must be used to guarantee the project requirements during construction.

1 INTRODUCTION

The increasing population in metropolitan areas requires a concomitant upgrade of the infrastructure. The majority of the infrastructure is subterranean, especially in congested urban areas. Due to the pre-existing structures on the surface, the construction of new projects is subject to specific restrictions such as subsidence and/or noise limitations during construction. In urban areas, the ground generally consists of sedimentary soil and/or highly weathered rock mass. Both types of ground are prone to major displacements during tunneling. These settlements control the entire design process due to the project limitations, as compliance with the design requirements may demand additional support systems including ground freezing, jet grouted columns or pipe jacking, which are time and cost intensive.

An alternative support system is the "Pipe Roof Umbrella" System, which is also referred to in literature as "Steel Pipe Umbrella" (Oreste & Peila 1998), "Umbrella Arch Method" (Kim et al. 1996), "Pipe Fore-Pole Umbrella" (Hoek, 2003), "Long-Span Steel Pipe Fore-Piling" (Miura, 2003) or "Steel Pipe Canopy" (Gibbs et al. 2002). Compared to this system the previously mentioned pre-support systems are stiffer but pipe roof systems are less time and cost intensive. These facts have led to an increase in the use of the pipe roof method without an accompanying increase in the knowledge about the ground support interaction associated with this system.

Inclinometer chains, installed parallel to the pipe roof support, were used to perform in situ measurements in order to obtain a better understanding of this support system. The measurements of the inclinometer chain were linked to the geodetical displacement measurements taken inside the tunnel and on the surface. These measurements observe the longitudinal distribution as well as the magnitudes of settlements in the crown level of the tunnel (Volkmann et al. 2003). The outcome was a geotechnical model for pipe roof systems.

Additional laboratory investigations were performed on the ground and the pipes in order to obtain their strength- and stiffness parameters. Both the geotechnical model and the parameters, describing the behavior of the applied materials, were used for the numerical investigations.

2 TYPES AND DEFINITIONS

The pipe umbrella system is one among the group of pre-support systems. The terminology for pre-support systems is not clearly defined and in order to avoid confusion with other systems a brief description is given below.

The aforementioned terms are simply descriptions of the system itself. Steel pipes, and sometimes fiberglass pipes, are installed from the actual tunnel face to the front (fore-poling system) in an umbrella or canopy shape around the area to be excavated (Figure 1).

Figure 1. West portal of the Birgl tunnel (AUSTRIA) supported by a pipe roof.

The diameter of the steel pipes is usually between 60 mm and 200 mm with a wall thickness of 4 mm to 8 mm. The length of one umbrella is generally 12 m or 15 m. The excavated length underneath (length of a pipe roof field) ranges from 6 m to 12 m. When the end of a pipe roof field is reached, there is still a part of the pipe remaining in the ground ahead of the face. This length is called the "overlapping length" of the pipe roof system.

3 SYSTEM BEHAVIOR

The observation and the interpretation of movements caused by tunneling is one of the principles when using the New Austrian Tunneling Method (NATM) (Rabcewicz 1944, Rabcewicz 1975). The observations and their interpretation are used to control the ground support interaction. Specific evaluation techniques allow the prediction of changes in the ground conditions in front of the face (Steindorfer & Schubert 1997). The support system is continuously adapted to the actual ground conditions encountered during tunneling, leading to economical construction progress. This is possible as the measurements represent the ground-support interaction and not the ground or the support reaction separately. The observed interaction is commonly referred to as System Behavior (Goricki 2003, ÖGG 2001).

The main issue with developing the geotechnical model for pre-support systems is that the geodetical survey only measures the system behavior in the already supported section of a tunnel, while the pre-support systems primarily influences the system behavior ahead of the supported tunnel. The observation of the system behavior, influenced by a pipe roof system, was enabled by performing measurements

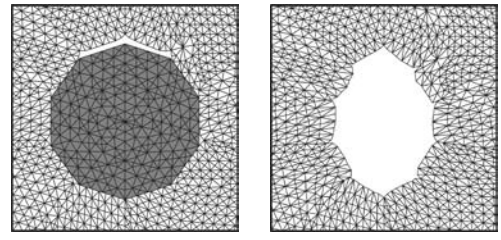

Figure 2. Result of a numerical study in UDEC on the deformation characteristic of the cased drilling system (left) and the pre-drilling system (right) (Volkmann & Schubert 2006).

with horizontal inclinometer chains, installed in the tunnel crown.

4 MEASURED BEHAVIOR

4.1 *Installation*

Conventional drill jumbos or special machines can be used to install the pipes. From the geotechnical point of view, there are two different methods for the installation: the pre-drilling system and the cased-drilling system. The significant difference is, when using the cased-drilling system the pipe follows directly behind the drilling bit providing immediate support for the installation hole. When using a pre-drilling system, the hole for the installation is drilled first and in a second step, the pipe is installed in the unsupported hole. In weak ground a pre-drilling system carries a higher risk for settlements than a cased-drilling system (Figure 2) (Volkmann 2004).

In weaker ground the stress transfer related to the drilling of the installation holes may cause the closure of the annular gap between the ground and the pipes before the excavation under the pipe roof starts. However, this closure does not result in any significant pre-stressing and hence the internal forces of the pipes are still practically zero. The initial loadings are not influenced by the flushing method (water or air) used to remove drill cuttings. However, one must consider that the use of water may result in a decrease in the engineering performance of the ground. Additionally, the fan of pipes operates as a drainage system until the pipes are grouted (Sellner 2005).

4.2 *The first meters*

The space that is needed for the installation of the next pipe roof fan requires a constant widening of the profile during the excavation of a pipe roof field. The new installation generates a ring of shotcrete at the end and/or the beginning of every pipe roof field. During the excavation of the first 1 to 3 rounds after the installation, the inclinometer measurements presented lower

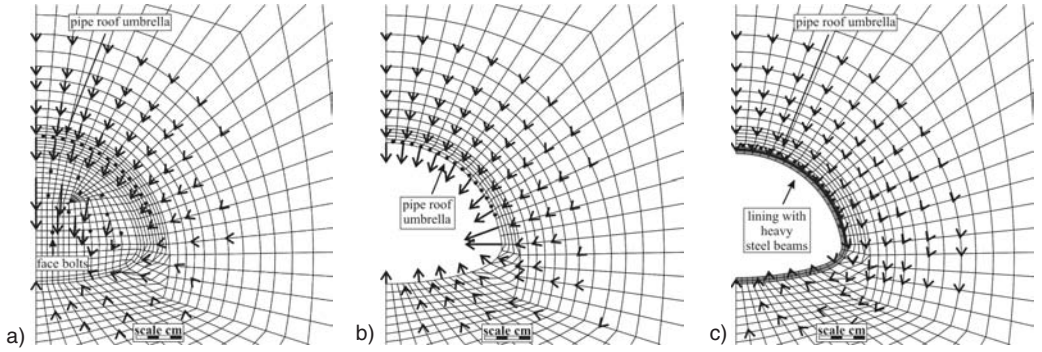

Figure 3. Three cross sections showing the displacement vectors normal to the tunnel axis; (a) 2 m ahead of the face, (b) in the unsupported span, (c) 2 m backwards in the supported section (one excavation round only).

settlement magnitudes. This observation is explained by the stiff shotcrete arch that creates a foundation for the longitudinal arching effect during stress transfer processes.

4.3 *Normal excavation rounds*

The foundation effect of the stiffer shotcrete ring decreases with distance. The data from two case studies show the following rounds of excavation induce a uniform settlement characteristic. This characteristic contains the magnitudes and positions of the measured settlement values relative to the face and the three-dimensional behavior in the already supported sections (Figure 4 for example). It depends on the strength- and stiffness contrasts between the ground and the installed support.

4.4 *Last meters*

Depending on the ground quality and the height of the tunnel, the effectiveness of the pipe roof foundation ahead of the face decreases with decreasing length. This decrease in effectiveness is associated with an increase of the settlements ahead of the face. Therefore, when the pipe roof support system is used to minimize displacements caused by the excavation a new pipe roof should be installed before the foundation effectiveness decreases. When the pipe roof system is only applied to increase the stability of the unsupported span, further rounds may be excavated as long as the stability of the face is guaranteed.

5 BASIC GROUND DISPLACEMENT

The numerical results shown in the Figures 3a, 3b, 3c, and 4 are calculated with the program "Fast Lagrangian Analysis of Continua in three dimensions" (FLAC-3D). Although the Trojane tunnel (Slovenia) was constructed in a slight hillside situation with a few buildings on the surface, the numerical model was created using the assumption that the tunnel was constructed in a topographically flat area. The selected section, with a crown cover of 15 m, was supported by a pipe roof system to help minimize surface displacements within a major fault zone (UCS $\ll$ 1.0 MPa) where distress to surface structures had been observed. The input parameters were determined by laboratory tests (ground, pipes), as well as taken from literature (ground, shotcrete) (Zlender 2003, Aldrian 1991, Müller 2001). Further information on these calculations can be found in Volkmann et al. 2006. The displacements presented in the Figures 3a, 3b, 3c, and 4 result from excavating only one 1.0 m long excavation round.

5.1 *Radial displacements*

The shown cross sections are 2 m ahead of the face (Figure 3a), in the middle of the unsupported span (Figure 3b), and 2 m backwards in the supported section (Figure 3c). All three figures demonstrate that the orientation of the incremental displacement is almost perpendicular to the shape of the tunnel in the area where the pipe roof is installed.

The maximum displacement vector in Figure 3a is about 3.0 cm but is situated in the area to be excavated later. The maximum displacement in the zone where the pipes are installed is 2.1 cm.

The displacement vectors in the unsupported span (Figure 3b) have nearly the same magnitude (2.0 cm) and are practically uniform around the upper section of the tunnel perimeter. The displacements only increase to 3.3 cm in the region below the installed pipes (lower sidewall).

Due to the very stiff support system in the supported section behind the face, the displacements decrease to 0.5 cm only 2.0 m behind the unsupported span (Figure 3c).

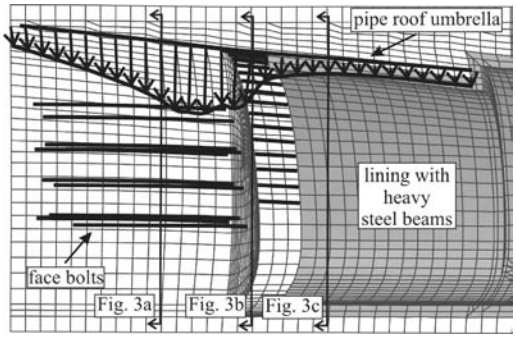

Figure 4. This longitudinal section shows the vertical and longitudinal displacement in the crown (one excavation round only).

5.2 *Distribution of displacements in the longitudinal direction*

Elastic numerical calculations normally result in 30% of the total displacements ahead of the face (Steindorfer 1998). When the stress level is higher than the strength of the ground near the tunnel the displacement distribution changes considerably, resulting in significantly higher displacements ahead of the tunnel face. The strength weakening characteristics of the material associated with the post peak behavior control these changes. This condition agrees with the measured data from the Trojane tunnel where up to 80% of the total displacements occurred ahead of the supported section in the tunnel.

Figure 4 exemplifies a calculated displacement distribution in the longitudinal section. The calculated values increase to 2.5 cm approximately 1.0 m ahead of the face while the displacement vectors in the supported section are lower than 0.5 cm. In the other direction, the settlement values start decreasing with distance.

This example shows that the displacements are orientated against the excavation direction in the sections ahead of the face, except the last 2.0 m ahead of the face. This area moves vertically or slightly in the excavation direction. In the unsupported span and in the first supported meter the displacements are orientated towards the face. The previously supported region again displaces against the excavation.

6 GEOTECHNICAL BEHAVIOR

The internal forces of the pipes are almost zero after the installation, comparable other passive support measures (rock bolts). The stress transfer, due to the previous excavation steps, has an influence on the ground and on the already installed support. The newly installed pipes are not affected by previous activities, whereas every construction process after the installation, that causes a stress transfer, starts to activate the support effect of the pipes. The displacements mainly caused by the excavation process during tunneling so the three-dimensional displacement characteristic control the activation of the support effect after the installation of the pipe roof.

Each pipe is founded in the ground (ahead of the face) as well as on the lining (behind the face) in the longitudinal- and radial direction. The strength and stiffness of the pipe roof therefore depend on both the ground properties as well as on the time dependent strength and stiffness properties of the lining (shotcrete, steel beams).

6.1 *Radial support effect*

Figure 5 presents the calculated result of the ground pipe interaction after every second excavation step. The pipes bend primarily at two positions with ongoing excavation steps under the pipe roof as long as the pipe foundation effectiveness does not decrease ahead of the face. One position in this example is 3 m ahead of the face. The second one is 1 m behind the face. These sections indicate the positions where the pipes operate as support and where the pipes transfer the loads to the ground and the lining. The supported section is between chainage 47 and 50 (for bottom line) while on both ends of this area the loads are transferred to the foundation regions. The position ahead of the face corresponds to the orientation change of the displacements shown in Figure 4. The loads are only transferred in the longitudinal direction and the pipe roof support does not create any arching perpendicular to the tunnel axis. It is therefore necessary to model each pipe individually in the numerical simulation; because in numerical calculations both a stiffer homogenized region as well as the use of shell elements would additionally cause an arch effect perpendicular to the tunnel axis. Both simplifications could lead to an underestimation of the displacements and/or to an overestimation of the stability conditions.

This pipe roof support effect is affected by the bending of the pipes so the second moment of the area defines the activation speed of the support effect by bending. Pipes with a larger diameter activate a more powerful support effect at similar displacements compared to smaller diameters. The pipe wall thickness, on the other hand, defines the critical moment and/or the maximum bending.

This example demonstrates that a pipe roof system supports the face region, the unsupported span, and sometimes a short zone at the beginning of the lining (fast excavation). The support effect decreases in these critical sections the risk against possible local or global failures associated with the tunnel face.

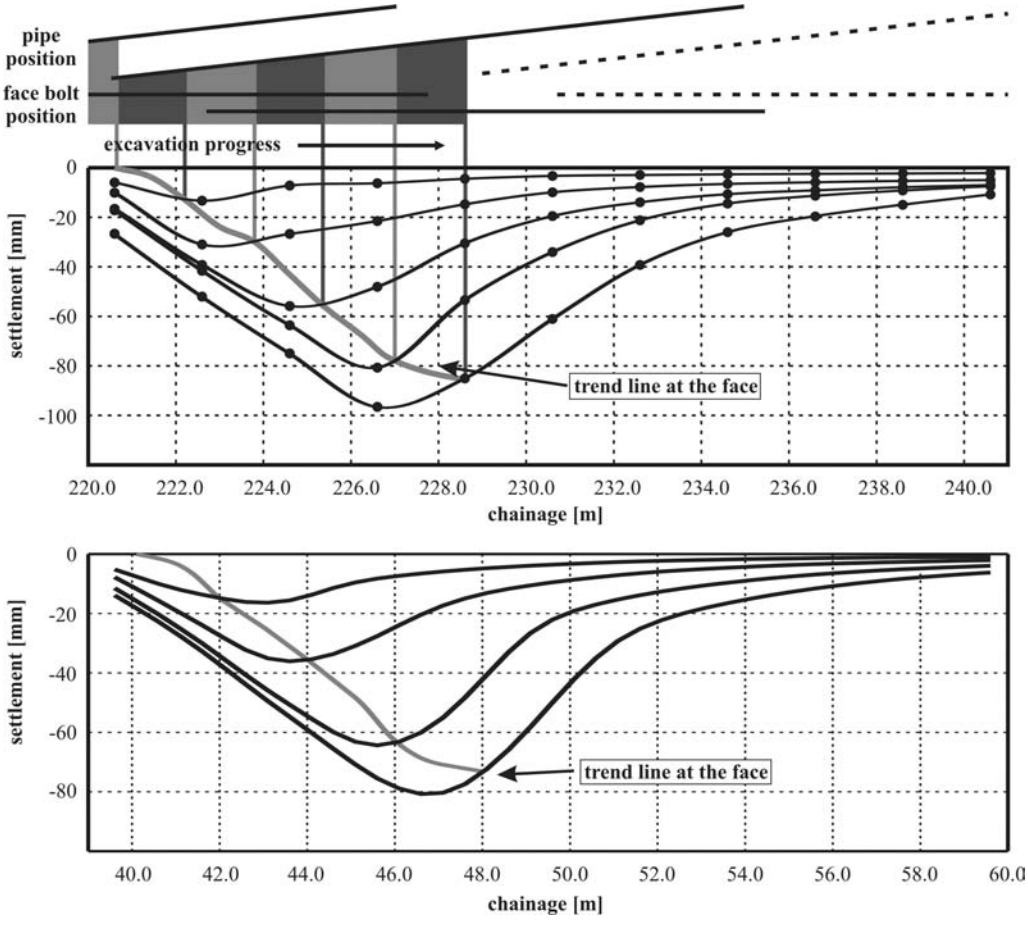

Figure 5. This deflection curve diagrams demonstrates measured settlement values from the Trojane tunnel (upper diagram) and results of a three-dimensional numerical calculation (lower diagram) after every second excavation round.

6.2 *Longitudinal support effect*

The stiffness of a steel pipe is much higher compared to the stiffness of ground that needs additional support by a pipe roof system during tunneling. The relative movements in the longitudinal direction therefore create a second support effect of pipe roof systems during excavation. The pipes are subjected to longitudinal compression. This influences the stress distribution ahead of the face positively so the displacements in the ground decrease ahead of the face.

This support effect is controlled by the area that can be used for the transfer of interaction forces so the outer pipe diameter defines the activation of this support effect.

6.3 *Pipe gap in the unsupported span*

Both previously mentioned support effects are also influenced by the number of pipes. This design parameter and the diameter of the pipes define the remaining gap in between the pipe roof pipes. A local arching effect in between the pipes (Stöckl 2002) increases the stability in the unsupported span and decreases the overbreak volume as long as this local arch can be formed.

A comparison of calculated results can be found in Volkmann & Schubert 2006. Those results explain both the effect of larger pipe diameters and different numbers of pipes on the displacement characteristic.

6.4 *Validation of numerical results*

Complex three-dimensional numerical calculations are influenced by all input parameters. These include geometric conditions, material properties, installed support systems, and time dependent changes of strength- and stiffness properties.

The comparison of the measured and calculated displacements (Figure 5) for this case study shows good

agreement ahead of the face, in unsupported-, and supported sections. This fact provides evidence that the relevant mechanisms, which occurred during the excavation of the Trojane tunnel, could be reproduced in the numerical calculations.

7 CONCLUSION

The advantages of being cheap and less time consuming during the installation, increased the use of Pipe Roof Support systems over the last few decades even though, neither formulas nor clear rules for the design of this pre-support system were determined. An intensive monitoring campaign, including settlement measurements ahead of the face at the tunnel level, enabled the determination of the geotechnical model for this support system. Using this knowledge design parameters of the Pipe Roof System were investigated in numerical calculations.

The results of the numerical investigations demonstrate that the pipe roof system supports the critical section around the heading by transferring the radial loads to both the ground in the front as well as the lining in the supported section. This support effect increases the safety because the risk, that local or global failures occur in the working area, decreases.

Compared to the stiffness of the ground, the high stiffness of the steel pipes positively influences the stress distribution ahead of the supported section. This effect and the radial support around the heading decrease the settlement amounts.

Numerical calculations enable an adaptation of the pipe roof support system by a knowledge-based change of the design parameters: overlapping length, pipe dimensions, and number of pipes. So the calculated system behavior can be optimized with respect to the project requirements.

ABSTRACT: A series of centrifuge model tests has been conducted to investigate ground movements around tunnel heading reinforced by so called pre-lining structure. The outcomes have been evaluated by direct comparison with the numerical model analysis. The results show that a pre-lining structure influences the progress of ground deformations above the tunnel heading. The research work undertaken also highlighted the complexity of the problem and its potential for future research development.

1 INTRODUCTION

1.1 *Background*

In an urban environment the need for construction of tunnels for transportation or utility systems is always present. For practical reasons such as accessibility, serviceability and economy these tunnels are constructed at shallow depths. Since the ground near the surface consists very often from soils or weak rocks, the shallow tunnels are usually constructed using either tunnel boring machines or tunnelling methods based on NATM (New Austrian Tunnelling Method) principles often combined with certain type of soil or rock improvement and reinforcement. These techniques are used to modify stresses within the layers of soil adjacent to underground works and/or to modify geotechnical parameters of the soil. So-called pre-lining methods form one important group of available improvement processes.

As an alternative to field measurements of deformations associated with the underground excavation modelling of in situ prototype situations can be employed. Generally, tests may be performed on physical models where geotechnical centrifuge can become useful tool. To validate the physical models numerical analysis can be used.

Tunnel construction operating with the pre-lining structure is in general composed of two phases. During the first one the protecting arch made from concrete (pre-cutting), from jet-grouting columns or from steel pipes is created into the ground ahead of the tunnel face around its upper circumference. Due to technology of overlapping of each new arch with the previous one their resulting shape is of a truncated cone. The excavation of the new space under the protection of this structure is the second part of the process - see Figure 1.

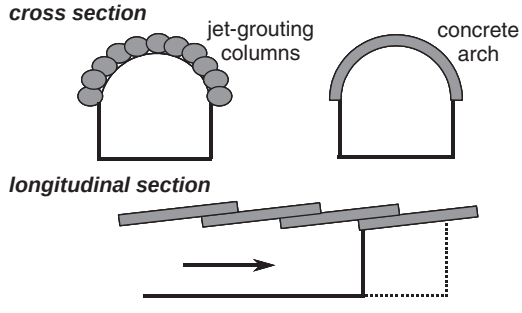

Figure 1. Principle of pre-lining methods used in tunnelling.

1.2 *Methodology*

Geotechnical centrifuge model testing was the method of investigation on physical models. Within the Czech Republic there is no geotechnical centrifuge laboratory in operation. The research work presented in this paper has been undertaken during the author's stay at City University in London (UK) under kind supervision of Professor R N Taylor.

Centrifuge testing allows the simulation of full scale prototype stress distributions with depth. This is due to the nature of centrifuge imposed loading – increase in radial acceleration imposed by the rotation of the centrifuge. With this technique, self-weight stresses and gravity-dependent processes are correctly reproduced and observations from small-scale models can be related to the full-scale prototype situation.

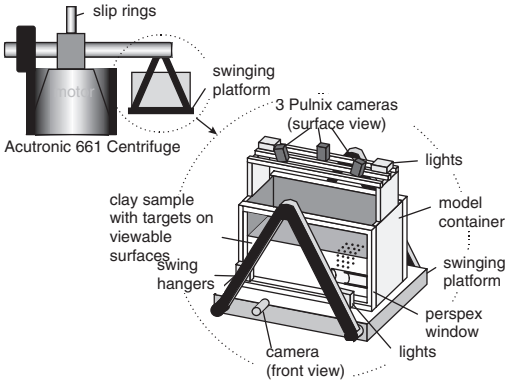

Figure 2. Diagram of the centrifuge and arrangement of the model (after Calvello & Taylor 1999).

Centrifuge models were conducted under 3D conditions. The tunnel was cut into overconsolidated kaolin clay material. Part of the tunnel was supported by a stiff lining while the heading was supported by the model of pre-lining structure together with air pressure within a rubber lining. Movements were generated by reducing the pressure in the tunnel so that tunnel heading started to collapse. A schematic diagram of typical centrifuge model used for this study is presented in Figure 2.

Finite element analyses were carried out using version 4.3a of SAGE CRISP finite element program and models were conducted as two dimensional under plain strain conditions and certain assumptions were made to approximately represent the three dimensional situation. All analyses were conducted at centrifuge model scale. Finite element analyses were evaluated by direct comparison with centrifuge model test results.

2 GEOTECHNICAL CENTRIFUGE – PHYSICAL MODELLING

2.1 *Tests undertaken*

A total of three tunnel heading tests were conducted. The aim of the test series was to observe and evaluate the effect of so called pre-lining structure installed ahead of tunnel face in reducing the risk of collapse of a tunnel excavation and also its influence on movements of ground above the tunnel. The diagram of the typical model set up is shown in Figure 3. All the tests were conducted with the same stress histories. They were pre-consolidated to 175 kPa (clay sample in consolidation press). Pore pressure equilibrium conditions were achieved at full acceleration on the centrifuge before the pressure reduction in the tunnel was carried out.

The model of a pre-lining structure is shown in Figure 4. The semicircular profile of a brass tube was used to model the stiff tunnel lining which occupied

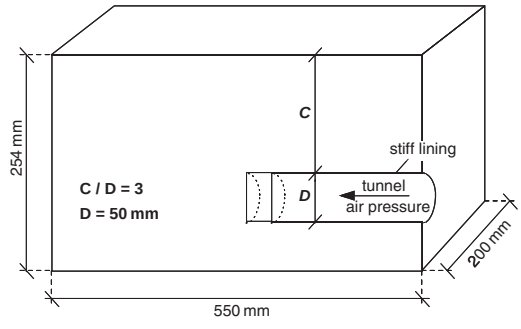

Figure 3. Diagram of typical model set up.

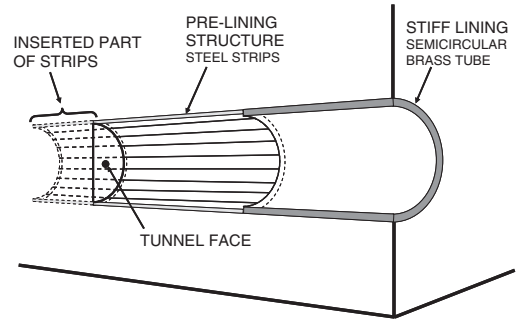

Figure 4. Pre-lining structure model.

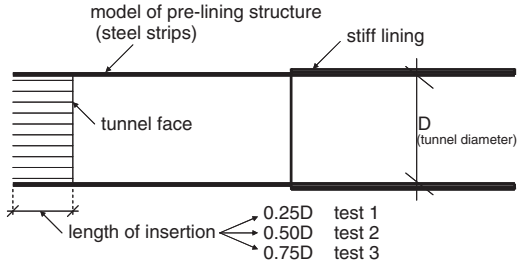

Figure 5. Geometry of the tunnel arrangement.

only approximately half of the tunnel length. The pre-lining structure was modelled by thin steel strips 6 mm wide and approximately 1.25 mm thick. They were pushed one next to another into the ground ahead of the tunnel face around the circumference of the face in order to create a protective shell around the ground to be excavated.

The rear part of these strips was supported by the stiff lining of the tunnel. The length of insertion of the strips ahead of the face was the difference between the tests (the ratio between the length of insertion and the tunnel diameter was 0.25 or 0.5 or 0.75 – see Figure 5).

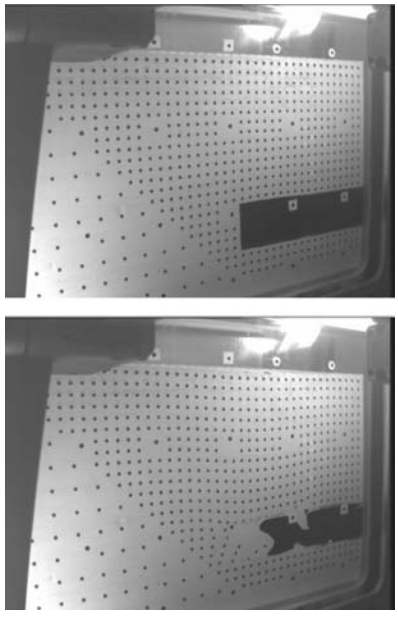

Figure 6. Digital images of Test 1 (before reducing the tunnel pressure & tunnel collapse in progress).

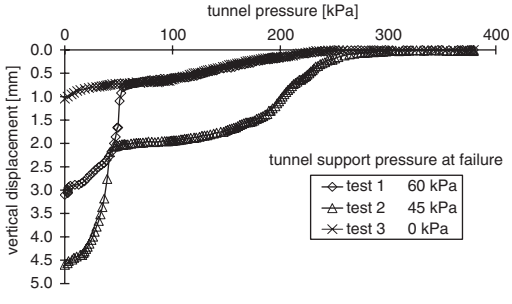

Figure 7. Tunnel support pressure at failure.

2.2 *Test results*

Digital images from the centrifuge mounted cameras were taken during the test and stored in the computer for later processing. In images presented in Figure 6 the pattern of black targets pushed into the front surface of the model can be seen. Special software was used to capture the black target positions from these images and calculate their coordinates and also changes in these coordinates during the course of the test.

In Figure 7 the vertical displacement near the ground surface directly above the centre of the unsupported length of the steel plates was plotted against the support air pressure. After decreasing the tunnel pressure to the value of about 200 kPa, the settlement process was initiated and stabilized at a value of 1 mm; then the collapse of the tunnel heading followed.

This shows that the pre-lining type of tunnel heading stabilization could prolong the period between the occurrence of the first significant deformations above the unsupported tunnel heading and final collapse of the tunnel. In another words, the pre-lining structure contributes with its structural capacity to the stability of tunnel crown. Other question is how this "structural" capacity is defined. In this case, the model was made of steel strips placed around the tunnel circumference and the collapse most probably occurred in the moment when these strips started to bend. The proper arching effect cannot be taken into account here, because the strips were not interconnected with each other.

As it is obvious from Figure 7, the curve for test 2 has almost entirely moved down by about 1.5 mm, which was caused by a mistake in the model preparation. During the test, all the targets on the front face of the model moved down. Despite of this event, the development of deformations near the surface and the collapse pressure can be read from this curve.

According to these observations, it was possible to say that the length of the part of a pre-lining structure, which remains inside the ground ahead of the tunnel face, plays a certain role at the tunnel heading stability. The longer the insertion into the ground is the stable the tunnel face and entire tunnel heading area.

Figure 8 shows the overall patterns of subsurface movements in the vertical plane passing through the longitudinal axis of the tunnel. The crosses indicate the initial coordinates of the targets, whereas the lines show their displacements vectors from the beginning of the tests (tunnel pressure 380 kPa) to failure (tunnel pressure 60, 45 and 0 kPa for tests 1, 2 and 3 respectively). In the figures, the vectors are magnified 4 times with respect to the grid scale. Displacement patterns do not vary significantly throughout all three tests. The biggest deformations of the ground above the tunnel occur approximately in the middle of the unsupported length of the steel strips. This is obviously dependant on the material the pre-lining structure model is made of. Using stiffer and more brittle material would definitely bring different results.

3 NUMERICAL MODELLING

3.1 *SAGE CRISP software*

The numerical analyses presented in this section were conducted using a non-linear elasto-plastic soil model (modified Cam-clay) and the finite element method. The focus was to model the soil sample stress history as accurate and closely as possible. Linear strain triangular elements were used together with coupled consolidation (Biot) facility in CRISP software. CRISP is an incremental finite element program which was developed at Cambridge University during the 1970's

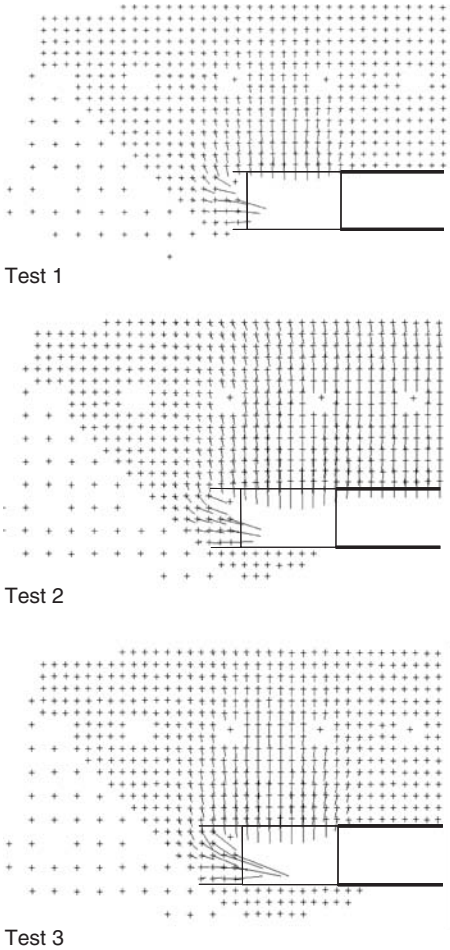

Figure 8. Displacement vectors from beginning of tests to failure.

specifically to carry out geotechnical analyses using Critical State framework to describe soil behaviour.

3.2 *Numerical models*

To model the three-dimensional problem by means of plane strain models needed to think through what potential pitfalls such simplification can bring. Three-dimensional centrifuge model was designed to reflect the overall acting of a tunnel heading while it is being excavated, which is truly three-dimensional.

The numerical analysis was planned as follows. Firstly, two cross-sectional models were conducted – see top of Figure 9. The first one (A) had completely same dimensions as the cross-section of the centrifuge model through the open tunnel. In the second one (B) the "tunnel" excavation was modelled as cut much

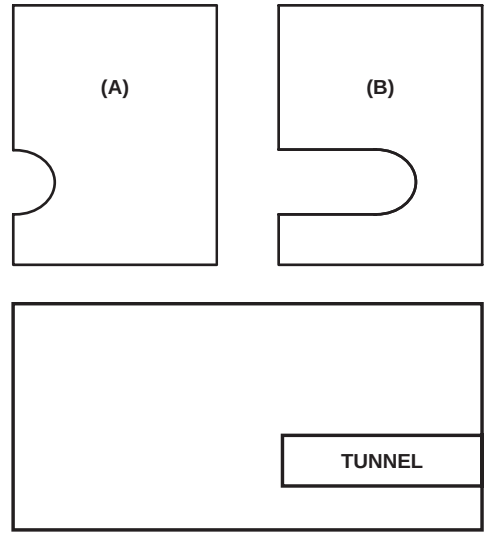

Figure 9. Cross-sectional representations for initial analyses (top) and longitudinal section, the main model for ground movement observation.

deeper inside the soil mass; the only reason being the intention to eliminate the contribution of the arching effect to the tunnel stability. The third model was the one of longitudinal section – see bottom of Figure 9. For all three models the sample stress history was the same, the dimensions of the models were as per the centrifuge models and the way of modelling the tunnel excavation remained the same (i.e. by reduction of supporting pressure inside the tunnel).

The reason for the two different cross-sectional models was to try to evaluate the difference between the progress of deformations during the collapse of the tunnel for these two. Next step was to try to apply this difference (in the form of some coefficient) to the results from the longitudinal section model because the three-dimensional acting of the tunnel heading is not reflected there. It was not necessary to model any tunnel lining here because the purpose of those models was only to asses the influence of different tunnel geometries on the movements of the ground above the tunnel.

The vertical movements at the ground level for both models (A) and (B) were compared, which is shown in Figure 10. As can be observed there is a significant difference between the failure progress in model (A) and (B). This is no surprise because in model (B) there is no physical support of the far left side of the tunnel cavity (tunnel arch far away) and so the vertical ground movements begin to progress straight after the tunnel support pressure reduction is initiated. The failure comes very soon in model (B), at around 330 kPa of tunnel support pressure, which is roughly 100 kPa

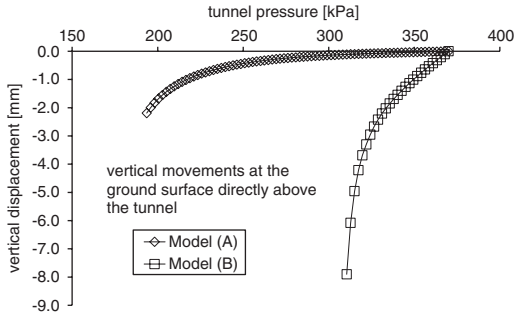

Figure 10. Comparison of the vertical movements at the ground level above the tunnel for models (A) and (B).

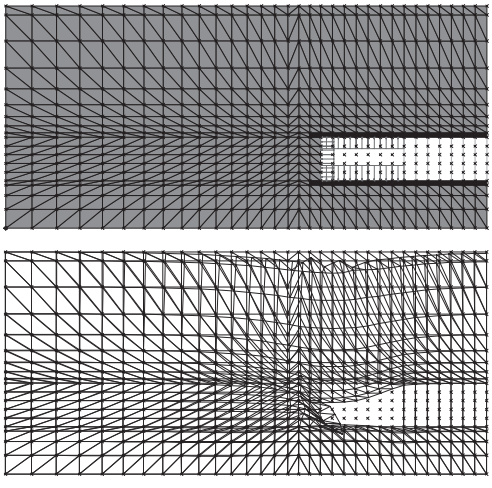

Figure 11. Longitudinal section, Test 1 model – original and deformed finite element mesh.

earlier than in model (A). Another feature which can be assessed is the gradient of the two settlement curves before the tunnel collapse. Vertical movements at the ground surface for model (A) increase with approximate gradient of 1mm per 420 kPa of tunnel pressure reduction whereas for model (B) the gradient is 1 mm per 19 kPa pressure reduction. This means the deformations in model (B) progress approximately 22 times faster than in model (A) during the tunnel support pressure reduction.

In the final stage of numerical modelling the longitudinal section finite element mesh was assembled and three model tests were conducted based on the centrifugal tests. Figure 11 shows the original finite element mesh for the longitudinal section model. The elements representing the stiff lining and pre-lining structure are distinguished by darker colour from the elements representing the soil. Shown here is Test 1

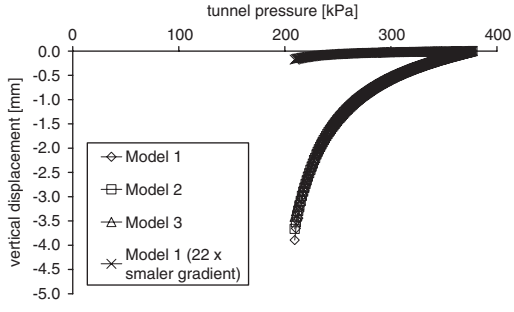

Figure 12. Near surface vertical movements directly above pre-lining structure – numerical analysis (compare with Figure 7).

with 0.25 D insertion length of the pre-lining structure ahead of the tunnel face. The second diagram represents deformed finite element mesh of longitudinal Test 1. The movements are presented at the time of tunnel failure and are magnified 4 times to emphasize their patterns.

4 COMPARISON OF RESULTS

The stress history, centrifugal loading and boundary conditions have been numerically modelled with great accuracy to the physical model tested on geotechnical centrifuge. The pre-lining structure has been modelled by simply swapping the soil elements around the tunnel cavity for linear strain isotropic elastic elements normally interconnected with the surrounding soil elements. This proved not to be an ideal solution. However, certain outcomes from both analyses can be compared and analysed here.

In Figure 12 vertical movements near ground surface directly above the middle of pre-lining structure from numerical models are plotted to be compared with the same situation from centrifuge models shown in Figure 7. At the first glance, it seems difficult to find any similarities between the two ground movement illustrations. Describing the centrifuge testing, it has been distinguished between different collapse pressures for the three model tests. Looking at them again, they are not too distant and all appear to be around 50 kPa (models 1 and 2). Model 3 carried on until the supporting pressure was zero without showing any signs of more rapid increase in vertical movements. Apart from being moved down (model 2 settlement curve) by approximately 1 mm, the shapes of model 1 and 2 curves are very similar. This was definitely the case of numerical models where all three model tests performed nearly identical pattern of ground movements above the pre-lining structure. This similarity in ground movements even for various lengths of pre-lining structure insertion into the

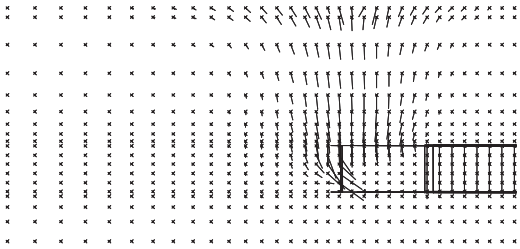

Figure 13. Model 1 – numerical test. Displacement vectors, magnified by factor 4, from beginning of tests to failure.

ground would suggest that it is not of such importance for tunnel heading stability how far the pre-lining will be inserted. However, these tests have been conducted with only one soil material type (consolidated kaolin clay sample with rather plastic behaviour) and it should be expected that for other types of soil or soft rock material this phenomenon would still play major role in overall tunnel heading stability.

The normalised vertical movement curve (22 times smaller gradient) in Figure 12 could be extrapolated further towards lower pressure values. Setting the collapse pressure value somewhere around 130 to 110 kPa would bring it closer to the centrifugal analysis values. The collapse pressures in this type of analysis depend to great degree on the material used to model the pre-lining structure. Since it is fairly difficult to find a numerical model which would closely describe such physical prototype as steel strips inserted into clay soil with elasto-plastic behaviour, the difference between 50 kPa (collapse pressure for centrifuge models) and 120 kPa (numerical models – extrapolated normalised curve) does not seem so unjustifiable.

In Figure 13 the overall patterns of subsurface movements are shown for Model 1 from numerical analysis (compare with centrifugal test data in Figure 8). The crosses in centrifugal model grid represent the positions of black plastic targets inserted into model front surface, whereas the crosses in numerical analysis represent the node positions.

5 CONCLUSIONS

The work that has been presented was conducted to investigate ground movements around a tunnel heading reinforced by so called pre-lining structure. The overall patterns of subsurface movements in vertical plane passing through the tunnel axis were modelled numerically with great degree of conformity with centrifugal tests. Both models show the "sagging" behaviour of the pre-lining structure supported on one side by the stiff tunnel lining and on the other by the soil which it protects. Both numerical and physical models showed very small or even negligible differentiating between different collapse pressures for the three model tests. This would suggest that the structural behaviour of pre-lining structure is more significant to tunnel heading stability than its length of insertion into the ground ahead of tunnel face. The main drawback is that the model experiments were limited to "green-field" site conditions and the findings have not been assessed against any field observations.

L-SurF – Large scale underground research facility for safety and security

Volker Wetzig
VSH – Hagerbach Test Gallery Ltd., Sargans, Switzerland

ABSTRACT: Security and stability rank among the most important aspirations in everybody's life. Mobility of people and reliable transport of goods are key issues in our society. Both economic growth and societal development rely heavily upon safe and secure infrastructure, in which road, rail and metro tunnels and other enclosed spaces of infrastructures are important elements. To date, the increasing awareness of safety and security caused by severe heavy accidents with partly enormous damage on health and goods and terrorist attacks in underground infrastructures, leads to the necessity of R&D projects that work on safety and security and make an improvement of both existing and projected infrastructure in enclosed spaces possible. This also finds its expression in the description of the 7th framework programme of the EC where safety and security is explicitly addressed as an individual topic for R&D activities. The European Community supports actively the design of new RTD infrastructure on a European level with the aim to both structure the European Research Area and to support the design and the construction or further development of research infrastructure which justify not only a national but a European wide support. The necessity for large scale test and R&D on safety and security in enclosed spaces – and correspondingly for adequate R&D facilities – was identified during the programmes of the 5th EU framework programme. The L-surF project is running with the 6th EU framework programme and will propose a solution to define a European wide R&D approach and real scale research facility which cover safety and security aspects in enclosed spaces.

1 THE IMPORTANCE OF SAFETY & SECURITY – THE EUROPEAN APPROACH

Security and stability rank among the most important aspirations in everybody's life. Mobility of people and reliable transport of goods are key issues in our society. Both economic growth and societal development rely heavily upon safe and secure infrastructure, in which road, rail and metro tunnels and other enclosed spaces of infrastructures are important elements.

To date, the increasing awareness of safety and security caused by severe heavy accidents with partly enormous damage on health and goods and terrorist attacks in underground infrastructures, leads to the necessity of R&D projects that work on safety and security and make an improvement of both existing and projected infrastructure in enclosed spaces possible. This also finds its expression in the description of the 7th framework programme of the EC where safety and security is explicitly addressed as an individual topic for R&D activities or in the fact that a first "European Conference on Security Research" was held in February 2006.

1.1 *EC supports the Design of New R&D Infrastructure*

The European Community supports actively the design of new RTD infrastructure on a European level with the aim to both structure the European Research Area and to support the design and the construction or further development of research infrastructure which justify not only a national but a European wide support.

Within the frame of the Sixth Framework Programme of the European Community, the L-surF project is run as a Specific Support Action (SSA) under the specific programme "Structuring the European Research Area", the project in other words responds exactly to the aims of the EC.

1.2 *The L-surF project*

L-surF, acronym of the project and abbreviation of Large Scale Underground Research Facility on Safety and Security, is a feasibility study. It is carried out through the cooperation of some of Europe's leading institutions on safety and security, started in March

2005 and will finish after 36 months, say in the spring of 2008. The five partners of the consortium are:

- VSH Hagerbach Test Gallery Ltd., Switzerland (Coordination)
- SP Fire Technology, Swedish National Testing and Research Institute, Sweden
- STUVA, Studiengesellschaft für unterirdische Verkehrsanlagen e.V. , Germany
- TNO, Netherlands Organisation for Applied Scientific Research, The Netherlands
- INERIS, Institut National de l'environnement industriel et des risques, France

The budget for the feasibility study is approximately 3.3 Mio €.

2 WHY L-SURF

2.1 *Various EC programmes*

A couple of EC funded RTD programmes on safety in underground infrastructures within the 5th Framework Programme, for example FIT (Fire In Tunnels), DARTS (Durable And Reliable Tunnel Structures), Virtualfires, Uptun (cost-effective, sustainable and innovative upgrading methods for fire safety in existing tunnels), SafeT etc, have been dealing with the improvement of safety in tunnels. The fact that all these programmes have been carried out, shows that the EC identified clearly the need for such efforts on safety and security in enclosed spaces.

The necessity for large scale test and R&D on safety and security in enclosed spaces – and correspondingly for adequate R&D facilities – was identified during these programmes and expressed at the First International Symposium on safe and reliable tunnels, held in Prague in February 2004. The projects of the 5th framework programme also showed a highly fragmented and a mostly unstructured research industry for safety and security in enclosed spaces with many national or even local "players" – a fact which must be addressed if a higher quality level of the R&D work and larger R&D infrastructures are considered being necessary. Also other issues are currently not taken care of sufficiently within the existing industry: Matters like education and training are entirely left to national or regional efforts, there are no harmonized test and R&D procedures available which makes it very difficult to compare R&D work carried out in various sites under various and often quite differing conditions etc.

2.2 *Large scale problems*

If one thing has become apparent from the EU co-financed projects such as mentioned above, it is that accurately assessing the safety level of complex systems such as tunnels on the basis of laboratory test on sub-systems and single elements, even in combination with advanced modelling techniques (CFD, FEA), is hardly possible. This is due to:

Figure 1. Preparation for water mist tests at VSH-Hagerbach test gallery.

Figure 2. Beginning of water mist tests at Hagerbach test gallery.

- scale effects
- unexpected (adverse or positive) interaction between (mitigating) measures
- limited (read: costly) options to validate models to realistic scale events
- a lack of understanding or even unknown physical phenomena regarding fire development (spread of fire to other vehicles or rolling stock)

As long as there is no correspondingly versatile test and R&D facility available that allows working under realistic conditions these problems can't be addressed properly. However such a facility is only possible to be set up on a European approach.

2.3 *Content of the design study*

In order to answer these questions and to overcome the identified shortcomings a basic analysis of all relevant aspects was needed.

A design – study seemed to be the most appropriate tool to do so.

Table 1. Responsibilities and objectives to achieve.

Task n°	Descriptive title	Leading participant	Short description and specific objectives of the task
WP 0	Project management	VSH	Steering and coordinating the project Implementing the business plan and setting-up of a legal entity for L-surF
WP 1	Integration	INERIS	Survey on existing or project development facilities, integrative activities to integrate existing and under development European research facilities and organisations, development of potential L-surF scenarios for integration within the ERA (European Research Area).
WP 2	Research needs	TNO	Identifying and prioritising of scientific and technological research necessities on safety and security in enclosed underground spaces, finding future users and clients of L-surF.
WP 3	Lay-out	VSH	Defining of civil-works, auxiliaries, installations of L-surF, evaluation of measures to minimise environmental impact, development of technical specifications for converting the geometry and the lay-out of the L-surF research facility.
WP 4	Equipment/ Measuring technique	SP	Defining of ultra-modern test methods and the corresponding use of measuring installations, development of technical specifications for innovative 2- and 3-dimensional data acquisition sensors.
WP 5	Activities	STUVA	Defining all the activities of L-surF (R&D, training and educations, external-services, maintaining and operating) in accordance with the existing national organisations and thus reshaping the European R&D – environment.
WP 6	Funding/ business plan	VSH	Fund raising for the realisation of L-surF, establishing a business plan for L-surF based on public private partnership (PPP) and evaluation of legal forms.

Aim of the project is to respond to all aspects mentioned and the main objectives of the design study are thus:

- to describe the constructional lay-out of the facility, based – if the concept is feasible – on a entirely new concept for easily creating any contours, shapes and sizes of enclosed spaces needed, but also all other aspects like installations, environmental impacts etc. The concept will allow novel approaches to R&D work, e.g.
- to describe innovative measuring sensors, based on the latest technologies (e.g. nanotechnology) available
- to evaluate the research needs and to outline the R&D – activities
- to develop an integration process for the existing and projected national facilities with their competences and researchers, thus restructuring and improving the relevant EU competence while simultaneously showing ways for using R&D funds more economically
- to show ways and means to raise the necessary funds for the different stages in the setting up of the facility
- to include a business plan for a new legal entity dedicated to the establishing of L-SURF

2.4 *The work-packages*

To reach this aim all tasks are grouped within six work packages (WP) within the implementation plan and briefly described including responsibilities and objectives to achieve.

2.5 *Short report of the actual state of the project*

One of the general decisions was the making of our choice of the bottom-up approach through a design study to the purpose. From our current point of view it was a good decision because it allows to carefully working out the relevant issues. However, the actual state calls for corresponding top-down activities. Safety and security have to stay main requests within the European Community's 7th Framework Programme. The European Strategy Forum on Research Infrastructure (ESFRI) for example has the role to support a coherent approach to policy-making on research infrastructures in Europe, and to act as an incubator for international negotiations about concrete initiatives. In particular, ESFRI is preparing a European Roadmap for new research infrastructures of pan-European interest. To find entrance into this roadmap is one of our targets of the next months.

3 THE L-SURF LEGAL ENTITY

Within the Design Study for L-SURF all relevant aspects for such a facility will be elaborated to a level that the facility could be established at least as a legal entity with the necessary structures and activities and that preliminary concepts and plans for the physical construction are laid out.

3.1 *Possibilities*

The legal form will first of all highly depend on what kind of organisations, public administrations and private companies will participate and in which way in the establishment of the legal entity and secondly on the business plan developed within the frame of the design study. For working out the legal form of the coming legal entity for the L-surF legal advice will be necessary and accordingly subcontracted. As a result the proposal for a legal form of the L-surF that finds approval of the consortium will be put into reality.

3.2 *Site of the new legal entity*

The choice of the site for the erection of the large scale research facility may also be a criterion in addition to the above mentioned criteria for the legal form, but moreover it will either open or eliminate possibilities for testing and training in connection with fire and smoke as far as environmental impact is concerned, which is a problem not to be sneezed. The analyses of both financial and economical aspects will probably strongest influence the decision where to establish L-surF.

4 CONCLUSION

Safety and Security are among the most urgent challenges of the European Community in the coming years. The EC answers to these challenges with its strategic initiative on safety and security, also in underground and enclosed spaces. The L-surF concept which is both about safety but also about security, because there are similarities in the effect and the need for large scale R&D, testing, training and education is certainly one part of these answers.

New high-speed railway lines Stuttgart 21 and Wendlingen-Ulm-Approximately 100 km of tunnels

W. Wittke
WBI – Prof. Dr.-Ing. W. Wittke Consulting Engineers for Tunneling and Geotechnical Engineering Ltd., Aachen/Stuttgart, Germany

ABSTRACT: For the large scale projects new high-speed railway line (NBS) Wendlingen-Ulm and Stuttgart 21, a total of approx. 100 km long single- and to a small extent also double-track tunnel tubes are foreseen.

In the course of the NBS Wendlingen-Ulm, among other structures, the 8.7 km long Boßlertunnel and the 4.7 km long Steinbühltunnel are planned. The Boßlertunnel is located in Brown Jurassic. Locally, squeezing rock is to be expected. The Steinbühltunnel is located in White Jurassic, which is locally strongly karstified. For both tunnels, it was investigated whether an advancing test section and through-going exploratory adits respectively would lead to a safer design with regard to construction costs and time.

A total of approx. 52 km single- and double-track tunnel tubes is foreseen for the project Stuttgart 21. The paper exemplary illustrates the Fildertunnel. With regard to tunneling, the tunnel sections in swelling unleached Gypsum Keuper are of major importance. The principle of resisting support is planned to be carried out.

1 INTRODUCTION

Approximately 100 km of tunnels are foreseen for the construction of the new high-speed railway lines Wendlingen-Ulm and Stuttgart 21. Tunneling in squeezing rock as well as in karstified rock is decisive with regard to construction time and costs of the tunnels for the new high-speed railway line from Wendlingen to Ulm (Wittke W. 2004b). The design and construction of tunnels in swelling rock is a major challenge in connection with the project Stuttgart 21.

2 NEW HIGH-SPEED RAILWAY LINE WENDLINGEN – ULM

2.1 *Tunnels*

The new high-speed railway line Wendlingen – Ulm is planned to go from Wendlingen, passing Aichelberg and Merklingen, to Ulm (Fig. 1). Four comparatively large tunnels are foreseen. The Albvorlandtunnel near Wendlingen is planned with a length of 7.9 km. The ascent to the Swabian Alb from Aichelberg to Merklingen with a length of approx. 13.5 km is also planned to go below ground. In this section, the line is crossing the Filstal. This valley needs to be spanned by a bridge. Therefore two separated tunnels, the Boßlertunnel with a length of 8.7 km and the Steinbühltunnel with a length of 4.7 km, are required. The fourth tunnel is the 5.9 km long Albabstiegstunnel near the city of Ulm (Fig. 1).

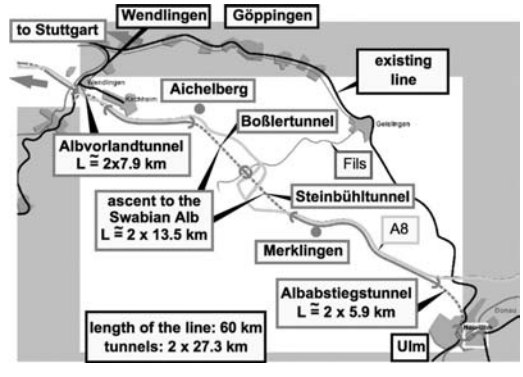

Figure 1. New high-speed railway line from Wendlingen to Ulm.

All tunnels are to be constructed as single-track tubes with cross-cuts at distances of $\leq$1000 m. The total length of all single-track tunnel tubes results to approx. 55 km.

2.2 *Boßlertunnel – Tunneling in squeezing rock*

For the ascent to the Swabian Alb to the west of the Filstal, the Boßlertunnel is planned with a length of 8.7 km (Fig. 2).

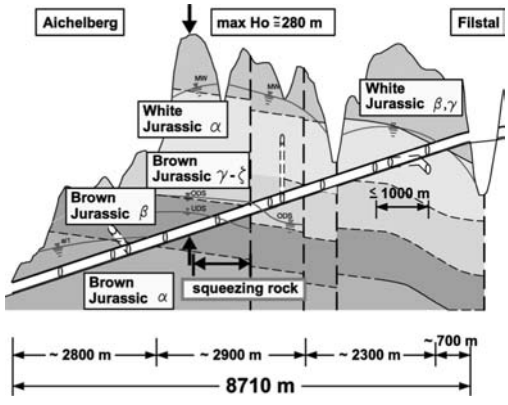

Figure 2. Geological longitudinal section, Boßlertunnel.

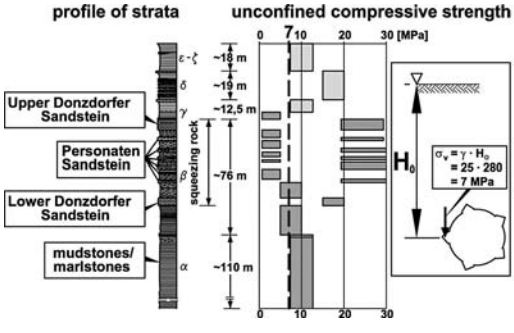

Figure 3. Layers of the Brown Jurassic.

Over a length of approx. 6 km, the tunnel tubes are crossing the layers of the Brown Jurassic (Figs 2 and 3). The Brown Jurassic α, which is also known as Opalinuston, consists of a sequence of mudstones and marlstones. The thickness of the Brown Jurassic β amounts to approx. 75 m. In the lower and upper part two sandstone layers, the Lower and Upper "Donzdorfer Sandstone", are located. The middle part is formed by an alternating sequence of mudstones and sandstones, the so-called "Personatensandsteinzone". Above the Brown Jurassic β, mudstones and marlstones, in which layers of limestone are embedded, are located. The permeability of the mudstones and marlstones is very low. The sandstone and the limestone are aquifers.

Above the Brown Jurassic the layers of the White Jurassic α to γ are located (Fig. 2). The White Jurassic α consists of an approx. 90 m thick sequence of marlstones. In the lower part of it mudstones are embedded and in the upper part limestones. The White Jurassic β and γ, which consists of limestones with deposits of marlstone and are partly karstified, are located above the White Jurassic α.

According to the results of explorations carried out up to now, several ground-water reservoirs exist in the Brown and White Jurassic, which are separated by mudstone and marlstone deposits with very low permeability. At the moment, the water pressures at the level of the tunnel tubes are estimated to be $\leq$9 bar for the White Jurassic.

Figure 4. Tunnel Yacambu (Venezuela), squeezing rock.

The unconfined compressive strength of the mudstones of the Brown Jurassic β, δ and ε to δ is comparatively low (Fig. 3). For the Brown Jurassic β, values of 0.5 and 5.0 MPa were evaluated. In the section in which the tunnel is located in the Brown Jurassic, the overburden amounts to 280 m. It cannot be excluded that in these layers the low strength of the mudstones will be exceeded during excavation of the tunnel tubes and squeezing rock conditions occur.

The effect of squeezing rock is illustrated in Figure 4. The Yacambu tunnel in Venezuela could not be completed for a long time, because the shotcrete support could not withstand the high rock pressure.

The excavation of the Boßlertunnel in the Brown Jurassic β with an overburden of some 280 m, therefore, is one of the challenges of the new high-speed railway line Wendlingen – Ulm. Using the shotcrete method, a yielding support could be taken into consideration (Rückel & Wittke 1991, Zimmer & Wittke 1996, Fig. 5). With regard to a possible TBM heading, it is presently planned to excavate an advancing test section in the Brown Jurassic β for additional exploration. If this full scale exploration leads to the conclusion that a TBM heading in the layers of the Brown Jurassic β, which are difficult with respect to tunneling, is associated with a too high risk, the tunnel section in the Brown Jurassic β would have to be excavated using the shotcrete method. In the remaining tunnel section of approx. 10 km, however, TBM headings could be carried out.

Figure 5. Shotcrete method in squeezing rock, deformable lining.

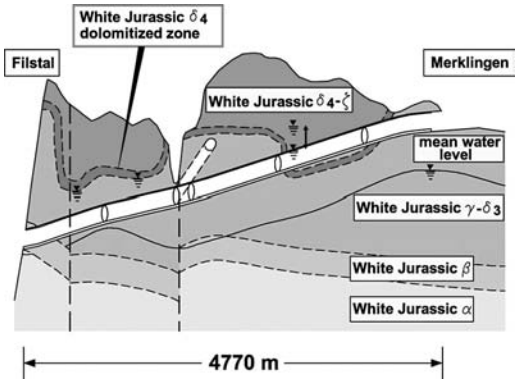

Figure 6. Geological longitudinal section, Steinbühltunnel.

2.3 *Steinbühltunnel – Tunneling in karstified rock*

Figure 6 shows a geological longitudinal section of the Steinbühltunnel, which is located to the south of the Filsbachtal. The length of this tunnel amounts to approx. 4.8 km.

The tunnel tubes are located in the layers of the White Jurassic β to δ_4 above the average water level. The alignment and the gradient were chosen correspondingly. The water level of the karst aquifer varies. During rainfalls, it is rising by several 10 m. Thus, also for this tunnel the water pressure is expected to be within 3 to 5 bars and the tunnel tubes need to be sealed along the whole circumference by a watertight lining which is dimensioned against water pressure.

The layers of the White Jurassic are karstified. In the Swabian Alb, many karst phenomena and cavities are known. Examples are the "Mordloch" (Fig. 7) and the "Falkensteiner Höhle", a 5 km long cave in the White Jurassic δ. Furthermore, karstified master joints occur in the layers of the White Jurassic β to δ (Fig. 8).

In Figure 9, the main types of karstification in the layers of the White Jurassic are illustrated.

Figure 7. Mordloch, karst channel in the White Jurassic β (Binder 1989).

Figure 8. Karstified master joints in the White Jurassic γ.

Figure 10 shows a vertical section through the cave "Laichinger Tiefenhöhle", in which the contour of one tunnel tube of the new high-speed railway line is plotted.

Since it cannot be excluded that karst phenomena of importance for tunneling are encountered during the excavation of the Steinbühltunnel, corresponding support measures are foreseen in the tunnel design. Figure 11 exemplary shows the support of a tunnel tube in case of a karst cavity located above the tunnel's roof. For stability reasons a concrete body is to be constructed between the tunnel and the karst cavity. Thus, the karst cavity as the main flow path will be maintained so that groundwater conditions remain unchanged during tunneling. Figure 12 exemplary shows the support in case of a karst cavity located underneath the invert of the tunnel.

Also for the Steinbühltunnel it was investigated whether the excavation of advancing exploratory adits in karstified rock is of use. This investigation led to the recommendation to drive two advancing exploratory adits located within the cross-sections of the tunnel tubes over the full length of the Steinbühltunnel (Fig. 13). From these adits, karst cavities adjacent to both tunnel tubes can be explored by seismic methods and supplementary drillings and also stabilized if required. If these measures are carried out prior to

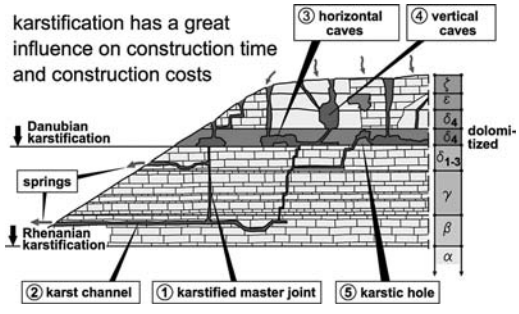

Figure 9. Main types of karstification in the White Jurassic.

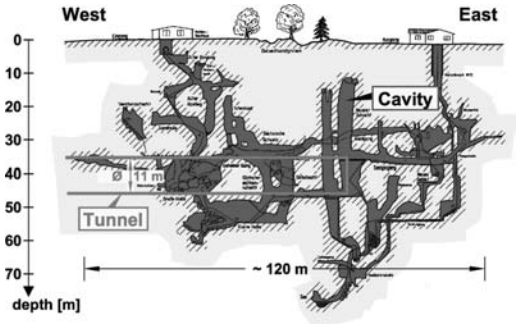

Figure 10. Possible cavities in the cross-section of the tunnel.

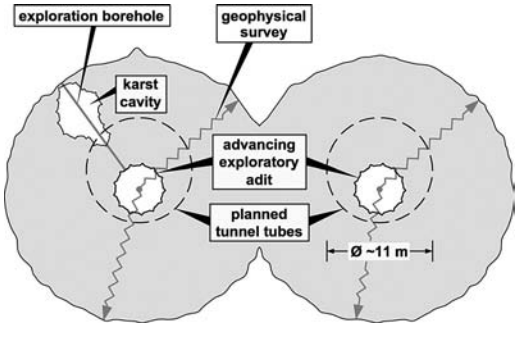

Figure 13. Exploratory adit in karstified rock, Steinbühltunnel.

the excavation of the tunnel tunnel tubes, the risk for TBM-tunneling is considerably reduced.

3 STUTTGART 21

3.1 *Tunnels*

In the city of Stuttgart, five tunnels are planned (Fig. 14). The tunnel Feuerbach with a length of approx. 3.2 km is connecting the high-speed railway line Mannheim-Stuttgart with the new main station. The Fildertunnel with a length of approx. 9.5 km shall provide the main connection from the new main station to the Stuttgart airport and further to the new high-speed railway line Wendlingen-Ulm. As further essential tunnel structures, the tunnel Bad Cannstatt with a length of approx. 3.8 km and the tunnels to Ober- and Untertürkheim are to be constructed. The tunnel Obertürkheim undercrosses the Neckar river in a comparatively low depth. The total length of this tunnel is approx. 6 km.

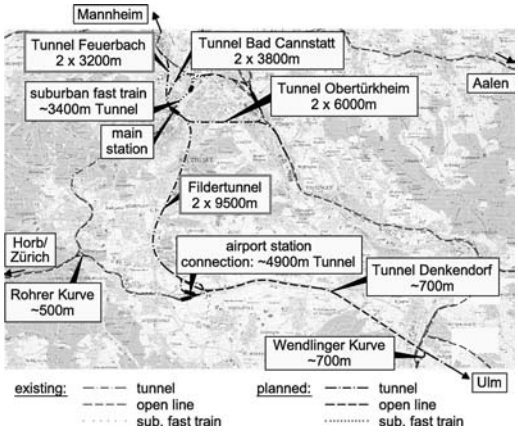

Figure 14. Stuttgart 21, overview.

To remove traffic from the ground surface and to improve the suburban fast train connections, additional tunnels with a length of approx. 3.4 km are planned. For the connection to the airport, further tunnels with a length of approx. 4.9 km are foreseen. In addition several comparatively short tunnels like the Rohrer Kurve, the Wendlinger Kurve and the tunnel Denkendorf are planned.

The total length of all single-track and double-track tunnel tubes for the project Stuttgart 21 is approx. 52 km. In the following, the Fildertunnel with its special features with respect to tunneling will exemplary be presented.

3.2 *Fildertunnel – Tunneling in swelling rock*

The Fildertunnel, which leads from the new Stuttgart main station to the Filder Plain, has a length of approx. 9.5 km (Fig. 15).

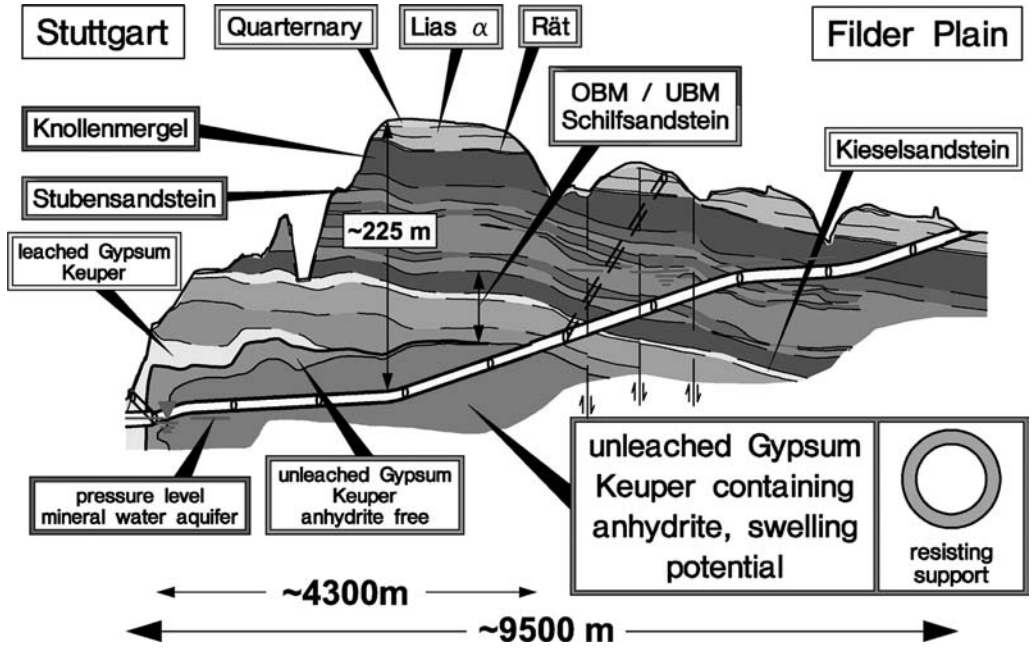

Figure 15. Geological longitudinal section, Fildertunnel.

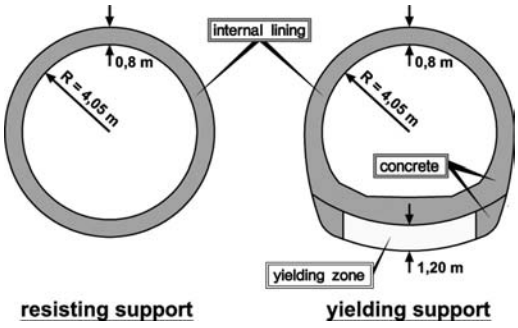

Figure 16. Design principles for tunnels in swelling rock.

The tunnel crosses all layers forming the valley of Stuttgart, which are located above the "Lettenkeuper". At the beginning of the tunnel, the cross-section is located in the leached Gypsum Keuper over a length of 200 to 300 m. In the following, it passes sulfate rock containing gypsum and anhydrite over a length of approx. 4.3 km. Here, the leaching front is located 30 to 45 m above the roof of the tunnel. Underneath the anhydrite level, which is located 20 to 30 m above the tunnel's roof, the sulfate rock consists mainly of anhydrite. The tunnel is located in the "Schilfsandstein", the "Kieselsandstein" as well as the "Unteren Bunten Mergel" and "Oberen Bunten Mergel" over a length of approx. 750 m. The sandstones and siltstones of the "Stubensandstein" are crossed by the tunnel over a length of some 2.5 km. The remaining tunnel sections are located in the "Knollenmergel" and the silty mudstones and sandy limestones of the Black Jurassic (Lias α).

The unleached Gypsum Keuper is a major challenge for design and construction of the Fildertunnel. It consists of a horizontal alternating sequence of sulfate-containing clay- and siltstones and pure sulfate rock. The sulfate is found in two different modifications, as gypsum and as anhydrite. Both modifications can be found at the same time, if the rock is dry. If water gains access to the rock, however, anhydrite transforms into gypsum. This chemical process results in an increase of the solid volume by approx. 60%. This volume increase is denoted as swelling.

The swelling behavior of the unleached Gypsum Keuper is also influenced by the water uptake of clay minerals.

The volume increase due to swelling causes major swelling deformations. If these are confined, great swelling pressures occur, which have led to severe damages of tunnel linings in many cases in the past.

The maximum overburden of the Fildertunnel amounts to 225 m. The design concept for the Fildertunnel is based on the principle of resisting support (Fig. 16). Thus, the lining is designed to resist the developing swelling pressure.

In a greater distance to the leaching front the unleached Gypsum Keuper has a very low permeability according to experience. Because of the comparatively great distance of the tunnel gradient to the leaching front, it is to be expected that the rock mass remains dry and thus no swelling occurs, if no water gains access to the rock during the stages of construction. This was an important criterion for determination of the gradient. Another criterion was to have the tunnel passing the leaching front in an area in which the overlaying rocks are almost dry. Furthermore, due to the chosen deep location of the gradient, a tunnel lining subjected to swelling pressure underneath the invert can be supported by a sufficiently thick rock layer consisting of hard rock. Thus, significant heavings of the tunnel tubes due to swelling are not to be expected.

The principles of resisting support and yielding support respectively are presently used for the design of tunnels in anhydritic, swelling rock (Fig. 16). In both cases, it is assumed that water to initiate the maximum swelling load and full swelling respectively is available in sufficient quantities. Consequently, the designed measures have to be carried out over the full length of the tunnel in swelling rock.

Based on observations, the hypothesis was made that, in the area of the transition from water bearing to anhydritic rock, self-sealing due to swelling occurs around the tunnel, if the resisting principle is applied. As a consequence of this self-sealing effect, seepage through the rock along the tunnel, and thus also swelling, is interrupted at a certain distance from the water bearing formation (Wittke M. 2003, 2004).

In a research project carried out by WBI, a rock mechanical and hydraulical model and a corresponding 3D-FEM-code have been developed, which describe the corresponding phenomena. It is expected that the results of this work will lead to remarkable cost savings along with the design of tunnels in swelling rock.

3.3 *Tunnel Feuerbach*

The tunnel tubes to Feuerbach run through both, the unleached Gypsum Keuper containing anhydrite and the leached Gypsum Keuper (Fig. 17). Within the approx. 150 m long tunnel section located near Feuerbach, which crosses the zone containing anhydrite the principle of yielding support is foreseen. Within the approx. 420 m long anhydrite containing tunnel section located near the planned main station as well as in the following more than 1 km long section containing anhydrite the principle of resisting support is ought to be carried out. Here, according to the results of exploration seepage water is to be expected only to a very limited degree. If during excavation unexpectedly heavings due to swelling occur a changeover to the more expensive principle of yielding support is planned.

Estimation of multi-well dewatering induced pile foundation settlement in phreatic zones

Y. Xiang, S. Chen & C. Yu
School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: Dewatering induced soil consolidation may cause additional settlement of nearby pile foundations. A simplified procedure is adopted to estimate pile foundation settlement induced by multi-well dewatering in phreatic zone, and sensitivities to various parameters can be analytically calculated. A synthesized case analysis indicates: (1) when the drawdown surface is above the pile tips, the dewatering-induced pile foundation settlement is influenced by the drawdown, consolidation of soil surrounding the pile shafts and strength of pile-soil interaction; (2) when the phreatic surface is lowered deeper than the pile tips, the additional pile foundation settlement due to the consolidation of the underlain soils should be accounted for; and (3) due to the additional negative skin friction exerted on the pile shafts above the initial phreatic surface as well as the additional compaction of the soil beneath the pile tips, dewatering induced pile foundation settlement could be larger than the settlement of nearby soils.

1 INTRODUCTION

1.1 *Background*

In urban areas there often exist tall buildings and overpasses that are mostly supported on pile foundations. Restrained by spatial and/or other environmental conditions, some geotechnical and underground excavations have to be carried out in the vicinity of existing piles. When the excavations are below the water table, artificial dewatering is needed in order to provide the undertaking a relatively dry condition. Dewatering of the ground may cause increases in the effective stress and the compression of the soil, and consequently the settlements of the nearby piles.

1.2 *Present work*

In order to estimate the pile foundation settlement induced by artificial dewatering, the drawdown of each dewatering well and its effect on each pile are estimated, then for multiple wells, neglecting inter-well and inter-pile interactions, linear superposition of the effects of the wells amounts to the total dewatering-induced action on the pile foundation, which then can be employed to calculate the corresponding pile foundation settlement. The sensitivities of the pile foundation settlement thus obtained with respect to the related parameters, including the total pile length, the pile length below the initial phreatic surface, the Poisson's ratio and the modulus of compression of the soil, the drawdown at pile location, the distance between pile tip and the depressed phreatic surface, and the pumping rate, can be analytically calculated. A synthesized case analysis of a near-pile dewatering situation for the construction of a metro tunnel in Beijing is presented.

2 CALCULATION OF PUMPING-INDUCED PILE FOUNDATION SETTLEMENT

2.1 *General procedure*

Dewatering induces soil settlement, as a result of soil compression due to the increase in the effective stress caused by groundwater drawdown, and such soil settlement exerts negative skin friction on nearby pile shafts and thus causes additional pile foundation settlement. The following procedure (Chen & Xiang 2006) is employed to estimate the dewatering induced pile settlement: (1) calculation of pumping induced groundwater drawdown, (2) calculation of the corresponding effective stress and compressive strain increments, (3) calculation of the corresponding negative skin friction on pile shaft, (4) calculation of the dewatering induced pile foundation settlement.

2.2 *Calculation steps*

2.2.1 *Calculation of drawdown*

For a partially or fully penetrated well in phreatic zone, pumping induced groundwater drawdown can be

calculated by using the theory developed by Neuman (1972, 1973, 1974):

$$w(r,z,t)=\frac{Q}{4\pi T}\int_0^\infty 4yJ_0(y\beta^{1/2})[u_0(y)+\sum_{n=1}^{\infty}u_n(y)]dy \tag{1}$$

where Q denotes pumping rate; T initial transmissivity, a product of horizontal radial hydraulic conductivity, K_r, and thickness of the phreatic zone, H; J_0 zero-order Bessel function of the first kind; $\beta = K_z r^2/K_r H^2$, with K_z being the vertical hydraulic conductivity, and r the horizontal radial distance; z the vertical location; u_0 and u_n denote known functions with parameters involving the storage coefficient, the hydraulic conductivity, time of pumping duration, initial phreatic zone thickness, position of the pumping screen, specific yield of the ground, and coordinates of the point of interest.

When multiple wells are involved, the linear relationship between the drawdown and the pumping rate allows superposition for calculation of the total drawdown.

2.2.2 *Calculation of effective stress and compressive strain increments*

As shown in Figure 1, the depressed piezometric surface at the pile may be above or below the pile tip. With the objective being to evaluate the total effective stress increment, it is convenient and rational to average the effective stress and the corresponding compressive strain over the vertical range of drawdown (assuming instantaneous consolidation and vertical 1-D compression):

$$\bar{\varepsilon}=\frac{\overline{\Delta\sigma}}{\overline{E_s}} \tag{2}$$

where with the bar symbolizing averaging, $\Delta\sigma$ denotes the effective stress increment in the soil around the pile, E_s the modulus of compression (with soil settlement as the subject of concern, harmonic averaging can be employed for layered soils), and ε the compressive strain.

For case (a) as shown in Figure 1(a), the averaged effective stress at the pile can be expressed as:

$$\overline{\Delta\sigma}=\gamma_w\cdot w_c/2 \tag{3a}$$

and for case (b) as shown in Figure 1(b):

$$\overline{\Delta\sigma}=\gamma_w\cdot l_p/2 \tag{3b}$$

where w_c represents the drawdown at the pile center location, and l_p the pile length in the phreatic zone.

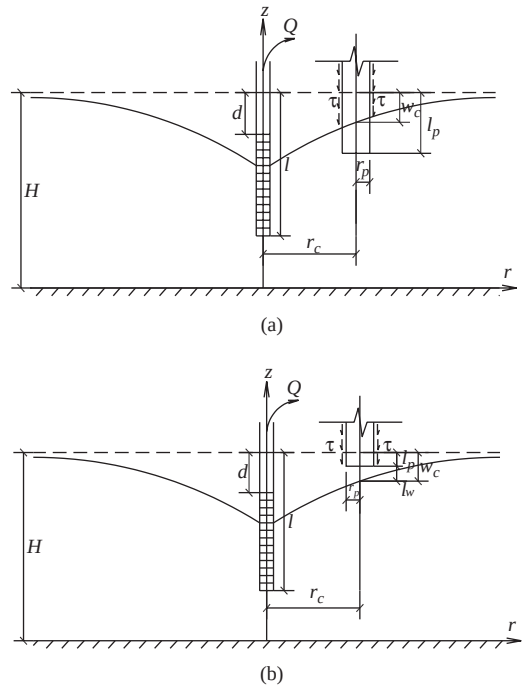

Figure 1. Effects of dewatering on a nearby pile: (a) $w_c \le l_p$, (b) $w_c > l_p$ (τ denotes the dewatering induced negative skin friction on pile shaft, w_c drawdown at pile center, l_p the pile length below the initial phreatic surface, and l_w the distance between the pile base and the depressed piezometric surface below).

2.2.3 *Calculation of negative skin friction on pile shaft*

According to Randolph & Wroth (1978), the relationship between the soil settlement, s, and the induced skin friction, τ, can be assumed as:

$$\tau=\frac{G_s}{r_p\ln(r_m/r_p)}\cdot s \tag{4}$$

where G_s denotes the averaged shear modulus of the soil around pile shaft, r_p the pile radius, r_m the effective radius of influence, $r_m = 2.5L\rho(1-\nu)$ with L, ν and ρ being the effective pile length influenced by the dewatering-induced negative skin friction, the Poisson's ratio and the ratio of the shear modulus at the pile mid-depth to that at the tip, respectively.

The pumping induced soil settlement can be estimated as, for case (a):

$$s=\bar{\varepsilon}w_c \tag{5a}$$

and for case (b):

$$s=\bar{\varepsilon}l_p \tag{5b}$$

2.2.4 *Calculation of pile foundation settlement*

Denoting the surcharge load that the negative skin friction amounts to as F, using a semi-theoretical method recommended in the Chinese code (China Ministry of Construction 2002), the total pile settlement can be calculated as:

$$\delta = \psi \sum_{j=1}^{m} \delta_j = \psi \sum_{j=1}^{m} \frac{F}{abE_{sj}} (z_j \alpha_j - z_{j-1} \alpha_{j-1}) \tag{6}$$

where a and b denote the length and width of the pile foundation base, respectively, E_{sj} stands for the modulus of compression of the jth layer of soil below the pile tip, z_j the distance of the bottom of the jth soil layer below the pile tip, α_j a coefficient for the averaged incremental stress over the range of z_j, Ψ an empirical coefficient, and m the number of soil layers adequate for calculation of pile settlement. Both α_j and Ψ can be obtained via empirical tables, and m is related to the depth of calculation, z_m, which must satisfy:

$$\Delta\delta_m \le 0.025 \sum_{j=1}^{m} \delta_j \tag{7}$$

where $\Delta\delta_m$ stands for the settlement of the soil zone Δz distant above z_m, and Δz is an empirical number dependent on the pile diameter.

Substituting all the interim relationships into equation (6) yields the following expressions:

$$\delta = \psi \sum_{j=1}^{m} \frac{\pi l_m \gamma_w w_c^2 (2\nu - 1)}{2(\nu\text{-}1) abE_{sj} \ln 20} (z_j \alpha_j - z_{j-1} \alpha_{j-1}) \tag{8a}$$

$$\delta = \psi \sum_{j=1}^{m} \frac{\pi l \gamma_w l_p^2 (2\nu - 1)}{2(\nu - 1) abE_{sj} \ln 20} (z_j \alpha_j - z_{j-1} \alpha_{j-1}) + \frac{\gamma_w (l_p + w_c)}{2\overline{E_s}} l_w \tag{8b}$$

for case (a) and (b), respectively.

3 EXAMPLE

3.1 *Sensitivity calculation*

Shown in Table 1 are the relevant parameters of a typical soil profile for the construction of a metro line in Beijing, where excavations often have to be conducted in the vicinity of municipal overpasses supported on pile foundations. Consider a phreatic zone with the water table located 10 m below the ground surface, a pumping well with a flow rate of 2.4 m^3/h and a pile of a length 10.5 m and a diameter of 1 m located 10 m away from the well. Treat the well as a line sink along its perforated portion (neglecting well storage and presence of seepage face), and the phreatic zone with a thickness of 14.3 m is assumed to be homogeneous and isotropic with an averaged hydraulic conductivity of 0.0928 m/h, a storage coefficient of 2.4×10^{-3} and a specific yield of 0.24. Referring to Code for Design of Building Foundation (China Ministry of Construction 2002), Ψ is assumed to be 0.2.

Table 1. Physical-mechanical parameters of soils.

Soil layer	Thickness/m	E_s/MPa	v	G_s/MPa
sand & gravel	13.4	19.8	0.27	6.3
silt	0.8	11.4	0.30	3.3
sand & gravel	3.8	43.9	0.26	14.2
pebble	6.3	87.8	0.2	32.9
clay	4.8	10.2	0.3	2.91

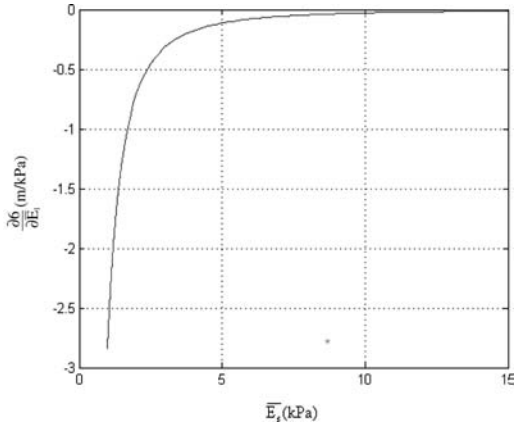

Figure 2. Sensitivity of the pile settlement in case (b) with respect to the averaged modulus of compression of soil.

The sensitivities of the pile foundation settlement with respect to the relevant parameters can be easily calculated by using the expressions in equations (8a) and (8b). For example, the pile settlement in case (a) is not explicitly related with the averaged modulus of compression of the soil around the pile shaft, whereas at steady state, the depressed phreatic surface is below the pile tip, corresponding to case (b), the sensitivity of the pile settlement with respect to the averaged modulus of compression of the soil around pile shaft can be calculated as shown in Figure 2.

3.2 *A synthesized case analysis*

Dewatering is needed for the construction of a metro tunnel in Beijing, with the same soil condition as in Table 1, and a total of 13 wells, each with a pumping rate of 2 m^3/h, are employed. As shown in Figure 3 and Figure 4, two pile foundations of a municipal overpass are located at the left and the right hand sides of the tunnel, respectively; the 1# foundation consists of

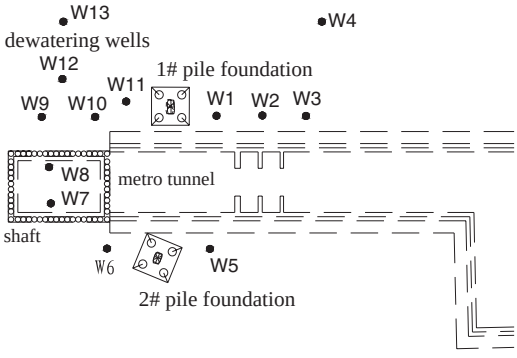

Figure 3. Layout of dewatering wells and pile foundations.

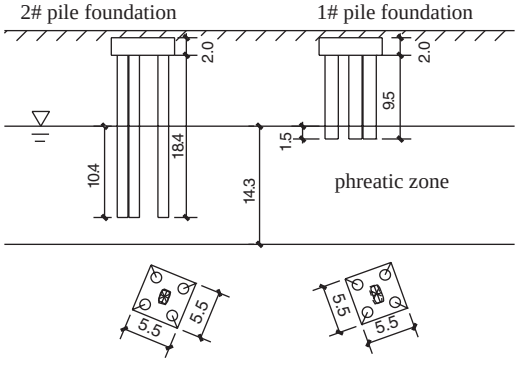

Figure 4. Profile of phreatic zone and pile foundations (m).

four piles of a diameter 1.5 m, and the 2# foundation four piles of a diameter 1.2 m. The relative distances between the wells and the pile foundations are shown in Table 2.

Shown in Table 3 are the dewatering induced drawdown, negative skin friction, additional force and pile foundation settlements, from which the following observations may be obtained:

(i) For the 1# foundation (with shorter piles), during the earlier stage of pumping, when the depressed phreatic surface is above the pile tips, the additional forces on the piles and the foundation settlement increase quadratically with the drawdown, and when the depressed phreatic surface goes below the pile tips, the compression of the soil below the pile tips due to consolidation results in further foundation settlement until steady state is reached, even though there is no increase in the additional forces on the piles.

(ii) The 2 # foundation consists of longer piles, thus the depressed phreatic surface in the entire dewatering operation is always above the pile tips, and the additional force and settlement increase with pumping duration and the final values at steady state are larger than those for the 1# foundation.

(iii) Because of the combined effect of the negative skin friction on the portion of pile shafts that is above the depressed phreatic surface and the consolidation settlement of the soil below the pile tips, the dewatering induced pile foundation settlement could exceed the consolidation settlement of the surrounding soil.

Table 2. Horizontal distances between wells and pile foundations (m).

4 SUMMARY

The main influencing factors for dewatering induced pile foundation settlement in phreatic zone include: drawdown, seepage and deformation characteristics of soil, and the interaction between soil and pile. A theoretical model for multi-well pumping in phreatic zone, an averaged effective stress approach and a linear elastic interaction model are adopted to estimate the dewatering induced pile foundation settlement. Illustrative examples, including sensitivity calculation and a synthesized case analysis, are presented.

Two situations may be distinguished: (1) when the depressed phreatic surface is above the pile tip, the pile settlement are mainly influenced by drawdown, consolidation compression of the soil around the pile shaft and the degree of interaction between soil and pile, the additional force and the pile settlement increase with the drawdown squared; (2) when the phreatic surface is depressed to below the pile tip, the consolidation of the soil below the pile tip needs to be included. The dewatering induced pile foundation settlement could exceed the settlement of the surrounding soil as a result of the combined effect of the negative skin friction on the portion of pile shafts that is above the depressed phreatic surface and the consolidation settlement of the soil below the pile tips.

Estimation of rock load for the design of 2-arch tunnel lining

Kwangho You
University of Suwon, Hwasung-Si, Kyeonggi-Do, Korea

Myung Sagong, Jun S. Lee
Korea Railroad Research Institute, Uiwang-Si, Kyeonggi-Do, Korea

ABSTRACT: In this study, the existing methods proposed to estimate relaxed rock load due to a tunnel excavation are compared and analyzed. Also a new approach, by which the stress relaxed zone around an excavated tunnel periphery can be systematically estimated, was suggested for the design of 2 – arch tunnel lining. To this end, local factors of safety are calculated from the redistributed stresses after the excavation of a tunnel. The height of the relaxed rock load is inferred based on the assumption that the stress relaxed zone might coincide with the region corresponding to the local safety factor of 2.0 or 3.0. The new approach proposed in this study has the advantage of estimating the height of rock load regardless of the shape of a tunnel and the ground conditions. Since the height of the relaxed rock load is estimated from the local factor of safety, which is a relatively clear criterion, the designer's subjectivity involved in the design of concrete tunnel lining might be reduced.

1 INTRODUCTION

The estimation of rock load is very important for the design of tunnel lining. Terzaghi's rock load method, Bierbäumer's equation, empirical methods based on RMR and Q system, and numerical approaches have been mainly used for the estimation of rock load.

To estimate rock load of a tunnel excavated in rock mass, Terzaghi's rock load classification table, RMR index, or Q value can be used but these methods are merely empirical. The Terzaghi's and Bierbäumer's proposed equations are also applied. However, these equations were derived based on the limit equilibrium theory with the assumption that the rock mass was continuous. In numerical approaches, on the other hand, rock load is inferred from the stresses behind shotcrete or plastic zones occurred due to tunnel excavation during the stability analysis of tunnels. Nevertheless, these approaches are so ad hoc that the estimated rock load may be different designer by designer.

In this study, therefore, the existing methods are compared and analyzed, and a new systematic way is demonstrated to estimate the stress relaxed zone of a tunnel due to excavation. Also, the proposed method is applied for the design of 2-arch tunnel lining.

2 THE ESTIMATION OF TUNNEL ROCK LOAD

2.1 *Terzaghi's equation*

Terzaghi(1946) applied the failure mechanism shown in Figure 1 to calculate rock load which a tunnel lining should support when the tunnel was excavated in cohesionless dry coarse soil. Vertical rock load (P_{roof}) was suggested by Equation (1) for shallow tunnels.

$$P_{roof} = \frac{\gamma B}{2K\tan\phi}(1 - e^{K\tan\phi\frac{2H}{B}}) \quad (1)$$

where B is the relaxed range ($= 2[\, b/2 + m\,tan(45 - \phi/2)]$), v is the unit weight of rock mass, K is coefficient of lateral earth pressure, ϕ is friction angle, b, m, and H are the width, height, and depth of a tunnel respectively.

For deep tunnels, the vertical rock load was also suggested as follows;

$$P_{roof} = \frac{\gamma B}{2K\tan\phi}(const.) \quad (2)$$

2.2 *Bierbäumer's equation*

Bierbäumer (1913) assumed that the shape of stress relaxed zone occurred due to tunnel excavation might

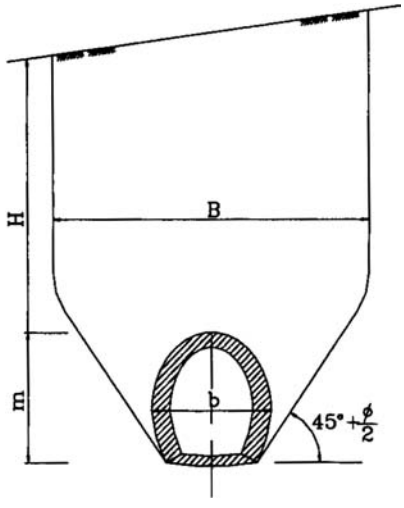

Figure 1. The assumed failure mechanism for Terzaghi's rock load.

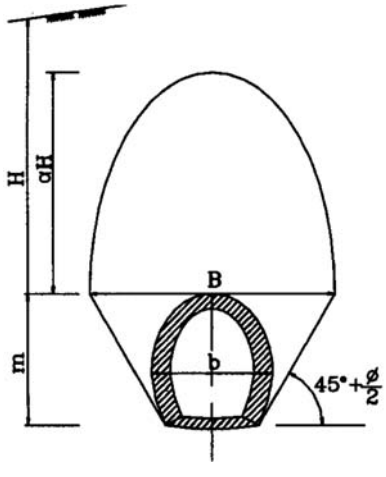

Figure 2. The assumed relaxed zone of Bierbäumer.

be a parabola as shown in Figure 2 (Part, 2003). In Figure 2, b is the internal friction angle of rock mass, m is the tunnel height, and B is the width of the relaxed zone.

As can be seen in Figure 2, the upper relaxed zone acts on the tunnel along $45+\phi/2$ inclined plane as a vertical load. The height of the relaxed zone (h) is assumed to be proportional to the depth of the tunnel (H); $h=\alpha H$ (α is reduction factor). At tunnel crown, the vertical relaxed load (P_{roof}) can be given as follows;

$$P_{roof} = \alpha H \nu \tag{3}$$

where, ν is the unit weight of rock mass. And the reduction factor can be obtained as follows;

- when H is very small;

$$\alpha = 1 \tag{4}$$

- when $H \leq 5B$;

$$\alpha = 1 - \frac{\tan\phi \tan^2(45-\phi/2)\, H}{b + 2m\tan(45-\phi/2)} \tag{5}$$

- when $H \geq 5B$;

$$\alpha = \tan^4(45-\phi/2) \tag{6}$$

2.3 *Empirical approaches*

2.3.1 *Terzaghi's rock load classification*

Terzaghi (1946) proposed rock load classification for steel rib support and then Rose modified it as shown in Table 1 in 1982. In the system, rock load conditions are divided into 9 categories. However it is very subjective and can be applicable only for the horseshoe shaped tunnels.

2.3.2 *Approach based on the RMR classification system*

Unal(1983) proposed the following empirical equation for the estimation of vertical rock load (P_{roof}) based upon RMR values which a tunnel should be supported:

$$P_{roof} = \nu b\left(\frac{100-RMR}{100}\right) \tag{7}$$

where ν is the unit weight of rock mass and b is tunnel width.

2.3.3 *Approach based on the Q system*

Barton et al. (1974) proposed an empirical equation for the estimation of vertical rock load (P_{roof}) based on Q values as follows;

if the number of joint sets ≥ 3;

$$P_{roof} = 2\,Q^{-1/3} J_r^{-1} \quad (kg/cm^2) \tag{8}$$

if the number of joint sets <3 ;

$$P_{roof} = \frac{2}{3}\sqrt{J_n}\,Q^{-1/3} J_r^{-1} \quad (kg/cm^2) \tag{9}$$

where Q is Q value, J_n is the number of joint sets, and J_r is the joint roughness coefficient.

Also, horizontal rock load (P_{wall}) can be calculated from the same equations applied for P_{roof} with the transformed Q value (Q′) according to Table 2.

2.4 *Numerical approach*

Chun and Shin (2001) investigated a methodology to estimate rock load numerically for the design of concrete lining of a tunnel. They assumed that concrete

Table 1. Terzaghi's rock load classification (Rose, 1982).

Rock condition	RQD	Rock load height, H_p(m)	Remarks
1. Hard and intact	95 ~ 100	0	Light limiting required only if spalling or popping occurs.
2. Hard stratified or schistose	90 ~ 99	0 ~ 0.5b	Light support, mainly for protection against spalling. Load may change erratically from point to point.
3. Massive, moderately jointed	85 ~ 95	0 ~ 0.25b	
4. Moderately blocky and seamy	75 ~ 85	0.25b ~ 0.20 (b + m)	Types 4, 5 and 6 reduced by about 50% from Terzaghi values because water table has little effect on rock load. (Terzaghi, 1946; Brekke, 1968)
5. Very blocky and seamy	30 ~ 75	(0.20 ~ 0.60) (b + m)	
6. Completely crushed but chemically intact	3 ~ 30	0.60 ~ 1.10 (b + m)	
6a. Sand and gravel	0 ~ 3	1.10 ~ 1.40 (b + m)	
7. Squeezing rock, moderate depth	NA	(1.10 ~ 2.10) (b + m)	Heavy side pressure, invert struts required. Circular ribs are recommended.
8. Squeezing rock, great depth	NA	(2.10 ~ 4.50) (b + m)	–
9. Swelling rock	NA	Up to 250ft irrespective of value of (b + m)	Circular ribs required. In extreme cases, use yielding support.

Note: b: tunnel width, m: tunnel height.

Table 2. Transformed Q value.

Range of Q value	Q′
$10 < Q$	5Q
$0.1 \leq Q \leq 10$	2.5Q
$Q < 0.1$	Q

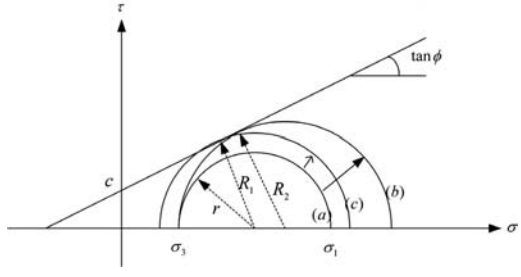

Figure 3. Local factor of safety.

lining must support the whole load when the shotcrete lost its support capability after long period time.

They compared two ways of calculating rock load which the lining supports. One way is that rock load can be proportional to the size of the plastic zone occurred around tunnel excavation periphery. The other way is that rock load can be a function of radial stresses occurred behind shotcrete.

As the results, it was concluded that the radial stresses behind shotcrete might not be properly used as rock load because it became much greater around lower corner than around crown and its magnitude was very small. Also when the rock load is estimated to be proportional to the size of plastic zone, it can be very sensitive to the ground properties such as cohesion and the coefficient of lateral earth pressure etc. Therefore, they recommend that great care must be given in estimating ground parameters for the design of tunnel lining.

3 LOCAL SAFETY FACTOR OF A TUNNEL

In numerical analysis, state of stresses can presented at each elements in terms of principal stresses (σ_1 and σ_3) as shown in Figure 3. This stress state is, in general, depicted by a Mohr's circle (*a*) with a radius *r* in

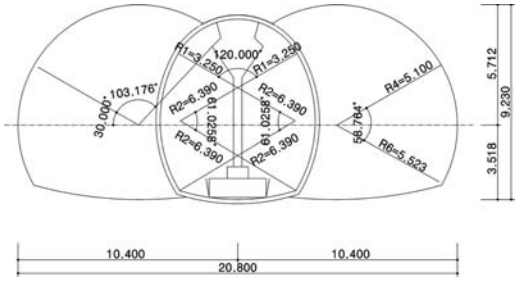

Figure 4. Tunnel section of interest.

the σ-τ plane. Failure is assumed to occur when the circle touches the failure envelope. If failure occurs at a certain stress state, σ_1 should increase keeping σ_3 unchanged until the circle touches the failure envelope like circle (*b*). (Itasca Consulting Group, 1999). Also, failure can be reached by increasing the radius of the circle keeping the center of a circle fixed like circle (*c*). The ratio of two circles' radii (R_1/r, or R_2/r) is a kind of strength/stress ratio in a given state of stresses and is often called as 'local factor of safety (FS)'.

In this study, local factor of safety is obtained with the assumption that failure occurs by increasing σ_1 and keeping σ_3 unchanged. The maximum principal stress at the moment of failure (σ_{1f}) can be written as follows;

$$\sigma_{1f} = (\frac{1+\sin\phi}{1-\sin\phi})\sigma_3 - 2c\sqrt{\frac{1+\sin\phi}{1-\sin\phi}} \quad (10)$$

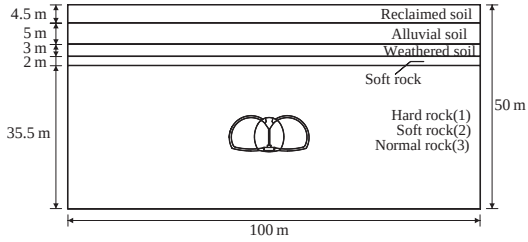
This approach can be very effective in explaining how close the failure is at each element. In addition, it is very useful in searching potential weak zones from tunnel excavation and the zone where supports are required (You, et al., 2000).

$$FS = \frac{R_2}{r} = \frac{\sigma_3 - \sigma_{1f}}{\sigma_3 - \sigma_1} \quad (11)$$

Therefore, it is expected that the size of relaxed zone occurred by tunnel excavation could be found by finding the contour of local safety factor of 2.0 or 3.0.

4 NUMERICAL ANALYSIS

In this study, a numerical analysis was performed to estimate rock load height for the design of 2-arch tunnel lining. The 2-arch tunnel has a cross section of 20.8 m wide and 9.23 m high as shown in Figure 4. In numerical modeling, the construction sequence are simplified into 3 stages; excavation of center tunnel (stage I), excavation of left arch tunnel (stage II), and excavation of right arch tunnel (stage III).



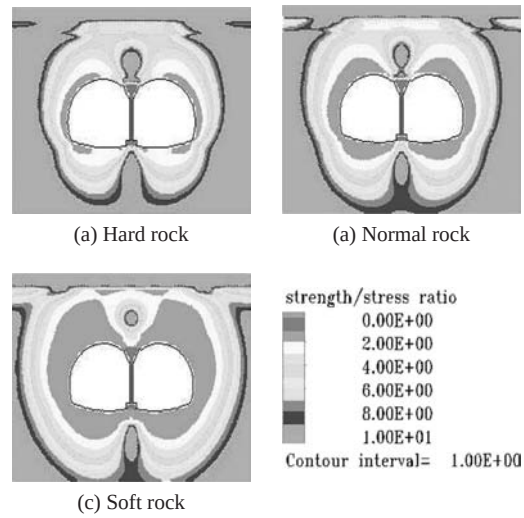


Figure 5. Configuration of numerical analysis.

Table 3. Properties for layers.

Layer	Unit weight (tf/m^3)	Cohesion (tf/m^2)	Friction angle (°)	Deformation modulus (tf/m^2)	Poisson's ratio
Reclaimed soil	1.8	1.0	27	800	0.35
Alluvial soil	1.8	0.5	28	900	0.40
Weathered soil	2.0	1.0	30	3,000	0.30
Soft rock	2.3	10.0	33	260,000	0.27
Normal rock	2.6	20.0	34	300,000	0.25
Hard rock	2.7	30.0	38	550,000	0.22

(a) Hard rock (a) Normal rock

(c) Soft rock

Figure 6. Contours of local safety factors at final construction stage for 3 different rock conditions.

As can be seen in Figure 5, reclaimed soil layer, alluvial soil layer, and weathered soil layer are located at the top of the tunnel. Three different layers; hard, soft, and normal rock layer at which the tunnel is located was modeled respectively to get an idea how ground conditions influence the rock load height. The properties of each layer used for the numerical analysis are listed at Table 3.

Table 4. Estimated thickness of relaxed zone.

Layer	Excav. stage	Elevation of local safety factor (m)		Thickness of relaxed zone (m)		Elevation of tunnel crown (m)
		FS = 2.0	FS = 3.0	FS = 2.0	FS = 3.0	
Hard	I	9.44	10.0	0.59	1.15	8.85
rock	II	10.0	11.6	0.7	2.3	9.3
	III	10.3	12.25	1.0	2.95	9.3
Normal	I	10.07	10.75	1.22	1.9	8.85
rock	II	11.4	13.25	2.1	3.95	9.3
	III	11.95	13.9	2.65	4.6	9.3
Soft	I	11.4	12.45	2.55	3.15	8.85
rock	II	14.6	17.1	5.3	7.8	9.3
	III	15.75	17.15	6.45	7.85	9.3

FLAC version 3.4 was used for the numerical analysis. At each element, the local safety factor was calculated and its contour was obtained at 3 different construction stages. Figure 6 shows the contour of local safety factors at construction stage III which is the final stage of the construction. The thickness of relaxed zone which can be considered to be rock load height was obtained by subtracting the elevation of tunnel crown from the elevation of local safety factor contour and the results are arranged in Table 4.

From Table 4 and Figure 6, it can be known that as rock conditions become weaker and construction advances, the relaxed zone expands and its thickness increases. Especially, it can be concluded that local safety factor of 2.0 or 3.0 can give a realistic rock load height for the design of concrete lining. In addition, this approach can be effectively used as a systematic way of estimating rock load height for concrete lining design.

5 CONCLUSIONS

In this study, the existing methods of estimating rock relaxed load were compared. A systematic way was proposed to estimate the relaxed zone around a tunnel periphery due to the excavation for the design of 2-arch tunnel lining. In this approach, first of all, local safety factor is calculated from the redistributed stresses due to the tunnel excavation. Then rock load height is estimated based on the assumption that the region corresponding to the local safety factor of 2.0 or 3.0 might be the relaxed zone.

The proposed approach in this study is independent of the shape of a tunnel and ground conditions since rock load height is estimated from a fairly clear and well established criterion of local safety factor. Additionally, it is expected that a tunnel designer' subjectivity might be avoided in the design of concrete lining.

ACKNOWLEDGEMENTS

This study was partly funded by the Korea Institute of Construction and Transportation Technology Evaluation and Planning under Korean Ministry of Construction and Transportation in Korea (Grant No.: 05-D01, Development of Water Control Technology in Undersea Structures). The authors deeply appreciate the authorities concerned.

An analytical solution of shield tunnel based on force method

Xiaomin You, Zixin Zhang, Yongsheng Li
Department of Geotechnical Engineering, Tongji University, Shanghai, P.R.China

ABSTRACT: Based on the released assumption of the given distribution of soil resistance pressure, the 'force method' is used to determine the internal forces, displacements and the distribution range of soil resistance of shallow shield tunnel lining. This paper considers those factors which would affect the distribution range in detail, such as tunnel geometry, stiffness, soil resistance coefficient, etc. The comparison is also made between the numerical results and the analytical solution under the same condition. And the analytical solution makes a good agreement with the numerical results.

1 INTRODUCTION

With the rapid development in modern city, people's demands for convenience in commuting and living are expanding, while the city space is limited. Recent advancements in tunnelling construction technology help to mitigate the problem, for its virtue to minimize the influence to superstructures and so people's daily life.

Nowadays, shield tunnels in urban area have two points in common, i.e. large section and shallow embedded depth. The outer diameter of shield tunnels constructed in Shanghai in recent years has increased from 6.2 m to 15 m while the ratio of thickness versus diameter correspondingly decreased from 0.060 to 0.043. To reduce the influence to the surrounding environment, the embedded depth of shield tunnel should be 1–1.5 times of its diameter (Zhang et al. 2004). However, shield tunnels are usually embedded at the depth less than its diameter, especially when they are advanced away or close to shafts. Shanghai Yangtse River Tunnel with diameter of 15 m is embedded 6.9 m when near the shafts.

On the other hand, different design models (Morgan 1961, Muir Wood 1975, I.T.A. 2000) are presented with the advancements in theoretical analysis. Models (Lee et al. 2001, Koyama 2003) based on Force-method are still widely used even in today, for the reason of clear mechanics concepts and simple and effect calculation. However, in most common models, soil resistant pressure is assumed to be distributed in the range of 45°∼145°. Considering the special characteristic of large section, relative thinner thickness and shallow embedded depth for current tunnels, whether the distribution of soil resistant pressure will change and how the effect this kind of change will bring to behavior of tunnel lining should be carefully studied.

The purpose of this paper is to develop an analytical solution for shield tunnel to study the change of distribution of soil resistant pressure. The proposed solution is then compared with conventional model solution and numerical simulation results.

2 DEDUCTION BASED ON FORCE-METHOD

The proposed solution focuses on the change of the distribution of soil resistant pressure around tunnel lining, so the existence of joints is not under consideration in this paper. Tunnel lining is assumed to be a continuous circle ring, and the load pattern is shown in Figure 1. The loads $p_1 \sim p_6$ on the tunnel lining have been defined

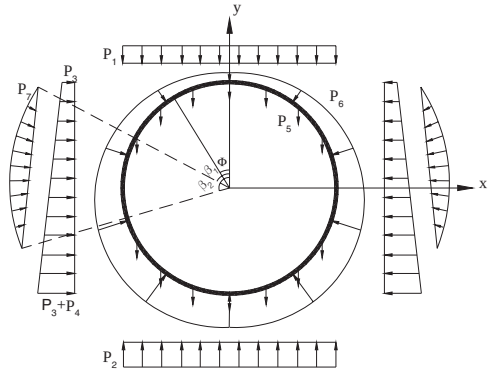

Figure 1. Load Condition of Tunnel Lining.

by Liu & Hou 1991, where p_1 is the vertical earth pressure at crown of lining; p_2 is the reaction pressure at bottom of lining; p_3 is the horizontal earth pressure at the crown level of tunnel lining; p_4 is the additional horizontal earth pressure at the bottom level of tunnel lining; p_5 is the self-weight of tunnel lining; and p_6 is the hydrostatic pressure. In the proposed solution, the distribution of soil resistant pressure p_7 ranges from β_1 to β_2. The soil resistant pressure, p_7, is defined as:

$$P_7 = -K\delta \cdot \cos(A\varphi + B\pi) \tag{1}$$

where δ is the largest radial displacement of tunnel lining, which is assumed to be at the middle of β_1 and β_2, $A = \pi/\Delta\beta$, $B = (\beta_2 - 3\beta_1)/\Delta\beta$, $\Delta\beta = \beta_2 - \beta_1$. β_1 is the first angle where the radial displacement is zero, measured from the vertical direction; β_2 is the second angle where the radial displacement is zero, also measured from the vertical direction. K is the soil resistance coefficient. The typical values of K are shown in Table 1.

For the convenience of describing the deduction, the sign conventions in this paper are: the bending moment is positive when the inside surface of tunnel lining is subject to tension; the axial force is positive when the tunnel lining is subject to compression; the shear force is positive when it tends to make the lining rotate counterclockwise.

For the symmetry of tunnel structure and load pattern, the model for calculation can be simplified as Figure 2, and the Force-method equation can be given as follows:

$$\begin{cases} \delta_{11}x_1 + \Delta_{1p} = 0 \\ \delta_{22}x_2 + \Delta_{2p} = 0 \end{cases} \tag{2}$$

where x_1 and x_2 are, respectively, the bending moment and the axial force at the elastic centre; δ_{ii} is the displacement at the location of x_i on the direction of x_i due to the unit force $x_i = 1, i = 1, 2$; Δ_{ip} is the displacement at the location of x_i on the direction of x_i due to the loads around the tunnel lining.

Solve the Equation (2), and then x_1 and x_1 are given as follows:

$$\begin{cases} x_1 = -\dfrac{\Delta_{1p}}{\delta_{11}} \\ x_2 = -\dfrac{\Delta_{2p}}{\delta_{22}} \end{cases} \tag{3}$$

Let $x_1 = 1, x_2 = 0$, and $x_1 = 0, x_2 = 1$, respectively, then the internal forces, $\overline{M}_1$, $\overline{N}_1$, $\overline{Q}_1$ and $\overline{M}_2$, $\overline{N}_2$, $\overline{Q}_2$ are:

$$\begin{cases} \overline{M}_1 = 1 \\ \overline{N}_1 = 0 \\ \overline{Q}_1 = 0 \end{cases} \text{ and } \begin{cases} \overline{M}_2 = -R \cdot \cos\varphi \\ \overline{N}_2 = \cos\varphi \\ \overline{Q}_2 = -\sin\varphi \end{cases} \tag{4}$$

According to the virtual work principle, δ_{11} and δ_{22} can be determined by

$$\begin{cases} \delta_{11} = \int_0^{\pi} \dfrac{\overline{M}_1^{\,2}}{EI} ds = \dfrac{R\pi}{EI} \\ \delta_{22} = \int_0^{\pi} \dfrac{\overline{M}_2^{\,2}}{EI} ds = \dfrac{R^3\pi}{EI} \end{cases} \tag{5}$$

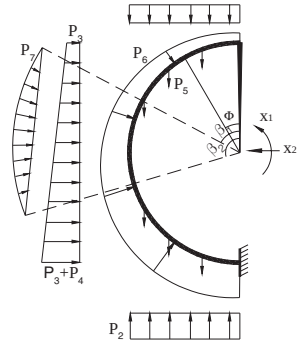

Figure 2. Simplified model for calculation.

Table 1. Typical values of soil resistance coefficient for clay (Zhang et al. 2004).

Ground Condition	Clay					Sand		
	Silt	Soft	Medium	Stiff	Very stiff	Loose	Dense	Very dense
$K(10^3\text{kN/m}^3)$	0	0∼5	5∼10	10∼30	30∼50	0∼10	10∼30	30∼50
SPT N-value	0∼2	2∼4	4∼8	8∼25	>25	<15	15∼30	>30

The internal forces, M_p, N_p, Q_p, caused by surrounding loads, is the accumulation of seven loading cases as shown in Figure 1:

$$\begin{cases} M_p = \sum_{j=1}^{7} M_{pj} \\ N_p = \sum_{j=1}^{7} N_{pj} \\ Q_p = \sum_{j=1}^{7} Q_{pj} \end{cases} \tag{6}$$

where M_{pj}, N_{pj}, Q_{pj} are bending moment, axial force, and shear force due to the loading case j, respectively.

For loading case 1–6, the solution is as usual one. However, the solution for case7 is as follows:

$$M_{p7} = \begin{cases} 0 & 0 \le \varphi < \beta_1 \\ \dfrac{\Delta\beta K\delta R^2}{\Delta\beta^2 - \pi^2}\left[\Delta\beta\cos(A\varphi + B\pi) + \pi\sin(\varphi - \beta_1)\right] & \beta_1 \le \varphi < \beta_2 \\ \dfrac{\pi\Delta\beta K\delta R^2}{\Delta\beta^2 - \pi^2}\left[\sin(\varphi - \beta_1) + \sin(\varphi - \beta_2)\right] & \beta_2 \le \varphi \le \pi \end{cases} \tag{7}$$

$$N_{p7} = \begin{cases} 0 & 0 \le \varphi < \beta_1 \\ \dfrac{-K\delta R}{\Delta\beta^2 - \pi^2}\left[\Delta\beta^2\cos(A\varphi + B\pi) + \pi\cdot\Delta\beta\sin(\varphi - \beta_1)\right] & \beta_1 \le \varphi < \beta_2 \\ \dfrac{\pi\Delta\beta K\delta R}{\Delta\beta^2 - \pi^2}\left[\sin(\beta_1 - \varphi) + \sin(\beta_2 - \varphi)\right] & \beta_2 \le \varphi \le \pi \end{cases} \tag{8}$$

$$Q_{p7} = \begin{cases} 0 & 0 \le \varphi < \beta_1 \\ K\delta\cdot R\dfrac{\pi\cdot\Delta\beta\left[\sin(A\varphi + B\pi) - \cos(\varphi - \beta_1)\right]}{\Delta\beta^2 - \pi^2} & \beta_1 \le \varphi < \beta_2 \\ -K\delta\cdot R\dfrac{\pi\cdot\Delta\beta\cdot\left[\cos(\varphi - \beta_1) + \cos(\varphi - \beta_2)\right]}{\Delta\beta^2 - \pi^2} & \beta_2 \le \varphi \le \pi \end{cases} \tag{9}$$

Based on aforementioned equations, Δ_{1p} and Δ_{2p} can be written as:

$$\begin{cases} \Delta_{1p} = \sum_{j=1}^{7} \Delta_{1pj} \\ \Delta_{2p} = \sum_{j=1}^{7} \Delta_{2pj} \end{cases} \tag{10}$$

Where Δ_{1pj} and Δ_{2pj} are for the loading case j ($j = 1, \ldots, 7$), and can be written based on virtual work principle.

For loading case 1–6, the solutions for Δ_{1pj} and Δ_{2pj} are also as usual ones. However, for case7,

$$\begin{aligned} \Delta_{1p7} &= \int_0^{\beta_1} \frac{\overline{M}_1 M_{p7}}{EI} ds + \int_{\beta_1}^{\beta_2} \frac{\overline{M}_1 M_{p7}}{EI} ds + \int_{\beta_2}^{\pi} \frac{\overline{M}_1 M_{p7}}{EI} ds \\ &= \frac{K\delta\cdot R^3\Delta\beta}{EI\left(\Delta\beta^2 - \pi^2\right)}\left[-\frac{2\Delta\beta^2}{\pi} + \pi\left(\cos\beta_1 + \cos\beta_2 + 2\right)\right] \end{aligned} \tag{11}$$

$$\begin{aligned} \Delta_{2p7} &= \int_0^{\beta_1} \frac{\overline{M}_2 M_{p7}}{EI} ds + \int_{\beta_1}^{\beta_2} \frac{\overline{M}_2 M_{p7}}{EI} ds + \int_{\beta_2}^{\pi} \frac{\overline{M}_2 M_{p7}}{EI} ds \\ &= \frac{K\delta\cdot R^4\Delta\beta}{2EI\left(\Delta\beta^2 - \pi^2\right)}\left\{-\frac{2\Delta\beta^2\pi\left(\cos\beta_1 + \cos\beta_2\right)}{\Delta\beta^2 - \pi^2}\right. \\ &\quad + \pi\left[(\pi - \beta_1)\sin\beta_1\right. \\ &\quad \left.\left. + (\pi - \beta_2)\sin\beta_2\right]\right\} \end{aligned} \tag{12}$$

Based on the previous equations, the values of δ_{11}, δ_{22}, Δ_{1p}, Δ_{2p} are obtained, so the redundant forces, x_1 and x_2, can be expressed by Equation (3), and then the total internal forces can be given by the following equation:

$$\begin{cases} M = \overline{M}_1\cdot x_1 + \overline{M}_2\cdot x_2 + M_p \\ N = \overline{N}_1\cdot x_1 + \overline{N}_2\cdot x_2 + N_p \\ Q = \overline{Q}_1\cdot x_1 + \overline{Q}_2\cdot x_2 + Q_p \end{cases} \tag{13}$$

The following is to determine the radial displacement of tunnel lining and the distribution range of soil resistant pressure. In the simplified calculation model, the center of tunnel lining would have a settlement. Here, we assume the settlement at the lining center has the same value as the tangential displacement at the lining where $\varphi = \pi/2$. Then the final radial displacement, u, can be expressed as:

$$u = \sum_{j=1}^{7} u_{pj} + u_x + v_o\cdot\cos\varphi \tag{14}$$

where u_{pj} is the radial displacement due to the loading case j; u_x is the radial displacement due to the reluctant forces; v_o is the tangential displacement in the simplified model. Based on virtual work principle, u_{pj} can be given as:

$$u_{pj} = \int_{\varphi}^{\pi} \frac{\overline{M}_u M_{pj}}{EI} R d\alpha = \int_{\varphi}^{\pi} \frac{R\sin(\alpha - \varphi)\cdot M_{pj}}{EI} R d\alpha \qquad j = 1, \ldots, 7 \tag{15}$$

where $\overline{M}_u$ is the bending moment at α due to the virtual unit force acting on the tunnel lining along the direction of radius at φ.

For the redundant forces x_1 and x_2:

$$u_{px} = \int_{\varphi}^{\pi} \frac{\overline{M}_u M_x}{EI} Rd\alpha = \int_{\varphi}^{\pi} \frac{R\sin(\alpha-\varphi)\cdot\left(\overline{M}_1 x_1 + \overline{M}_2 x_2\right)}{EI} Rd\alpha = \frac{x_1 R^2}{EI}(\cos\varphi+1) + \frac{x_2 R^3}{2EI}\sin\varphi(\pi-\varphi) \quad (16)$$

v_o, the tangential displacement where $\varphi = \pi/2$, is consist of two parts, one for seven loading cases and the other for the redundant forces, given as follows:

$$v_o = \sum_{j=1}^{7} v_{opj} + v_{ox} \qquad j = 1,\ldots,7 \quad (17)$$

where v_{oj} is the tangential displacement where $\varphi = \pi/2$ due to the jth loading case,

$$v_{opj} = \int_{\frac{\pi}{2}}^{\pi} \frac{\overline{M}_{vo} M_{pj}}{EI} ds = \int_{\frac{\pi}{2}}^{\pi} \frac{R(1-\sin\varphi)\cdot M_{pj}}{EI} ds \quad (18)$$

where $\overline{M}_{vo}$ is the bending moment due to the virtual unit force acting on the tunnel lining along the tangential direction at φ.

For the redundant forces x_1 and x_2,

$$v_{ox} = \int_{\frac{\pi}{2}}^{\pi} \frac{\overline{M}_{v0} M_x}{EI} ds = \int_{\frac{\pi}{2}}^{\pi} \frac{R(1-\sin\varphi)\cdot\left(\overline{M}_1 x_1 + \overline{M}_2 x_2\right)}{EI} ds = \frac{x_1 R^2}{EI}\left(\frac{\pi}{2}-1\right) + \frac{x_2 R^3}{2EI} \quad (19)$$

3 COMPARISON

3.1 *Analysis of the parameters*

Soil resistant pressure in the new analytical solution is not known initially, so radial displacement has to be calculated by iterations until the value and the distribution range are in accordance with soil resistant.

Here two cases are chosen, one in sand layer and the other in clay layer to do the analysis. As shown in Table 2, all the natural parameters of the soil are from the actual project constructing in China.

3.1.1 *Effect of horizontal soil pressure coefficient*

The effects of horizontal soil pressure coefficient are examined by comparing the results of the case in clay layer embedded 0.7D with different horizontal soil pressure coefficient. For the convenience to describe, β is defined as $\beta = (\beta_1 + \beta_2)/2$ which describes the general location and $\Delta\beta$ describes the distribution range of soil resistant pressure.

The result of distribution of soil resistant pressure is shown in Figure 3. In Figure 3, two curves of $\Delta\beta$ do not show clear trends with the increase of K_0 until K_0 reaches 0.65, while both of the two β curves have the same trend. The values of β decrease obviously with the increase of K_0. It decreases more quickly at higher value of K_0. As shown in the figure, when t/D = 0.043, β decreases 2.5 degrees when K_0 increases from 0.35 to 0.65, while β decreases 2.25 degrees when K_0 increases from 0.65 to 0.70. On the other hand, the thickness of tunnel lining is also another factor to influence the results. For the case of t/D = 0.060, β totally decreases 2.5 degrees while β decreases 5.75 degrees in the case of t/D = 0.043.

The aforementioned observations have shown the effect of horizontal soil pressure coefficient. The increasing horizontal soil pressure coefficient will intensify the inhomogeneity of horizontal earth pressure, which means that additional horizontal earth pressure at the bottom level of tunnel lining,p_4, will take great weight to determine the internal forces in the tunnel lining, if the embedded depth is smaller comparing with the tunnel diameter.

Table 2. Detailed information about cases adopted in analysis.

	R	h_w	γ	γ_w	K	
Cases	m	m	kN/m^3	kN/m^3	kN/m^3	K_0
Clay layer	5	0	16.9	10	5000	055
Sand layer	5	0	19.8	10	10000	0.25

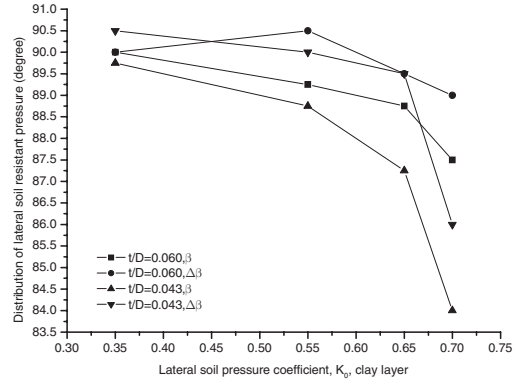

Figure 3. Distribution range of soil resistant pressure Vs. K_0.

3.1.2 *Effect of soil resistance coefficient*

The effects of soil resistance coefficient are examined by comparing the results of the case in sand layer embedded 0.7D with different soil resistance coefficient. The result of distribution of soil resistant pressure is shown in Figure 4.

In Figure 4, both of the two curves of β have some decrease with the increase of soil resistance coefficient K, and the one with thinner tunnel lining (i.e. $t/D = 0.043$) decreases a little more than that with thicker tunnel lining (i.e. $t/D = 0.060$).Both of the two curves of $\Delta\beta$ in Figure 4 have shown relatively obvious increasing trend with the increase of K. The increasing $\Delta\beta$ describes the extended range of soil resistant pressure, and the one with thinner tunnel lining (i.e. $t/D = 0.043$) increases much more than that with thicker tunnel lining (i.e. $t/D = 0.060$). As shown in the figure, $\Delta\beta$ increases 6 degrees in the case of $t/D = 0.043$, while $\Delta\beta$ only increases 2.5 degrees in the case of $t/D = 0.060$ when K increases from 0 to 50000 kN/m^3.

The effect of soil resistant pressure is obtained from the aforementioned observations. The soil resistance coefficient, K, as the significant factor to determine the value of the soil resistant pressure and the displacement of tunnel lining, directly describes the interaction between soil and tunnel lining.

3.2 *Comparison with different solutions*

To verify the proposed analytical solution, different solutions are used to analyze the same case with characteristic parameters of soil from the real project (Sha 2005, shown in Table 3). The results of conventional model and FEM are compared with those from the new analytical solution. The numerical simulation adopts the professional finite element software, PLAXIS-2D.

Figure 5 shows the numerical model, in which soil is decomposed into solid elements and tunnel lining is simulated with beam elements. Figure 6 shows the meshwork of tunnel lining.

With the proposed analytical solution, two significant parameters controlling the distribution of soil resistant pressure, β and $\Delta\beta$, are 89° and 93°, respectively, which means the acting range of the soil resistant pressure has moved and extended along the tunnel lining. Comparisons of internal forces calculated by the proposed analytical solution, conventional model solution and FEM are shown in Figure 7, Figure 8 and Figure 9, respectively.

In Figure 7, both the results from the proposed analytical solution and the conventional model solution

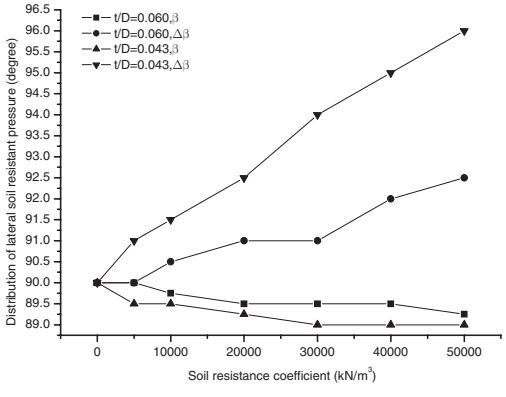

Figure 4. Distribution range of soil resistant pressure Vs. K.

R m	h_w m	H* m	t m	γ kN/m^3	γ_w kN/m^3	C kPa	φ °	SPT N-value	K_0	K kN/m^3	E_c* kN/m^3
5	0	7	0.43	19.8	10	1	38	18.7	0.33	20000	22000

* H is the embedded depth and E_c is compression modulus.

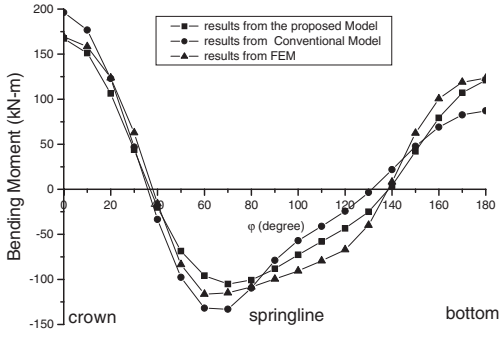

Figure 7. Comparison of bending moment.

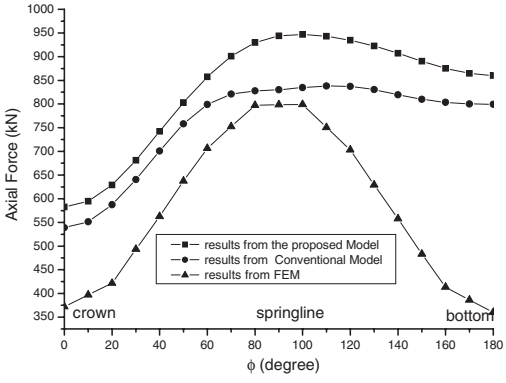

Figure 8. Comparison of axial force.

are generally accordant with those of numerical simulation, while the former results agree with those from FEM better than the latter. Before φ reaches 70°, all the results of the three curves reasonably agree with each other and after 70°, the curve of proposed analytical solution is closer to the curve of FEM than that of conventional model solution both in shape and value. The difference between the curves of proposed model and FEM is about 10%∼30% and the difference between the curves of conventional model and FEM is about 20%∼60%.

Figure 8 shows the comparison of axial force calculated by different solutions. As shown in the figure, neither the curve from proposed analytical solution nor the curve from conventional model solution is close to the curve from FEM. The reason should be relevant with the truth that FEM adopts the continuum mechanics model, in which the surrounding soil layer and the tunnel structure is treated as a whole, so the soil layer can also bear some loads, while in the other two solutions, the soil layer is only considered as loads.

The comparison of shear force from different solutions is shown in Figure 9, where the curve for the

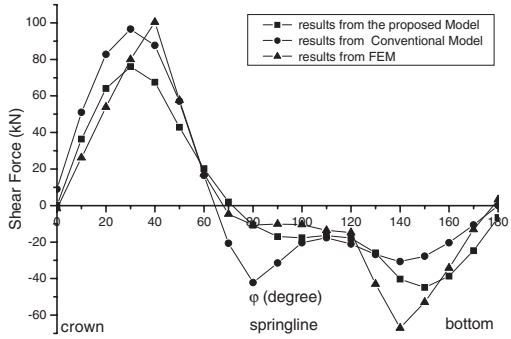

Figure 9. Comparison of shear force.

proposed analytical solution agrees with the results of FEM better than that for the conventional model solution, which is also consistent with the comparison of bending moment in Figure 7.

Based on the previous comparison of internal forces, the proposed analytical solution is relatively more suitable to analyze the shallow tunnel than conventional model, considering the change of distribution of soil resistant pressure.

4 CONCLUSION

Based on the Force-method, this paper develops an analytical solution for shield tunnel to study the change of distribution of soil resistant pressure, the effect of horizontal soil pressure coefficient and soil resistance coefficient, with consideration of different ratio of lining thickness versus diameter. The proposed solution is compared with conventional model solution and numerical simulation results. On the basis of the calculated results, the following conclusions can be drawn:

(a) For a given soil resistance coefficient and a shallow embedded depth, the distribution of soil resistant pressure is significantly effected by the value of horizontal soil pressure coefficient, K_0, and also the ratio of thickness versus diameter is a influencing factor. In the typical range of 0.35∼0.70 for K_0, the soil resistant pressure moves up along the tunnel lining. The magnitude of change in large highway tunnels (t/D = 0.043) is 2.5 times of that in subway tunnels (t/D = 0.060).

(b) For a given horizontal soil pressure coefficient and a shallow embedded depth, the distribution of soil resistant pressure is significantly effected by the value of soil resistance coefficient, K, and also the ratio of thickness versus diameter is a influencing factor. In the range of 0∼50000 kN/m^3 for K, the distribution range of soil resistant pressure

extends along the tunnel lining. The magnitude of extension in large highway tunnels (t/D = 0.043) is 2.4 times of that in subway tunnels (t/D = 0.060).

(c) The results predicted by the proposed analytical solution are compared with those of numerical simulation and the conventional model solution. The comparison indicates that the proposed solution agrees more reasonably, and it provides a new approach to better predict and make the preliminary design of shield tunnel lining.

Expert system for D&B tunnel construction

C.W. Yu & J.C. Chern
Sinotech Engineering Consultants, Inc., Taipei, Taiwan

ABSTRACT: To improve the technology for drill and blast tunnel construction in Taiwan, an expert system consisted of data bank, tool bank and decision making auxiliary system has been developed. Various tools can be used efficiently in carrying out data collection, processing, analysis and evaluation work required in the tunneling process. Using the successful tunnel case histories data learned from the past experiences, the system can provide multi-expertise assistance on the decision of support system and excavation procedures to be adopted in the construction site. The system can also provide rational estimation on the tunnel deformation under the selected support system and construction procedure with the aid of an artificial neural network approach. Application of the system to actual tunnel construction is given for demonstrating the capability of the system.

1 INTRODUCTION

The engineering practice for drilling and blasting (D&B) tunnel construction in Taiwan adopts similar approach used in the western countries. In the design stage, support requirements and construction procedures were pre-determined by using empirical rock classification method, mainly based on limited geological information and rock mass conditions obtained from the preliminary investigations.

During construction, actual rock mass rating was obtained at the tunnel face, and appropriate support system and construction procedures were selected and implemented. Monitoring instruments were installed for observing the performance of rock masses surrounding the tunnel. Revision and remediation were made on the support system or construction procedures, if necessary, to achieve a safe and economic tunnel construction.

However, due to the poor rock condition often encountered in Taiwan, excavation large span tunnel through poor quality rock mass has resulted in numerous engineering difficulties in the past two decades. These difficulties included uncontrolled excessive tunnel deformation, serious damage to the support system and even tunnel cave-in.

Figure 1 shows an example of driving a large span tunnel through a fault zone in northern Taiwan by using the traditional rock classification method. It required systematic pre-stressed tendons and re-mining and re-supporting the tunnel to overcome the uncontrolled excessive deformation. Controversies over the adequacy of tunnel support design and construction procedures based on experiences of different geological environments have become issues for the local tunneling community. This also calls for the development of a more rational system to deal with the processes in D&B tunnel construction. This paper presents the system and its application in a tunnel construction project.

Figure 1. Systematic pre-stressed tendons, re-mining and re-supporting had to be used to control large deformation of tunnel through a dry fault zone in the construction of the Second Freeway in northern Taiwan.

2 EXPERT SYSTEM FOR TUNNEL CONSTRUCTION

The tunnel expert system compiles expert knowledge and tools for facilitating the data collection and processing, data analysis and evaluation, and decision

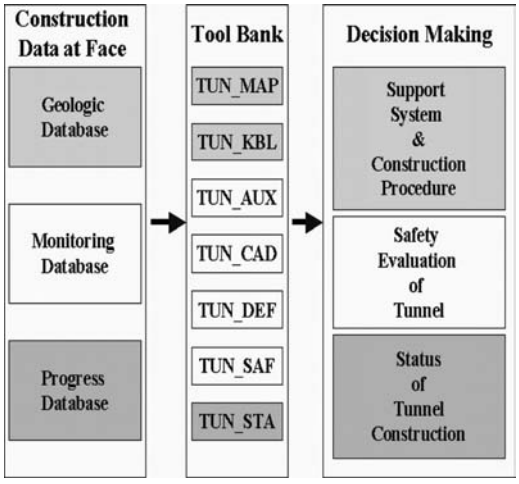

Figure 2. Working processes of the expert system developed.

TUN_SAF	Tunnel Safety Evaluation
TUN_STA	Construction Status Demonstrating

making in the tunnel construction processes. Figure 2 shows the working processes of the system.

The working processes contain 3 major blocks, i.e., (1) construction data collection at the site, (2) tool bank for various data processing, analysis, simulation and evaluation, and (3) decision making for support design and construction procedures recommendation, safety evaluation and construction status demonstration.

The functions of each module in the tool bank are outlined in Table 1. The working process will be described further in the following sections.

3 TOOL BANK

The tool bank of the expert system comprises of 7 subsystems as shown in Table 1, and the main functions of the subsystems are:

(1) Geological Information Collecting and Processing System (TUN_MAP) utilizes digital image taken on the tunnel face to retrieve the geological information for statistical analysis of joint systems and production of developed geological map of tunnel surface.
(2) Key Block Analysis System (TUN_KBL) can be used to perform key block analysis from the actual recorded joint information or statistically generated joint information.
(3) Construction Decision Making Auxiliary System (TUN_AUX) is a case history based artificial intelligence system for making multi-expertise recommendations on tunnel support system and construction procedures.
(4) Tunnel Deformation Prediction System (TUN_DEF) is an numerical analysis data based artificial neural network system for providing a rational estimation on the tunnel deformation under various geological and construction conditions.
(5) Tunnel Construction Simulation System (TUN_CAD) provides numerical analysis programs for carrying out back analysis of monitoring data and forward prediction analysis of tunnel performance by simulating the construction processes in the field.
(6) Tunnel Safety Evaluation System (TUN_SAF) utilizes the monitoring tunnel deformation for evaluating the safety of tunnel construction by using a case history based empirical tunnel safety criterion.
(7) Construction Status Demonstration System (TUN_STA) uses the records collected during tunnel excavation, including geological information, monitoring data and construction progress records, for demonstrating the status of tunnel construction.

The application for some of the systems will be demonstrated by the results of case study presented.

4 DECISION-MAKING MODULES

Decision-making modules include the recommendation of optimum tunnel support requirement and construction procedures, tunnel deformation estimation and safety evaluation during tunnel construction stages. It also provides the status of tunnel construction for better control of construction progress and tunneling conditions by the tunnel engineer.

4.1 *Optimum support requirement*

A Decision Making Auxiliary System (TUN_AUX) is a case-based artificial intelligence system together with the traditional empirical rock classification system. The working processes of system TUN_AUX are shown in Figure 3.

In the field, the parameters, including the tunnel span, strength of rock material, rock mass classification and overburden depth, collected are used for the

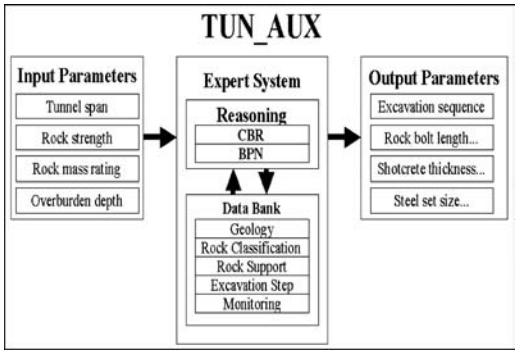

Figure 3. Flow chart of application of rock support decision-making auxiliary system.

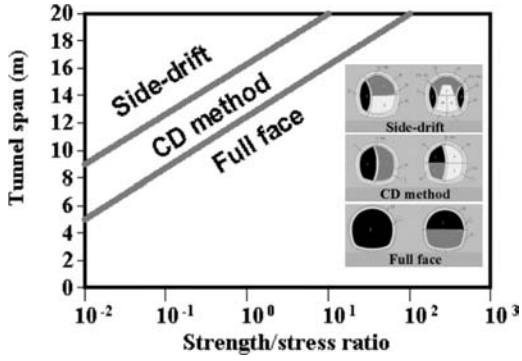

Figure 4. Optimized chart for selecting a suitable excavation procedure according to tunnel span and the strength stress ratio.

expert system. TUN_AUX can give a multi-expertise recommendations on the major support elements such as the length and spacing of rock bolts, thickness of shotcrete, size and spacing of steel sets, etc.

4.2 *Optimum construction procedures*

The Decision Making Auxiliary System (TUN_AUX) also provides a function for the recommendation of optimum construction procedure. The excavation procedures suitable for various tunnel spans and ground conditions were categorized into full face, central diaphragm (CD) and side drift. Based on the expert knowledge collected from experienced tunnel engineers and the results of construction simulation under various tunneling conditions, the optimum construction procedure is suggested by the tunnel span and strength/stress ratio at the construction site. The chart for selecting a suitable construction procedure is shown in Figure 4. Figure 5 shows the construction of a four-lane freeway tunnel under poor ground and very shallow rock cover by using dual side-drift method. Severe unstable condition was developed in a 3-lane adjacent tunnel with top heading and benching procedure.

4.3 *Tunnel deformation estimation*

Tunnel Deformation Prediction System (TUN_DEF) provides an estimation on the magnitude of tunnel deformation expected under various geological and construction conditions. The system was developed based on large amount of 3-D numerical simulations of the tunnel construction under various geological conditions, excavation sequences and support measures. Tunnel deformations, including roof settlement, horizontal convergency, as well as plastic zone thickness were given by a back propagation artificial neural network from the data base. It is intended to provide a rough estimate on the order of magnitude of tunnel deformation expected as guidance for tunnel engineer.

Figure 5. Four-lane freeway tunnel driven by dual side-drift excavation method adjacent to a shallow slope.

4.4 *Tunnel safety evaluation*

Empirical tunnel safety criterion based on case histories in Taiwan (Chern, et al. 1998) is used in the safety evaluation of tunnel. In the criterion, the information of the tunnel inward movement (δ), tunnel radius (R), rock mass strength (UCS) and actual performance of tunnel case histories were used to establish 3 warning levels of tunnel safety and the necessary measures to be taken.

Below warning level I, tunnel is considered to be in stable condition, and no special measure is required. Between warning levels II and III, tunnel is susceptible to instability, and review of support system and construction procedures adopted should be made. Above warning level III, tunnel is in unstable condition, and remedial measures should be taken to stabilize the tunnel.

Figure 6 shows the flow chart of tunnel safety evaluation using TUN_DEF and TUN_SAF systems.

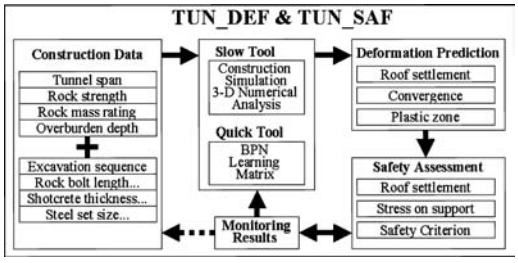

Figure 6. Flow chart of tunnel deformation prediction and safety evaluation.

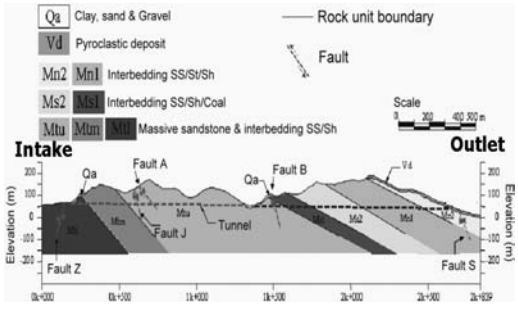

Figure 7. Geological profile of the flood diversion tunnel.

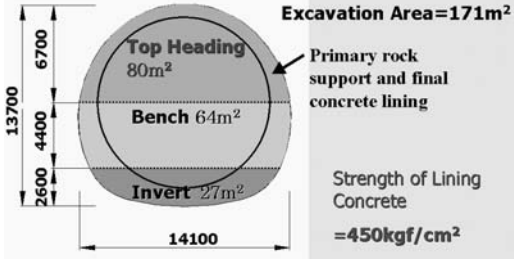

Figure 8. Tunnel section showing the excavation span and excavation steps.

5 CASE STUDY

To illustrate the application of the system developed, a case study on a flood diversion tunnel in northern Taiwan is presented.

The diversion tunnel is 2,835 m long driving through sedimentary rock formation of Miocene Age. The geological profile is shown in Figure 7. The maximum excavation span is 14.1 m and was excavated in 3 stages as shown in Figure 8. The major difficulties encountered in tunneling are associated with the fault zones and the disturbed zones adjacent to a volcanic intrusion.

The rock support system was designed according to the traditional RMR rock classification method.

Table 2. Suggested support elements predicted by the system.

Support type	Advance per round	Rockbolt length	Shotcrete thickness	Steel-rib size
Design Type III	1.0–1.4 m	4 m	20 cm	G220*
Design Type IV	0.8–1.2 m	6 m	25 cm	G220*
Suggested Type III	1.5–2.0 m	6–8 m	20–25 cm	H125†
Suggested Type IV	1.0–1.5 m	8–10 m	20–25 cm	H150†

* Use lattice girdle. †Use H-beam.

Figure 9. The highly disturbed rock exposed at 2k+008.

Five support types were proportioned according to the RMR rating. The rock support requirements were also examined by using the expert system TUN_AUX during construction. The results for type III and type IV rock are shown in Table 2 along with the original design of support system.

Most of the tunnel sections belong to the good quality rock with type II and type III support systems. The type III support adopted worked quite well. However, in a disturbed zone adjacent to the volcanic intrusion near station 2k+008, the poor quality rock mass (Figure 9) with RMR values in the range of 28 to 34 showed squeezing behavior under 140 m overburden stress. The monitoring results during tunnel excavation are shown in Figure 10.

The monitoring data for top heading excavation showed potential unstable condition according to the tunnel safety evaluating system TUN_SAF as shown in Figure 11. This proved to be true by the tunnel convergence occurred during subsequent benching.

Reviewing the support requirement and excavation procedure, it was found that the expert system would suggest a more conservative support system and excavation procedure. These can be shown by the longer bolt length as suggested in Table 2, and excavation by CD or side drift method recommended as shown in Figure 12.

Before benching, various remedial measures were further studies by using 3-D numerical simulations.

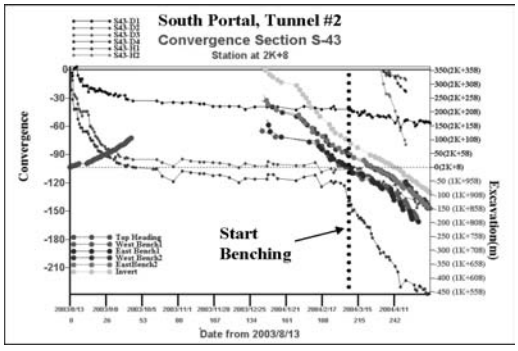

Figure 10. Monitoring results during tunnel excavation in disturbed zone near 2k+008.

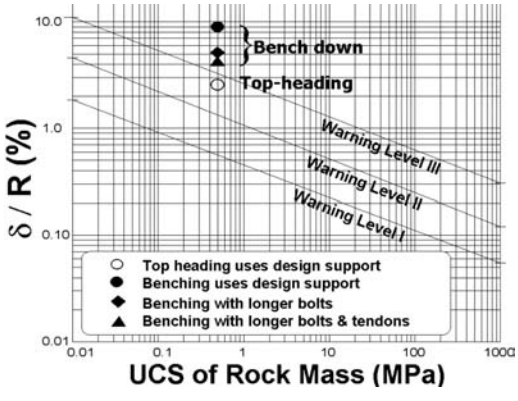

Figure 11. Potential unstable condition according to TUN_SAF evaluation.

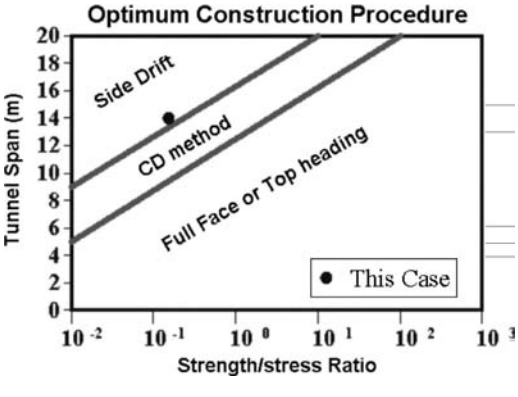

Figure 12. Excavation by CD or side drift method as recommended.

The predicted tunnel deformations after benching down are shown in Figure 11. Due to limited option available at the construction site, only additional 9-meter long systematic bolts were installed to enhance the tunnel stability. The tunnel did not suffer from severe unstable condition during benching, but rather large tunnel convergence occurred with accompanying cracks of shotcrete in the tunnel crown area. This is also predicted by the tunnel safety evaluation system as shown in Figure 11.

6 CONCLUSIONS

An expert system consisted of tools and expert knowledge for performing construction data collection and processing, data evaluation and analysis, and decision making assistance in the working process of D&B tunneling was developed. The results of preliminary application of the system in the construction of a flood diversion tunnel showed the system can provide efficient tools for carrying out various data collection, analysis and evaluation work in the tunneling process. Rational suggestions on support requirement, construction procedure and safety evaluation can also assist the field engineer in the decision making process.

However, In a practical application sense, the system developed is considered to be a prototype due to the lack of precedence and case histories with sufficient accuracy covering wide range of tunnel conditions. For further improvement of the system, trial application and collection of additional case information are still needed.

Progress of drill and blast tunnelling efficiency with relation to excavation time and costs

S. Zare & A. Bruland
Department of Civil and Transport Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: The productivity and efficiency of the drill and blast method have been investigated by means of NTNU prediction models for excavation time and costs since 1975, when the first time and cost models were published. The technological developments have improved the productivity in terms of increased advance rate and reduced excavation costs. For a typical 60 m^2 road tunnel assuming 100 working hours per week, the normal advance rate without rock support installation is increased from 50 m/week to 80 m/week, i.e. 60% improvement and the excavation costs are reduced from 16000 NOK/m to 10200 NOK/m, indicating a 36% reduction from 1975 to 2005.

1 INTRODUCTION

The drill and blast method has for long time been used for excavation of underground spaces in rock for various applications. The method may be applied in tunnels, rock caverns and mines. The major part of underground excavation in Norway is drill and blast (Norwegian Tunnelling Society 2004).

The Department of Civil and Transport Engineering at NTNU has recently published updated models for blast design and excavation time and costs (NTNU 2006a,b,c). The models are developed based on field studies and technological progress of different elements involved in the tunnel excavation process. The models can be used through all phases of tunnel projects for:

- Economic dimensioning
- Choice of alternative
- Time planning
- Cost analysis, tender, budget and cost control
- Choice of excavation method and equipment

The first version of the models was published in 1975 and has later been updated and revised five times. From the first publication, substantial development has been achieved in drilling jumbos, drilling tools, explosives efficiency, loading and hauling equipment as well as HES regulations.

The paper reviews the latest versions of the NTNU prediction models for excavation time and costs, as well as technological developments. Then development of the productivity and cost efficiency of the method by means of empirical prediction models for excavation time and costs has been investigated since 1975.

2 TIME AND COST MODELS

2.1 *Time model*

The complete time or advance rate model is published in NTNU 2006b. The model is based on the round cycle time consumption. The round cycle is divided into four major operations:

I Drilling and charging
II Ventilation
III Loading and hauling
IV Scaling and rock support

The operations I and III are divided into three different categories of time, i.e. fixed lost time (rig time), proportional operational time and incidental lost time. The time consumption for each operation is given in NTNU 2006b for various tunnel cross sections.

By applying the model for 3 km tunnel length, 5 m drillhole length, 48 mm drillhole diameter, parallel hole cut, medium rock drillability and blastability and 100 working hours per week, the weekly advance rate without rock support installation varies from 100 m/week for 10 m^2 tunnel to 54 m/week for 120 m^2 tunnel, depending on equipment combination and number of drilling hammers (Zare & Bruland 2006b).

2.2 *Cost model*

The cost model is based on detailed cost calculation for excavation operations, i.e. drilling, charging,

scaling, loading, hauling, additional work, niches and labour. The complete cost model is published in NTNU 2006c. Equipment and material prices, labour wages and expected life time for equipment are main input for detailed cost calculation. Depreciation, interest, wages, repairs and power consumption are included in the costs of each operation. Linear or degressive depreciation method is assumed, depending on equipment type and repair costs over life time.

In addition, 10% extra for unforeseen costs and uncertain assumptions is added in the end to the excavation costs. As in the time model, rock support cost is not included in the excavation costs, in order to provide the basis to compare the costs for different tunnel cross sections. The amount of rock support much depends to the rock conditions and tunnel application.

The equipment combinations are chosen according to the tunnel cross section and excavation method, i.e. track tunnelling for cross sections up to 16 m^2 and trackless tunnelling for cross sections between 16 m^2 and 120 m^2.

For rough estimation, the excavation costs for a tunnel with the same assumptions in the time model, varies from 6500 NOK/m for 10 m^2 tunnel to 17500 NOK/m for 120 m^2 tunnel, depending on equipment combination and number of drilling hammers. The costs input are based on June 2005 price level.

3 TECHNOLOGICAL DEVELOPMENT

3.1 *Drilling*

Currently, computerised hydraulic drilling jumbos with different level of automation are widely used in drill and blast tunnelling (Atlas Copco 2004, Sandvik Tamrock Corp. 1999). The current generation of drilling jumbos is designed for high productivity, quality drilling, and comfortable working conditions for operators.

The drill plan is stored in the drilling jumbo computer and therefore the face does not need to be marked up; the navigation is done by laser alignment and is very precise in deciding the position of the drilling jumbo. The excavated tunnel profiles can be scanned by electronic instruments, whereby over-break and under-break can be recorded to be used for the optimisation of the drilling process in the coming rounds (Nord 2003).

3.1.1 *Rock drills*

Obviously, invention of the hydraulic rock drills in the 1970s was a great progress in drilling speed, economy and improvement of the operator's working conditions. Figure 1 supports the fact and shows general development of rock drills and jumbos.

As an example, one may look at the Cop 3038. The latest rock drill from Atlas Copco is designed to increase the penetration rate in hard rock tunnelling. According to Atlas Copco; the Cop 3038 is 50% faster than its predecessor Cop 1838 ME, the time saved with Cop 3038 compared to Cop1838 ME on 3-boom jumbos in a 90 m^2 tunnel could be about 40 minutes per round. The high penetration rate may be utilized in limited space to replace 3-boom to 2-boom jumbos (Mining & Construction 2004).

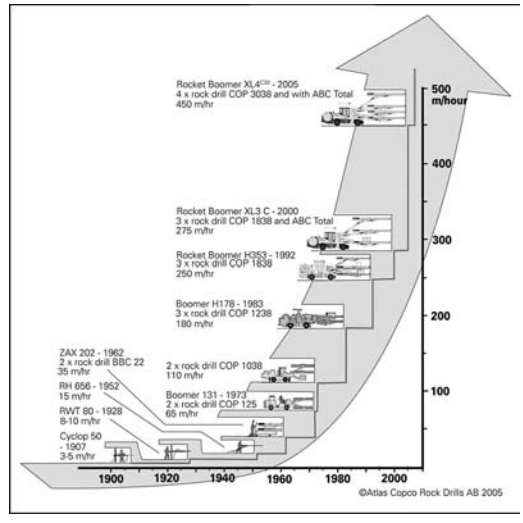

Figure 1. Drilling development 1905–2005, drilled metres per hour and operator (Atlas Copco 2006).

Table 1. Development of Atlas Copco hydraulic rock drills for face drilling (Mining & Construction 2004).

Type	Year	Impact power	Impact rate
COP 1038HD	1973	12 kW	42–60 Hz
COP 1238ME	1983	12 kW	40–60 Hz
COP 1440	1986	21 kW	70 Hz
COP 1838ME	1990	18 kW	60 Hz
COP 1838HF	2000	22 kW	73 Hz
COP 3038	2004	30 kW	102 Hz

The Cop 3038 delivers the same energy per percussive blow as the Cop 1838 ME, but the frequency has been increased from 60 to 102 Hz.

In the Table 1 the development of Atlas Copco hydraulic rock drills for face drilling is presented.

3.1.2 *Drill steel*

Drill bits, drill rods and shank adapters may be referred to as the drill steel, which has been concurrently developed with introduction of more powerful hydraulic rock drills. New conical thread system, Magnum SR35, is devised to cope the weakness of the old threads. The advantages of the new thread

system are intended to solve rod breakage at the bit end, less tendency for deviation when collaring, straighter holes, and longer service life (Atlas Copco 2004).

The rod length has also increased, even though the 18 feet rods are common in civil tunnelling and gives around 5 m drilled length, the tendency towards longer round is increased (Nieminen 2003) and some tunnels have been excavated with 6 m round length (Tunnelling and Trenchless Construction 2005).

3.2 *Charging and explosives*

Emulsion explosives combined with non electrical initiation system like NONEL have increased the safety of the charging and blasting operations and become more efficient.

The pumpable emulsion explosives, SSE (Site Sensitised Explosives) are not explosives until pumped in the hole, which means safety in transportation and handling (Johansen & Mathiesen 2000, Atlas Copco 2006).

The modern emulsion explosives are oxygen-balanced, producing a minimum of noxious fumes and far less smoke (Olofsson 2002), provides better working conditions and less ventilation requirements.

The emulsion explosives are water resistant and can be used when water is a problem and ANFO can not be used efficiently.

In addition, the pumpable emulsion explosives can be pumped into the blastholes by a computer controlled system and the amount of explosives in each hole and total explosives consumption can be measured, which can be used to control the amount of explosives in different holes in the face, especially in the contour and row nearest the contour where less explosives is needed for smooth blasting (NTNU 2006a, Zare & Bruland 2006a). The measuring system may also help to control the uncharged length of blastholes for optimum blasting results.

Recently, after a feasibility study, a prototype machine for automatic charging of emulsion explosives was completed and tested in Norway (Hermann & Elvoy 2004). The project is meant to reduce the time consumption for drilling and charging by 20% with improved work safety. The charging system is mounted on the drilling jumbo as a separate boom and charging is accomplished automatic during drilling without human interface at the face, in compliance with the regulations that prohibits simultaneous manual charging and drilling at the face.

3.3 *Ventilation*

The harmful gases and dust particles above the certain level of acceptance must be removed by the ventilation system.

For the cost efficiency and improvement of the work environment, the intelligent ventilation system is developed and tested in two tunnels (Lima & Blindheim 2004). The project includes development of new duct materials and duct support system as well as recording of air quality and automatic control of the ventilation fans.

3.4 *Loading and hauling*

The loading and hauling capacity is dependent on the tunnel cross section size and excavation method. Using adequate size equipment as the cross section increases is an efficient way to increase loading capacity. By NTNU field studies in large cross sections (NTNU 2006b), a capacity up to 500 lm^3/h is attainable when using wheel loader and dump truck combination and the loader is fully utilised, i.e. the loader is not waiting for a hauling unit.

Crusher, conveyor belt and mucking trains are also employed in drill and blast tunnels. The average capacity is 300 m^3/h (understood as loos cubic metre). 500 m^3/h should be achievable by the method in the future (Girmscheid & Schexnayder 2002). The crusher and conveyor belt is used as part of "high performance drill and blast excavation concept" which uses a suspended platform system for higher performance. Even though, the crusher capacity is the limiting factor, by other benefits of the method, the total cycle performance has been increased by 30% (Girmscheid & Schexnayder 2002).

3.5 *Rock support*

Rock bolts and sprayed concrete (shotcrete) are two common types of rock support, both developed towards more durable; high strength, and quick installation by means of mechanised and automated equipment.

CT-bolt, the newest bolt type in the market can first be used as an ordinary end-anchored bolt for temporary support and later on be grouted to a permanent bolt (Norwegian Tunnelling Society 2004).

During the past two decades the sprayed concrete has faced a significant improvement; today fibre-reinforced sprayed concrete by wet mix method is widely applied.

Sprayed concrete robot is one of the modern equipment for applying sprayed concrete. The capacity by manual spraying is less than 5 to 8 m^3/h, while using robot it reaches up to 20 m^3/h (Girmscheid & Moser 2001). The robot has better safety and quality control.

By the NTNU models it possible to estimate excavation time and cost including rock support, but since the rock support much depend on the rock mass conditions, the time and costs which are presented in the paper do not include the rock support.

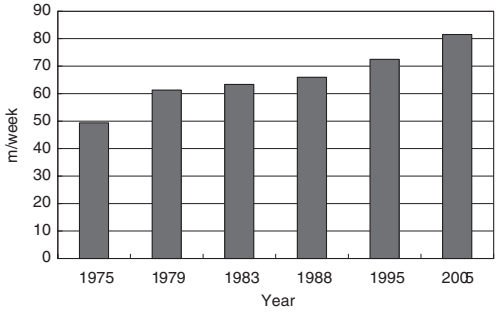

Figure 2. Development of weekly advance rate for a 60 m^2 tunnel.

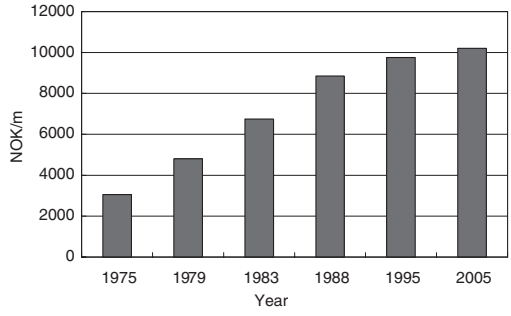

Figure 3. Development of uncorrected excavation cost for a 60 m^2 tunnel.

4 TIME AND COST TRENDS

To investigate time and cost trends or productivity and efficiency of the method, a 60 m^2 tunnel with 3 km length is chosen as a typical two-way road tunnel. Medium rock blastability and rock drillability is assumed.

The advance rate per week and unit costs per tunnel metre without rock support installation are estimated from 1975 to 2005 by the NTNU models. The NTNU model was first time published in 1975 and has been revised five times; in 1979, 1983, 1988, 1995 and 2005.

Weekly advance rate is shown in Figure 2. The weekly advance rate is normalised based on 100 hours working time per week. The advance rate is increased from some 50 m/week to 81 m/week during the past 30 years, indicating a 60% increase in production rate. The excavation method itself does not change significantly, development in the equipment capacity and efficiency, tools and materials leads to that the current tunnel will be excavated faster and the excavation time is shortened.

For example in 1975 the maximum penetration rate for medium drillability was 140 cm/min whilst in the recent model of 2005, it reaches to some 300 cm/min and the maximum loading capacity for same size cross sections is increased from 160 sm^3/h to 280 sm^3/h.

The uncorrected excavation costs are shown in Figure 3, the unit cost is presented in Norwegian Kroner per metre of tunnel. The cost in Figure 3 is not corrected for price level; only representing the unit excavation costs in each year. To find the comparable figures, the cost must be corrected for price level.

The Department of Civil and Transport Engineering at NTNU has published a cost index for construction equipment (NTNU 2006d). The corrected excavation costs are shown in Figure 4. The trend of excavation cost is not consistent such as the time trend (Fig. 2). One reason is different working hours per week; which is 112 hours in 1975, 75 hours in 1979 and 1983

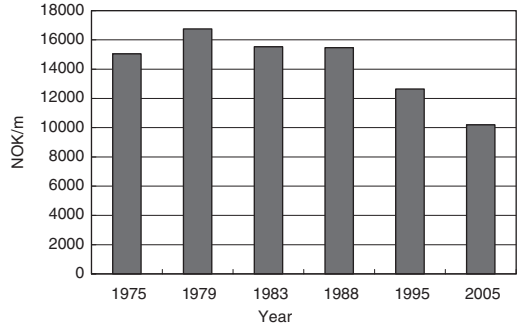

Figure 4. Development of excavation costs for a 60 m^2 tunnel, price level June 2005.

models, and 100 hours for the rest. Based on 100 working hours the costs for 1975 model should be higher and for the 1979 and 1983 models, lower than the presented values.

In spite of this minor deviation the excavation cost is decreased from some 16000 NOK/m to 10200 NOK/m, indicating a 36% reduction. The technological development is the main reason of decreasing cost trend. Changes in the investment tax and interest rate are included in the price level correction.

5 CONCLUSIONS

In line with development in tunnelling, the productivity and efficiency of the drill and blast method has increased. Drilling is now using computerised drilling jumbos with various levels of automation, faster rock drills and more durable drill steel. Charging is accomplished safer and more efficient by using NONEL detonators and emulsion explosives which causes less pollution and is not considered as an explosive until placed in the holes. Ventilation may utilise intelligent ventilation system. The loading and hauling capacities

are increased and advanced rock support equipment with higher performance is employed.

By means of the NTNU prediction models, the investigation shows substantial increase in the productivity and reduction in the costs. For a 60 m^2 road tunnel, the productivity has increased 60% and the cost has been reduced by 36% from 1975 to 2005.

Furthermore, the time and cost trends confirm the importance of updated models for time and cost prediction. The NTNU models are unique and should be revised based on technological development in the excavation methods and equipment.

ACKNOWLEDGEMENTS

The paper is prepared as part of the first author's PhD research project financed by the Ministry of Science, Research and Technology of Iran.

Analysis of the ultimate states of the underground tunnel lining

Ing. Jaromír Zlámal
POHL cz, a.s., Prague, The Czech Republic

ABSTRACT: Evaluation of the load-bearing capacity of underground tunnel linings under emergency conditions (as with structural cracks and deformations), must be conducted rapidly, and in a way that static analysis will immediately reveal points of fault, stress and excess loading, as well as areas of spare capacity. Coefficient *s* of bearing capacities, calculated according to measures of internal forces and within technical parameters, can give an immediate indication of the state of a tunnel lining. Analysis, by mathematical modelling of such extreme states, can reveal points in the lining structure which are close to capacity limits, and points where spare capacity is very small. Use of this method for two different cases of lining deformations in the Prague Underground demonstrate its simplicity, speed and reliability.

1 INTRODUCTION

During construction and use of underground rail tunnels made from reinforced concrete segments, the lining is only rarely in a state nearing the limit of its bearing capacity, and only very rarely in a state which is actually at that limit. (For such extreme conditions, the term 'ultimate state' of the structure will be used.)

However, once the structure reaches the ultimate state, there is typically very little time to decide what measures to take in order to stabilize the structure. Suggested mitigations are usually based on detailed static analysis of the tunnel lining.

For this type of analysis, a static model of the structure is created and extreme conditions are simulated in numerous runs, such that deformations in the model are maximally close to the real situation of the tunnel.

The goal of this study is to evaluate the load bearing capacities and reserves, of concrete circular tunnel linings with inside diameters of 5,1m, as used in the Prague Underground.

The tunnels were installed beneath apartment buildings and stress on the structures (cracks and deformations), were evident with only visual examination. However, the design of the tunnels and their geometry allows for their use with minimal mitigation when actual deformations are not considered extreme.

2 METHOD OF ANALYSIS OF THE ULTIMATE STATE

The design of each structure has to satisfy two basic but often contrasting conditions – the structure has to be economical and safe. Underground structures are continuously loaded by stress and deformation, which can be expressed mathematically on the basis of structural mechanics. The durability of the structure is defined by three factors:

- *support structure*
- *load applied on the structure*
- *natural environment surrounding the structure*

Static computation reveals the bearing-capacity of the lining at the rock mass, considering rock-support interaction. To apply the computation that is closest to our real circumstances, we will use static parameters M_i, N_i, T_i to establish the ultimate state of the structure. Based on this analysis, it is then possible to decide what measures would be necessary to stabilize the tunnel lining structure if its ultimate state is reached. Let $p_{Umax}(t)$be the limiting bearing-capacity of the tunnel lining, $p_{Lmax}(t)$ the limiting loading capacity of the tunnel lining (Fig. 1), and p_i, p_j the loading in points i, j for the calculated static values M_i, N_i, T_i and M_j, N_j, T_j then

$$p_{i(t)} = f\,(M_i, N_i, T_i);\; p_{j(t)} = f\,(M_j, N_j, T_j) \qquad (1)$$

The limiting bearing-capacity of the tunnel lining corresponds to static values of M_U, N_U, T_U, so we can simply write

$$p_{Umax(t)} = f\,(A_b, A_s, R_b, R_s) = f\,(M_U, N_U, T_U) \qquad (2)$$

where A_b is the effective area of concrete, R_b is the strength of concrete, A_s is the effective area of steel

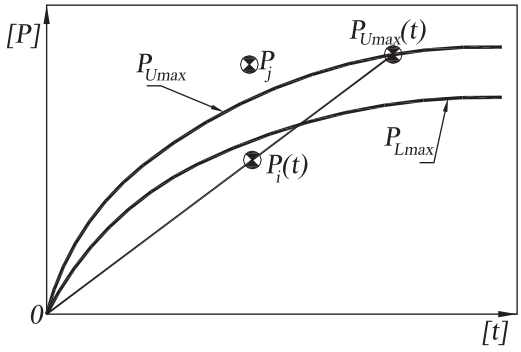

Figure 1. The limiting bearing-capacity and the limiting loading of the tunnel lining.

reinforcement, R_s is the strength of steel reinforcement. If we compare values of the loading $p_i(t)$ a $p_j(t)$ and the bearing-capacity $p_{Umax}(t)$we can then evaluate the bearing-capacity of the tunnel lining in points *i* and *j*. If loading $p_j(t)$ is less than $p_{Umax}(t)$then

$$p_i(t) < p_{Umax}(t) \tag{3}$$

governs inequality. We can say that the tunnel lining satisfies the limiting conditions of the bearing-capacity.If loading $p_j(t)$ is greater than $p_{Umax}(t)$ then

$$p_j(t) > p_{Umax}(t) \tag{4}$$

governs inequality. Here we can say that the strength limit is overrun and the bearing-capacity of the construction is unsatisfactory. The coefficient of the bearing-capacity of the lining *s* is defined as the ratio of $p_{Umax}(t)$ and $p_j(t)$

$$\frac{P_{U\max(t)}}{P_{i(t)}} = s \tag{5}$$

the bearing-capacity of the tunnel lining is then specified by the coefficient s_i on the whole perimeter of the tunnel lining. Where the value s_i {5} is smaller than 1,

$$s \leq 1$$

the construction's total strength is unsatisfactory. The limiting bearing-capacity of the lining is usually reached at one point only, and other static calculations of the lining are usually necessary to evaluate the lining for limiting state usability (deformation) and the limiting state of cracks.

3 UNDERGROUND TUNNEL LINING

We will conduct analysis of the ultimate state of the tunnel lining using bearing capacity coefficient *s* on

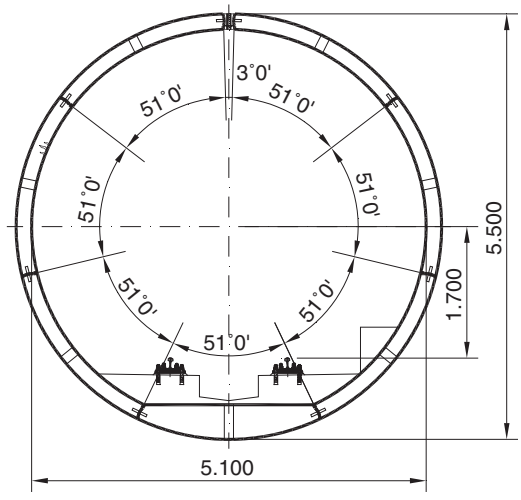

Figure 2. The tunnel lining of the Prague Underground.

two samples of reinforced concrete lining in track tunnels of the Prague Underground. In one of the cases, there was only one visible horizontal crack in the lower part of lining, and in the other case, there were two horizontal cracks visible in the upper part of lining. Linings were at the limit of bearing capacity, so after the static analysis was conducted, measures towards stabilizing the lining were taken. The inside diameter of the lining is 5,1 m, width is 0,2 m, and the base is 0,62 m wide. Concrete B400 was used in horizontal reinforcement of concrete tubing 4×Ø12 mm and vertical reinforcement Ø8 mm, steel 10 425. Separate tubings (segments) are connected by hinges, and each tubing has openings for grouting. Rings are 1m wide and they are not connected with each other. Levels between tubing are prepared to be filled with waterproof mortar. The shape of the concrete segments lining is on Figure 2.

4 POLYGONAL COMPUTATION METHOD

This computation method (used for analysis) is universal and able to affect any shape of construction and allows ease of change to the input parameters for calculation (loading, construction and geotechnical parameters). However, the calculation informs us about deformation and internal forces in lining only and says nothing about the state of stress in the rock mass. The exact shape of the tunnel lining is replaced by a polygon. Radial rods imitate rock mass with hinge connections at the corner points of the polygon.

Action of the rock mass on lining is imitated by the outside active loading applied in the corner of the polygon, and the passive resistance of rock is imitated

by Winkler's springs. The calculation runs in iterative cycles and in the first iterative cycle all radial rock imitative rods are in function, and the calculation runs until all tensile rods are removed and all pressed radial rods are in function only.

The characterization of the elastic rods can be written in the form

$$\overline{K}_i = K_{(\sigma)} \frac{l_i + l_{i+1}}{2} b \tag{6}$$

where $K_{(\sigma)}$, the coefficient of elastic resistance of rock, depends not only on geotechnical parameters of the rock, but also on the shape of the construction and is usually determined according to B.G. Galerkin.

$$K_{(\sigma)} = \frac{E}{R(1+\nu)} \tag{7}$$

where l_i is the length of the member of the polygon and b is the width of the ring, which is usually 1,0 m. Let us assign the deformation and the movement of i joint U_i, V_i, θ_i and internal forces of i joint X_i, Y_i, M_i and outside loading $\underline{X}_i, \underline{Y}_i$.

We then download the columnar matrix $\{P_i\}$ for the internal calculation parameter, and columnar matrix $\{P_i\}$ for outside loading, where

$$\{P_i\} = \begin{Bmatrix} U_i \\ V_i \\ \theta_i \\ X_i \\ Y_i \\ M_i \end{Bmatrix}; \qquad \{P_i\} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ \underline{X}_i \\ \underline{Y}_i \\ 0 \end{Bmatrix}; \tag{8}$$

So we take the reaction of the supports as the internal forces for i joint, inclusive of the deformation of elastic supports, leading to the changed coefficient $[K_i]$ which affects computation parameters. In general, case loading can be applied to any joint (joints have unique numbering, with the label j).

The matrix notation of the equation for calculating parameters for the joint n, including known perimeter conditions, has the form

$$\{P_n\} = \prod_{i=n+1}^{1} [K_i]\{P_o\} + \sum_{j=1}^{n} \prod_{i=n+1}^{j+1} [K_i]\{\underline{P}_i\} \tag{9}$$

where $\{P_o\}$ is a columnar matrix of initial calculation parameters.

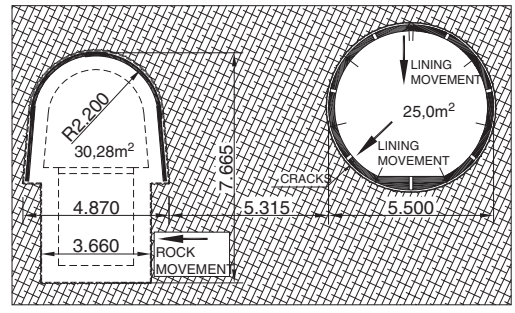

Figure 3. Ultimate state of tunnel lining as a result of drilling the gallery and base sump 38 m long.

5 ANALYSIS OF ULTIMATE STATES

5.1 *Tunnel with a lack of resistance on the side of lining*

The rock mass had lost resistance on the side of the track tunnel lining during drilling of both the gallery and the base sump. At the time of drilling the space for the base sump, tectonically irregular rock mass shifted into the sump space causing the tunnel lining to become deformed. Cracks and crushed zones appeared on the bottom segment of tunnel lining that joins the gallery Figure 3.

In this case, the tunnel lining needs to be restored, as deformations were in the range of centimetres. The primary gallery lining was 4.87 m wide and 7.66 m high, and the tunnel lining outside diameter was 5.5 m. The gallery was drilled after the drilling of the metro tunnel, at 10.5 m axis spacing and 38 m length. The gallery and base sump drilling surface was 30.28 m^2, tunnel drilling surface was 25.0 m^2, spacing of drilling was 5.3 m. The gallery was drilled into Ordovician rocks, in Bohdalecke layers with cover 38.5 m.

After visual observation of cracks in the lining, a detailed analysis of the state of the lining was conducted using bearing capacity coefficient s, results are shown in Figure 4, which illustrates the bearing capacity of the metro structure. At the point of deformation and its immediate surroundings, the value of bearing-capacity coefficient is close to 1. This means, that the bearing capacity of the lining is spent at these locations and it is necessary to take mitigating action to ensure lining stability. The analysis showed two locations on the tunnel lining that are close to capacity limits, although visually the cracks were observed only in one location. The second point close to bearing capacity limits had cracks that were facing the rock wall. The values of the bearing-capacity coefficient higher than 1 represents places with spare capacity. Figure 4 clearly shows points where reconstruction of crushed areas are necessary.

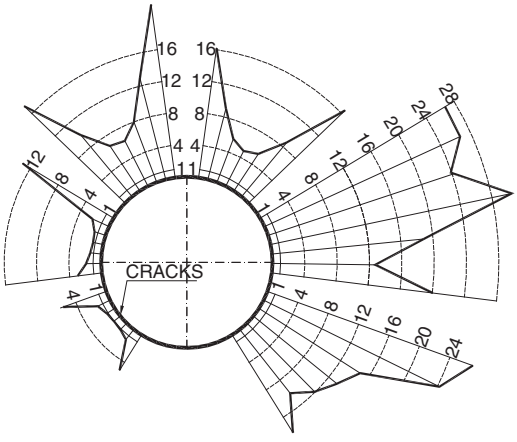

Figure 4. Graph of bearing capacity coefficient of tunnel lining with a lack of side resistance as result rock shift behind metro tunnel lining.

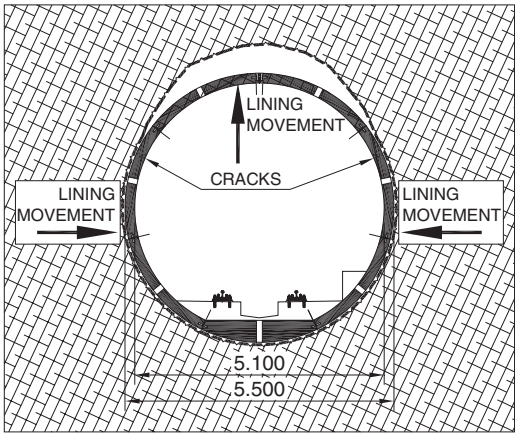

Figure 5. Ultimate state of metro tunnel lining as a result of empty space above the arch at least 8 m long.

5.2 *Lack of resistance in arch of lining*

The same mass concrete lining also reached another ultimate state. After a longer time of use horizontal cracks 8 m long appeared in the concrete tubings (segments) in the upper part of tunnel lining. Crushed places appeared and joint fillings started to fall out. The first signs of damage appeared already in 1990, and the problem was monitored during regular nightly checks of the metro. In 1991, the damage got worse, with the number cracks growing and underground water was starting to seep into the structure. At these points, the metro tunnels go through folding rocks of earlier Paleozoicum, belonging to Ordovicum.

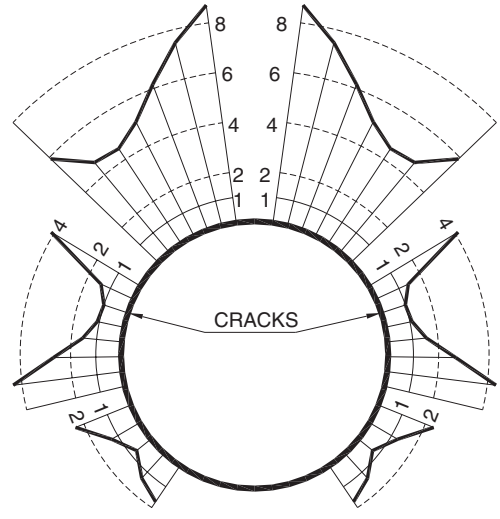

Figure 6. Graph of bearing capacity coefficient with lack of resistance in the upper part as result of an empty space at least 8 m long over the arch. Bottom is bearing capacity overrun also, but cracks are on the outside of the lining and could not be seen.

The largest part of cracks in the tubings appeared in points of contact between Bohdalecke and Vinicke layers, where the horizontal tectonic line is, according to geological research. The cover over the arch of the tunnel lining at this point was 42 m. By modelling different ultimate states of the tunnel lining, we discovered that this kind of deformation is possible only if there is an empty space above the arch of the tunnel.

After this analysis the lining in the arch was drilled through and results of the static analysis was confirmed. There was an empty space above the arch of the lining along the length of cracks. Analysis showed, that on the left and right side of tunnel lining there are two places at the limit of bearing-capacity, although there were cracks only on one place. The second spot at the limit of bearing capacity had rock facing cracks Figure 6.The bearing-capacity reserves shows values of coefficient *s* higher than 1. There were no cracks observed in these places. Reconstruction of crushed areas is necessary at the points where bearing capacity coefficient *s* is close to 1.

6 CONCLUSION

The coefficient of the bearing capacity of the lining *s* describes reserves in the bearing capacity of the lining, and also shows the point where ultimate state will be reached first.

The location of the critical point of the lining depends upon the loading, resistance of the rock and material parameters of the lining.

After evaluation of analysis results we concluded that for simple projects, the static analysis results calculated by the polygonal method are safest, on the condition that this calculation method is supplemented by another analysis, e.g. calculations reviewing the overburden, the pillar of rock or the settlement.

For simple analysis of a tunnel lining, the polygonal calculation method is fully sufficient. Results of detailed analysis of bearing-capacity coefficient *s* of the tunnel lining were presented in a form of graph and they were confirmed by deformations visually observed. Further detailed analysis showed that there are other points of ultimate state of the lining. At these points, cracks are on the outside of the lining and could not be seen from inside the tunnel. Analysis of the ultimate state of the structure can locate points that are very near to the bearing-capacity limit, and direct preventive measures to these points, as well as points where the reserve capacity is very small. Use of this method for two different cases of lining deformations of the Prague Underground demonstrates its simplicity, speed and reliability.

ABSTRACT: In this work, the redesign studies and the construction of the ground anchorages of the portal structure of a shallow urban tunnel, which is located on the main transportation artery of Black Sea Coast Road, are given. This tunnel has been constructed near an old existing tunnel under heavy traffic conditions and surrounded by residential area. During the research studies of the design stage, restricted number of boreholes was opened because of the expropriation problem. In view of the site observations and information obtained from these boreholes, it was observed that the rock encountered at the portal sites is a weathered and weak volcanic rock composed of medium to fine-grained pyroclastic material. Due to this reason, a portal structure that consists of bored piles, ground anchorages and cut and cover was designed. The original project of the tunnel was approved by General Directorate of Highways in December 2000. The construction of the tunnel was started at June 2003. After completion of the first test anchorage, it was observed that it could be pulled out only one third of the design load. After solving the expropriation problem, additional boreholes could be opened and the existing project was redesigned using the new data. During the construction of anchorages, special care was given and the monitoring of the portal structure was performed using load cells, extensometers and inclinometers. This study contains two main parts: Firstly, the redesign of the pre-stressed anchorages and construction techniques of them for improving the capacity will be given and then the evaluation of the monitoring data during construction of portal structure will be explained.

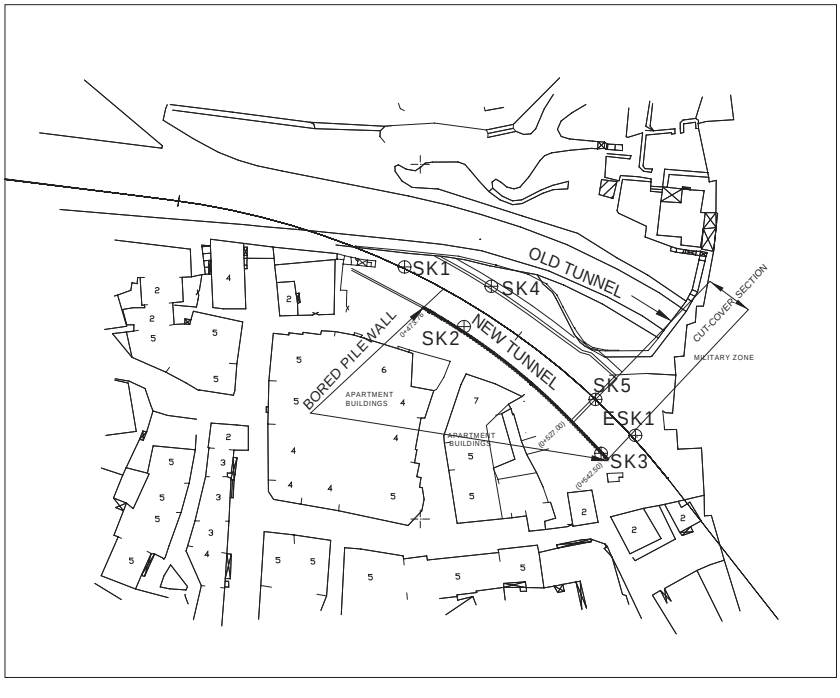
1 INTRODUCTION

Kalepark Tunnel, which is the scope of this study, is located on the main transportation artery of Black Sea Coast Road, city crossing of Trabzon. It is a shallow urban tunnel that is surrounded by residential area and located under a historical reputational area and military zone. This tunnel has been constructed near an old tunnel under heavy traffic conditions and surrounded by residential area (Photograph 1). The length of new tunnel was 144 m including 15.5 m and 28.5 m cut and cover sections at entrance and exit sections respectively. The horizontal distance between the old and new tunnel at the entrance and exit portals are 11 m and 20 m, respectively. The overburden of the new tunnel is varied between 2.5–3.5 m at portal areas and the maximum overburden through the tunnel is 11.5 m.

In the entrance zone there was a permanent excavation from 6.5 to 13.5 m depth. In 1997, during the research studies of the design stage, restricted numbers of boreholes were opened because of expropriation problem. Only four boreholes were drilled during the tunnel research studies at that time. As it was shown in Figure 1, ESK-1 borehole, quite far from deep permanent excavation, was representative for the portal structure. In view of the site observations and information obtained from these boreholes, it was observed that the rock encountered at the portal sites is a volcanic rock composed of medium to fine-grained pyroclastic material. Due to this reason, a portal structure that consists of bored piles, ground anchorages and cut and cover were designed. Besides, at the design stage it is advised that the confirmation of the geotechnical values and the assumptions of the project should be checked. The original project of the tunnel was approved by General Directorate of Highways in December, 2000.

During the design stage, the geotechnical model for the right section of the entrance portal, which is the scope of this study, was described as weathered tuff and

Photograph 1. A view from entrance portal of Kalepark Tunnel.



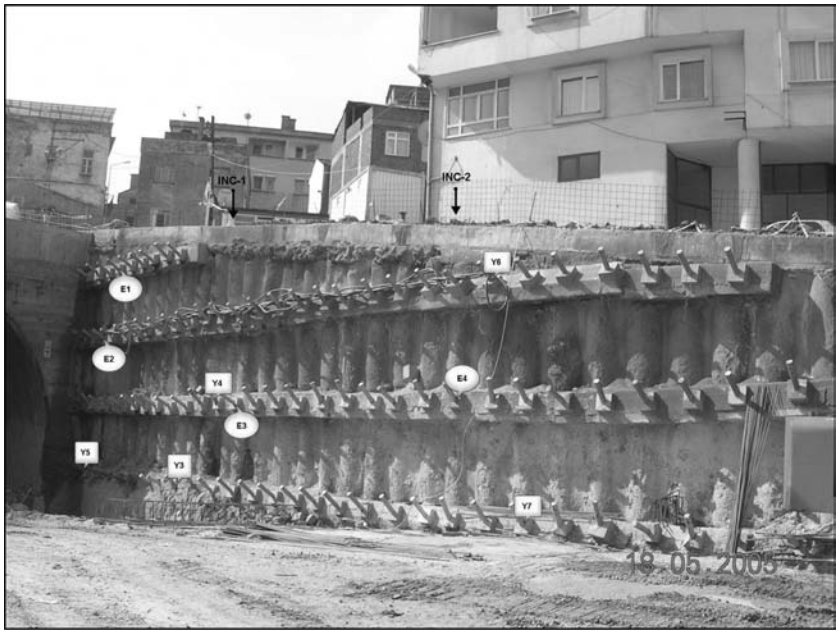


Figure 1. Plan view of Kalepark Tunnel entrance portal and the location of boreholes.

Photograph 2. Monitoring system and retaining structure of Kalepark Tunnel.

agglomerate that contains clay layers. The retaining structure of the entrance portal at the design stage was determined as bored pile wall with pre-stressed ground anchorages (Photograph 2 and Figure 1).

The construction of the tunnel was started at June, 2003. Construction and research studies for comparison were performed simultaneously. After solving the expropriation problem, additional boreholes were drilled. Bored piles were constructed. Three pre-stressed anchorages at the first row were constructed and anchor tests were performed. During the drilling process of anchorages, it was seen that soil around the anchor bond length was containing water. The test results were not in consistent with the project values as it was expected. During anchor tests, some of the anchorages could be pulled out only one third of the design load. In view of the evaluation of the new borehole data, the results of anchor tests and the observations made during the pile drilling, it was concluded that the foreseen geotechnical evaluation was different from the actual site. Due to this fact, the existing project was redesigned using the new data.

2 GEOTECHNICAL EVALUATION

2.1 *Geotechnical evaluation at the first design stage*

The site was described as weathered, weak and water susceptible tuff and agglomerates containing thin clay layers. The rock quality designation (RQD) values are zero and the core recovery ratio (TCR) values were differing from 5–43%. The water level was approximately 10 m below the ground surface. The strength parameters for the weathered tuff and agglomerate and clay layers were decided as $c = 100$ kPa, $\Ø = 25°$ and $c = 0.5$ kPa, $\Ø = 9–10°$, respectively. Using these parameters, intermittant bored piles (Ø80) with 15 cm clear space and pre-stressed ground anchorages were designed.

2.2 *Geotechnical evaluation at the construction stage and new project studies*

At the entrance portal four additional boreholes were drilled. Two of these boreholes (SK2 and 3) could be representative for the right section of the portal. Pressuremeter tests were performed in these boreholes.

Unfortunately, no additional boreholes that could give information about the fixed anchor zone were drilled because of residential buildings surrounding the site. In order to overcome this problem, results of anchor tests were evaluated. From this investigation, it was seen that, approximately the first 4 m of the geotechnical profile was formed of road fill. Then, highly weathered and water susceptible clayey tuff was encountered up to approximately 10th meter. After this layer, weathered tuff with 0–60% RQD value and 30–80% TCR value is laid down. The water level was 2.70–5.45 m below the ground surface. The water level was different from the former boreholes, the main

Table 1. Soil parameters used in the redesign stage.

Layer	c′ (kPa)	Ø′ (°)	E (kPa)	ν
Fill	0.5	27	7500	0.33
Tuff 1	2.0	27	15000	0.30
Tuff 2	10.0	28	25000	0.30

reason for that was thought as the percolation of the surface runoffs and the percolation of water due to surrounding buildings.

The pressuremeter test results were used in determining the elasticity modulus and friction angle of the layers. Menard and Calhoon Methods were used and it was seen that friction angle values obtained from Calhoon method gives more conservative values than Menard Method. As it was a permanent excavation, without any boreholes drilled at the anchor fixed zones and since it was a residential area, lower values were chosen as design friction values. Moreover, lower cohesion values were chosen as shown in Table 1 due to reasons mentioned above.

From the results of the evaluation of new borehole data, the results of anchorage tests and the observation made during the pile drillings, the parameters used in the redesigned project was given in Table 1.

3 PROJECT DESCRIPTION

3.1 *New design project details*

The safety of permanent retaining structures in such residential areas is very important. In the entrance portal structure, the depth of the excavation was varied between 6.5 m to 13.5 m. As expected, horizontal and vertical displacements are normally occurred in every deep excavations. But it is important to keep these deformations in permissible limits in this project due to surrounding built-up area.

At the redesign stage, the construction of the intermittant bored piles (Ø80) with 15 cm clear space was constructed. Firstly, the existing bored pile wall was taken into consideration and redesign was performed by considering new parameters obtained from new investigations. The location of pre-stressed ground anchorages is another important factor since the construction was located in a residential area. All the buildings near the portal structure were reevaluated and the anchorage patterns and inclination of anchorages were decided.

On the other hand, the pre-stressed anchorages and pile wall of the system were modeled by finite element program PLAXIS. In this program all the construction stages can be modeled with any loading conditions. Forces acting on the ground anchorages and pile wall can be evaluated for all stages of the construction.

The design of retaining wall was made based on six typical types of solution depending on the depth of excavation and surrounding buildings near to the excavation. The working loads of the anchorages were calculated from the program. Additional analyses were performed in order to see the displacements occurred at prescribed locking loads. By evaluating the results of the analyses, locking loads for the ground anchorages were adjusted. As a result of these analyses, it was seen that the anchorage working loads (service load) were varied between 20–30 tons.

Horizontal and vertical displacements just near and around the retaining walls were restricted between 5–15 mm depending on the neighboring conditions. As a result, no any visible cracks were observed around the permanent excavations.

The moment and shear capacities of the piles were high. Depending on that fact, pre-stressed ground anchorages were designed as they located at every space between piles in the new design project. As a result of this pattern, the dimensions of breasting beam would be smaller and the construction rate would be fast. The anchorage pattern in the design project was determined as 0.95 m × 2.5 m (horizontal × vertical). Because of the adjacent buildings, the inclination of the anchorages was 20°, 25° and 35° from the horizontal. These inclinations were applied variably ±2 degrees in horizontal direction of the breasting beams, in order to prevent the fixed anchor zone interactions. After the construction of anchorages, the anchorage tests were made and it was observed that the working loads can be carried by these anchorages.

3.2 *Practical aspects in ground anchorage constructions*

Drilling and grouting methods are the main practical aspects that influence the anchorage capacities. Suitable diameters of augers (minimum 15 cm) were used in drilling operation in this project. After drilling without using any water, hole was filled with grouting material immediately in order to prevent the collapsing of the hole-walls. The ground anchorage assembly then was located through the grouted hole before setting time of grout. Some grout material was come back from the hole and some of it was percolated to the surrounding soil as was expected. Therefore, a post grouting process was found necessary to get desired capacities. Special packers were designed just between the free and fixed parts of the ground anchorages. A grout pipe entering into this packer was used to give grouting material. Thus a barrier was formed between free and fixed zones. After 1 to 3 hours, a post grouting was performed under 2 to 4 bars through another grout pipe. Thus, the final fixed zone of the anchorage does not contain any voids that may be produced after primary grouting which was performed by tremie method. The diameter of the fixed zone is also greater

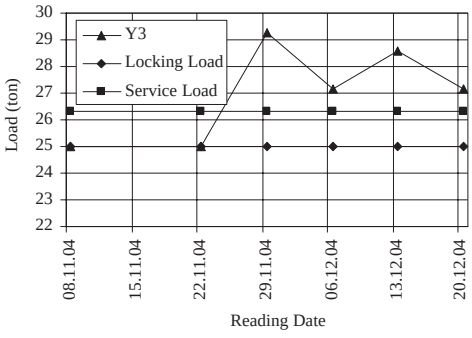

Figure 2. Data measured from load cell Y3.

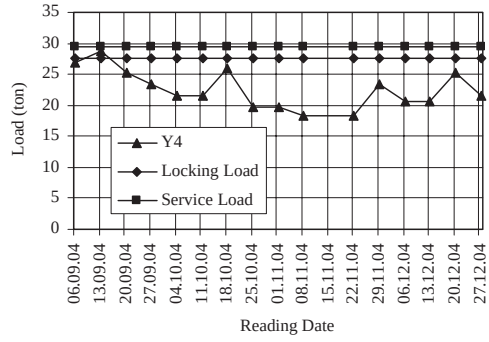

Figure 3. Data measured from load cell Y4.

after this post grouting process. All of these increase the capacity of the ground anchorages.

4 ANCHORAGE TESTS, MONITORING AND EVALUATION

Anchor tests were done during construction according to SIA 191 Standard. The anchor tests were performed in order to check the design assumptions.

4.1 *Anchor tests*

The working loads of the ground anchorages were about 60 tons in the original project. These capacities were found quite high after testing first anchorages. Additional site investigations confirmed these results. The working loads of the anchorages were decreased in the redesigned project. The results of anchor tests were satisfactory in the redesigned project. Thus, the permanent excavations were finished based on new site investigation and design studies with special measures in ground anchorage constructions as mentioned above.

4.2 *Load cell readings at anchorages*

Five load cells were located at the anchorages in order to monitor the load distribution (Photograph 2). The load variation during the construction process was followed with periodical readings.

As it can be seen from the Figures 2,3,4,5,6 during the intermediate construction stages, some data measured from Y3, Y5, Y7 load cells are 3, 4, 3 tons higher than service loads respectively. But it was observed that, the final readings taken after completion of the retaining wall showed that, the loads acting on the anchorages were all lower than the service loads.

4.3 *Extensometer results constructed on pile wall*

Four extensometers were located at the pile wall in order to monitor the deformations during construction. (Photograph 2). The values measured were followed

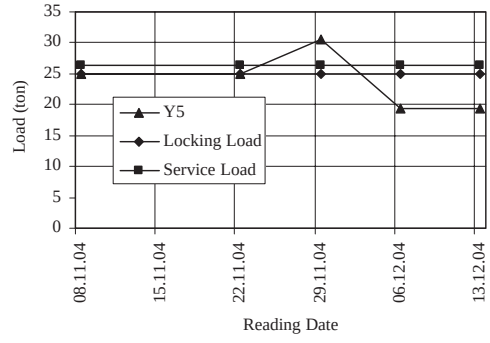

Figure 4. Data measured from load cell Y5.

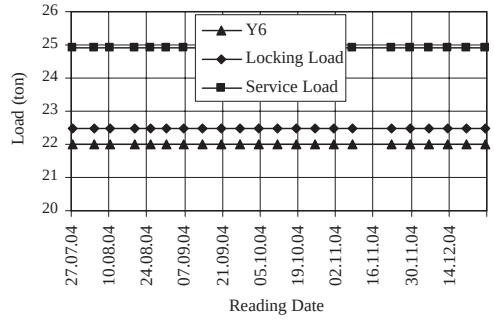

Figure 5. Data measured from load cell Y6.

with periodical readings and is given in Figure 7. The results were showed that, maximum measured deformations were about 80% of the calculated ones.

4.4 *Inclinometer measurements constructed on behind the pile wall*

Two inclinometers were located in order to control the displacements during the construction of the portal structure (Photograph 2). If the measurements taken

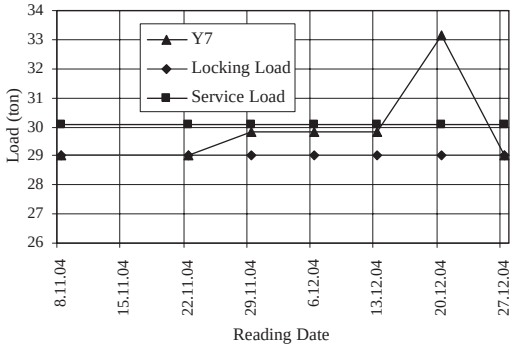

Figure 6. Data measured from load cell Y7.

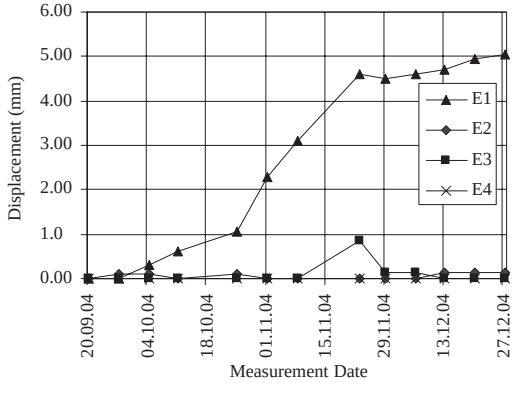

Figure 7. Data obtained from extensometer E1, E2, E3, E4.

from inclinometers and the extensometer data (E3 and E4) are compared, it is seen that the maximum displacement values are in 5–8 mm and convenient with each other.

5 CONCLUSION

In this case study, the importance of the confirmation of the assumptions at the project stage due to compulsory incomplete research studies was seen. Loads measured from the load cells at intermediate stages may show higher values than assumed ones in project due to improper construction sequence. Excavation, breasting beam and anchor construction activities should be adjusted carefully so that no any horizontal and vertical excavations are to be performed without locking the neighboring ground anchors. But on the other hand, by cross checking the inclinometer and extensometer readings it was concluded that no additional support was needed. As a result, detailed research studies, anchor tests and confirmation of project assumptions and also monitoring have vital importance on the safety of retaining structures especially in built up areas.

The influence of vibrations and noise on the housing development on the cover of the Mrazovka tunnel in Prague during tunnel driving and its putting into service

L. Bartos & L. Bartos jun.
Bartos- Engineering, Brno, The Czech Republic

ABSTRACT: This paper sums up the knowledge acquired from measuring the seismic and acoustic impacts on the housing development on the cover during the tunnel driving of the Mrázovka tunnels and after putting the tunnels into full service. The inhabitants complained mainly about the noise propagating through basement rocks into the building construction and housing premises, i.e. vibrations within the audible frequency spectrum during the night. During day-time the complaints were scarce due to the raised level of noise from the nearby roads. The results of measurements of vibration and acoustic effects caused by blasting as well as machinery used in the underground during the working process are compared with the limits permissible according to the valid regulations and standards. After putting the tunnels into service, vibration and noise measurements were carried out that proved that even with low cover thickness (12 m) the vibrations and noise propagating into the buildings are below the human perception threshold. The motor-traffic in the tunnels can by no means exert negative influence on the comfort of living in the respective housing development.

1 INTRODUCTION

This paper deals with the summary and assessment of the data obtained from seismic impact measurements affecting the housing development on the cover during the tunnel driving of the Mrázovka tunnels and after putting the tunnels into full service.

The complexity of geological conditions represented by the Letná shales of both monotone and flysch-type evolution, Libeň shales and Řevnice quartzites did not allow a unified technique of rock fragmentation to be specified for the sequential excavation of the tunnels. For fragmentation of hard or very hard rocks (over 60 Mpa) i.e. namely Letná shales of flysch-type evolution and quartzites blasting was therefore used. Otherwise mechanical technologies of driving were used.

The vibration effects sources were:

a) blasting, applied in sequential tunnel driving using NATM driving (New Austrian Tunnelling Method)
b) machinery used in construction technology
c) current motor- traffic on nearby roads

After finishing the construction of the tunnel, vibration effects in the tunnel, caused by motor- traffic and propagating through the rocks into building constructions in the cover, were investigated.

2 PERMISSIBLE VIBRATION LIMITS

Depending on the character and duration of the vibrations, the permissible limits for building constructions in the stage of failure O (no harm) according to the technical standard (ISO) were set:

a) for blasting maximum vibration velocity (v_{max})
b) for long-term impact load by virtual value of vibration speed
c) for steady periodical load by effective value of vibration speed (v_{ef})

2.1 *Blasting*

The permissible limits of dynamic excess load for building constructions that were found in the field of operations (with frequency characteristic of seismic impacts over 50 Hz) were set for reference points

(the lowest construction spot, bottom construction) in the following range:

Assessed structure – characteristics	Resistance class	V_{max} (mm/s)
Dilapidated buildings, nonconforming to building rules, historic building	A	6 až 15
Common masonry buildings up to 3 levels	B	15 až 30
Big masonry buildings (brickwork or blockwork), well reinforced panel and prefabricated buildings from concrete elements	C	20 až 40

The blasting limits were represented by the lowest values in the given range. Thus the variety in the construction and technical state of buildings, their age, and way of foundation reflected. Engineering communications and service pipelines that find themselves under the surface in shallow depths have a markedly higher dynamic resistance (40 to 100 mm/s) and therefore represented no limit to blasting.

2.2 *Technical bumps from machinery*

Dynamic reponse caused by long-term impact load or stabilized periodic vibrations is given by virtual value of vibration velocity $v^{ef(1)}$ in mm/s:

Resistance class	Vibration velocity $v^{ef(1)}$ mm/s			
	Construction class according to Czech standard ČSN 730031			
	U	I	II	III
A	0.2	0.4	0.7	1.1
B	0.4	0.6	1.0	1.8
C	0.7	1.5	2.0	2.8
D	0.9	2.0	2.5	3.5

Construction class II : civic and residential constructions

The given values are valid for the so called reference point.

2.3 *Vibrations in protected parts of the constructions*

Vibrations in the protected indoor parts of the constructions are judged from the Hygienic regulations about "health protection from unfavourable effects of noise and vibrations". For the protected indoor parts, the decisive role will be played by low-frequency wake-up elements (app. 10 to 80 Hz).

The highest permissible virtual values of vibration acceleration a_{etp}(interrupted and continuous vibrations) for dwelling rooms, time of the day (06–22) and time of the night (22–06) for the given 1/3 octave medium frequency range are presented in the table:

Frequency range 1/3 octave (Hz)	a_{ez} (m/s^2)	a_{etp} (m/s^2) 06–22 o'clock	a_{etp} (m/s^2) 22–06 o'clock	a_{etp} (m/s^2) 06–22 o'clock	a_{etp} (m/s^2) 22–06 o'clock
		Interrupted and continuous vibrations		Repetitive bumps (1 to 3 × daily)	
2	0.0036	0.0072	0.0051	0.0576	0.005
5	0.0045	0.009	0.0063	0.072	0.0063
8	0.005	0.01	0.0071	0.08	0.007
20	0.0125	0.025	0.0176	0.2	0.018
40	0.025	0.05	0.0352	0.4	0.035
80	0.05	0.1	0.0705	0.8	0.07

a_{ez} – basic vibration acceleration value (no corrections).

The highest permissible weighted frequency acceleration level L_{awp} of building constructions in protected indoor parts depend on the type of the room, daytime and vibration influence on man, or vibration acceleration virtual value a_{ewp}, respectively.

	L_{awp} (dB)		a_{ewp} ($m.s^{-2}$)	
Room type	day	night	day	night
Dwelling rooms	77	74	0.0072	0.005

The highest permissible bump acceleration weighted values in constructions (max. 1 to 3 occurences a day):

	L_{awp} (dB)		a_{ewp} ($m.s^{-2}$)	
Room type	day	night	day	night
Dwelling rooms	95	74	0,056	0,005

3 PERMISSIBLE NOISE VALUES

The limit site work noise values from hygienic regulations:

7 to 21 o'clock ……. 65 dB(A)
6 to 7, 21 to 22 o'clock. ….. 55 dB(A)
22 to 06 o'clock……..……. 45 dB(A)

4 VIBRATION MEASUREMENT RESULTS

4.1 *Blasting*

From the set of bumps measured on 47 houses, caused by shooting and blasting while driving the tunnels (western and eastern), maximum bump values were assessed, including other technical parameters:

Constr.	Length (m)	m_{evn} (kg)	$m_{celk.}$ (kg)	L (m)	Cover (m)	$v_{max.}$ (mm/s)
Western tunnel	325	2.4–3.2	60–110	2	42–50	5
Western tunnel	148	0.4–0.8	10–15	1	15–18	14.5
Machine room	105	2.4–5.3	75–132	2	50–65	5.2
Branch A	180	2.4–6,0	60–223	2	38–40	2.2
Eastern tunnel	235	0.6–2.4	30–93	1–2	30–32	9.8
Eastern tunnel	135	0.4	6–10	1	15–20	14.5
Branch B	100	0.6–1.6	15–45	1	20–22	11.1

Table legend:
m_{evn} – equivalent charge
$m_{celk.}$ – total charge for the blasting event
L – pull.

The set dynamic stress permissible limits of the monitored constructions were kept in all cases.

4.2 *Machinery*

The results of vibration effects measurements concerning the machinery used underground, such as rigs, winding machines, pneumatic drill units, which were transported into groundfloor rooms of dwellings, exceeded the hygienic limits for night with cover thicknesses 12 to 16 m (max. 58.5 dB or $a = 0.1$ m/s^2, resp.). For the cover thicknesses from 18 to 20 m the hygienic limits were already kept, thanks to increased vibration loss in the cover (below 55 dB, or 0.07 m/s^2 resp.). On higher floors permissible limit values were registered, thanks to the vibration loss in the construction.

In order to compare the effects of different vibration sources, measurements of vibration caused by motor-traffic were carried out with buildings on the main roads, to assess the "the backgroung vibration". The maximum vibration values measured, depending on the distance of the passing vehicles (3 to 6 m), ranged $v_{ef} = 0.2$ to 0.6 mm/s.

4.3 *Motor-traffic in tunnels*

After putting the tunnels in service, measurements were carried out on the groundfloor level of the houses above the tunnels, to find out the maximum

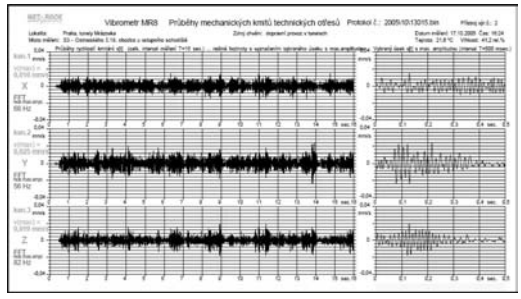

Figure 1.

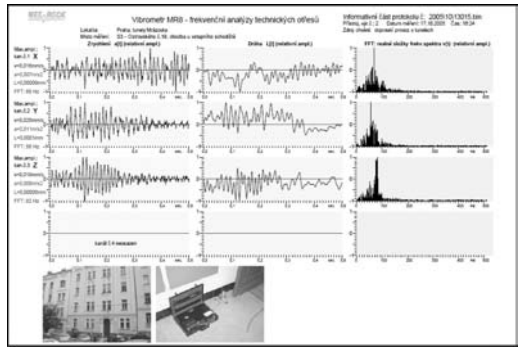

Figure 2.

vibration and noise values propagating into the buildings. The measurements proved that even with low cover thickness (app. 12 m), both vibration and noise values transmitted are below the threshold of human perception, i.e. $L_{awp} = 59$ to 65 dB, or vibration acceleration value $a_{awp} = 0.001$ to 002 m/s^2, respectively.

The motor-traffic in the Mrázovka tunnels can by no means exert negative influence on the comfort of living in the housing development.

Mechanical vibrations record diagram of technical bumps (vibration velocity) caused by motor – traffic in the tunnel, as registered on the groundfloor of 19 Ostrovská St. house (12 m above the tunnel vault) – figure 1.

Interpretation of path deviation, acceleration and frequency analysis from vibration velocity record – figure 2.

Motor – traffic vibration measurement record in the tunnel with interpretation according to a hygienic regulation – figure 3.

5 RESULTS OF NOISE MEASUREMENTS

5.1 *Blasting*

The noise measurements from blasting, propagating through the rock, proved no excess to the maximum

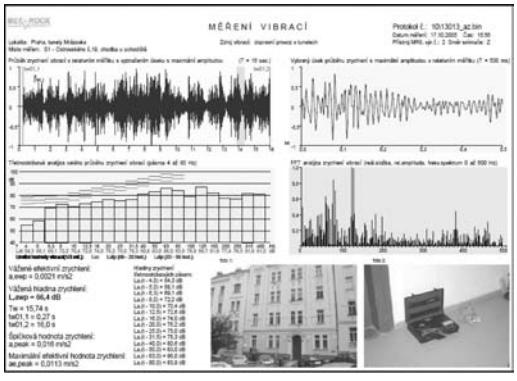

Figure 3.

acoustic pressure equivalent level for daytime (40 dB), with maximum values in parts of housing development with low cover reaching 35 to 38,5 dB. From 21 to 07 o'clock there was no blasting going on.

5.2 *Machinery*

Maximum acoustic pressure equivalent levels in inhabitated places caused by construction works, i.e. drilling, driving, rock fragmentation, lining demolition etc. were within permissible range (below 55 dB) for cover thickness of 18 to 20 m during daytime, with maximum vibration level of 53.5 dB. With lower cover thickness (12 to 16 m) the maximum vibration level was 61.5 dB. Fot nightime the only technology applicable was machine drilling with acoustic level below 30 dB.

5.3 *Motor-traffic in the tunnel*

The motor-traffic noise in the tunnels was also considerably below the human threshold of perception.

6 SOLUTION OF COMPLAINTS

When driving tunnels in the vicinity of housing development there were complaints about vibration and acoustic effects of blasting. Because these two elements combine and work concurrently, they are percieved as physiologically unpleasant bumps with vibration velocity of 3 mm/s.

Therefore people attribute to them common cracks in painting, plaster and masonry which, in fact, have a totally different cause.

There were frequent complaints from nearby surroundings even about vibration and acoustic effects of driving or drilling, which propagated through the cover into the houses and caused disturbances especially during the night.

All the complaints were dealt with by the developer, were discussed by the monitoring board and investigation into their justification was commanded. Through systematic checking of blasting bumps and through blasting charges adjustment the permissible limits of dynamic excess load were kept in all houses. In critical parts, blasting was reduced to the minimum applicable values and the process was segmented.

There were several complaints from the distance of 100 and more meters, claiming serious disturbances to construction elements (fallen stone bridge, fallen retaining wall, disturbance of newly constructed villa and some old houses). After inspections being carried out it was concluded that these claims are unsubstantiated and had different causes.

The unjustified claims of these damages were proved by a variety of measurements, the very nature of the disturbances and the statement of their real causes.

Advanced online monitoring for urban tunnelling projects

N. Benecke, P. Althaus & U. Kalz
Deutsche Montan Technologie GmbH, Essen, Germany

ABSTRACT: Tunnelling in urban environments causes several impacts to existing buildings and infrastructures as well as to the urban population. In particular surface movements, sound and vibrations from tunnelling work (e.g. tunnelling machines, blasting or rams) may have negative impacts on people up to damages on existing buildings and infrastructures. Therefore a monitoring system is urgently needed to know as early as possible about any surface movements and vibrations to take measures to avoid damages. More and more calls for proposals for urban tunnelling projects require monitoring systems for these purposes. An advanced online monitoring system with alert function is presented in this paper. The system includes different components for continuous monitoring of surface movements (e.g. DGPS, TPS and radarinterferometry) and vibrations (seismic event registration) with high accuracy and reliability. Also remote data-transmission and real-time alert functions are included. Especially some examples from practise will demonstrate the effectiveness of the system.

1 INTRODUCTION

Wherever tunnel projects are being developed in urban environments, the knowledge about geodynamic and environmental conditions plays a crucial role in the management and reduction of risks. Important data required are three-dimensional surface movements and vibrations, both for the whole area as well as for individual objects, which are exceptionally sensitive to deformations and/or vibrations, e.g. houses or infrastructures. For a long time DMT is measuring surface movements and vibrations as a service contractor for mining and tunnelling industries as well as for governmental agencies in Germany and worldwide. With regard to the increasing demand for information and cost effectiveness, DMT is in a continuing process to integrate advanced surveying, remote sensing and geophysical techniques.

This contribution deals with:

- Deformation monitoring using online GPS and TPS techniques as well as differential SAR interferometry, and
- Vibration monitoring.

Depending on the conditions of each single project the monitoring conception, possibly containing traditional survey as well as online-methods, radarinterferometry or vibration monitoring, has to fit the specific demands on site. Typically early-warning features and automatic reporting and documentation features are realized.

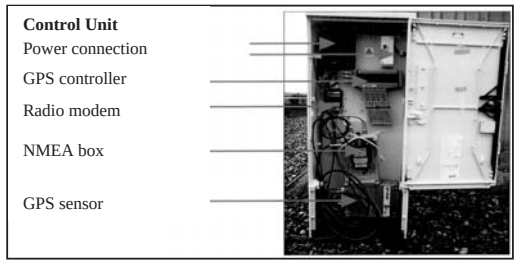

Figure 1. Control unit for GPS real time station.

2 DEFORMATION MONITORING

2.1 *GPS-Real-Time-Monitoring*

For a period of 17 months three public buildings in a city in Western Germany have been monitored by GPS real time measurements during underground mining operations. Therefore on each building a GPS station has been mounted inaccessible for the public (see Figures 1 and 2). Additionally a reference station has been operated over the whole monitoring period.

All stations have been linked. All captured data have been transmitted to a central processor unit, where an direct data evaluation has been realized (Figure 3). The data have been captured with a frequency of 180 seconds. This frequency has been proven and tested in several projects, but also other frequencies up to 1 second are possible.

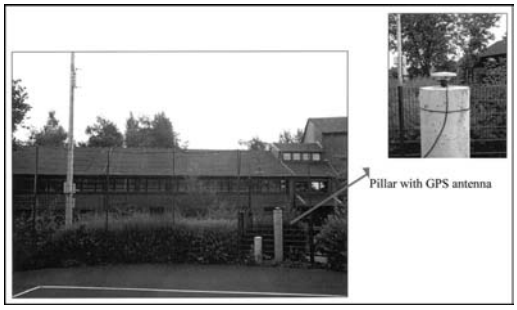

Figure 2. Secured pillar with GPS antenna.

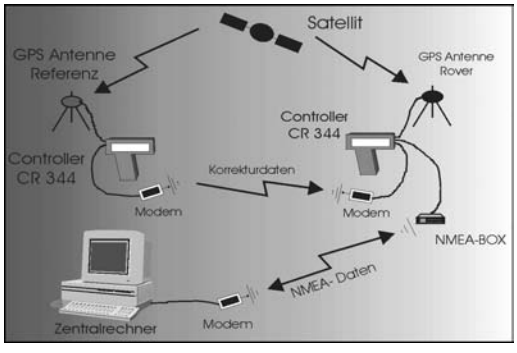

Figure 3. System components and cross linking.

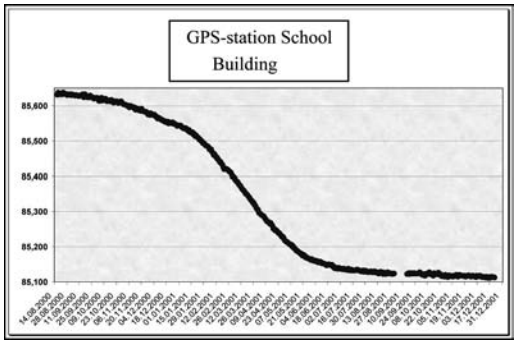

Figure 4. Measured vertical movements.

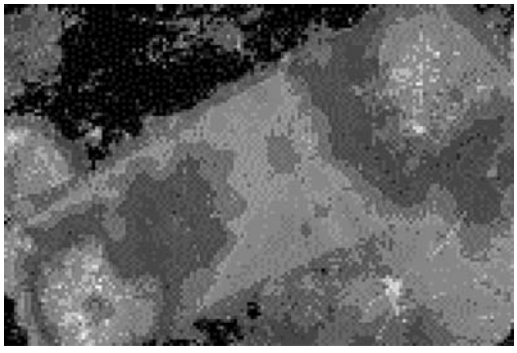
Meanwhile similar measurement designs have been used successful in several mining and tunnelling projects. If reasonable defined thresholds for horizontal and vertical movements can be set up. In case of overstepping these thresholds an alert will be send immediately to a computer or mobile phone.

In Figure 4 the effect of a mining induced subsidence is shown. These data are compared to subsidence modelling data to find abnormous behaviour. Subsidence modelling at DMT covers all kind of effects from tunnelling, mining in 3D and time dependent.

Figures 5 and 6. Monitoring system with totalstation and pillar with prism.

GPS-Real-Time-Monitoring is especially applicable for monitoring single objects, e.g. public or historical buildings, sensitive industrial plants and infrastructures, which have to be monitored for longer periods (several months up to years) with high accuracy. Reasons therefore will be specific sensitivity against movements, expected large damages or public interest.



In comparison of different measurement methods, GPS-Real-Time-Monitoring start with high basic costs, but with very low running costs. In opposite traditional repeating measurements have linear increasing costs with each repetition. Therefore it is necessary to calculate for each project the individual break-even-point from which the real-time monitoring system is cheaper than traditional measurements (Benecke et. al. 2001).

2.2 *Totalstation monitoring*

A shaft, closely located to residential buildings, has been reconstructed over a period of 10 months. During the construction movements with damages to the residential buildings have been feared. For monitoring the movements a continuous monitoring with a Totalstation and 10 monitoring points (pillars with prism) have been installed (Figures 5 and 6).

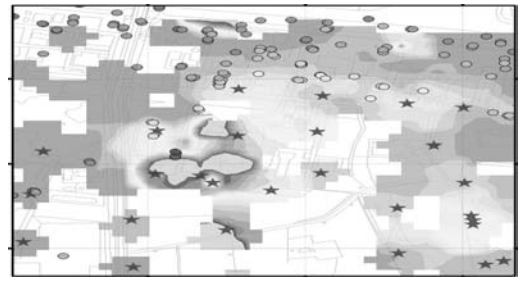
The totalstation has been erected on a nearby building and has been connected with a central processor unit by radio control to drive automatically to each of the prisms for measurements each 20 minutes. The measured data have been transferred directly to the processor unit for evaluation. Additionally an alert system has been integrated, which send an alert SMS to the mobile phones of the site manager and the responsible surveyor in case of movements bigger than 1 cm.

The use of totalstation monitoring is especially reasonable if several points on a small object or area have to be monitored over a long period. Every measurement point needs only a prism. Therefore a large number of points can be measured very cost effective. As a pre-condition a stable position for the totalstation is needed. Alternatively the movements of the

Figures 7. Surface movements detected by radarinterferometry in an oilfield.

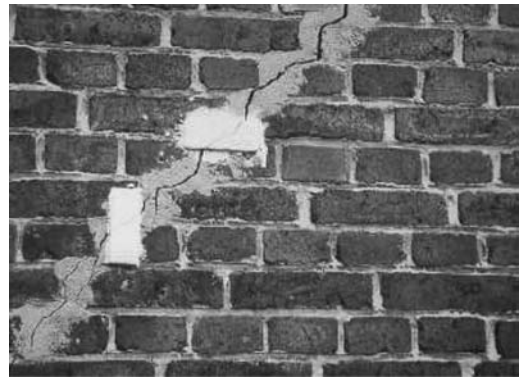
totalstation can be measured simultaneous by real-time GPS (Korittke et. al. 2004).

2.3 *Radarinterferometry*



A dense monitoring of large area surface movements of with traditional methods as mentioned above is time consuming and expensive. Instead radarinterferometry is coming up as an innovative and at least very economically methods for this purpose. In addition only radarinterferometry can look into the past for several years by processing older scenes. DMT and partners have developed an integrated conception for monitoring surface movement in large areas with influences from underground mining, oil and gas exploitation and groundwater measures.

Using data of current satellites ERS, ENVISAT or ALOS as well as archives data of ERS since 1992, it is possible to detect small movement rates of few millimeters per year with good spatial coverage and point density, especially in urban or less vegetated areas. Figures 7 and 8 point out typical results (Wegmuller et. al. in prep.).



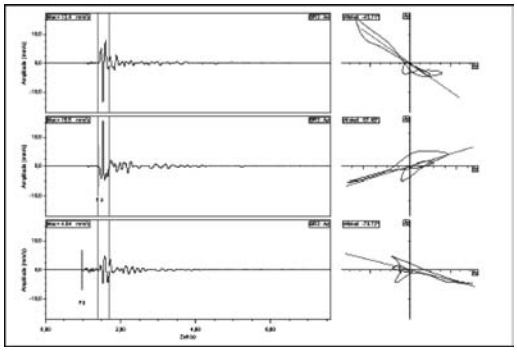
2.4 *Vibration monitoring*

Tunnel construction activities often cause serious vibrations, e.g. from blasting, drilling or machine driving. If the tunnel construction work is located close to buildings or infrastructures, the vibrations are potentially able to induce damages to these objects (Figure 9) or strongly affect people living in the neighborhood.

The following example deals with blasting during tunnel excavation. Depending on the specific blasting scheme drill holes have to be executed at the rock face to contain the blasting agent. The allocation of blasting time levels and the time lapses are driven by the blasting scheme. Of course, the tunnelling is running through different geological strata, therefore the used

Figures 8. Surface movements detected by radarinterferometry in a salt caverns field.

Figures 9. Damage from vibrations.



blasting schemes are varying in dependency on rock strength, tectonics and other geological features.

Outside the source vibration waves occur due to the elastic behaviour of the rock. There are different mechanisms of wave propagation, which lead to different types of waves. In practise the wave propagation is affected by additional factors, e.g. damping, reflection, refraction or conversion.

The registered vibration at the place of imission is a superposition of all relevant wave types. How vibrations caused by blasting affect a building can be registered by basement measurements in 3 rectangular directions and can be visualised in a hodogram (Figure 10).

Different wave types can be identified in the hodogram by their typical signatures. Of course, the registration of the vibrations has to be done with calibrated instruments (Figure 11) and have to meet the valid standards, e.g. in Germany DIN 45669. The registration can be performed as one-day measurement, but typically long-term measurement with online registration, database, and early- warning and alert system. Often additional sound measurements are made.

The evaluation of imissions caused by vibrations is important for the permission of any blasting activity as well as for liabilities in case of damages.

Figures 10. Hodogram.

Figures 11. DMT vibration monitoring instrument SuMo.

In case of changing operational parameters a prediction of the expected vibrations can be provided as well as an optimization of the blasting to minimize the vibrations can be proposed (Althaus et al. 2002).

All the techniques mentioned above can be combined together in an environmental impact documentation system including:

- GIS based topographic maps
- Subsidence monitoring with GPS, TPS and radarinterferometric satellite scene processing
- Sound and vibration database
- Model calculation
- Blast optimisation
- Document database for quality control
- Automatic reporting and documentation
- Early warning and alert systems

3 CONCLUSIONS AND OUTLOOK

Surface movements and vibrations are important impacts of mining and tunneling activities. The monitoring of these impacts is necessary for different reasons, e.g. permit procedure, preservation of evidence and documentation of damages or better prevention against damages.

The examples have shown innovative, but operational conceptions to monitor surface movements and vibrations, especially with advanced online monitoring techniques.

Geotechnical monitoring of the Valik tunnel construction near Pilsen

Radek Bernard, SG-Geotechnika a.s. Praha
Geologická, Praha

ABSTRACT: This paper describes geo-monitoring of the Valík tunnel construction near Pilsen. General description of geology uncovered during the tunnel drive and an overview of construction works is given. Geo-monitoring, carried out during the tunnel construction, its main objectives and measurement techniques are presented in detail. Data acquired as part of geo-monitoring was collected, presented and archived using the Barab© online database system, developed by SG-Geotechnika. In conclusion, assessment of geo-monitoring benefits, including financial savings, are presented.

1 INSTRUCTIONS

Tunnel drive of the Valík tunnel under the Valík hill between municipalities Černice and Utušice is a part of the construction of the 510/1B highway D5 from Prague to Rozvadov and the highway by-pass of the city of Pilsen. Full-scale geo-monitoring of the tunnel drive is carried by our company, SG-Geotechnika, for the client, ŘSD ČR, Praha.

These highway tunnels are 390 m, or 380 m long respectively, (the bore portion of 330 m) and are formed by two independent tunnel tubes less than 12 m wide and 8.2 m high (definitive lining). The maximum longitudinal grade is 4% descending to the West. Both tunnel tubes are in close proximity without a rock pillar. They are separated by a central reinforced concrete pillar constructed in advance, leading to significantly lesser extent of surface land take in the area affected by the construction (discussed in detail later). Construction of bored tunnel sections is designed as double skin with intermediate insulation. For stability and static reasons, it was necessary to construct countervaults in both primary and secondary casings along full bore lengths. Tunnel bore was done according to the guidelines of the New Austrian Tunneling Method (NATM).

1.1 *Geology encountered during tunnel bore*

The bore encountered Proterozoic sediments, slightly metamorphosed rocks of the Blovice-Teplice series. These Proterozoic slates, mostly greyish-brown in color, in the central bore portion higher in silica, are complemented by greyish-black graphitic slates of varying thickness. Slates are weathered to strongly weathered and limonitized near cracks. Strong tectonic effects are prominent as slates are fissured, in places intensively.

Several dyke structures, ranging from decimeters to tenths of meters, appear in the massif. Weathered to strongly weathered grey-beige porphyry and grey-greenish metabasalt (spilite), weathered to a varying degree are common. Tunnel excavation took place in predominantly dry conditions with local and insignificant groundwater water leaks in the lower vault of the tunnel sections. Neither tectonic fissures nor dyke structures were considered to be the source of groundwater.

Results of detailed geological engineering survey lead to the assignment of one basic technological grade of rocks for the tunnel bore according to the NATM. The grade is 5a, further subdivided into grades 5aI, 5aII and 5aIII, where 5aIII was used in the most favorable geological conditions and 5aI in the most unfavorable ones. Complete geotechnical monitoring was proposed for these technological grades and forms the main topic of this paper.

1.2 *Description of construction works*

Field work commenced in November of 2003 and the western, Rozvadov portal was excavated. The Prague portal was excavated at the same time as the bore of the central section of the tunnel (May–August of 2004). The tunnels' bore was initiated by the drive of the central tunnel from the mentioned Rozvadov portal. Concrete work on the mid-pillar began in September, 2004, and the bore of the main tunnels could begin in early October. Concrete work on the mid-pillar was completed in late January 2005 and satisfied project requirements for further tunnel excavations.

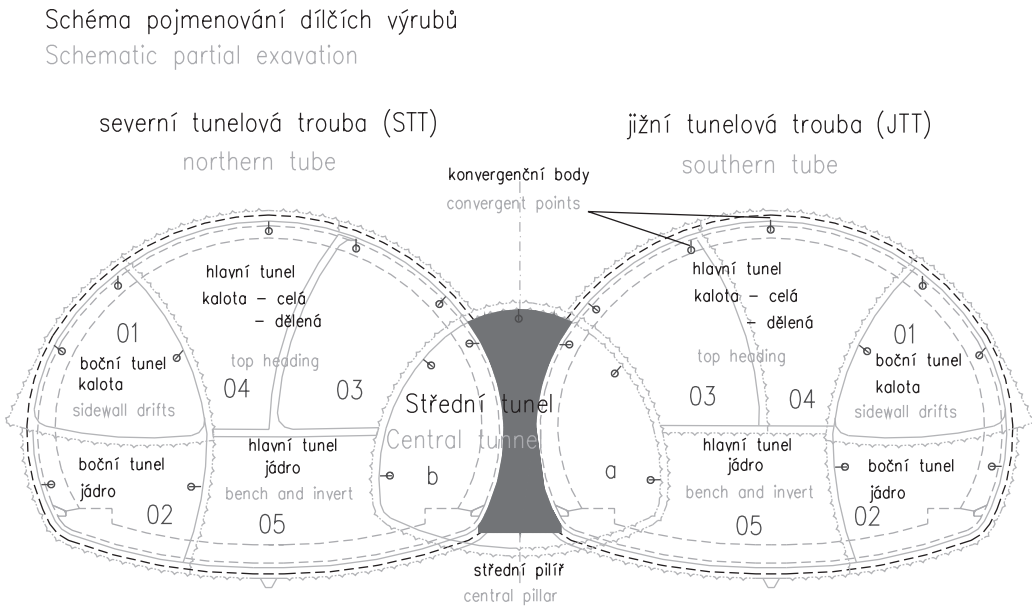

Figure 1. Progression of partial tunnel bores.

Figure 1 shows the progression of bores, divided by a combined method into sections using predominantly a less common, and more time consuming vertical division. This method was used due to complex geology encountered during the bore of an exploration gallery in 2002 and minimal overburden thickness above the tunnels ranging from 5 to 15 m along the tunnel length. Tunnel height is 16 m and width 12 m (primary lining).

The front portion of all divided stopes passed under an 18 m long micropilot umbrella, drilled in two rows from the Rozvadov portal. Similar measures were used to prevent the end-points of bores from breaking through in the Prague portal. Subsequent to the passage of the central tunnel bore (approx. 50 m^2) under the above mentioned security micropilots, the contractor proceeded with a two-part bore using calottes with a slight lead in the left portion (in the bore direction). Evaluation of all available measurements acquired during the initial bore (in approx. 30 tunnel meters, or TM), the IG documentation and recommendations of the GTM office formed the basis of the decision of RAMO members to proceed with the bore using calottes in full profile. This decision turned out to be favourable as the remaining section of the central tunnel was bored the same way leading to considerable time savings. The bottom, or lower vault of the mid-tunnel was closed every BTX 6–7 steel frames while leaving 2–3 m of bench at the forefield.

Generally positive conditions during the bore of the central tunnel resulted in the overall favourable assignment of technological NATM grade which turned out as more beneficial to the developer than the original project assumption. Minimal overbreaks were documented during the bore of the central tunnel, for the most part described as fortuitous as they were caused by tectonic disturbance or intensive cleavage of the rock massif. This was not expected as during the bore of the exploration gallery, high rates of overbreaks from bored profile were reported (approx. 15 m^2). As it turned out, this exploration gallery, placed in the profile of the mid-tunnel, had a positive impact on the tunnel drive acting as an anchor ensuring the stability of the forefield. Minimal rate of overbreaks in this tunnel section was due to the use of tunnel dredger in medium hard rocks in approx. $^2/_3$ length of the mid-tunnel. The use of non-explosive methods of rock excavation did not cause substantial disintegration of the surrounding rock mass. Permanent rainfall deficit, recorded since 2003, leading to gradual subsidence of groundwater levels by 3–4 m was another positive factor in tunnel excavation. The bore of main tunnel tubes commenced in September–October 2004 and was completed during May of 2005. Only first two NATM grades were used during the excavation of the two main tunnels. Owing to these facts it is obvious, that geological conditions during these tunnel drives were quite diverse as relatively favourable conditions during the bore of the central tunnel were not matched during bores of the surrounding main tunnels.

The overall geological conditions of tunnel drives were relatively simple lithological environment but

very complex tectonic framework. Several orogenic phases affected Proterozoic rocks and subdivided them into separate blocks. These blocks were unevenly moved and turned which is obvious from measured foliation. In addition, repeated tectonic movements occurred on some fault planes.

2 GEOMONITORING

2.1 *Geotechnical monitoring (GTM) of the Valík tunnel construction*

Geotechnical monitoring is an integral part of the New Austrian Tunneling Method (NATM) which is used during construction of most tunnels in the Czech Republic. The purpose of geo-monitoring is to provide sufficient information about the response of the rock massif to the bore of the tunnel. An important objective is continuous cross-referencing of project's assumptions with the reality and obtaining information for the assignment of NATM grades to stopes. Geomonitoring during the Valík tunnel construction included the following measurements and observations:

- forefield monitoring by means of geological engineering
- measurements of slope deformations in excavated sections of portals
- convergent measurements in tunnels
- surface terrain subsidence measurements (transverse subsided basin and longitudinal wave)
- extensometric and inclinometric measurements in wells from the surface
- tension measurements using tensometers on the contact between rock and primary lining and in secondary lining
- tension measurements using pressure cells in primary lining of the mid-tunnel and in the central pillar
- seismic control measurements of the effects of blasting operations on the surroundings
- measurements of the actual shape of stopes and the primary and secondary linings
- control measurements of concrete strength using Schmidt's hammer
- control measurements of forces in bolts and ties
- complex monitoring of the cottage settlement Amerika (pasportisation)

Complex evaluation of interaction between the rock massif and the tunnel lining required measurements in 3 aggregate profiles. Convergent, extensometric and inclinometric measurements were carried out in these profiles as well as measurements of tension in primary lining, tension measurements on the contact between primary lining and the rock massif and measurements of surface terrain deformations. Complex analysis and evaluation of geotechnical measurement results in relation to all completed measurements and actually observed geotechnical conditions, particularly in aggregate profiles. All measurements described above were regularly placed on the Barab© internet online server at the GTM office with access provided to all qualified construction participants, including invited experts. Evaluation of all types of measured data, – in relation to determined warning situations constituted a very important activity of the GTM office. Criteria for determination of warning situations were set prior to construction by the project engineer from static computations based on measurements done during the bore of the exploration gallery. These criteria were regularly refined during construction from periodic evaluations of measurement results (Monitoring Committee) – depending on the new information on the behavior of the underground construction.. In addition, static calculations were updated during the course of tunnel bore taking into account new observations. Thus, warning situation parameters were adequately refined. In relation to the evaluation of GTM results and warning situations, measures concerning the following issues were taken:

- measurements and evaluation of geomonitoring (rate of measurements, measurement type modifications, speed and method of evaluation)
- emergency regime (direction and speed of information flow and decision making process)

modifications of bore technology and lining reinforcement (according to RDS), work safety and its organization (according to the construction accident plan)

2.2 *Evaluation of geotechnical measurements from the bore of the mid-tunnel*

As described above, bore of the mid-tunnel was done predominantly according to a horizontal division (calotte and lower vault). The entire profile of the mid-tunnel occupied an area of approximately 71 m^2 (calotte of 50 m^2 and lower vault approx. 21 m^2). During convergent measurement in the front part of the tunnel, individual five-point profiles were designed in 10 m spacing and from 30 TM station every 20 m. Due to the occurrence of a thick disturbance spanning over more than half of the bored profile, RAMO members decided to add an inserted KVG profile in this section. The threshold value of warning situation was different for individual points due to the location of each point on the lining. Generally, the lowermost warning threshold of all points was 13 mm in the vertical and 11 m in the horizontal direction. These values fall into the 3rd warning stage on a five stage scale – *the state of cutoff acceptance*. Maximum deformation measured in the mid-tunnel was 11 mm in the vertical and 10.5 mm in the transverse direction. We can conclude that measured deformation values of KVG points on primary

lining of the mid-tunnel fell at most into the IInd warning stage and therefore it was not necessary to adopt any special measures during the tunnel drive.

Similar evaluation of deformation measurements on surface including extensometric and inclinometric surveys was carried out. Maximum deformation measured from extensometric wells was found on the lowest tie No. 4 within the 3. aggregate profile at station 30 TM. The value of 12.6 mm was measured on extensometer 24.22 which is situated slightly left (in the direction of bore stations) from the longitudinal axis of the tunnel. Measurements on the same extensometer yielded a maximum deformation of 10.4 mm at its head (the warning situation at the surface is set to 40 mm). It is obvious, that deformation of the deepest tie of the extensometer is almost identical as the deformation of its head at the surface. This is caused by the presence of a minimum overburden at station 30 TM of approx. 6 m which does not allow for the formation of a natural rock vault in surrounding rocks above the bored tunnel. Largest absolute deformations were measured on profile No. 3 which is clearly caused by lesser overburden above the tunnel and highly problematic geological conditions at the initial portion of the construction. Deformations on subsequent transverse profiles (190 a 290 TM), measured at individual extensometric ties, reached values of around 5 mm. Interestingly, maximum deformations on all transverse profiles, recorded during the bore, were not observed at extensometers along the axis above the tunnel, but rather, always at accessory extensometers (see scheme on Figure 3) located on the right hand side in the bore direction. Encountered foliation and dip angles of about 80° were a contributing factor as maximum deformation did not evolve along a vertical but followed the dip of the foliation. Maximum measured surface deformation (13 mm) along a longitudinal axis

Figure 2. Division of bores inside the tunnel during the drive of the south tunnel tube.

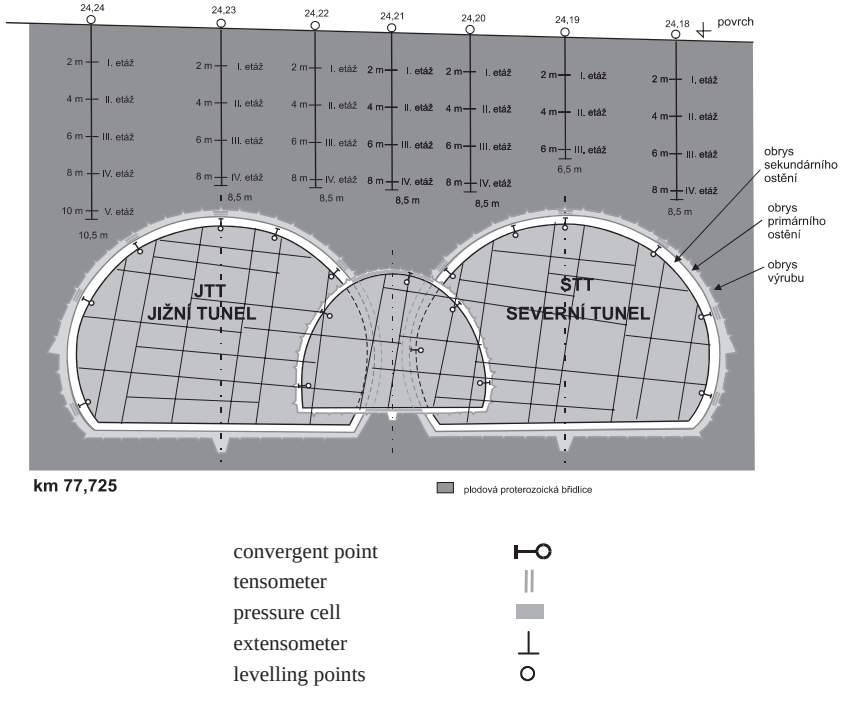

Figure 3. Scheme of measuring elements in the 3. aggregate profile (30 TM).

above the mid-tunnel, measured within the longitudinal subsidence wave, was recorded at point No. 22 at the tunnel station 310 TM.

Lesser horizontal deformations of 4–7 mm were recorded in the surrounding rock massif in six inclinometric wells during the bore of the mid-tunnel. The deformation propagated always in the direction from the inclinometers towards the tunnel. Minimal deformations at this stage of the construction were affected by the fact, that individual inclinometers was approx. 8 m from both sides.

Continuous control GTM measurements of encountered overbreaks using a profile machine turned out to be an independent and useful method during the construction of the Valík tunnel during the bore of the mid- and main tunnels. The client delegated the responsibility for these measurements to the geomonitoring office and therefore was responsible for random measurements done by the contractor. Individual documents on stope profiles were given to construction technical supervisors by means of weekly protocols always prior to RAMO meetings in order to secure possible approvals for overbreaks by the client.

2.3 *Description of work flow and brief evaluation of GTM during the bore of main tunnels*

Main tunnel drives (North and South Tunnel Tubes) commenced during the end of September and beginning of October, 2004. Bores with vertical division of individual parts began from the Rozvadov portal gradually through individual side tunnels (gothic galleries). Following-up approx. 30 meters of the side tunnel bore, the main calottes of the main tunnels were bored. Under close supervision, they were bored in one take (not divided, as proposed in the project), see Figure 2. After boring of a section of the main calotte, (approx. 50 m), the core of the tunnel was mucked and the bottom closed along the full length of the lower tunnel vault. After closing of the bottom, the partition between the side gallery and the middle part of the tunnel was dismantled and the full profile of the primary tunnel lining was formed. Maximum transverse deformation of 12 mm in the South Tunnel Tube was recorded at the inserted profile No. 20 (due to intersected rock disturbance) at station 59 TM. Deformations, measured in the North tunnel reached slightly higher values. This was caused by a less favourable geological situation encountered during the bore of the South tunnel as the rocks were weathered to a higher degree, particularly at the initial third of the bores. Maximum vertical deformation was recorded on profiles No. 6 (90 TM) and 7 (110 TM). Both measured values of 19 mm came close to the set levels for warning situation. These values were recorded during additional excavation works and construction of a stall near both profiles. Maximum transverse deformation of 13 mm was measured on profile No. 2 (20 TM) (the value of warning situation).

Maximum deformation at the terrain surface of 31 mm within the 3. aggregate profile at station 30 TM. In contrast, extensometric measurements in the rock massif yielded a maximum deformation of 47.5 mm at the lowermost tie of the extensometer 24.05, located above the vault of the South Tunnel Tube, in the 2nd aggregate profile at the station 190 TM. The mentioned additive vertical deformation is affected by the passage of the bores of the mid-tunnel and all partial components of large tunnels.

Due to gradual drop in groundwater levels to the lower tunnel vault level in 2002 to 2005, hydrogeological observations of tunnel bores indicate isolated minimal inflows of groundwater only at the tunnel bottom. Long-term GTM observations and monitoring in surrounding water wells confirmed no effects and subsidence of groundwater levels due to the construction of the Valík tunnel.

2.4 *Contributions of geomonitoring to the construction thus far*

Results of measurement evaluations and recommendations of the GTM office formed the basis of the decision not to use division of the calotte stope of the mid-tunnel according to the project. After approx. 10 meters of drive behind the micropilot umbrella (18 m long), the entire upper part (calotte) was bored as one profile, of an approx. diameter of 50 m^2 under constant supervision of the GTM office. As per measurement results, anchoring in the lower vault in the most favourable grade 5aIII was not carried out. Adopting of these decisions (approved by RAMO), savings of more than a month of planned bore works in the mid-tunnel were made in addition to saved financial resources for unused BTX truss rip, spared anchors and air-placed concrete.

Similar situation occurred during the bore of main tunnels (10/2004 to 05/2005) as the GTM recommended to RAMO to simplify the design of the division of both tunnels. Thus main calottes of both tunnels were bored as one stope. At the same time, in accordance with the recommendation of the GTM office, securing of micropilots BODEX above the tunnel vaults was not completed. The original project called for drilling of these from chapels built above the upper tunnel vault. The simple reason was not to endow the overburden massif by technological water from drilling which would likely make the forefield situation considerably worse, under the circumstances. Due to the above mentioned measures the time frame for tunnel boring was shortened by more than 4 months and considerable financial resources were saved.

3 CONCLUSION

Albeit documented very difficult geological conditions of the Valik tunnel and close scrutiny of the public in the affected region, it was possible to deal with these difficulties very successfully. This was possible due to the contractor's discipline, project engineer's experience and a well functioning geo-monitoring expert team. Even prior to the tunnel trial operation in October, 2006, it was concluded, that the more costly but unique solution with the reinforced pillar will provide considerable financial savings due to reduced surface land take – as opposed to similar large highway construction projects.

The use of guide lines in tunnelling

G. Cassani & L. Mancinelli
Rocksoil SpA, Milan, Italy

ABSTRACT: In several conditions, design of tunnel is based on a limited number of data, deduced from geological and geotechnical investigations, laboratory and in-situ tests, bibliography information and experience. This kind of approach obliges the designer to make strong hypotheses that have heavy influence on his product. Guide lines allow to

– define different possibilities of application of a same section type, modulating the quantity and the quality of the reinforcements on the basis of the real ground or rock conditions in conventional tunnelling;
– calibrate working parameters as a function of the front conditions in mechanized tunnelling.

Real-time monitoring activity, geological observation and analysis of working data are the instruments that drive every choice, proceeding by fitting real needs and reducing risk.

In works, like tunnelling, where costs are high, the introduction of variability can optimize a design, making all process cheaper and safer.

1 INTRODUCTION

Guide lines represent a modern approach to design that are used increasingly by engineers and are now present in numerous official national and international regulations. In general terms they are a set of criteria that allow variability in the application of a design and constitute an integral part of it.

This approach is particularly useful when predictive work leaves too much open to chance, a situation which may be due to many different factors.

From a geotechnical viewpoint, and more particularly from that of the construction of tunnels whether excavated using tradition methods of mechanised means, the use of guide lines appears to be of fundamental importance.

Survey data is in fact often limited and insufficient at the design stage to justify fully deterministic approaches such as statistical approaches. In the past, this limit was not overcome until the operational stage when the real conditions became clear, giving rise to quite a number of problems in terms of safety, operations and, in the final analysis, contracts.

The idea of defining guide lines for construction operations is designed to solve all these not inconsiderable problems before work starts, by acting while still at the design stage and therefore in terms of general organisation.

From a practical point of view, guide lines for tunnel construction allow a series of quantitative and qualitative possibilities in the application of a design. The engineer defines different activities or action on the basis of the studies carried out that can be proposed according to the conditions encountered. For underground tunnels this concerns initial ground support, ground improvement work and the placing of the finally lining.

For mechanised excavation, performed using a tunnel boring machine (TBM), the variability relates entirely to the manner in which the machine advances and is operated.

2 TRADITIONAL EXCAVATION

The construction of underground tunnels has always required excavation and support operations to be adapted to the actual in situ conditions encountered. In design terms this translates into defining different tunnel section types to be employed as a function of requirements. A certain type of initial ground support, ground improvement, drainage and lastly final lining is specified for each tunnel section type. All these items, except for the final lining, can be easily defined in terms of ranges of variability within which they can be applied. Final linings on the other hand possess very rigid geometries for a given tunnel section type which is determined by the area excavated and the inner profile which must be complied with.

The criteria for selecting when to apply these variable items constitute a fundamental working instrument for the approach discussed here. It is monitoring

Table 1. Variability in traditional excavation.

Item	Modifiable quantity
Shotcrete	Rate of reinforcement, strength class and frequency of implementation
Steel ribs	Interval
Radial roof bolts	Number, length and frequency with which placed
Ground improvement at the face	Number, length and geometry
Ground improvement around the tunnel	Number, length and geometry
Ground improvement at base of ribs	Number, length and geometry
Drains	Number, length, frequency with which placed and geometry
Tunnel advances	Length
Stage at which final lining is cast	Distance from face

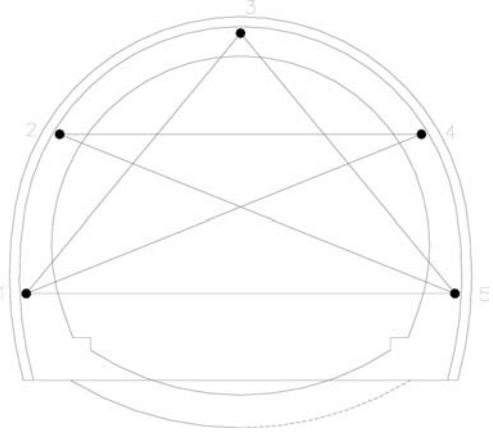

Figure 1. Section type for tunnel monitoring – Convergences.

operations which furnish the necessary information in terms of extrusion at the face and cavity convergence, when tunnelling underground.

A list is given below of the main items typically subject to variability, which are then briefly mentioned and described.

It is important to always keep in mind that the guide lines must contain an indispensable consistency between the different items subject to variability; many of these are *de facto* intrinsically interrelated one with the other.

2.1 *Shotcrete*

Shotcrete, together with steel ribs or radial roof bolts, constitutes the primary lining of an underground tunnel. Its thickness is generally limited by the area excavated and the geometry of the final lining. It can be reinforced to a greater or lesser degree using different types of steel wire or mesh, or different percentages of fibre and even the type of mix used can be easily modified. It can be placed on each tunnel advance or after a number of advances depending on the behaviour of the excavation.

2.2 *Steel ribs*

Steel ribs have the same fixed geometry within a given section type. In the case of cylindrical section types, the interval at which they are placed can be easily varied. They are usually placed on each tunnel advance. When variable section types are used (truncated cones) if the intervals at which the ribs are placed changes then so does the geometry; they are in fact different from each other within the range of the tunnel advance. In this case it is advisable to develop a new section type.

2.3 *Radial roof bolts*

Roof bolts are mechanical elements for supporting the roof arch. They can be placed with a large variety of geometries (different types of grid) according to need. The number can also be easily changed in real time. They can be placed on each tunnel advance or after a number of advances depending on the behaviour of the excavation.

2.4 *Ground improvement at the face or around the tunnel*

Ground improvement at the face or around the tunnel, consisting of cemented tubes, injected tubes or jet-grouting, for example, constitute very important advance support elements for the progress of operations. They can be adjusted very easily in terms of the number and length, factors which will also be related to the length of tunnel advance decided. It is often only the number of elements which is varied because of supply and operational considerations. Finally the reciprocal positioning of the elements can be optimised and modified.

2.5 *Ground improvement at base of ribs*

Ground improvement at the foot of ribs, also consisting of cemented tubes, injected tubes or jet-grouting, for example, constitute elements of protection against potential local instability. As with the ground improvement techniques already described, these too can be easily varied in terms of number, length and geometry.

2.6 *Drains*

When water is present, section types are often fitted with appropriate drainage structures consisting basically of PVC tubes with valves. In terms of design, these are always allowed for as possibilities and can

therefore be varied in terms of presence/absence, number, length and geometry to optimise drainage capacity.

2.7 *Tunnel advances*

A tunnel advance is the length of tunnel excavated which is performed before proceeding to place primary linings. It can be easily varied according to the context. This quantity obviously affects many of the items already described.

2.8 *Stage at which final lining is cast*

The casting of the final lining is performed as a function of the response of the cavity to excavation. If convergence or extrusion values are high, it may be advisable to cast linings closer to the face, either just for the tunnel inverts or even for the roof arches. These activities must be defined during construction, considering work on the construction site and real operations *in situ.*

In addition to the items specified, the following can be considered as particular intervention covered by guide lines: ground freezing, placing of special ribs or of steel struts in the tunnel invert, etc.

3 TUNNEL EXCAVATION WITH TBM

When excavation is mechanised, many aspects of the application of the design are necessarily decided before work starts in such a way that they cannot be changed. These include the dimensions of the machine, the type of machine, the geometry and the characteristics of the final lining. These factors must in fact be decided before proceeding with the works. There is one single cross section for tunnel advance and there is no concrete possibility of changing it.

The guide lines intervene in terms of excavation operations. A list of the main items typically subject to variation is given below.

Here too, it is monitoring that furnishes information on which decisions on construction operations are based. Activity involves both observations of movements at the surface and analysis of machine operating parameters. At present the latter items can be varied continuously and, by exploiting the latest technology for data transmission, this can even be done remotely. Combined study of all items allows works to proceed with minimum side effects on the surface and with guarantees of greater safety margins.

The technical objective is basically that of keeping the value for volume lost (the space invaded within the cavity by the excavated material before support structures take effect) to a minimum and consequently minimising surface subsidence responsible for damage to structures or infrastructures that may be present.

Table 2. Items for TBM.

Modifiable quantity
Torque
Advance velocity – Quantity of material extracted
Containment pressure at the face
Conditioning of the material treated in the excavation chamber

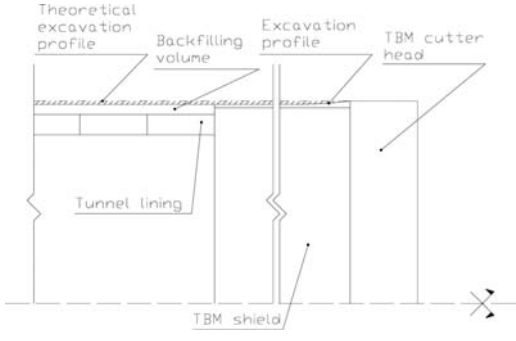

Figure 2. TBM Work diagram.

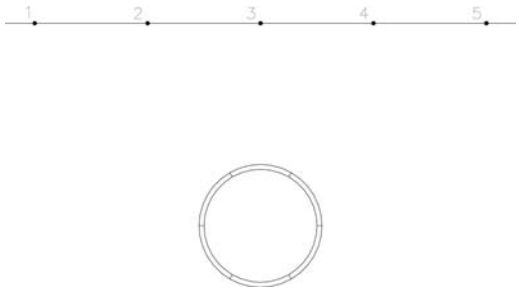

Figure 3. Section type for surface monitoring.

3.1 *Torque*

Torque is the stress exerted by the action of the shield at the front of the TBM. It can be selected as a function of the consistency of the material excavated. Its value is closely correlated with the pressure in the excavation chamber for machines designed for this type of excavation.

3.2 *Advance velocity – Quantity of material extracted*

The advance velocity is closely correlated with the quantity of material extracted. A proper balance between these two items leads to good performance in the execution of the works, without causing dangerous over excavation (too much material extracted) or unadvisable TBM advance (too high a value for the torque).

3.3 *Containment pressure at the face*

Various machines allow the face to be supported by applying pressure to it. This pressure makes it possible to counter thrusts and water, if present, coming from the ground. Proper application of pressure allows tunnel advance to be optimised and surface subsidence to be kept to a minimum.

3.4 *Conditioning of the material in the excavation chamber*

The material loosened by the TBM and present in the excavation chamber is usually conditioned before it is extracted. The treatment in question consists of adding appropriate material to produce a mixture that can be easily conveyed away.

4 CONCLUSIONS

The definition of underground designs and, more specifically, of tunnel designs contains a series of intrinsically unknown factors. This aspect is in itself, however, well known as a result of experience above all. As we have seen Guide lines constitute an excellent instrument for managing these random elements, a set of criteria which define how a design can be implemented in practice. As is happening increasingly more often, they are starting to form part of the designs themselves, basically constituting a fundamental element of the application.

The guide lines must therefore be thought of as a set of rules which make the design dynamic. Design therefore loses its character as a precise definition of activities and becomes a more complex entity which responds more appropriately to real requirements.

Rio de Janeiro subway – Challenges of the access tunnel to the Cantagalo station

Aluisio de Abreu Coutinho Jr.

ABSTRACT: The Rio de Janeiro Metro Line 2 was expanded recently in 1230 m, including the new Cantagalo Station. In this stretch, the tunnel and station were excavated mainly in sound gneiss. To connect the station to the highly populated Copacabana area, a 95 m long, main access tunnel connecting the station to the entrance area at Praça Eugênio Jardim, had to be built. This 9.1 m wide and 11.6 m high tunnel had to cross sharp and irregular transitions between the sound gneiss and a silty residual soil, underlying a sedimentary sand, below groundwater.

The access tunnel, additionally, crosses under a specially settlement sensitive building. The 11 story high, approx. 60 years old building, is founded on shallow footings. Few of the footings are bearing on rock and the remaining on sedimentary sand, which, is characterized by a loose to medium dense condition.

Sand compaction resulting from vibrations due to drill and blast excavation technique induced less than 15 mm additional settlements in the footings on sand, but lead to important structural damages.

To avoid further deterioration of the already critical structural condition, this building was underpinned with 84 root piles and 1.50 m thick reinforced concrete slab.

The main difficulties encountered during tunnel excavation under this building, the mitigating construction method adjustments, and building performance are detailed in the paper.

1 INTRODUCTION

Rio de Janeiro has a population of approx. 10 million inhabitants and is continuously growing. As so many other big cities, traffic is one of the main problems and, therefore, Line 2 of Rio de Janeiro Metro was recently expanded in another 1230 m, adding the new Cantagalo station. Excavation works are finished and delivery to operation is due in 11/2006.

The south area of Rio de Janeiro is densely populated and, especially in Copacabana, where Cantagalo station is located, buildings are concentrated in a relatively narrow strip between the shoreline and steep mountains. These particular conditions oriented main design guidelines, which located the main subway line inside the rock massif, beneath mountains. Only access tunnels and relatively short crossings are constructed beneath buildings and roads.

During the construction of the access tunnel, significant damage to a specific building was detected. To avoid further deterioration, the building was underpinned with 84 root piles and a 1.5 m thick concrete slab.

After completion of underpinning, excavation continued without further problems.

2 PROJECT DESCRIPTION

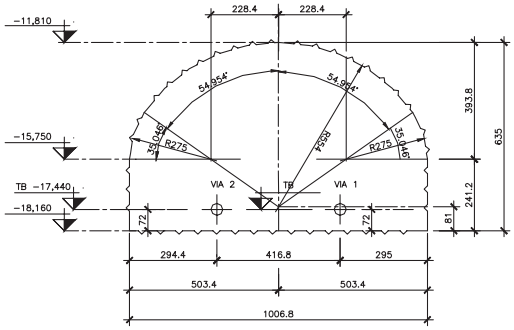
The recently built Metro stretch is 1230 m long, including approx. 1 km of a twin lane tunnel and a 180 m long cavern, where Cantagalo station is located. 3 short access and ventilation tunnels where also constructed. Figure 1 presents typical cross sections of the tunnels.

The main line tunnel and the station were excavated mainly in sound gneiss, occasionally crossing faults and weathered zones.

To access the station, 2 relatively short tunnels, approximately perpendicular to the main line, were build, crossing from the sound gneiss, through weathered gneiss and sedimentary sands, beneath several relatively old, more than 10 story high buildings, founded on direct footings.

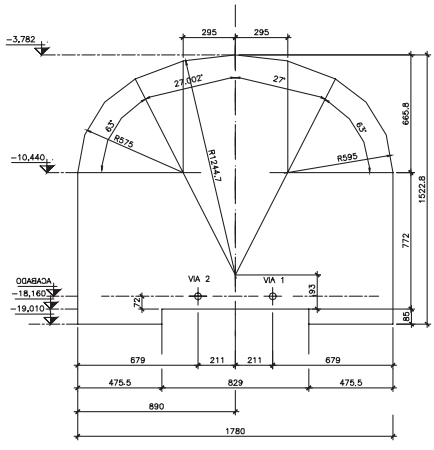
Figure 2 presents a schematic view of the lay-out of the project:

The access tunnel connects a cut & cover entrance structure, where the main public will enter the Metro, to the station. This excavation was built using 80 cm thick and 25 m deep diaphragm walls.



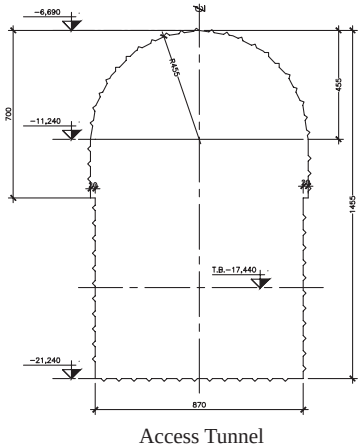
The emergency tunnel is connected to a 10 m diameter and 20 m deep circular shaft.

Excavation method in rock was conventional Drill & Blast, using a 3 boomer Jumbo.



Along the access tunnels, drill & blast method was used, where applicable, and conventional excavation with hydraulic excavators, front-loaders and hammers.

Along critical stretches, like fault zones, 62.5 mm tubular metallic forepolling was used, together with cement grout injections.



The access and emergency tunnel excavation was protected by horizontal and vertical Jet-Grouting, used together with 62.5 mm tubular metallic for pollings.

Line Tunnel

Station Tunnel

Access Tunnel

Figure 1. Typical tunnel cross sections.

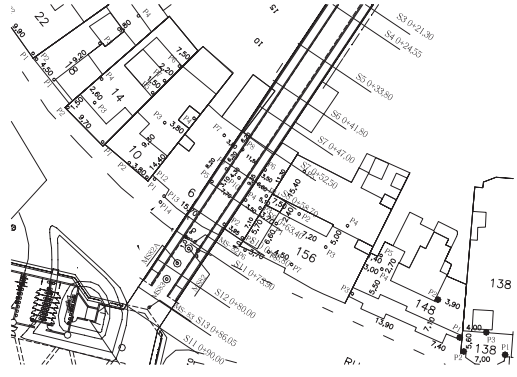


Figure 2. Plan view of the access tunnel. In the lower left corner, the cut & cover section.

Aerial View of buildings above access tunnel.

An extensive monitoring program was foreseen, mainly monitoring surface settlements of buildings and instrumented cross sections, as well as water level. Inside the tunnels, convergence and settlements were also measured. Additionally, periodic visual inspections of buildings located in the vicinities of excavations, to detect cracks and other signs of differential movements.

3 GEOLOGICAL BACKGROUND

The typical geological cross section along the line tunnel and station tunnel is a relatively thin silty residual soil cover, occasionally covered by colluvial soils, and its transitions to the sound gneiss.

Local gneisses are Kinzigitic, generally with three sets of discontinuities, one of then associated to the southward dipping xistosity. Rock quality index Q is in general between 15 and 35, and as low as 3 to 4 at faulted zones.

Along the 2 access tunnels (access tunnel and emergency tunnel) a transition from the conditions above, close to the station, to a cross section with the crown of the tunnels in saturated sedimentary sands, and side walls in residual soils and its transitions to the sound gneiss, occurs. The transition is sharp and irregular. Similar conditions where encountered in previous sections of Rio de Janeiro Metro (Nieble et al, 1998; Mello et al, 1998; Mello et al, 2001, Bilfinger et al, 2001).

Figure 3 below presents a typical longitudinal section along the access tunnel.

The sedimentary sands are loose to medium dense, with and NSPT blow count between 5 and 20. Natural groundwater level is some 8m above tunnel crown.

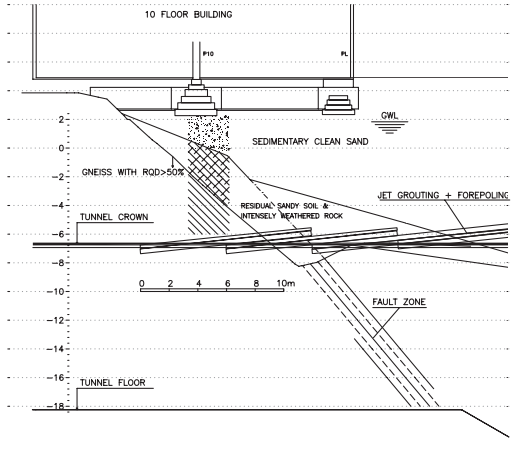

Figure 3. Geological cross section.

4 STRUCTURAL PROBLEMS – DESCRIPTION AND INTEPRETATION

Settlements, as mentioned, previously, were continuously monitored, including building no.6 of "Praça Eugênio Jardim". Settlements of some of the monitored columns started to increase with excavation still 15 m behind the buildings. Other columns showed no movements and, in some cases, slight heave. After visual inspections, severe cracking of walls and structural elements was detected (Photo 1). Calculated differential settlements were still only 1:480. Construction methodology was changed, reducing advance rates, but the settlements continued, with some columns not settling. Figure 4 presents the layout of the settlement gauges and Figure 5 the recorded settlements of these gauges.

Analysis of available data showed that the direct footings beneath some of the building rear columns

Photo 1. Cracks inside the building.

Figure 4. Plan view of building and settlement gauges location.

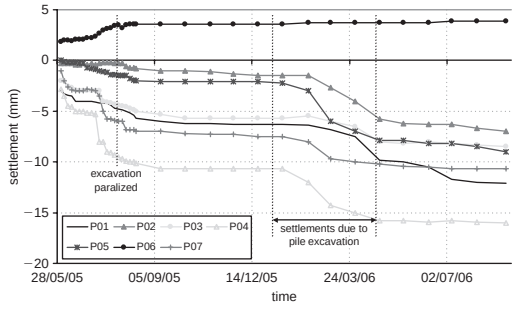

Figure 5. Building settlements.

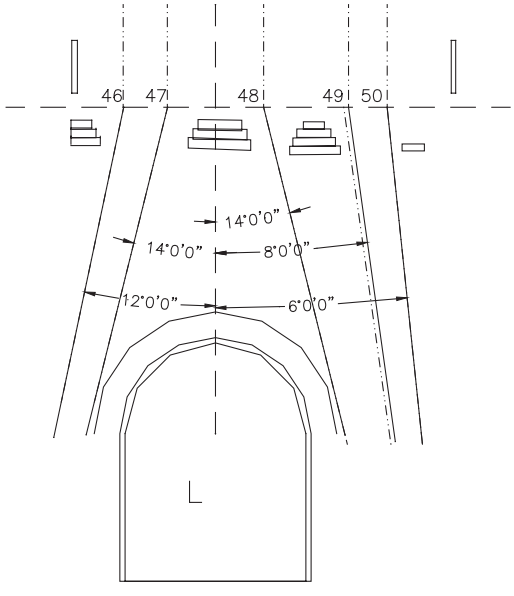

Figure 6. Schematic cross section of the access tunnel and the root piles.

were founded on residual soil or rock, the remaining footings being founded on the typical Copacabana sand.

Analysis of the structure showed that average bearing pressures applied by the footings on the subsoil was around 350 KPa. And in opposition to a standard foundation design, there were no structural cantilever beams to balance the eccentric load at the peripheral footings.

Structural damage seemed to be excessive, when compared to differential settlements; however, probably, the building settled, during construction and 60 years of use, suffering considerable distortions and, when the settlements increased slightly due to tunnel construction, the effects were significant.

Interpretation of cause of the settlements was that the vibrations due to the blasting caused compaction of the loose to medium sand and the footings resting on it. On the other side, the foundations on rock/residual soil, did not settle; instead, some of the footings showed slight heave, interpreted as being associated to high horizontal/sub horizontal in situ stress relief due to the excavation. Similar results (heave) where observed on other stretches along the line.

Evaluations by the designer and an independent consultant showed that the risk of severe structural damage due to additional settlements was high and should be avoided. Considering that the excavation was still not beneath the building itself, the only solution that could be considered safe was underpinning, with the use of root piles. Figure 6 shows a schematic cross section of the tunnel, the building and the root piles.

5 SOLUTION

The solution conceived consisted of 84 root piles and a 1.5 m thick concrete slab. The root piles were concentrated in the region were the original footings were founded on the sedimentary sands.

The root piles were founded in the sound rock, avoiding direct loading of tunnel crown. Additionally to the underpinning, horizontal jet grounting and forepoling with 63.5 mm dia. steel tubes were used to guarantee treatment of the interface between the rock, residual soils and sedimentary sands.

The existing footings were incorporated to the slab using pre-stressed Dywidag bars. Adequate concrete adherence was ensured along the 1.5 m length where piles crossed the slab.

This enabled creation of a monolithic behavior that was confirmed by checking differential settlements between slab and columns, during subsequential tunnel excavation.

6 PERFORMANCE

The building settled less than 1mm after the completion of the underpinning system and of tunnel conclusion.

During tunnel excavation it was noted that although the horizontal jet grouting system resulted in a moderately improved soil strength, it was not watertight, and therefore a risk of a progressive piping failure was high. Deep wells previously drilled from the building basement, and horizontal vacuum drains were activated in order to control groundwater pressure and mitigate this risk. Some minor settlement associated with groundwater lowering was induced to the neighbor buildings, however with no structural damage.

7 CONCLUDING REMARKS

The behaviour of the more than 60 year old building, suffering severe cracking with only limited settlements showed that the routine type of induced settlement analysis, where distortions are evaluated and compared to predetermined limit values, should be revisited. Previous settlements, not measured and technically documented, can reduce normally considered safety margins.

The underpinning solution showed adequate performance; after its construction, no additional significant settlements were measured and adverse behaviour detected.

Jet grouting soil treatment was not capable of creating an impervious barrier or reduction permeability significantly; this behaviour probably associated to the extremely variable rock-soil interface.

Prediction of subsidence during tunnel construction

K. Grossauer & R. Leitner
Institute for Rock Mechanics and Tunnelling Graz University of Technology, Austria

W. Schubert & P. Sellner
3G Gruppe Geotechnik Graz ZT Gmbh Graz, Austria

ABSTRACT: Stress redistribution, ground loss and change of groundwater table in the course of tunnel excavation cause surface settlements. These surface movements may cause damage to structures above and beside the tunnel. Experience shows that the timely and spatial influence of underground excavations on the surface settlements varies in a wide range. The domain of influence mainly depends on the ground structure and properties, the quality and quantity of the tunnel support as well as on tunnel dimension and the construction method. In some cases the surface movements are limited to some meters ahead and aside of the tunnel and stabilisation is reached within a few days after excavation. In other cases an extended surface area is influenced for a long period and the stabilisation process is slow. Accurate predictions of surface movements are difficult in the design phase. To enable a timely adjustment of the construction method an extensive observation program in the tunnel and on the surface is established in many cases, and warning and alarm criteria defined to ensure safety and serviceability. These levels and criteria of the observed properties should consider not only fixed values – such as maximum settlements – but account for the evolution of these parameters (i.e. settlement path or history). It is indispensable to consider the timely development of surface movements in all three dimensions over the time and as a function of the tunnels progress. Efficient and easy to use procedures to predict and check the surface movements are required to ensure a safe and economical construction. Numerical methods require a more or less time consuming input, calculation time and interpretation work, limiting their applicability for the day-to-day use.

An efficient way to predict displacements caused by tunnel excavation is to use analytical functions that describe the movements as a function of time and the face advance. A procedure based on analytical functions has been developed to support the prediction of the tunnel performance and surface movements. The tool can also be used to study the influence of variations of the tunnel progress and support on the surface movements. In this way the construction planning can be optimized in a way to minimize damage to surface structures. Two case histories from shallow tunnels in Austria are used in this paper to illustrate the application of the prediction tool.

1 INTRODUCTION

To prevent surface structures from (excessive) damage due to surface movements (subsidence) an extensive observation program in the tunnel and on the surface is established in many cases. The measurements describe the actual state of the system consisting of ground and support. The monitored values can be compared to values from the design allowing judging whether the system behaviour is in a "normal range" or in an "abnormal one" (see the design procedure described in ÖGG, 2001). Considering the time depending evolution of displacements and to ensure an adequate reaction time usually warning levels and alarm levels or criteria are defined, dependent on local requirements. Those levels are determined at a rather cautious level at the beginning of construction work and are updated with increasing knowledge of the system behaviour. Additionally, the observation of trends may be used as a criterion for "normal" or "abnormal" behaviour.

To ensure safe and economic tunnel projects a detailed description of the system behaviour and its "normal" range is indispensable and has to be defined during the design phase. For the judgment of the systems state and to check the efficiency of different measures routine predictions are required during the construction which describe the expected reactions of the ground to the excavation and support. These predictions are compared to the observed behaviour on a daily basis. Any deviation between prediction and observation must be related to either a wrong estimation of the geological model in combination with wrong or inaccurate material parameters and/or an inadequate prediction to the construction's response to the stress redistribution. In both cases measures have to be established in time to ensure safety and economy.

The definition, the prediction and the comparison of the system behaviour requires a calculation method which considers various inputs as ground properties, support properties and construction methods. This calculation method should also allow estimating the efficiency of additional measures or mitigation measures in time.

2 STATE OF THE ART & METHODS REQUIRED

During design the expected normal system behaviour is determined and various alarm levels and alarm criteria defined and continuously updated during construction, if required. The use of displacement monitoring data is quite effective for describing, predicting and controlling the system behaviour. Additionally other parameters like pore water pressures, lining stresses, ground stresses and so on can be monitored.

Practice has shown that sometimes the projects success is hampered by shortcomings in the definition, the prediction and the observation of the system's behaviour. A few points which have to be considered when dealing with surface settlements in tunnelling are listed below:

- Sometimes certain values are compared to a predefined fixed threshold instead of accounting for the evolution of the displacement. Especially when differential settlements of the surface areas (subsidence troughs across as well as along the tunnel axis) may damage or reduce the serviceability of an object, it is indispensable to consider the timely development of surface movements in all three dimensions over the time and as a function of the tunnels progress.
- During the construction the tools or techniques used for the prediction are time consuming and therefore costly. This may or will lead to a low frequency in the update of the prediction and consequently to a late identification of unacceptable displacement trends. Efficient and easy to use procedures to predict and check the surface movements are required to ensure a safe and economic construction.
- Current prediction techniques such as analytical solutions (see Park 2005, Chou & Bobet 2002) are limited in their prediction accuracy due to simplifications. Although an extended surface area is influenced for a long period and the stabilisation process is slow (Burland 2001), common analytical methods can only be used for estimating the maximum settlement trough perpendicular to the tunnel axis. In addition such methods do not consider relevant influencing factors, such as excavation rates and methods, different support types and ground conditions leading to inaccurate predictions. Certain counter measures (as additional bolting, installation of temporary top heading invert, etc.) can not be judged with regard to their efficiency. To be on the safe side the tunnel engineer has to overdesign the support accepting cost increase. Thus the prediction tools should account for the ground properties, the supports, and the excavation rate and method.
- The commonly pure empirical assessment of the system behaviour may lead to problems in the case of change of personnel on site. Former experience is difficult to communicate if no consistent rules are established. Thus such rules have to be developed, which describe the timely and spatial local development of certain values and allow predicting the system's state.

In the design phase mostly numerical simulations are used to predict subsidence. These time consuming simulations may consider influencing parameters as size of the structure, overburden, ground structure and quality, ground water conditions, excavation method, supports and progress rate. However, the knowledge of the parameters of the ground, the ground-support interaction, quality of construction, the influence of ground water disturbance etc. is limited during the design phase. In addition, numerical models contain simplifications and constraints regarding the material parameters and the difficult choice of an appropriate material law (see Kofler 2002, Potts & Zdravkovis 2001), which further decrease the accuracy of the prediction. Due to computational limitations surface and subsurface structures are rarely integrated in the numerical model and consequently the ground model needs to be updated during construction and the real behaviour controlled by monitoring. These drawbacks, as well as the effort required make numerical simulations unsuitable for a day-to-day updating of the geological-geotechnical model and its alarm levels. Quick, flexible and easy to use tools are required to continuously predict and control the system behaviour.

3 PROPOSED METHOD

An efficient way to predict the system behaviour of underground excavations is to use analytical functions, which describe the displacements as a function of time and the face advance (tunnel progress). The displacement behaviour of the rock mass and support basically is represented by function parameters. These parameters can be back-calculated from data of case histories. Using those function parameters the development of displacements of the tunnel wall and the ground surface can be predicted. Artificial intelligence methods (expert systems) interlink the function parameters and appropriate ground and support features. Special visualization techniques of the results allow an easy recognition of critical conditions. The tool can also be used to study the influence of variations of the tunnel

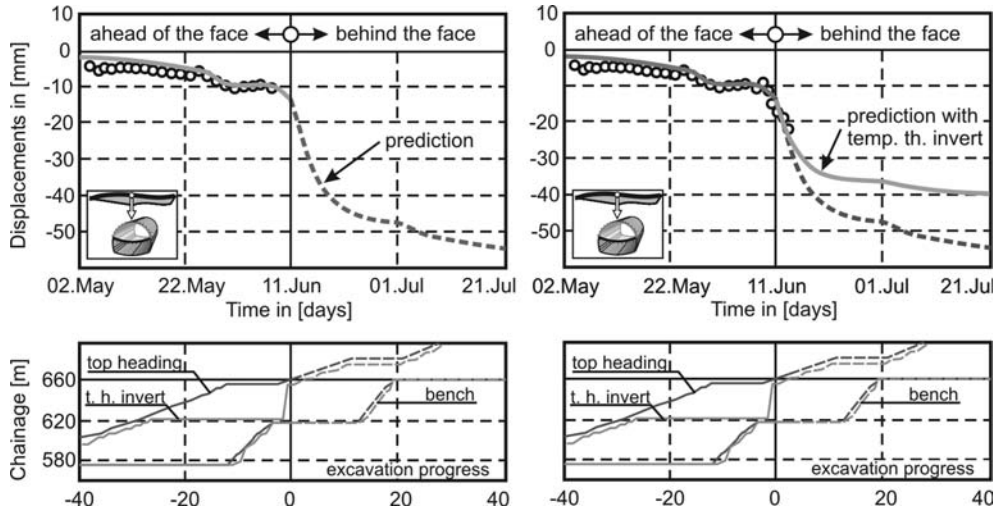

Figure 1. Time – displacement history plot for the surface point. Measured and predicted displacement history some days before (left side) and after (right side) the face passes the monitoring section 661.

progress rate and support type on the surface movements. In this way the construction planning can be optimized in a way to minimize damage to surface structures. The proposed method (GeoFit©) provides the following major advantages (Sellner, 2000):

- it predicts and simulates the evolution of displacements over time depending on the tunnel progress,
- it is an efficient, quick and easy to use procedure using graphical user interfaces and calculation takes a few seconds only,
- it considers relevant inputs, such as supports, excavation sequence and ground conditions,
- it allows to establish certain "rules" predicting critical system states in advance by considering both, the evolution of the function parameters and displacements over time or tunnel advance, and
- a continuous comparison of the monitoring results to warning levels is possible.

4 PRACTICAL APPLICATION

4.1 *Prediction technique and how to set counter measures*

The first example illustrates the technique for the subsidence prediction of points above a shallow tunnel which underpasses a freeway. The tunnel is situated in a tectonic melange and is excavated according to the NATM. The prediction technique proposed is demonstrated on the monitoring section 661.

Figure 1 shows the time – displacement history plot for the considered surface point in the upper axis system and the construction advance in the lower diagram. The zero reading was done approximately 110 m before the tunnel face passed the monitoring section on 11th of June. The circles in the displacement plots represent the monitored subsidence, which are used to back calculate the four function parameters X, T, C and m. The solid grey line shows the back calculation ("fitting") and the dashed line represents the predicted displacements according to the back calculated function parameters and a progress rate, which was extrapolated for the next few days.

In this case, the subsidence prediction for this monitoring section is done three days before the tunnel face reaches this section (see left side of Figure 1). It can be seen, that the settlements will reach a maximum value of about 60 mm. The accuracy and reliability of the prediction can be checked by looking on the development of the function parameters along the alignment.

Figure 2 (left side) shows the back calculated function parameters for the system behaviour which should show a reasonably "smooth" trend as they are correlated to certain geological-geotechnical properties of the ground (Grossauer, Schubert & Kim, 2002; Schubert, Button, Sellner & Solak, 2003). Abrupt changes in magnitude are most unlikely except there are abrupt changes of ground conditions. In this case the back calculated function parameters follow a rather consistent trend which increases the prediction's accuracy and reliability. If changing rock mass conditions are expected, the parameters can be modified accordingly. Methods for short term prediction of rock mass conditions are described by Steindorfer (1998) and Sellner & Steindorfer (2000).

If expected displacements exceed the acceptable range additional measures can be set in time. The

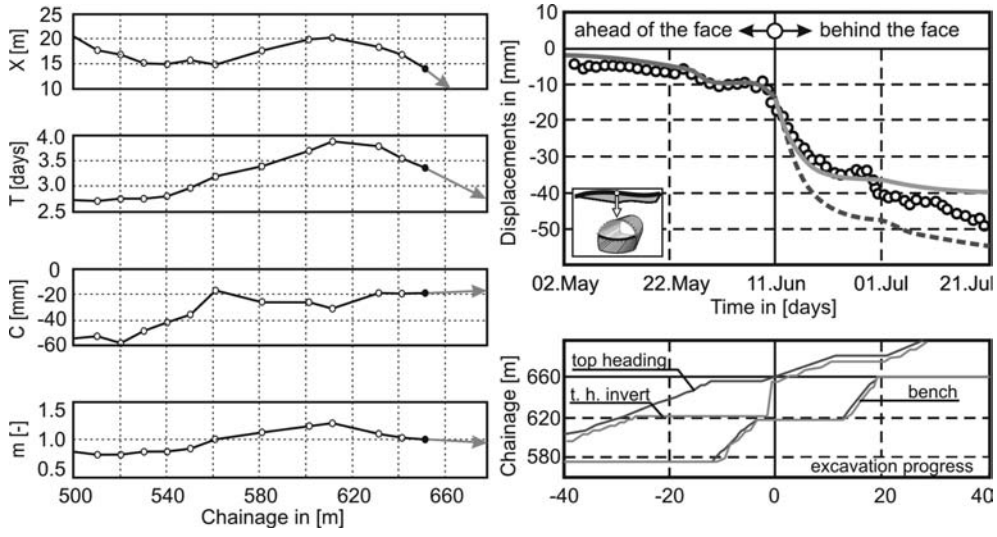

Figure 2. Trend of the function parameters X, T, C and m along the tunnel axis (left side) and the comparison of predicted and observed subsidence (right side) for monitoring section 661.

efficiency of such counter measures is shown in figure 1 (right side). The grey solid line shows the expected settlements considering that a temporary top heading invert is installed. The final displacement on the surface will be reduced by approximately 20 mm.

The right side of figure 2 shows a comparison of the finally observed and the predicted surface settlements due to top heading excavation. The prediction fits the monitoring with a high degree of accuracy until the 28th of June. On this day the bench excavation reaches the monitoring section resulting in additional displacements. For this excavation step an analogous prediction can be performed but is not shown here.

4.2 *Early detection of problem areas*

The next example shall demonstrate the potential of detecting critical situations in time and check the effectiveness of mitigation measures. The example is derived from a tunnel at shallow depth in very poor ground conditions. An intense observation program was conducted. The left part of figure 3 shows the observed subsidence (circles) and predicted (solid line) subsidence of a single observation point on the surface. The right part of figure 3 shows the outline of surface structures and the tunnel alignment. The dark dots represent the monitoring points on the surface. When the tunnel face has reached chainage 785 m a displacement prediction is performed (shown here as contour plot) which represents the surface settlements when the face will be located at chainage 825 m. The dark area ahead of the tunnel indicates settlements exceeding the defined alarm level.

To meet displacement restrictions, countermeasures have to be taken. In this case a temporary top heading invert is installed and the bolt density increased. The efficiency of these measures is predicted and shown in figure 4. The left part shows the settlement of the surface point in case of installing the temporary top heading invert and intensifying bolting (solid line). For comparison the settlements without additional measures are shown too (dashed line). Due to the installation of the top heading invert and the denser bolting pattern the settlements are significantly reduced and the defined alarm level will not be exceeded.

The prediction of subsidence can be performed for any time or chainage and visualized with movies, contributing to detect critical areas in advance. A better understanding of the timely and spatial influence of the construction on the subsidence can be archived.

The visualisation as plan view or three dimensional surface plots is of significant importance when dealing with surface inclinations. A two dimensional evaluation of observations along a monitoring sections will not show the total inclination but the projection of the inclination which is of lower quantity.

5 CONCLUSION

Considering subsidence, two main features can be found. Firstly, they can be measured and observed long before the tunnel passes the domain of interest. Secondly, they may cause damage on surface structures due to a variety of settlements, movements,

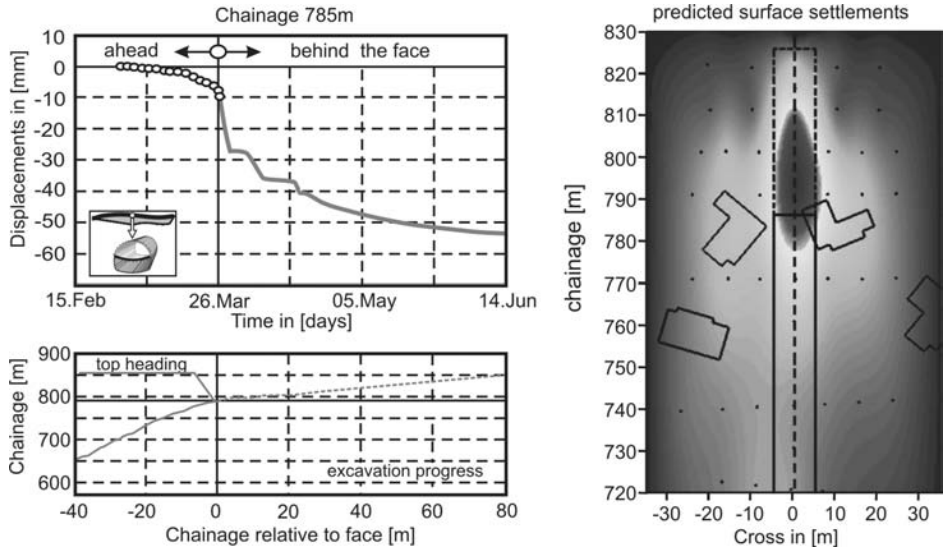

Figure 3. Left side: Settlement prediction for a single point on the surface; right side: outline of surface structures, tunnel alignment and contour plots of predicted subsidence without additional measures.

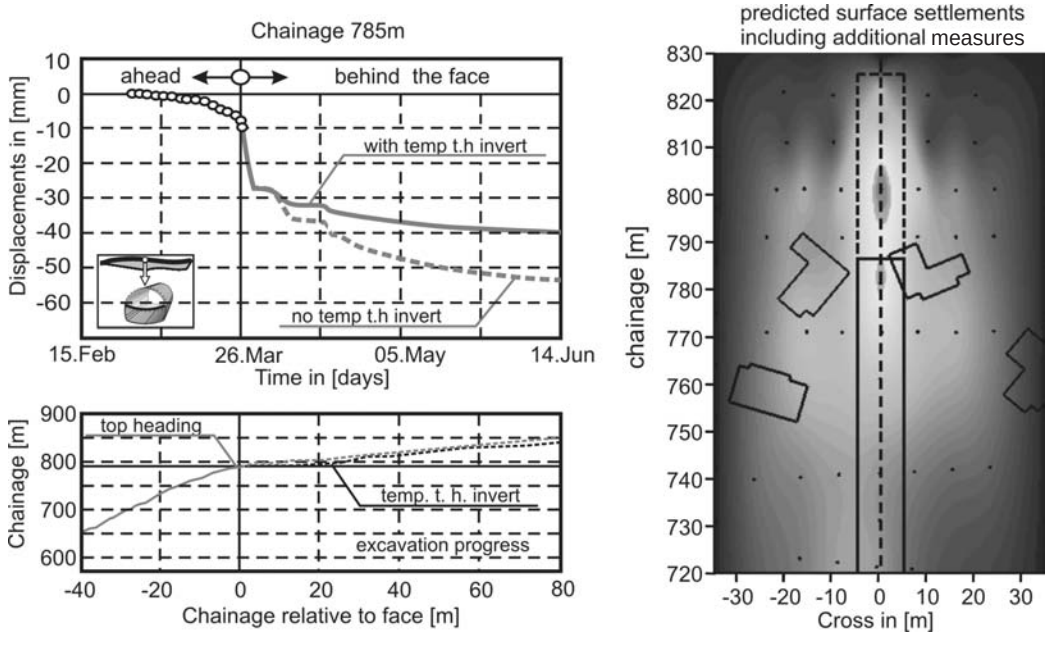

Figure 4. Left side: Settlement prediction for a single point on the surface; right side: outline of surface structures, tunnel alignment and contour plots of predicted subsidence considering additional measures.

rotations, and deflections. This requires that the engineers permanently control the settlement trough above an advancing tunnel and its compatibility to surface structures. The degree of damage is reduced by predicting displacements and establishing measures to reduce or compensate them. As a matter of fact, pre-displacements can be observed and used to back calculate the displacement behaviour of the ground in an early stage resulting in a better understanding of the ground's reaction to tunnelling and thus in a better

quality of the subsidence prediction for any stage of the tunnel project.

The proposed method provides tools for back calculation and prediction of subsidence and supports the tunnel engineer in his daily work. A permanent comparison of predicted "normal behaviour" and observed "real behaviour" allows to detect critical domains in time and to set counter measures. The efficiency of the planned counter measures can be checked "virtually" before implementation.

The decision making process regarding support and construction method can be supported with this method. The basis of the predictions – the function parameters and the resulting definition of the system behaviour – is stored and thus reproducible. This storage of decisions represents a specific knowledge, a correlation of geological, geotechnical and construction parameters, which can be used for further sections and projects.

Monitoring of ground massif using TR-GEO georadars while drifting tunnels

S.V. Izyumov
Geological Prospecting Co., Ltd, Moscow, Russia

I.I. Goltsman
MosInzStroi, Moscow, Russia

ABSTRACT: Geological Prospecting Co., Ltd has gained for nearly a decade a lot of experience in practical application of TR-GEO georadars on construction sites in Moscow. TR-GEO georadars are designed for remote sounding of grounds and other structures with low and moderate absorption of electromagnetic waves: hard rocks, wet sandy grounds and sandy loams as well as low wet clay loams. Various areas of practical application of TR-GEO georadars as well as results of monitoring are discussed in this paper.

1 INTRODUCTION

Geological Prospecting Co., Ltd has been involved with development and application of TR-GEO georadars for nearly a decade. This article gives examples of practical applications of TR-GEO georadars as well as short description of their design and software used.

2 SHORT DESCRIPTION OF TR-GEO GEORADARS

2.1 *Principle of operation and field of application*

TR-GEO georadars are designed for remote sounding of grounds and other structures with low and moderate absorption of electromagnetic waves: hard rocks, wet sandy grounds and sandy loams as well as low wet clay loams. They are able to detect local irregularities (metallic and dielectric ones) as well as boundaries of ground layers differing from each other in electrical parameters. The performance of georadars is based on radiation of video pulse having wide spectrum and recording of video pulses being reflected from irregularities. The results of processing of those signals make it possible to make an image of reflecting boundaries of irregularities of structure under sounding presented as three-dimensional one or as vertical cross-sections. The georadars in use differ in range of operating frequencies, dimensions of antennas, resolution and depth of sounding. Performance data for TR-GEO georadars are given in Table 1.

TR-GEO-01 and TR-GEO-02 georadars are designed for imaging of geological cross-sections, for detection of karst cavities, decompaction zones in ground, boundaries of lenses, floating earth, alluvial sediments, local objects – metallic or dielectric ones (big boulders) of no less than 0.3–0.5 m in size as well as for location of cables and pipes.

Table 1. Essential characteristic of TR-GEO georadars.

Georadar	Dimensions of antenna (cm)	Average frequency (MHz)	Maximum depth* (m)
TR-GEO-D	$100 \times 90 \times 20$	20–30	30
TR-GEO-D	$55 \times 55 \times 13$	120–150	15–20
TR-GEO-01	$40 \times 40 \times 7$ $41 \times 33 \times 5$	150–200	10
TR-GEO-02	$25 \times 25 \times 5$ $30 \times 20 \times 5$	150–250	5–7
TR-GEO-03	$12 \times 12 \times 3$ $8 \times 8 \times 3$	~1000 ~1500	1

*The depth of sounding is given for sandy ground with moderate moisture content.

Figure 1 shows the most recent model of TR-GEO-01 georadar. TR-GEO-03 georadar is designed for detecting faults in building constructions, voids, cables, pipes, local objects of no less than 0.05 cm in size as well as for measuring the depth of pavement layers.

The signals are recorded by antenna unit moving over surface under sounding. A small gap (1–5 cm) between antennas and surface is allowable during moving. The best results are achieved with close contact between antennas and ground and with even surface

Figure 1. TR-GEO-01 georadar.

of ground. The antenna unit moves usually along several parallel profiles. When counting the coordinates one can use distometer. The distance between adjacent profiles depends on how close the supposed object under sounding is placed and makes up to 0.2–1 m. To achieve the more accurate locating of object the range of moving area of antenna unit over surface should be approximately twice as large as the depth of object under sounding.

TR-GEO georadars are equipped with slot antennas. This provides for a large "front to back" ratio, i.e. low level of parasitic reflections from objects placed in air half-space. This feature is of special value when foreign objects are available, when operating radar in close vicinity to walls of buildings as well as in conditions of strong electromagnetic interference. If necessary the antennas are additionally screened by blocks of resistive material.

2.2 *Methods of processing of signals*

Radar Program is used for recording and processing of signals. Signal processing consists of preliminary processing, deconvolution algorithms, three algorithms of three-dimensional focusing and algorithms of three-dimensional visualization.

The preliminary processing includes detection of directly between the antennas passing signal and deduction of that signal from all recorded signals. The preliminary processing includes also subtraction of low-frequency component which remains as a result of non-complete deduction of slowly attenuating exponential of directly passing signal. If required also "noise" which as a rule originates from multiple signal reflections becomes subject to zonal filtration. Such a "noise" appears in particular when sounding over surface of reinforced concrete constructions. The elimination of occasional thermal noise as well as of electromagnetic interference is achieved through accumulation and multiple averaging of signals. The numerical value of accumulation of measured data in each point of time base is given as a function which is in increase towards the end of time base and which ensures the required "signal – noise" ratio over all radar time base. This function takes into account exponential attenuation of reflected signals in ground. The averaging of signals is also effected as the georadar slowly moves along the profile within short distances defined by distometer.

The result of preliminary processing represents the sum of signals reflected from objects. Every signal of this type reflected from local object or from dividing line appears as attenuating oscillating signal consisting of several (3–5) half-periods. The algorithms of deconvolution make the transformation of those reflected signals into signals which consist of one half-period, or those algorithms specify moments of appearance and amplitude of reflected signals. Radar Program uses following deconvolution methods: method of inverse filtration, method of least squares with regularization method developed by A.N. Tikhonov. Also correlation and autocorrelation methods were investigated. The autocorrelation method provides for searching for similar reflected signals in adjacent positions of the antenna unit.

3 RESULTS OF MONITORING OF GROUND MASSIF USING TR-GEO GEORADARS

Geological Prospecting Co., Ltd has gained for nearly a decade a lot of experience in practical application of TR-GEO georadars on construction sites in Moscow. We consider various areas of practical application of georadars as well as results obtained using TR-GEO georadars. Following are results of preliminary processing presented as vertical wave profiles.

3.1 *Monitoring of ground mass when drifting tunnels*

The sounding ahead of tunneling machine is necessary due to risk of hitting and destroying underground utilities which were mismarked or unmarked on geological cross-sections. Furthermore available geological cross-sections of ground do not often correspond with actual geological mass. This is due to impossibility of drilling appraisal wells in conditions of dense urban building. Lenses, buried channels and alluvial cuttings can be smaller in size than the distance between wells.

Monitoring of ground ahead of face of collectors under construction allowed for timely detection of several objects including five metallic water mains pipes, two gas mains pipes, one ceramic collector, one high-voltage cable, five buried appraisal wells, two large water-filled karst cavities with volume of 150 m^3 as

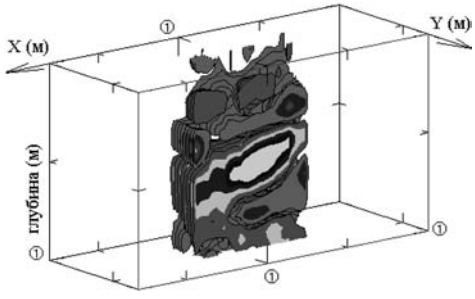

Figure 2. Results of sounding of five shells of 152 mm caliber in clayer ground.

well as of a great number of large in size boulders. Twenty nine shells of 152 mm caliber with length of about 50 cm, which have been remained in ground since World War Two, were detected. Figure 2 shows results of sounding on the spot of mass burial of those shells. Five shells were placed closely to each other at distance of about 0.5 m from tunnel face.

3.2 *Sounding from surface to check geological cross-sections*

This type of sounding is necessary when drifting tunnels and other shallow utilities in particular when using micro-tunnelling method. The results of georadar sounding are used in combination with data on well prospecting in order to image or check geological cross-sections between geological appraisal wells.

3.3 *Sounding of rocky ground*

The sounding in galleries and transport tunnels being under construction in rocky grounds seeks detection of fractures and faults in rocky mass. Figure 3 shows the process of sounding in engineering gallery of transport tunnel while Figure 4 shows one of sounding results. As a result of sounding fractures at distances of up to 3–4 m were revealed (shown by arrows).

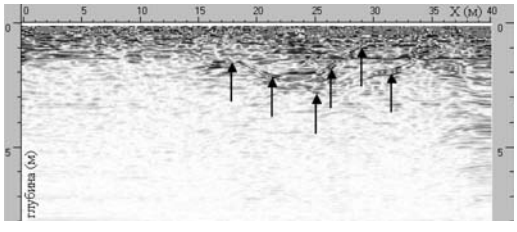
3.4 *Sounding of urban underground utilities*

When laying new pipes or cables or proceeding with repair works of old mains it is necessary to know the exact disposition of all underground utilities and their expansions which are available at particular place. It often occurs that old underground utilities are unmarked on geological maps. It can lead to failures or breakdowns of tools when laying new mains.

3.5 *Sounding on construction sites*

In this case the sounding seeks surveying of geological subbasis as well as search for karst cavities and buried cellars on future construction sites. Let us give

Figure 3. Sounding of engineering gallery of transport tunnel using TR-GEO-02 georadar.



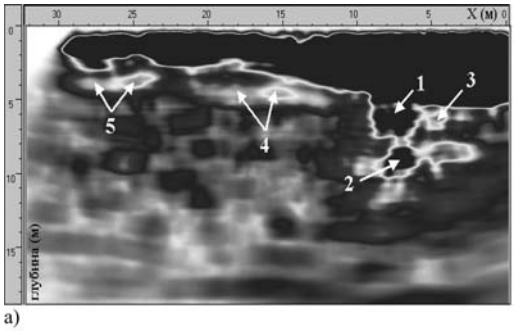


Figure 4. Results of sounding of fractures in rocky ground using TR-GEO-02 georadar.

an example of sounding which resulted in detecting of buried cellar on the spot of intended foundation pit. Figure 5a shows results of sounding after making focusing. Figure 5b shows photo depicting the wall of excavated foundation pit on site under sounding. The irregularities in the resultant picture correspond with dug-up reinforced concrete constructions. Always use the Figure caption style tag (10 points size on 11 points line space). Place the caption underneath the figure (see Section 5). Type as follows: 'Figure 1. Caption.' Leave about two lines of space between the figure caption and the text of the paper.

3.6 *Application of georadars when laying underground utilities using micro-tunnelling method or further trenchless technologies*

This type of sounding seeks searching for industrial and natural inclusions (large boulders) as well as checking of location of underground utilities. The detection of those objects allows for correct engineering of a run and for avoiding failures when proceeding with micro-tunnelling.

Ground surveying is necessary to be carried out upon completion of construction works because when drifting using micro-tunnelling machine voids and decompaction zones in ground are sometimes formed. Sounding of one of collectors using TR-GEO radars which carried out by Geological Prospecting Co., Ltd upon construction completion has revealed those decompaction zones what was verified by following checking.

a)

b)

Figure 5. Results of sounding after making focusing (a) and wall of foundation pit which has been dug out on the spot of sounding (b).

3.7 *Sounding of mine tunnel walls when proceeding with monolith pressed concrete lining*

The sounding using high-frequency radars (with average frequency of 1 (GHz) makes it possible to detect potential faults in lining as well as to control the thickness of concrete walls of tunnels. The sounding using radars with lower average frequency seeks detection of karst cavities and wet zones in the immediate vicinity to mine tunnel. The sounding using radars with lower average frequency seeks detection of karst cavities and wet zones in the immediate vicinity to mine tunnel.

4 CONCLUSIONS

The results of practical activities carried out by Geological Prospecting Co., Ltd demonstrated that it is strongly necessary for ground condition to be controlled using TR-GEO georadars and that TR-GEO georadars are appropriate to successfully solve this task.

Application of tunnel information system for construction supported by international cooperation

C.Y. Kim, K.Y. Kim, Y.Z. Lee, S.W. Hong, S.H. Baek, & K.W. Seo
Geotechnical Engineering Research Dept., Korea Institute of Construction Technology, Korea

Wulf Schubert
Institute of Rock Mechanics and Tunnelling, Graz University of Technology, Austria

Y.S. Seo
Department of Earth and Environmental Science, Chungbuk National University, Korea

ABSTRACT: The system (ITIS, Intelligent Tunnel Information System) which can manage and analyze the tunnel information in design and construction stage has been developed through several years' research. This system is being modified and improved for the international sharing of tunnel construction information. Since each country has each management system for tunnel construction information, the new system should allow the different forms of information. In this research, Austrian system (DEST, Data Evaluation System for Tunneling) is adopted for the international cooperation with Korea. The system under development (ITCISS, International Tunnel Construction Information Sharing System) is operated in web-based environment. Therefore, it is possible that the tunnel construction information can be shared and cross-reviewed internationally by use of ITCISS.

1 INTRODUCTION

Recently, tunnels with length over 10 km are constructed increasingly all over the world including Europe and Asia. In Korea, various tunnels are planned to be constructed for express way, subway, railway and utility. However, tunneling cost in Korea is relatively higher than in Europe, thus current problems of tunnel construction in Korea should be investigated. Sufficient investigation and analysis of European tunnel construction information is also required for the precise comparison. Tunnel construction information (monitoring, face mapping, construction history etc.) and its practical use on site should be examined carefully for the establishment of the sharing system because the philosophy of tunnel design and construction could be different between countries.

In this research, core components of tunnel construction information are determined by analyzing various management systems of tunnel construction information and the standard relational database model is established for international tunnel construction information sharing system (ITCISS). Also, internet-based ITCISS is developed to share tunnel information during construction between Austria and Korea for the initial development. In addition, ITCISS is designed in consideration for extension of this system and connection with other countries.

2 TUNNEL INFORMATION SYSTEM

2.1 *Requirements of database system*

The data stored in the system would be provided from many construction sites of different countries, which have not only conventional and compatible type of information but also their unique type of information characterized by their own construction method, construction condition, geological environment and so on.

The requirements of database system for the storage and manipulation are:

- That the data would be stored in a commercially and practically acceptable database standard, enabling future access and migration.
- That the data could be protected against unauthorized access, and was secure during use from accidental or deliberate corruption.
- That the data could be accessed as soon as it becomes available at any location.
- That manipulation and display of the data would need no special knowledge and should be intuitive for the user.
- That creation of data by the contractor should be simple and consistent, using commonly available software and transmission techniques.

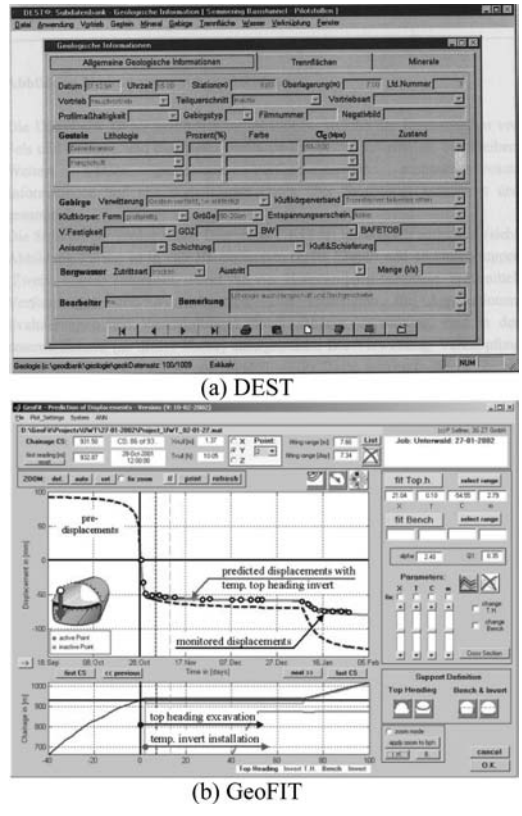

Figure 2. DEST & GeoFIT GUI feature.

2.2 *Existing system*

ITIS (Intelligent Tunnel Information System) had been developed by Korean Institute of Construction Technology (KICT) for the purpose of integrated D/B management, analysis and visualization system for geotechnical projects especially tunnel construction in Korea (Hong et al. 2002, see figure 1) ITIS is being modified to make up integrated tunnel construction information system both in domestic and foreign countries.

For tunnel information system shared between different countries, several important constraints such as database structure, system architecture, environment and infrastructure of operation should be considered. The first counterpart country is decided to be Austria because New Austrian Tunnelling Method (NATM) is applied commonly in Korea.

DEST (Data Evaluation System for Tunnelling) is an in-house database system developed by Institute for Engineering Geology and Applied Mineralogy of Graz University of Technology. Geofit is an in-house software developed by Institute for Rock Mechanics and Tunnelling of Graz University of Technology for the interpretation of geodetic monitoring data (see figure 2).

3 INTELLIGENT TUNNEL INFORMATION SYSTEM (ITIS)

3.1 *System outline*

Arriving at the correct design for the information system before embarking on its development is very important. Site investigation, tunnel design and construction data are generally existed in forms of manually completed documents, project reports, regional geotechnical maps and geotechnical relational database, etc. And the analysis of these data that located against some form of map or plan is generally two dimensions. ITIS is an integrated D/B management, analysis and visualization system for geotechnical projects especially in tunneling. It is a true client-web server database system. The client-web server model for distributed computing allows multiple client PCs to request data from a single server PC on which resides a database and the software for servicing client requests. The structure of ITIS is shown in figure 3.

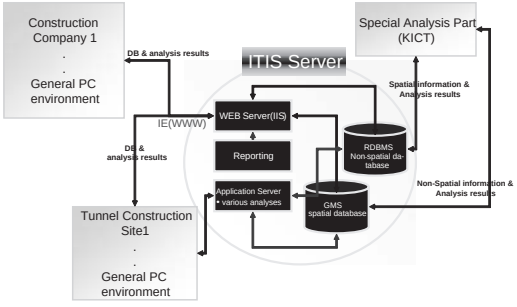

Figure 3. System structure of ITIS.

3.2 *Visualization of the information*

In ITIS system, the techniques of 3-D visualization and VR are used to visualize a complicated geotechnical structures in the 3-D space and many kinds of analysis and investigated data in tunneling. Because tunnel construction is performed under 3-D space with complex discontinuities such as fault, joint and bedding, 2-D drawing design is difficult to figure out, so 3-D graphic technique is necessary to utilize and give out information rapidly and efficiently. Besides, VR technique can make users control all the movements and actions not by programmers but by his willing. That is, users can enter into VR space, experience the defined world, and interact each other by their eyes, ears and hands. Thus, it is one of the substitutive recommendations to apply VR technique to visualization of geotechnical information in order to make users comprehend it easily. All useful information acquired from 3-D graphic technique and site investigation can be used to simulate many possible and critical circumstances that may be faced or experienced during construction. In addition, VR is helpful to choose the appropriate construction procedures(see figure 4).

4 ITCISS (INTERNATIONAL TUNNEL CONSTRUCTION INFORMATION SHARING SYSTEM)

In this research, two different systems (ITIS (Korea) & DEST (Austria)) are to be integrated for sharing system of tunnel construction information. Numerous experience and construction information are stored in each system, so that ITCISS can be a very meaningful tool in the light of combining them with powerful analysis modules in one system. For this purpose, all the data should be produced under consistent quality control and the various types of data (figures, pictures or qualitative description) should be digitized and managed in an appropriate system.

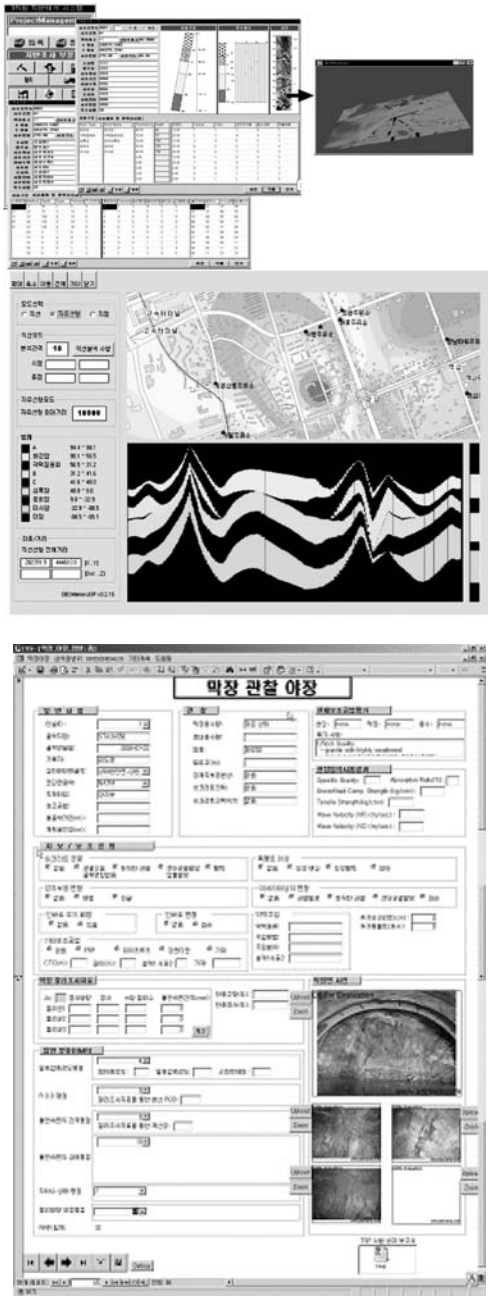

Figure 4. Visualization of the information in ITIS.

Table 1 shows the differences of ITIS and DEST. To combine the database systems and access in each country, linkage between ITIS and DEST was developed as shown in figure 5.

Table 1. Comparison of ITIS and DEST.

Item	ITIS	DEST
System architecture	On-line Networking RDBMS	Stand-alone General DBMS (non relational)
Principal functions	GIS-application (Visualization/Various stability analysis modules included)	Powerful analysis for monitoring (with GeoFIT module)
DB items	Non changeable DB schema (Unified database)	Changeable DB schema by user (Site-specific database)

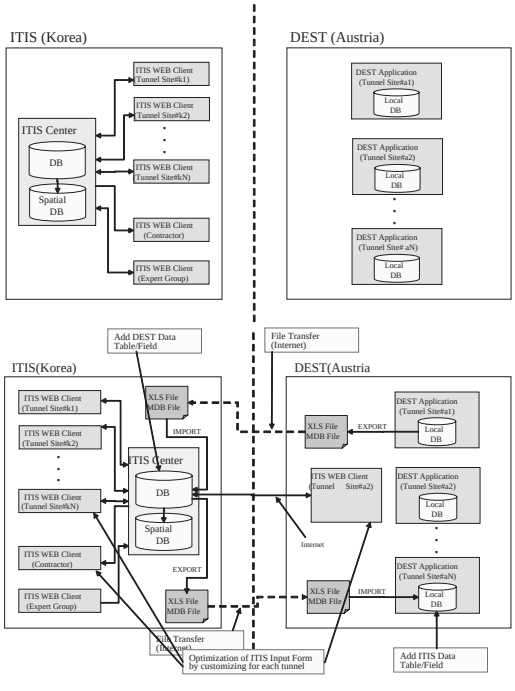

Figure 5. Linkage between ITIS and DEST in ITCISS.

5 CONCLUSIONS

This paper introduced improved way of utilizing tunnel construction information as a model system sharing international tunnel construction information. Advanced system to share tunnel construction information between countries can be meaningful not only in accumulation of various experience and data but also in cooperation of on-line support for decision making on site.

Several topics are being researched, related with database system. For instance, the database system of construction information will be used for the research of the expert system for tunneling, prediction of tunnel displacement or risk Assessment of excavation. The application of this database system will be enhanced more and more in the future and the cooperation with related countries will produce a fruitful result.

ABSTRACT: The aim of this paper is to present information about results of measurement of the influence of underground water level back rise on secondary lining of large tunnels and on the surface development. Measurement results and related conclusions provide investors with sufficient information in order to enable them decide about the timing of repairs of the surface development damaged by tunnelling.

1 INTRODUCTION

The results concern two tunnel structures in Prague which were commissioned in 2004. These were: Mrázovka road tunnel with the cross-section of 165 square meters and Kobylisy one bay driven underground station on line IV-C with the cross-section of 220 square meters.

As both structures are located in densely built-up municipal areas, extensive surveying took place both under ground and on the surface and it continued even after commissioning of both structures. This was not usual with other structures.

Both tunnels were constructed using similar technology – New Austrian Tunnelling Method and their complete perimeter was provided with pressure insulation. After the construction is completed, the underground water level rises back to its original level, loads the tunnel structure, and influences also the surface.

As both tunnel structures are located in different geological conditions, results of measurement of their impact on the surface differ considerably.

First measurement results on Mrázovka tunnel were published during the 28th ITA International Congress in Sydney in 2002. Other measurements Since 2002, when insulations and secondary tunnel lining were completed, and after the commissioning of the tunnels, additional measurements were carried out. These measurement have given some interesting and surprising results.

Due to the scope of this paper, we are only able to provide elementary information relating to the topic hereof. List of literature at the end of this paper provides more details about publications containing details about the monitoring and construction issues.

2 MRÁZOVKA TUNNEL

2.1 *Basic data*

Mrázovka road tunnel consists of two three-lane tubes which further fork into two-lane and single-lane tubes in driven tunnel forking. The tunnel is one kilometer long.

The most difficult part of tunnel construction was the passage under Ostrovského street where five-storey apartment houses are located (Figure 1).

The bedrock in this area consists of silty-clayey shales. The total thickness of overlaying formations above the tunnel vault was 9.0 meters. From that, 3.5 meters consisting of weathered shales and 5.5 meters consisting of partly weathered shales. The eastern tunnel tube also intersected with quartzites. Surface layers consist of made-up ground and deluvial gravel and sand deposits. The total overburden height is 16.0 meters. Distance between the tunnel profile vault and the foundations of the buildings was as short as 12.0 meters. Remedial grouting was carried out from the exploratory tunnel with the aim of improving the overburden quality. Compensation grouting was carried out under three buildings during the western tunnel tube construction.

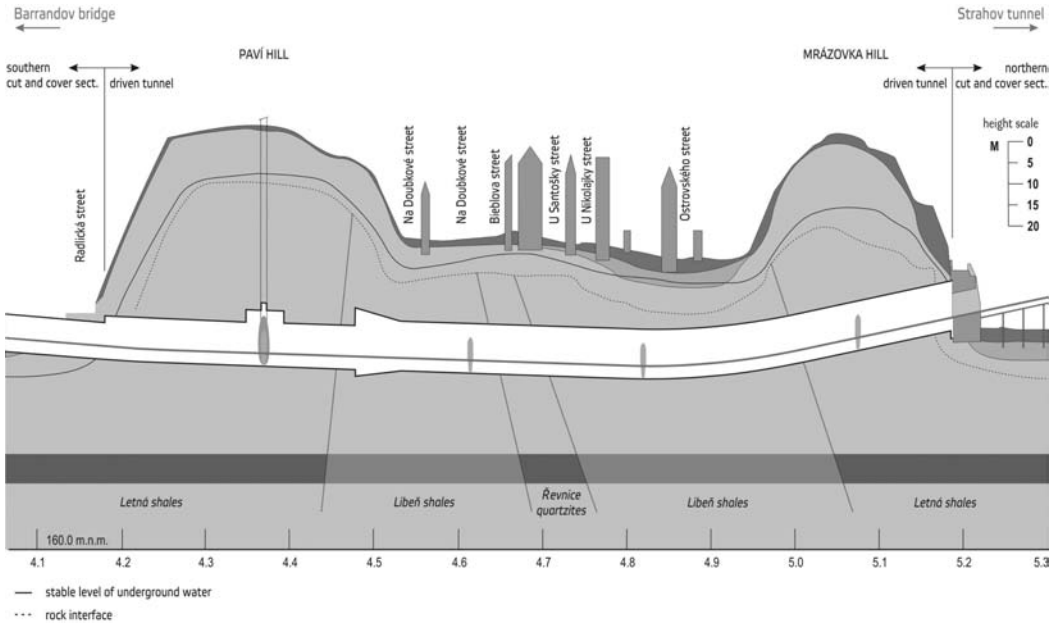

Figure 1. Longitudinal section of Mrázovka tunnel.

2.2 *Consequences of the underground water rise in Ostrovského street*

Significant oscillation of the underground water level both in the capping mass and in the bedrock occurred during tunnels construction. The soil mechanics theory and subsidence calculations show that surplus loading and resulting compression occur in emerged soils (strata in which the underground water level drops). These deformations subsequently propagate to the surface and various effects causing terrain deformations and subsidence of buildings on the surface thus sum up (tunnel driving, underground water level decrease, sealing and compensation grouting).

- exploratory tunnel construction in the western tunnel tube (Figure 2) .....20 mm (from that the calculated effect of the underground water decrease by 14 meters stands for 10 mm)
- gradual driving of the western and eastern tunnel tubes.....45 through to 51 mm (causing additional decrease of the underground water level by 8 meters with unidentified contribution to the overall deformation. Expert estimates indicate between 5 and 10 mm).

The total deformations on the surface ranged between 65 and 71 mm (Figure 3).

It is therefore possible to state that the impact of the underground water level decrease after the overall underground water level decrease by 22 meters, construction of the tunnels, and after completion of primary lining in both tunnels represented the terrain subsidence by approximately 15–20 mm. After the full insulation of both tunnel tubes was completed and after the secondary lining was constructed, the underground water rose back to the original level which was registered before commencement with tunnel construction. Monitoring has indicated terrain rise by 5 mm and rise of the buildings by 8–12 mm. Reasons for this can be seen firstly in relieving the ground layers re-saturated with water and secondly in the great static lift force of approximately 1.6 MN per meter of each tunnel tube (Archimedes' principle).

Theoretical analysis would be a speculation because the soil does not behave as an elastic material and changes of the deformation modulus depend on stress condition of the ground. Undoubtedly, there have also been at least partial degradation of the ground environment in the tunnel overburden.

Reverse deformations of the buildings in Ostrovského street represented approximately 50% of the values caused by the underground water level decrease.

Such a great rise of 8–12 mm was not expected and some previously reconstructed structured had to be repaired again. Owners of the buildings insisted on immediate repairs right after completion of tunnels driving while the reverse deformations occurred some 18 months later due to the time required for construction of complicated secondary lining in the tunnels.

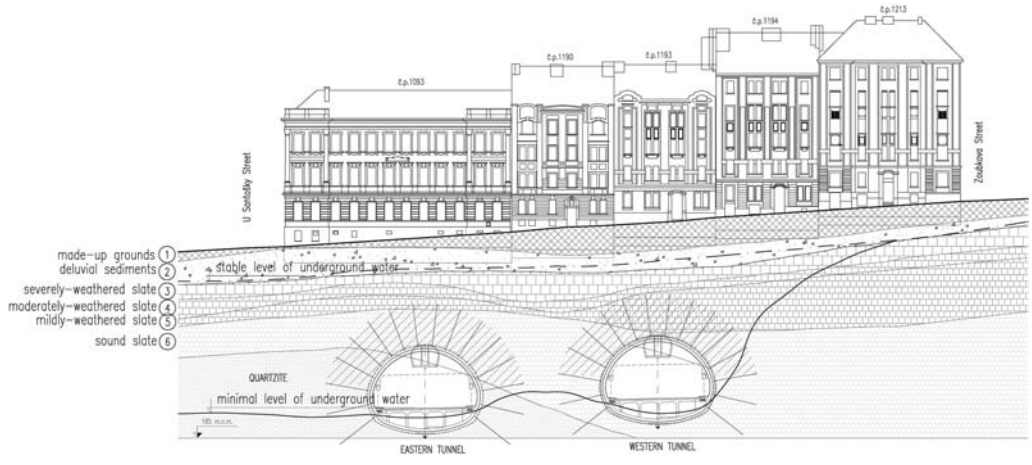

Figure 2. Cross-section in Ostrovského street.

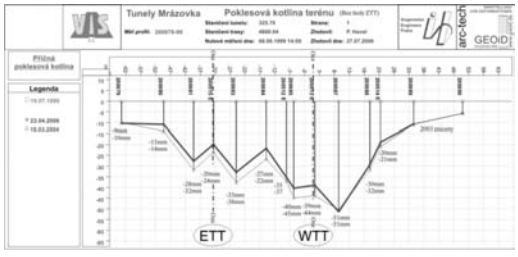

Figure 3. Subsidence though in Ostrovského street.

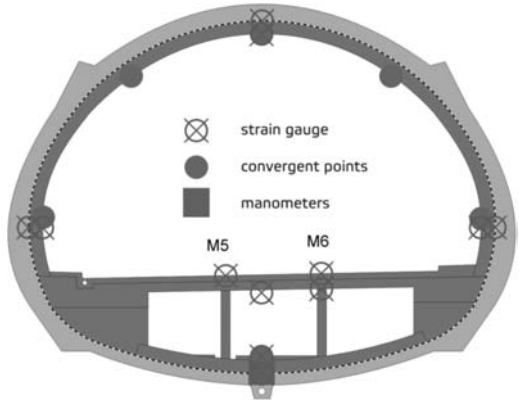

Figure 4. Measuring points placement in the tunnel.

2.3 *Impact of underground water rise to the tunnel structure*

The impact of the underground water level back rise has been documented firstly by the movement of the metering points installed on the secondary lining of the tunnels (Figures 4, 6), and secondly by changes of stress in the deck, which forms part of the secondary lining structure (Figure 5).

From the time perspective, the following essential terms have to be mentioned:

- completion of driving and primary lining execution (underground water decrease by 22 meters) in 06. 2002
- secondary lining construction in both tunnels in 06. 2003
- packing of the tunnels and closing of pumping pits, underground water level rise in 06. 2004
- commissioning of the tunnels 26.8. 2004
- back rise of the underground water level to the original level recorded before commencement with construction in 04. 2005.

2.4 *Stress in the deck*

When designing the cross-section of the three-lane Mrázovka tunnels, a non-standard solution of the lower parts of the secondary lining has been adopted. The deck structure supporting the road is used as a strutting bar in the lining structure (Figure 4). This eliminated the necessity of strengthening the bottom of the tunnel and increasing its profile.

The structural design of the deck has respected the requirement on observing the maximum crack width in order to ensure the corrosion protection of the reinforcement.

Stress of the deck reinforcement was measured during the monitoring and results of this measurement are documented on Figure 5 .

During the first phase (June, 2003–November, 2003) when the underground water level was low, the

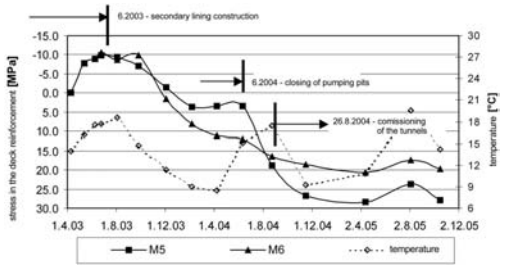

Figure 5. Stress in the deck reinforcement.

Figure 6. Secondary lining deformations.

deck acted as a compression brace. Once the insulation was closed and the underground water level rose, the compressive stress changed into tensile stress during December, 2003 and since then the deck acted as a tendon with reinforcement tension values between 20 and 28 MPa. The increase of the values which took place before April, 2005, corresponds to the underground water rise back to the original level.

2.5 *Secondary lining deformations*

Hydrostatic pressure represents dominant part of the overall loading of the secondary lining. Movement of six points in a number of diameters along the tunnel length and stress inside the lining were measured within the framework of the monitoring (this is described in a separate article).

Resulting movement of metering points in the secondary lining in the three-lane tunnel under Ostrovského street are documented in Figure 6 (vector scheme). Individual frames indicate dates and absolute values of measured vertical deformations at each particular point.

The diagram shows that the hydrostatic pressure affecting the bottom of the tunnel is so considerable that it lifted the tunnel tubes by 4–11 mm until April, 2005 despite of the overburden resistance. Other loading factors also occur and there is no doubt that after many years, when the primary lining degrades, the ground pressure will rise considerably. This upward movement of the tunnel tubes has contributed to lifting the terrain and surface development in Ostrovského street as indicated in the previous section of the paper.

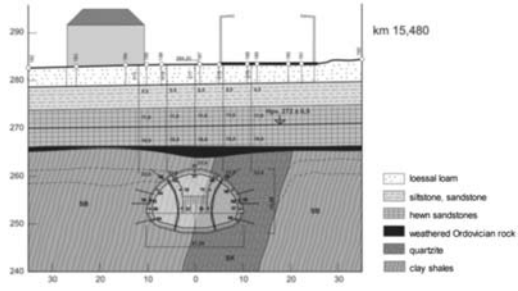

Figure 7. Cross section.

3 KOBYLISY ONE BAY DRIVEN STATION

3.1 *Basic description*

Kobylisy single-aisle underground station is located in the densely built-up center of Kobylisy. The large cavern is 148 meters long and the theoretic stope area was 220 square meters (which is approximately 30% more than in the case of Mrázovka tunnels). The excavation width is 21,2 m.

The rock environment, in which the tunnel was driven, consists of Ordovician skalecké shales and skalecké quartzites. This geologic environment is characterized by extraordinary inhomogeneity of the rock environment and by a great heterogeneity of geotechnical properties as for example strength, deformation properties, shear strength on discontinuities, stability, saturation, and permeability. As regards the mechanical and physical properties, this rock environment is similar to that in which Mrázovka tunnels were constructed. However, both locations differ in the geology of the overlying strata. The overburden of the stope consists of thick sub-horizontal formation of hewn sandstones which establish a bearing element above the cavern stope. This bearing slab has favorably influenced the development of deformations in the vicinity of the stope and on the terrain surface. The total overburden thickness is 22 meters.

3.2 *Monitoring results*

Geotechnical monitoring established in advance before commencement with the construction works has focused on monitoring the deformation behavior of the tunnel lining, stope overburden, terrain surface, and buildings on the surface.

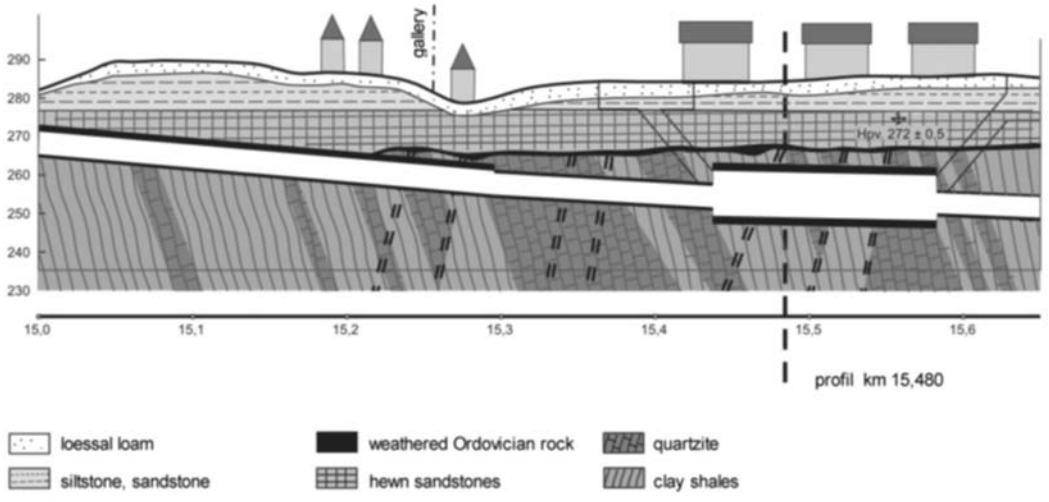

Figure 8. Longitudinal profile.

Another important part of the geomonitoring was the underground water level monitoring in the overlaying strata (in the rock of horizon). These surveys have been carried out in 21 wells and in four observation boreholes.

The measurement results have shown that construction of the cavern and line tunnels caused decrease of the underground water level by 1–2 meters only. Wells with the depth over 11 meters did not dry out at all. This documents the productiveness of the cenomanský aquifer.

For the purpose of monitoring the effects of underground water level rise after insulation and secondary lining completion, we have selected a characteristic levelling profile on the terrain surface located at chainage 15.480 km. Underground water level monitoring was carried out during the entire construction duration, as well as after its completion. The results have indicated that the saturation with water and the underground water stabilization to the original level took approximately one year.

The levelling profile on the terrain surface located at chainage 15.480 km was subject to systematic geodesic surveying during the entire term of driving works, i.e., until the half of 2003 when the deformations stabilized at approximately 45 mm.

Outside the scope of the monitoring project, we executed leveling surveying of points in profile June 17, 2004 and June 1, 2004 after the final lining was completed and after the underground water stabilized back at its original level. The results are illustrated in the Figure 9. The results shown below indicate that, unlike at Mrázovka, the effect of lift force on the terrain surface denivelation has not occurred here. It is

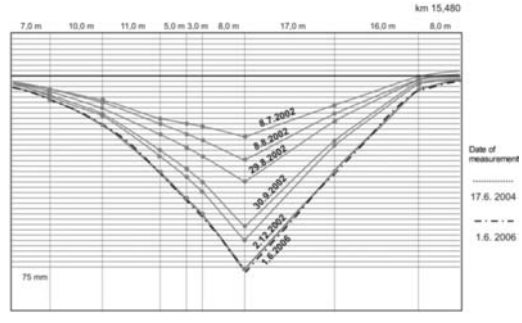

Figure 9. Levelling measurement in KM 15.480 profile.

obvious that despite of the considerably greater volume of the cavern (and therefore also greater lift force), the overburden thickness and its stability given by the Ordovician formation and the sandstones are the decisive factors for the balanced state of the underground structure.

4 CONCLUSIONS

1. The paper informs about results of monitoring two large tunnel structures in Prague from the perspective of underground water effects and its back rise after commissioning of the structures in 2004. Two structures with different geological conditions were compared.
2. As regards Mrázovka tunnels where significant decrease and subsequent rise of underground water

level was encountered, the monitoring and calculations identified deformation effects of underground water decrease between 15 and 20 mm in the area of Ostrovského street (from total deformations between 65 and 71 mm).

3. Back rise of the water caused lifting of surface structures by 8–12 mm, i.e., approximately 50% of the value caused by the underground water level decrease. This lifting occurred approximately one year after the secondary tunnel lining completion and after the end of water pumping from the pits under the tunnels.
4. In similar cases of tunnels with full insulation and in the hydrogeological conditions with soil overburden, it is necessary to carry out final repairs of surface buildings only after full underground water level rise and after stabilization of the buildings confirmed by leveling measurements.
5. Monitoring of Mrázovka tunnel still continues (subject to approval of the operator) and its continuity can be beneficial for design of other large tunnel structures.

Geotechnical support of construction and operation of the Underground and transport tunnels

N. I. Kulagin, Sc. D. & K. P. Bezrodny, Sc. D.
NIPII Lenmetrogiprotrans OJSC, St. Petersburg, Russia

ABSTRACT: Geotechnical monitoring applied by the Institute in the design, construction, and operation of the Underground of St. Petersburg and transport tunnels is presented. Its structure and survey methods used are discussed. The results are presented in brief. In 1993, the Lenmetrogiprotrans Institute, in addition to its design and survey functions, became also a research facility. It has established a special division comprising three laboratories for geotechnical, geophysical, and environmental research. Development and implementation of geotechnical monitoring in the design, construction, and operation of the Underground and transport tunnels has recently become one of its major priorities.

1 ST. PETERSBURG UNDERGROUND

As St. Petersburg is Russia's second city in terms of its population (5 million), the problems of development of up-to-date passenger transport are very acute, all the more so because the city is located on over 40 islands in the Neva's estuary, while the existing bridges are heavily overloaded with ground transport.

Currently, St. Petersburg has 4 operating underground lines about 130 km long (face-to-face length) with 59 stations. The Underground daily carries over 3.0 million passengers, and its proportion in the total passenger traffic is constantly growing. A feature of its construction engineering geology is that under the mass of labile aqueous soils of quaternary strata (peat, sands, sandy loams, ribbon clays, and boulder rocks) there is a quite thick stratum of dense dry Proterozoic clays, which are a convenient environment for both construction and operation of underground facilities. Therefore, the city's underground space at these depths is mostly allocated for the Underground construction. An advantage of great depths (40…80 m from the ground surface) in these conditions is that construction in dense clays has a very slight effect on the city's life and on preservation of historically valuable monuments and compact city housing, especially in the historic center, and offers high roadheading rates.

As examples of station facilities where geotechnical monitoring has been used in the construction and operation, we will review three stations.

Sportivnaya Station (Fig. 1) is a two-storey single-vaulted interchange station for two Underground lines at once. Prior to designing, a large set of research efforts by physical and mathematical simulation methods was carried out. On the basis of these results, a design was developed for the station that for the first time ever, in such geological conditions, enabled construction of such a colossal underground facility with a sectional area of abt. 430 m^2. During the construction, field geotechnical monitoring with the use of various instrumentation was provided, which has been carried out also in operation for 9 years up to this day, and which enabled updating of the design parameters of tunnel structures.

Krestovsky Ostrov Station: Tri-vaulted, of a tower type, for one Underground line. For the first time in St. Petersburg's conditions, it was built entirely of reinforced concrete, without shaped cast iron components, with the three tunnels' lining extruded into the rock, and with the tower installation's girders prestressed between themselves. During the construction, geotechnical monitoring was applied with various sensors mounted in structures, which also continues during operation.

Admiralteyskaya Station: Tri-vaulted, of a tower type, for one Underground line. It is located under the city's historic part at a considerable depth.

Prior to designing, research by physical and mathematical simulation methods was carried out. Its results enabled solutions in the design documents for the station's facilities and its erection technology that ensure minimum surface sagging.

The middle hall was driven with a forepoling temporary arched concrete support installed in a slot made with a specially designed bar (Fig. 2).

During the construction, geotechnical monitoring of the station's facilities and ground surface was set up, which still continues during the line operation. Prior to the station tunnels driving, a system of compensating injection into the rock was built on the surface,

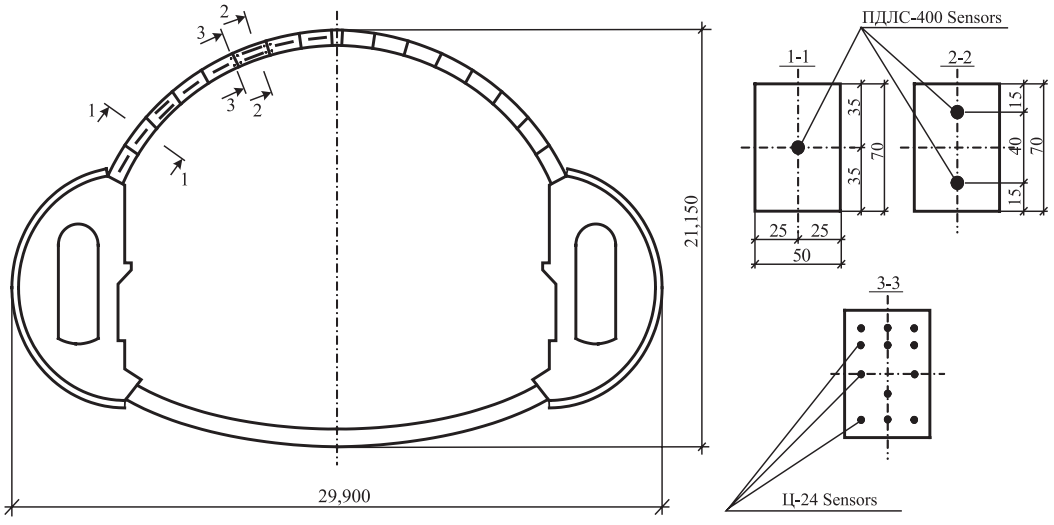

Figure 1. Sportivnaya Station: Arrangement of sensors in the top vault.

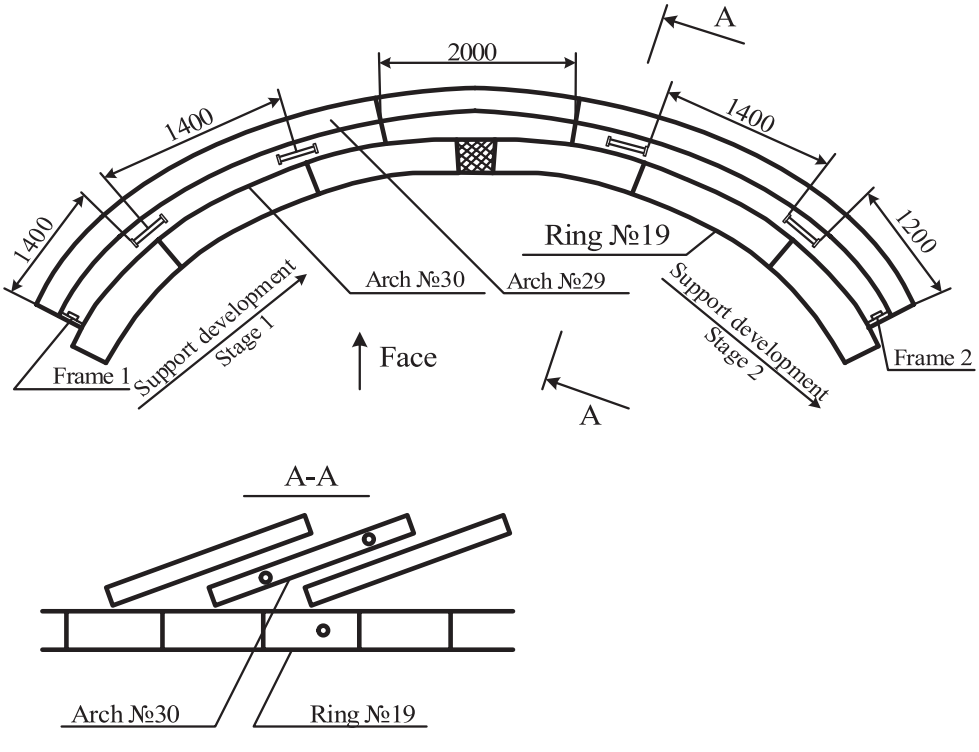

Figure 2. Arrangement of sensors in Arch No. 30 of the forepoling support.

with a grid of deep-seated reference points. During the tunneling, the system allowed to greatly reduce buildings' setting, to prevent their deformation by injecting solidifying spacer fluids into the strata movement zone under buildings (Fig. 3), and to preserve historic buildings without any distortions.

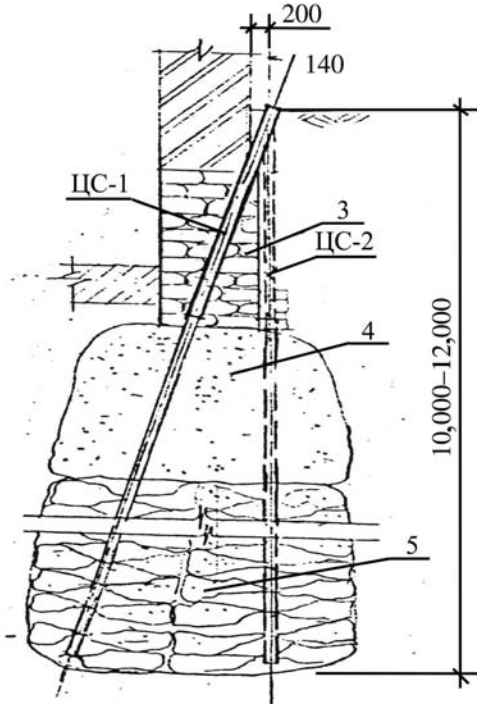

Figure 3. Compensatory injection soil fixing: LIC-1,2 – injection holes; 3 – building foundation; 4 – fixed soil under the foundation; 5 – compensating injection zone.

Geotechnical monitoring enabled to get full information on strain-stress states of the "station structures-soil block" system in every phase of construction and operation.

We should dwell in more detail on geotechnical monitoring in the design, construction, and operation phases of the new route of St. Petersburg Underground tunnels between Lesnaya Station and Ploschad Muzhestva Station, in quaternary aqueous soils at hydrostatic pressures of up to 0.5 MPa.

The tunnels were driven by a tunnel-boring machine with face surcharging at the depth of 50 m to 55 m, 1573 m long in single-track terms (Fig. 4).

To survey the soil block, 162 vertical survey holes 60 to 120 m deep were drilled at various design stages. Static sounding was made in 16 holes. 48 holes were drilled to install strain sensors in them. At 137 points, subsurface geological radar was applied from the surface to a depth of up to 90 m by ultra-broadband (UBB) sounding. Gravity prospecting was performed at 396 points, seismic survey, at 953 points, temperature survey, at 319 points, resistivity sounding, at 700 points, and caliper logging, at 115 points; cleanup pumping was performed in 19 holes; 696 soil samples were taken.

Extremely difficult geological engineering and hydrogeological conditions along the tunnel route, the one-side tunneling technology and lining design solutions that were novel for those conditions, and several questions posed by research organizations required development and implementation geotechnical monitoring of construction safety and subsequent safe operation of tunnels.

Monitoring comprised the following tasks:

– observation of lining strain-stress states in the plane perpendicular to the tunnel axis and along the tunnel axis

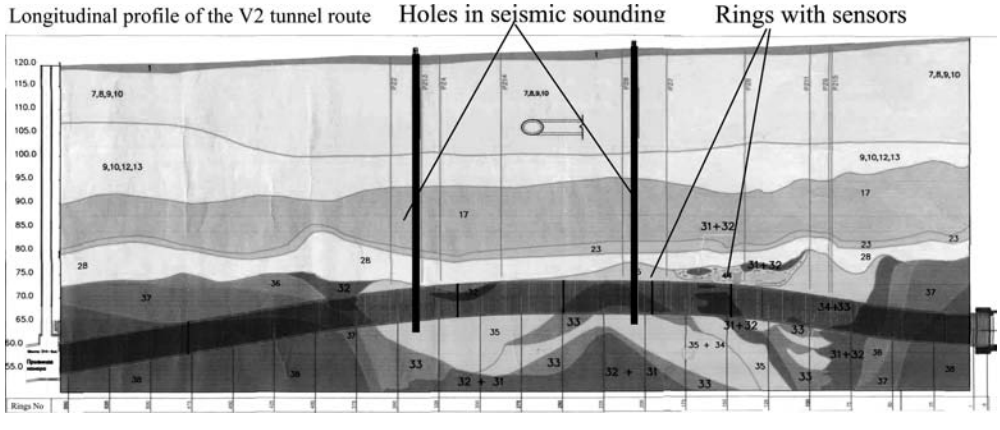

Figure 4. Longitudinal profile of the V2 tunnel route.

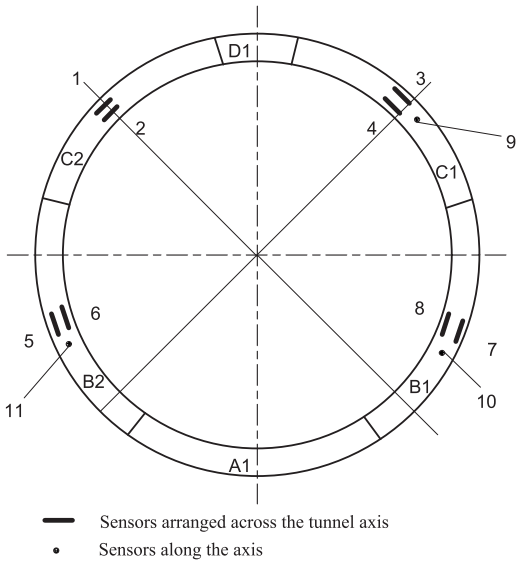

Figure 5. Arrangement of sensors in a lining ring.

– observation of linear and angular shifts of annular and radial lining joints
– observation of hydrostatic and pore pressure variations in the block
– monitoring of variations of geological engineering and hydrogeological conditions
– observation of surface shifts and structures during tunneling
– observation of inner geological processes
– detection of cavities not filled with fluid behind the tunnel lining
– acoustic sounding of the soil block.

The tunnel lining, 710 cm in outside diameter, was assembled from wedge-shaped rings to ensure the tunnel lateral and profile turning. The average width of a ring is 1.4 m. The ring consists of six reinforced concrete blocks 35 cm thick.

20 rings (Fig. 5) of the lining, with 220 sensors mounted thereon, were installed in both tunnels during their boring.

The sensor measurements showed that the normal tangential stresses were far below the concrete ultimate strength, all stresses are far below the ultimate compression, and their distribution along the lining perimeter is close to uniform.

The compression values between and within the rings are retained along the tunnel, following the temperature changes inside it. The dynamic stresses from trains passing make 1…3% of the static values.

The observations of the lining block joints with an error of 0.01 mm showed their practical invariability.

The pore pressure in the block was changing with the tunnel-boring machine approaching; after the tunneling, it stabilized and slightly varied with atmospheric pressure variations.

The method of UBB radar ranging from the ground surface along the tunnels' route was used to monitor expectable changes in the geological engineering and hydrogeological conditions before, during, and after the tunneling. These results showed their invariability.

The geodetic measurements of the ground surface, and buildings thereon, showed that the overall sagging from the two tunnels driving did not exceed 20 mm.

The ultrasonic detection showed that the stand-off between the soil boundary and the lining was filled with solidifying fluid of the preset thickness in every part.

Acoustic sounding of the soil block was performed before and after the tunneling and during operation. The tunneling actually did not affect the condition of soils near the tunnels.

Subsequent operation of the tunnels did not cause any vibratory liquefaction of soils. Moreover, the S-wave speed rates are far from the threshold criterion when such an effect is possible.

Prior to the tunnels' startup, an attitude position monitoring system was assembled in the first track tunnel. The system operates automatically and enables monitoring of the X-coordinate (length of the monitored tunnel sector between Planes 1–9), Y-coordinate (horizontal coordinate of the plane perpendicular to the tunnel axis), and Z-coordinate (vertical coordinate of the plane perpendicular to the tunnel axis) (Fig. 6).

During the observations, the variation of the length of the monitored tunnel part (624.8 m) was oscillatory. The maximum span of oscillations throughout the period of observations was about $\pm$ 6 mm relative to the average measurement error value.

The variation of the maximum shift of the monitored tunnel part in its center was within $\pm$ 5 mm both horizontally and vertically.

This information indicates sufficient stability of the monitored object throughout the period of operation of the tunnel attitude position monitoring system.

Elongation/contraction of the tunnel is related to seasonal temperature variations therein, and its vertical changes, to loads from trains in the morning, afternoon, and evening, and no-load in the night time.

2 TRANSPORT TUNNELS

The Institute has developed a system of geotechnical monitoring starting from the design stage and through the construction and operation support stages.

Monitoring purposes:

– safety during construction
– safe operation
– information about the strain-stress states of the "block-support-lining" system, geological

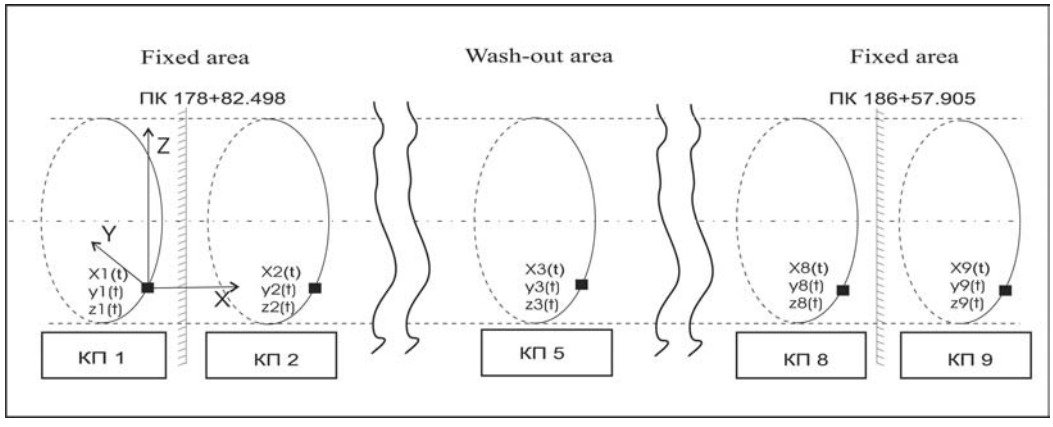

Figure 6. Attitude position monitoring system of Tunnel No. 1 by 9 monitored planes.

engineering and hydrogeological conditions ahead of the tunnel face, and actual physical/mechanical properties of soils, to take timely action to prevent development of negative processes
– generation of a data bank for assessment of construction risks and feasibility of analog design.

It should be noted that surveys conducted at various stages of designing do not provide sufficiently detailed data on the geological engineering and hydrogeological conditions along tunnel routes, especially for subvertical structures.

Geotechnical monitoring comprises the following stages:

– updating of geological engineering and hydrogeological conditions ahead of the tunnel face by the ultra-broadband (UBB) radar method at distances of up to 100 m
– analysis of the strain-stress states of the soil block and the "block-support" system in the working area by the electromagnetic emission re-cording method
– analysis of the strain-stress states of the "block-support" system using string transducers, or by the excavation pattern shift
– determination of actual stress-strain and strength properties of the soil block in the bored part of the tunnel by seismic profile shooting and by measured stresses in the structures
– on the basis of the results obtained, updating of design documentation as regards modifications in the tunneling processes and support design, and application of special techniques
– assessment of hydrostatic pressures and water production, and updating of drainage system designs
– observation of movements of the ground surface and structures thereon, and where necessary, actions to keep buildings and structures in their proper status
– geotechnical monitoring system switchover to the tunnel operation mode
– generation of a data bank for the tunnel.

Such geotechnical monitoring is provided actually in all transport tunnels under construction.

On the basis of completed geotechnical monitoring and surveys of tunnels, we develop experimental and theoretical methods of analysis of the strain-stress states of the "block-support-lining" system, and study the effect of operating loads on the system interaction variations. We analyze the degree of peripheral soil degradation and its influence on operation of the entire system. On the basis of a new-generated and updated geotechnical monitoring results data bank, we assess construction risks and feasibility of analog design.

As of this day, the following field observation methods have been invented/developed by the Institute:

– seismic methods
– ultrasonic methods
– electrical survey
– electromagnetic emission recording
– ultra-broadband (UBB) geological radar sounding
– analysis of hydrostatic and intrastratal pressures using string transducers
– stress testing in operated structures: by partial relieving, in concrete structures, and by magnetostriction, in steel/ironwork
– analysis of strain-stress states of supports/lining using string transducers, or by the excavation pattern shift.

The use of geotechnical monitoring in the construction of underground railways and transport tunnels in cities enables getting complete information about processes going on in the soil block, and timely engineering action for preservation of buildings and structures on the day surface.

Influence of the primary support stiffness on the surface subsidence during tunnel construction

J. Likar & M. Venta
University of Ljubljana, Faculty of Natural Sciences and Engineering, Slovenia

ABSTRACT: The usage of underground structures is increasing which is the reason that in many cases construction takes place in heavy and difficult geological geotechnical conditions. The main goal to reduce surface settlement on the minimum is connected with stiffness of the primary lining and effective protection excavation face against deformation process realized in rock pillar ahead the excavation. The construction process was modelled with *PLAXIS 3D tunnel program*. Input parameters were determined by 3D back analyses with Soft-Soil-Creep (SSC) constitutive material model, which takes into account rheological phenomena. 3D development of stress-strain fields during the tunnel excavation was performed to show major stress-strain changes in the surrounding rocks and support elements. The calculations showed that during excavation of the top heading substantial deformations are developed ahead of the top heading. Influence of the support stiffness has strong connection with amount of surface movements above the tunnel.

1 INTRODUCTION

The influences of tunnelling on surface in areas of low overburden are sometimes still difficult to predict, despite contemporary computer techniques. The cause for that could be in quite changeable physical and mechanical properties of the surrounding rocks mass and soils and also in selected construction method related with stiffness of primary support, which is installed after the excavation.

In technical literature at this area we could find some numerical models, which deals with relations between stresses and strains in the support system and surrounding rock mass for different distances between closed primary support and the face of excavation also for the particular stiffness of the support system.

In fact this is the effect of the support stiffness in function with surrounding rock mass in which the stiff support system has the biggest contribution. Stiff support system is usually combination of steel support together with shotcrete, rock bolts or anchors and also with additional support systems like steel pipe roof, micro piles, temporary invert with elephant foot, etc. In rocks with low bearing capacity, the arrangement of stresses and the amount of deformations which occurred, could be a serious problem regarding to the acceptable surface subsidence. In reality deformations in tunnel shell usually make no problems with stability and excavation process. The technological procedures are schematic shown in the Figure 1.

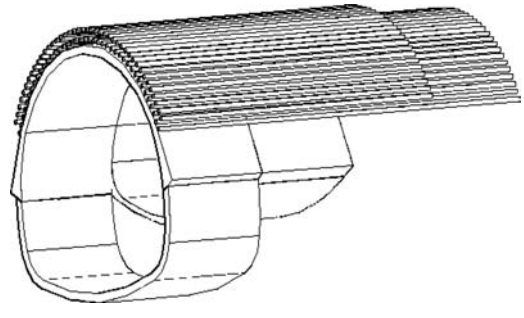

Figure 1. Technological sequences during the tunnel tube excavation.

Regarding to that, this demands detailed analysis of stiff support effect taking in to account development of deformation fields with excavation progress and installation of primary support.

2 SOME NUMERICAL MODELS WHICH DEALS WITH STIFFNESS OF PRIMARY SUPPORT SYSTEM

The question, which is related with the share of primary state in rock mass, which the support system has to take over, is in professional literature treated in different ways by many authors (Whittaker and Frith,

1990; Kim and Eisenstein, 1998; etc.). But in latest past, the usage of complicated models were less desired, because it took a lot of knowledge and time for engineers to obtain some results in practice and on the other hand the input parameters were complicated and difficult to define with standard laboratories tests. This causes some problems at planning and execution of detailed laboratories tests, which also could had limited practicability at wider area of the surrounding rock. This fact is quite related with inhomogeneous and anisotropic behaviour and anomalies, which often occur in surrounding rock mass. Reduction factors, which were used by some authors, show us, that they were fully aware of the complexity of rock mass structures.

Experiences that we have with usage of that numerical models indicated, that they are useful for tunnels or others underground objects with low overburden, which are construct in compact rock mass with high cohesion. In cases, where the rock mass has low cohesion, the results are questionable and not so reliable. Kim in Eisenstein 2006 suggested, that calculation method developed by Schwartz in Einstein 1980, could be used, when the quotient came to $L'_d/R < 1$. In this equation the $L'_d = 0.7\,m$ is the distance between the excavation face and the centre of gravity of the latest closed segment of primary lining and $R = 5.5\,m$, which is the equivalent radius of excavation.

In our case is $\lambda_d = 0.7 - 0.57(L'_d/R) = 0.63$, which corresponds their recommendation.

3 TECHNICAL PARTICULARITY OF CONSTRUCTION OF THE TROJANE TUNNEL AT THE SECTION OF SHALLOW COVER CLASS

The construction of the tunnel at the section of shallow cover class was adjusted to unfavourable conditions. The following working phases were performed:

(a) An excavation of top heading was carried out in 5 phases with simultaneous protection of working face by wire mesh Q189, 15 cm thick shotcrete. 35 pieces of 15 m long IBO rock bolts with bearing capacity 250 kN and over covering at 5 to 7 m were also installed. The amount of excavation step was 0,8 m.
(b) After excavation of the 3rd phase, the steel support was installed, which included 2 steel segments IPE 180 and 2 steel micro piles at every side of top heading, with length 6 m and 64 mm in diameter.
(c) After excavation of the 4th and 5th phase, temporary invert was installed with the thickness of 25 cm and one layer of wire mesh Q283. Also the second layer of wire mesh Q283 and shot concrete was installed, so that final thickness of primary support came to 35 cm.

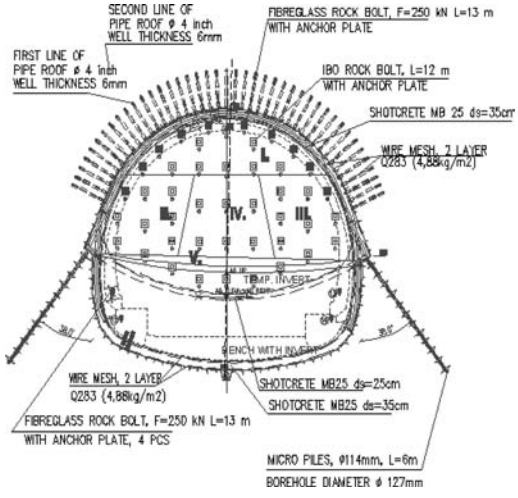

Figure 2. Cross section of tunnel tube with supported measures.

(d) An installation of pipe roof contained 42 pieces of pipes with 114 mm in diameter and over covering of 5 to 8 m.
(e) An excavation at top heading was followed by excavation and installation of primary support at bench and invert. Distance after working face of top heading was 10 to 20 m with excavation step 0,8 m.

Figure 2 presents the cross section of the tunnel tube with the supported measures.

4 CHANGES OF STRESS STRAIN RELATIONS IN ROCK-SUPPORT SYSTEM AROUND THE TUNNEL'S WORKING FACE

Excavation in low bearing and tectonic damaged rocks like tectonic clays, clay grain and gravel stone, which are present at the section of Trojane was connected with large amount of stress strain changes in front of the working face and wider area around the tunnel. In mostly clayey and relatively soft rocks, the influence was 3D or even 4D in front of the working face, where D stands for the diameter of the tunnel tube. This phenomenon was extremely unfavourable because of influence to the time dependent subsidence at the wider area. From the so far completed analysis and engineering interpretations, it could be estimated that large amounts of clayey components essentially influence the time dependent deformations. That was significant for the right judgment of possible deformations in a long time period.

Very heterogeneous geological structure and primary damaged rocks were often indicated in the differential subsidence of tunnel sidewalls. That also

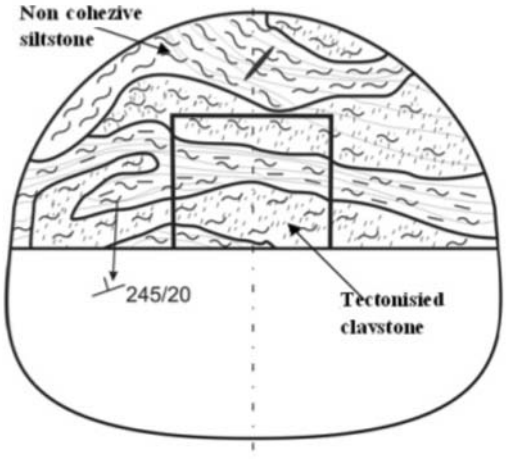

Figure 3. Typical geological cross section of the tunnel tube Trojane (East left tube).

unfavourably affected the governing of the amount of deformations in the tunnel roof and on the influential section at surface.

5 BACK STATIC ANALYSIS OF STRESS STRAIN FIELDS

Modern computer techniques based on numerical methods make quick and qualitative assessment of the changes, which are the result of excavation and installation of the support system. Anyhow, input parameters, which we obtain from standard laboratory and in situ tests, are not always quite realistic, comparing results from analysis obtained with those parameters to actual influences that developed between excavation and support measures. These statements were confirmed during construction of the Trojane tunnel, especially on the sections with clayey material.

Absolute values of the deformations calculated with analysis for estimation were quite smaller than those that actually occurred during the construction and later on. It is interesting that values of the differential deformations were more in accordance with the measured values.

The reasons for increased deformations are:

- The fact that in two-dimensional analysis the three-dimensional effect is not considered which is essential for this kind of rocks.
- The fact that input parameters, especially deformational, which we obtain from standard laboratory and in situ tests are not always quite realistic.

The application of the two-dimensional static analysis for realistic assessment of deformational fields demands much lover values of the input parameters.

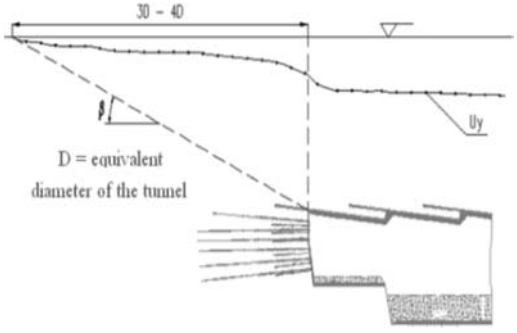

Figure 4. Angle of influence and deformations on the surface due to tunnel excavation.

This contradicts the correct scientific and engineering work. Figure 4 presents in schematic form the influence of excavation on the surface above the tunnel.

5.1 *Influence of support system stiffness and rock pillar in front of the working face*

Influence of the supporting system stiffness on amount and time depended behaviour of deformations is essential for an adequate planning of construction. Increased stiffness of supporting system could be achieved in several ways:

- By installing the supporting system, which ensures a quick undertaking of additional loads, which are the consequence of the excavation;
- By excavating and supporting its sections, e.g. excavation with side gallery, where balance is reached in smaller cross sections;
- By installing the auxiliary support elements with low deformability for increasing stiffness of rock pillar in front of the working face;
- By combining it all.

The question of the intensity of increasing the stiffness of rock pillar in front of the working face by installing the auxiliary supporting elements, which allow normal evolution of the technological process of excavation and support, remains. This understanding is essential for normal operation with fewer interruptions and more continuous construction work.

So far it hasn't been determined, how increasing stiffness of rock pillar in front of the working face by installation of auxiliary support elements effects on technology of excavation and supporting. This understanding is essential for normal operation with fewer interruptions or more continuous construction work.

5.2 *Results of back geotechnical analysis*

3D analysis of stress strain relations were made with software PLAXIS Tunnel 3D, Version 2.0.

SHELL + TH 21 (ES.C. = 15000 MPa)	5.741.400,00	54.305,65

Geotechnical input parameters for calculation of stresses and strains in supporting system and surrounding rock were partially determent in previous investigations. The values are presented in Table 1.

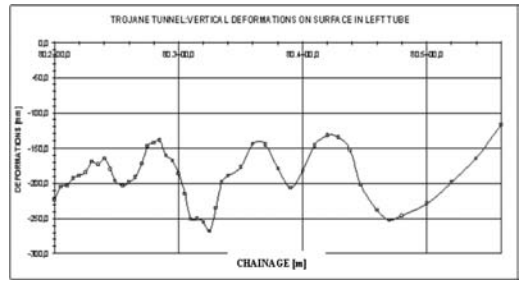

Figure 6. Measured subsidence on the surface along the longitudinal axe of the tunnel tube.

The simulation of excavation and primary supporting were carried out in such manner that first, the excavation and supporting in top heading in the length of 10 m were performed.

This was followed by the excavation and installation of supporting elements at bench, invert and top heading for 10 m more. Excavation and supporting step was 0,8 m. Deformations were in amount of 200–250 mm in the tunnel and 150–200 mm on the surface. These values are similar to those measured at many points. A part of these measurements is presented in Figure 6, where we could see irregular subsidence, which is a consequence of the extremely unfavourable geologic and geotechnical conditions on this section.

The way of excavating and supporting was the same at this section, but over covering of the pipe roof in the sections of bigger deformations was greater, even in the range of 8 m. This caused the stiffness to increase in the roof section of top heading together with primary support, which contained 2 steel segments IPE 180, 2 micro piles, wire mesh and shotcrete of final thickness of 35 cm.

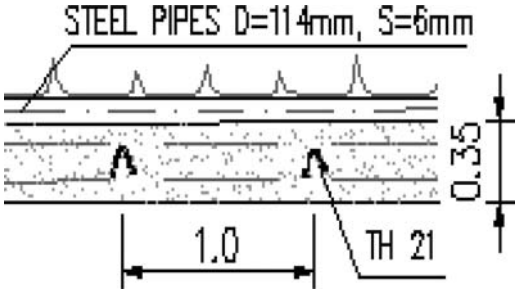

Figure 7a. Standard support elements with steel pipes, steel rib, wire mesh and shotcrete.

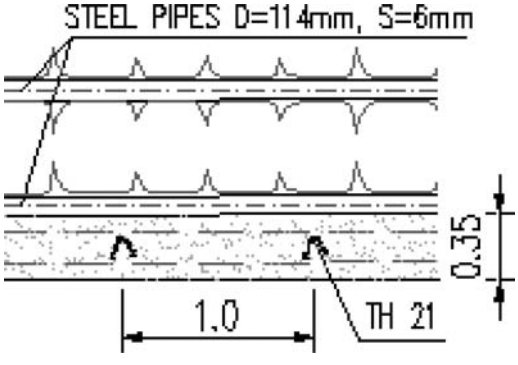

Figure 7b. Support elements with double steel pipes, TH21 steel rib, wire meshes and shotcrete.

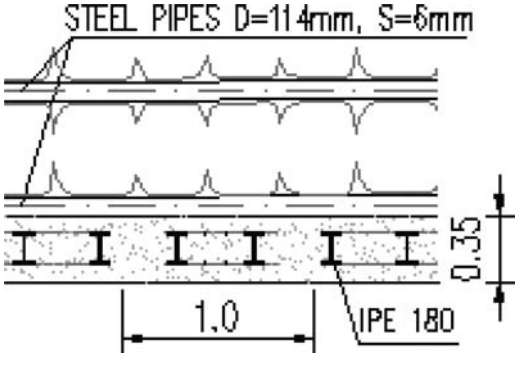

Figure 7c. Support elements with double steel pipes, double IPE180 steel rib, wire meshes and shotcrete.

The results of calculation are presented in figure 9 in form of deformation field. In calculation was also included passive resistance of rock bolts and shot concrete lining in working face in amount of 250 kN/m^2.

Comparison between deformation fields obtained with consideration of single pipe roof and over covered

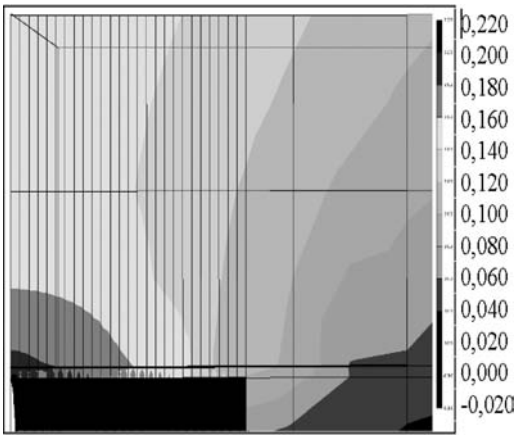

Figure 8a. Deformation fields for normally over covered pipe roof.

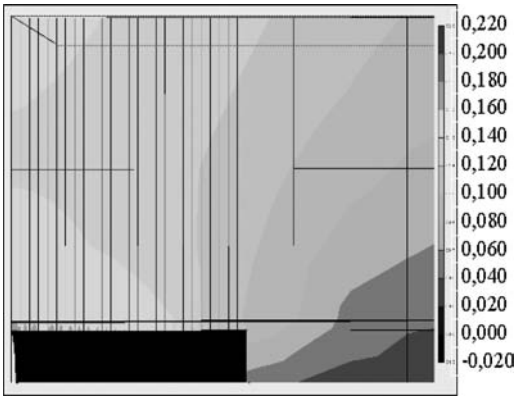

Figure 8b. Deformation fields for fully over covered pipe roof.

pipe roof shows us that influence of increasing stiffness in soft ground is important. Deformations on surface are 20–30% smaller when double pipe roof is used. This was also established during the construction, where in sections with over covered pipe roof deformations were smaller.

Figure 8a and Figure 8b shows differences in deformation fields for normal over covered and fully over covered pipe roof.

5.3 *Time dependent processes*

Development of deformations at the time of excavation and primary supporting of the tunnel is distinct in carbonic rock, since evolution of deformations is completed only in time period of 180 days or more.

This was also established in analysis with finite element method, where soft soil creep model was used.

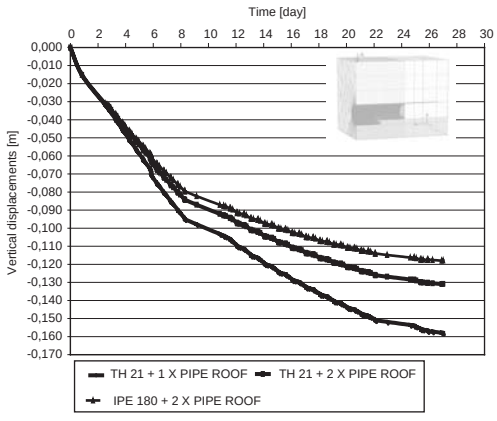

Figure 9. Time dependent surface displacements calculated for different stiffness of the primary lining.

In calculation the hardening of shotcrete was simulated, which gives us increased stiffness of support. During the construction, the support stiffness was also increased with installation of stiff steel segments (2 IPE 180 on section of excavation 0,8 m). The weakness of this combined steel and shotcrete system is that quality of filling in the empty spaces around the steel segments is not easily achieved.

6 CONCLUSIONS

- Tunnel construction in specific conditions such as in low bearing time dependant rocks under habited area depends of the technological procedure and primary support lining, which were used.
- The area of the surface displacements caused by tunnel excavation is closed to geological and geotechnical conditions and type of surface relief with dipping of the natural slopes and local stabilities.
- The results of presented numerical analyses of the surface displacement caused by tunnel construction were usable. Time dependant displacements which were presented help us to make danger volume assessment of objects on the surface.
- Comparison between calculated and measured displacement show us, that this method can be used in similar geological and geotechnical circumstances.

Deformation behavior of west Mao Mountain highway tunnel in gravel deposits layers during excavation

L.Y. Tong, S. Y. Liu, C.H. Shen & L.M Liu
Transportation College, Southeast University, Nanjing, Jiangsu, P.R. China

ABSTRACT: Construction of the large-span tunnel and other underground space in urban areas is of particularly challenge because it has impact on the adjacent existing buildings, public transportation and resident living. Accordingly, stability and deformation behaviors of the surrounding rock and soil are the major concerns for the tunneling construction control. The experiences and techniques of large-span tunnel construction are mostly accumulated from rock and soil tunnel construction. However, relatively rare experiences have been reported on gravel tunneling. A case study of west Mao Mountain tunnel on the Ning-Chang highway, China, is carried out in this paper. Systematic monitoring on the displacements of ground surface and surrounding rock is undertaken for evaluation the deformation behavior of gravel tunnel during excavated. Moreover, with the measurement data, displacement-based back analysis is introduced to get the Young·s modulus of gravel deposits. The findings are useful for design optimum and construction control for this project or other projects with similar conditions.

Keywords: Large-span, gravel deposits, west Mao Mountain Tunnel, deformation, back analysis.

1 INTRODUCTION

A number of urban tunneling and other underground space construction take place as the social demand for public transportation and communication increases, such as large-span highway tunnel, subway, underground supermarket and parking lots, civil defence projects, etc. Accordingly, the adjacent structures, ground surface transportation and even resident living are subject to the surrounding rock and soil movements and potential damages due to tunneling. In general, the tunnel and underground space projects are constructed in rock or soil stratum. However, gravel deposits, which kept properties between rock and soil, are often encountered at such locations as floodplain, valley, piedmont and seacoast. The typical projects involved the Paghuashan tunnel for Taiwan High Speed Rail project, the tunnels traversing Yangtse Rive in Nanjing or Wuhan, China. Valuable knowledge and experiences for rock or soil tunnels have been already accumulated. However, the experiences for the design and construction of the gravel tunnel are still lacking.

The west Mao Mountain tunnel in the Ning-Chang Expressway is selected as an example in this study. With the displacement measurement data that carried from gravel excavation, deformation behavior of the surrounding rock is discussed in detail. Then, based on the vault settlement data, back analysis is undertaken to get the Young·s modulus of gravel deposits using the SHUGUANG FEM software designed by Tongji University of China.

2 BACKGROUND OF WEST MAO MOUNTAIN TUNNEL PROJECT

The Ning-chang expressway travels across the hills of south of Jiang-su province, China, of which the most critical project is the Mao mountain tunnel with mining over 1.5 km. The tunnel consists of a major twin-track tunnel with typical oblate cross-sections of 170 m^2 excavated faces and one emergency interpenetration tunnel between the uplink and downlink lines. Among the two subsections, the west Mao Mountain locates at the hillside of the Tao-hill with maximum span of 17.21 m and maximum height 12.04 m, the uplink and downlink of which contain three driveways respectively. The space between the tunnel axial lines of the two tracks is 51 m maximum and 34.35 m minimum. The total length of the west Mao Mountain is 1034 m.

According to the investigations and tunnel excavated areas, the characteristics of the west Mao Mountain tunnel can be summarized as follows:

- ultra-shallow overburden. The overburden mostly varies from a few meters up to a maximum of approximately 50 m. 80% of the tunnel route is under 50 m, especially, part of the section is

opencast (35 m length). The length of the overburden under 7 m of the downlink reaches 115 m.
- large-span, oblate shape.
- complex geological conditions and low classification of the surrounding rock. 52.7% of the surrounding rock is type II and 26.8% is type III.

Combined with the topography and the geological conditions, the west Mao Mountain tunnel was excavated and supported following the principles of the New Austrian Tunneling Method (NATM), except that the portal sections and ultra shallow overburden sections, where the strongly pre-support technology using large steel pipe shed or advanced grouting small pipe was applied. Moreover, at the opencast area, the covered excavation method (cover first and then excavated) is adopted. The composite lining structure consists of the initial support system and the inner reinforced concrete lining, the former structure includes rock bolts, wire mesh, shotcrete, and steel arch girder. The EVA waterproofing membrance are in the gap between the initial support and the inner lining. The excavation scheme is cross diaphragm (CRD) method. Fig. 1 shows its typical cross section geometry and the excavation steps.

3 GEOLOGICAL AND HYDROLOGICAL CONDITIONS

3.1 *Stratum and lithology*

The route of the west Mao Mountain Tunnel from west portal to east portal passes through many rock formations. These are gravel deposits, conglomerate, andesite and tuff formations. Among these formations, gravel information is a rare occurrence in tunneling, which makes the excavated workings difficult. The total length of this layer is more than 500 m and the maximal buried depth is greater than 30 m. The cause of gravel formation is eluvial on the piedmont. The color of the gravel deposits is mainly dust-color, or gray-purple. It is formed with loosely pebbles and gravels cemented by clay and sandy clay. The percentage of the gravel block is 20∼50% and with the depth increases, the percentage is reaching 50∼70%. The size of gravel particles is from fine to large coarse, the diameter of which is 5∼20 cm, some reaches 50∼80 cm. In general, the diameter of the block at the top of the deposits is smaller than that at the bottom. The gravel formation consists of mainly gray to white quartz sandstone and grey to purple clastic sandstone. Due to very high content of gravel particles, the original gravel formation behaves as generally hard and brittle. Moreover, the other rock stratums have large numbers of joints.

3.2 *Geological structural features*

The tunnel locates at the active Mao Mountain fault zone. However, there are few major faults crossing the tunnel alignment except in the vicinity of the east portal area, where an inverse fault locates between the Pu-kou group conglomerate and the Long-wang-shan group tuf. Correspondingly, many unrecorded small faults were found during tunnel excavating. Generally speaking, the geological conditions change along the tunnel route drastically.

3.3 *Hydrological conditions*

The groundwater is mainly porous phreatic water and bed rock fissure water. The underground water quantity is small controlled by rainfall mainly. However, in view of the characteristics of shallow overburden, particular area with weak structural plane combination is deserved to considering.

3.4 *Rock mass classification*

Considering the engineering geological and hydrogeological conditions, rock mass structure, RQD index and other influencing factors, the appropriate classification of the surrounding rock is proposed as Table 1. Class II, mainly consisting of gravel deposits, signifies very poor conditions. The excavation face is unstable without pre-supporting measures. Class III signifies poor conditions, mainly consisting

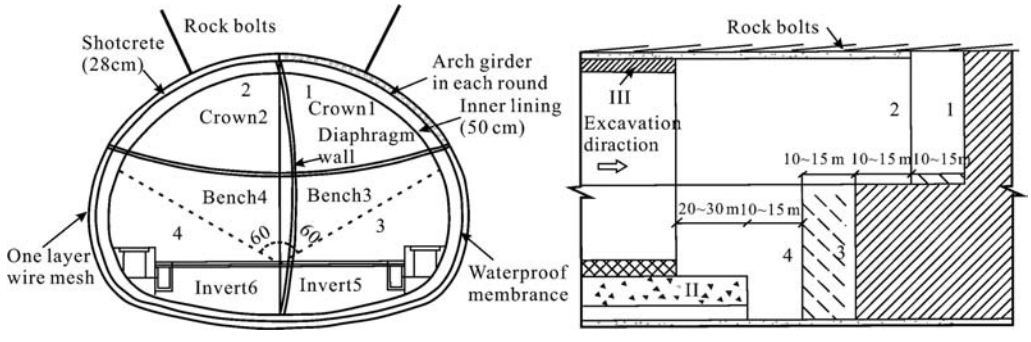

Figure 1. Typical cross-section of west Mao Mountain tunnel excavated by CRD method.

of strongly weathered conglomerate and tuff, which requires pre-supporting measures also. In Class IV, the underground conditions are to be considered good and the excavation face is always stable without pre-supporting.

4 MEASUREMENT AND ANALYSIS OF DEFORMATION BEHAVIOR OF WEST MAO MOUNTAIN TUNNEL

4.1 *Main monitoring scheme*

Systematic in-situ monitoring is an integral part of NATM. According to the geological conditions and surrounding environment, the original design sets up primary monitoring management value. During the excavation and support workings for the mined tunnel, the continuous measurements allowed the modification of the monitoring management value and to assess the original design assumptions. Three kinds of displacements are measured: ground surface settlement, vault settlement and horizontal convergence, shown as Fig. 2. In addition, monitoring of stress and strain on the rock-lining-structure contact has been carried out by installing rock pressure cells, strain gauges and steel bar gauges at main sections. So the stress distribution is studied by the measured surrounding rock pressure, shotcrete-lining stress, steel arch stress and inner lining stress.

The installation instruments, the locations and the space can be adjusted according to the actual engineering conditions. The monitoring frequency can also be changed according to the alert value and the measurement data. For the west Mao mountain tunnel, monitoring cross-sections for the ground surface settlement measurement were provided within the west and east portals area, the ultra shallow area, with an average space of 10 m. Moreover, the number of the sections at every monitoring area should be larger than 3. The cross-sections for vault settlement and horizontal convergence measurement were generally installed at regular intervals of about 5∼10 m at the class II or III surrounding rock area along the longitudinal axis. The monitoring sections consisted of five to seven displacement monitoring points for the three-dimensional (3D) monitoring of the tunnel.

Table 1. Summary of the rock mass classification results in the project area.

Route	Total length (m)	Surrounding rock type II	III	IV	Percentage of Class II and III
Uplink	452	215	62	175	61.3%
Downlink	582	330	215	37	93.6%

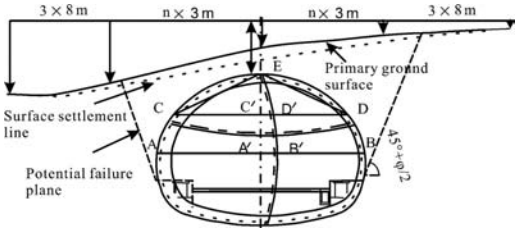

Figure 2. Scheme illustration of displacement monitoring system.

4.2 *Transverse surface settlement measurement and characteristic results*

Due to shallow overburden and poor geological conditions, the safety of tunnels itself and adjacent structures are subject to ground movements when constructing. In the beginning, the working field clearance in the west portals resulted in ground collapse, which signified the importance of the pre-support systems for gravel deposits. With the strongly pre-support system using large steel pipe shed or advanced grouting small pipe, which formated curtain effect, the ground settlements had been controlled to a range from 0 to 40 mm almost, and only few points reached to a maximum of approximately 50 mm. The results show that the deformation was controlled under safety and expected estimates. However, the settlements at the area with NATM system instead of strongly pre-support system were relatively larger, which also didn't reach the limit values. The transverse settlement range is about 36 m symmetrical relative to the tunnel axial line, which is influenced by the overburden. So the interaction between uplink and downlink tunnels is very weak at the space of 34.35 m to 51 m.

Just shown as Fig. 1, the tunnel cross-section has such sequential excavation and NATM supporting stages: crown 1, crown 2, bench 3, bench 4 and invert, reducing the open surface of each face, thereby decreasing the potential for collapse. The distances between crowns, benches and invert excavation were restricted by logistics and settlements monitoring. The measurement data showed that the settlements caused by crown 1, crown 2, and the rest stages were 11 mm, 7 mm, 5∼12 mm respectively (shown as Fig. 3). The longitudinal settlement scope along the route was about 10 m before the excavating face and 20 m after the excavating face, which was influenced by the production rata. That is, the sufficient space was required to at least 30 m for regular advances.

Such information indicated that the diaphragm wall, invert filling and arch support are very important for deformation control, and the strongly pre-support system and CRD method conforming to NATM principles were most appropriate and advantageous for such large-span tunnel in gravel deposits.

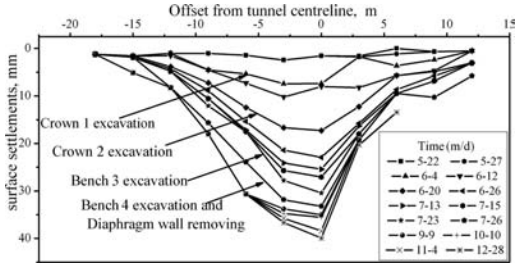

Figure 3. Measured ground surface settlements due to excavation of the different stage (cross section of FK24 + 797).

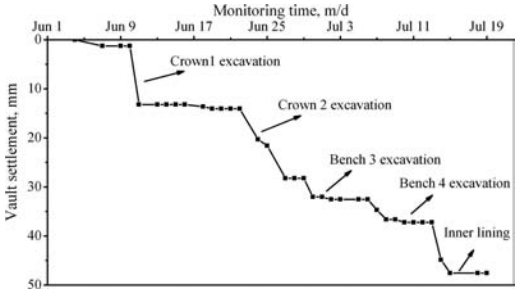

Figure 4. Vault settlements due to excavation of the different stage (cross section of FK24 + 797).

4.3 *Vault settlement measurement and characteristic results*

The characteristics of vault settlement were similar to that of the ground surface settlement. Moreover, the vault settlement value at the west portals supported by large steel pipe shed was 10 mm smaller than that at the cross-sections supported by normal NATM method. The maximum total vault settlement was approximately 33 mm. In fact, the actual value was approximately 50 mm because of the installation of monitoring points was slightly delayed. The measurement data showed that the vault settlements caused by crown 1, crown 2, benches excavation and diaphragm wall removing, were 5∼15 mm, 5 mm and 17 mm respectively (as shown in Fig. 4). The abrupt increase of the settlement after a period of apparent stabilization indicated that next excavation stage was beginning to process. The vault settlement results also indicated that the sequential excavation and predesigned support methods were most advantageous at the gravel formation.

4.4 *Convergence measurement and characteristic results*

The characteristics of horizontal convergence measurement were similar to that of the ground surface and vault settlements (as shown in Fig. 5). The maximum total convergence value was about 30 mm. The

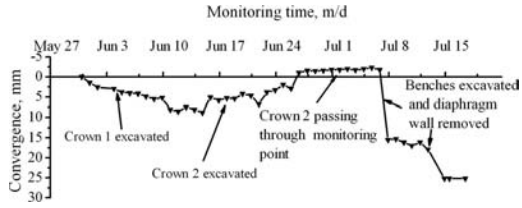

Figure 5. Convergence due to excavation of the different stage (cross section of FK24 + 797).

developing process can be described as: The convergence measurement was continually increasing at the crown1 steps; then, when the crown 2 was excavated, with the supporting of the diaphragm wall, the convergence was abnormally decreasing and when the latter crown 2 face passed through the crown 1 face, the value became inverse; After that, with the excavation processing, the convergence tended to stabilization until the benches were excavated and the diaphragm wall was removed; Finally, after the convergence was stabilized, the inner lining working was undertaken.

5 DISPLACEMENT-BASED BACK ANALYSIS AND EVALUATION OF THE RESULTS

According to the field measured displacements mentioned-above, the back analysis was carried out using the GeoFBA2d software, that is, the SHUGUANG FEM software designed by Tong-ji University, China. Several general optimizing methods are provided, including damped least square method, genetic algorithm, simulated annealing genetic algorithm, mixed genetic algorithm, and Simplex method. This paper selected the genetic algorithm for back analysis. The purpose of back analysis was to obtain the actual Young's modulus of the surrounding rock and to tell the engineers what would happen in subsequent construction stages by utilizing the information obtained in the former stages.

5.1 *Computational model*

A set of assumptions was made as follows:

- the gravel information can be considered as isotropic media, the constitute model of which is elastic-plastic Drucker-Prager model.
- the rock bolts can be simulated as cable element. The initial support system including steel arch and shotcrete can be simulated as beam element, just as the diaphragm wall. The contacts between rock bolt or initial support and surrounding rock, initial support and inner lining, can be simulated as Goodman element. The invert filling and inner lining concrete are simulated as solid element, parameters of which are C20 and C30 concrete, respectively.

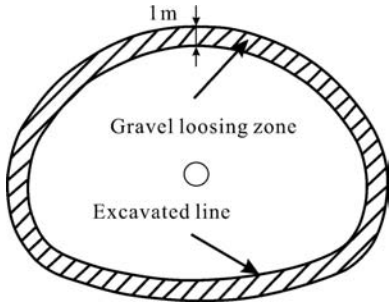

Figure 6. Illustration of two-medium model considering surrounding loosing zone.

- the release loading coefficient is introduced to simulate the three dimensional effect of the excavation in the 2-D model. In this paper, the coefficients pre and after the initial support system installed were 0.3 and 0.5 respectively. The residual 0.2 was for the inner lining.

Taking into account rock loosing zone in the surrounding rock due to tunneling, this paper presents the displacement back analysis based on the two-media model (shows as Fig. 6). The loosing zone is 1 m out of the excavated line. The modulus of the residual soil within the excavated line was the same as that of the loosing zone. The vault settlement was applied for back analysis.

Before back analysis, the measured data should be modified according to the following equation:

$$\mu=\mu_m+\mu_1+\mu_2 \quad (1)$$

where μ_m is the field measured value, μ_1 is the value caused by the delaying of the measuring points installation, μ_2 is the value caused by the former excavated faces which did not reach the measured point. In this paper, the modified scheme was to increase the measured data by adding the value measured at the first day.

5.2 *Strategy and process of back analysis*

The typical cross-section, FK24 + 797, was selected as an example for back analysis, the sequential excavation stages of which can be simplified as follows:

step1: crown 1 excavating; step2: crown 1 initial supporting and diaphragm wall setting; step3: crown 2 excavating; step4:crown 2 initial supporting; step5; bench3 excavating; step6: bench3 initial supporting; step7: invert5 lining; step8: invert5 concrete filling; step9: diaphragm wall removing; step10: bench4 excavating; step11: bench4 initial supporting; step12: invert6 lining; step13: invert6 concrete filling; step14: inner lining.

Table 2. Initial estimated material parameters for back analysis.

Material	Young's modulus (MPa)	Poisson's (ratio)	Unit weight (kN/m^3)	Cohesion (kPa)	Internal friction angle (°)
Gravel loosing zone	back analysis	0.35	25	100	35
Primary gravel formation	200	0.35	25	100	35
Invert concrete filling	26000	0.25	20	100	40
Inner lining	30000	0.2	25	5000	55

Table 3. Structural element properties for the back analysis.

Material	Young's modulus (MPa)	Unit weight (kN/m^3)	Cross section area (m^2)	Inertia moment (m^4)
Rock bolt	210000	78	0.000197	/
Initial support	28500	25	0.273	0.00173
Diaphragm wall	28500	25	0.174	0.0004378

5.3 *Results of back analysis*

As the gravel tunnel is generally conducted in stages, field measurement and back analysis are often associated with each of those stages. That is, what is found at stage *i* must or is expected to tell something about what might happen in stages $i+1$, $i+2$, and so on. The comparison between the field monitoring and the predicted displacements then can be conducted. According to the results, the parameters and even the models can be modified so as to obtain reasonably accuracy. The range of the pre-set Young's modulus of loosing zone is $0.05 \times 10^6 \sim 0.2 \times 10^6$ kPa.

Results of the analyses have been partly shown in Table 4. As can be seen from the Table, predicted vault settlement values based on step3 and 4 of the tunnel are in very close agreement with the field measurements. The Young's modulus predicted by the two-media model for gravel loosing zone are 82.35 MPa, 158.24 MPa and 121.76 Mpa respectively. Corresponding to the relative error analysis (shown as Table 4), the average Young's modulus of the loosing zone is 140 MPa. Compared to the primary elastic modulus, 200 MPa, the value decreased 30% due to excavating.

Table 4. Back analysis results based on vault settlement measurement of different excavated steps.

No.	Excavated steps	Modified field measurement (mm)	Predicted displacement (mm)	Relative error (%)	Predicted modulus (MPa)
Based-on step 2	Step-2	14.51	14.23	1.93	82.35
	Step-3	15.35	18.64	21.43	
	Step-4	22.48	24.21	7.70	
Based-on step 3	Step-2	14.51	10.21	29.63	158.24

	Step-3	15.35	16.7	8.79	
	Step-4	22.48	22.63	0.67	

5.4 *Application of the results: forward FEM analysis*

Moreover, forward FEM analyses of typical cross-sections were conducted using the predicted Young's modulus, which was not included in this paper limited, but the detailed data can be seen in the reference (Li H.B., 2005). The deformation trends of ground surface and surrounding rock were predicted and analyzed along the total route of the tunnel. According to the characteristics of displacements and stress distribution, some advices should be presented as follows:

- corresponding to the sequential multi-stages construction of CRD method in gravel formation, the timely invert supporting and filling are important for deformation control. The installation of the diaphragm wall should also be considered as an essential support structure, the integrality of which should be insured at some sections with large deformation. The removing time of the diaphragm wall was also strictly controlled.
- some positions with large concentrated stress at special cross sections should be additional reinforced, such as the vault area, steel arch foot area, partially initial support, joints between vault and diaphragm wall.

6 CONCLUSIONS AND RECOMMENDATIONS

For successful tunneling in difficult geotechnical conditions or in sensitive environments, monitoring and evaluation techniques are indispensable. This paper provides a detailed insight and valuable experience in cycling for future large-span gravel tunnel and other underground spaces construction, particularly in urban area. The experiences gained from such complex geo-monitoring and back analysis workings can be summarized as follows:

- the deformation behavior of the large-span tunnel during constructing at gravel information is obtained by systematic displacements monitoring and back analysis workings. The results also showed that CRD method using the sequential excavation model could be used for the preliminary design of NATM tunneling for the conditions used in this research. Especially, at the shallow overburden sections and portals, the strongly pre-supported system using large steel pipe shed or advanced grouting small pipe is also recommended.
- displacement back analysis based on the two media model, which considering losing zone, is introduced. The predicted average Young's modulus of the gravel loosing zone is 140 MPa, which is decreased 30% compared to the primary gravel stratum. The predicted displacement also has good agreement to the field measurement data.
- finally, in order to preventing accidents and reducing maintenance costs, the excavation of this critical gravel tunnel should consider all things, such as the geological conditions, construction method, support system, field displacements and stress monitoring, working productivity, facilities, management approach and the overall performance.

EPB-Tunnelling control and monitoring in a urban environment: the experience of the "Nodo di Bologna" construction (Italian High Speed Railway system)

V. Marchionni
S. Ruffillo scarl, Bologna, Italy

V. Guglielmetti
Geodata S.p.A., Turin, Italy

ABSTRACT: The realisation of tunnels in a sensitive urban environment and complex geological conditions requires an accurate, integrated, excavation management approach. The mechanized tunnelling permits to minimize the impact of the excavation on the surface existing structures but it is mandatory to guarantee an accurate control of the face stability and a constant monitoring of the effects on surface. This paper puts in evidence that the choice of the optimal excavation methodology alone is important but not sufficient; only the rigorous application of excavation procedures, including the strict control of the EPB-machines parameters integrated to the continuous monitoring of the effects of the excavation on surface, in terms of settlements, is the key to the success of a tunnel project, specially in sensitive environment.

The realisation of the "lotto 5" of the High Speed Rail system in Bologna represents an example of the application of the above mentioned integrated methodology for the excavation of two 9.4 m diameter, 6.1 km long, twin tunnels using EPBs.

1 INTRODUCTION

The excavation of tunnels in an intensely urbanized context requires particular methodology in order to minimize the effect on the surface existing structure and facilities.

Mechanized tunnelling technologies have been developed, in the last decades, to control the face stability and that of the roof and to minimize surface settlements. Nevertheless, there are some ground and environmental conditions requiring not only the use of an appropriate excavation technique but also the application of a rigorous and integrated methodology that comprehends: the assessment of risk and development of a risk management plan, specific excavation procedures and real-time monitoring of excavation parameters and surface settlements, the "Plan of Advancement of Tunnel" (PAT), a method that allows to adjust the design and control parameters during excavation.

The aim of this paper is the description of the successful application of this integrated methodology for the realization of the "lotto 5" of the High Speed Rail system in Bologna.

2 THE "LOTTO 5" BOLOGNA HIGH SPEED RAILWAY PROJECT

2.1 *General description*

A section of the new High Speed Rail Line Milan-Naples, which crosses the city of Bologna, an intense urbanized area, is foreseen for the most part underground.

In 2000, the joint venture S.Ruffillo (Acciona-Salini-Ghella) was awarded the contract for realizing the Lot 6 of the Project, under passing the city of Bologna. The Project starts at the North abutment pier of the Savena Bridge (km.$0+000$), south of the city, and ends at the new Central Station (km.$7+375$); it consists of the following main structures:

1. A trench tunnel and a launch shaft (for the TBMs), double track, from km.$0+000$ to km.$0+958$;
2. Two EPB tunnels ("Pari" and "Dispari" tunnels), single track, 9.4 m diameter, starting from km.$0+958$ to km.$7+075$;
3. An Emergency Shaft ("Via Rimesse" Shaft) at km.$4+820$ and a Ventilation Shaft at km.$6+857$;

Table 1. Tunnels characteristics.

Total single tunnel length	6112 m
Start chainage	km.0 + 960
End chainage	km.7 + 072
Excavation technology	EPB
Tunnels axis distance	15 m
Overburden (min-max)	15–21 m
Inner lining diameter	8.3 m
Outer lining diameter	9.1 m
Excavation diameter	9.4 m
Excavation section	69.81 m^2
Max tunnel slope	1.5%

4. A transition shaft (TBM's exit and "Bologna" parking) from km.7 + 075 to km.7 + 235;
5. A conventional tunnel, double track, from km.7 + 235 to km.7 + 350, connecting the transition shaft to the Central Station.

The excavation of the first EPB tunnel started in July 2003 and the second excavation started in November 2003. The completion of the excavation was achieved for both TBMs at the end of may 2006.

2.2 *Geological layout*

Ground conditions are very heterogeneous and comprise soft marine clays, sands and alluvial deposit (mainly gravel).

In the first part of the alignment, up to km.2 + 150, the tunnels are excavated in sea clay and loose sandy deposits (Pliocenic Clay and Yellow Pleistocenic Sands) below the water table while the second part, in Savena river deposits, consisting of mainly gravel and sand layers with a high percentage of fines (lenses of clay and silt).

The heterogeneity of the ground excavated represented a critical aspect because the excavation conditions, in terms of surface settlement response and machine's behaviour, changed very rapidly.

2.3 *Choice of excavation methodology*

The two tunnels start at the S.Ruffillo quarter, south of Bologna, and from km.0 + 960 to km.1 + 500 underpass an electrical power plant and a recently built store. From approximately km.1 + 500 to km.7 + 075, the alignment runs below one of the main Italian railway roads, the Bologna-Florence line, that lies on an 8–12 m high embankment.

The average overburden thickness ranges from 15 to 21 m (at the bottom of the embankment), with a minimum value of 5 m in the first 100 m of excavation.

In order to minimize the impact on surface, the Client imposed a mechanized excavation methodology (EPB, Slurry shield or Mix shield), i.e. a technology to minimize the needs to modification of the ground and the disturbance to the ground water regime.

Table 2. Main characteristics of RME370SE machines.

Cutter-head diameter	9.377–9,402 m
Tail shield diameter	9.364 m
Shield length	10.7 m
Number of Thrust Jacks	36
Length of cylinders	2250 mm
Total machine length (w/ back up)	195 m
Max EPB pressure	3.5 bar
Max penetration rate	0.08 m/min
Max thrust force	100.000 kN
Max cutterhead Torque	24.000 kN*m
Cutting head opening ratio	34%
Number of earth pressure sensors	8
Number of longitudinal grouting lines	6
Number of foam injection lines	8

The Contractor has chosen two EPB Machines, due to the following:

– geological and geotechnical conditions (variable ground conditions, and the presence of gravel up to 100 mm diameter.);
– the respective experiences of the two lead Companies in the Contract J.V. for the underground works (Acciona in Madrid and Barcelona) and Ghella (in Valencia and Caracas);
– environmental problems related to the slurry disposal and the treatment plant.

The two tunnels are parallel for most of the alignment (up to km.6 + 650 approx), and the distance between the tunnels is only 5.6 m. The minimal distance between the tunnels represented one of the most critical aspects of the excavation.

The-twin tunnel solution was imposed by the Client and the Designer (TAV S.p.A. and Italferr S.p.A.) due to safety reasons for the train passengers and because the realization of a unique 14 m diameter double-track tunnel, with minimal overburden (1–1.5 diameter), would have caused critical differential settlements for the existing infrastructures, facilities and buildings on surface.

As a matter of fact, during the excavation it was verified that, due to the small distance between the 2 tunnels, the ground encountered by the 2nd EPB machine was more disturbed by the 1st tunnel excavation and presented lower geotechnical characteristics; as a consequence of this effect, during the EPB excavation it was necessary to apply more restrictive control parameters and a higher level of excavation control of the second tube.

2.4 *EPB machines characteristics*

For the excavation, two LOVAT Machines, RME370SE, 19600 (Emilia) and 19700 (Felsinea), were chosen. The main characteristics of the EPB machines are shown in Table 2.

3 EPB EXCAVATION MANAGEMENT

3.1 *First phase of the project*

The excavation was done in two distinct periods:

1 from July 2003 up to October 2004: from pk.0 + 980 up to pk 3 + 050 (1st TBM) and pk.2 + 440 (2nd TBM);
2 from May 2005 up to May 2006 (end of excavation – pk. 7 + 375).

A number of geotechnical complexities, contractual constraints and settlement problems stopped the excavation in October 2004 when 32% of the 1st tunnel and 23% of the 2nd one were completed.

With the aid of the opinion received by the Dispute Review Board, the excavation stoppage was resolved at the end of May 2005.

On resumption, the Contractor Acciona-Ghella set up a rigorous and extensive monitoring system, in terms of TBM parameters and effect on surface implemented with the assistance of a Consultant (Geodata Spa) responsible for EPB excavation operation control.

3.2 *The excavation control system*

The factors that were identified as essential to restart and strict control of the excavation, have been:

1. Production of a detailed TBM Advance Plan (PAT-Geodata Spa) for each 300 m of excavation and for each TBM, so that all the parameters and design issues related to tunnelling were effectively addressed before the excavation. During the excavation of every 300 m of tunnel, the Consultant back-analysed the main TBM parameters, the geotechnical conditions and effects on surface, to check the appropriateness of the used and recommended values. After that, they defined, also considering the interferences with the existing surface structures, the excavation procedures and TBM parameters for the next 300 m stretch;
2. The constant presence of a tunnel engineer in order to collect all the excavation parameters and control the respect of working procedures for all tunnelling phases to ensure that the TBM operations were carried out in a proper manner;
3. Setup of a Technical Desk for reviewing and analysing both the daily and weekly TBM excavation reports, in which the range of operating conditions, recorded parameters, and any significant events, and the relevant effect on surface (settlements, distortion on structures, Volume loss) were summarised.

A weekly meeting (attended by technicians from the Consultant, the Client and the Contractor), where the week's performance was reviewed and the draft PAT for the future excavations was analysed, completed the control procedures.

Table 3. Alarm and Attention Thresholds for controlling EPB pressure above water table.

	Attention threshold (bar)		Alarm threshold (bar)	
	Lower	Upper	Lower	Upper
TBM 1	1,2	1,6	1,0	1,8
TBM 2	1,4	1,9	1,2	2,1

3.2.1 *Parameters*

The fundamental parameters controlled during excavation were: Face Support Pressure, Muck "Apparent Density", Extracted Muck Weight, Tail Void Grouting volume and pressure.

Initially, on the basis of all geotechnical and general design data and using numerical simulation results, reference values for face support pressure were calculated and an operational range, between upper and lower levels (the so-called Attention Thresholds) were identified.

An Alarm Thresholds was also set, that when reached, the excavation would stop automatically (see an example in Table 3). The reference support pressure was defined and measured in the highest sensor located within the bulkhead, 1.5 m below the crown.

To keep the face pressure within the operational range, the TBM operators used the normal control devices, such as the machine advance speed and the screw conveyor rotation speed. During stops, either long, e.g. for maintenance, or short, e.g. for ring assembly, bentonite slurry was automatically injected into the excavation chamber. This operation was giving an immediate response in terms of re-lifting face pressure and was much more efficient than foams, used only for ground conditioning. During excavations it was verified the face pressure to be of paramount importance in controlling the surface settlements. In spite of the high advance rates, the EPB pressures, for both TBMs, were maintained above 1.5 bars, often 2 bars, minimizing the pre-subsidence phenomenon.

In order to minimize the risk of air bubbles in the chamber crown due to an excessive use of foam, an air valve was periodically opened to evacuate the air.

To control how full the plenum was, the "apparent density" parameter (Geodata 2003) was utilised. By measuring the face pressure at different heights and dividing by the height difference between them, calculated the apparent density of the muck inside the chamber. A vertical pressure gradient and an "apparent density" near or less than unit, identified the accumulation of air bubbles within the plenum.

Also the amount of extracted muck is fundamental for controlling the face stability and settlements; consequently an additional balance and one volumetric scanner were installed on the main belt conveyor of each TBM, before the restart. Data from only one of

the balances was used (the 2nd one being for reserve), and the values measured were compared in real time to the theoretical excavation volume, defined as the product of the section area of the excavation per advance speed multiplied by the in-situ density of the material.

The same control was also applied to the scanner measurement for a double check. To control the muck extraction, the TBM operators controlled the rotation of the screw conveyor (proportional to the muck extracted) and the TBM advance speed (proportional to the total excavated quantity of muck), maintaining the face pressure within the range of attention threshold values.

Backfilling around the segments, an important element for controlling surface settlements, was carried out using a longitudinal grouting system composed of 6 double-oval lines. During every excavation cycle, about 6.15–6.5 m^3 (theoretical value as a function of external teeth wearing) of grout was pumped up to a pressure value at the crown 0.5 bar higher than the measured EPB pressure. The quantity of grout pumped was automatically recorded and visualised. Furthermore, for double-checking the grout volume values recorded, a manual measurement of the grout level in the basin has been implemented before and immediately after the single excavation cycle.

3.3 *Monitoring system*

A specific monitoring system was developed in order to get all the required information in real time into a specific database on web-platform (GIDIE – Golder Associates Srl), to understand the soil behaviour and the potentially-affected-structures response during the different excavation phases and to decide for eventual countermeasures.

All the raw data (geotechnical, structural, topographical and TBM's) were stored in the job-site dedicated server, which was accessed periodically by the GIDIE web database for self-updating in order to allow for a real time on-line query by the authorized users (i.e. the Client, the on site TBM Consultants, the tunnel engineers).

In particular, the following measures and data were collected into the system:

Soil behaviour around the excavation area:

19 geotechnical sections with multipoint extensometers, in-place inclinometers and piezometers;

TBM Parameters:

Almost 200 EPB parameters were constantly recorded (every 5 sec) and made available in real time through the web site to the Client and the Consultant.

Real time surface areas and interferences response to excavation:

1. surface railway embankment, existing buildings and structures settlements and movements;

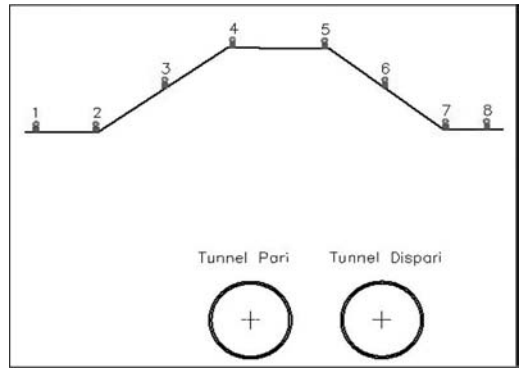

Figure 1. Typical settlement monitoring points through a section on railway embankment.

2. bridges and underpasses settlements and movements.

3.3.1 *Monitoring measurements and alarm levels*

Due to the sensitivity of the urban area above the excavation and in particular of the existing railway embankment, a continuous topographical monitoring system was necessary.

The system was realized through total stations (TS) and topographical prisms installed on the railway embankment, on the buildings and existing structures (bridges and underpasses), potentially affected.

All the measurements were recorded, real time transferred and processed in order to calculate the coordinates for each monitoring point.

Approximately, 150 buildings and infrastructures and 230 topographical sections, spaced at 25 m, perpendicular to the alignment of the tunnels, guaranteed the monitoring of the embankment and the potentially affected area.

Sections with 8, as in Figure 1, or 2 topographical measuring points succeeded one another:

For each tunnel 50 m ahead and 130 m behind the machines' face, the potentially affected area was constantly monitored and all the data automatically downloaded to a web site GIDIE every 3 hrs, with an accuracy of ± 2 mm.

Furthermore, the automatic calculation of Volume Loss (V_p) due to the excavation, according to O'Really and New '82, was performed every 3 hrs. All the data were then analyzed and automatically compared with the predefined alarm levels calculated by the Designer for the different kind of interferences (V_p for topographical sections, differential settlements for bridges and viaducts, distortions for buildings).

For every topographical section the followings graphs and values were automatically visualized on the web site:

– Single point settlements and movements vs. time and TBM advance rate;

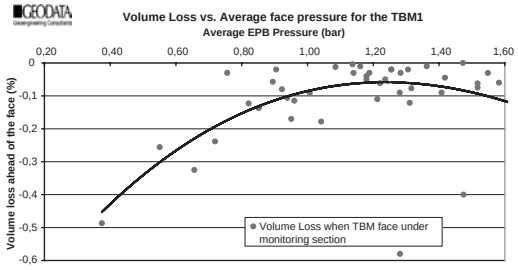

Figure 2. Relationship between Volume loss and average EPB pressure (Volume loss back-analysed from the portion of settlement occurred ahead of the face).

– Volume loss (V_p) vs. time or advance rate;
– Settlement profiles (longitudinal and transversal);
– Geotechnical and structural measurement vs. time.

3.3.2 *Monitoring results*

As a matter of fact, the back analysis of the surface settlements, compared with the excavation parameters, has proven to be the most efficient way to evaluate the response of the ground towards TBM excavation and the interferences of one TBM with the excavation by the other later on.

The excavation control consultant have continuously analyzed the settlements data to correlate volume loss and settlements with the EPB pressure (see Figure 2), taking in consideration also short/long stops.

As shown in Figure 3a, the implementation of stricter TBM excavation controls reduced significantly the settlements to a maximum value of 2 cm and the volume loss to values of about 1,2%, a result absolutely satisfactory considering that most of excavation was performed in granular soils. As already mentioned, even with these stricter controls it was not possible to limit settlements for TBM2 (see Figure 3b) as low as those for TBM 1 because of the stress changes in the ground as result of the 1st tunnel excavation.

3.4 *Compensation grouting operations*

For the excavation of the twin tunnels underneath the railway line in operation, a series of protective measures had to be implemented in order to minimize the effects of the tunnelling operation to the adjacent structures and in particular to railways bridges. These measures comprised of the conventional protection like consolidation grouting, as well as the active settlement control with compensation grouting where the potential damage was relatively high.

One important structure was the railway brick bridge called "Ponte Vecchio" which passes an important inner city street. The bridge spans 2 sections of railway embankment and is 130 m long (9 arches) and the axis of the twin tunnel were about 24 m below ground surface, which yields a cover between the

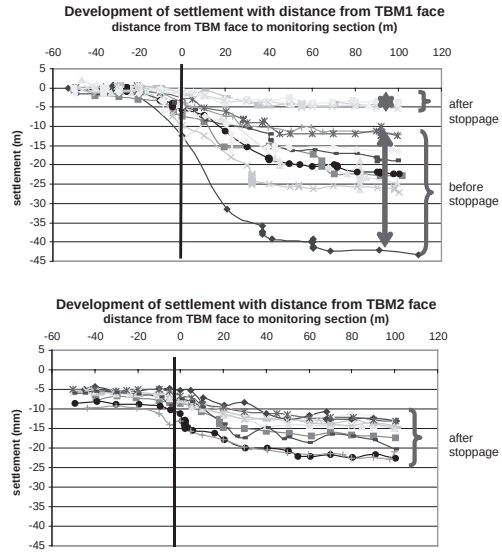

Figure 3. Development of settlements with distance from the face for TBM1: comparison between 1st phase and 2nd phase of the excavation (fig. 3a – top) and TBM2: 2nd phase of the excavation (fig. 3b – below).

footing and the top heading of the tunnel section of about 10 m. The differential settlement between two adjacent piers had to be limited to l/3000, where l denotes the free span of the arch. Moreover, this ultimate limit state has to be covered by a safety factor, reducing the before mentioned limit by another 30%.

As a consequence, the allowed differential displacement between the main arch piers was limited to 5,0 mm, whereas the maximum value for the standard arches was 2,7 mm. Due to these strict limit, compensation grouting was employed, in combination with strict control of TBMs excavation.

A JV of Trevi Spa and Keller Srl were responsible for the compensation grouting. Prior to the arrival of the TBMs, an array of 96 grouting pipes (maximum length of 68 m) in two layers with a spacing of 1,5 m were installed using directional drilling technology, creating a "semi rigid grout cushion" beneath the base of the piers and above the crown of the tunnels (see Figure 4).

The railway bridge was surveyed with a real time hydrostatic levelling system (measurement every 15 min). In order to get a comprehensive view of the deformations occurring on the structure, the hydrostatic levelling system (93 measuring points with a precision of ± 0.5 mm) was arranged at three levels of the bridge, as shown in Figure 5. During the TBMs, passages the differential settlements of the bridge piers were limited controlling the volume and pressure of grout injected through the appropriate

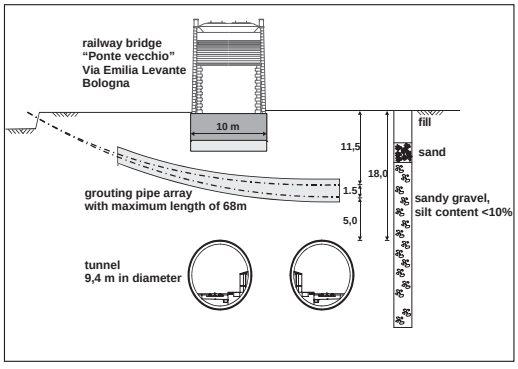

Figure 4. Typical cross section of the compensation grouting.

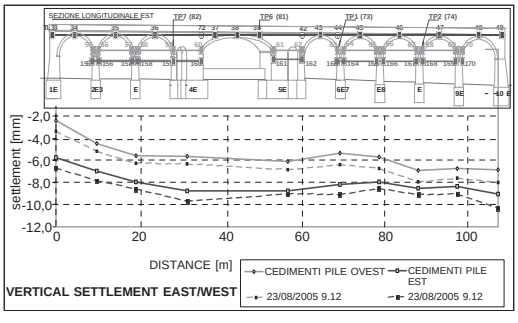

Figure 5. Final settlement profile for the "Ponte Vecchio".

grouting pipes-valves and by rigorously controlling the EPBM excavation parameters.

Continuous monitoring and observation of the settlements and TBM parameters indicated the amount of the lifting using compensation grouting during the excavations. In addition, due to the measured interference of the 1st tunnel on the 2nd one, it was necessary to increase the face pressure in TBM 2 by an additional 0.3bar and to decrease its operational range. After the 2nd TBM excavation, the bridge piers settled by 10 mm maximum with a differential settlement between 2 piers of 2 mm maximum (see Figure 5). The proper use of compensation grouting and excavation parameters demonstrated that settlements of a very sensitive structure could be well controlled.

3.5 *Results and performances*

The average performances of the two machines were 8.2 ring/day = 12.3 m/day (TBM 1) and 9.33 ring/day = 14.0 m/day (TBM 2), taking in account the working days. In the first phase of the excavation, the machines were operated 24 h/day, 5 days/week; the first one was stopped for some time to allow the excavation of the cross-connections by conventional method; the second phase of the tunnel (after the restart in May 2005) was excavated working 24 h/day, 7 days/week, without any planned stoppage (except maintenance and repair).

Best day for both TBMs: 25 rings per day (37,5 m/d)

Best month: 612 m/m for the first TBM (March 2006) and 635 for the second one (April 2006).

Best month for the two TBMs together: 1.182 m/ month in April 2006.

The performance of the two machines during the last three-month reached 3.200 m of twin tunnel!

All the impressive performances were achieved working strictly in EPB mode with the plenum always full of material and under pressure of 1.5 to 1.8 bars at the crown, following the design specifications.

4 CONCLUSIONS

Special technologies have been developed to control the stability of the face and roof of the tunnel in order to minimize surface settlements. The actual application of such technology for achieving the specified goals requires: appropriate ground characterization, risk assessment and development of a risk management plan, appropriate TBM choice, Plan for Advancement of Tunnel (PAT), specific excavation procedures and real time monitoring of excavation parameters and surface settlements.

The experience of the "Nodo di Bologna" construction has demonstrated that following this "design-monitoring-adaptation running method" in one word "the PAT Method", it is possible to control the face stability and the settlements level in urban areas and difficult ground conditions, without any consequences on the machine's performances: on the contrary, the recorded performances have been very near to the best results recorded in the world in similar conditions.

Monitoring of structures and environment under construction and service of underground transportation projects in Russia

V. E. Merkin
Research Center "Tunnels and Metro", JSC TsNIIS, Moscow, Russia

S. N. Vlasov
Russian Tunneling Association

ABSTRACT: Basic tasks of monitoring are formulated. The information on the results of realization of the monitoring program when building large transportation tunnels in Moscow with regard to the state of underground constructions being erected and environment is presented.

In the package of works on construction of underground transportation projects in large towns of Russia the great emphasis is placed on systematic instrumental supervision (monitoring) of actual state of the structures under construction and natural and urban environment.

Such monitoring is aimed at provision of service reliability of tunnels, ecological safety and preservation of buildings and structures near by the tunnels under construction.

Monitoring is designed for definition of the following actual data:

- physical, mechanical and geometrical characteristics of the constructions under supervision and their comparison with the corresponding design requirements;
- components of stress-strain state of the structure, starting from the moment of erection up to stabilization of its loads. This makes it possible to introduce changes operationally into the design decision during the construction process and if the structure is under service to evaluate its carrying capacity reserve and durability and to propose, if necessary, reasoned measures for repair and rehabilitation works, accounting for the detected defects;
- deformation of ground surface, buildings and utilities;
- changes in groundwater level, air and soil composition.

Comparing the monitoring data with their allowable meanings and prediction, emergency situations might be avoided if timely to respond to the dangerous tendencies (to change the tunnelling mode, to take protective measures, etc).

The normative base for solution of the above problems is considered to be specifications for design and manufacture of constructions, being developed for each project, technological regulations, where sequence and methods for work performance are indicated, and a network of observation stations.

According to the recorded observation results of the latter and with consideration of geomechanical prediction, basing on solution of the problem of joint deformation of "underground structure-soil" system, the state and dynamics of stress-strain state change of the lining and soil during construction is evaluated. Besides are specified the range of devices, the places for their installation and measurement intervals.

The works performed on construction of a set of Lefortovo (1990–2002) and Serebriany bor (2003–2007) transportation tunnels in Moscow, designed by Public Joint Stock Company "Metrogiprotrans", may serve as the most obvious examples of full scale realisation of the monitoring program applied for the new projects.

The peculiarity of those tunnels construction was their location in nature reserve and historical areas of the great town, legislatively protected against man caused interference.

So, for construction of transportation lines in those areas was selected the most sparing method among the advanced ones – TBM boring with the use of precast waterproof lining.

To realise such method "Herrenknecht" Bentonite TBM "S-164" and "S-290" were used for construction of transportation tunnels of Ø14.2 m and a service tunnel of Ø6.28 m respectively.

Accounting for particular engineering and geological conditions of the tunneling route and the

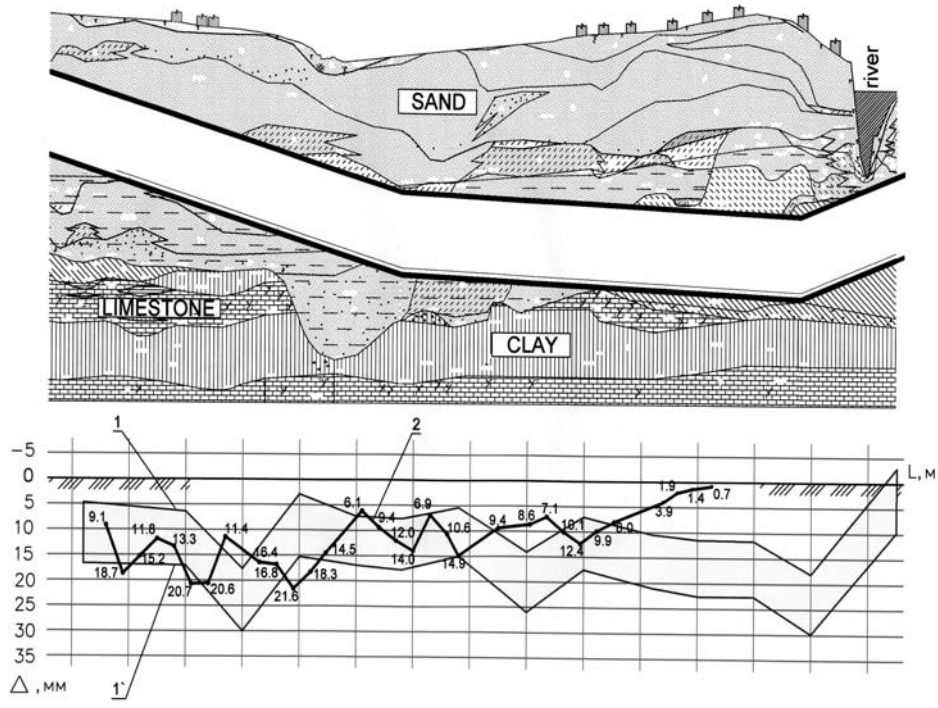

Figure 1. Design (1, 1′) and actual (2) surface settlements under construction of Serebriany bor tunnels in Moscow.

capabilities of TBM and on the basis of geomechanical calculations probable deformations of the soil massif were predicted, among them settlements of surface and bases of buildings and structures, located within the zone of tunneling works effect.

On the basis of such prediction and available results of primary inspection (before the construction start) on the state and ultimate allowable deformations of the structures under operation engineering measures were taken, if required, to ensure their safety (Figure 1).

The calculations assume that soil shift under bentonite shield tunnelling takes place due to size difference of the excavation and the lining to be erected with consideration of partial (pessimistic prediction, 1′) or complete (optimistic prediction, 1) filling of the generated gap by grouting mortar (see the design scheme in Figure 1).

Later on after tunneling of the first 150–200 m that prediction was corrected, accounting for actual measured settlements, which made it possible to raise significantly the prediction accuracy, to specify precisely the face pressure and, in some cases, to reconsider the measures designed for preservation of on-surface structures and utilities.

At present it can be already stated that the adopted technological decisions and work practice and procedures in combination with operational analysis of monitoring data have resulted in driving of Ø14.2 m tunnels by means of "Herrenknecht" bentonite shields with mean advance rate of 8–10 m per day under minimal (not more than 12 mm) surface settlement without emergencies and environment effects.

Measurements in the tunnel have also revealed a certain reserve of lining carrying capacity and showed that the influence of the moving shield on the forces in the lining had been recorded at the length from 100 to 150 m depending on the soil type and route curvature (Figure 2).

When constructing tunnel sections by cut and cover method, the data on the developing deformations of the cut enclosure structures were analyzed and compared with the data, obtained by "PLAXIS" program. As a result their failure has been prevented due to timely installation of additional braces. Besides, surrounding buildings and near by utilities have been saved due to soil strengthening by cementation.

The main task in the process of construction of various infrastructure projects (buildings, underground car parks and utilities) not far from the operating metro lines is to exclude or at least to bring to allowable minimum the construction effect on stress-strain state of the tunnel lining. So, before the work starts there shall be carried out inspection of the actual tunnel condition. The degree of its carrying capacity compliance (with

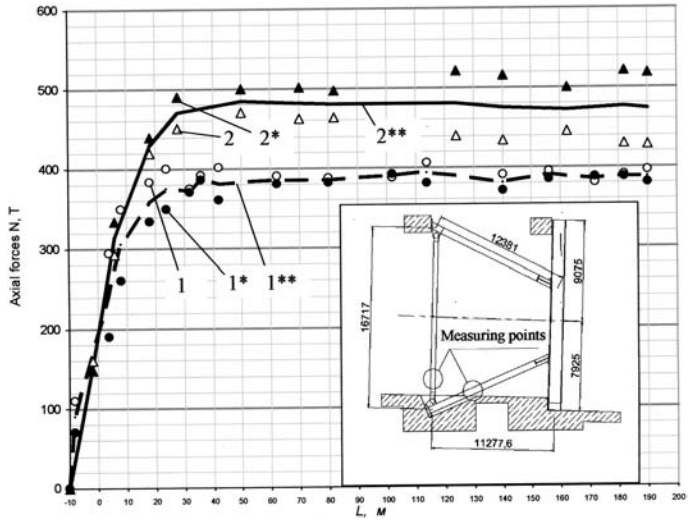

Figure 2. Forces in braces of start trust frame under TBM traveling.
1,1* and 1** – forces in the left brace, in the right brace and mean value in braces of Lefortovo tunnel, respectively.
2,2* and 2** – forces in the left brace, in the right brace and mean value in braces of Serebriany bor tunnel, respectively.

consideration of recorded defects) with the supposed effects of the new construction being defined, special protective measures shall be recommended.

In most cases they comprise compacting and filling cementation of voids and unpacked soil behind the lining, detected by geophysical methods, and monitoring of stress-strain state of metro structures during new construction. Monitoring is in particular stated in the metro instructive documents as the required control element for observance of agreement conditions with regard to the new construction project.

Operational information data on the compliance of the changes recorded in the tunnel state with the metro requirements, for example on permissible deformations of the lining and rail track in the tunnel, are considered to be the criteria for evaluation of the construction effectiveness.

Our large experience gained has proved the necessity in the above mentioned works. Thanks to the latter not only emergency but any extraordinary situations during underground construction in Moscow have been avoided.

Geotechnical monitoring of the excavation exploratory galleries for the Dobrovského Tunnel in Brno

D. Rupp & J. Pavlík & L. Klímek
GEOtest Brno, a.s., The Czech republic

ABSTRACT: Constantly unacceptable high density of traffic in Brno urgently requires relief in terms of large traffic structures. As part of the constructed Large City Ring Road in Brno, the cut – and – cover Husovický tunnel and mined Pisárecký tunnel on the highway feeder Prague Radial Road already been constructed. Preparation of the third structure – the Dobrovského tunnel has finished. The future tunnel construction what to be started this year.

Three exploratory galleries were completed in August 2003, whose purpose was to find optimal technology of excavation as well as total design solution of the construction.

Object of the exploration was the tunnel route consisting of two tubes in lengths of app. 1250 m from which more than 1000 m fall on the mined part. Commission for the exploration estimated the excavation of three exploratory galleries with approximately triangular cross section in the area of tunnel tubes at the bases of their vaults, which will be used during the future construction of the tunnel structure.

Geotechnical monitoring consisted of the measurement of gallery convergence, of deformation of rock mass during excavation of the galleries both in boreholes, both on the surface and pressure in lining. Geotechnical monitoring has continued even after finishing of the excavation to the present days.

Article evaluates results of the measurement during the excavation of the galleries and after excavation to the present days. Realized monitoring activity proved the possibility of construction of the designed tunnel structure and set the conditions for the design intent to be accomplished.

1 INTRODUCTION

Geotechnical exploration of the Dobrovského tunnel and engineering-geological conditions in the locality are described in the article "Geotechnical Exploration for the Dobrovského Tunnel in Brno" in section 2.

Excavation of exploratory galleries and geotechnical monitoring were done after completion of engineering-geological investigation. A consortium of companies Štoly Dobrovského was delegated to be the general contractor of the geotechnical exploration. It consisted of GEOtest Brno, a.s. – leader of the consortium guaranteeing the exploration results, and three construction companies Metrostav, a.s., Subterra, a.s. and ŽS Brno a.s. responsible for excavation of the galleries and connected engineering works.

Three exploratory galleries were completed in August 2003, whose purpose was to find an optimal technology of excavation as well as total design solution of the construction. The purpose of realization of the exploratory galleries and connected exploratory works are presented in the mentioned article in the section 2.

2 GEOMONITORING

Extensive geotechnical monitoring, realized both galleries and from surface in locations of the concentrated exploration was an integral part of the exploratory works. Four groups of geotechnical boreholes were installed in area of the IIB gallery in the line of the tunnel II and two groups of boreholes for geotechnical monitoring were installed in vicinity of the IB gallery (tunnel I).

Extensometric boreholes, observing vertical deformation of the massif in three depth levels based on distance from the face, were located in the tunnel axis. Original measurement was realized sufficiently in advance, still in times when the approaching excavation had no impact on the extensometer. The own measurement consisted of both manual measurement of distance between the extensometer anchors and its head and geodetic measurement of height of this head. Deformations of the lowest anchors, installed in the level of 0.5–1.0 above top of the calotte, after elimination of the surface settlement reached values of 5.0–29.5 mm based on geology and vicinity of the adjacent gallery.

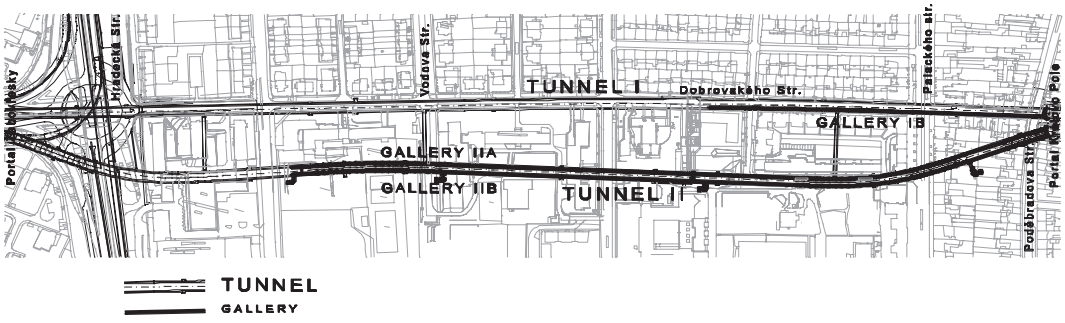

Figure 1. Exposure of galleries and designed tunnels in urban area of Brno.

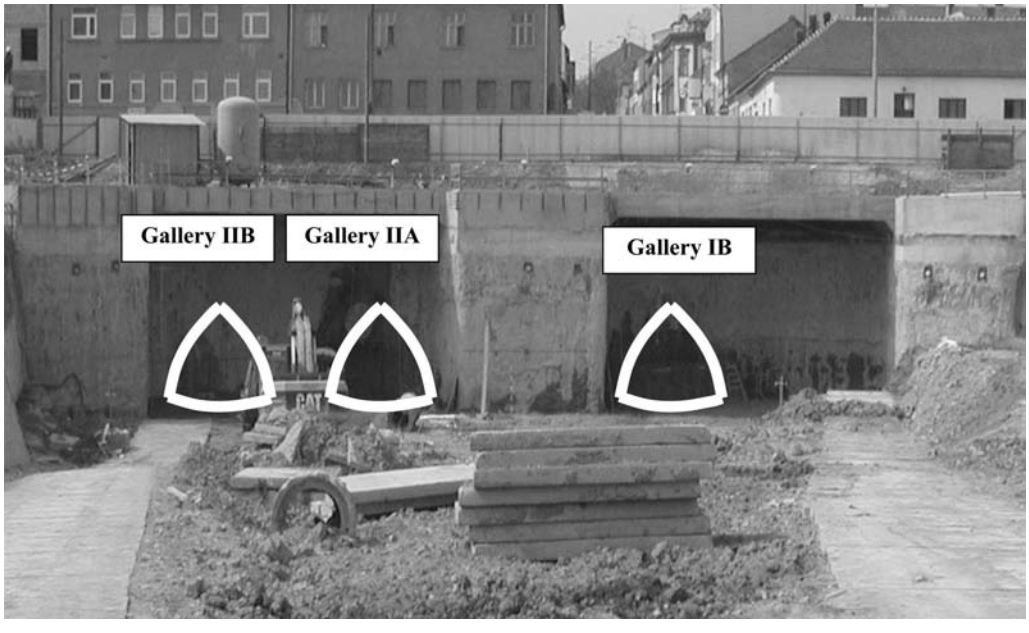

Figure 2. Schematic view at the mouth of the exploratory galleries in the provisory portal Královo Pole.

In distance of 1.0–1.5 m from lining, bores for precise inclinometry were carried out to observe vertical movements of the massif. Bore depths were designed for the measurement to encounter those parts of the rock massif where deformations are expected in connection with realization of the exploratory galleries, but also of the future tunnel tubes. Schematic position of the monitoring boreholes is shown on the Figure 3.

Vertical deformations reached, upon passage through the gallery and subsequent settling at the level of the underground work, values between 4.5–13.0 mm. Curves of vertical movement proved that even in depth of 23 m below the gallery floor the deformations are not yet entirely settled, which was

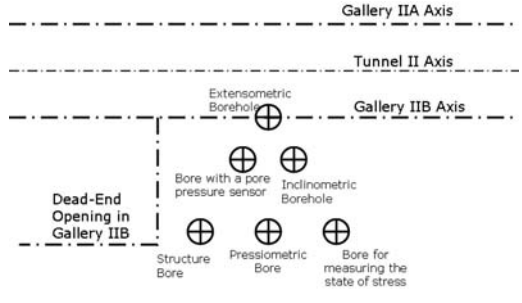

Figure 3. Schema of the position of the monitoring boreholes.

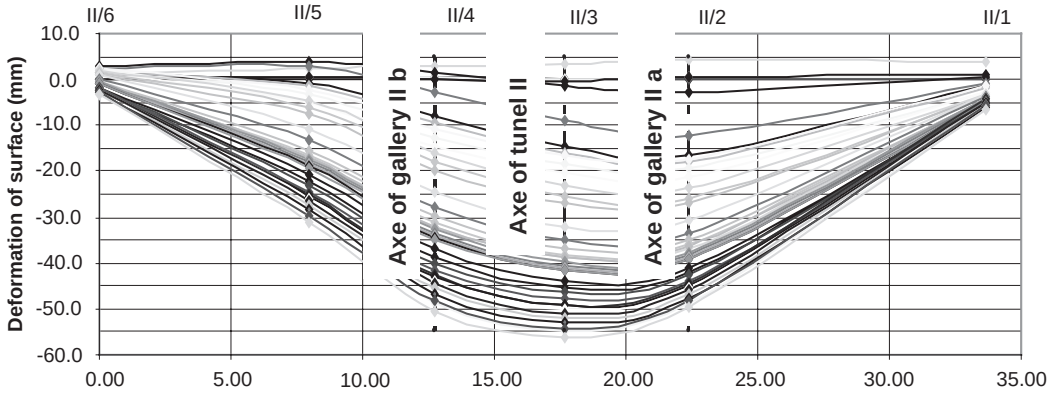

Figure 4. An example of deformation of surface.

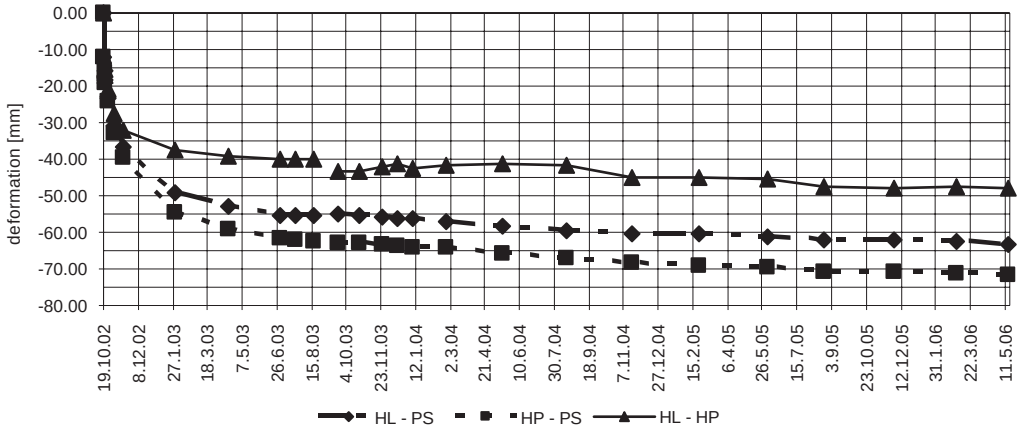

Figure 5. An example of results of convergence measurements.

obvious from the curves of deformation running from bore bases.

Close to the gallery lining, three bores were installed to measure changes in pore pressure we installed in bores in depth, where the floor of the exploratory gallery during the passing excavation was at the time. From the measurement was an apparent large decrease of pore pressures at the time of the passing gallery to less than 10 kPa.

Nets of bores for the geotechnical monitoring remained intact for future use within the frame of fully-profile excavation of the tunnel tubes.

The aforementioned measurements, realized by employees of Stavební geologie Praha, a.s., meant to analyze behavior of the rock massif based on passing of the underground work. Frequency of the measurement changed with approaching and retreating of face of the exploratory gallery to and from the measured bores.

Size and shape of the settlement through were observed from surface. Bores of depth 0.80 m served max) for stabilizing of points of precise leveling, which formed a network of profiles running perpendicularly to gallery axes. Vertical movement of points was measured based on the passing face of the gallery below profiles. These measurements were realized by INSET, s.r.o.

Monitoring in the galleries was mainly focused on the observation of deformations in the lining and leveling. Convergence profiles, which observed the mutual movement of three points, were equipped every app. 150 m. Leveling measurements of convergence profile points and profiles stabilized by surveyors that serve for guidance of the work were measured between 20–40 mm, in extreme cases, for instance given by unfavorable geology in initial sections of the excavation, up to 85 mm. As for leveling measurement of the lining, attention was focused namely on heaving of center of the floor (35 mm and settlement of bases of the mining support frames (app. 10 mm).

Sensors of pressure on the lining were installed behind the lining in three profiles so called pressure cells. The cells were installed at selected places as a contact between the rock and lining. The sensors, which submitted relevant values, recorded the increases of pressures behind the lining upon moderation between 120–400 kPa. Convergence measurements and measurements of pressure on the lining were commissioned by SG Geotechnika, a.s. geodetic measurements were carried out by employees of the measuring department of GEOtest Brno, a.s. and IGM s.r.o.

From the measured processes of length changes, observed by the convergence measurement and vertical movements, analyzed by the leveling measurement, it was possible to determine the progress of these movements in future. During the convergence movement, approximation of wall centers and the floor were observed – the following charts show observed lengths characterized as lines between the points designated HL – point in central section of the left-wall reinforcement, HP – point in central section of the right-wall reinforcement and PS – point on the center of the floor reinforcement. During the leveling measurement, vertical movements were observed beside the previous points also in the floors points at its ends. From these measurements it was possible to calculate inflexions of the floors (difference between measured movements of the floor center and average of measured movements at its end) and total movements of the gallery profile as an average of measured movements of centers of the reinforcing elements.

It was discovered that upon diminution of impacts of the proceeding excavation (advance of the face by 5–15 m from the measured profile), or of excavation of an adjacent gallery, deformations generally settled exponentially. Therefore, result of the measurement allowed determining regression of the deformation on time. Coefficient of the curves and final curves were determine by calculation using step-by-step approximation of the reliability coefficient to one, which was the quite a few times the case for the convergence measurement – measured values of the prediction interval thus lied directly on the curve of the theoretical deformations.

3 EVALUATION OF RESULTS OF THE GEOTECHNICAL MONITORING

As results of the realized exploratory activity and geotechnical monitoring showed, the tunnel structure will be excavated in an environment of overconsolidated Neogene clays with specific attributes that need to be respected during the design of its

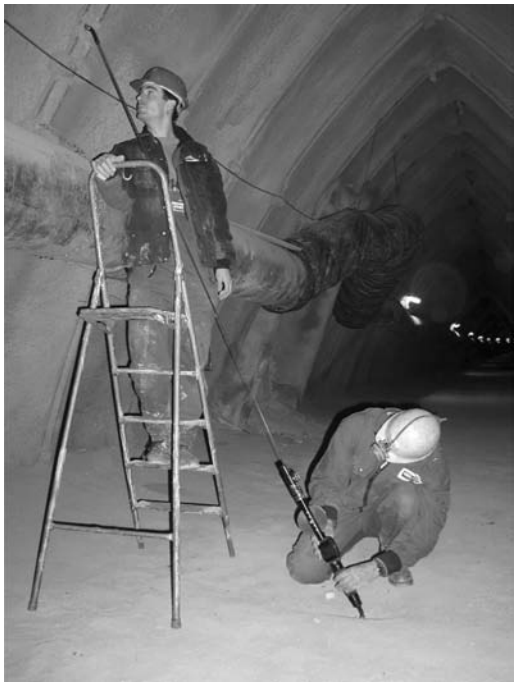

Figure 6. The convergence measurement in the exploratory galleries.

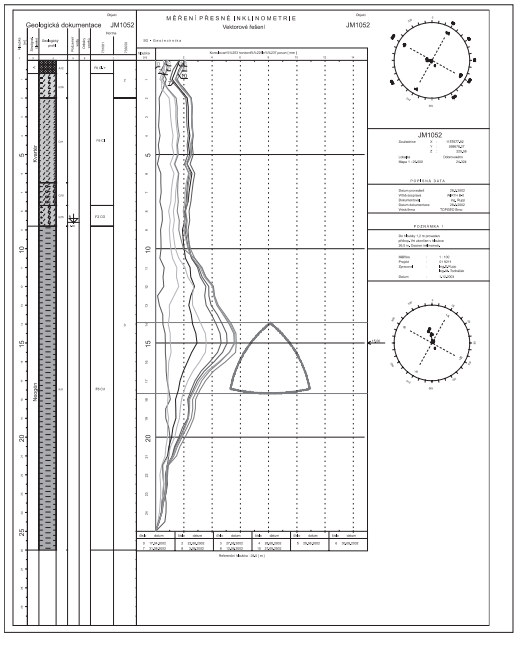

Figure 7. An example of results of inclinometric measurements.

dimensions as well as during the technology of realization. This environment is marked by relatively low strength, high contraction, slow creep and volume modifications due to changing water amount.

There is very positive factor in very low permeability of the clay massive, and therefore running groundwater will be unfavorably affecting the excavation only in sections adjacent to the exit portal, where the cut penetrates into Quaternary rocks. Nevertheless, the clay massive holds some water, which is discharged from the massive after longer disburdening by the excavation otherwise not secured by non permeable lining along the entire periphery. The described phenomenon was observed in most test galleries as well as those galleries where front bases of the lining experienced damp places.

4 CONCLUSION

The monitoring of behavior of rock massif during excavation of the exploratory galleries and three years after its finishing showed, that deformation of surface and underground openings had developed after assumption of the project. The results of the realized measurement thus proved possibility of construction of this designed tunnel as the significant transport structure very important to the life in the city of Brno.

An optimised monitoring of critical buildings adjacent to tunnel construction in urban area

S.H. Shin, C.Y. Kim, K.Y. Kim, K.S. Jue & S.W. Hong
Korea Institute of Construction Technology (KICT), ilsan-Gu, Gyunggi-Do, South Korea

ABSTRACT: This paper presents a new strategy for determining an optimum position of monitoring point and criteria with which judgment is made if the settlement values at the point are critical or not for a significant structure adjacent to tunnel construction. The position and criteria are differently given to each structure by considering its geometry and exact position. It is unlikely to the conventional monitoring scheme undertaken by a fixed criterion applied at certain monitoring points that are also intuitively placed. The strategy proposed is based on an iterative scheme by incorporating the so-called Intelligent Tunnelling Information System (ITIS). Details of the iterative procedure are described with an illustrative example. In the example, the settlement criteria at three different damage levels are given at an optimum monitoring point.

1 INTRODUCTION

A number of urban tunnel constructions take place as the social demand for public transportation increases, in which the major concerns would be not only for safety of tunnels itself but also for safety of adjacent structures to the tunnels. The safety of the adjacent structures is subject to ground movements due to tunnelling. Intensive studies have been made to date in this topic (KICT, 2000; Kim et. al., 1998; Son, 2003). In general, a prediction of ground movements and potential damages of the adjacent structures are carried out, in which a number of damage parameters such as angular distortion, deflection ratio, etc. are involved (KICT, 2000). Monitoring on the adjacent structures is also undertaken for evaluating their damages during tunnel construction. The number of monitoring points might be limited because of economical reason, etc., at which ground settlements and tilts would be monitored periodically.

In the circumstance, a new strategy is proposed for determining an optimum location of monitoring point as well as evaluation criteria at various levels for assessing the monitored values of settlements. Such information is given for individual structure independently. The strategy is based on an iterative procedure of assessing the structures with respect to the gradually increasing ground settlements in various steps, which are automatically performed considering the exact location, geometry and mechanical properties of individual adjacent structure. An illustrative example for showing how the proposed strategy works is given.

1.1 *Typefont, typesize and spacing*

Use Times New Roman 12 point size and 13 point line spacing (Standard;text tag). Use roman type except for the headings (Heading tags), parameters in mathematics (not for log, sin, cos, ln, max., d (in d*x*), etc), Latin names of species and genera in botany and zoology and the titles of journals and books which should all be in italics. Never use bold, except to denote vectors in mathematics. Never underline any text. Use the small font (10 points on 11 points) for tables (Table tags), figure captions (Figure caption tag) and the references (Reference text tag).

Never use letterspacing and never use more than one space after each other.

2 STRATEGIES PROPOSED

2.1 *Determination of an optimum monitoring point*

With limited number of monitoring points, an attempt is made to determine an optimum monitoring point at which a maximum settlement may take place. The strategy is based on an iterative scheme. Considering a 3D trough of ground settlements, the shape and quantities of the trough will vary as the tunnel goes ahead. The deformation of the structure will progressively grows up, thereby leading to progressive change of its structural damages at certain levels. The progressive deformation of the structure can be check up by automatic calculation of 3-D settlements at the foundations of all the columns of the walls consisting

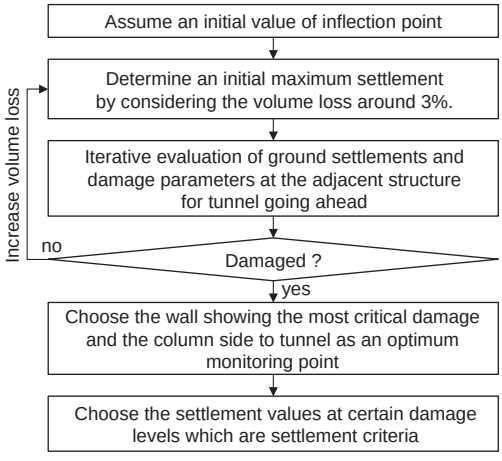

Figure 1. Plane view of the tunnel site concerned.

of the structure. From the results, conventional damage parameters of all the walls can be calculated at every stage of tunnel progresses. The theoretical background on the 3-D settlement trough and ITIS can be found in the literature in details (Kim, 1998).

A schematic diagram for determination of an optimum monitoring point is given in Figure 1. Based on the damage parameters for the walls calculated, one of the walls, which shows the most critical values at several excavation stages, can be chosen and then a column of the wall side to tunnel would be a suggested monitoring point for the structure. In progressive prediction of the deformation of the structure, initial values for a maximum settlement and inflection point, which are involved in 3D equations of the ground settlement trough (Kim, 1998), should be required *a priori*. The values will be arbitrarily chosen which should be big enough to make at least one of the walls damaged on purpose. An inflection point can be determined by a ground loss which is in general 1%∼3%. However, bigger values of the inflection points from assumption of about 6% ground loss, are fixed first in this study. Then a big maximum settlement of about 100∼200 mm is applied for the automatic progressive calculation of settlement tough. It is noted that the chosen values should be confirmed to be insensitive to determination of the monitoring point. This aspect has been confirmed by a number of verification tests that, however, is not given in this paper.

2.2 *Giving settlement criteria to the optimum monitoring point determined*

As shown in Figure 1, settlement criteria can be given to the optimum monitoring point determined by the manner addressed in previous chapter. A variety of the existing evaluation charts could be involved for the purpose (Son, 2003). In this study, the evaluation charts by lateral strain vs. angular distortion (Boscardin & Cording, 1989) is used, on which a number of line plots for all the walls under consideration can be made through all the progressive stages. One of the lines that reaches first to the boundary between the damage levels given in the Boscardin' chart can be easily determined by ITIS. On the line determined, the settlement value at the calculation stage of reaching to a boundary between damage levels becomes the settlement criterion at the damage level within the boundary. Note that settlement criteria at certain monitoring point of an adjacent structure vary depending on its geometrical characteristics and lateral distance from tunnel axis.

3 ILLUSTRATIVE EXAMPLE

The strategy proposed here was applied to the design stage of the Ban-Song Subway Line. Attempts for giving an optimum monitoring points as well as evaluation criteria at different damage levels has been made for total 18 significant buildings adjacent to tunnel construction. By page limitation, only an application case is given in this paper. The plane view of the tunnel site is shown in Figure 2, in which the building concerned in this paper is located on the 11th section in Figure 2. A brief field description at location of the building is given in Table 1.

First of all, the settlements parameters such as maximum settlement and inflection point and damage parameters of the building are predicted for safety evaluation by using ITIS system (KICT, 2000). The prediction is made by a neural network trained from a number of field monitoring data available in the system. The settlement parameters predicted are given in Table 1. The location of the building and variation of the damage parameters of its walls through construction stages are also shown in Figure 3.

As shown in Figure 3, all of the damage parameters predicted by the tunnel passed through seems to be within a safe domain so that no structural damage may take place. The 3D view of the damage assessment is also shown in Figure 4. Herein, the colours on the walls represent the level of damage parameters predicted for the walls, all of which are in safe range. However, the building is crucial for this site so that it is needed to place a monitoring point on the building for confirming the safety throughout tunnel construction.

By the strategy mentioned in previous chapter, another set of settlement parameters is assumed in which the settlement parameters are determined at around the ground loss of 6%. Then, the iterative calculation of ITIS is carried out again checking up the damage parameters varying on an evaluation chart. As a result, damage parameters of the 6th wall shows the

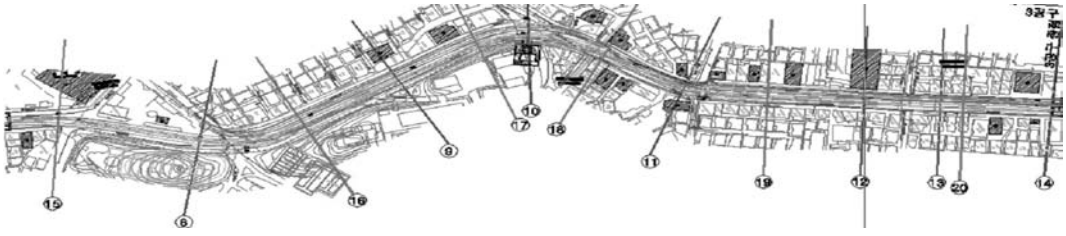

Figure 2. Plane view of the tunnel site concerned.

Table 1. The predicted and assumed settlement parameters with brief field description.

Tunnel depth	Water level	Pattern no.	Maximum settlement predicted	Inflection points predicted	Ground loss predicted	Maximum settlement assumed	Inflection point assumed	Ground loss assumed
15.71 m	6.23 m	PD-3A	15.1 mm	14.5 m	0.926%	100 mm	14.5 m	6.132%

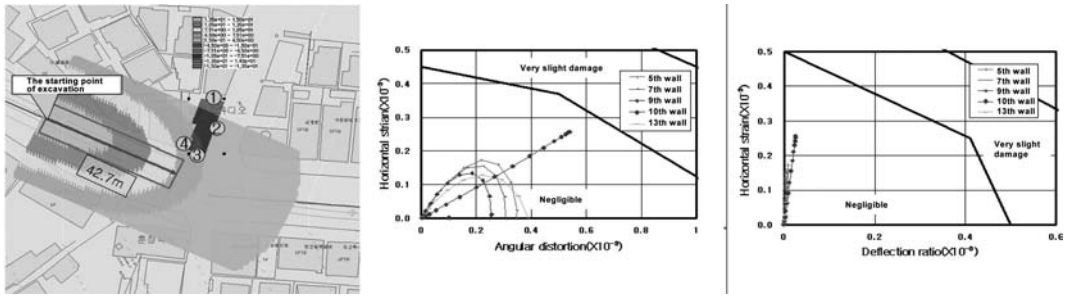

Figure 3. An adjacent building concerned and progression of damage parameters calculated.

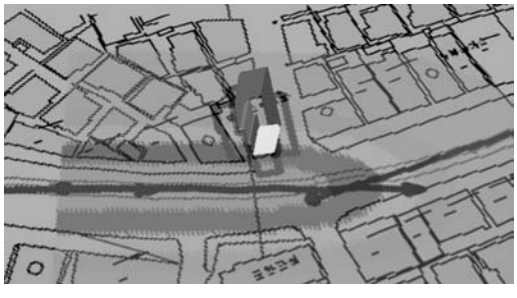

Figure 4. 3D view of damage assessments by ITIS.

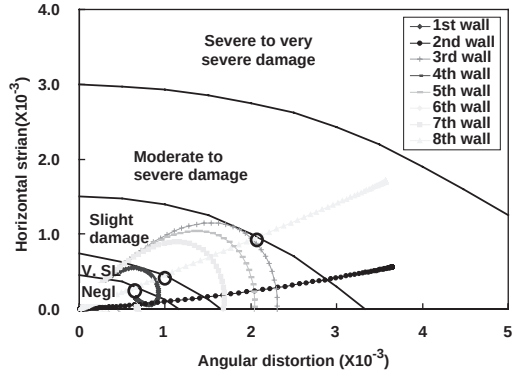

Figure 5. A chart used for determination of settlement criteria.

most fast progress as shown in Figure 5 so that the column of the wall side to tunnel is decided as an optimum monitoring point which can be seen in Figure 6 as an example. In addition, the ground settlements of the column are picked up at the stages circled in Figure 5. The stages are on boundaries between different damage levels. In this case, three settlement criteria have been given at three different levels of structural damages. The settlement criteria decided are 15.1 mm, 23.67 mm, 54.37 mm at damage level I, II, III, respectively. The damage level I, II and III represent to be very slightly damage, moderate to severe damage and severe to very severe damage, respectively as shown in Figure 5.

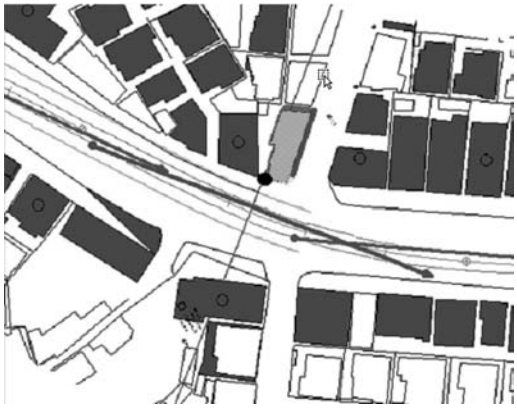

Figure 6. An optimum monitoring point determined by the proposed strategy.

4 CONCLUSIONS

This paper proposed a strategy to determine an optimum monitoring point and settlement criteria at the point for significant structure adjacent to tunnel construction. The criteria will be used for making an engineering judgement on deformation of the structure monitored at several levels of damages. It can be seen in the scheme that the strategy allows us to minimise installation of monitoring points but not to miss any severe symptoms of structural damages taking place on the structure. To date, monitoring point has been installed intuitively at which the same settlement criteria have been applied, even if the same settlement at the monitoring point can lead to the different damages on the wall. Therefore, the settlement criteria should be decided based on the damage parameters expected. As the damage parameters will depend on geometry and position of the adjacent structure, it is reasonable to give settlement criteria differently for each structure by taking into account the geometry and position of the structure which are achieved by the strategy proposed in this paper. An illustrative example has been given to show how to achieve the purpose. Moreover, more verification of the strategy and field application will be made, which will be reported again in future.

Zemtas A. S., Ankara, Turkey

ABSTRACT: A shallow urban tunnel has been constructed with conventional method at a residential area in Black Sea Region of Turkey. The excavation and support measures of the tunnel were designed considering soft rock conditions (highly weathered tuff-agglomerate) from site explorations. An extensive monitoring plan was performed to control the design considerations, interaction of the tunnel construction with surrounding structures and influence of the new tunnel excavation on the old tunnel under traffic. During the excavation near to the west portal of the tunnel, deformations and cracks were recorded at the ground surface, fortress masonry walls and one storey buildings inside the fortress area. By evaluating geological documentation, monitoring data and other records such as water discharge measurement, the mechanism of the instability problem was analyzed and required measures were determined. The measures comprised mainly grouting application in limited areas to prevent developing of the instability problems. This paper contains analyzing of data during the tunnel excavation and countermeasures to avoid adverse influence of the tunnel excavation.

1 INTRODUCTION

Design and construction of a shallow urban tunnel requires special considerations due to several reasons. During the determination of the alignment and site investigations local factors limit extent and quality of site investigation data. Changes in stratification and properties of layers in short distances are not unexpected facts. Empirical and analytical solutions or numerical modeling provide tools to determine support measures, predict deformations due to tunneling induced ground movement; surface, subsurface settlement, lateral deformation of the ground, longitudinal movement of the ground ahead of the tunnel face. However the prediction of those values depends on the quality of input data. Due to the nature of shallow tunneling, change in situ stress and hydrogeological conditions bring higher influence on surface buildings.

Design considerations should be checked during the construction with monitoring of both subsurface and surface movements, impact on nearby buildings and services. Geotechnical monitoring capabilities both at surface and subsurface provide early detection of negative effect of tunneling on nearby structures and taking measures on time. Improvements in evaluation methods suggested by Sellner et al 2004 and measuring devices such as chain inclinometer installed to the pipe roof systems explained by Volkman & Schubert 2006 increase those capabilities.

Figure 1. View from the west portal.

Kalepark Tunnel is a typical shallow urban tunnel with a maximum overburden of 21 m in a residential area. Tunnel with three lanes was planned to construct at a distance of 30 m from the axis of the old tunnel due to the traffic requirements (Figure 1).

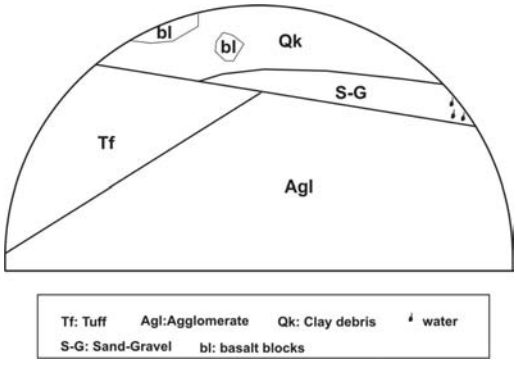

Figure 2. Face mapping from km: $0+549$.

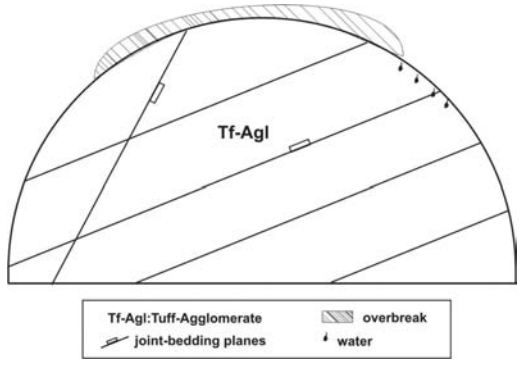

Figure 3. Face mapping from km: $0+567$.

Site investigation works consisting limited boreholes and geological mapping of outcrops could be realized and tunnel design was performed accordingly. Tunnel excavation was designed as sequential excavation; top heading, bench and invert. Support system includes fibre reinforced shotcrete, steel ribs, rock bolt, forepoling, shotcrete and rock bolting at the face if required Due to the high expenses for nationalizing works, structures with historical importance and varying types of buildings around the tunnel area, geotechnical monitoring and evaluation gained importance.

2 GEOTECHNICAL DESCRIPTION

The rock at the tunnel area is highly weathered tuff and agglomerate. Tuff and agglomerate is overlaid by clay debris containing basalt boulders. A layer of loose sand-gravel is encountered between tuff-agglomerate and clay debris at the first 25 m from the west portal. Highly weathered and water susceptible tuff-agglomerate has low strength. After 25 m advance from the west portal, tuff and agglomerate shows bedded structure. The bedding planes contain clay and calcite filling and rock mass is highly fractured. The water level was encountered at 10.5 m below the ground surface in the boreholes at the design level. During the tunnel construction the water income from the loose sand-gravel layer at the shoulders was observed as leakage in the first meters of the tunnel excavation. Water discharge increased with the tunnel advance. The rock mass conditions encountered during the top heading excavation are shown in two representative face mappings from km: $0+549$ and $0+567$. At km $0+549$ clay debris and loose sand-gravel layer were encountered at the upper part of the top heading. Water inflow from the sand-gravel layer resulted in overbreak at the shoulders (Figure 2).

At km: $0+567$ tuff and agglomerate at the face is highly fractured. Overbreak was observed at the crown. Water inflow from the right part of the face has a discharge rate of 0.4 lt/min (Figure 3).

3 MONITORING AND EVALUATION

An extensive monitoring program was performed both at the surface and inside of the tunnel. Measuring station in tunnel was established with a distance of 5 m and absolute measurements at five points in cross section were recorded during the construction. Before the construction, structures were examined; their type, actual condition and position relative to the tunnel were recorded.

The structures in a determined zone in portal area were nationalized. Topographic measuring stations at the ground and buildings were established. Strict acceptable limits for settlement values (absolute, differential settlement, rotation) were not determined due to varying characteristic of buildings such as reinforced concrete multistory buildings, masonry fortress walls etc. Extensometers were planned to set according to topographical measurement results.

When top heading excavation arrived km: $0+570$, cracks were recorded at the ground surface, fortress walls and one storey buildings inside the fortress area. Figure 4 shows measuring points at the ground and fortress wall, position of the structures and fortress walls relative to the tunnel and recorded cracks.

To evaluate the mechanism bringing failures at the ground surface and structures, the displacement measurements inside the tunnel, crack development and deformation measurements from surface stations were evaluated with combination of tunnel advance data and water discharge rates. The displacement amounts in the tunnel are less than 1 cm and no failure was observed at the support elements; no cracks at the shotcrete or sign of overloading in rock bolts.

The measurement result showed that the deformations at the ground surface and fortress wall increased with increasing discharge rate. Considering the

Figure 4. Plan view from west portal area showing measuring points, cracks and grouting areas.

deformation graphs and geological structure from face and surface mappings it is concluded that high water discharge due to tunnel excavation cause immediate settlement at the granular material. Tunnel support had required capacity to carry the additional load due to this fact. However masonry structures are sensitive to these movements and cracks occurred.

Damage in the masonry walls and buildings were evaluated according to the classification of visible damage of structures suggested by Burland 1995. The crack widths at four measuring stations were measured as 4–20 mm (Figure 6, Figure 7, Figure 8, and Figure 9). Typical crack widths of the masonry walls were 15–25 mm and classified as category of damage- 4, normal degree of severity-severe.

Because no other failure is observed in nearby structures and inside the tunnel, required measures were determined to rehabilite the structure and strengthen the foundation by cement grouting. This solution is also to prevent development of the failure with bench and invert excavation.

4 REMEDIAL MEASURES

Grouting application with vertical and inclined boreholes was planned in three zones (Figure 4). Location, inclination and extend of the grout holes were

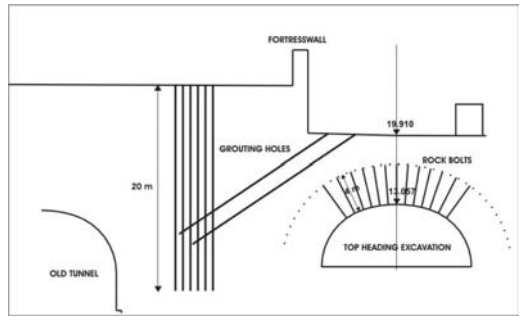

Figure 5. Grouting application at km: 0 + 560.

determined according to the crack measurements, position of the old tunnel, bolted area around the new tunnel, fortress wall and the buildings (Figure 5).

The benefits of the grouting were:

- to fill voids in formation,
- to increase resistance against deformation,
- to supply strength,
- to reduce conductivity,
- to control ground water table and seepage.

0.5 m*0.5 m square pattern is designed. But during construction according to monitoring records this pattern could be revised.

In cement grouting, the following principles are considered:

- Grouting is applied in 2 m levels
- Applied pressure (bar) is calculated from the following equation:

$$P=0.23*H \quad (1)$$

where H: distance between top of borehole and middle of each level (meter)

- Water cement ratio was decreased from 3:1 to 5:7 in stages. At the last stage sand (5%–20%) was added to the grout mix.

At Station A in Zone 2, crack width on the fortress wall was measured 20 mm before the grouting application within a month. Grouting at that region was completed in the next month. The deformation rate decreased during ground improvement and 5 mm deformation was recorded. After the completion of the grouting at that area no further deformation was detected (Figure 6).

At Station B in Zone 1, crack width on the fortress wall was measured 4 mm before the grouting application within 13 day period. During grouting lasting 19 days around Station B the deformation rate increased and deformations arrived 11 mm. After the completion of the grouting at that area deformations at Zone 1 stabilized (Figure 7).

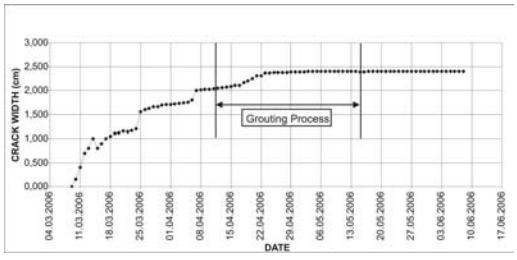

Figure 6. Crack width measurements from Station A.

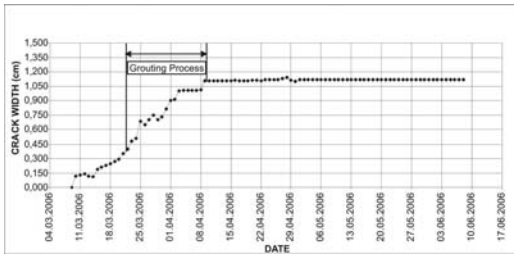

Figure 7. Crack width measurements from Station B.

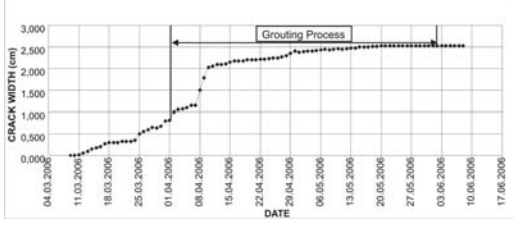

Figure 8. Crack width measurements from Station C.

At Station C in Zone 3, crack width on the fortress wall was measured 8 mm before the grouting application within 3 weeks. Due to the large size of that area grouting took 2 months. A sudden increase of 10 mm was recorded after start of the grouting. At the end of the application deformations was 25 mm. Stabilization of the deformation was achieved with grouting (Figure 8).

At Station D in Zone 1, crack width on ground surface was measured 4 mm before ground improvement within 2 week period. Grouting took 10 days near this Station. Similar deformation rate was observed during the grouting process. At the end of the grouting deformations reached to a final magnitude of 7 mm (Figure 9).

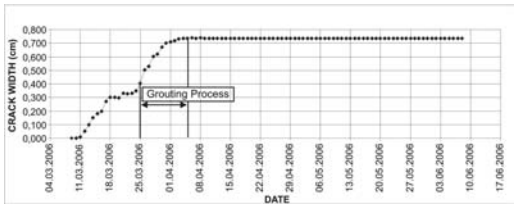

Figure 9. Crack width measurements from Station D.

Grouting was applied in three distinct zones to stabilize deformations on the fortress wall and ground. A close pattern of grout holes were applied. The success of the ground improvement was checked with the measurement of the crack widths at the measurement stations.

5 CONCLUSION

Due to characteristic of urban tunnels (soft rock/soil conditions, low overburden, groundwater level, nearby structures and services), monitoring of tunnel induced movements at the ground surface and buildings, change in ground water level are necessary to control negative influence of tunnel construction. Monitoring results should be analyzed with tunnel advance data and geological documentation to evaluate the mechanism of tunnel induced movements and failures at the surface. The measures to stop or limit deformations at the surface can be determined as stages. The effectiveness of the measures can be evaluated by continuous monitoring during all stages. The measures can be taken inside the tunnel or at the surface. For an economical solution type and extend of the measures should be determined considering failure mechanism.

Longitudinal surface settlements induced by EPB tunneling in Bangkok Clay

S. Suwansawat
Department of Civil Engineering, Faculty of Engineering
King Mongkut's Institute of Technology Ladkrabang, Thailand

ABSTRACT: This research studied extensive data on ground surface settlement and shield operation collected at the MRTA Bangkok project where eight Earth Pressure Balance (EPB) shields were used. It was found that three distinct zones of longitudinal surface settlement were observed irrespective of soil conditions. Zone 1 originates ahead of the shield where the ground begins to deform. Zone 2, the largest portion of overall settlements, initiates a short distance in front of the shield face and develops largely over the shield body. Zone 3, begins after shield passing and after the tail void grouting has being performed. Operational parameters such as face pressure and penetration rate affect the magnitude of surface settlements within each zone. Large settlements found in Zone 1 are associated with low face pressure and low penetration rates. In contrast, if applied face pressures and penetration rates were very high, less surface settlements or even ground heave occurred in Zone 1. Face pressure and penetration rate also affect settlements in Zone 2 during shield passing. However, settlements occurred in Zone 3 were mainly influenced by tail void grouting.

1 INTRODUCTION

The Bangkok MRTA project is the first phase of an integrated transportation plan for Bangkok, to be implemented in conjunction with other schemes, by the Metropolitan Rapid Transit Authority (MRTA). The project of 20-kilometers of twin tunnels is subdivided into two main tunnel sections namely, the North Tunnel Section and the South Tunnel Section, which in turn are divided into Sections A, B and C, D, respectively (Figure 1). The tunnel alignment covers heavily congested areas of the city. Each of the twin tunnels is 6.3 meters in outer diameter and 5.7 meters in inner diameter. Each section uses two shields, one each for excavating the northbound and southbound tunnels. Hence, eight EPB shields were used in total for the entire project. Due to comprehensive arrangement of instrumentation both in the field and in the shields, the information is available so that the effect of tunneling variables on the development of ground deformations can be studied. Details of the project can be found in Suwansawat 2003.

There are two objectives in this research: (1) to evaluate the behavior of ground movements associated with EPB shield tunneling and (2) to investigate effects of EPB shield operational parameters on ground movements. Measurement results recorded from various types of instrumentation installed in the project including settlement markers and extensometers to measure maximum surface settlements above the tunnel centerline. Additionally, since readings were taken over time covering a period between before shield approaching and after shield passing, surface settlement markers also allow one to observe longitudidal surface settlement profiles and to study how they develop during shield passing.

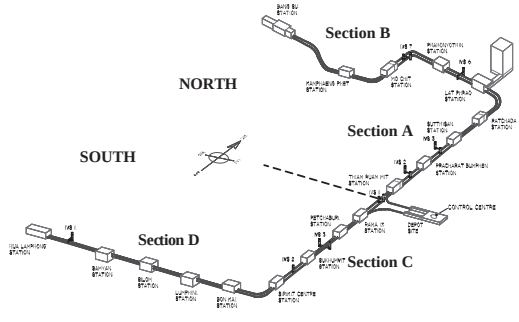

Figure 1. Bangkok MRTA route.

2 SUBSURFACE CONDITIONS

Bangkok lies in the Chao Praya delta plain. Its topography is low and flat being approximately 0.5 to 1 meter above sea level. For the MRTA project extensive field explorations and laboratory programs were carried out. Subsurface conditions along the MRTA

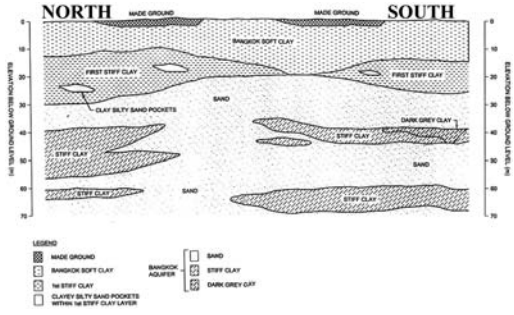

Figure 2. Subsurface conditions along the MRTA tunnel.

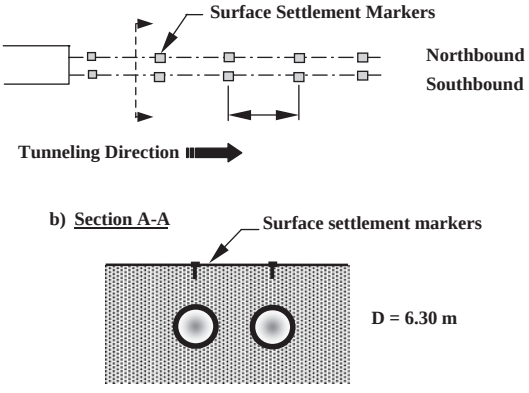

Figure 3. Instrumentation layout of the MRTA project.

project can be also subdivided into the North Tunnel section and the South Tunnel section.

For the North section, the soil profile is very uniform with soft clay underlain by stiff clay along the tunnel alignment. In this tunneling section, the horizontal-twin tunnel is excavated mostly within the stiff clay layer (i.e. about 15–25 m below ground surface) but with some parts in the sand. For the South section, most of the tunnel alignment is also mostly located within a stiff clay layer. However, in some part of the route, tunnels are stacked so that the lower tunnel is excavated in a sand layer.

3 GEOTECHNICAL INSTRUMENTATION

In the MRTA Project, large amounts of surface settlement markers and settlement arrays were installed to measure surface settlements during excavation. Typically, surface settlement markers were installed approximately at 50 meters intervals along the tunnel alignment as shown in Figure 3. The primary objective of the measurements with settlement markers is to measure maximum surface settlements above the tunnel centerline. Additionally, since readings were taken over time covering a period between before shield approaching and after shield passing, surface settlement markers also allow one to observe longitudidal surface settlement profiles and to study how they develop during shield passing.

Consequently, results from the instrumentation provide engineers with useful information to design appropriate measures for preventing damage to existing structures induced by EPB tunneling. Note that monitoring frequencies adopted in the MRTA project depended upon shield position. For example, readings were taken every day before and after shield passing but increased to higher frequency (i.e. every 2–4 hours) during shield passing in order to capture the development of surface settlements.

4 SURFACE SETTLEMENTS

4.1 *Tunnel Section A*

Section A is a part of the North Tunnel Section. Most of the tunnel in this section was excavated within the stiff clay layer. Note that only the first tunnel is studied since only the impact of the first shield on ground deformations is considered. The EPB shield used in this section was operated by controlling the amount of excavated soil that was extracted from the face by a screw conveyor. The face pressure was used as a control parameter during the excavation process. This pressure was monitored by pressure cells installed inside the earth chamber.

To allow a clearer relationship to be established between surface settlements and tunneling, settlement data were plotted against the shield face position as shown in Figure 5. As can be seen from the figure, the ground surface began to deform about 30 meters ahead of the shield. As the shield advanced close to the measurement section, larger settlements developed and accelerated over the shield body. Subsequently, the settlement ceased after the shield arrived at 15 m. behind the measurement section. Figure 5a shows the settlement measured at the ground surface over the lining ring no. 49 labeled "*a*" in Figure 4a. As the shield passed the section, the average face pressure was only 30 kPa. (Figure 4b). Large surface settlements occurred while the shield approached the measurement section particularly in the plane of the shield face. This observation is in agreement with laboratory experiment results shown in reported in earlier studies (i.e. Kimura and Mair; 1981, and Atkinson and Potts; 1977) in which ground tended to move towards the tunnel face in the centrifuge test. Additionally, large settlements significantly extend over the shield body but ceased about 15 m. (i.e. 2-shield diameter) behind the face. Subsequently, beyond this point, the settlement showed a small change after shield passing.

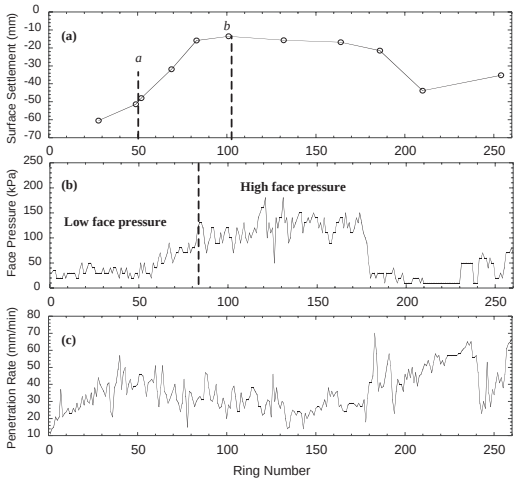

Figure 4. Surface settlements, face pressures, and penetration rates recorded in Tunnel Section A.

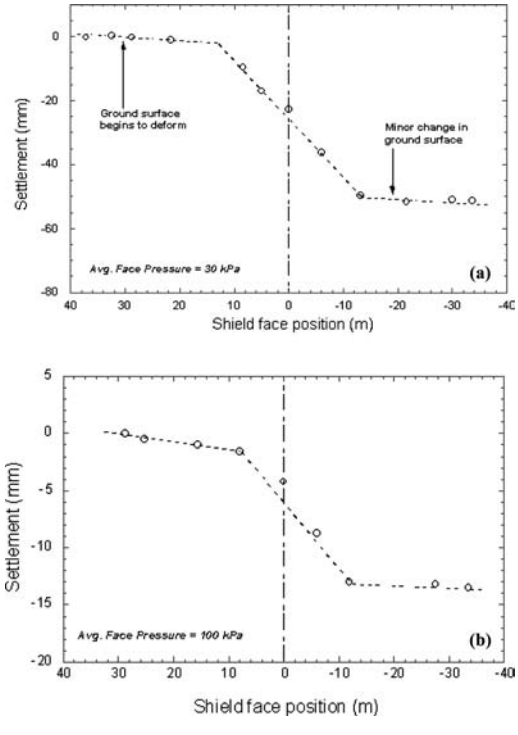

Figure 5. Surface settlements Longitudinal surface settlement profiles measured at location (a) "*a*" (Ring No. 49-SB), (b) "*b*" (Ring No. 101-SB).

After the SB shield was driven 72 m away from the launching station and 60 segmental rings were installed, the shield was stopped, equipment backup

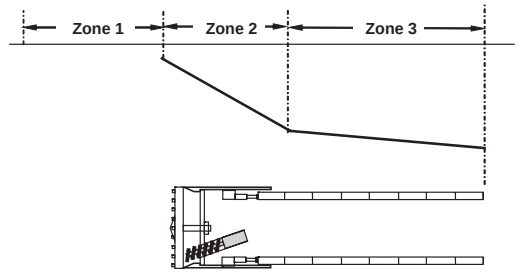

Figure 6. Schematic diagram of a typical longitudinal suface settlement profle.

trains were set up, and all temporary supports were removed. This was the end of the initial drive and the shield then resumed the excavation again. From this moment on, the SB shield was able to increase the face pressure up to 180 kPa (Figure 4b). To investigate the relationship between surface settlements and the shield progress, location "*b*" was selected for investigation. Average face pressures during shield passing were 100 kPa for location "*b*". The operation is in the "earth pressure balance mode," where surface settlements can be minimized by adjusting the face pressure equal to the surrounding earth pressure during excavation.

Surface settlements versus the shield face position in locations "*b*" is plotted in Figure 5b. In the figures, the maximum settlements were 13 mm. Obviously, the section has less settlement than section "*a*" (∼ 50 mm), where low face pressure was applied. This confirmed the assumption made previously that the face pressure applied during shield passing has a significant effect on the magnitude of surface settlements. Typically, shield operators need to drive the shield under a controlled face pressure to minimize the surface settlement.

Based on these observations, surface settlements induced by EPB tunneling can be divided into three zones regardless of face pressure level namely, (1) Zone 1, (2) Zone 2, and (3) Zone 3 as shown in Figure 6. The first zone originates approximately 30 m ahead of the shield, where the ground surface begins to deform. The surface settlement then continues to develop as the shield advances close to the measurement section. About 10 m in front of the shield, the surface settlement significantly increases and accelerates over the shield body. This stage of the surface settlement creates a clear inflection point separating "Zone 1" and "Zone 2". As observed in Section A, the surface settlement in Zone 2 is the largest portion of overall settlement induced by the EPB shield. After the shield tail passes the measurement section (i.e. about 15 m from the shield face), the settlement development begins to slow down; this is the beginning of Zone 3. The surface settlement in this final zone stops about 30 m after shield passing.

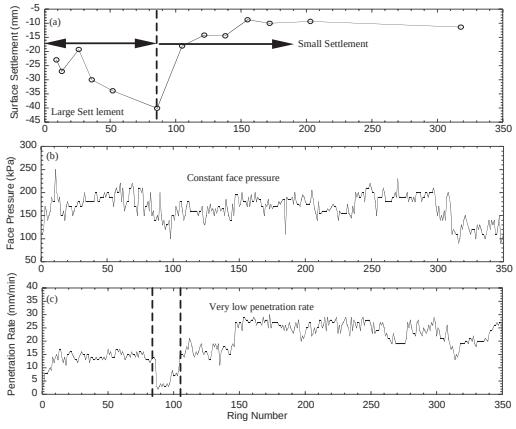

Figure 7. Surface settlements, face pressures, and penetration rates recorded in Tunnel Section B.

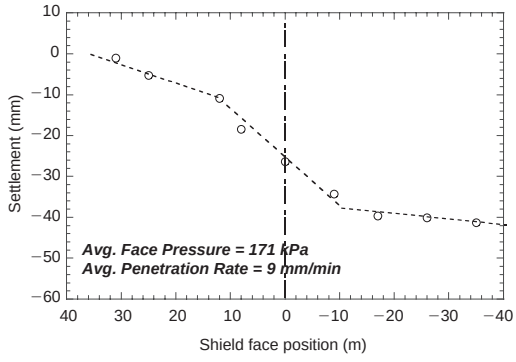

Figure 8. Longitudinal suface sttlement profile measured over ring No. 86-SB in Section B.

4.2 *Tunnel Section B*

Soil conditions of the tunnel in Section B are very similar to those of Section A, where most of the tunnel alignment was excavated within the stiff clay layer. Surface settlements measured in this section were recorded along the tunnel alignment as shown in Figure 3. At the beginning of the tunnel drive, relatively large settlements were observed even though the shield was operated at high face pressures (i.e. 150–200 kPa).

One of the factors that affect the ground response in the early stages of excavation is the inexperience of the tunnel crews. Furthermore, if one takes a detailed look at the shield penetration rates plotted in Figure 7c, it was found that the shield was driven at only 10–30 mm/min at the beginning of the excavation. In particular, between rings No. 80–100, the penetration rate was very low (i.e. less than 5 mm/min in some sections). Unlike other tunnel sections, a pipe transport technique was adopted instead of muck locomotives. This technique required the rate of pumping to be related to the shield advance/penetration rate or vice versa. Hence, this becomes a limitation in this tunneling section in that the shield cannot be shoved at high penetration rates. Evidently, such a low penetration rate was found to be associated with large surface settlements measured over the shield, particularly at ring No. 86 as shown in Figure 7a. To explore the behavior of ground response during shield passing, surface settlements recorded over the ring No. 86 were plotted against the shield position as shown in **Figure 8**.

The shape of the longitudinal surface settlement is similar to that of Section A with three distinct zones. Particularly Zone 2, settlement over the shield body is also the largest portion of the settlement. The surface settlement in Zone 1 appears to be relatively large (i.e. 11 mm at the transition point between Zone 1 and Zone 2), while the surface settlement in Zone 3, where the shield already passed the section has the smallest settlement. Based upon this observation, although the shield was operated at high face pressures during excavation in Section B, the surface settlements were still large as long as the penetration rate was very low. This suggests that penetration rate may also be a factor affecting the magnitude of surface settlements.

4.3 *Tunnel Section C*

Tunnel Section C is a part of the South Tunnel Section. Unlike other sections, the northbound shield was launched first. Most of the tunnel alignment was excavated entirely within the stiff clay and the very stiff clay layers. The shield used in this section is very similar to the machines used in Sections A, and B. However, each shield was operated differently depending upon each contractor's practices. Maximum surface settlements and operational parameters were also measured here along the tunnel alignment as shown in Figure 9. As can be seen in Figure 9b, very high face pressures were applied at the early stage of the excavation causing significant ground heave. Additionally, the applied face pressure was oscillated in the initial drive because the shield operator was determining an optimum pressure balance mode by trial and error.

Unlike Section B, although penetration rates recorded in the initial drive were relatively low (Figure 9c), the ground surface did not settle but heaved instead. It seems that the effect of very high face pressure dominated the behavior of ground response at this location. After the shield excavated the tunnel for a distance and the shield operators succeeded in obtaining an optimum operation, relatively constant face pressures and penetration rates were recorded. At this stage, the EPB shield can achieve low surface settlements during excavation.

Surface settlements were plotted against the distance from the shield face as shown in Figure 10. As

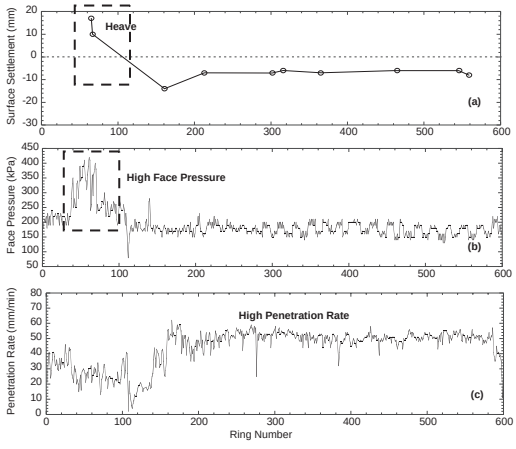

Figure 9. Surface settlements, face pressures, and penetration rates recorded in Tunnel Section C.

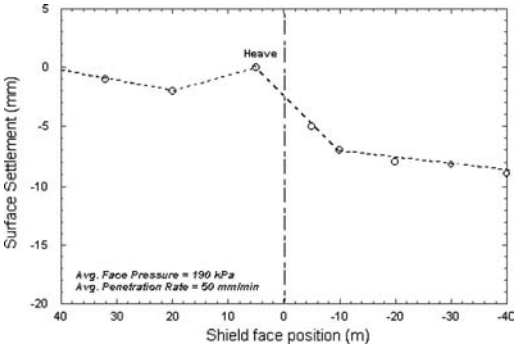

Figure 10. Longitudinal surface settlement profile measured over Ring No. 303-NB.

can be seen in the figures, the ground began to deform 30–40 m ahead of the shield. However, as the shield approaches the measurement sections at a distance of 3–5 m in front of the shield, the ground experienced a small heave before it subsided over the shield body. If one makes a detailed observation of the face pressures recorded in these sections, it was found that the applied pressure was relatively high during shield passing. Furthermore, penetration rates were also high (Figure 9c). Hence, the combination of these factors may have caused heave.

Based on the observation of Tunnel Section C, the face pressure and the penetration rate have impacts on the magnitude of surface settlements. It was found that if the face pressure is very high, ground heave will be observed regardless of the penetration rate. If the face pressure is low and the penetration rate is also low, relatively large settlements will be observed. Finally, if medium level face pressure and high penetration rate are used, some surface settlements will be found.

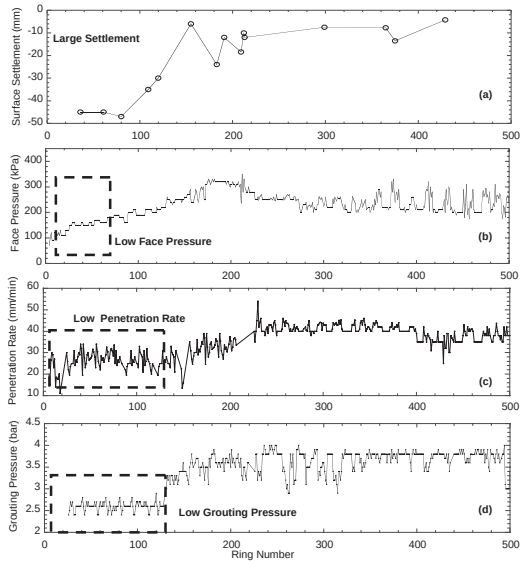

Figure 11. Surface settlements, face pressures, and penetration rates recorded in Tunnel Section D.

4.4 *Tunnel Section D*

In Section D, the southbound tunnel was excavated first and followed by northbound tunnel approximately one month later. Therefore, only the southbound tunnel is considered here. As in the other sections, surface settlement markers were installed along the tunnel alignment to measure the maximum and the development of surface settlements during excavation. Furthermore, extensometers were installed along the tunnel route in both the southbound and northbound tunnels to monitor subsurface settlements of the ground immediately above the tunnels in Section D.

Figure 11 shows maximum surface settlements measured along the southbound tunnel. Operational parameters including face pressure, penetration rate, and grouting pressure were also recorded. As can be seen in the figure, substantial surface settlements occurred within the initial drive zone. Within this zone, the learning curve of the crew may play an important role as well as operational parameters. For instance, Figure 11b shows low face pressures observed in the initial drive. After the initial drive, the shield developed greater face pressure that was built up to greater than 200 kPa. Obviously, in the pressure build up zone, smaller surface settlements were observed.

As can be seen in Figure 11c, in the early stage of excavation, penetration rates are relatively low. In addition, the grouting pressure applied at the early stage was also low (Figure 11d). Hence, the combination of low face pressures, low penetration rate, and low grouting pressure may also contribute to large surface settlements observed at the initial drive.

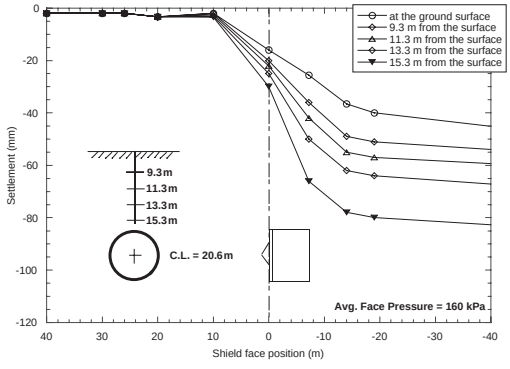

Figure 12. Subsurface settlements measured on RE-T5-001 over Ring No. 61-SB.

Within the initial drive zone, extensometer RE-5T-01 was located above ring no. 61. Large ground deformations were found over the shield crown at the monitoring depth of 15.3 m from the ground surface, and the magnitude of ground deformation decreases with decreasing monitored depth as illustrated in Figure 12. It was found that the ground began to subside approximately 10 meters ahead of the shield face and its deformation accelerated substantially over the shield body. The deformation then increased only slightly after the shield tail passed and no significant settlements were observed about 30 m after shield passing. Large ground settlements occurring ahead and over the shield may result from low face pressures and low penetration rates applied during shield passing.

Although very large ground deformation developed over the shield body as shown in the measurement section, the development appeared to slow down considerably as sharp inflection points of settlement curves were observed over the shield tail. Tail void grouting was performed at the segmental lining right behind the shield. This caused the inflection in the settlement curve. Note that tail void closure is a component causing ground deformation because of the gap between lining and ground. If no grouting was adopted to fill the void, the deformation in Zone 2 would extend further.

5 CONCLUSIONS

Based upon observations, in most cases, longitudinal surface settlements induced by EPB shield tunneling can be divided into three zones regardless of soil conditions namely, Zone 1, Zone 2, and Zone 3. Zone 1 originates ahead of the shield where the ground begins to deform. However, it should be noted that in the case of very high face pressures and high penetration rates, the ground might experience heave ahead of the shield in Zone 1. Zone 2 initiates a short distance in front of the shield face and develops significantly over the shield body. Also regardless of soil conditions, Zone 2 was found to be the largest portion of overall settlements. The final zone, Zone 3, begins after shield passing and after the tail void grouting has being performed. Operational parameters affect the magnitude of surface settlements within each zone. Large settlements found in Zone 1 are associated with low face pressure and low penetration rates. In contrast, if applied face pressures and penetration rates were very high, less surface settlements or even ground heave occurred in Zone 1. Face pressure and penetration rate also affect settlements in Zone 2 during shield passing and tail void grouting was found to influence settlements occurred in Zone 3.

Tunnel excavation by controlling water pressure in the ground with unevenly distributed water bearing strata

H. Takahara, J. Yorita & Y. Tuzuki
Iiyama Railway Construction Office, Japan Railway Construction, Transport and Technology Agency, Nagano, Japan

H. Takahashi
Kumagai Gumi Co., Ltd., Nagano, Japan

ABSTRACT: It is difficult to technologically assess the pressure and volume of the water in the ground near the excavating face. Therefore, long drainage boring has been adopted to reduce the pressure and volume of water on the assumption that the aquifer is evenly distributed. If high-pressure aquifers are locally distributed, however, it is difficult to reduce the pressure and volume of groundwater sufficiently by long drainage boring while stabilizing the cutting face. Therefore, the authors have developed a tunnel excavating method that combines long drainage boring and short drainage boring.

1 INTRODUCTION

The cutting face has been controlled in mountain tunneling by the NATM through evaluation of physical properties of the ground and deformations caused by excavation. In unconsolidated ground, it is very important to keep track of groundwater status in order to maintain the stability of the face.

Against this background, the authors have developed a new method for face control through confirmation of the presence of groundwater ahead of or near the face, and of groundwater pressure and volume, in the Tomikura sector of the Iiyama Tunnel. This paper reports a NATM tunnel excavation method that uses a new technique for water pressure control.

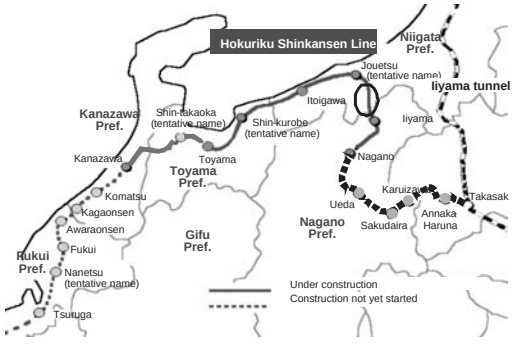

Figure 1. Hokuriku Shinkansen Line.

2 OUTLINE OF THE PROJECT

The Iiyama Tunnel is a mountain tunnel with an approximate length of 22 km that is located on the Hokuriku Shinkansen Line between Nagano City and Joetsu City, and connects Iiyama City in Nagano Prefecture with Myoukou City in Niigata Prefecture. The tunnel consists of six sectors and the Tomikura sector is the second sector counting from Nagano. Its total length is approximately 4,500 m. The overburden exceeds 200 m; the upward gradient from the beginning of the tunnel is 30 per mill, the highest point is approximately 152.700 km from Takasaki and the downward gradient at the end of the tunnel is 30 per mill. Construction work commenced in 1998, and a passage was successfully opened on the Joetsu side. At present, excavation is under way toward the Iiyama side, and the main tunnel excavation length exceeds 4,300 m.

The geology in the area of the Iiyama Tunnel is sediment formed in the process of elevation and subsequent terrestrial deposition of shallow sea regions at the end of the Tertiary Era and beginning of the Quaternary Era. In addition, the tunnel is located in the northern Fossa Magna, an area with advancing fold formations and prominent deformations in the geological structure. The ground of the Tomikura sector is made up of the Haizume Formation and the Nishiyama Formation of the Pliocene Era, and the Shiiya Formation and Teradomari Formation of the Miocene Era. Currently, excavation work is under way in the

Haizume Formation that is composed of alternate layers of sandstone, mudstone and conglomerate with a low degree of consolidation.

3 TECHNIQUE FOR CONTROL OF WATER PRESSURE

3.1 *History*

Unconsolidated sandstone layers make up the geology of the Tomikura sector, and surveys pointed out the possible presence of large volumes of groundwater under high pressure. Furthermore, though the groundwater level was confirmed to have been lowered after drainage boring, pressurized groundwater ingress was found in the face. There was therefore the fear that since the aquifer distribution would be uneven, ordinary drainage boring would be unsatisfactory to correctly grasp the existence of aquifer. In unevenly distributed aquifers such as in the construction sector in question, it is impossible to sufficiently reduce the pressure and volume of groundwater using long drainage boring alone and consequently it is very difficult to stabilize the face.

To deal with this problem, the authors have developed a tunnel excavation method that combines long drainage boring, to confirm the geology and groundwater volume and pressure ahead of the face, and short drainage boring, the purpose of which is to confirm the geology and aquifer status in the vicinity of the face, and to conduct drainage.

3.2 *Long drainage boring*

3.2.1 *Implementation method*

Long drainage boring is carried out at lengths in the range 100 to 200 m, with the objective to confirm the geological structure and the distribution of aquifers ahead of the face. In the event that aquifers are confirmed, groundwater volume and pressure are measured at the mouth of the bored hole, and the results are reflected in face control. The basic concept of long drainage boring is as follows:

1) In order to grasp the geology in the entire sector, it is necessary to implement core boring in such a manner that two succeeding borings overlap each other at their ends. They serve as drainage holes in the event that water ingress is found.
2) Construction positions that will enable prompt lowering of the groundwater level are selected with consideration to geological inclination and sedimentary status.
3) Borings are conducted so that they overlap on both sides of the face, even when water is not found.

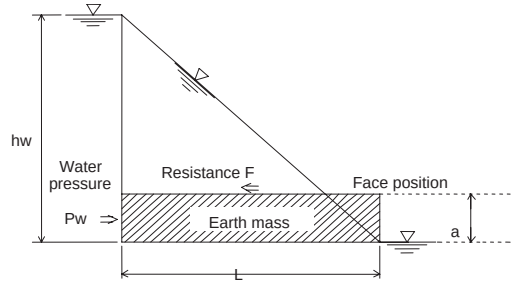

Figure 2. Schematic diagram of hydraulic.

3.2.2 *Control method*

In long drainage boring, a limit hydraulic gradient was taken into consideration as a control criterion in order to determine the pros and cons of excavation. The covering rock in front of the face was considered as a soil mass (width a × height a × depth L), and the balance between the water pressure (Pw) applied on the soil mass as described below and the resistance (F) of the soil mass to water pressure was taken into account and used as the control criterion.

$$PW = \gamma w \times hw \times a \times a$$

$$F = \gamma' \times (4\,hr + 2a) \times a \times L \times \tan\phi + 4a \times L \times C$$

a : sectional side length of soil mass (tunnel) (m)
L : soil mass length (covering rock length) (m)
γw : unit weight of water (1.0 t/m^3)
hw : piezometric head (m)
hr : thickness of overburden that contributes to resistance (m)
γ' : submerged unit weight of soil (1.0 t/m^3)
C : cohesion of soil mass (tf/m^3)
ϕ : angle of internal friction of soil mass (degrees)

In principle, the frictional force to the vertical load, which is equivalent to the overburden thickness, is estimated as resistance. However, consideration given to the possibility of loosening ground in the vicinity of the tunnel, or progressive failures starting from the face, the calculation was made conservatively, that is the overburden thickness hr is deemed to be zero, and only the dead weight of the soil mass is evaluated.

When Pw=F, the limit hydraulic gradient (iC = hw/L) is given as follows.

$$iC = (4C + 2a \times \gamma' \times \tan\phi)/a \times \gamma w$$

If C = 0 and $\phi = 30°$ assuming unconsolidated sediment ground, then the limit hydraulic gradient is approximately unity. Furthermore, a safety factor 1.5, the value that is used when exploring the possibilities for ordinary boring, is applied, and L/h = 1.5 is taken as the control criterion. However, considering the

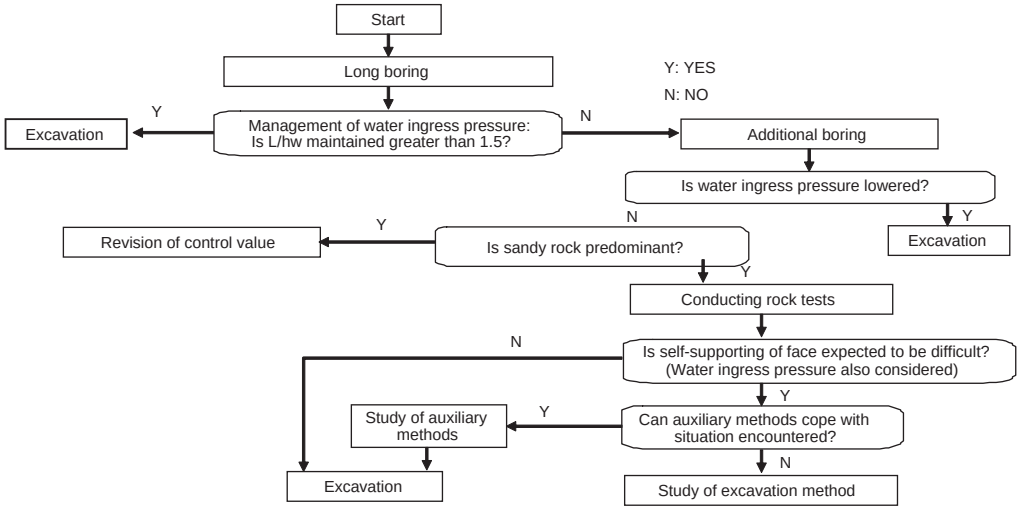

Figure 3. Flow of long boring management.

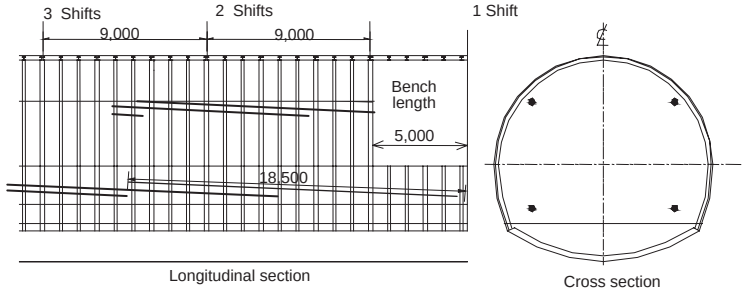

Figure 4. Schematic diagram of short boring.

ground status, the values for C and ϕ are revised and the control criterion is set anew. Figure 3 is a flowchart of the long drainage boring process.

3.3 *Short drainage boring*

3.3.1 *Implementation method*

The purpose of short drainage boring is to confirm whether there is locally distributed groundwater, which could not be found with the long drainage boring, around the face, and in the event that such groundwater exists, to lower the water level. Similar to the long drainage boring, it assesses the volume and pressure of groundwater and reflects the results in face control. The short drainage boring is carried out using FIT pipes that are used in forepoling, with a 9-meter pitch. The borings are made at a total of four points in the face – left and right shoulders and left and right on the bottom half (Figure 4). The length of the drilling is fixed to 20 m. The basic concept of short drainage boring is as follows.

1. It is implemented in order to confirm the presence of unevenly distributed groundwater that is associated with the inhomogeneous quality of the ground.
2. It is implemented also in places where water drips have been found.
3. The implementation position and frequency are modified more easily than those in the long drainage boring.
4. In the event that high-pressure groundwater is confirmed, excavation is terminated and necessary countermeasures are explored.

3.3.2 *Control method*

The control value was set such that a sufficient resting force could be ensured, maintaining face stability. In line with "Railway Structural Design Standards for NATM Tunnels in Urban Areas" and based on previous experience, the condition for application of this method in ground with sandy soil is that the pressure

28	151 km 352 mR	136	1,500.0	0.310	10

head in front of the face should be less than +10 m from the face center. If the pressure head in front of the face is more than +10 m, a technique for lowering the water level should be considered in addition. Thus, water ingress pressure of 0.1 Mpa was set as the control criterion.

In the event that water-caused destabilization of the face is confirmed in the process of excavation, in which water pressure is controlled using the provisional reference value, auxiliary methods and drainage techniques are applied in order to stabilize the face and a downward revision of the reference value is studied. In the event of upward revision of the reference value, the resistance of the ground layers to water pressure is separately evaluated through core sample tests.

4 WATER PRESSURE MEASUREMENT RESULTS

4.1 *Long drainage boring results*

Part of the long drainage boring results are shown in Table 1.

The necessary length of the covering rock in this table is based on the control criterion, and the criterion was satisfied up to boring No.16. In boring No.17 a water pressure of 1.5 MPa was recorded, and the necessary length of the covering rock could not be attained under the initial control criterion. The core boring showed that the covering rock was made up mainly of mudstone. Referring to the properties of the ground, the authors revised the control criterion. As a result, covering rock length of more than 1/3 of the pressure head was set as the control criterion for this area (covering rock length of 50 m).

Determining the position where the preceding long drainage boring is to be implemented is extremely important in order to correctly grasp the geological conditions as soon as possible. The geological structure of the Tomikura sector is characterized by standing layers and there is a tendency for new layers to appear from the left on the face. Based on these geological conditions, a decision was taken to bore first the left of the face. Below is a description of the patterns of water volume in long drainage boring so far.

1. A large volume of water ingress was encountered through advance boring on the left side, while boring on the right side water ingress volume and pressure were not significant.
2. Large amounts of water ingress were confirmed in layers that had not been reached in the previous boring.

Based on the above findings, macroscopic lowering of groundwater level in the vicinity of tunnels was confirmed using the long drainage boring method.

4.2 *Short drainage boring results*

Water pressure has been measured 40 times so far. The measurement results are shown in Figure 5.

These results show that in some cases water pressure in the aquifer is relatively high even though the water ingress volume is small. Possible explanations for this are that the water bearing strata are of low permeability and have a high-pressure head, or that the groundwater is confined in an artesian condition.

Therefore, there is a high possibility that short drainage boring may prove efficient in reducing locally distributed groundwater level that cannot be lowered using the long drainage boring.

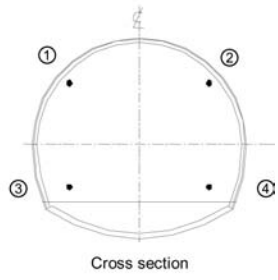

Figure 5. Results of short.

An example of this is a point located 151.541 km from Takasaki. There, water pressure exceeding the control criterion (0.1 MPa) was recorded in the upper right shoulder section during short drainage boring. The process implemented at this point was as follows.

1. In the course of excavation the rock bolts located few meters before the face have been pushed out approximately 20 cm.
2. After a water drainage hole was drilled again, there was a spurt of a large amount of water again.
3. Excavation was terminated and short drainage boring was performed. Water ingress was not found anywhere except for the upper right shoulder section, but high water pressure was confirmed in the course of drilling in the upper right shoulder section and drilling failed around the 12th meter.
4. Short drainage boring was performed again near the face, and water volume of 43 liters/min and water pressure 0.115 MPa were confirmed.
5. Water pressure exceeded the control reference value. Accordingly two drainage borings with L=30 m were made.
6. After confirming the reduction of water ingress volume and pressure following the drainage boring, a second short drainage boring was made in the upper right shoulder section at the point 151.541 km. Then, reduction of water ingress volume and water pressure was confirmed and excavation was resumed.

In short drainage boring made in areas other than the upper right shoulder, almost no water ingress was confirmed, which probably means that the geology was inhomogeneous. Also, long drainage boring performed in this area confirmed relatively high water pressure in the strata, and locally distributed aquifers, in which drawdown could not be sufficiently performed through long drainage boring, were recognized in advance using short drainage boring.

5 BENEFITS OF THE DEVELOPMENT

A system was constructed to constantly keep track of ground conditions in the vicinity of the face that is based on a systematic combination of long drainage boring and short drainage boring. This system enables early recognition of face status and determination of appropriate measures in advance.

Furthermore, since short drainage boring uses forepoling and face bolts to control water pressure around the face, it is not necessary to drill additional holes, and pressure is easily controlled as a part of the auxiliary processes. Thus, this development enables significant improvement of safety and economic efficiency by minimizing time required.

6 CONCLUSIONS

This development is particularly efficient in tunnel excavation in ground with a low degree of consolidation and large volumes of groundwater since it enables accurate evaluation of groundwater and water pressure around the face (a potential cause of collapse). It also sufficiently lowers groundwater level, and thus improves the safety of excavation operations. Therefore, it is recommended that in the future tunnels constructed under similar circumstances are excavated using the new control techniques developed in this sector that utilize the short and long drainage boring methods.

ABSTRACT: The stability of the underground structure is very important not only from the point of view of the structure itself, but also from the point of view of other structures. Therefore, the evaluation of the process of deterioration can help us very much. In the first part of the paper the ageing of the structures in the scope of their life cycle will be described. The whole process of deterioration is important but limited to certain time intervals and is able to give signals about changes in macro-scale. The second part of the paper is focused on the adaptation of new methods: micro technology of monitoring – such as MEMS (Micro Electrical Mechanical Systems) and wireless technologies for data transfer. It is obvious that such new technologies have to be assessed for the ability to deliver data continuously and for their safety and solidity. At the end of the paper the application of the measurements on the Prague metro's lining is mentioned.

1 INTRODUCTION

Recently a great attention is devoted to the problem of structure ageing. Relatively significant proportion of engineering structures were constructed during the last century, whereas an average service life in industrialized countries is roughly 50 years. Therefore there are two basic questions. The first one is dealing with problem of ageing generally and with the influence of this ageing on structural safety. The second one is connected with the most appropriate time when to carry on a small repair or complete reconstruction or substitution of the old structure by a new one. The decision-making process is also affected by an access to the structure. For example the quality of a motorway surface can be easily checked, while more complicated are checks of bridges and underground structures. The presented paper concentrates on underground structures, especially on metro systems and is one of the outputs from the European project "Ageing of underground structures". Hence the problems regarding the most appropriate time for remediation together with the possibilities and significance of monitoring are described here. The requirement for continuous monitoring is stressed as there are minimum demands on operating staff, especially when the signals from the underground are monitored with the help of wireless technology on the surface.

Monitoring of micro cracks can give us highly significant signals when some unexpected change is registered. Real time monitoring of continuous crack development together with the defined maximum allowable crack opening size can define more precisely the expected service life. For underground structures as for similar engineering structures a usual service life is nowadays about 120 years. Different certificates are required by the authorities for the materials to be used in such structures in order to guarantee the specified service (design) life. Nevertheless, for such important structures as metro is, it would be very useful to be able to predict the time at when this limit state will be reached. We would expect much longer time than is the usual expectancy. For many underground structures the result of monitoring will be very useful in this matter. Therefore some proposals how to approach this problem are described in more details. These proposals are part of the above mentioned common European research project.

2 AGEING OF STRUCTURES

Engineering structures require monitoring, expert inspections, and periodic maintenance in order to determine their state and define when is the best time to carry out repair works instead of expensive and time-consuming reconstruction, usually accompanied by closure of traffic in not to far distant future. The monitoring of the ageing process of underground structures has a substantial importance because signs of deterioration may remain unnoticed. Due to the complicated access, the identification of the signs of underground structures might be difficult. The subsequent repair works or even reconstructions are usually more complicated and more expensive in comparison with new construction.

The deterioration process of underground structures is mainly influenced by the surrounding aggressive environment, external or internal loading and traffic. The whole ageing process can be accelerated by defects of load bearing structure, which are stated for reinforced concrete in Table 1 (Soga et al., 2005).

The whole process of deterioration can be divided into four phases:

1. Latent period – this stage follows the construction of structure. The deterioration and decreasing of the quality doesn't occur.
2. Progressive period – the deterioration curve decreases with time, the first cracks and subsequent possible seepage can appear.
3. Acceleration period – the deterioration curve decreases rapidly, the cracks develop, the reinforcement rusts and concrete degrades. It leads to a loss of the section of the structural member.
4. Deteriorated period – the quality of structure permanently decreases, the strength of material looses, which results in collapse of structure.

The phases of deterioration and deterioration curve are demonstrated on Figure 1. It is evident, that effect of repair works depends significantly on time. If the reconstruction of the underground structure is done in the accelerated period, a suitable state can be achieved with minimum costs. In case of late reconstruction in the deteriorated period it will require much higher costs in order to achieve the same level of desired quality of reconstructed structure.

Table 1. Summary of deterioration categories for reinforced concrete.

Deterioration category	Seriousness
1. Progressive corrosion of steel reinforcement bars through continuous water seepage or repeated cycles of humidity and dryness. Rust and rust fluid is detected on the surface of the concrete.	The seriousness can be minor at this stage before this situation becomes one that requires urgent measures.
2. Cracks have been generated within the concrete as a result of corrosion of the steel reinforcement bars. An increase of rust fluid and swelling in the vicinity of the cracks is detected.	If swelling is identified in the vicinity of cracks, there is the possibility that exfoliation has occurred.
3. Diagonal and intersecting cracks	When cracks have been generated in a regular pattern or when the cracks are concentrated, this may indicate that the design mechanical strength has not been achieved.
4. Falling of concrete debris as a result of expansion of rust due to corrosion of the steel reinforcement bars.	This is a situation that is close to becoming an urgent one.
5. Progressive corrosion of the steel reinforcement bars that are exposed (phenomenon that occurs at the cross section of steel reinforcement bars).	The rate of corrosion of the steel reinforcement bars accelerates. If it is left unattended, there is every possibility that the situation will develop into an urgent one.

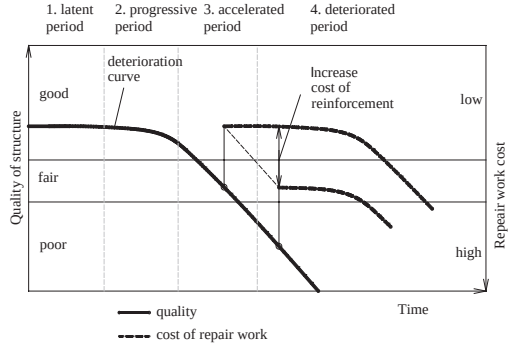

Figure 1. Life cycle of ageing structure.

3 THE PROJECT OF MONITORING

The main aim of the European research project is a development of a complex wireless monitoring system Underground M^3 that is to be able to provide data for assessment of tunnels ageing grade. The system is to be designed for cracks detection using a special computer vision and for monitoring using the latest advances in micro electrical mechanical systems (MEMS) and in wireless data transmition. This potentially cheap monitoring technologies can significantly reduce the costs of tunnels operation i.e. maintenance, renewals,

repairs and reuse planning. Underground M^3 system development consists of four stages:

- micro detection – real time damage detection using computer vision,
- micro monitoring – MEMS strain sensors,
- micro communication – in ground wireless systems with power harvesting,
- system integration, data management and decision making.

3.1 *Micro detection*

Due to public pressures to run metro systems for 24 hours as well as limited human resources, we expect that the current method of network-wide human visual inspection will be difficult to conduct in the future. Instead of network-wide visual inspection of underground infrastructure by means of direct inspection (in person) or remote measures using geometry inspection devices, there is a need to conduct inspection more rapidly and automatically. In the frame of this European research project it is proposed to develop a real-time damage detection system using new advances in computer vision compared to the existing surface imaging technologies. It is important to note that the currently available technologies are static camera-based, whereas the new system utilizes video camera for fast data acquisition during inspection. The proposed system will detect surface cracks and color changes. In the proposed "Micro detection" system, the images taken from a video camera that is carried by an inspector or a robot will be put together by image mosaicing and will be registered automatically into a spatial coordinate system using the real time Camera Pose System recently developed at Cambridge, see Figure 2.

This system allows the images to be registered independently of the camera position (that is, the inspector does not need to be at the same location for every inspection even under different light conditions). Using the "super-resolution" technique of multiple video images, the quality of images that show cracks and surface deteriorations is improved.

3.2 *Micro monitoring*

Once significant anomalies or cracks are detected, there is a need for more intensive monitoring. Pointwise strain measurements are often suitable for certain above-ground building components (such as column and beams) because the strains do not change rapidly within these components. In underground infrastructure, this is not the case; there is large change in strain within a short distance by the soil-structure interaction because the external ground forces vary spatially. We therefore propose that the solution for underground

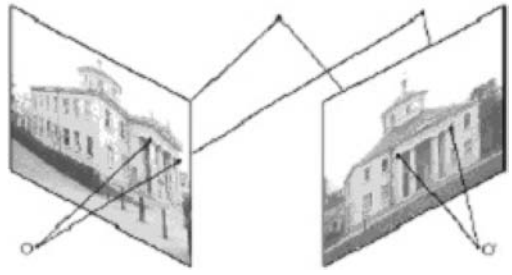

Figure 2. Camera pose system (Soga et al., 2005).

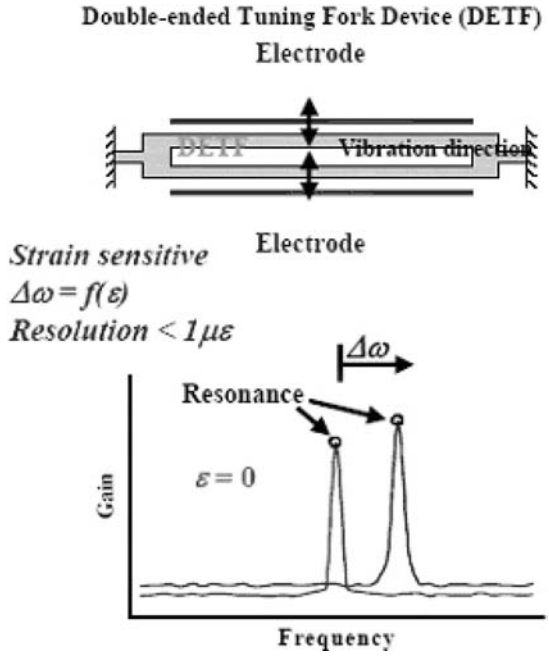

Figure 3. Schematic and principal of MEMS prototype.

infrastructure monitoring is the use of low cost sensors of a distributed nature. The project teams aim to develop low-cost MEMS strain or displacement sensors through the course of the project. Simultaneous readings from multiple sensors, possibly placed with diversity of space orientation, will allow for determining the spatial distribution of strains with high accuracy. An example of a MEMS resonant strain sensor that will be developed from existing prototype for the project is shown in Figure 3.

The basic principle is to couple the strains axially onto a vibrating beam. The added strain energy in the beam shifts its resonant frequency. The strain can be inferred by monitoring the shift in resonant frequency. Modeling of such an electromechanical resonator requires the inclusion of a stimulus and a

sensing transduction mechanism between the electrical and the mechanical domain. Electrostatic transduction is to be used in the project due to the good scaling properties with dimension and the relative ease of interface with control and detection electronics. Both parallel-plate electrostatic drive as well as comb-drive actuation principles will be explored. The controller electronics comprises of a sustaining amplifier that maintains resonant motion compensating for damping and other losses and accurately controls the amplitude and frequency of oscillation. Other types of low cost MEMS strain/displacement sensors will be investigated as well, including piezoelectricity as the transduction principle for silicon strain sensors. In all cases, technology fabrication processes would require either surface or bulk micromachining with proper etch-stop mechanisms.

3.3 *Micro communication*

The data obtained from the micro-monitoring sensors needs to be transmitted effectively to infrastructure owners. This also involves communication to other underground infrastructure owners since it is common that a failure or activity associated with one type of infrastructure impacts on or induces another failure in neighboring infrastructure. Problems also arise from the complex structure of monitoring and maintenance operations adopted by ageing infrastructure owners. It is often the case that discrete information and technical knowledge of circumstances surrounding pipeline or tunnel failures are scattered within a company. There is therefore a need to develop a common communication protocol (CCP) in which sensors in one type of infrastructure can effectively communicate with sensors in surrounding infrastructure. Recent advances in wireless communication allow us to do this easier than before when old fashioned hard wire communication was used. We propose the use of IMOTE/STARGATE technology (see Figure 4) currently developed by Intel.

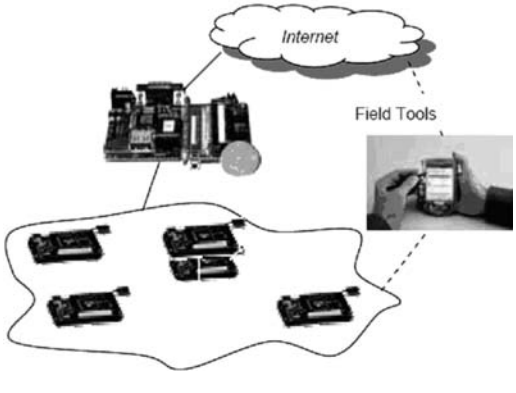

Figure 4. Network wide communication.

IMOTE is a generic wireless communication system and incorporates a small processor coupled with TinyOS that can perform data processing before sending the information to the main server. Since most available wireless technologies are limited to working in air, their use for underground infrastructure may be restricted, especially with regard to sending data between non-connecting underground infrastructures. This project will integrate IMOTE and in-ground wireless technologies, allowing the development of a trans-infrastructure network that transmits signals both through soil and air.

To ensure maximum efficiency and network life, the proposed micro-communication systems will operate under low power consumption conditions. In addition, we propose to develop an energy harvesting unit integral with MEMS/Wireless communication technology that will power these devices. This solution is practical as the sensors will be used for long-term monitoring and as a result will not be required to make measurements very frequently. It is proposed to use the energy available in the surrounding environment (e.g. harnessing energy from pressure fluctuations and wind flow while trains are running).

3.4 *System integration, data management and decision making*

Once the data are gathered, there is a need to interpret the data effectively to make appropriate decisions. The key for a successful development of Wireless Sensor Network systems with innovative sensors is identification of the fundamental causes of failures and associated warning signatures. This is often a difficult task due to the nature of the failure modes, involving complicated interactions between Internet Field Tools the underground structures and the surrounding ground. The monitored data will be used to update the understanding of the on-going soil-structure interaction and model parameters for future prediction needs to be selected through a parameter optimization process. The proposed research includes the following development of assessment tools for long-term performance prediction:

(a) Tool 1: Predicting deformation developments of underground infrastructure. The following aspects will be assessed: (i) Magnitude of cracks (including crack pattern analysis), (ii) Deformation of underground shape, and (iii) Load bearing capacity (including the corrosion of reinforcing bars/dowels and steel segments).
(b) Tool 2: Decision support system with automatic diagnostic capabilities. The tool will assess the subsequent impact on underground function based on the inspection and survey results, using past experience and numerical analysis.

In order to develop a data analysis and expert system for Underground M^3, the following three levels of data interpretation will be adopted.

- 1st level: Compilation of all data sensors, including a rough analysis of the measurements, in order to identify those sensors providing limit values. A simple comparison with limit strains would be a convenient procedure to identify potential critical zones. Post-processor software is required in order to manipulate the information in a user-friendly manner.
- 2nd level: Mechanical analysis of the potential critical areas. Only some zones would require further analysis. That includes a finite element analysis of the 3D geometry involved in the zone (i.e., the lining, the surrounding ground, any buildings affected by the underground structure, etc.). An optimization module should be used to identify parameters of the materials, in order to assess the integrity of the structural elements. Identification of models or geometry could be attempted as well, if the complexity of the problem requires such extension.
- 3rd level: Suggestion of actions to be undertaken by the manager, regarding the maintenance of the underground infrastructure. This task will be performed by an expert system software that integrates all the information provided by the preceding levels and also the experience accumulated from previous analyses.

3.5 *In-situ macro measurement*

In order to incorporate new technologies into existing underground infrastructure, it is proposed to install conventional monitoring devices so that the performance of the new technologies can be properly evaluated. The macro monitoring experiments proposed for deformation measurements are:

- tiltmeter, which can provide an accurate history of structure deformation – movement,
- tape extensometer, which is used to detect and monitor changes in the distance between two reference points,
- VW crackmeter, which is able to measure the deformation of cracks and joints.

Geophysical methods such as seismic tomography or geophones, which can give more information about changes in material properties with depth (of the tunnel lining) and it is planed to use them at selected field sites.

4 SELECTION OF APPROPRIATE PLACE FOR MONITORING IN-SITU MEASUREMENT

The choice of the appropriate locality with respect to the project aims and objectives was carried out and the Prague Metro was selected as the main location. In order to gather relevant information, the selection of the location for monitoring is very important. For this purpose selected sections of Prague's metro were visited and inspected. Figure 5 shows general view into a double track tunnel of Prague's metro. After checking through the chosen Prague metro's sections, few trial sites were selected.

On Figures 6, 7 and 8 are presented three examples of traced defects on selected trial sites. On these macro-cracks in-situ measurements – macro-monitoring will be realized and in parallel on nearby micro-cracks micro-monitoring will be performed. The final decision about monitored profiles will be compared with numerical modeling and specified as a result of the soil-structure interaction occurring at the sites.

Figure 6. First example of traced defects – transversal cracks and their simple monitoring using plaster tags.

Figure 7. Second example of traced defects – longitudinal cracks across one lining section.

Figure 8. Third example of traced defects – both transversal and longitudinal cracks.

5 CONCLUSIONS

The importance of the monitoring of underground structures behaviour is becoming very important nowadays as it can help us to understand the development of the structure in time. At the same time the monitoring is becoming a multidisciplinary matter as it is combined in expert system with theoretical knowledge of the structure and results from numerical models. Also the development of such micro-monitoring devices integrates knowledge from currently available techniques in in-situ measurements, advances in micro-technologies in electronic engineering and wireless technology.

ACKNOWLEDGEMENT

The authors wish to express their gratitude to the Grant Agency of the Czech Republic for research project GA 103/06/1257 "Research of Ageing of Underground Infrastructures with the Help of Micro-measurements and Monitoring" for allowing preparation and presentation of this paper.

ABSTRACT: This paper presents the results of 3D numerical analysis on a case history in which tunnelling caused groundwater drawdown and associated ground settlements. The dynamics of the effect of groundwater on the tunnel behavior and the ground settlements are thoroughly investigated by analyzing the results of analysis. The results highlighted the role of groundwater drawdown on the ground settlements and on the tunnel behavior. Based on the results, the ground surface settlement characteristics associated with groundwater drawdown are identified. Practical implications of the findings from this study are discussed.

1 INTRODUCTION

In response to the demand for significant upgrade to existing infrastructures in Korea the subway system in Seoul (Seoul Metro) is being undergone a recent major expansion. One example is the construction of Line 9 which runs underground from Kimpo International Airport on the western part of Seoul towards the Gang-Nam business district, located in eastern part of Seoul. As the entire route is aligned in close proximity to Han River and under heavily populated areas, such as Yuido, Banpo, and Gang-nam business districts, the geotechnical aspects of tunnelling conditions are rather difficult with high groundwater table.

Tunnelling beneath the groundwater table causes changes in the state of stress and the pore water pressure distribution. In such tunnelling problems, the tunnelling work inevitably causes water inflows into excavated area, thus causing the change in the pore water pressure distribution. The direct environmental consequence of water inflows during tunnelling is the drawdown of groundwater level in the surrounding aquifer (Yoo 2005). The related ground subsidence occurring as a result of the reduction in water pressures in the soil layers can damage nearby structures/utilities (Figure 1). One of the major case histories illustrating damage due to ground settlement associated with tunnelling-induced groundwater drawn is perhaps the Romeriksporten tunnel in which the highspeed railway tunnel construction caused more 1 m of ground subsidence due to groundwater drawdown, raising significant technical and political issues pertaining to the effect of tunnelling on surrounding environment (NSREA 1995).

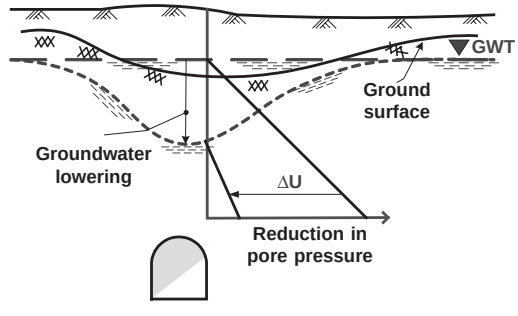

Figure 1. Illustration of ground settlement associated with tunnelling-induced groundwater drawdown.

This paper focuses on the interaction mechanism between tunnelling and groundwater in soft ground tunnelling. A 3D stress-pore pressure coupled finite element analysis was conducted on a tunnelling case

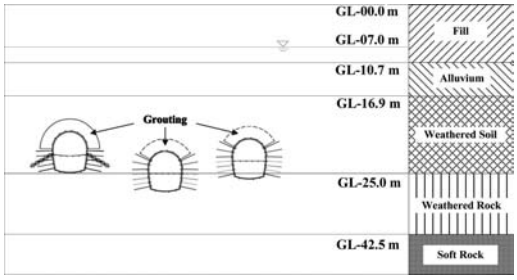

Figure 2. Transverse tunnelling condition.

of the Seoul Metro expansion project in which the tunnelling caused significant groundwater drawdown. Based on the results, the interaction mechanism between the tunnelling, groundwater lowering, and ground settlement was identified.

2 SITE CONDITION

2.1 *Subsurface condition*

The subsurface condition for the site under consideration is characterized by multi-layers of soil, including an alluvial deposit and a residual soil, with high groundwater table. Typical stratigraphy includes a 7∼10 m thick miscellaneous fill material including sand, gravel, and silty clay. Underlying the fill layer is a 7 m thick alluvial deposit followed by a 15 m thick decomposed granitic soil layer underlain by a weathered granitic rock layer having RMR values ranging 10 to 20. The weathered granitic rock layer is followed by a soft to hard granitic rock layer with RMR values ranging from 26 to 38. The hydraulic conductivity of the residual soil layer is on the order of 2×10^{-6}m/s. The groundwater table is relatively high at GL -3 m, located in the alluvial layer, thus leaving the entire tunnel is to be excavated through the water bearing weathered soil despite as shown in Figure 2. The geotechnical properties of the each layer are summarized in Table 1.

2.2 *Tunnelling condition*

The tunnel section considered in this study is approximately 350 m long and consists of three parallel tunnels with slightly varying elevation, as marked in Figure 2. The left most tunnel is returning (RE) tunnel, center and right most tunnel are west bound (WB) and east bound (EB) tunnels, respectively. The sequential excavation method (Eisentein & Sorensen 1986) was adopted. The cover depth of the tunnels is approximately 20 m on average, and therefore most of the tunnel sections run through the weathered soil deposit as mentioned.

Figure 2 illustrates cross sections of the tunnel with the standard support patterns adopted in the design.

Table 1. Geotechnical properties of ground.

Type	γ (kN/m^3)	c' (kPa)	ϕ' (deg)	E (MPa)	ν	K (cm/sec)
Fill	18	0	27	6	0.40	3.8×10^{-4}
Alluvial	25	25	30	10	0.40	3.8×10^{-4}
Weathered soil	25	15	33	50	0.33	2.4×10^{-4}
Weathered rock	25	50	35	120	0.30	8.8×10^{-5}
Hard rock	26	100	35	200	0.25	5.0×10^{-5}

Note: γ = unit weight, c' = cohesion, ϕ' = internal friction angle, E = young's modulus, ν = poisson's ratio, K = coefficient of permeability

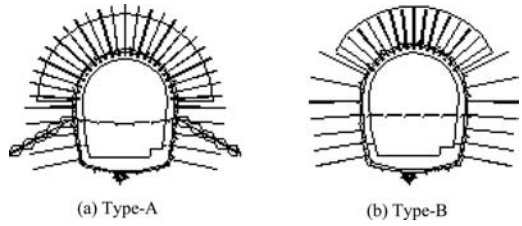

Figure 3. Standard support patterns.

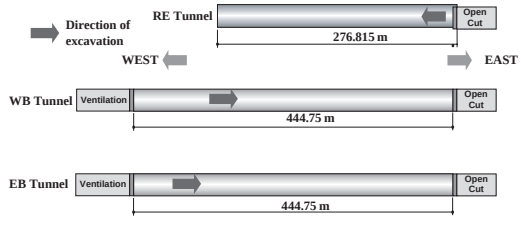

Figure 4. Excavation sequence.

The three tunnel sections has the same cross section of a maximum height and width of 8.4 m and 11.4 m, respectively, giving a net excavation area of approximately 100 m^2. The bench cut method was adopted with one segment excavation length of 0.8 m. The support system consists of a 0.16 m thick steel fiber reinforced shotcrete (SFRS) layer with 3 m long system rock bolts. In order to promote the face stability, the pipe roofing technique with fiber-reinforced pipes (FRP) of 60 mm in diameter was adopted. Note that the top heading distance between the EB and WB bound tunnels is kept approximately 20 m. The excavation sequence is that the WB and EB tunnels are excavated with the top heading distance of 20 m. Upon completion of the approximately 300 m long WB and EB tunnel, the RE tunnel is then excavated from the east, as given in Figure 4. Details of the tunnel design are summarized in Table 2.

Table 2. Support pattern summary.

Support pattern	SP-A	SP-B
Gound condition		
0.5D above crown	Residual soil	Weathered rock

3 3D COUPLED FINITE ELEMENT ANALYSIS

3.1 *Fundamentals of stress-pore pressure coupled analysis*

The commercially available finite-element package ABAQUS (ABAQUS 2003) was used for analysis which is capable of simulating the stress-strain-strength behavior of ground in stress-pore pressure fully coupled manner. Note that the importance of carrying out the stress-pore pressure fully coupled analysis for tunnelling cases where the interaction between the tunnelling and groundwater takes place has been discussed by Yoo (2005).

A porous medium is modeled approximately in ABAQUS by attaching the finite element mesh to the solid phase. A continuity equation, equating the rate of increase in liquid mass stored at a point to the rate of mass of liquid flowing into the point within the time increment, is written in a variational form as a basis for finite element approximation as Eq. (1).

$$\int \sigma : \delta\varepsilon dV = \int t \cdot \delta v dS + \int \hat{f} \cdot \delta v dV \quad (1)$$

Where dv is a virtual velocity field, $\delta\varepsilon = sym(\partial\delta v/\partial x)$ is the virtual rate of deformation, σ is the true (Cauchy) stress, t are surface tractions per unit area, and $\hat{f}$ body forces per unit volume. For coupled analysis, $\hat{f}$ includes the weight of the wetting liquid.

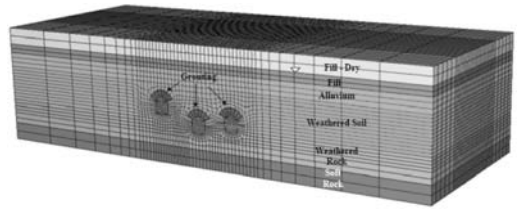

Figure 5. Finite-element model used in the analysis.

$$f_w = (sn + n_t)\rho_w g \quad (2)$$

Where ρ_w is the density of the wetting liquid and g is the gravitational acceleration, which we assume to be constant and in a constant direction. Considering this loading explicitly so that any other gravitational term in $\hat{f}$ is associated only with the weight of the dry porous medium. Equation (1) can be rewritten as Eq. (3):

$$\int_V \sigma : \delta\varepsilon dV = \int_S t \cdot \delta v dS + \int_V f \cdot \delta v dV + \int_V (sn + n_t)\rho_w g \cdot \delta v dV \quad (3)$$

where f are all body forces except the weight of the wetting liquid. The liquid flow is described by introducing Darcy's law or, alternatively, Forchheimer's law.

The continuity equation is satisfied approximately in the finite element model by using excess wetting liquid pressure as the nodal variable (degree of freedom 8), interpolated over the elements. The equation is integrated in time by using the backward Euler approximation. The total derivative of this integrated variational statement of continuity with respect to the nodal variables is required for the Newton iterations used to solve the nonlinear, coupled, equilibrium and continuity equations.

3.2 *Finite-element modeling*

Figure 5 shows the finite element model adopted in this study, consisting approximately 57,000 nodes and 53,000 elements. The finite-element mesh extends to a depth of two times the tunnel diameter (D) below the tunnel spring line and laterally to a distance of 8.0D from the returning and east bound tunnel centerline. At the lateral boundaries, displacements perpendicular to the boundaries were restrained whereas pin supports were applied to the bottom boundary.

With regard to the hydraulic boundary conditions and with reference to Figure 5, a no-flow condition was assigned to the vertical boundaries perpendicular to the tunnel drive. The pore water pressures on the left and right vertical boundaries are assumed to be constant throughout the analysis at the original

groundwater level of GL-3 m. The locations of the lateral and bottom boundaries are selected so that the presence of the artificial boundaries does not significantly influence the stress-strain-pore pressure field in the domain.

The ground and the shotcrete lining were discretized using 8-node displacement and pore pressure elements with reduced integration (C3D8RP). The rock bolts were modeled using the 2-node 3D truss elements. With regard to the material modelling, the soil and rock layers were assumed to be an elasto-plastic material conforming to the Mohr-Coulomb failure criterion together with the nonassociated flow rule proposed by Davis (1968), while the shotcrete lining and the rock bolts were assumed to behave in a linear elastic manner. The geotechnical properties for the ground given in Table 1 were used for analysis. The young's moduli of the shotcrete and rock bolts were chosen as 10 GPa and 21 GPa, respectively.

The actual tunnelling process consisting of a series of FRP grouting, excavation, and lining installation stages was closely simulated in the analysis by adding and removing corresponding elements at designated steps. After establishing the initial stress and pore pressure conditions with appropriate boundary conditions, the step-by-step tunnelling process pertinent to the bench cut excavation method, was then simulated. Note that the excavation sequence of the east and west bound tunnels as well as the returning tunnel was closely simulated as given in the design documents.

4 RESULTS AND DISCUSSION

4.1 *Ground settlement*

Figure 6 illustrates the development of ground surface settlement trough with the tunnel excavation. Also shown in this figure are the measured settlement values using the geodetic method. As seen in Figure 6, the tunnelling-induced ground surface settlement trough tends to become noticeable well before the WB tunnel heading reaches the section. The WB and EB top heading advance further deepens the trough causing a maximum settlement of 220 mm upon completion. One interesting trend is that the excavation of RE tunnel does not significantly increase the maximum settlement but tends to widen the trough.

The results of the total stress analysis without considering the stress-pore pressure coupled effect yields much smaller, less than 50% of that from the coupled analysis in terms of maximum settlement, and narrower settlement trough as shown in Figure 7, demonstrating the importance of carrying out stress-pore pressure coupled analysis when predicting the tunnelling-induced ground settlement.The effect of face advance on the ground settlement is better illustrated in Figure 8. As seen approximately 60% of the

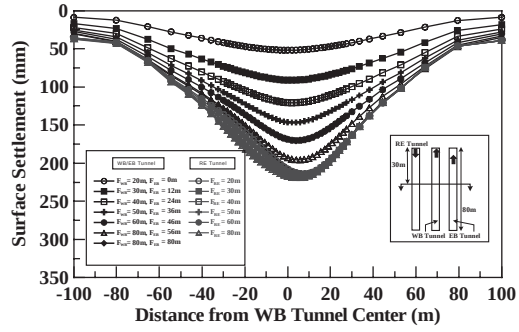

Figure 6. Ground surface settlement trough at various stages of tunnel.

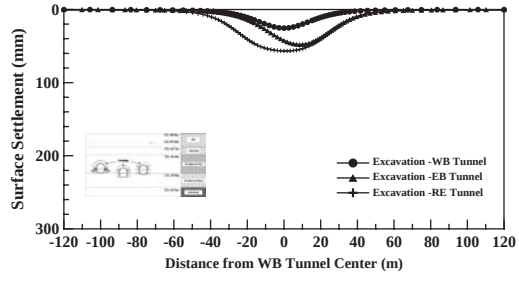

Figure 7. Settlement troughs from total stress.

maximum settlement at the measuring point A takes place before the top heading of WB tunnel reaches the section. The passage of top headings of the WB and EB tunnels further causes the rest 40% of the settlement as seen in this figure. The trend of which a significant portion of the total settlement occurs well ahead of the tunnel heading is a direct consequence of the groundwater drawdown caused by water inflow from the non-grouted excavated boundary. Note that the groundwater drawdown curve at the measuring point A, shown in Figure 9, resembles that of the surface settlement. In addition, as expected the settlement trough extends laterally approximately 80 m showing a larger inflection point ($i = 42$ m) than cases without groundwater drawdown. Again the groundwater drawdown is responsible for the trend shown in these figures as discussed by Yoo (2005).

4.2 *Tunnel deformation*

Figures 10∼12 illustrate the longitudinal crown settlement profiles for WB, NB, and returning tunnels at various locations of respective tunnel top heading. It is of worth noting that approximately 2/3 of the final crown settlement occurs before the top heading reaches the corresponding section. Compared to which typically 30 to 40% of final crown settlement occurs

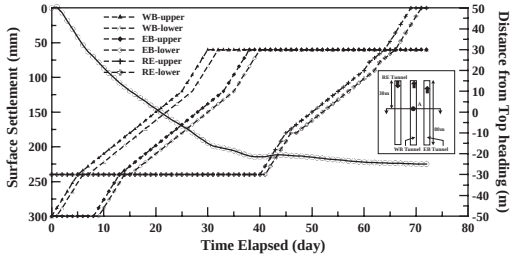

Figure 8. Development of settlement at point A with tunnel excavation.

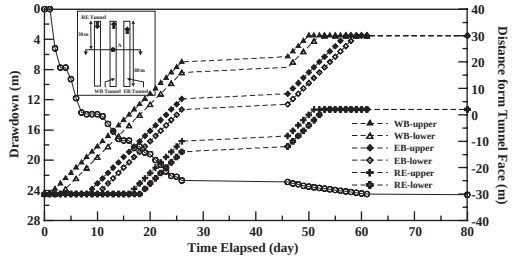

Figure 9. Groundwater drawdown with tunnel advance at point A.

before top heading reaches such pre-settlements values appears excessive and again such a trend is due to the groundwater drawdown ahead of the tunnel heading. It should therefore be expected that the traditional geodetic measurement technique being performed in-tunnel can only measure 30∼40% of final crown settlement. This may lead to unsafe-side estimate of tunnel stability in terms of the tunnel convergence. This is well illustrated in the measured data plotted in these figures as they represent only 20 to 30% of the final crown settlement predicted by the 3D analysis. Care should therefore be exercised when interpreting the tunnel deformation measurements for tunnelling cases where tunnelling accompanies groundwater drawdown.

Another of importance trend is that the final crown settlement for the RE tunnel is only 60% of those for the WB and EB tunnels. This is due primarily to that the RE tunnel excavation takes place under much lower hydraulic head as the WB and EB tunnel excavation significantly lower the groundwater level to the RE crown. The shear strength of the ground around the RE tunnel is thus expected to be greater than the WB and EB tunnel as the effective stresses are larger.

CONCLUSIONS

This paper presents the interaction mechanism between tunnelling and groundwater in soft ground. A 3D stress-pore pressure coupled finite element

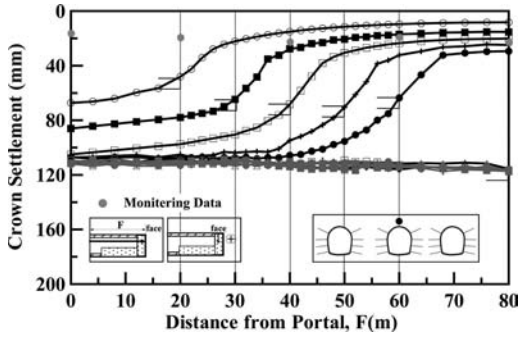

Figure 10. Longitudinal crown settlement at various stages (WB tunnel).

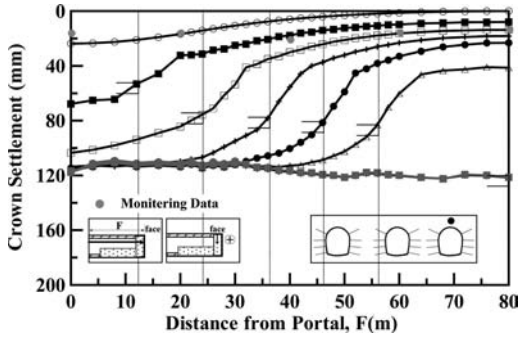

Figure 11. Longitudinal crown settlement at various stages (EB tunnel).

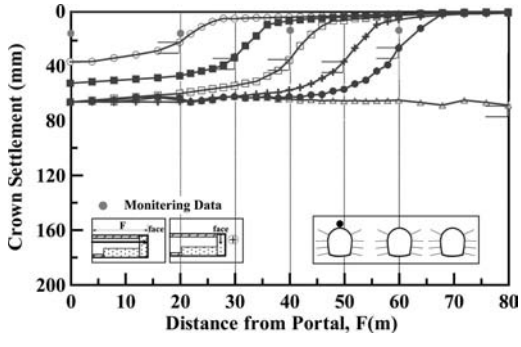

Figure 12. Longitudinal crown settlement at various stages (returing tunnel).

analysis was conducted on a tunnelling case of the Seoul Metro expansion project in which the tunnelling caused groundwater drawdown. Based on the results, the following conclusions can be drawn.

1. When tunnelling accompanies groundwater drawdown, a wider and deeper ground surface trough should be expected.

2. For cases where groundwater is lowered during tunnelling, significant portions, more than 50%, of the final crown and surface settlements may take place before tunneling heading reaches. Special care should therefore be exercised when interpreting the measured tunnel deformation data using the conventional in-tunnel geodetic method.
3. One way of improving tunnel stability during excavation is to lower groundwater level. This is well illustrated in the RE tunnel excavation.

Integrated design and construction of Klashnice tunnels

P. Anagnosti
Civil eng. faculty Belgrade University, Serbia

D. Lukich
Civil eng. faculty Subotica, Serbia

ABSTRACT: Twin tunnels Klashnice in construction on the new highway E-661 in Republic Srpska (Bosnia) situated between Banja Luka City and its airport, have been designed basing on the contemporary tunneling construction procedure using primary support structure composed of reinforced spray concrete with radial ground anchors. The design and structure dimensioning was controlled using 2D "PHASE 6" software. The dominant rock mass along the tunnels consists of metamorphic rocks with flysh like structure with alternating marls and silica (chert) layers dipping at app. 30° along the tunnel axis. The max overburden is app. 50 m but the most of the tunnel length has its overburden thickness of the order of 30 m. The construction of the 375 and 480 m long tunnels is in progress, and the regular convergence measurements are used for control of the primary support behavior.

The paper describes the main points of the design and construction behavior of the primary support structure as the components of the unified procedure required for the optimum result in tunneling.

1 GENERAL DATA

Klashnice tunnels situated on the Highway E-661 Gradishka – Banja Luka in Republic Srpska consist of twin-tube dual carriage motorways. Each tube has the excavation cross section 11.70 m in its width and 9.25 m in its max height. The upper part of the profile is made with the radius of 5.85 m; the lower part is made as the rectangular with the height of 3.45 m. The traffic clearance is 9.50×4.80 m. The longitudinal slope of the invert is directed from the middle of the tunnel towards its portals, 1.66% towards the exit and 0.63% towards the entrance. The detailed design and construction works are contracted as the "turn key job" and at this date substantially performed by Integral Co. Banja Luka, The construction works started in 2004 year and substantial completion is expected in 2006 year.

2 GEOTECHNICAL CONDITIONS

The bed rock along the tunnel alignment consists of metamorphic "diabase – chert formation" that is predominantly composed of clayey and sandy schists, with sporadic inclusions of tectonized limestone and chert blocks. The basic clayey or marly rock constituents are irregularly weathered particularly in milonite zones. The overburden at the ground surface consists of gravelly – clayey colluvial deposit that may have thickness of 3 to 6 m. Another unfavorable feature is the shallow depth of the tunnel with overburden thickness above the tunnel crown that varies from 25 to 35 m for the most of the tunnel length. The very long gently sloping (app.15°) ground at the tunnel exit area, created unfavorable conditions for the stability of the long and deeply excavated slopes at the portal entrances.

The ground investigations consisted of 8 bore holes that provided the cores for visual examination and for laboratory tests on small sized monoliths. The performed bore holes thus provided mainly lithological and structural information of the rock mass along the tunnel alignment, and the ground water conditions. The geophysical soundings provided the most valuable data of seismic velocities ranging from $Vp = 3.8$ km/s and $Vs = 1.75$ km/s for the most competent rocks to $Vp = 1.8$ km/s and $Vs = 1.15$ km/s for the least competent rocks. The ground water presence has been attributed to its local percolation from the ground surface during rains and / or snow melting periods. The seismic impact which in the region of Banja Luka has PDE value of ground max acceleration of the order of 0.17 g has had minor influence to the support design of the tunnel structure. Its significance is however high for design of the surface structures

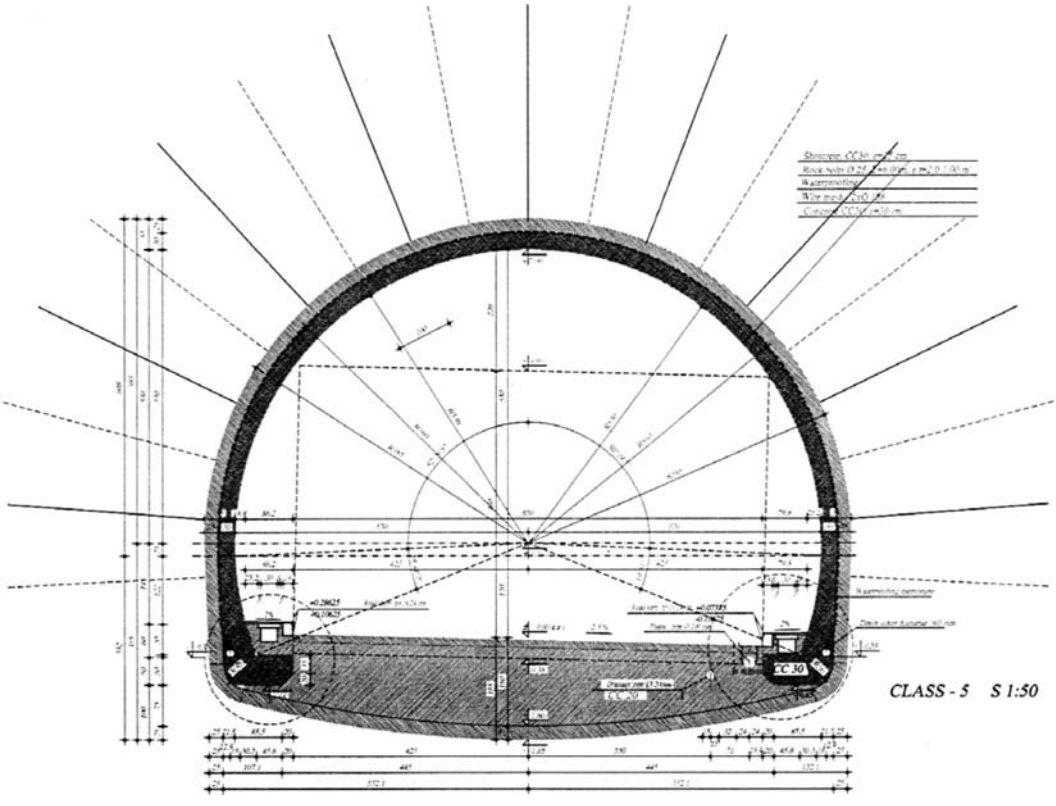

Figure 1. Klashnice tunnel tube type section.

and in portal areas. In general the design rock mass rating assessment (based on Bieniawski et. al. charts) resulted in RMR = 30 to 50 points for the most competent and RMR = 20 to 30 points for the least competent rocks. The design parameters (strength and deformability) for simulation of the rock mass and primary support behavior were derived from RMR rating. The additional empirical constants related to unconfined compression strength have been extensively used as the basic rock mass parameters. These constants have been then used for the estimate of mechanical properties of rock mass along the tunnel axis on the basis of the Hoeck – Brown contemporary empirical relationships between GSI and rock mass strength, and deformability. The cited "GSI" – Geological Strength Index has been recently extensively used as the basic rock mass parameter.

3 TUNNEL DESIGN AND CONSTRUCTION

Both tunnel tubes have been designed as "integrated rock – support" structure with rock support primary structure types classified in three basic support categories. It has been therefore anticipated that the rock competence is "good enough" to form the supporting ring around the excavation in jointed interaction with the primary support that allows the mobilization of the rock mass strength in vicinity of the supported excavation. The primary support has been designed to carry the rock mass pressures permanently i.e. without any interference with the final lining function. This approach resulted in the selection of the three classes of primary supports. In the most competent rock (RMR = 40 to 50 points), the primary support. consists of 15 cm thick sprayed concrete (with the compressive strength not less than 30 MPa), radial rock bolts at 2 m/2 m spacing, 4.5 m in length and standard reinforcement mesh of 4.2 mm bars at 10 cm spacing in both directions. This category however was used in the smallest length, of the order of 5 to 10% of the total tunnel length.

In the least competent rock (RMR = 20 to 30 points), the primary support consists of 25 cm thick sprayed concrete, radial rock bolts at 2 m/1.0 m spacing 5.5 m in length and two standard reinforcement meshes of 6 mm bars at 15 cm in both directions. The "inverted U" arched steel sections were placed

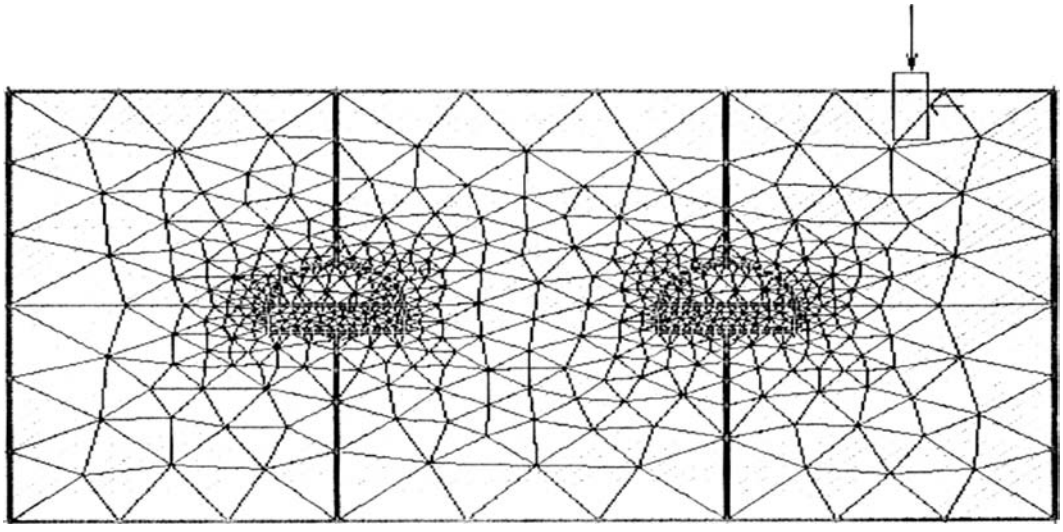

Figure 2. FEM modeling for twin tubes.

at the spacing from 0.5 to 1.0 m, as deemed necessary. This type of support has been used along app. 50 to 60% of the tunnel length. In the rock of intermediate competence (RMR = 30 to 40 points), the primary support consists of 20 cm thick sprayed concrete (30 MPa compressive strength), radial rock bolts at .0/1.5 m spacing 5.0 m in length, and two standard reinforcement meshes of 5 mm bars spaced at 15 cm in both directions.

The "inverted U" arched steel sections were placed at the spacing from 1 to 1.5 m, as deemed necessary.

After the completion of the primary concrete structure, the inner side of the sprayed concrete is covered first by the permeable geotextile liner and, then the waterproofing PVC membrane is fixed to prevent any ground water intrusion.

The permeable geotextile liner directs all eventual intruding waters to the collection pipe drains situated at the invert level at the both sides of the tunnel invert. This final lining is designed to carry the required infrastructure (lighting, fire protection, monitoring, traffic signs and other necessary facilities),and to provide adequate appearance inside the tunnel.

4 CONSTRUCTION PERFORMANCE

The excavation and primary support structure for the rocks of the cited competence usually applied within the sprayed concrete and rock bolting system (mainly quoted as NATM method), consists of the sequential excavation of the top heading following the excavation of the bench.

The cited procedure has been controlled by convergence measurements carried out in five points, one in the tunnel crown and two points on its left and right sides. At the installed marks the vertical and horizontal components of the inner sprayed concrete surface have been monitored for the period required for their stabilization. These measurements also indicated the requirements for forming up the section improving the support or to decreasing the length of unsupported excavation, and the possibility to compare the predicted values of primary support displacement to the actual ones. The original design provision of the cited procedure was based on the length of the fully supported top heading and bench section not less than 20 m in length before the start of the sequential excavation of the invert part. The excavations and primary support of the left tube was required to advance at least 30 m in front of the heading top of the right tube. The alignments of the tubes have been designed with inner (intermediate) rock mass space of app. 16 m thus providing the independent rock mass – support structure interactive relationship.

On the basis of performed numerical construction simulation (excavation and primary supporting) in 2D conditions by "PHASE V.6" software, the control of the actual displacements appeared reasonably well predicted for the better rock mass conditions and for the deeper parts of the tunnel.

This procedure was designed and performed in Klasnice tunnel, as no-blasting procedure, also with separate sequential excavation and the final – secondary lining consists of 30 cm thick reinforced concrete (30 MPa concreting of the lowest part of

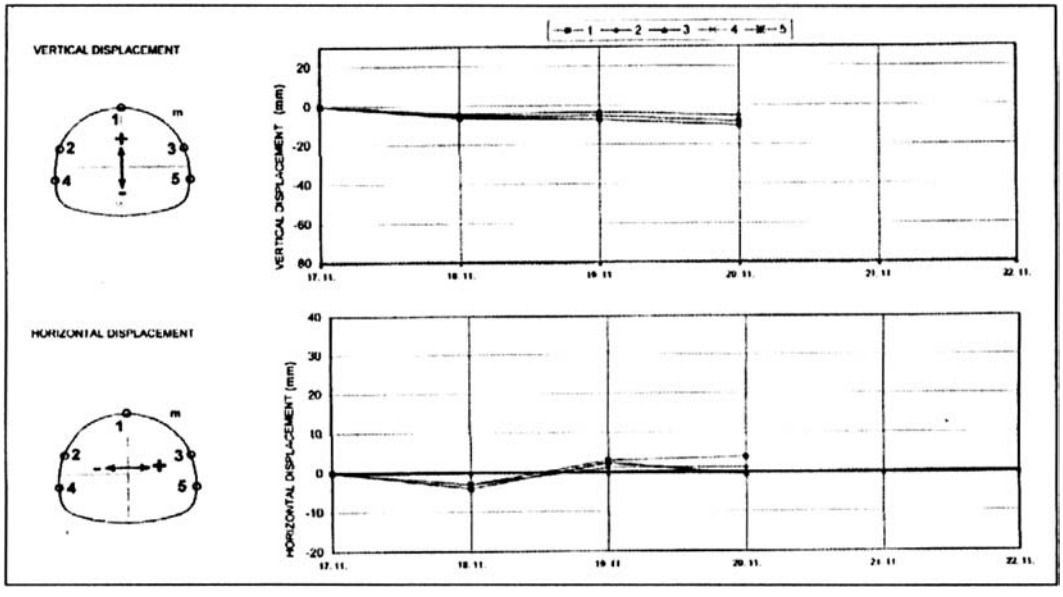

Figure 3. Type records for convergence measurements.

the invert as the latest step in CC) that is placed in conventional manner using movable formwork .

However the parts of the tunnel situated in the least competent rocks and being at the most shallow overburden thickness conditions, appeared less suitable for performed numerical simulation, that resulted in stronger support requirements and at the location app. 100 m from its exit the construction of the heading in the right tube was interrupted (in June 2006) by the rock fall in the length of app. 15 m forming the cave at the surface with the radius of app. 30 m at the collapse location the rock mass overburden thickness from the tunnel crown to the ground surface was app. 15 m thus indicating the limits of the reliable numerical simulation of the tunneling in the rocks of the low competency, such as appeared at the Klashnice tunnel.

The impact of this event on the construction timing and on the completion of the right tube required the fast and appropriate action for restoring the construction of the right tube. As the most adequate remedial procedure is envisaged the application of 20 m long fore poles – "umbrella" pre-support closely spaced steel tubes 4 inch dia, for forming up the complete arch above the designed excavation and primary support section. Then the step by step excavation of the collapsed rock mass and construction of 50 cm thick primary support ring fixed in the undisturbed rock mass at the lower part of the tunnel section is considered. The ground conditions at the tunnel exit have been considered in the design of the portal walls as "only conditionally safe" for a short period of time after excavation during dry season, the final stability had to be attained by backfilling of the excavated space above the tubes built as a "cut and cover" structures. The overall coordination of the works in this area was not fully performed to the cited requirements thus the development of instability of the area was prevented by retaining structure made of the row of closely spaced concrete piles made at the right side of the left tube.

5 LESSONS AND CONCLUSIONS

The "integrated design and construction" principle in tunneling often called by the acronym NATM, has been applied in the construction of Klashnice twin tube tunnel which substantial completion is expected in 2006. One of the basic requirements for the application of this tunneling procedure is the capability of the contractor to provide flexible and often very rapid modification of the initially designed excavation and primary support structure. The application of the cited flexibility is facilitated whenever the tunnel design is based on the already available experience in similar ground conditions, and previously performed estimates of the rock competence using RMR or some other reliable rating scale. The use of the available numerical simulation software is very helpful whenever the ground conditions correspond to the numerical models of rock mass used in the applied software, considering also the geometry limits of the model as important constituents to attain the proper

relationships with actual states. Nevertheless many important factors governing final stability of the primary support are to be learned during the construction period, and the changes of the rock mass competency associated with the size of the rock mass in question shall be constantly monitored and in an appropriate manner introduced into the structural reanalysis of the primary support. This is of the paramount importance particularly in case of the rock masses of low competence such as described in the case of tunnel Klashnice.

Still, even in inferior ground conditions, with accepting of occasional mishaps, such as local collapse of the top heading roof or/and front side, the "integrated design and construction" conceptual approach has its significant advantages comparing to the previously used firm design provisions for the primary support, that is inevitably linked to an overestimate of support requirements, particularly in poor ground conditions.

It is therefore, for the rocks similar to that were met in construction of Klashnice tunnel, the flexible approach in determination of final primary support dimensions, governed by the field experience gained during construction, shall be considered as fully appropriate. It is also important to stress that the geometry of the tunnel section and in particular its overburden rock thickness play very important role in selection of the excavation and support construction sequence and determination of necessary support strength.

The time factor, in tunneling is of primary importance, particularly in potential collapse situations, but also for the expedient completion of the already excavated or partially supported length. The monitoring of the performed support structure, was made mainly by convergence measurements, but also by monitoring of other important features such as cracks in sprayed concrete, appearance of percolating water etc.

All other records including the geotechnical rating of the rock mass during excavations are contributing to the timely completion of the tunnel structure, and provide the most reliable background for either improving support structure strength or decreasing its thickness, reinforcement number of anchors, etc.

Tunneling in an urban critical area – A case study

J.M. Carvalho & A.T. Cavalheiro
Departamento de Engenharia de Minas – FEUP & CIGAR, Porto, Portugal

P. Teixeira
Golder Associate Portugal

ABSTRACT: A 700 m road tunnel crossing very heterogeneous granite formations within a critical area of the city of Porto, Portugal, in which around 400 m were excavated below groundwater according to NATM principles, has been open to public use in 2005. The average excavated section area is 100 m^2 with a cover varying between 2,7 m and 21 m. The concerned area is quite challenging from a geological/geotechnical point of view – very heterogeneous Porto granite rock mass overlaid by residual soil – as well as from a technical/environmental and social point of view – intense traffic, densely constructed and under construction area having some problematic old nearby buildings with delicate foundations. The question of whether or not explosives should be used in such an environment has been a very controversial issue. Following various geotechnical, geophysical, vibration surveys, reports and feasibility studies, the tunnel has been successfully excavated using mainly blasting techniques and, whenever necessary, mechanized means. During the tunnel excavation a comprehensive seismic vibration monitoring survey took place aiming at preventing damage risks as well as optimizing subsequent blasting diagrams. The present report, following a brief summary of some project key issues regarding namely the final feasibility study, adjusted in-situ strategies during the excavation works, monitoring procedures and safety measures, presents seismic vibration monitoring data treatment procedures and an example of the promising preliminary results aiming at improving the geological/geotechnical model inference along the tunnel alignment.

1 INTRODUCTION

In 2005 opened to public use a 700 m long shallow -cover varying between 2,7 m and 21 m – urban road tunnel in the city of Porto, putting an end to a several years long process. Although the initial geological/geotechnical site investigation program was concluded in 1995, throughout the following ten years several hindrances delayed the conclusion of the project namely doubts regarding whether or not explosives should be used, causing a two year interruption in the tunnel excavation.

In fact, the involved urban area is rather critical from a geological/geotechnical point of view – very heterogeneously weathered Porto granite rock mass overlaid by saprolitic soil – as well as from a social/environmental point of view – densely constructed and under renovation area, with some problematic nearby old buildings. Following some studies and technical advices pointing to the inadequacy of using blasting techniques in such an environment, a feasibility study was then undertaken (Carvalho et al., 2003) in order to assess the possibility of using explosives to excavate the 400 m mining tunnel sector.

The main conclusion of the study was the predicted adequacy of using explosives in a maximum of two thirds of the total length of the tunnel. Nevertheless, considering the critical urban area involved, it was advised a continuous cautious blast monitoring, beginning with a predicted initial advance of 1 m per blast. It was also expected that the monitoring would indicate the subsequent possibility of further advances reaching a predicted maximum around 2 m.

The tunnel excavation works, using mainly explosives, restarted in January 2004, the heading tunnel excavation finished in July 2004, and the complete excavation finished in October 2004.

Following a brief description of the mentioned feasibility study key points as well as of the tunnel project including, namely, excavation works, monitoring strategy and safety measures (Carvalho et al., 2005) the focus will be in the under development procedures, and some preliminary promising results, for the treatment of the seismic monitoring vibration data acquired during the opening of the tunnel, aiming at improving the geological/geotechnical model inference along the tunnel alignment.

2 SUMMARY OF FEASIBILITY STUDY

In order to assess the adequacy and advantage of using explosives along the tunnel excavation, vibration tests were carried out in two selected areas, taking advantage of at the time existing surface excavations. Several holes, drilled in the rock mass, were loaded with weighted ammonia gelatine 33% charges and data acquisition took place at the surface in selected representative places, namely close to foundations of nearby buildings.

Extensive exploration of the optimization algorithms especially implemented in MatLab language for this purpose allowed the selection of three sets of values, for the used Langefors & Khilstrom equation parameters, considered representative of the rock mass. Results pointing to the advantageous possibility of using explosives allowed the dimensioning of a drilling and blasting design adjusted to imposed legal constraints, namely by the 20 mm/s PPV threshold allowable by the Portuguese NP-2074 safety Standard "Evaluation of the influence in buildings of vibrations due to blasting or similar effects".

The mentioned three sets of optimized parameter values were then used in a particle velocity formula in order to obtaining tables of theoretical explosive charges for different distances from source, depending on the considered admissible PPV thresholds, according to Portuguese, Spanish and Swedish safety standards.

Based in the obtained tables for particle velocity thresholds – distance – maximum admissible charge, simulations were performed for the three considered data sets, considering different maximum admissible velocity scenarios. These simulations led to mapping of the tunnel susceptibility to being excavated by explosives, assuming a calculated drilling and blasting design.

The synthesis of many simulation results led to the conviction that using explosives in two thirds of the total tunnel length was an adequate solution.

The vibration tests allowed a good picture of time window lengths having higher peaks as well as determining relevant signal frequency bandwidths. This kind of analysis allowing namely an estimation of the minimum advisable time-delay between consecutive detonations, is rather important for the planning of micro-delaying in the blast global design, in order to minimize the total wave amplitudes resulting from the sum of effects due to sequential blasting.

It was suggested a blasting diagram based on the heading and benching method with fun cut central ring, comprising two main phases, respectively for the heading tunnel and for the bench, having the first phase three distinct sequential sub-phases.

As referred, the main conclusion of the study was the predicted adequacy of using explosives in two thirds of the total length of the tunnel with initial exploratory advances of 1 m.

3 TUNNEL OPENING

3.1 *Some generic project data*

The two-way road tunnel (Fig. 1) is part of an E-W traffic corridor of the town global traffic network. The tunnel has a total length of around 700 m from which 400 m were excavated in very heterogeneous granite formations according to NATM principles.

The average excavated section area is 100 m^2, the cover varied from 2.7 m to 21 m, the water load above the tunnel varied from 3 m to 12 m, and the volume of removed terrain was about 40.000 m^3. On the surface, along its alignment, are located several very sensitive old buildings.

The predicted geological/geotechnical conditions (Fig. 2) along tunnel alignment show a very heterogeneous underground formation changing from W1 massive granite to W6 residual saprolitic soil. This model was later up-dated namely in the less surveyed, by drilling, W6-W5-W4 zone.

3.2 *Tunnel excavation*

Based on available geological and geotechnical information it was possible to define six E-W geotechnical tunnel segments using a G1 to G5 geotechnical classification related to the conventional W1 massive granite to W6 residual saprolitic soil classification.

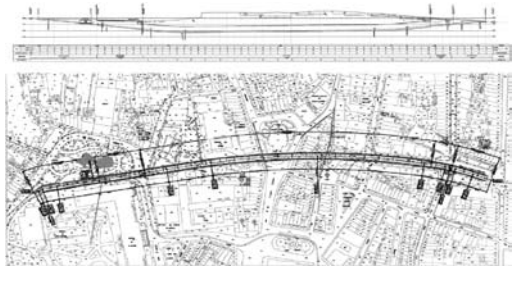

Figure 1. Tunnel alignment and cross section in top.

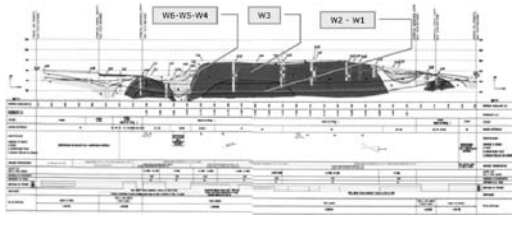

Figure 2. Predicted tunnel geological/geotechnical section.

The excavation was carried on using blasting techniques wherever possible and otherwise mechanical means were used, namely: roller-head, excavator bucket or hydraulic hammer. The excavation in poor ground is usually phased, accompanied by immediate shotcreting in order to minimize collapses of surrounding terrain and related surface settlements.

Excavation took place simultaneously from both sides, first for the total heading tunnel and next to the bench subdivided in two phases.

3.3 *Blasting*

In order to optimize the blast design constrained by Portuguese Standard NP-2074 PPV threshold, additional in-situ essays were carried on. Those results, combined with previously obtained ones in the mentioned feasibility study, lead to the finally adopted Langefors & Khilstrom equation parameters different from those previously obtained. Nevertheless the main conclusions of the feasibility study remained valid, namely the adequacy of blasting techniques use and the average advance per blasting event under the 20 mm/s PPV threshold adopted value.

The most advanced blasting control is presently, based on electronic detonators. In the present case the use of electronic detonators allowed optimizing the heading tunnel excavation method changing the initially suggested phased approach by a unique blasting event for the full front face (Fig. 3). The initially proposed phased approach has been adopted when mechanical excavation was used in weak clayish ground. In addition and among other advantages, electronic detonators allowed an excavation total time reduction of one month.

Figure 4 shows the blast diagram for second excavation phase, comprising the depicted two sub-phases "Bancada" and "Soleira" of the benching phase.

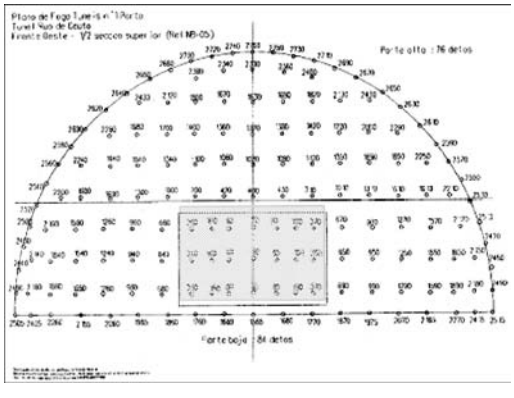

Figure 3. Heading tunnel: drilling design (blasting time sequence) with a 3 rows V shaped central ring.

The worst disturbance and possible danger in using explosives in an urban environment is due to induced propagating seismic vibrations. In order to monitor the attained vibration level at surface during excavation, before each blasting round was placed in the surrounding area a network of White Industrial Seismology, Inc. Mini-Seis seismographs that registered the ground induced vibrations. The analyzed results were used namely to tune the charges of the next blasting sequences and to identify and locate in the blasting diagram the charge responsible for exceeding the adopted PPV threshold, if this would be the case.

From more than a thousand of events, their PPV and predominant frequencies were registered in daily reports. The experimental distribution of PPV readings is very well fitted by a lognormal distribution as Figure 5 shows.

Presently, the mentioned acquired vibration data is being used in the subsequently presented methodology.

3.4 *Monitoring and safety measures*

Considering the very sensitive urban zone involved, a careful monitoring network has been installed at ground surface, buildings and underground. It has been controlled the displacements in buildings and terrain, the water level and the seismic and acoustic vibrations. All along the excavation geological/geotechnical characterization of crossed zones took place.

The monitoring campaign used the following equipments and procedures: accurate topographic survey at selected surface and in building locations; vertical

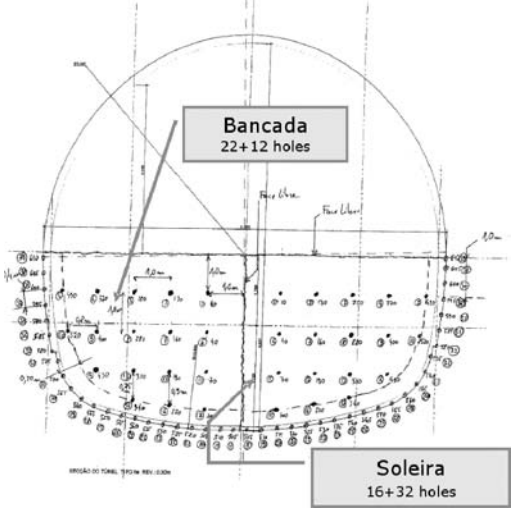

Figure 4. Two sub-phases of second excavation phase drilling design.

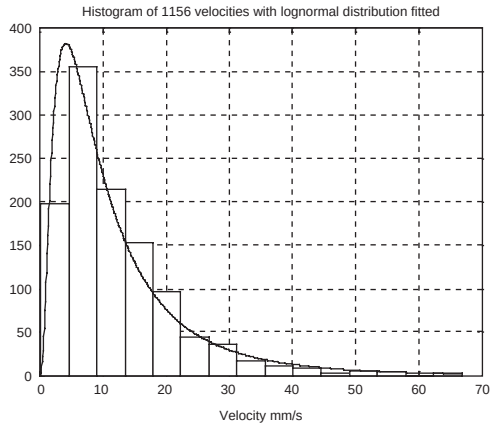

Figure 5. PPV histogram fitted by a lognormal distribution.

extensometers at surface; inclinometers for measuring horizontal deformation in depth; piezometers for water level control; tiltmeters for measuring displacements, namely rotational, in buildings; intensive survey of cracks was also made.

Every building considered in risk of damage during excavation was previously verified in order to establish adapted safety measures and, during excavation works, data from monitoring survey was analyzed in order to decide whether or not were necessary further safety measures.

4 VIBRATION DATA TREATMENT

Next will be presented a seismic monitoring vibration data treatment approach aiming at improving the ground characterization between the tunnel front, where blasting events take place, and the surface vibration monitoring detecting devices.

The fraction of the ground crossed by the generated seismic energy, between an underground single detonation and a receiver, may be considered a system/filter applied to an input signal, $s_i(t)$, whose output signal, arriving at the receiver, is $s_o(t)$. The Fourier transform of $s_o(t)$:

$$S_o(f) = \int_{-\infty}^{\infty} s_o(t) \cdot e^{-i2\pi ft} dt \qquad -\infty < f < \infty \qquad (1)$$

contains the amplitude and phase information of every frequency present in $S_o(f)$. Assuming an invariant receiver, the changes observed in $S_o(f)$, are mainly caused by the type and characteristics of the traversed ground and in a much minor degree by changes in the detonation characteristics.

In a blasting sequence, the recorded three component seismogram contains the information related to a number of different overlapping individual blasts whose overall frequency content is expected to vary with space or time.

The conventional Fourier transform of the registered seismogram does not allow establishing any correspondence between space or time and frequency domains. In order to establish such a correspondence will be used a windowed Fourier transform calculated by the Matlab function "specgram.m". This function splits the signal into overlapping segments, windows each with a Hanning window vector and calculates the spectrogram from signal, as a time-localized sequence of Fourier transforms.

In order to investigate the possibility of using this methodology to correlate the different ground characteristics/features along tunnel alignment with their distinctive associated frequency content, some seismograms were selected, corresponding either to different tunnel geotechnical sections or vibration monitoring positions.

In an ideal situation, the system impulse response i(t) or its equivalent, in the frequency domain, transfer function I(f), can be deterministically calculated.

Assuming an idealized input signal, $s_i(t)$, resulting from a detonation, as a Dirac impulse function, $k \times \delta(t)$ and the fraction of ground crossed by the seismic energy as a linear, stable system of constant parameters, the output signal, $s_o(t)$, reaching the receiver could be deterministically calculated as the convolution of $k \times \delta(t)$ by the ground impulse response, that is $k \times \delta(t)*i(t)$. In reality the recorded signal "results" from a sequence of partial convolutions associated with several crossed ground sections and overlapping seismic waves due to the sequential blasting events.

The preliminary results obtained with the referred approach are promising, pointing to the possibility of capturing, in the frequency domain, some geotechnical/geological relevant ground characteristics/features.

4.1 *Some preliminary results*

As an example, two seismic vertical component records, W432032 and W432036, were chosen corresponding to the monitoring at ground surface of the same blasting event, in which the heading tunnel excavation progressed 1,5 m eastwards and the maximum explosive charge in each of the 130 blasting diagram holes was 0,5 Kg. Figure 6 shows the partial geological/geotechnical predictive model section along tunnel alignment in which both blasting and monitoring took place. The blasting took place around PK 0+444 and the detecting devices were respectively located at surface around PK 0+443 for record W432032, almost vertically in respect to blasting, and around PK 0+473 for record W432036. The respective linear distance between blasting and detection was around 14,23 m and 32,27 m. Blasting took place close to an interface between two distinct grounds, corresponding to

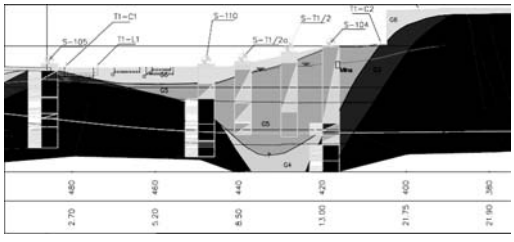

Figure 6. Predicted geological/geotechnical partial section.

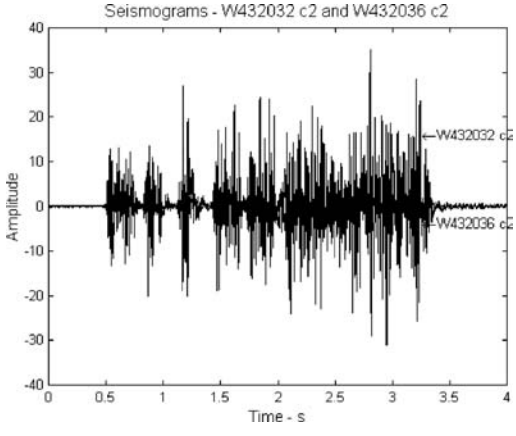

Figure 7. Seismograms W432032 and W432036.

different geotechnical predictive sections, G5 and G6 eastwards in the direction of tunnel progress and G2 and G1 westwards.

Figure 7 shows the two referred vertical detecting transducer records, W432032 and W432032.

The two seismograms amplitude spectra, after normalizing both spectra areas, are shown in Fig. 8 in which can be compared their global frequency content. The unit area normalization allows a clearly observable higher filtering effect of sections G5 and G6. In fact, although the traveled distance is significantly longer for record W432036, whose average trace amplitude is much smaller than for record W432032, the global filtering effect of the crossed ground is significantly less evident.

The referred effect is graphically put in evidence in Fig. 9 in which the difference between W432032 and W432036 amplitude spectra is shown, up to 275 Hz frequency. Negative frequency amplitude values correspond to the differential significantly higher filtering effect of the ground above the blasting event when compared with the predominantly G1 and G2 segments.

In Fig. 10 the phase spectra of both seismograms show the higher phase shift change rate global effect of sections G5 and G6 when compared with sections G1 and G2, accordingly to what could be expected.

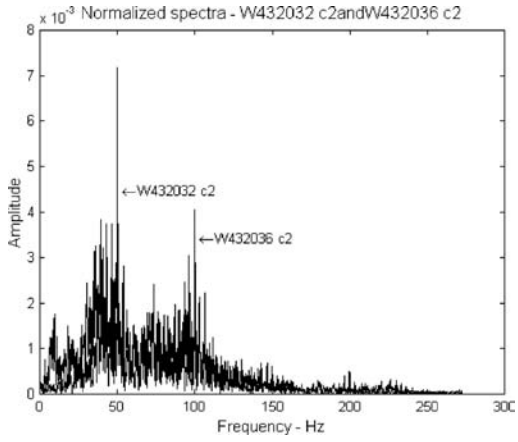

Figure 8. Signals W432032 and W432036 normalized amplitude spectra.

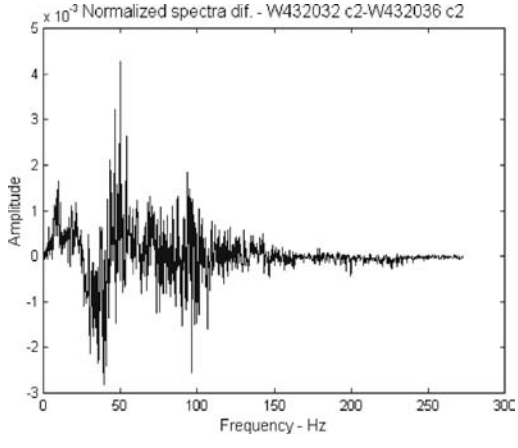

Figure 9. Signals W432032 and W432036 normalized amplitude spectra difference.

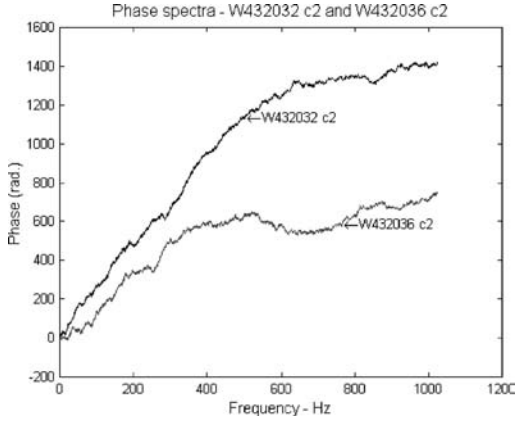

Figure 10. Signals W432032 and W432036 phase spectra.

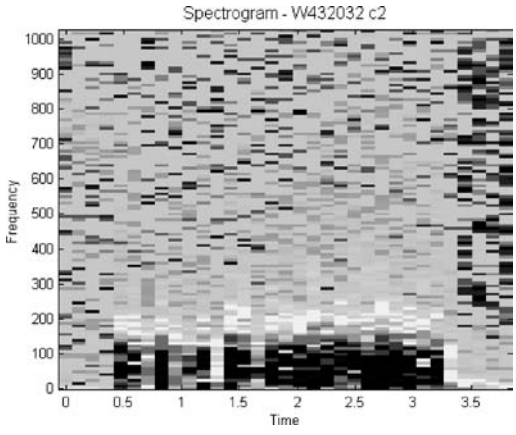

Figure 11. Spectrogram of W432032 seismic record.

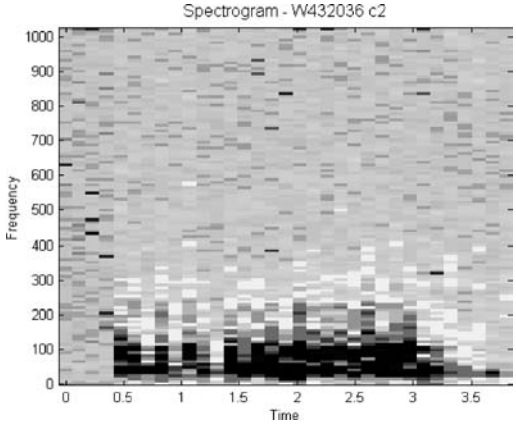

Figure 12. Spectrogram of W432036 seismic record.

As previously mentioned the conventional Fourier transform does not allow establishing any relationship between time or space domains and frequency domain. The next two figures showing the spectrograms of records W432032 and W432036 illustrate graphically the associated differential filtering effects in both cases as a function of time using a selected Hanning window. Its length may be adequately adapted in order to obtain a convenient spectra distribution along time.

In addition, to evaluate the relative energy absorption between both grounds, the following approach has been used.

The decrease of amplitude due to absorption for elastic waves in rocks and a given frequency appears to follow an exponential law with distance (Sheriff & Geldart, 1982):

$$A = A_0 e^{-\eta x} \tag{2}$$

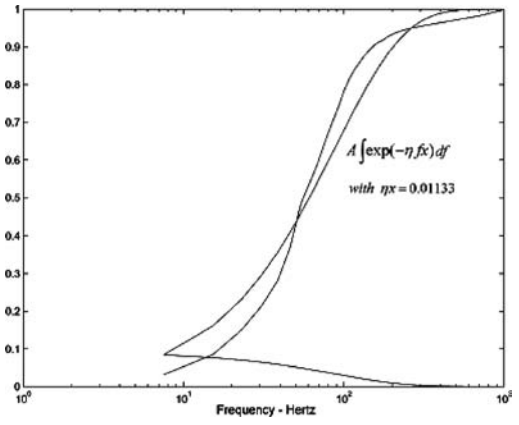

Figure 13. W432032 data fitted by the cumulative normalized module of Equation 3.

where A and A_0 are amplitude values of a wavefront at two points a distance x apart and η is the absorption coefficient. Experimental evidence suggests that the absorption coefficient η is approximately proportional to frequency, that is, $\eta \times f$ is roughly constant for a particular rock, so the final form that relates attenuation with frequency and distance is:

$$A = A_0 e^{-\eta . fx} \tag{3}$$

The adjustment of η, made with Nelder-Mead simplex search algorithm of Matlab Optimization Toolbox, on the records W432032 and W432036 normalized spectra cumulative curves, lead respectively to the following unit η values: $\eta_1 = 7,97 \times 10^{-4}\,\mathrm{m}^{-1}\mathrm{s}$ and $\eta_2 = 2{,}08 \times 10^{-4}\,\mathrm{m}^{-1}\mathrm{s}$, which means that attenuation in the first situation was, approximately, four times the attenuation in the other one. Figure 13 shows the obtained fit for record W432032.

5 CONCLUSIONS

Following a brief summary of the long process related to the opening of a road tunnel in the city of Porto, this report presents the preliminary results of vibration seismic data treatment. The generic aim of the present approach is to take advantage of data obtained during vibration monitoring surveys of underground excavation works with explosives in sensitive urban areas in order to gain a better understanding of the involved rock/soil mass formations. The promising preliminary results point to the possibility of reducing the uncertainty associated with the predictive initial geological/geotechnical model updating process.

The final objective of the described approach is to develop a methodology capable of capturing, in

the frequency domain, the "signature" of distinctive geological/geotechnical relevant ground characteristics/features allowing an optimized risk damage control.

ACKNOWLEDGMENTS

The authors are grateful to GOP-EM, a Porto townhall municipal enterprise for all the support, namely in providing information.

Construction of city service tunnel in Ostrava without preliminary protection of surface

Karel Franczyk
Subterra, a.s., The Czech republic

Karel Dolinek
Tchas, a.s., The Czech republic

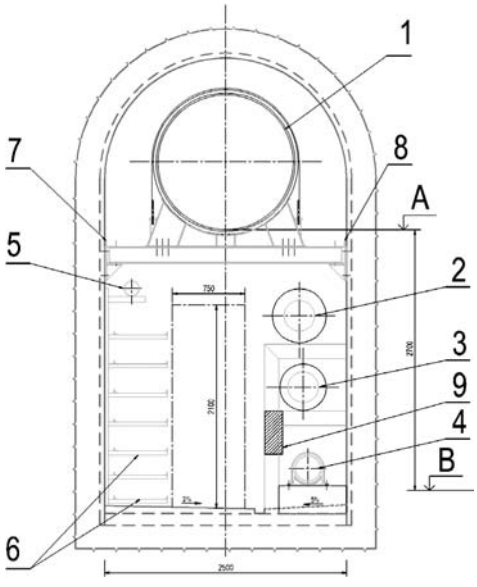
ABSTRACT: There is a long history in building city service tunnels in the Czech republic, especially in Prague and Brno. That tunnels are very sensitive to surface and protection of buildings. Therefore it is usuall to do a general protection of the surface facilities as a preliminary means before the construction starts. Those means (typically jet grouting, deep walls, etc) are however very expensive and not always are neccessary. During the city service tunnel construction in Ostrava, completed in 2003–2005 a very different way was chosen. The protection of surface was completed after precise measurements of settlements, ground water table changes, etc after decision of the group of experts. Thus the means were tailored to a specific problem and were limited in time, extend and cost. The way was very flexible and enabled to solve particular problems differently under specific conditions. The paper describes the observation methods, the decision making procedure, the protection means (grouting, chemical grouting, micropilots, jet grouting, bolting, etc), the final effect on the surface as well as the estimation of the cost saving, that has been significant towards the general protection method. The paper also briefly describes the project itself from the very beginning to the end, including the unique design of sewer positioning, and all experiences from the completion.

1 INTRODUCTION

The challenge that city of Ostrava in general,designers and contractors had been facing in 2002 was to build a service tunnel – nearly 2 km long – in the city centre conditions with many buildings close along, many of them disturbed by mining activities in a past, under heavy traffic roads and crossings, with gas explosion hazard due to methane occurrence and able to involve/apart from central heating, cables, water supply, etc.) a gravition sewer pipeline 1400 mm ID to 600 mm ID including all house connections.

2 IMPLEMENTATION OF TEAM DATA

Investor: Statutory City of Ostrava, Investment Department, Co-financed by the European Union, ISPA Fund, and Environment Ministry of the Czech Republic. Contractor: Ostavské kolektory consortium. Leader of the consortium: Subterra, a.s. Member of the consortium: Tchas, division Ingstav Ostrava. General designer: Hutní projekt Ostrava, a.s. Engineer : Consortium Technoprojekt – Halcrow JV. Building office: Ostrava.



3 CONSTRUCTION DATA

Implementation period : 1. January 2003 to 30. November 2005. Tunnel length : 1769,57 incl. The 112 m of sewer gallery. Contract value : 702 mil CZK.

4 BRIEF CHARACTERISTICS OF THE CONSTRUCTION

It is a City service tunnel right in the historical centre of Ostrava that joins the service tunnel in Poděbradova Street, completed in 1999. Already during that construction it showed that when constructing the service tunnel network, the main difficulty will be the existing integrated sewer system deposited approx. 3 to 4 m deep under the street surface. In Poděbradova St., the sewer system renewal was solved using a new sewer pipe place in the excavation on both sides of the service tunnel.

The state of the City Centre sewer system resulted in a logical requirement by the City Council, that a problem-free rainwater and wastewater drainage be solved together with the service tunnel construction. The original study dealing with the City Centre service

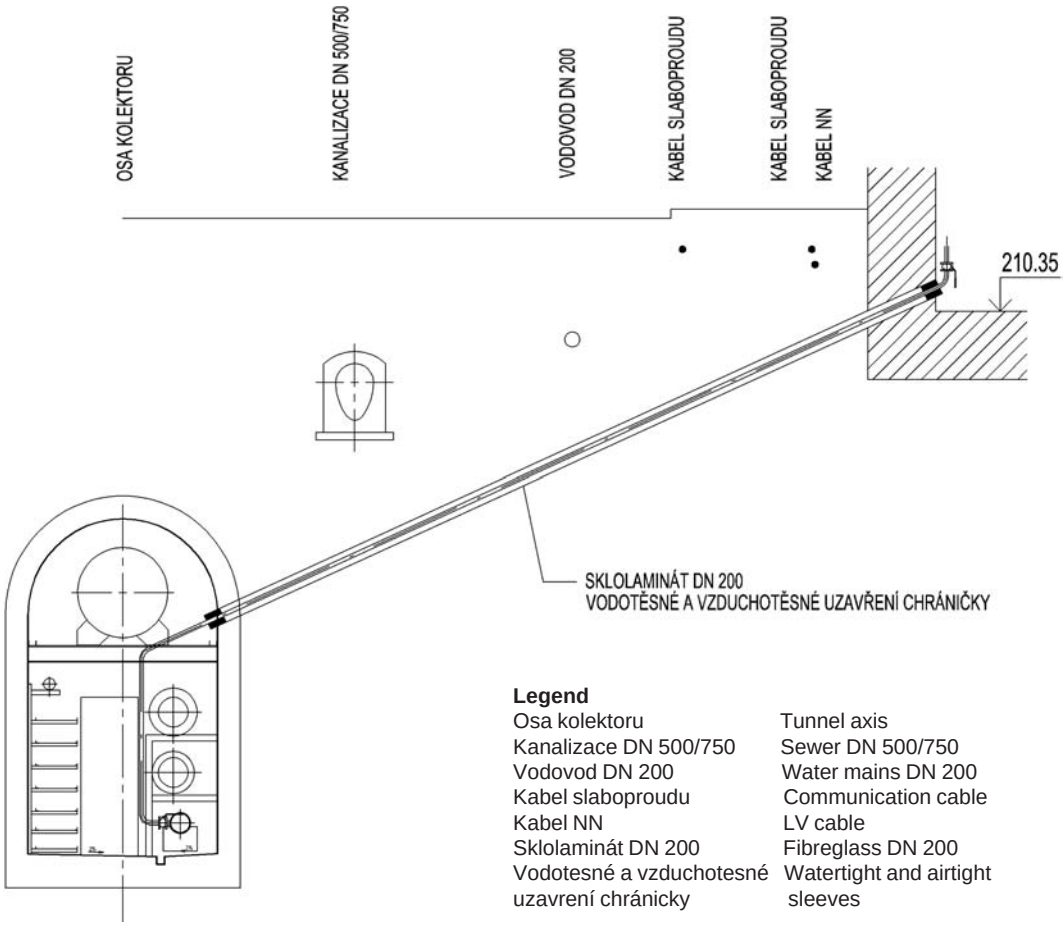
tunnels proposed the placement of a new backbone sewer under the service tunnel. That, however, resulted in the following environmental problems:

- Repumping the wastewater and rainwater from the Ostrava City Centre
- Operating sewerage pumping station in the City Centre
- Operating costs of repumping the wastewater and rainwater reach the value of several million crowns during the tunnel lifetime



Therefore, during the Construction preparation, a goal was set that the tunnel provide also gravity drainage for the wastewater and rainwater away from the City Centre.

Such a requirement lead to verification of series of designs where the sewer pipe was placed on structures as well as in underground tunnels and finally a completely unconventional location of the sewer pipe was designed in the tunnel calotte. Since there is, from the urban point of view, a stabilised development in the City Centre around the tunnel, this enabled the long-term solution for a problem-free rainwater and wastewater drainage without the necessity of future excavations in the streets.

Geologically the tunnel was situated on the joint of two geological forms – neogene clays from the bottom and tercial gravels from the top. As clays have been waterproof whereas gravels are very permeable, the typical problem was dealing with huge water inflows. Another problem was changing character of the ground were both clays, as well as gravels changed many of its physical and geotechnical data very frequently.

The City Centre Service Tunnel is 1668 m long and along its whole length it was driven employing a mining method. 112 m long sewer tunnel – also driven – also forms a part of the Construction. The whole tunnel has a uniform width of 2.5 m and its height varies according to the diameter of the sewer pipe from 3.6 to 4.5 m. The driving was done classically, employing a new Austrian tunnelling method, mostly with two benches, in a lesser part in a full profile. The driving was done from six access points (shafts) simultaneously. After the tunnel was completed, five shafts were filled up and one created the Central Entry in the tunnel. Possible occurrence of methane under Ostrava could complicate the Construction; therefore some conditions applicable in coal mining had to be observed (methane indication, non-explosive design of electrical equipment, ventilation, etc.)

To connect surrounding buildings, local connecting sleeves have been constructed connecting the building to the tunnel. The sleeves, too, have been constructed using trenchless controlled drilling from the tunnel. Sleeves for heating and drinking water, gas connection, LV connection and telecommunication cable as well as sewer connection have been brought to every building along the tunnel. Sewer connections from the street gullies as well as from particular buildings are

Legend

Osa kolektoru	Tunnel axis
Kanalizace DN 500/750	Sewer DN 500/750

Sklolaminát DN 200	Fibreglass DN 200
Vodotesné a vzduchotesné uzavrení chránicky	Watertight and airtight sleeves

connected to new connecting manholes connected using trenchless technology to the sewer pipe in the service tunnel.

The new connecting manholes located in the pavement edge, or in the road, close to the kerb stone, allow a controlled connection of the house connections as well as street gullies. At the same time, such system provides for a possibility of connecting new sewer connections. Thus, 7518 m of connections have been constructed.

Gradually, the existing sewer branches, sloping towards the tunnel, were connected to the main sewer duct in particular intersections.

Drinking water mains, central heating, sewerage and some HV cables were placed in the completed service tunnel. Gradually, according to the needs, other HV cables, telecommunication cables, cable TV and others will be added. Supporting equipment and sleeves for houses, as well as in the intersections for connecting the adjacent streets, are prepared for all the energy distribution systems.

5 VERBAL DESCRIPTION OF THE CONTRACTOR'S CONTRIBUTION TO THE LIMITATION OF ADVERSE IMPACT OF THE CONSTRUCTION ON ENVIRONMENT

The Construction was implemented in the very centre of the City of Ostrava. In spite of that, apart from minimal occupation of land near the access shafts, the Construction in no way restricted the City traffic and transport. All the tramway, trolleybus and bus lines, as well as all the roads and walkways were preserved, even in the areas right above the large tunnel chambers (e.g. the K1 chamber's clearance is 7 metres and is situated mere 3 metres under the major intersection of Sokolská and Českobratrská Streets; during the construction, the intersection was fully operational). During the construction, all the requirements by the City concerning the noise, transport and dust were observed using the available technology (silencing the machine elements, using the continuous non-reload transport of concrete mixture with top panels over

the pouring areas, sprinkling when spraying concrete, removing the excavated materials only in the time specified by the City, etc.) In spite of a fact, that the tunnel goes in the city center all along buildings, none of the buildings had been stabilised before the construction to be preserved. There were measurements undertaken on all buildings as well as on the terrain itself, pointing the emergency as well as critical values of settlements for each of the buildings. The whole tunnelling was done under protection of roof bolting on a face. In case of touching the emergency points on measurements, other means were undertaken like jet grouting, micropilots and grouting of conventional materials. Thus – 6 buildings have been eventually protected by deep walls from the influence of the construction. This was however still much more economical solution as most of all buildings needed no protection at all. Even though some other 10 buildings have been repaired after the construction finished, these repairs were only cosmetic ones and the total costs of the construction remained considerabely lower compared to a possibility with uniform protection of buildings before the commense of the tunnel construction.

6 CONCLUSION

The project has won prices for "Environmental friendly construction of 2005" and "Water and sewer construction of 2005" in the Czech republic. It also applied for the International NO DIG AWARD on the ISTT conference in Brisbane in October 2006. At the time when this paper was written, no result on that was known.

ABSTRACT: The 1,440 m long Sitina tunnel is the major structure built under the Lamacska cesta – Stare grunty section of the D2 Motorway project in Bratislava, the capital of Slovakia. The project is considered an extremely complicated as there is a number of aspects which had to be considered under the tunnel driving phase. In the first place, the tunnel was driven under the conditions of a highly weathered and altered granite formation and low overburden. The project also faced the challenge relating to the closeness of the site to the existing urban area. Driving work was executed downhill of and close to the research institute complex equipped with a number of sensitive measurement devices and the Zoo serving as the recreation zone for the inhabitants of the city.

1 INTRODUCTION

Bratislava, the capital of the Slovak Republic, is situated on the Vienna – Bratislava – Budapest line connecting three capitals on the river Danube. With its position close to Vienna and benefiting from the European TwinCity Bratislava – Vienna project, the town is facing the great development perspectives and hence necessitates for an intensive and complex solution in the field of transport infrastructure.

Moreover, the necessity to complete the basic infrastructure in Bratislava has sharpened due to the long-lasting failure to solve this problem.

Motorways D1 and D2 (Fig. 1) are the crucial lines of the transport infrastructure of the town. The Lamacská cesta – Stare grunty section including the Sitina tunnel is the last missing section of the D2 motorway connecting the Czech Republic and Hungarian borders, with a branch line to Austrian borders. The western part of the town currently suffers for the combined transit and urban traffic load concentrated to the Patronka junction area, the most heavily trafficked junction in Bratislava with the average number of 65 thousands vehicles daily passing through. The completion of the D2 Lamacska cesta – Stare Grunty motorway section would release the Partonka junction from the traffic burden and finally create the motorway section by-passing the centre of the town, which allows the urban roads to get released from the transit and outskirt urban traffic.

Figure 1. Project location on the city map.

2 LOCATION AND HISTORY OF PROJECT

The efforts aimed at solving the critical transport situation on the western road access to the town are more than 10 years old. First studies mentioning a tunnel-based solution were worked out in 1980s. In 1995, a technical study was developed for the Slovak road administration providing 9 alternatives of the connection of the Lamač D2 Motorway section to the Lafranconi Bridge. A number of alternative solutions, including 3 tunnel-based ones, were worked out in addition to the initial solution – the left by-pass underrunning the railroad and Patronka junction. The multi-criteria evaluation showed the solution including the 1.5 km long Sitina tunnel routed through the uphill bearing the same name to be the most advantageous. The land-use permit documentation for the chosen alternative was worked out in 1998 and the building-permit documentation in 1999–2001.

In the urban territory it was extremely hard to design a suitable corridor acceptable as the consensus considering all stakeholders' interests within the location concerned. Routing of this motorway section close to the Zoo recreation zone and the Slovak Science Academy buildings with a number of workplaces which could have been affected by the motorway section constructed and subsequently operated in their close neighbourhood raised the demand for specific solutions.

The first specific task included a thorough preparation of environmental and seismic monitoring. Based on the results of the noise, vibration and emission monitoring a number of measures including the adjusted working time and schedule aimed at minimizing the impact of the motorway construction, especially the necessary tunnelling works, onto the surrounding environment, were worked out and subsequently implemented under the construction phase.

Also, the noise and emission impact of the motorway in service had to be thoroughly considered. The anti-noise measures included the extension of the cut-and-cover section and location of the tunnel faces in from of the Academy area, and a system of anti-noise barriers behind the tunnel exit in Mlynská dolina close to the Zoo. The geographic situation of Bratislava and the local microclimate provide favourable conditions for the dispersion of emission in the atmosphere. Considering all the aspects, no additional measures were necessary to improve the tunel emission dispersion.

The tasks relating to the construction logistics and ensuring the smooth public transportation had to be faced in the design-preparation and construction phase too. The site included a number of heavy-trafficked public roads requiring a multiple traffic diversion and ensuring the site traffic access to both tunnel forefaces and minor sites of the structures designed on the existing road lines. Moreover, the time schedule of the project had to consider the traffic intensiveness on the adjacent roads varying in the course of day and organize the heavy site traffic so as to avoid the main traffic-peaks.

The tender for the project announced in the second half of 2002 awarded the contract to one of the three bidders, the Japan-Czech Joint Venture Taisei Corporation – Skanska. The total length of the motorway section is 3.3 km. The overpassing junctions and especially the first two-tube tunnel within the Slovak motorway network are the main structures within this section. The construction of the tunnel started in the summer 2003. The driving of both tunnel tubes was completed in the spring months of 2003. Building works on bearing structures ran concurrently with tunnel drilling. In 2005, the construction of the cement-concrete paved road was completed. The trial operation in the tunnel is expected to start after the installation of the tunnel operational and technology equipment is completed in 2007.

3 BASIC SPECIFICATIONS OF THE TUNNEL

The Sitina tunnel will be composed of two one-way tunnel tubes. In case of the traffic closure of one tunnel, the remaining tube will be used for two-way traffic. The transportation and engineering prognostic studies expect the traffic load in the tunnel to exceed 20,000 vehicles per 24 hours in both directions as soon as in the year of its putting into service. This is why no but the two-tunnel solution was acceptable for this project. The locations of both tunnel faces, as well as their elevation and directioning, were determined by the current use of the lots concerned and their development, and by the need to minimize negative environmental impacts as much as possible.

Basic technical specifications of the tunnel are as follows:

- Traffic area 7.5×4.8 m
- Excavation area: 79 – 98 m^2
- Tunnel length: 1,440 m; 1415 m
- Driven tunnel length: 1189 m, 1159 m
- Lay-byes: 1 lay-by in each tube
- Cross connections: 4 person passages, 1 emergency access passage
- Emergency niches: one per 150 m
- Fire niches: one per 90 m
- Tunnel ventilation: longitudinal

Both tunnel tubes have been divided into particular driven sections and cut-and-cover sections built in the open construction excavations at both tunnel faces. These sections were be filled after the construction was completed. A more than 200 m cut-and-cover tunnel section in the Academy area, which is actually built on the surface, was included into the project in order

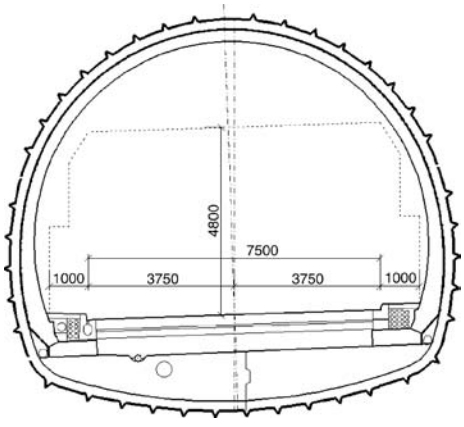

Figure 2. Typical cross-section of the driven tunnel with invert.

to protect the area concerned against the negative site-traffic impacts (noise, emissions).

The driven tunnel tubes (fig. 2) can be also divided into inverted tunnel sections built due to less favourable geological conditions and the sections without any invert built in generally more favourable conditions. The share of the inverted sections in the total driven tunnel footage reached 13%. The inverts are situated mainly in the face-adjacent sections and in the tectonically corrupted zones.

4 GROUND CONDITIONS

The Sitina tunnel was mostly driven in granitoid formations of the Sitina uphill situated in the meeting point of the Male Karpaty (Small Carpathians) Mts. and Lamacsky prielom valley. The uphill massif was characterized by heterogenous formation due to various tectonic fault zones along the entire tunnel. Rocks adjacent to tectonic fault zones were strongly altered, partially intensively mylonitized, creating a formation of mixed clay minerals and altered rock fragments. Except for granitoid formations, there were converted rock partings often intensively mylonitized, found along the tunnel route. Biotic paragneiss was the dominant type of converted formations. During tunnelling works, the massif was quite dry, underground water occurred mainly due to waterfall and was limited to weathered formation partings.

A relatively small height of the tunnel overburden varying from 4 to 32 m was also a significant tunnelling factor (fig. 4). The low overburden not exceeding 12 m was found in the portal sections and in two local depressions along the tunnel route. The rock arch over the tunnel excavation profile cannot be created in the sections with the low overburden.

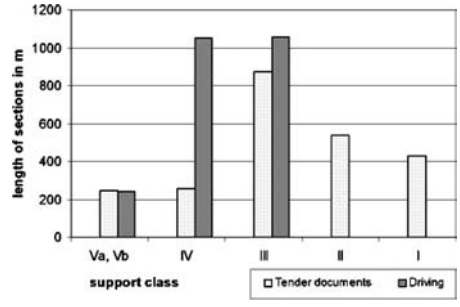

Figure 3. Comparison of total amount of expected and actual support class length for both tunnel tubes.

The tunnel lining structure had to be fully loaded by the overburden in these sections.

5 CONSTRUCTION METHOD

Construction work was launched in the summer in 2003. First, the tunnel faces were built in the south in the Mlynská dolina valley and in the north close to the SAV area. In the late 2003, both tunnel tubes started to be driven from the south face in the Mlynská dolina valley, and in the next year tunnelling works were launched on the north-face sites. The west tunnel tube was finally cut-through in March 2005 and the eastern tube in May 2005.

All tunnelling works were carried out in compliance with the New Austrian Tunnelling Method. The tunnel was vertically divided into the top heading, bench and invert, if appropriate. The applied 150 to 250 mm shortcrete primary lining was reinforced using one or two steel welded mesh and steel lattice girders. Also, the tunnel was systematically radially anchored using the 4 to 6 m long SN anchors. The stability of the tunnel roof was ensured using fore poles and 4 to 8 m long IBO anchors. The face and the tunnel roof were protected by a 12 m long micropile umbrella roof over the tunnel arch in the face-adjacent sections with a low overburden.

During tunnelling works in both tunnel tubes, the actual rock formation conditions showed to be less favourable if compared to the tender documents (Frankovsky & Snopko 2006). Support classes II and I with a 2.0 and 2.5 m advance could not be used. Moreover, the explosion works assumed in the tender documents have been significantly reduced since mechanical excavation could be used within a large portion of tunnel tubes. See Figure 3 and Figure 4 for comparison of assumed work and actual driving.

The system of geotechnical measurements applied during the Sitina tunnel construction have been applied in compliance with current driving practice according to the NATM principles using tunnel deformation

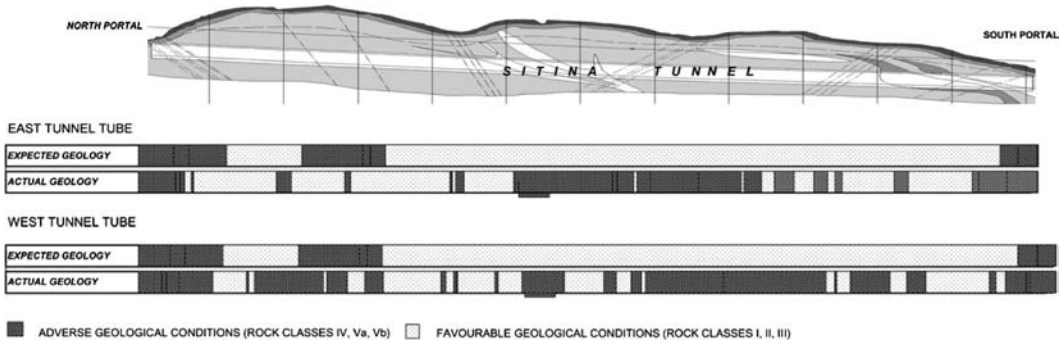

Figure 4. Longitudinal profile with comparison of expected and actual geologic conditions.

(convergences) measurement, surface deformation measurement, extensometric measurement, inclinometric measurement, face slope deformation measurement, measurement of the stress in the primary lining and contact stress values and measurement of then stress in the secondary lining concrete. Deformation progress of the massif formation was characterized by mostly limited, fast maturing deformations usually not exceeding 25 mm. Local maximum values of radial tunnel deformations did not exceed 76 mm.

The thickness of the final lining of the driven tunnel is 300 mm, or 350 mm in lay-byes. The standard length of the final lining blocks is 10 m. The reinforcement of the final lining was designed on the basis of the static calculation results assuming that the massif load will be partially borne by final lining and partially transferred by the primary lining. The reinforced lining blocks of the driven tunnel were applied along the face-adjacent sections with the low overburden, in the sections with a significant deformation performance or local failures of the tunnel roof stability, in lay-byes and in the blocks including emergency cross-connections. The total number of 56 fully reinforced blocks represents 24 % of the footage of both driven tunnel tubes.

6 DIFFICULTIES DURING TUNNEL DRIVING

There are many ambiguous factors, especially in tunnel construction, which could not be foreseen at the design stage. Therefore, it is important to workout the "Action-Measurement-Interpretation-Evaluation". The protocol considering the special urban tunnelling aspects has been developed for the Sitina Tunnel project (Zuzula et al. 2004).

Following the common procedure, the Geotechnical Committee was established at the first stage of the project in order to overcome any difficulties within the project. The Committee was created by the National motorway society (the Client) and was composed of designers, engineers, geologists and Contractor representatives. The project is located in the urban area and many factors relating to adjacent spaces had to be considered such as noise, vibration and ground settlement due to tunneling works.

The difficulties faced under this project included cave-ins occurring due to the adverse geological conditions under the blasting at cutting stage which required interruption of works resulting in delayed performance and representing potential danger to workers and people in the adjacent areas. The project considered 4 major cave-ins and procedures were worked out to eliminate the relating risks. These procedures enabled the implemented step-by-step solutions to be confirmed under the project execution stage. The developed procedures can be divided as follows:

- investigation of the reasons for cave-in occurrence;
- additional survey aimed at localization of potential cave-ins occurrences;
- identification of the cave-in occurrence mechanisms,
- respective support pattern changes.

The following characteristics have been detected and conclusions made on the basis of the rock formation surveying using the sample cave-in occurrences:

- the sufficient strength of the rock (80–160 MPa);
- the partial occurrence of clay in the rock joints;
- the cave-ins cannot be foreseen using the results of the cutting face surveying: the face was firm and stable before blasting;
- no symptoms were detected during the drilling of forepoles;
- difficulties in the cave-in localization based on the additional survey carried out from the surface.

The situation is similar to the so-called "domino effect". Several reports dealing with these issues have been already published in Japan. There are a number of cracks in rock formations which use to be stable under the internal stress conditions. Once the cutting face is uncovered, the unbalanced stress conditions result in the rock element slides along the existing cracks affecting the existing rock joins. The extension of the breakage is determined by the directioning and

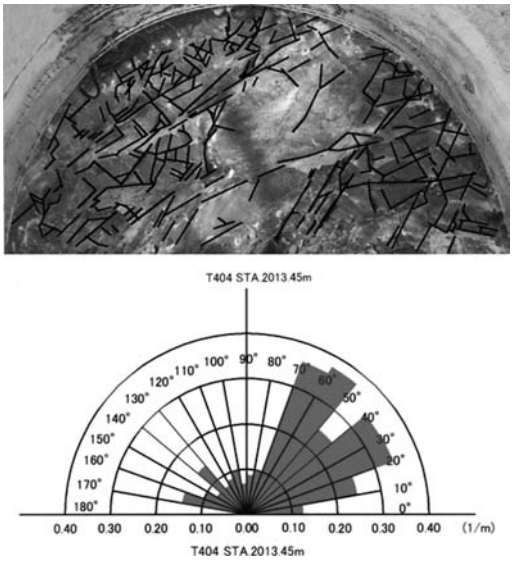

Figure 5. Observed joints in the cutting face.

strength of the face. The rock joint orientation and frequency was observed and more than 100 cutting faces have been examined to explain this mechanism and phenomena as shown in Figure 5. It was stated that the acceptable deformation falls within the range of 0.3–0.4% based on the allowed dilatancy. It means that the probability of sliding of the rock elements is reduced under the stable internal pressure conditions (Tanimoto et al. 2006).

Moreover, the 2-dimensional DEM (Distinct Element Model) simulation was carried out on the basis of the information on the orientation and frequency of joints (Fig. 6). This simulation proved that if the friction angle of joints is small (close to zero), huge sized cave-ins can occur easily (Iwano et al. 2006). Finally, the support pattern showed in Figure 7 has been adapted. The pattern is considered the combination of systematic forepoling and face boiling aimed at increasing the internal pressure of the rock elements.

Geological conditions, less favourable that expected, brought other problems. As geological conditions were worse, driving steps were shorter and the used support was required to be heavier. Moreover, the progress of work was interrupted several times due to the cave-in occurrence. Rock Classes I and II, which had been expected over 40% within of tunnel driving, did not appear at all (fig. 3). More adverse geological conditions than expected raised the necessity to apply a heavier support pattern to the same rock class. Finally forepoling and face-bolting was installed regularly, which resulted in the extension of working time.

Therefore, the Contractor, upon the Engineer's consent, introduced the following acceleration methods in order to keep the set scheduling of the project: the

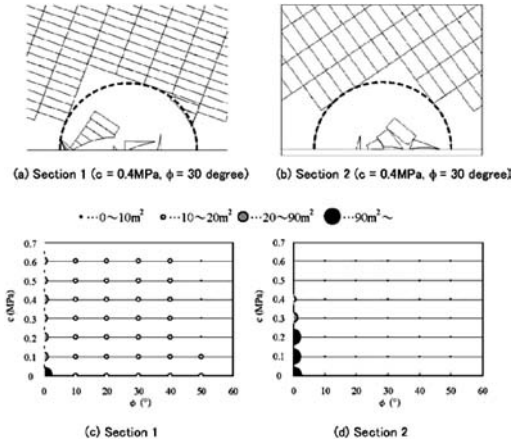

Figure 6. Simulation model for the mechanism of cave-in occurrences.

extension of working time; the increased frequency of noise and vibration measurements; the evaluation of the amount of the explosives used; the installation of the anti-noise barrier and reduction of the amount of explosives used; driving from the other portal demanding mobilization of additional resources, additional slip form.

The construction of the tunnel within the urban area laid considerable restrictions upon the progress of works. In this particular case, the following had to be considered:

- the Slovak Academy of Science performs various important experiments and vibration resulting from blasting works might influence the results;
- there is a horse riding school keeping horses and helping children with special needs located above the tunnel; horses might get shocked due to blasting works and injure some children;
- there is the ZOO area spread close to the tunnel portal and blasting works and/or heavy machinery might produce disturbing noise and vibration.

The following measures have been introduced to minimize the above listed undesirable impacts:

- test blasting: vibrations were measured ahead under the test blasting in order to evaluate the negative impact and determine optimal amount of explosives;
- anti-noise barrier: an effective noise barrier was built up in order to extend working hours to 24 hour a day;
- reduction of the amount of explosives (step blasting): the cutting face was divided into two or three parts form the point of blasting works in order to reduce vibration;
- pre-announcement: daily announcements of planned blasting times were issued and a special

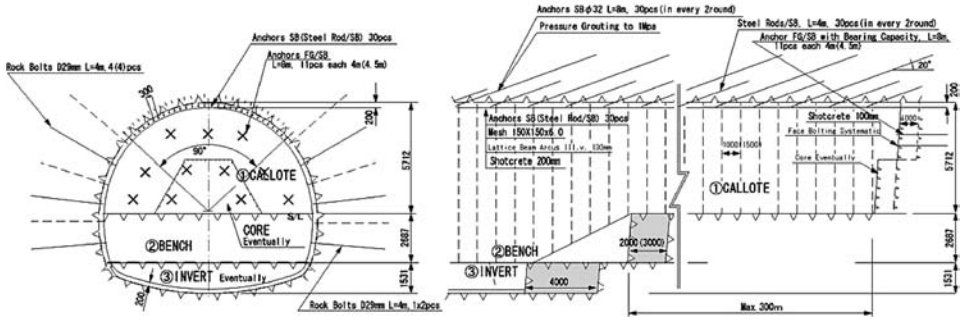

Figure 7. Support class IV with special measurements.

Figure 8. South portal of Sitina tunnel in september, 2006.

announcement was provided 30 minutes ahead of each explosion;

– accountability: regular communication and visits of particular subjects (institutions and inhabitants concerned) within the adjacent areas were introduced to explain conditions occurred under the project.

7 SUMMARY

The construction conditions of the projects located within urban areas are limited and special attention has to be paid to the adjacent areas and facilities. Definitely, the construction period is getting longer and the probability of work delay, interruption or stoppage is increased due to such restrictions. Moreover, if some difficulties occur within a highly developed area, the project costs may significantly increase and it takes a long time to remedy the damages. In addition, it is vitally important to enhance cooperation with particular subjects (institutions and inhabitants concerned) within the adjacent areas to assure proper progress of the projects. The accountability of project members, i.e. the Client, and the Designer and the Contractor is essential to ensure such cooperation.

The completion of the D2 Motorway section in Bratislava including the Sitina tunnel will significantly improve traffic conditions in the town. However, the entire region is under continual development and the capacity of the newly built roads will be exceeded soon.

Traffic conditions in Bratislava could be further improved by the construction of a "zero" by-pass of the town including an approximately 10 km long tunnel routed through the Malé Karpaty (Small Carpathians) Mts. massif. Nowadays, this project reached the technical surveying level. However, the expert public as well as the inhabitants of Bratislava believe that in the near future they will be able to find resources to implement this demanding engineering project.

ABSTRACT: The Takaoka Tunnel on the Hokuriku Shinkansen Line is a 6,918 m long tunnel built in the northern part of Nagano Prefecture using the New Austrian Tunneling Method (NATM). It was divided into the northern (3,990 m long) and southern (2,928 m long) sections. The tunnel crosses under an expressway at a vertical distance of about 15 m. Because the soil is soft silt with many fissures (N values: 10 to 30), it was concluded that ordinary tunneling methods could cause large settlement problems. Therefore, a pipe roofing (ϕ 812.8 mm) method was used in the planning stage as a countermeasure. This study reports on a newly developed method applying two-dimensional numerical analysis to three-dimensional phenomena incorporated in the structural design for the pipe roofing. Also reported is a monitoring system for excavation directly below the expressway, which feeds back the measuring results for surface ground settlement.

1 INTRODUCTION

The Takaoka Tunnel on the Hokuriku Shinkansen Line is located between 131 km 550 m to 138 km 490 m from Takasaki, the origin of the line. It is a double track tunnel (6,918 m long) running through the Nagaoka Hill area along the right bank of the Chikuma River flowing in the northern part of Nagano Prefecture.

The Nagaoka Hill area consists of a northern section, topographically relatively rugged hills over 400 meters above sea level, and a southern section of gently rolling hills 380 meters above sea level at Chausu Hill, the highest point.

The southern section of the Takaoka Tunnel is located on the southern block of the Nagaoka Hill area, and the tunnel length is 2,928 m. The earth covering varies from 1D to 5D. The tunnel crossed under or near many structures, including an expressway and power transmission towers, as well as blocks of apartments and houses.

This study reports on execution directly under the expressway routed in soft silt, a representative geological characteristic of this region.

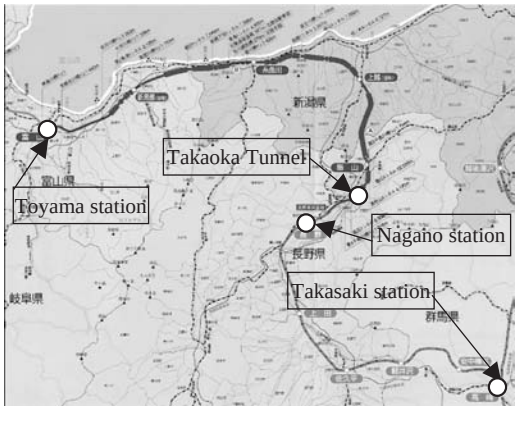

Figure 1. Location map.

2 OUTLINE OF GEOLOGICAL FEATURES

The geology surrounding the Nagaoka Hill area over the tunnel contains soils deposited on the bottom of a lake, including secondarily deposited pyroclastics, silts, sands and gravel coming from the Izuna volcano. These soils consist of the Sarumaru layer, corresponding to the Quaternary Pleistocene prophase, and the Toyono layer, corresponding to the metaphase, which are covered with the Nango layer, considered to be Pleistocene anaphase. Since the strata belonging to later generations are distributed throughout, it can be said that the geology is very soft and gently rolling. In addition, because the Nagaoka Hill area consists of risen hills formed by a strong diastrophism and the active Nagaoka Fault, the strike fault and slope of the

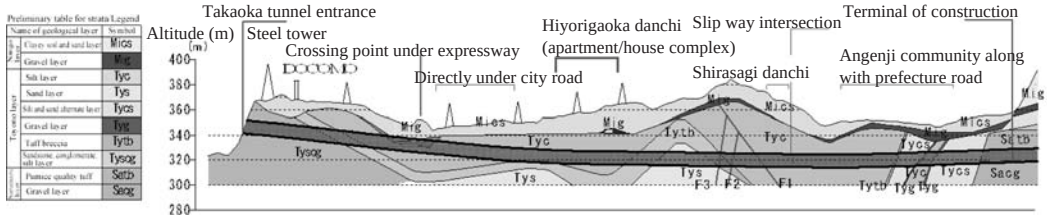

Figure 2. Longitudinal.

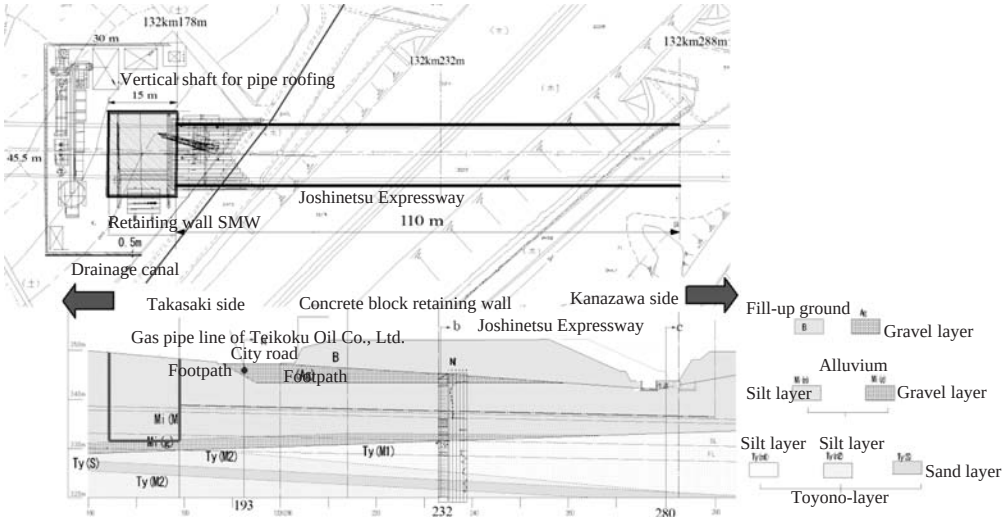

Figure 3. Interconnection with expressway: Plan view.

strata around the hill areas are complicated and varied over a short distance, as well, the silt layer has many fissures. Furthermore, since there is an aquifer sand layer and a gravel layer in a narrow area, an overflow of soil could occur, coupled with the multi-fissure silt. The silt layer, which is shown on the cross section of the tunnel, is the Toyono layer. Its unconfined compressive strength is as small as 0.8 Mpa (8.0 kgf/cm^2), and both the modulus of deformation and competence factor are also low level, around 20 MN/m^2 and Gn < 1.5 respectively (see Figure 2).

3 CROSS POINT WITH EXPRESSWAY

The Takaoka Tunnel crosses the Joshinetsu Expressway at a vertical distance of about 15 m (embarked ground: 7 m, natural ground: 8 m) and the level cross angle is about 45 degrees at around 132 km 230 m from Takasaki. The earth covering is less than 1D. Accordingly, there is the possibility of affecting the expressway, such as settlement caused by the tunnel excavation, resulting in obstacles to vehicle traffic. Therefore, it is necessary to minimize the effect on the ground structure of the expressway when the tunnel is excavated.

4 STUDY OF AUXILIARY MEASURES

From the soil test results and execution results achieved in the past, it is clear that the silt layer ranged on this area is of a younger generation. Therefore it becomes a high-level silt layer that is deformable because of the large influence of the fault. In the tunneling done so far, application of a long-distance end bearing method, long-distance end plate method, side wall preceding method, upper and lower halves shotcrete invert method, etc., controlled ground settlement and allowed successful excavation without problems.

For the crossing below the expressway, in order to ensure traffic safety, a management reference value has been established. It was determined that the extent of the ground settlement was 50 mm and the settlement gradient was 10/1000 rad. To establish the reference value, the road administrator was consulted, with reference to the “Guidance of Execution Technology

Table 1.

End bearing method:	Control effect for settlement	Economical efficiency	Execution properties	Evaluation in total
Modified high-pressure jetting method:	Δ	Δ	Δ	Δ
Long-distance steel pipe end bearing method:	Δ	○	○	Δ
Pipe roofing method:	◎	Δ	◎	◎

for Neighboring Construction" (Edit Committee for Guidance of Execution Technology for Neighboring Construction, March 1997).

In order to meet the management reference value, measures required for the tunnel excavation were studied. In the study, it was understood that the fill-up ground (about 7 m) had an interaction load with the tunnel. Accordingly, it became necessary to securely support the interaction load coming from the fill, as well as the crown protection.

First, the end bearing method was studied comparatively (Table 1). In addition, since the load directly above the tunnel is borne with the end bearing method, it needed to provide a certain length for end bearing. In addition, settlement at the legs was assessed, making it is necessary to study the natural ground around the legs. For the end bearing necessary to control settlement of the surface ground, the pipe roofing method was used. Steel pipes were arranged on the periphery of the tunnel. Before tunneling, a line of highly rigid pipes surrounding the natural ground was adopted, the result of a study looking into economic efficiency and execution properties. In addition, for constructing the pipe roofing, it was necessary to consider controlling settlement caused by piling the pipe roofing, because of the severe management reference value for where the expressway crosses. Therefore, an auger screw excavation method was not adopted. Instead, a small diameter pipe jacking method was used on the pile driving area. For the pipe diameter, the minimum diameter able to operate in the pipe, i.e., ϕ 812.8, has been selected to prepare for possible accidents.

5 VERIFICATION WITH TWO-DIMENSIONAL FEM ANALYSIS

A two-dimensional FEM analysis was applied to verify effectiveness for crown protection and settlement control of legs with the pipe roofing. Since a two-dimensional FEM analysis is an analysis to make

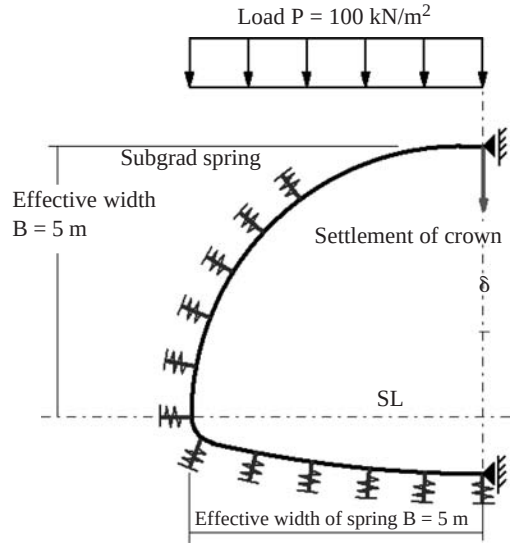

Figure 4. Calculation model for timbering spring.

traversal verification of the tunnel profile, it is difficult to gauge effectiveness in the longitudinal direction of the tunnel. Thus a method was studied for the two-dimensional FEM analysis with the longitudinal girder effect of the pipe roofing. Next, the number of roof pipes to be piled to achieve effective action, without affecting the soundness of the adjacent structures, was studied.

5.1 *Prediction of settlement by means of modeled girders*

Models of girders on an elastic floor were used to study the longitudinal effects. Taking modeled girders as roof pipes, and taking the modeled elastic floor (springs) as the natural ground between tunnel timbering and pre-excavation area, the settlement of pipe roofing for the upper half of the excavation phase was estimated.

For the spring value in the tunnel timbering, taking the modeled plane framework as the tunnel's transverse direction (upper-half profile) (Figure 4), the value of the spring for the tunnel timbering work was calculated from the crown displacement. This was done by measuring the loading unit (load) on the combined member consisting of steel timbering and shotcrete. For the spring value of the pre-excavation terrain, the ground spring obtained from geological data was set up. The rigidity of the roof pipe was converted by equalizing the numbers of piling under 150° (20 pipes) with piling intervals of roof pipes by using a combined member, and considering heating concrete.

The analysis was achieved with the modeled girder on the elastic floor by setting up the above-mentioned

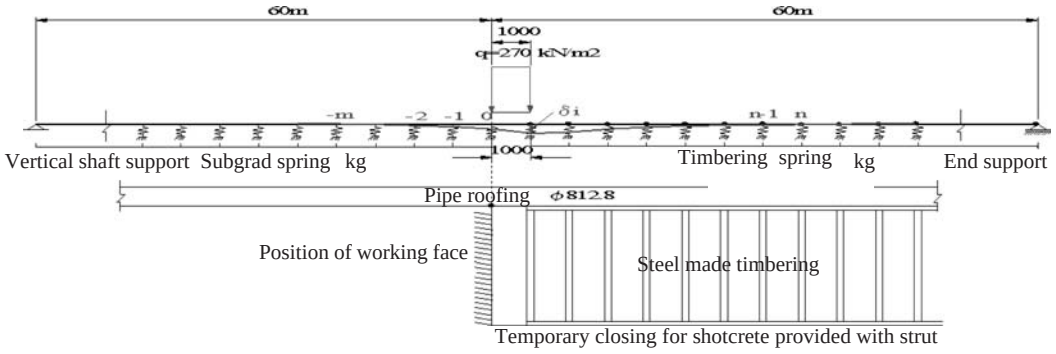

Figure 5. Model for girder.

conditions as shown in Figure 5. The analyzing method was such that all settlement values obtained at every point were summed (under a state that the center portion where the largest settlement of the roof pipes was estimated) and was excavated 1 m. The roof pipes lose sub-grad reaction by excavating 1 m, and the upper portion of the pipe roofing bears the load of the natural ground. In this analysis, both natural ground and fill ground loads were regarded as the total load to be applied.

As a result, the total settlement (accumulated settlement) became 31.0 mm. Since the result could be considered as settlement, including consideration for the longitudinal girder effect, the total settlement was regarded as the crown settlement at completion of excavation of the upper half of the tunnel.

5.2 *Two-dimensional model of pipe roofing*

The crown settlement at completion of excavation of the upper half of the tunnel obtained from the modeled girder was applied to the identical step in the two-dimensional FEM analysis. The two-dimensional FEM analysis model for the analysis was applied at piling work with 150°, also the case of the modeled girder. For rigidity of the pipe roofing, the converted rigidity calculated for the modeled girder was taken. In order to fit the crown settlement, the elementary width having a modulus of deformation equivalent to pipe roofing was studied. Further, material values, such as dead weight of natural ground portion and the pipe roofing portion and so on, were applied to each value.

In addition, in carrying out the analysis, non-linear elasticity analysis was applied to the dynamical model based on the actual results of this terrain in the past. Formalization of no-linearity was in accordance with "Non-linear model by means of destructive accessibility" (*NATM Design and Execution guidance*, Japan Railway Construction Public Corporation). For the classification of the natural ground according to geological time, the Toyono layer with a high concretion grade was classified into soft rock and Nango layer with low concretion grade was classified as earth and sand. The sub-grad physical properties values, such as initial coefficient of elasticity and shearing strength, were estimated by taking the N value as the parameter from analyses of the boring survey data, soil sampling test result and in-situ test results.

As the result of the analysis under these conditions, the tunnel crown settlement of the two-dimensional FEM analysis model was 35 mm. This was compatible with the total settlement of the pipe roofing of 31.0 mm derived from the study with the modeled girder.

5.3 *Comparative analysis of pipe roofing installation range by means of two-dimensional FEM analysis*

By using the elementary width of the pipe roofing and converted modulus of deformation acquired from the analysis, comparative analysis of the steel pipe installation range was achieved. There were four models for this study: upper and lower half models, 180° model, 150° model, and a model modifying 150° model with adding improvement of side wall preceding method. Each model was named from A to D. Table 2 shows the analysis result.

Next, acceptability of the analysis result was studied. Specifically observing the surface ground settlement of the last step for models A to C, which only incorporated the pipe roofing as the auxiliary measures method, there were differences in surface ground settlement among the models. It was considered for this reason that there was a gravel layer (Mi-g) on the Nango layer, of which the N value was higher than those of the others. It was considered that models A and B, where the pipe roofing piling areas reached to the gravel layer, suppressed settlement at tunnel legs, and that overall settlement was controlled. On the other hand, for model C, because it did not reach to the gravel layer, it was considered that the settlement at the tunnel legs was larger than those of the others. Consequently, the entire settlement would become larger.

Table 2. Analysis results.

Analysis model	A	B	C	D
	Degree(°)			
Piling range for pipe roofing:	Upper and lower halves			
		180		150
Auxiliary measures	–	–	–	
	Improvement of side wall			
	mm	mm	mm	mm
Settlement of crown:				
Upper half	2	14	35	35
Last	4	32	65	52
Settlement of surface ground:				
Upper half	1	12	30	30
Last	2	27	56	45

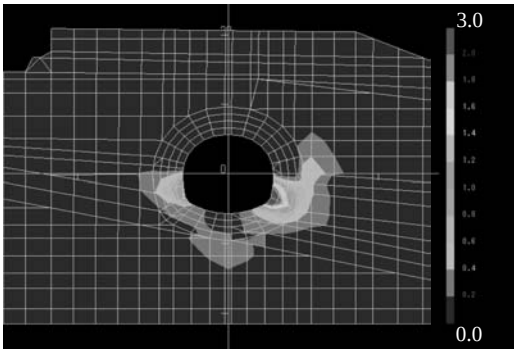

Figure 6. Analysis result for model B (Maximum principal strain).

From the value of the predetermined management reference value (50 mm), 30 mm, which was 60% of the reference value (50 mm × 60%), was taken as the primary management reference value. This was the result of a comparative study of models satisfying the primary management reference value, where model A showed 2 mm and model B showed 27 mm. It was clear that these two models, where the side walls were protected with the pipe roofing, were superior in controlling the effect of the surface ground settlement. On the other hand, even though the side wall of model C was protected by modification of the side wall preceding method in parallel (similar to model D), model C could not satisfy the 30 mm requirement. Furthermore, it was understood that the improvement with injection was not perfect.

As the result of studying the analysis results and problems occurred during actual execution, as well as considering economical efficiency, model B, where settlement control was reliable (piling range of pipe roofing was 180° and numbers of pipes are 22) was selected. In addition, before starting the tunneling work, studies were made for improving the lower half side wall preceding method, for upgrading the timbering work, and for improving the batholith as auxiliary tunneling practices for settlement larger than the estimation.

6 SCHEME OF EXECUTION OF PIPE ROOFING

It is necessary to execute the pipe roofing in advance of tunneling to protect the arched cross section of the tunnel, as preparation of a vertical shaft was considered as the execution base. The location of the vertical shaft was selected at the Takasaki side (around 132 km 170 m) across form the expressway where the geological stability was relatively high and a temporary site was easily available. The execution length of the pipe roofing was decided from 132 km 178 m to 132 km 288 m considering operability of the vertical shaft itself and protection of fill-up structure of the expressway at the Takasaki side (Figure 3). The tunneling was decided to start from the Kanazawa side to go to the Takasaki side.

The position of the vertical shaft adjoins a city road and also adjoins the fill-up ground of the expressway. Therefore it is necessary to consider not only the effect on the expressway but also the effect on the natural gas pipe line routed under the city road. Accordingly, a soil cement method involving high rigidity was planned for the earth retaining structure to be able to control deformation and looseness of peripheral natural ground. In addition, since building the pipe roofing in the vertical shaft requires enough working space inside the vertical shaft, an earth anchor method was adopted to retain the soil.

7 CONCLUSION

In this analysis, in order to consider the longitudinal girder effect of the pipe roofing, analysis was done using modeled girders, and equivalent rigidity for the pipe roofing was achieved in the two-dimensional analysis. In addition, by applying FEM analysis, where reproducibility was high with the many fissures shown in analyses in the past, the NATM measures at the crossing point at the expressway were studied. Furthermore, the scheme of execution was prepared, which included protective measures for the gas pipeline running along the expressway and the measuring plan, as well as temporary facilities, such as the vertical shaft necessary for the pipe roofing. We would like to proceed with the execution upon reflecting on the analysis results acquired in the past and the data obtained from the measurement to the execution, and by paying attention to ensure safety.

The Prague new connection tunnels

Michal Gramblička
SUDOP Praha a.s., The Czech Republic

David Cyroň
Metrostav a.s., The Czech Republic

Miroslav Chyba
Subterra a.s., The Czech Republic

ABSTRACT: As usual for large civil engineering projects, the history of preparation of the New Connection project is very eventful. Ways to replace the tens-of-years-old connection of the Prague Main Station from the north and east, being insufficient in terms of the capacity and technical level, have been sought from the fifties. As this railway connection has been possible via the Vítkov single-rail track connection only, a change of this condition is only viable by development of new railway lines between the Main Station and Masaryk Station on one side, and Libeň, Vysočany and Holešovice on the other side. This is the origin of the project name The New Connection. The works commenced in 2004, and the conclusion is scheduled for 2008. The tunnels consist of two cut-and-cover sections, where, in a joint construction trench, the individual rail lines are joined with the mined sections. The tunnels link to a four-track viaduct on the west and a double-track viaduct and a track in an open cut on the east. The year 2005 saw the excavation of the construction trenches. The year 2006 saw excavation of 100% of the length of the tunnels.

1 HISTORY OF THE PRAGUE RAILWAY JUNCTION

The network of railway tracks and stations in the Prague territory developed by connecting new railway lines from various directions, where each of the lines built its own station, without anybody to take care of proper interconnections. This is how the first Prague railway station originated in 1830, before the Bruska Gate, on the second horse railway line from Prague to Pilsen. Fifteen years later, the Northern State Railway Line from Olomouc to Prague was opened to traffic, and the area of the current Masaryk station was selected for its Prague station (to be shared in the future with the railway line to Dresden, which was in the planning phase then). Another Prague station originated in 1862 in the Smíchov district under the name of the Prague Station, in the framework of the construction of the Czech Western Railway Line from Prague to Pilsen. The Franz Joseph Railway Line from České Budějovice to Prague originated in 1871, simultaneously with Franz Joseph Station (the today's Main Station) at the bottom of Vinohrady hill. The modern history of the Prague Railway Junction started in 1910, when the Prague Railway Station Committee originated. Its task was to find a way to a comprehensive solution of the Prague railway network, with an idea of separation of the passenger service from the freight service and its centralisation to a central passenger station. The realisation of the first actions was suspended or delayed due to World War I. All complementary structures improved the traffic function, although, they were not able to remove the lack of conception in the historic construction development. In addition, the outdated railway facilities started to collide with the city's functions and requirements for development.

Masaryk Station 1850.

2 THE NEW CONNECTION – PART OF THE PRAGUE INTEGRATED TRAFFIC AND RAILWAY CORRIDORS

The first solution of this project was brought forward at the turn of the 1950s and 1960s when a redevelopment of the Prague Rail Junction was considered. Along with a change in social conditions at the beginning of the 1990s, an enormous increase in movement of persons took place, in the field of commuter traffic mainly. Most jobs, the attractive ones above all, are concentrated in the Prague conurbation. This fact is connected with a continually growing demand for daily transport of citizens. Not all of this demand can be satisfied by urban mass transportation and car traffic. It is therefore not a less important purpose of the New Connection project to get the suburb transportation to the city centre, and to incorporate the railway traffic into the integrated system of traffic in Prague (PIT) and its vicinity. This will be possible only when the construction of the New Connection and subsequent modernisation of the Main Station are completed.

As probably known today even outside the sphere of the professional public, there are sections of European railway corridors currently under construction passing through the Czech Republic. The Corridor I between Děčín and Břeclav, which was completed in 2002, passes through Prague, as well as the corridors III (from Cheb to Plzeň) and IV (from Horní Dvořiště and České Budějovice) which are in preparation.

This means that, in addition to inland trains, also new-generation interstate trains will arrive to Prague, reaching a velocity of 160 km/h in our conditions. It must be stated that the construction of the New Connection affects its surroundings too.

The existing railway connection between the Main Station and Libeň via the Vítkov tunnel and Hrabov track connection will be cancelled, and the land used today for the railway traffic will be abandoned. It is expected that a cycle and pedestrian track and connected quiet zones will be established on the track bed of the current Vítkov railway line. This solution will connect Vítkov hill with the adjacent buildings of Žižkov.

3 ENGINEERING, GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

The configuration of Vítkov hill was changed in the past by quarrying and by the construction of the National Monument. The assumed location of quarries was situated to the area of the Army Museum, the southern and eastern edge of the National Monument, and to the area at the bottom of Vítkov hill on the south. The height of the quarries reached even 10 m. In addition to this large-scale quarrying activity, a lot of minor quarries existed in this series of the Skalec quartzites. The quarries were backfilled up to the surface level with materials containing mainly the rock (quartzite) dug during the construction of the National Monument.

Vítkov hill is a significant morphological element in Prague's landscape. Its ridge is formed by the denudation-resistant Skalec quartzites. The beds of the Skalec quartzites are about 100 m thick; in the south and north they are divided stratigraphically and tectonically from the overlying series of measures of the Dobrotivy shales or Šárka shales. The contact between the Šárka shales and Skalec quartzites found in the northern slope of Vítkov forms a geological profile which has been placed on the list of sites of nature conservation. The excavation will encounter the Palaeozoic, Middle Ordovician Šárka shales and the overlying Dobrotivy series of strata in a facies of the Skalec quartzites.

East portal of North tunnel.

East portal of South tunnel.

Originally the ground water table was restricted to the bedrock with relatively wide range of the levels, depending of precipitation. The original hydrogeological conditions have changed due to the construction of underground spaces under Vítkov (civil-protection shelters with ventilation systems and wells securing the cooling and supply systems, the pedestrian tunnel, railway tunnel, sewers etc.). Because a majority of the underground spaces are found under the alignment of the designed railway tunnels, it is obvious that the railway tunnels will be excavated under the standing level of the ground water table.

4 THE TUNNEL DESIGN

The southern Vítkov tunnel is 1,365 m long. Out of this length, 1,250 m was built by mining methods. The north tunnel is 1,316 m long. Out of this length, 1,151 m was built by mining methods. The tunnels are interconnected by four cross-galleries at an overall length of 100 m. In the final condition, they will be used as escape ways. They are equipped with fire-check doors with signalling, fans and fire dampers. Cable and hydrant lines are also interconnected through the cross-galleries.

The space before the entrance and exit portals of the tunnel are accessible for road vehicles; mustering areas for mobile fire appliances are prepared on both sides.

The layout of the areas is accommodated to the needs of the excavation work so that the movement of mining equipment and vehicles during the tunnel driving is possible.

The 0.20–0.30 m thick temporary lining is designed according to the NATM principles. It consists of sprayed SB20 concrete reinforced with two layers of steel mesh, friction bolts expanded by pressurised water and three-section lattice girders. The horizontal excavation sequence is applied, with the top heading vault having the shape of an ideal 6.05-radius semi-circle.

The advance per cycle ranges from 1.0 to 2.0 m. Steel forepoles are either driven or inserted into pre-drilled boreholes ahead of the face in the top heading sections where instability is a threat. The distance between the top heading and sidewall drift faces varies from 50m to 120m, depending on the rock mass quality.

West portals of tunnels.

Double- to triple-length rounds, i.e. 2.0 to 6.0 m long, are applied to the sidewall drifting or to the closing of the profile by the invert.

The excavated cross-section area grows from 96.22 m^2 at the excavation class III, through 97.51 m^2 at the class IVa, to a maximum of 106.84 m^2 and 108.13 m^2 at the higher classes IV b and V a (involving the invert structure) respectively. Percentage classification of the excavation along the mined tunnels was designed in accordance with the results of the geological investigation. The anticipated need for the application of the higher classes (V a about 36%, IV about 34%, III about 30%) was not confirmed.

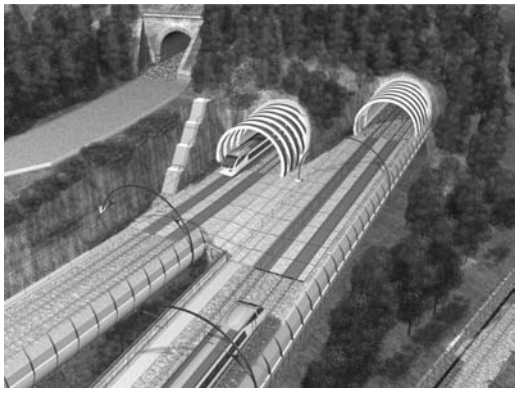
The deciding lengths of the completed tunnel excavation were categorised as the easiest class III; only the pre-portal sections were driven in the excavation class V a. About the middle of their length, the tunnels are crossed by the pedestrian tunnel connecting Tachovské Square in Žižkov with Thámova Street in Karlín. The tunnels pass at a distance of 6.50 m above the pedestrian tunnel.

The pedestrian traffic was be protected during the excavation by means of steel frames and timbering placed between a frame and the lining.

The excavation of the Vítkov tunnels commenced on 27.5.2005 and 15.8.2005 in the southern tunnel and northern tunnel respectively. The situation at the southern tunnel excavation face was favourable in an extent that allowed Metrostav a.s., the contractor, to abandon the excavation sequence V a designed for the top heading, carry out a length of 90 m without blasting, and apply the easiest class III at a distance of 134 m from the portal.

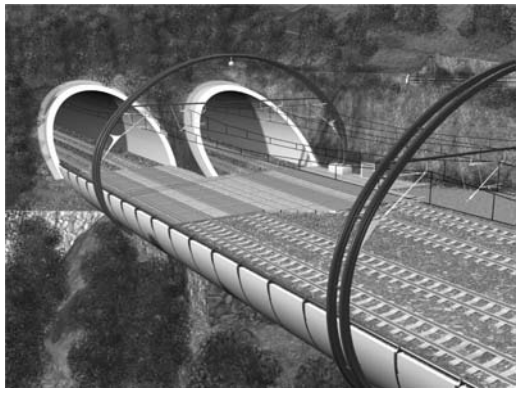
The most important structures that were passed under by the tunnels with the overburden less than 40 m are the building of the National Monument and the equestrian statue of Jan Žižka of Trocnov. A FEM structural analysis was developed for the prognosis of the rock mass behaviour. The analysis resulted in a prediction of a total subsidence value of 12 mm following the passage of the two tunnels. The reality was different – 24 mm.

A seismic measurement system was designed and maximum charge weight limits were set to enhance the protection of the building and the statue.



The cast in situ concrete final lining is designed both reinforced and unreinforced, 50:50 in proportion by the length of the sections.

Travelling formwork sets will be used for the casting. The length of the casting blocks of 12.50 m corresponds to a half of the 25 m distance between safety recesses. The horizontal alignment is determined by a rock crest of Vítkov Hill; the tunnel alignment follows its longitudinal axis. The distance between centres of the two parallel tunnels is of 30 m on average, with a minimum of 3 m and maximum of 42 m (under the National Monument grounds). The routes consist of straight sections and curves (648 m and 602 m radii for the southern tunnel and 902 m and 3602 m radii for the northern tunnel).



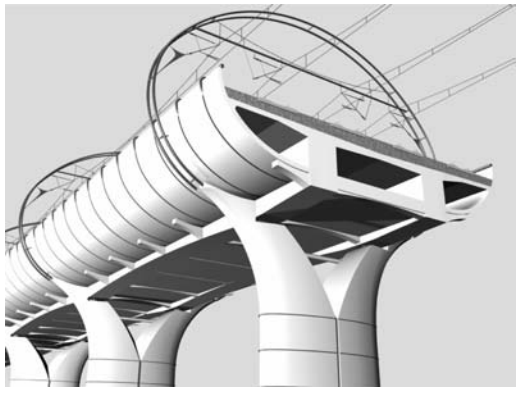
The alignment of the tunnels descends in the east-west direction on a gradient of 0.33%; downhill excavation will take place.

Survey of pre-construction conditions

In addition to low buildings at sports grounds, there is the National Monument on Vítkov hill with a monument to Jan Žižka found above the tunnel route. The structural condition of the building of the National Monument, that was used in the course of its life for various purposes (starting from a monument during the First Republic, through a Wermacht storage during World War II, and a mausoleum after the war) and was left more or less without systematic maintenance, is not good. Despite the fact that the tunnel excavation did not threaten the structural condition of the building, increased attention was paid to the structural elements, wall cladding and individual items of work of art. There is an equestrian statue of Jan Žižka of Trocnov in front of the building, above a grave of the Unknown Warrior. This statue, one of the world's largest equestrian

East portals.

West portals.



statues, was thoroughly observed in the framework of the geotechnical measurement program.

5 THE DESIGN OF PORTALS

The deciding length of the tunnels was be driven from the east portal, whose location is in the centre of the construction operations designed to improve the uncared northeastern slopes of Vítkov Hill. There will be a modern park in the final condition, connected with the city centre not only via transit tunnels but also via a cycle track. This track will link the park outside Prague Main Station with Balabenka via an existing single-track line (to be abandoned subsequently), and with a part of the Vysočany/Harfa location which is being newly developed. The construction works started in the autumn 2004 by the site preparation and development of access roads to the tunnel portals. New revetment walls allow the existing rail line to be operated until the moment of the opening of the new tracks running through the newly built tunnels to traffic. The muck is removed both by rail and road-based transportation.

The construction trenches at the portals are designed in a manner guaranteeing that rock pillars with a minimum width of 3.5 m to 10 m remain between the cut-and-cover and the mined tunnels. The walls of the pillars are supported by 15 m to 27 m high double-stage vertical anchored micropile walls consisting of 108/16 mm steel tubes. The walls are stabilised by permanent cable rock anchors 8.0 to 22.0 m long.

A 0.25 m thick layer is applied to the surface of the walls. The toes of the walls are keyed into the areas of vaults of the existing railway tunnel; therefore the condition of the vaults was paid extraordinary attention during the grouting operations. Once the cut-and-cover double-track tunnels are completed, they will be backfilled. A thorough condition survey of all above ground and underground structures was performed prior to the works commencement. A detailed monitoring system has been designed in compliance with the NATM principles.

The four-track railway trestle bridge over the locomotive depot of Masaryk station belongs undoubtedly among the very interesting structures of the project. It is connected to the western (entrance) portal of railway tunnels. It solves connection of the tracks to the northern gridiron of the Prague Main Station. It is a unique, 450 m long, pre-stressed concrete bridge structure for four running tracks.

6 CONCLUSION

The Vítkov tunnels solve the connection of Prague's centre with the future high-speed railway lines coming from the east and north of the Czech Republic. Apart from this, they will allow the suburban service and inter-urban lines to pass across the city in the east-west and north-south directions.

Development of rock fracturing method, and application of EG-Slitter Method to the tunnel

Toshiaki HARA & Mitsumasa OKAMURA
Toda Corporation, Tokyo, Japan

Tetsu KIMURA & Kouji ISHIYAMA
Nishimatsu Construction Co., Ltd., Kanagawa, Japan

ABSTRACT: The tunnel constructions, near the residential zone or the constructs, are increasing yearly. The conventional excavation methods are unsuitable in these areas, because it is becoming the critical issue for noise and vibration control engineering to excavate controlling the large shock wave, noise and the accident by falling rocks.

So we developed the new rock fracturing technique to be characterized by the non-blasting hard rock excavation. This new construction techniques are named the continuous Slit, EG-Slitter (Elastic Guide-rod Slitter) Method.

The process of the hard rock fracturing method in the tunnels is firstly cutting tunnel faces and periphery faces into the small blocks surrounding by cutting free faces with EG-Slitter, and next we break up the tunnel face extending continuous slit by oil wedges, finally we break the rocks with breakers.

In this paper, it was described the development of the new formation of continuous slit method, EG-Slitter , and the application of this method to the tunnel excavation.

1 GENERAL INSTRUCTIONS

Rock fracturing method is one of the tunnel construction methods. The first stage of this method is cutting of the faces and the periphery free faces. Second stage is quarrying stones on the cutting faces. This rock fracturing methods (EG-Slitter method) is available to the hard rocks of the unconfined compressive strength 100～200 MPa in the prohibiting Blasting method, but it is not efficiency as compared with Blasting method. The process of the EG-Slitter method) is shown in Figure-1.

The process of the rock fracturing method is as follows;

① Drilling the free faces
② Drilling the dividing holes
③ First fracture by the oil wedge, etc.
④ Second fracture by the breaker, etc.

The technical characters of the EG-Slitter Method are on the process ① and ②.

2 THE EG-SLITTER METHOD

The EG-Slitter Method is developed by the experiments in the tunnel sights and the testing of concrete blocks.

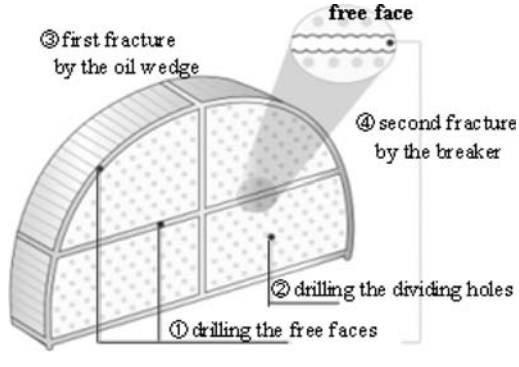

Figure 1. The outline of the Rock fracturing method.

2.1 *Characters of the system*

Figure-2 shows the EG-Slitter system. The system is composed by the hard rod and Elastic short guide rod attached on the guide cell of the tunnel faces drilling machine, jumbo. And Figure-3 shows the how to make drilling holes on the free faces. We make the pilot drill hole and dividing hole, contracting Elastic guide rod. After this the short and expanding guide rod is put into the pilot hole, and the next hole is digged by the bit supported with the hard rod and Elastic guide rod,

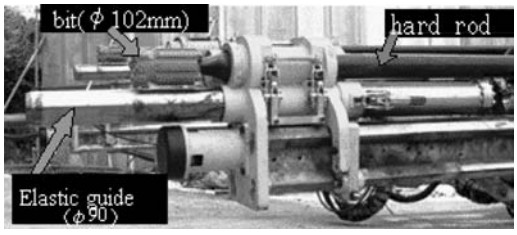

Figure 2. EG-Slitter system.

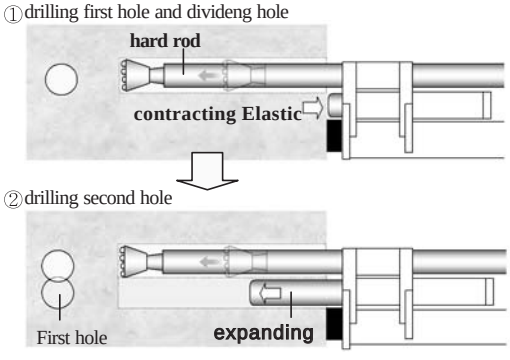

Figure 3. The system of the drilling free faces.

so we can excavate straight periphery free faces. We continue the work and it makes free face quickly.

Characters of the EG-Slitter system as follows:

① It is unnecessary the excursive machine.
The EG-Slitter system fits to guide cell of the drill jumbo which is the instrument used usually in the tunnel constructions, so it is unnecessary the excursive machine.

② It can excavate straight drilling used by the hard rod. And it is not curved to the next-hole by the hard rod, so we can excavate easily free faces on the tunnel face.

③ The length of the Guide rod is 50 cm.
In the case of short guide rod, the troubles of the drilling are increasing, and it is discharged rock powder simply. The other methods have a long Guide rod and many troubles in the pilot hole.

④ The Elastic guide rod is equipped.
The drill jumbo always have the elastic guide rod. The excavating efficiency on the free faces is higher than the common rock fracturing system.
The high drilling capacity of the EG-Slitter method is shown in Figure-4. It is more quick drilling compared with the usual drilling method used in the tunnel construction.

2.2 *The movement of the EG-Slitter*

We have the experimentation of the EG-Slitter movement on the concrete block.

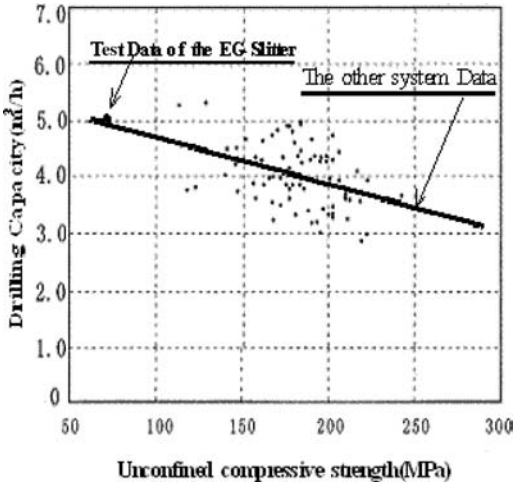

Figure 4. Drilling Capacity of the EG-Slitter system.

Figure 5. Experimentation on the Concrete Block.

Figure-5 shows the EG-Slitter system drilling the free face on the concrete blocks. It is smooth drilling and it can make the clear free faces.

3 EXAMPLE OF THE APPLICATION TO THE TUNNEL CONSTRUCTION

We applied the EG-Slitter Method to the tunnel excavation.

3.1 *Geology of the tunnel sight*

The extremely hard granite distribute with Vp value of 4.5 km/s which was measured by the seismic refraction method, and with unconfined compressive strength of 80~150 MPa, and rare crack. The geology of the tunnel is coved by the granite.

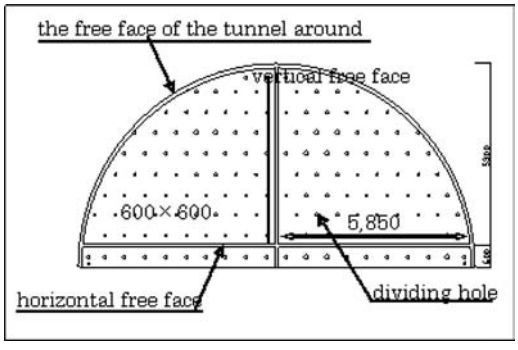

Figure 6. The drilling pattern of the free faces and dividing holes.

3.2 *The reason for development*

There are many homes around the tunnel portal, so we built soundproof shelter and soundproof doom in these cases surrounding the tunnel. In these areas, we cannot use the Blasting method. So we applied the EG-Slitter Method to the tunnel excavation.

3.3 *The drilling pattern of the EG-Slitter Method to the tunnel face*

The drilling pattern of the free faces and dividing holes is shown in Figure-5.

3.4 *The Excavation of the tunnel*

In Figure-6 and Figure-7, it means the free face and the dividing holes constructing by the EG-Slitter. That process of EG-Slitter operation is very smooth.

3.4.1 *The noise condition*

It is very silent and noise level is less than 55 dB in the near homes around the tunnel portal.

3.4.2 *Excavation by the EG-Slitter*

It can be very smooth and efficiency excavation of the free face and dividing holes, and powder is flow out easy.

Figure-7 shows the excavation in the tunnel face.

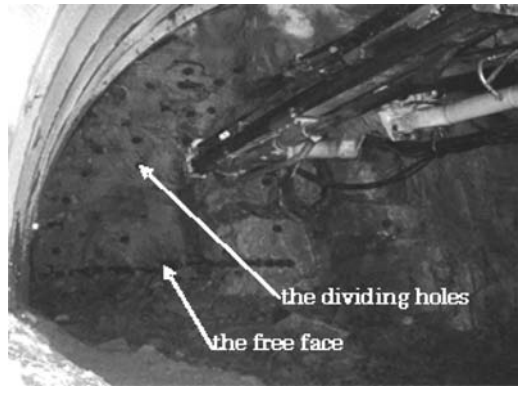

Figure 7. The free face and the dividing holes.

Figure 8. Free faces by the EG-Slitter system in the tunnel face.

The free faces digging by the EG-Slitter system is shown by Figure-8.

Vertical free faces, Horizontal free faces, and Incline free faces are drilled easily, and accurately by the EG-Slitter system.

4 CONCLUSION

The EG-Slitter method system was applied to the tunnel excavation, and it can drill very efficiency free face and dividing holes.

After this, we would like to applying the EG-Slitter system to many tunnels excavation.

The Sir Adam Beck II intake tunnels – homage to the builders

David Heath
Ontario Power Generation, Niagara Falls, Canada

Clair Murdock
Construction Consultant, Vancouver, Canada

ABSTRACT: The 1,280 MW Sir Adam Beck II Hydroelectric Project was constructed in the 1950's, at Niagara Falls, Ontario, Canada. The twin intake tunnels total over 17 kilometers in length and pass deep below the City of Niagara Falls. The tunnels were excavated using drill and blast methods, with a top heading and bench approach. The shot rock was loaded with electric shovels and transported to the five shafts with off-highway trucks. The tunnel muck was hoisted to the surface by skip and transported by truck to disposal areas. The volume of underground excavation for the 15.55 meter diameter tunnels and the shafts exceeds 3,500,000 cubic meters, then and now the largest underground civil works excavation by drill and blast in the Western Hemisphere. The lining required over 900,000 cubic meters of concrete. All of this work was completed in three years, remarkable progress, considering the technology of the day, comparing very well with the rapid excavation and tunnelling methods of the twenty-first century. Big, fast, and deadly- at least 20 lives were lost in construction accidents.

1 SIR ADAM BECK

1.1 *Beck's accomplishments*

Adam Beck was an early proponent of publicly owned electricity grids, opposing the privately owned companies which he felt did not adequately serve the needs of the people. With the slogan "Power at Cost", he was appointed in 1906 as the first chairman of the Hydro-Electric Power Commission of Ontario, better-known as Ontario Hydro, now called Ontario Power Generation. He created the Queenston Chippawa power station, which was renamed after him. The subject of this paper, the Sir Adam Beck II Project (SAB II) was also dedicated to his memory, to recognize his enormous contributions to the progress of the people of Ontario.

1.2 *Beck's life*

Adam Beck was born in 1857 in Baden, Ontario to German immigrants. Beck worked in his father's foundry as a teenager and later went into business with his brother William, manufacturing cigar boxes. Their business flourished and Adam Beck became a wealthy man. He was elected mayor of London, Ontario several times and also was elected to the Ontario legislature, where his public power campaign took flight. Knighted by King George V in 1914, Beck died in 1925.

1.3 *Beck's words*

Beck-"The gifts of nature are for the people". His statue still commands the intersection of University Avenue and Queen Street in downtown Toronto. "Nothing is too big for us. Nothing is too visionary."

The essence of Beck's leadership was in his vision.

2 THE NIAGARA RIVER

2.1 *Drainage area*

At Niagara Falls, the Niagara River drains an area in Canada and the United States of 583,000 square kilometers. This is larger than all of France (547,030 square kilometers) or greater than Germany, the Czech Republic, Austria and Slovakia combined (567,802 square kilometers).

2.2 *Flow*

The 140 year average instantaneous flow of the Niagara River is 5,876 cubic meters a second. Because of the modulating effect of the Great Lakes upstream (Lakes Superior, Michigan, Huron and Lake Erie) the flow at Niagara is very steady, as compared to other major rivers of the world. The maximum flow is less than triple the minimum flow, whereas other major rivers'

flow may vary by factors of 15 to 30, passing great torrents where there was previously only a trickle.

2.3 *The Falls*

Niagara Falls is, by volume, the world's greatest waterfall. The American Falls are 260 meters wide and carry 10% of the flow. The Canadian, or Horseshoe Falls are 670 meters wide, and carry 90% of the flow. The falls were formed some 25,000 years ago, as the retreating glaciers exposed the Niagara Escarpment, permitting the waters of Lake Erie, which previously flowed south, to flow northward into Lake Ontario. The falls have eroded the soft shales and limestones of the escarpment at an average rate of 1.2 meters a year and they now stand 11 kilometers from their origin at Queenston. The rate of erosion has been substantially reduced, due to hydro-electric diversions and riverbed remediation work.

2.4 *History*

Known to the Iroquois people for thousands of years, the name Niagara means, from their language "thunder of the waters". The awesome spectacle was described by explorer Father Louis Hennepin in 1678, who called them "a vast and prodigious Cadence of Water". Charles Dickens wrote "I seemed to be lifted from the earth and to be looking into Heaven". The first exploitation of the power of the falls came in 1759, when Daniel Joncairs built a small canal above the falls to power his sawmill. The first generation of electricity at Niagara Falls, in 1881, was sufficient to light the Village of Niagara Falls, New York, power a few local mills and illuminate the Falls at night, using 18 carbon arc lights.

2.5 *Tourists and tourist power*

Over 14 million people visit Niagara Falls each year. The 1950 Niagara River Water Diversion Treaty between Canada and the United States provides for the most beneficial use of the waters, with varying minimum flow requirements over the Falls, dependent on time of day and the time of the year. In the daytime, from April 1st to October 31st, the flow must be not less than 2,832 cubic meters per second.

For the remaining five months of the year and at night during the other seven months, the flow over the falls may be reduced to not less than 1,416 cubic meters per second. These figures represent roughly ½ and ¼ of the Niagara's average flow. Power production in Canada and the US is exactly tailored to fit water availability, with a very close compliance to the minimum flow requirements.

2.6 *Sharing the water*

Canada and the United States share the available water equally, with a small adjustment of 141 cubic meters per second in Canada's favour, recognizing two Canadian diversions into the Great Lakes watershed. The Long Lac and Ogoki Rivers originally flowed into the Hudson's Bay watershed.

2.7 *Installed hydroelectric capacity*

On the US side of the Niagara River, the Robert Moses Generating Station and the associated Lewiston Pump GS (pump-turbine) have a total capacity exceeding 2,575 MW. On the Canadian side, The Sir Adam Beck I and Sir Adam Beck II Generating Stations, along with the SAB Pump GS (pump-turbine) and two associated smaller plants at St. Catherines, Ontario have a total capacity of 2,235 MW. In total then, with 64 generators (18 of those being reversible pump-turbines), Canada and the US have 4,810 MW of generating capacity at Niagara. Recent upgrades to the US and Canadian generating units are reflected in the figures above. Excavation of the third intake tunnel for the Sir Adam Beck complex is now underway, to augment OPG's diversion capacity. A fourth tunnel remains under consideration, along with additional OPG generating capacity.

3 THE MAJOR COMPONENTS OF THE SIR ADAM BECK II PROJECT

3.1 *The Control Dam on the Niagara River*

The control dam extends 600 meters into the Niagara River from the Canadian shore. It has 18 sluices, each with a clear span of 30.5 meters, separated by piers 4.25 meters wide and 28 meters long. The 18 sluice gates are of the 'fish-belly type', hinged at the upstream sill, affording no obstruction to the passage of ice when in their lowered position. The Control Dam ponds the water, called the Grass Island Pool. This is the primary control of intake water levels for both the US and Canadian sides of the river.

3.2 *Two intakes of the Johnson-Wahlman type*

The Johnson-Wahlman design looks like a very long mouth-organ lying on its side. Ice on the Niagara River is of concern every winter. Following extensive model-testing, each intake was designed to be 152 meters long, with varying heights and depths for the slots. The sills for the intake slots are set 7.6 meters below river level, while the lintels vary from 5.8 to 2.4 meters below the water level. Behind the slots is a gathering tube of increasing cross section leading to the intake gates. The 180 tonne gates have a clear span of 13.7 meters and are 17.7 meters high.

3.3 *Two parallel concrete-lined tunnels*

The two tunnels are on 76 meter centres, excavated to a diameter of 15.55 meters and lined to a finished

diameter of 13.72 meters. The nominal thickness of the concrete lining is 0.91meters. Tunnel No. 1, which follows the longer outer course around the curving Niagara River, is 8,707 meters long, while Tunnel No. 2, following the shorter inner course, is 8,323 meters long. Each tunnel is designed to carry 565 cubic meters per second, although testing showed a possible capacity of 650 cubic meters per second. Water velocities at these two capacities are 3.8 meters per second and 4.4 meters per second respectively.

3.4 *An open canal*

As the tunnels approach the outlet portal, they rise at an angle of 30 degrees and converge, to discharge their flow into an open canal leading to the forebay. The portals are at the southerly side of the St. David's Gorge, a prehistoric river channel filled to a great depth with glacial drift materials and debris, unsuitable for tunnelling. (The third tunnel, now under construction and at greater depth goes under the Gorge). The canal is concrete lined through the Gorge section. The overall canal length is 3,622 meters, with a width of 61 meters.

3.5 *A forebay with headworks*

The forebay widens from the canal, reducing water velocity to about 0.9 meters per second. The headworks structure is 267 meters long, the entire width of the forebay. It is here that control of the water entering the penstocks is maintained. There are 32 openings on the upstream side of the headworks, two for each of the 16 penstocks.

3.6 *16 concrete-encased steel penstocks*

Each of the 16 penstocks is 5.8 meters in diameter and 152 meters in length, of welded steel construction. Plate thickness at the upper end is 16 mm, increasing to 36 mm at the lower end. Each penstock was built of 68 prefabricated rings, brought to the site by road. They were installed on the 60 degree slope of the excavated cliff face and welded in place, followed by an X-ray inspection of each circumferential weld. The penstocks were encased in 60 centimeters of concrete to protect them from rapid and extreme temperature variations.

3.7 *A 16 unit powerhouse*

The powerhouse is located on the left river bank in the Niagara Gorge, just upstream of the SAB I powerhouse. The SAB II powerhouse is 350 meters in length, 19.2 meters in width and 15.2 meters in height. The 16 turbines are of the Francis type, operating at a head of 89 meters. The main transformers which increase the generator voltage from 13.8 to 230 kV are located on an outside deck behind the powerhouse superstructure. Three single-phase transformers are provided for each pair of generating units, for a total of 24 transformers. Excavation for the draft tubes was carried out behind a cofferdam in the Niagara River, to a depth of 13 meters below water level.

3.8 *A 6 unit pumped-storage powerhouse*

The pumped-storage generating station pumps water into a storage reservoir during low demand periods, for reuse in heavy demand periods. The reservoir area is 304 hectares, with a drawdown of 7.6 meters. Usable storage is 19,000,000 cubic meters, equal to about 4 ½ hours of full flow from the two tunnels. The reservoir is bounded by a dike of about 7,400 meters in length, varying in height from 5 to 20 meters. The perimeter dike contains 2 million cubic meters of zoned fill, mostly built with tunnel muck. The reversible pump-turbines operate through head ranges of 18–27 meters in pump mode and 12–24 meters in generating mode.

3.9 *Overall cost and schedule for SAB II*

The final cost for the SAB II project was $343,742,000, giving a unit cost of $245.00 per kW of installed capacity, about 1/10th of today's hydroelectric costs. Construction started in April, 1951 and the first unit commenced production on April 30, 1954, just 37 months later. By mid-1955 12 units were on line, and all 16 units were producing power in early 1958. Ontario Hydro decided, in response to their mid-1952 forecast of sharply-increasing demand (and a year after work had started on the first tunnel) to add a second intake, a second tunnel and six more units, in addition to the six units originally planned. Later, in 1953, Hydro decided to add four more, bringing the final total to 16 units, plus adding the pumped-storage project. The availability of the last four units delayed the overall project completion into 1958, but all the 'original' 12 units were on line within 52 months of breaking ground.

3.9.1 *Employment, work regime and contracting*

Project employment peaked at 7,655 persons. The nominal work week was 5 days. Tunnel workers worked 9.6 hours a day, surface workers 8.8 hours, giving work weeks of 48 and 44 hours- the difference was for underground travel and cage time. Workers requiring accommodation were housed in three temporary camps- Chippawa Camp, near the intakes; Whirlpool Camp, near the downstream portals and Queenston Camp, near the powerhouse. Each camp had a cafeteria that would seat 600 men. All of the work (with the exception of the intake tunnels and the 5 shafts) was done by Ontario Hydro personnel. The tunnels were competitively bid, with each bid package comprising 2 shafts and about 3,600 meters of single tunnel. One contract was awarded to Rayner-Atlas, the other to Perini-Walsh. Ontario Hydro's mid-1952 decision

to add the second tunnel required negotiations with both contractors, as work was then under way on the first tunnel. The remaining portion of 1,100 meters of tunnel at the intake end was subsequently awarded to Perini-Walsh, who were out-performing Rayner-Atlas.

4 SHAFTS

4.1 *Locations*

Shafts are located midway between the two tunnels, which are at 76 meter centres. The five shafts range in depth to tunnel invert level from 60 to 101 meters.

The reasons for this range are three- the topography; the slope of the tunnel invert and the depth to the underside of the Irondequoit limestone. This is the most competent rock strata and it was decided to make the underside of the Irondequoit limestone the crown of the tunnel. The Irondequoit slopes up from the inlet end of the tunnels at a gradient of approximately 0.5%, with the tunnel crown following that relatively strong and consistent 2.4 meter thick band.

4.2 *Geology*

Following are the depths of various strata encountered in the excavation of Shaft #1, the deepest of the five shafts. The total depth is also shown.

4.3 *Dimensions*

Shafts #1 and #2, done by Rayner-Atlas, were sunk to rock using 9.75 meter inside diameter concrete caissons, with a wall thickness of 76 centimeters, giving an outside diameter of 11.27 meters. For Shafts #3, #4 and #5, Perini-Walsh chose to use sheet pile cofferdams, due to the lesser overburden depths at those locations. A tight international supply situation for steel sheet pile then prevailed, another factor for Rayner-Atlas in choosing to use concrete caissons. On reaching rock level the shafts were continued to tunnel invert grade at an excavated diameter of 9.75 meters. Temporary timber sinking head-frames were used, these replaced with steel head-frames of greater hoisting capacity, after the tunnel invert level was achieved. The muck loading pocket and the sump at each shaft were excavated a further 21 meters, at a diameter of 5 meters.

Table 1. Thicknesses of the strata encountered.

Strata description	Depth (m)	Total (m)	Notes/observations
Clay	7.3	7.3	From the surface
Sandy silt	16.8	24.1	Water table @ 14 m
Boulder clay, slabs	9.1	33.2	Top of rock
Lockport dolomite	12.2	45.4	Water-bearing rock
Dolomite/Gasport	8.5	53.9	Water-bearing rock
Gasport limestone	8.3	62.2	Water-bearing rock
Rochester shale	18.9	81.1	Tight- no water
Irondequoit limestone	2.4	83.5	>>Tunnel crown<<
Reynales dolomite	4.3	87.8	Tunnel horizon
Neagha shale	1.8	89.6	” ”
Thorold sandstone	2.4	92.0	” ”
Grimsby sandstone	12.5	104.5	” ”
		99.1	>>Tunnel invert<<
Power Glen shale	13.4	117.9	Muck pocket, sump
Whirlpool sandstone			Muck pocket, sump

4.4 *Overburden excavation methods- Rayner-Atlas*

The top few meters of soil inside the caissons was excavated by backhoe, followed by clamming. After the third lift of concrete was placed in the caisson, the total weight exceeded 1,100 tonnes but it just wouldn't go down. In addition, uncontrolled inflows of water under the cutting edge flooded the previously-dry excavation. Then ensued a series of ineffectual missteps, truly a comedy of errors, including: attempts to block the inflow from the inside of the caisson; placing 25 kilogram blocks of dry ice in pits dug inside the cutting edge, trying to freeze the soil, discontinued after five weeks because the carbon dioxide gas released by the melting dry ice became hazardous to the crew; grouting around the perimeter, this discontinued after 3 days of effort; driving an external ring of sheet pile, with this attempt much obstructed by the earlier grouting program, all of these measures with little success. It was then decided to continue with wet clamming but the caisson still wouldn't drop. Soil losses from the exterior piped to the surface, requiring backfill. The next effort required top-ballasting the caisson. With a top load of 562 tonnes of sheet pile, the caisson finally moved, bottoming-out on rock, and after 3 months of frequently-futile work. By contrast, Perini-Walsh, at their three shafts, and using the sheet pile rings proceeded uneventfully and in much less time.

4.5 *Rock excavation methods- Rayner-Atlas*

Work in each shaft was carried out on 8 hour shifts, working around the clock. Each shift had a 22 man crew. The average sinking rate achieved was 0.9 meters per day. Hand-held pneumatic pluggers, with drill steels of 0.9, 1.8 and 2.4 meters length were used to drill 65 holes on half the bench, with each round pulling about 1.9 meters. Drilling off half a bench took about 2.5 hours. A half bench took about 12 hours to muck, all done by hand. Crew access to the bench was by the muck buckets, rated at 1.4 cubic meters or 11 men. Mucking took over 70% of the total shaft-sinking time, exclusive of the timbering, which was done on Sundays by a special crew.

4.6 *Shaft bottom complications and hoisting*

Substantial structural steel arches and underpinning were required at the shaft bottom, to permit the safe excavation of the cross drifts to the main tunnels. The hourly-paid underground work force at Shaft #1 during this portion of the work totaled 240 men. During this period the permanent structural steel head frames and the electric hoists were installed. A typical shaft arrangement provided for 2 counter-balanced muck skips each of 10 cubic meter capacity and an 18 tonne capacity cage with counterweight. The cage was used for men, materials and the construction equipment, which included 15 tonne capacity Euclid Model 87FD off-highway trucks and 2 cubic meter Northwest Model 80 D electric shovels.

5 TUNNEL EXCAVATION

5.1 *Planning for the 15.55 meter diameter face*

Rayner-Atlas intended a full-face approach, using two multi-deck jumbos, one for the top portion and another for the lower, with mucking to be done with 0.7 cubic meter Eimco overhead loaders dumping onto a conveyor, to load 4 cubic meter muck cars, for locomotive haulage back to the shaft. This arrangement was shown to be inadequate, impractical, slow and unsafe. With Ontario Hydro's strong encouragement, Rayner-Atlas hastily adopted the more productive top heading and bench approach that Perini-Walsh was using, even copying the Perini-Walsh plans for the drill jumbo. That approach divided the face into a 9 meter high top heading excavated the full length of the section, followed by a 6.5 meter high bench, this work done on a second pass.

5.2 *Drilling and loading the heading*

For Rayner-Atlas' modified approach, the heading was drilled with a multi-deck rail-mounted jumbo fitted with 23 Ingersoll-Rand pneumatic drifters, 16 of which were column and bar mounted. Three drills on the top deck and four more on the rail bogeys were mounted on hydraulic booms which worked only in the vertical plane- the horizontal movement was manual. Jacklegs supplemented the four hydraulic booms for the bottom lifter holes. A round required 173 holes, drilled to 6 meters, using tungsten carbide bits. Electric blasting caps were used, with an overall powder factor of 1.6 kg/m^3. The toe of the muck pile was usually about 40 meters from the face, exceptionally as far as 55 meters. Considerable oversize was encountered, and the grizzly at the loading pocket was reset, from 60 cm × 60 cm to 90 cm × 90 cm openings. Rocks sometimes had to be hoisted off the grizzly by air tuggers and loaded into small trucks, for cage transport to the surface, when the grizzly became clogged with oversize. Up to 10 electric driven air compressors supplied as much as 212 m^3 of air per minute. In contrast, Perini-Walsh used fewer drills- 17 Joy drifters, but all on hydraulic booms and pulled rounds averaging 4.8 meters. A Perini-Walsh heading round produced 900+ cubic meters of muck.

5.3 *Scaling and rock support*

Scaling after the blast was difficult and dangerous, as much scaling was done manually from the jumbo decks. Additional scaling was done using the Northwest shovels and from the muck pile. Steel ribs (W8 × 20) 20 cm × 65 kg were set at 1.2 meter centres, blocked, and timber and steel lagging was installed. The ribs were in 4 pieces, hoisted by air tugger onto the drill jumbo decks and then man-handled into place. Several rock falls occurred in Tunnel 1 during August of 1952, requiring that 80 meters of tunnel be retimbered. Intermediate ribs were placed in some areas where the rock was suspect. On the breakthroughs between headings, the alignments compared within a few centimeters- on the money.

5.4 *Crew size and cycle times, for 2 headings*

After abandoning their fatally-flawed full-face approach and after copying the Perini-Walsh jumbo, Rayner-Atlas still didn't get it right and went cheap

Table 2. The Rayner-Atlas underground crew.

Category	Men	Notes and observations
Drilling	51	23 drills + jack-legs for lifter holes
Mucking	35	Drilling Hdg. A, Mucking on Hdg. B
Steel & timber	23	4+ steel sets required per round
Ventilation	4	1 shift only
Mechanics	19	
Total UG crew	128 men	(Add for electricians)

Table 3. Typical Rayner-Atlas cycle for a round.

Operation(s)	Time required		Notes and observations
Smoke out	0 hr.	30 min.	
Cleanup & scale	0	45	
Mucking	4	50	Perini-Walsh time- 4 hr 45 min.
Move in jumbo	0	30	Parked 60 m back from face
Drill, load, out	4	35	Road maintenance opportunity
Total cycle	11 hr.	10 min.	=2+ rounds in 24 hours

on their choice of drills, with higher labour costs as the result. Nonetheless, Rayner-Atlas excavated 173 meters of tunnel in 21 shifts, working two headings at once, during their best-ever 7-day production week. This required excavating 20,400 cubic meters.

5.5 *Mucking the heading and the bench*

Both contractors used similar equipment for loading and hauling- Northwest Model 80 D electric shovels and 10 cubic meter Euclid off-highway trucks. The shovel booms were cut down to give better clearance under the support ribs and lagging. Perini-Walsh, always the innovator, found a clever way to reduce truck turnaround time- they drove the empty Euclid onto a large steel plate resting on another steel plate and then rotated the truck around, to face in the opposite direction, with oil between the plates, and an air tugger used to spin the truck around- a steel-on-steel turntable. All Euclids were scrubber-equipped. Crews mucked one heading while drilling the other.

5.6 *Drilling the bench*

After cleaning the bench with compressed air and water jets, drilling proceeded using a rail-mounted vertical jumbo equipped with 17 drills, mostly Gardner-Denver. This jumbo ran on rails attached to the bottom of the ribs and it was moved forward with air tuggers. Each vertical hole was drilled to a calculated depth, producing a nearly circular invert shape.

The overall powder factor for the bench excavation was 1.45 kg/m^3, using packaged high explosives and electric caps. A muck pile about 15 meters long was left in place before blasting, to reduce fly rock. Rounds were loaded during drilling and were blasted at the end of each 8 hour shift. The average daily advance in Tunnel 2 was 30 meters, done over 3 shifts.

5.7 *Ventilation*

1.2 meter diameter steel ventilation ducts were brought up to within 60 meters of the top heading face. Reversible electric fans at the surface and at 250 meter intervals underground supplied 1,840 cubic meters of fresh air per minute to the tunnel. Reversing the fans expelled blast fumes. The duct and fans were removed for benching operations. Some supplemental unducted airplane-type fans were used to improve circulation while benching.

6 CONCRETE OPERATIONS

6.1 *Arrangement*

The nominal excavation size was 15.55 meters diameter, the finished size 13.72 meters. The 20 cm ribs and blocking are within the nominal 15.55 meters. With an average over-break of 25 cm, the concrete volume is 54 cubic meters per meter of tunnel. The lining was placed in 3 operations. First, two small curbs each 30 degrees above the invert, on which the concrete equipment would ride; secondly, the invert, covering the bottom 60 degrees of the circular lining; and finally, the upper 300 degrees.

6.2 *Concrete supply and delivery arrangements*

All concrete was supplied by Ontario Hydro from a wet mix central batch plant at Chippawa. This plant supplied much of the SAB II project. Rayner-Atlas used up to 17 three-axle dump trucks to haul the mix to delivery drop hoppers, at distances as great as 5 kilometers and on city streets. At intervals of about 150 meters, 25 cm diameter steel drop pipes were installed in holes that had been drilled in advance of the tunnel excavation. Hoppers in the tunnel caught the falling concrete. There were no re-mix facilities, but concrete segregation appears not to have been a problem. For the invert, concrete was transported to the placement location with a traveling and self-propelled pot gantry that rode rails set on the top of the curbs. The workers christened this gantry "The Queen Mary". For the arch concrete, a gantry was positioned under the drop hole and the dropping concrete was directed by chutes to twin Pumpcretes. 20 cm steel pump lines transported the concrete to the arch form, which was never more than 200 meters from the drop points. The form was fitted with numerous concreting access doors and a slick line filled the tunnel crown.

6.3 *Invert concrete*

Steel formwork panels were placed along the top sides of the invert section. The top of the side forms was the traveling surface for the drag screed and the finishers' access bridge. The drag screed was ballasted with rock and weighed about 11 tonnes. It was pulled ahead using a 3 tonne capacity air tugger on a 5 part line, anchored to steel pins set in the invert ahead. For batch plant and transport reasons, concrete placement was done on a single shift per day, although clean-up and form-setting went on around the clock. The record length placed in one 8 hour shift was 86 meters, while the average pour length was 40 meters. The Queen Mary was used to move the formwork and rails ahead. Stripping was started after a minimum 8 hours of curing. After the wood float and steel trowel finishing, the fresh invert concrete was covered with Fibreen bitumastic paper, for curing and protection. Richmond screw anchors were embedded near the top of the invert pour, as anchors for the arch form.

6.4 *Arch concrete*

Just before concrete placing, it was necessary to remove all the loose rock that had accumulated behind

the wood lagging, along with removing most of the lagging. This was done from a re-timbering gantry running on the curb rails. The arch forms were manufactured by Mayo, and as designed by Rayner-Atlas, who again got it wrong, by specifying forms that were too lightly-built and that blocked supply traffic on the completed invert, because the flimsy formwork required numerous bottom struts. The forms had to be reinforced underground, with doubling of ribs and replacement of inadequate steel members. The skin plate couldn't be changed underground and it became distorted, requiring continual repair work. Even the cast iron wheels carrying the arch form had to be changed to solid steel wheels, due to failure. Two arch forms were used by Rayner-Atlas, never one for anticipation or standardization. One form was originally bought at 18.3 meters length, the other at 24.4 meters length. Both were later lengthened by 3 meters, giving final form lengths of 21.3 and 27.4 meters. The forms ran on rails supported by beveled timbers resting on the curved invert. The forms were built in sections 6.1 meters long and these were the lengths moved ahead on shifting the form to the next pour. Vertical movement for stripping was 15 cm and each side panel could be swung in 22 cm- a two hinge form, with the hinges located just above the springline. It was generally possible to pour the form every day, with concreting done on a single shift, with 12 hours allowed for curing and then four hours to strip and move the forms ahead and prepare for the next pour. After moving the form into the new location and jacking it up to grade, the bottom edges of the two side flaps were bolted-in, using the Richmond screw anchor inserts that had been set into the top edge of the invert concrete. The average placing rates with the two Pumpcretes exceeded 100 cubic meters per hour.

6.5 *Grouting*

Following 60 days of concrete curing, the Cementation Company (Canada) Ltd., working as a sub-contractor to Rayner-Atlas, commenced their grouting operation. Cementation equipped the job with a C. F. Johnson surface batch plant and a Colcrete mixer. Grout was pumped in 40 mm steel lines to the underground injection plant. This consisted of three receiving agitator tanks for receiving and remixing grout from the surface and low and high pressure grout pumps, all equipped with pressure-limiting devices. All of this was mounted on a too-light gantry composed of sections of modular scaffolding. The gantry gave ongoing and completely avoidable aggravation and delay. Grout hole drilling off the gantry was with jacklegs and stoppers. For the invert, the drilling was done with wagon drills- wheeled undercarriages with mast-mounted drifters. After the low-pressure sequence using sand-cement grout, the high pressure grouting using cement-only grout was undertaken. This was followed by a series of test holes- drilling followed by grouting- very little grout was taken on the test sequences. The total job grout take was one third of expectations, due to the excellent filling at the crown of the tunnel with the air sluggers (a pneumatic placer) and the Pumpcretes. In Tunnel I, Rayner-Atlas gave very little attention to timely clean-up of excess grout in the invert and wound up chipping the pooled and hardened grout with pneumatic hammers. For Tunnel 2, timely grout clean-up was made routine, and at a lesser final cost.

ACKNOWLEGMENTS

The authors wish to thank the following engineers for their reviews, comments and other generous assistance in the preparation of this paper-

Mr. John Boots, BC Hydro, Vancouver, Canada
Mr. Bill Earis, BC Hydro, Vancouver, Canada
Mr. Scott Sylte, EBA Engineering, Vancouver, Canada
Mr. James Thomson, Oakville, ON, Canada

Královopolský Tunnel in Brno, CZ

V. Horák, J. Pechman & J. Rožek
Amberg Engineering Brno, a.s., Brno, The Czech Republic

ABSTRACT: The paper deals with the design of two parallel road tunnels passing under a densely built-up area on a ring road in the city of Brno. Major critical parameters for the construction will be adverse ground conditions in neogenous clay, large excavation cross-section, low overburden and an overlying residential area. Thorough geotechnical investigation included driving of three exploration adits and extensive surface and underground monitoring. The twin-tube tunnel of approximately 1250 m in length will be driven using NATM principles and core method of excavation, with short cut-and-cover sections. Low overburden in portal sections will necessitate the use of supplementary measures, such as pipe umbrellas and jet grouting. Special attention is paid to evaluation of estimated subsidence and to minimization of possible damage to existing structures. The project costs are about 100 mil EUR (tunnels only). The opening of the tunnel is scheduled for 2011–2012.

1 INTRODUCTION

1.1 *The project*

Section Žabovřeská-Dobrovského of the city ring road (VMO) forms an important part of the traffic system of Brno, as well as the national road network (road I/42) and the international road network (road E461).

- the project will be incorporated in the radial ring traffic system, whose three ring roads have graded traffic functions
- the construction represents a substantial step towards closing of the third outer ring, which will help decrease traffic loads on parts of the intermediate ring road
- accordingly, completion of the outer city ring road (VMO) will contribute further to directing through traffic away from the city centre

A twin-tube tunnel, 1.25 km long, is the key component of the project (Figs 1–2).

Figure 1. Layout of Brno traffic system.

1.2 *Principles of town planning and architectural solution*

The objective is to consistently separate residential areas from the through traffic and city ring road (VMO) traffic. At the same time, the existing green areas are considerably enlarged (Fig. 3).

To improve pedestrian connection between residential districts on both sides of the city ring road, two new footbridges will be built.

Extensive planting of trees and climbing plants in border zones should not only set off the living areas from the traffic, but also enhance the overall structural design (soft landscaping of the roundabout area and the area above the tunnel openings, green foot bridge, earth walls, ground shaping). Accomplished planting design also helps to minimize the visual impact of the traffic structure, so that even inhabitants of the upper floor flats see as little of the finished construction as possible.

The immediate environment will be developed into park-like areas using soft landscaping, street furniture and small architectural elements, with the aim to create an impression of small piazzas connected by footpaths. Closing off open inner courtyards by high fencing with climbing plants and green roofing on new buildings should round off the picture.

1.3 *Environmental impact of the construction*

The endeavour to minimize major impacts of the construction work on the environment was focused in

Figure 2. The tunnel layout.

Figure 3. Computer image of the western portal.

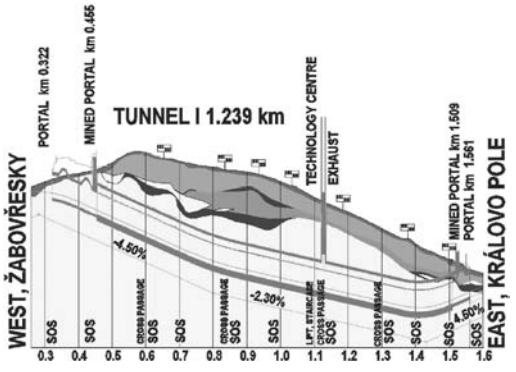

Figure 4. Longitudinal profile with geology.

particular on reducing noise and air pollution and on massive planting:

- Closing of the residential area of the streets Voroněžská and Záhřebská with noise barriers and earth walls, placing of the side ramps into covered galleries and their extension up to the bridge at Korejská street
- Noise protection walls and substantial green planting in front of the eastern tunnel opening
- Elimination or substantial reduction of exhalations around tunnel openings due to the use of controlled ventilation system in tunnels
- Sufficient height of the exhaust chimneys above the surrounding buildings in the area of technology and ventilation centre, installation of noise attenuators
- Forming of functional and achitecturally attractive areas for pedestrian traffic and recreation at Voroněžská street, Záhřebská street, Hradecká street – east and Královopolský tunnel opening
- Stabilization of the city floorscape in the new opening at the tunnel portal in Královo Pole

2 THE TUNNELS

2.1 *Layout overview*

The east-west tunnel tube – denoted Tube I – is located beneath Dobrovského street, the second tube – Tube II – is situated in parallel about 60 m to the south. Both tubes pass under a densely buit-up area, which means that the excavation will have to traverse under or near buildings up to seven storeys high. The tunnel is connected at both portals to large intersections with grade separation (see Fig. 2).

Tunnel tube I: total length 1237 m

The driven part is 1019 m long; cut-and-cover parts built in cased excavation pits are 168 m long in Žabovřesky and 50 m long in Královo Pole.

Tunnel tube II: total length 1258 m

The driven part is 1060 m long; cut-and-cover parts built in cased excavation pits are 149 m long in Žabovřesky and 49 m long in Královo Pole.

Both tunnel tubes are oriented in the west-east direction. The distance between the tubes varies between 6 and 70 m.

The longitudinal profile of both tubes had to be adjusted to the links to existing roads, while keeping two important trunk sewers in front of the Královo Pole portal intact. Moreover, the vertical alignment of tunnel axes is governed by the geology, more specifically the minimum necessary overburden thickness in clays (see Fig. 4). The resulting alignment has a sag vertical curve located in the bottom part, which means water will have to be pumped out of the lowest point both during construction and during operation of the tunnel.

2.2 *Geology*

The geological conditions in the area are monotonous. The top cover (3–10 m thick) is made up by fills and loess loams. Basis of the Quaternary cover is

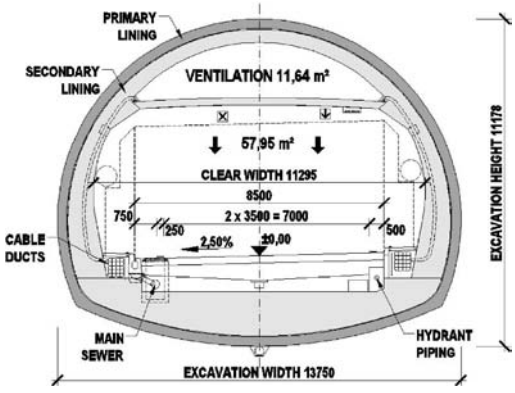

Figure 5. Standard driven tunnel cross-section.

represented in places by water-bearing gravel/sand terraces, which are not continuous. Its underlay is formed by limey, silty clays of Tertiary (Neogene) origin, so called Brünner Tegel in German. The thickness of the clay layer is several tens of meters – the bedrock was not reached by boreholes more than 60 m deep. Groundwater is bound to sandy gravel locations on upper Neogene horizon in the form of impoundments in the local depressions. The consistency of the Neogene clays is hard up to solid. From the point of view of plasticity the clays are highly plastic (MV or CV according to USC system) and in connection with groundwater highly squeezing. The cover thickness on both tunnels is approximately the same and ranges between 6 m up to about 21 m. The tunnels are vertically positioned in such a way that a minimum thickness of impervious Neogene clay cover of 2 to 3 m above the excavation is always secured.

2.3 *Design of the tunnel interior*

The standard driven cross-section is horseshoe-shaped with an arched invert (see Fig. 5). The excavation area is 125 m^2. The cross-section is divided by an intermediate ceiling into the traffic area and ventilation area. The tunnel lining is of double-shell type with intermediate waterproofing.

Primary excavation support is formed by steel arches and shotcrete reinforced with wire meshes. Steel plate girders are preferred due to their immediate bearing capacity. Total thickness of primary support is 350 mm. The tunnel is sealed with a closed waterproofing membrane. The final RC concrete lining has minimum thickness of 450 mm.

Tunnelling in areas with low overburden thickness or areas endangered by higher than permissible settlement will be supplemented with pipe umbrellas above the excavation roof.

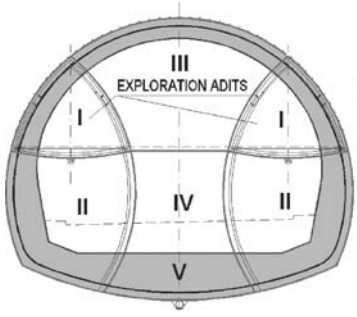
Due to the confirmed groundwater corrosivity (concrete-aggressive action), the primary lining is considered to be a temporary structure. Long-term load-bearing capacity is fully ensured by the reinforced concrete inner lining.

Table 1. The tunnel profile – basic technical data.

Length / Area / Volume	Amount
Basic width of the traffic lanes in the tunnel	3.50 m
Clear headway	4.50 m
Clear width between curbstones	8.50 m
Area of the traffic space	57.95 m^2
Ventilation area (air exhausting)	12.0 m^2
Primary lining with the thickness of 350 mm	11.95 m^3/ running meter
Secondary lining (min. thickness 450 mm)	32.53 m^3/ running meter
Tunnel excavation area	125 m^2

2.4 *Tunnel ventilation*

The tunnel is designed with a semi-transverse ventilation system. The clean air will be drawn into the tunnel through the tunnel openings. The polluted air will be channeled through the air ductwork situated above the suspended ceiling and exhausted centrally into the tunnel technology and ventilation centre located in approximately one third of the tunnel length. The exhaust air will be blown into the atmosphere with an increased speed from two chimneys 25 m high above the surrounding terrain. The ventilation of both tunnels will be separated and entirely independent.



The excavated parts in Žabovřesky and also in Královo Pole will be completed with auxiliary axial flow fans for additional air suction from the tunnel openings to minimize the emission of polluted air from the tunnel openings into the area of the housing estate Žabovřesky or into the residential part of Královo Pole.

2.5 *Tunnelling method*

A tunneling procedure with vertically and horizontally sectioned heading (so called Ulmenstollen, Paramentstollen in German) is proposed. The sequential excavation method incorporates the existing exploration adits (Fig. 6). The excavation will proceed from the eastern portal towards Žabovřesky. The construction of secondary liner will follow approximately 200 m behind the invert closure of the excavation support.

The secondary lining is made of cast in-situ reinforced concrete. To speed up the construction, the central part of the tunnel floor is made of precast elements, which will provide more or less continuous access to the tunnel face.

The estimated settlement trough is relatively narrow. According to mathematical models and forecasts

Areas of partial excavations:

I	12 m^2
II	24 m^2
III	29 m^2
IV	20 m^2
V	4 m^2
Total	125 m^2

Figure 6. Division of excavation.

the width of the settlement curve extends – depending on the cover thickness – up to the maximum distance of about 25 to 30 m from the tunnel axis. The maximum subsidence value reaches up to ca 110 mm directly above the tunnel axis at the location with minimum overburden thickness, otherwise the maximum value reaches 70 to 80 mm along the tunnel route.

2.6 *Safety construction measures*

Both tunnel tubes are connected by four cross passages. One of them is linked to an escape staircase and evacuation lift, which enables to escape directly to the open space.

Both tunnels are equipped with a 40 m long emergency lay-by.

Each tunnel is furnished with six emergency (SOS) stations with standard equipment. The emergency stations are built in on the right hand side in the direction of travel, while the hydrant niches are situated on the left. The stations are spaced 150 m apart.

Both the tunnel tubes and the escape routes including the underground rooms of the technology centre will be equipped with fire hydrant mains. The looped water supply system enables to cut off individual branches of the supply system in case of a major accident and is completed with additional dry standpipes in tunnel cross-connections and escape routes.

The drainage system is designed to prevent fire and flammable liquids from spreading inside the tunnel. It includes slot gutters and fire protection manholes. A water sump with a pumping station is located at the lowest point of each bore. The pumping station has a 100% capacity reserve including back-up and protection of pump units and remote control.

2.7 *Safety equipment*

As far as the operational safety is concerned it can be said that the tunnel's safety equipment satisfies the standard of the other two Brno tunnels already in operation. It also meets the requirements posed by the European Directive 2004/54/EC on the minimum

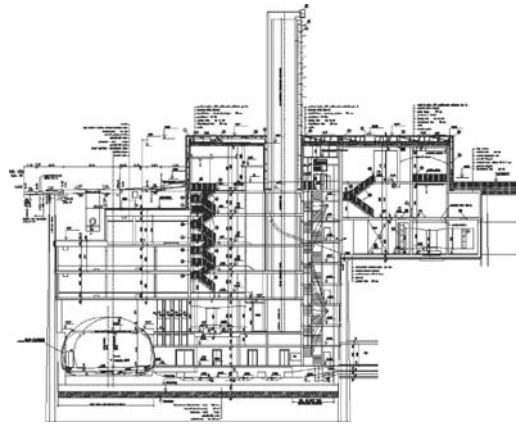


Figure 7. Cross-section of the technology centre.

safety requirements for tunnels in the trans-European road network. Since 1999 the city-owned company Brněnské komunikace operates a central tunnel control room (CTD) with round-the-clock service, to which all the systems of the new tunnel will be connected.

3 TECHNOLOGY AND VENTILATION CENTRE

It is necessary to provide corresponding room for the selected semi-transverse ventilation system (especially the ventilation fans) and for the other technological systems (lighting, power supply, traffic signals, communication) within the tunnel. The adequate space had to be fitted in the relative dense existing housing development. The underground object of the technology and ventilation centre will have the plan dimensions of 14×44 m, the depth of the escape route finish floor and the lowest floor level is 25.50 m under the terrain. The technology center will have altogether five underground floors and one ground storey, as well as two exhaust chimneys with the height of 25 m above the terrain.

The first tunnel tube passes through the bottom floor of the technology centre. This fact will be taken advantage of during the tunnel construction as the construction pit for the underground centre will give additional access for rock material removal and ventilation. The second tunnel tube – Dobrovského II – will be connected to the technology center by three adits – an escape route with cable duct and two ventilation tunnels. The ventilation tunnels will channel exhaust air through a separate air-handling plant (VZT) directly into the chimney. On the surface there will be only two relatively small buildings with an access road

Figure 8. Digital rendering of the surface buildings of the technology centre.

and two tall chimneys (see Fig. 8). The above-mentioned buildings will be architecturally integrated into the future multi-purpose building of the VFU (University of Veterinary and Pharmaceutical Sciences Brno).

4 EXPLORATION ADITS

4.1 *Objective*

The tunnel design has to cope with three main adverse consequences of the tunnel location: relatively difficult ground, comparatively low overburden and a number of existing buildings and utilities that could be affected on the surface. All this makes the construction an engineering task that is yet unparalleled in The Czech Republic.

A detailed technical survey of the endangered buildings and utilities was made. The documentation comprises records of about 260 buildings. Approximately 160 buildings will be monitored and measured during tunnelling.

The actual impact of the tunneling on the surface was verified during tunneling of the exploration adits. Three exploration adits with a total length of about 2000 m were driven. The adits are situated inside the future tunnel cross-section. They were driven by the same method as is assumed for the large tunnels so that valuable experience with working the rock could be gained. The results of the measurement programme and the monitoring of the adit excavation impact in the critical areas show that their implementation was more than justified.

4.2 *Construction of the exploration adits*

Two adits denoted IIa and IIb and 835 m long were driven in the tunnel profile of the tube Dobrovskeho II. One 365 m long adit with the designation Ib was excavated in the tunnel profile of the Dobrovského I tube. The adits were driven from the temporary tunnel

Figure 9. Temporary portal at Královo Pole in 2002.

portal in the Královo Pole construction pit. The temporary tunnel portal and the excavation pit at Královo Pole were designed and carried out so as to enable driving of both large tunnels.

The adits have the shape of isosceles triangles. The sides of the triangles are vaulted with the radius of the future tunnel lining. The invert is also arched. The lining is made of sprayed concrete with the thickness of 100 mm, which is reinforced with one layer of wire mesh and rigid frames made of mining sections K24 spaced in 1.0 m distance. The excavation area of each adit is 13 up to 15 m^2.

4.3 *Geotechnical investigation programme*

The geotechnical field tests were carried out in four short lateral drifts, which were driven from the IIa adit to the space outside of the future tunnel cross-section. The exploration boreholes, inclinometer, extensometer and levelling profiles were all situated near the lateral drifts. The locations of concentrated investigation were previously selected based on available data. Beside the above mentioned investigation techniques a detailed geological sequence was drawn up for each adit and several measuring cross-sections were set up, where convergence, change in shape and position of the lining and ground settlement were recorded in dependence on the excavation progress.

5 EXPERIENCE GAINED THROUGH TUNNELLING OF THE EXPLORATION ADITS

5.1 *Problems in the area of extremely low overburden*

Close to the tunnel portal in Královo Pole, about 50 to 80 m into the tunnel, the tubes have a very low cover thickness of 5 to 8 m. The most serious difficulties with respect to the settlement and deformations

of the overlying buildings were encountered here during tunneling of the IIa and IIb adits. A significant increase in the maximum settlement by ca 120% compared with the original assumptions occurred here. The maximum measured building subsidence was 56 mm and the inclination of the building exceeded the set critical limit.

The causes of the excessive subsidence can be summarized in the following items:

- A depression in the horizon of Neogene clays filled with gravel aquifer was reached without previous indication. That meant substantial, unexpected and long-term water ingress into the excavation of the IIa adit. It is interesting to note that the IIb adit, mere 6 m far from the IIa excavation, was almost dry.
- Two more stories were added to the former one-storied house – and the building permission for the extension was obtained – only a few months prior to the tunnelling start.

In spite of these problems the contactor managed to go through this critical locality without any further damage due to adopting additional technical measures and thanks to the combined effort of all interested parties.

The tunneling of the Ib adit, which is situated under the street, ran smoothly without unfavourable ground settlements. The assumed deformations were not exceeded.

5.2 *Mathematical modelling and prediction of the settlement trough development*

During tunnelling of the exploration adits a continuous evaluation of the obtained data took place. The exploration findings and measurement results were incorporated in a mathematical model created using the FLAC software. The results of the mathematical modeling were compared with the actually measured values. Subsequently the forecast of the tunnelling effects was elaborated. The predicted settlement troughs and ground deformations were determined for the entire length of both driven tunnels. A map of combined settlement trough for both tunnels was plotted using settlement contour lines. These forecasts were used as source data for the detailed evaluation and checking of the buildings in the settlement area of the future tunnels and for the design of their reinforcing measures.

5.3 *Evaluation of the acquired findings from the tunneling of exploration adits with respect to the engineering solution of the large tunnels*

Taking into account the findings from the tunneling of the exploration adits, the rock environment and the tunnel construction in the given area can be characterised in the following terms:

- The deformation development is long-term. The steady state is reached only a year after the passage of the tunnel face. The Neogene clay can be compared to a “viscous liquid” with respect to deformation effects.
- It was confirmed that deformations in the invert (invert heaving) influence substantially the overall displacement.
- Stiffness of the primary support has to be increased proportionally with the excavation area.
- Partial excavation steps have to be carried out and support has to be installed in the shortest time possible. Interruptions in excavation cycle result in increments in displacements and in settlement trough area.
- The settlement trough is relatively narrow. Points of maximum gradient lie approximately 20 m from the tunnel axis.
- Excavation in very shallow sections and under sensitive structures on surface requires additional measures, such as ground improvement, grout screens and pipe umbrellas, as well as the use of state-of-the-art boring techniques and grouting materials.

6 CONCLUSION

As of 2006, the construction work on the project has already started. The start of the excavation is planned for the spring of 2007. The authors are going to be involved in the detailed design as well as the building supervision and they hope they would be able to report on the projects headway at the WTC 2007.

Planning and design of the A3 Hindhead tunnel, Surrey, UK

T.J. Ireland & T.A. Rock
Mott MacDonald, London, UK

P. Hoyland
Balfour Beatty, London, UK

ABSTRACT: The A3 Hindhead project includes a 1.8 km long twin bore tunnel that is planned to commence construction in 2007. This paper describes the development of the tunnel design through the planning and design phases including the design for maintenance, and the innovative approach to tunnel support in the sand and 'soft rock' sandstone.

During the preliminary design period, the UK Health and Safety Executive (HSE) issued three Chemical Hazard Alert Notices (CHAN's) relating to a reduction in the allowable exposure levels of respirable silica and NO_x during construction. This caused us to compare SCL and TBM design and construction strategies and compare the risk profiles.

1 INTRODUCTION

The A3 Hindhead project located in Surrey, UK is a 6.7 km dual carriageway truck road that includes a 1.8 km tunnel being delivered under a Highways Agency Early Contractor Involvement (ECI) contract. This paper describes the development of the tunnel design through the planning and design phases including vertical and horizontal alignment, tunnel cross section, ground support measures, and the design of the tunnel structure to resist fire loading.

During the preliminary design phases both TBM and Sprayed Concrete Lining (SCL) methods were considered for construction, and a comparison between the designs is included. The differences in construction methodology including planning, and program are also discussed, and the different risk profiles outlined.

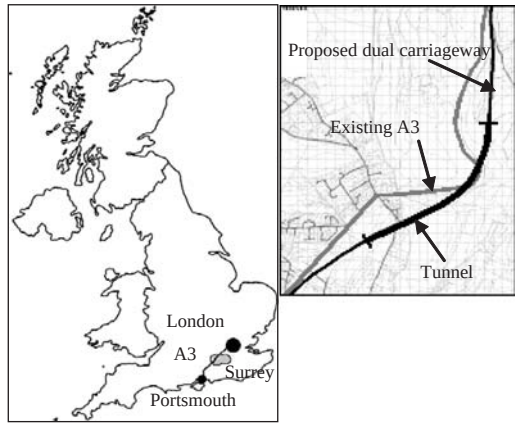

Figure 1. Project location.

2 PROJECT DESCRIPTION

The A3 Hindhead project is one of the schemes in the UK Government's Targeted Programme of Trunk Road Improvements. The project will complete the dual carriageway link between London and Portsmouth and remove a major source of congestion, particularly around the A3/A287 traffic signal controlled crossroads. Refer to Figure 1 for location details.

The project will deliver quicker, more reliable journeys on a safer road, and remove much of the present peak time "rat-running" traffic from unsuitable country roads around Hindhead. The centre of Hindhead will be freed from the daily gridlock that blights the area, with the result that the project will bring benefits to road users, local residents, and the highly prized environment.

2.1 *Planning phase*

The A3 Hindhead project has been planned since 1983 when it was included in the Government's Trunk Road program. The challenge for this project was balancing environmental impact with user economic benefits. Striking the right balance between these competing

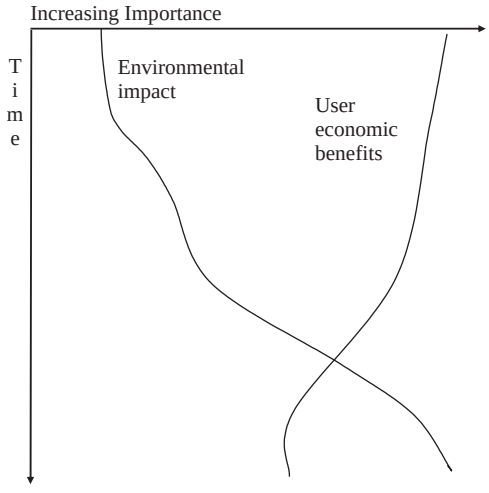

Figure 2. Change in approach to development of A3 Hindhead Scheme.

issues has taken over 20 years to resolve. Almost all the scheme lies within an 'Area of Outstanding Natural Beauty' (ANOB) with Site of Special Scientific Interest (SSSI) that are part of the Wealden Heaths SPA – an EU Designation that prohibits development except for "no choice" and national economic or safety considerations. The route passes through National Trust owned land which is classified as "in-alienable". It can only be compulsorily purchased against their wishes with the approval of the UK Parliament.

In the 19 years since the project was first mooted, and the commencement of the current phase of project development in October 2002 there has been a sea change in planning and approval thinking where economic benefits originally had primary importance and now environment damage mitigation is uppermost. This change in planning approach with time is shown on Figure 2. The key to a successful planning process in this case was to provide a tunnel under the environmentally sensitive areas, and to close the old A3 thereby reuniting sections of the SSSI/SPA. Other environmental benefits included the removal of intrusion and severance within the AONB, and the removal of air, noise and light pollution.

Part of the change in approach was the adoption by the Highways Agency of partnerships for scheme development. This was manifested on the A3 Hindhead project by the establishment of a Project Advisory Group (PAG) incorporating all the key stakeholders including the protectors of the environment such as National Trust, English Nature, Countryside Agency and English Heritage. The objective of the PAG was "*To assist in developing the tunnel scheme to minimize its impact on the built and highly prized natural environment, and one that is broadly acceptable to the local community, while ensuring that all impacts have been addressed*". Table 1 below outlines the project development timetable since inception in 1983.

Table 1. Project development time-line.

Date	Activity
1983	Enters Trunk Route Program
1987	Single Route Consultation
1988	Red Route confirmed as preferred
1992	Second public consultation
1993	Modified yellow route with bored tunnel announced as preferred route
1995	Work suspended
1998	Roads review – Road Based Study into tolling announced
1999–2000	Tolling Study
2001	Enters TPI
10/2002	ECI contract awarded
9/2004–2/2005	Public Inquiry
8/2005	Inspectors Report received
9/2006	Secretary of State decision
1/2007	Commence construction
7/2011	Open Tunnel
3/2012	Complete Scheme

2.2 *Early Contractor Involvement (ECI) contract*

The Highways Agency introduced the principle of "Early Contractor Involvement" in 2001. This new form of procurement is about bringing suppliers and designers together much earlier in scheme conception than previously occurred, allowing them to work together more closely. This allows more scope for innovation, improved risk management, better forward planning of resource requirements and minimization of long term environmental impacts, improved consideration of buildability and health and safety, shorter construction periods and reduced environmental impacts during construction. Overall, the early creation of delivery teams clearly offers the opportunity for better value and improved performance.

3 GEOLOGY

3.1 *Overview*

The geology of the Hindhead area comprises a sequence of fine grained sedimentary deposits laid down during the Lower Cretaceous period in near shore transgressive marine conditions on the margins of the subsiding Weald Basin. The tunnel is within the Hythe Beds – a 90 m thick sequence within the Lower Greensand Series formation.

The Hythe beds are variably sorted, highly glauconitic, variably bioturbated and cross-bedded sands and sandstones.

The Hythe bed unit is divided into 6 litho-stratigraphic subdivisions, 4 of which the tunnel passes through.

3.2 *Tunneling conditions*

The tunnel at the southern end passes through units Upper Hythe A and B which are similar units with an increasing number of sandstone bands with depth, described as '*medium dense thinly bedded and thinly laminated, clean to silty and clayey fine and medium SAND with subordinate weak to strong sandstone, cherty sandstone and chert*'.

The majority of the tunnel passes through the more competent Upper Hythe C and D, and Lower Hythe A units, described as '*Weak, locally very weak to moderately strong, slightly clayey fine to medium SANDSTONE with occasional thin beds of clayey/silty fine sand*'.

The remaining unit is Lower Hythe B which has been avoided by the tunnel as clays and sand become dominant in the lower half of the unit.

The sandstone within Upper Hythe C/D and Lower Hythe A has typical UCS values of between 2 and 5 MPa and is heavily fractured with 6 joint sets including the sub-horizontal bedding with mean fracture centers varying between 190 and 815 mm.

The tunnel is above the historically observed water table, with the maximum predicted water table exceeding the invert level in only 1 location. Refer to Figure 3 for geological longsection.

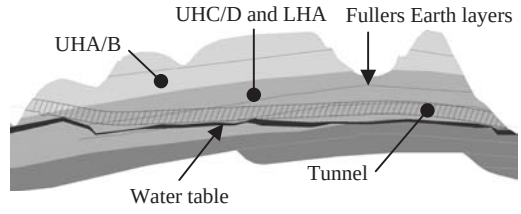

Figure 3. Geological longsection and vertical alignment (1H:4V).

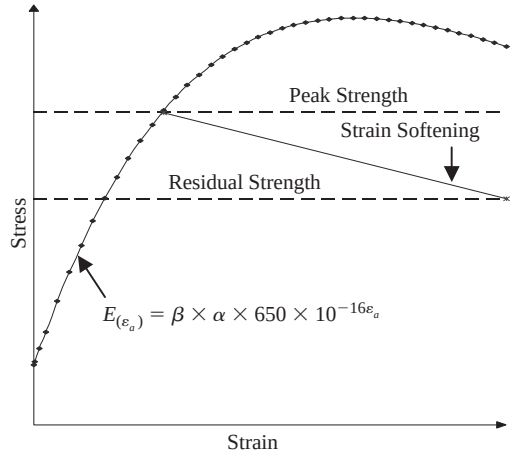

Figure 4. Ground model used for design.

3.3 *Ground behavior model*

A challenge for this project was to define a ground behavior model in an unusual material that has not been tunneled previously. The difficulties in interpretation stem from the weak to very weak nature of the sandstone material in combination with the content of up to 20% interbedded soil layers. A recurring challenge in tunneling is to determine the rock mass strength and stiffness, with empirical methods such as GSI, RMR or the Q-method (Bieniawski, 1984) often used. The strength and stiffness relationships that are the cornerstone of these methods are generally determined from data from significantly stronger rocks than the 2–5 MPa sandstone and do not take account of the influence from the soil layers leading to a significant overestimate of stiffness.

An extensive geotechnical investigation was undertaken with sonic testing, pressuremeters and triaxial testing all used to determine the Elastic Modulus of the rock mass. Pressuremeter testing was found to be the most reliable with the sonic testing over-estimating the stiffness, and the triaxial testing surprisingly under-estimating the stiffness in a number of cases. This was thought due to the difficultly in finding a 300 mm long specimen for testing in a material with 6 joints sets and an average bedding spacing of 190 mm. Fortunately some good quality rock joint shear box testing was undertaken that provided a lower bound for strength and stiffness interpretations.

The interpreted model used in design was a small strain stiffness model ($E_{(\varepsilon a)}$) that varied the stiffness of the rock mass with strain, and a Mohr-Coulomb strain softening model used for strength. Due to the large variation in cover from 16 m to 58 m the rock mass stiffness was also related to depth (α) in order to take advantage of the positive effect of larger insitu stresses as depth.

4 ALIGNMENT

The horizontal alignment for the tunnel was determined based on road design considerations and environmental constraints resulting in a reverse curve through the tunnel with a minimum radius of 1050 m.

The vertical alignment was determined based on geological constraints with the desire to minimize the length of tunnel through the sand at the southern end, to keep the tunnel above the water table and to also maximize the vertical clearance to the Lower

Hythe B material which has insufficient strength to carry horizontal stresses around the tunnel opening. The tunnel passes beneath the Devil's Punch Bowl which is a re-entrant, primarily spring-sapped valley system with erosion feeding backwards from the Hythe Bed/Atherfield Clay interface at the valley base. The crossing of the punchbowl provides a cover constraint to the tunnel, and the cover changes rapidly from around the minimum cover of 16m to the maximum cover of 58 m within a horizontal distance of 130 m.

The decision to follow the optimal tunnel material and to avoid the softer Lower Hythe B material results in a low point within the tunnel.

5 DESIGN

5.1 *Cross section*

The Hindhead tunnel consists of twin 2-Lane bores with cross passages at 100 m nominal centers. Refer to the typical cross section in Figure 5 below. Each bore has two 3.65 m lanes, with full batter curbs and 1.2 m wide verges on each side of the tunnel. The verges are required for sight-lines due to the horizontal curvature of the tunnel, to accommodate electrical services and also to provide wheelchair access to the cross passages and emergency points at 100 m nominal centers along the tunnel.

The vertical traffic gauge provided is 5.03 m with an additional clearance of 250 mm to the Equipment Gauge.

A continuous drainage system is utilised, located beneath the curb and verge with the cable duct bank. Other services such as the fire main, high voltage cables and pump mains are buried beneath the carriageway, with jets fans, lighting and communication cables contained within the crown.

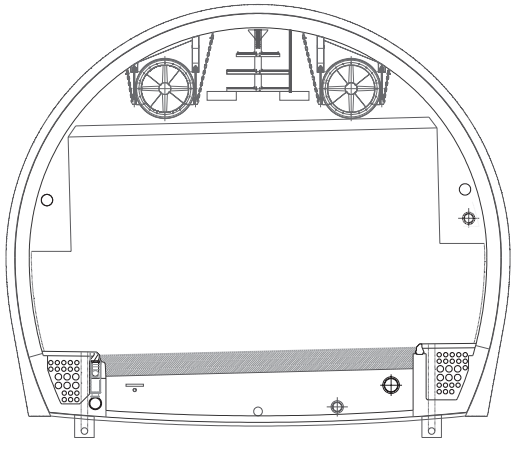

Figure 5. Typical SCL tunnel cross section.

These requirements result in a horseshoe shaped tunnel structure with an internal diameter of 10.6 m and an excavated diameter of 11.6 m.

5.2 *Fire and life safety provisions*

The tunnel has cross passages at 100 m nominal centers for escape to the non-incident bore. Cross passages include fire hydrants, dry pipe connections, fire extinguishers and emergency telephones. Emergency Points (EP's) are also provided at 100 m nominal centers located at the mid-point between cross passages. Each EP has an emergency telephone and fire extinguisher.

A longitudinal ventilation system comprising 20 jet fans per bore is provided for smoke control. Consideration was given during the preliminary design phase to the inclusion of a Fire Suppression system, however it could not be justified on cost benefit grounds. The decision was taken to make space provision for the future installation of a fire suppression system, should further evidence of the benefits become available or standards and or technology change.

5.3 *Design for maintenance*

Due to the life cycle cost of managing tunnel assets and more stringent health and safety regulations, the design team focused on minimization of whole life costs and the development of corresponding design details. Design for maintenance included:

- Minimization of unplanned maintenance interventions
- Consideration of the safety of maintenance
  - deletion of equipment where possible
  - selecting materials with the longest design life
  - Provision of safe maintenance access
  - Provision of replacement options for all infrastructure and equipment
- Maintenance risk assessments

Specific design initiatives incorporated in the works included:

- Provision of spare HV conduit and blind pits to allow replacement of HV cables in routine closures
- Modular hydrant connections allowing replacement in routine closures without disturbance of cable ducts and other services
- Relocation of in-tunnel sump to outside the tunnel by using a directional drilled gravity drain allowing maintenance access to sump without a tunnel closure

5.4 *Tunnel excavation and support*

The presence of the sand layers, in one location up to 2 m thick, led to the selection of sequential excavation

methods and support techniques commonly used in the Sprayed Concrete Lining (SCL) technique also known as the New Austrian Tunneling Method (NATM) where shotcrete is sprayed at the face following each excavation advance. Standard hard rock tunnel support techniques such as pattern bolting where not considered suitable due to the sand layers and the very low bond stress negatively impacting the effectiveness of rock reinforcement.

The tunnel is generally excavated with a full face heading followed at a distance by the bench excavation. Due to the generally stable nature of the ground and location above the water table, a closed invert is not required and the horse shoe shaped primary lining is supported on elephants feet. One main support type has been adopted through the sandstone with additional support measures such as spiling, face support wedges and/or face dowels to be triggered should an instability in the excavation occur. Refer to Figure 6 for details of the primary lining in the sandstone section.

In the sand section at the southern end the excavation will be carried out on dayshift only due to constraints on working hours and is made stable with the use of a steel pipe umbrella and face dowels. In this section three support types are required as the area of sand in the face transitions to a full sandstone face. Figure 7 shows a typical support type in the SAND section.

A principal innovation with the support measures is the design of primary lining as permanent. This is possible due to a number of advances in tunneling technology in recent years. Firstly, non-alkaline accelerators are now available with no loss in shotcrete strength with time. A recent innovation is the use of 3-D scanning survey equipment that provides excellent shape control for both excavation and spraying, and allows SCL tunnels to be constructed without lattice girders. This technique has been recently used successfully for the Heathrow T5 project (Williams et al. 2004). Historically the inclusion of lattice girders meant the primary lining had to be considered temporary due to the corrosion potential of the steel lattice girder within the primary lining. Spiling is envisioned in several locations due to adverse soil layers. This will be carried out with self-drilling Glass Reinforced Plastic (GRP) dowels, again with no adverse durability issues. The sprayed concrete will be reinforced with steel fibers as is required for safe installation, however the design does not rely on the flexural capacity of the steel fibers, and the lining is designed as plain concrete. This is possible due to the curved shape of the section with all moments resisted by axial forces within the lining.

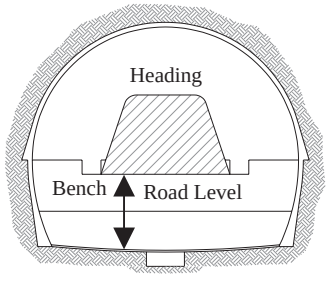

Figure 6. Typical primary lining through rock.

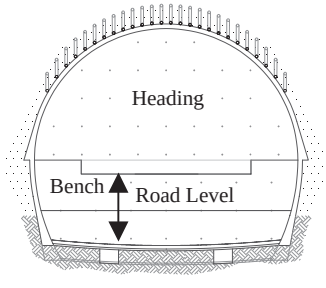

Figure 7. Typical primary lining through sand.

5.5 *Secondary lining design*

A secondary lining is provided to support the proposed sheet waterproof membrane, and also to provide fire resistance to the tunnel. The secondary lining is constructed from plain concrete, with all tensile loads in the lining resisted by the tensile capacity of the concrete. The main concern is to minimize the heat of hydration and shrinkage, and this is achieved with a 35% Pulverized Fly Ash (PFA) cement replacement mix design with low shrinkage. Fire resistance is achieved by adding 1–2 kg/m^3 of polypropylene fibers to the concrete mix in order to prevent explosive spalling. The precise dosage of fibers will be confirmed by fire testing.

6 COMPARISON BETWEEN SCL AND TBM TUNNEL OPTIONS

6.1 *Chemical Hazard Alert Notices (CHAN's)*

Towards the end of the preliminary design period, the UK Health and Safety Executive (HSE) issued three Chemical Hazard Alert Notices (CHAN's) relating to a reduction in the allowable exposure levels of Respirable Crystalline Silica (RCS) and NO_x during construction. The recommended changes to exposure levels are shown in the following Table 2.

All project development up to that stage has been based on excavation of the tunnel with diesel equipment. It was not possible to achieve these proposed limits with the diesel based construction methodology. The lower CHAN limits produced conflicting

Table 2. Details of Chan's

CHAN	Particulate	1989 COSHH regulations	Proposed limit (ppm)
28	NO	25 ppm	1 ppm
29	NO_2	3 ppm	1 ppm
35	RCS	0.3 mg/m^3	0.1 mg/m^3

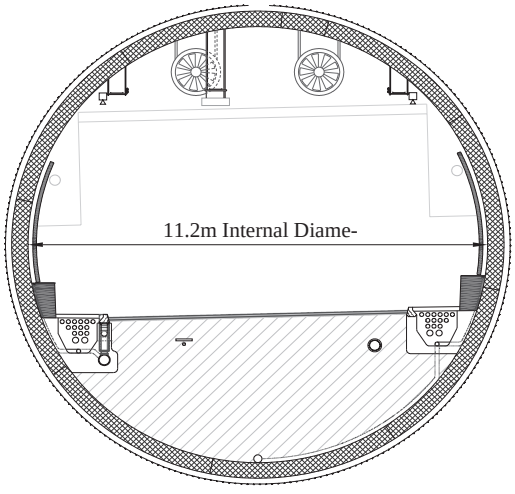

Figure 8. TBM tunnel cross section.

demands, as the lower NO_x limits require increased ventilation, but increased ventilation produces more dust causing problems with respirable silica.

This resulted in the consideration of an alternative method of construction, and a preliminary design prepared for a tunnel constructed using an Earth Pressure Balance (EPB) Tunnel Boring Machine (TBM).

6.2 *Comparison of SCL and TBM options*

The TBM tunnel cross section is shown in Figure 8 below. One of the benefits of utilizing a TBM was that it was no longer necessary for the vertical alignment to follow the optimal material for ground support. This meant that the tunnel could fall from south to north, allowing the deletion of the low-point sump. Another advantage of TBM construction was that a single-pass lining could be utilized. A fully gasketed segmental lining fire hardened with polypropylene fibers was proposed.

The main disadvantages with the TBM options were the openings required at cross passage junctions and for Emergency Points. The junctions are significantly more expensive for a TBM tunnel, and where the benefit cost ratio (BCR) for the Emergency Points was greater than 1 for the SCL tunnel, the cost of the opening for a TBM tunnel resulted in BCR < 1, however once a safety measure is proposed to the Emergency Services it is very difficult to withdraw it at a later date.

6.3 *Program*

There was a small benefit to the program for the TBM option however this was minimal due to the fact that the SCL tunnel is proposed to be excavated concurrently from 4 faces, whereas the TBM had to excavate 1 bore, and then be turned for excavation of the second bore. The total bore length of 3.6 km was insufficient to give the TBM option a significant program advantage. A tunnel of 2.5 km length would have been required to see a significant program advantage for the TBM.

Another disadvantage with the TBM option was the long lead time for the procurement of a 12.0 m diameter machine.

6.4 *Risk assessment*

A rigorous risk management procedure has been used through the project, and allowances for commercial risks are included in the project target cost. The assessed commercial risk for the SCL tunnel was significantly higher than for the TBM due to the larger potential impact from adverse ground conditions and the uncertainty of achieving the new exposure levels.

6.5 *Outcome*

An interim guidance note "Occupational Exposure to Nitrogen Monoxide in a Tunnel Environment" based on the ALARP principals applied to NO exposure limits has been prepared by the BTS (2006), was used to develop a modified SCL construction methodology such that NO limits of 3–5 ppm and the revised CHAN limits for NO_2 and RCS could be achieved. Additional measures include increased ventilation, more electric plant including an additional face conveyor and diesel plant conforming to the Stage III emissions standards in the Non-road Diesel Engines Directive. The modified SCL solution was still more economic than the TBM alternative.

7 CONCLUSIONS

The development of the planning and design of the A3 Hindhead project has been outlined in this paper. The main conclusions are:

- Projects through environmentally sensitive areas need to provide special mitigation measures in order to achieve planning consent.
- Tunnel details have been developed to avoid non-routine maintenance closures through the life of the tunnel.

- The design of the tunnel support includes a permanent primary lining possible due to:
  - Availability of non-alkaline accelerators
  - Use of 3-D laser scanning survey technology for control of robotic spraying equipment to achieve tight shape tolerances avoiding the need to use lattice girders
  - Use of self-drilling GRP spiles in areas of poor ground.
- Alternative designs have been prepared for an SCL tunnel and a TBM tunnel with the following conclusions:
  - Below a length of 2.5 km the TBM option had no program advantages
  - The TBM option had a lower assessed commercial risk due to the insensitivity to adverse ground conditions; however this was insufficient to overcome the increase in cost.
  - A modified SCL methodology that using ALARP principles for airborne pollutants in accordance with the BTS best practice document was developed.

Geotechnical investigations and construction conditions for the tunnel "Strazevica" on E-75 motorway near Belgrade

B. Jelisavac, S. Jotic, S. Savic, V. Vujanic, M. Roljic, M. Jotic & S. Milenkovic
The Highway Institute, Serbia

ABSTRACT: Geotechnical investigations and design of double – tube tunnel through the mount Strazevica, under the suburban settlement Resnik near Belgrade on E-75 motorway, lasted from 1987 till 1992. The length of the left tube is 745 m and 686 m for the left one. Day profile opening is 90 sq.m whereas the distance between respective tubes is 25 m. The width of driving carriageways is 11.5 m each. Maximum height of the surcharge is 35 m. The works for the right tunnel tube at the exit portal started in 1992 when 186 m of the tunnel were completed. After a long interruption, the works have been resumed in 2004 and till nowadays 500 m have been completed. In view of the fact that the tunnel is located within the urban zone, specific requirements and techniques for the portal construction along unstable slopes have been elaborated. The excavation was carried out in the terrain of complex geologic structure and hydrogeological properties. There are alternating replacements of sandy clays, clayey debris, marls and sandy limestone. New Austrian Tunnel Construction Method has been implemented.

1 INTRODUCTION

Double-tube tunnel "Strazevica" of length 745 m, i.e. 686 m is under construction along future E-75 motorway bypassing Belgrade on Pan-European Corridor X and this facility is passing under the suburban settlement Resnik. The tunnel is located in the curve with radius R-1000. Tube width without bracing is 15 m, height amounts to 8 m, in other words the surface is 90 sq.m. Maximum height of the surcharge under the central part of suburban settlement is 40 m, and on portals 5–15 m. The excavation began in 1992 when 186 m were completed. After a long interval due to the U.N. sanctions imposed to Serbia, the works have been resumed in 2004 and till nowadays some 500 m, within the right tube, have been completed. (Fig. 1)

2 INVESTIGATIONS AND RESULTS

Geotechnical investigations were made in two different times, namely for Preliminary and Main civil-engineering design. Following works were undertaken: detailed geologic mapping of terrain, testing by refraction seismic method, exploratory drilling survey, installation and monitoring of piezometers, laboratory testing of soil samples and ground water.

By synthesizing gathered data, we have been able to form longitudinal and cross-section geotechnical profiles of terrain, whereof quasi-homogeneous zones and geotechnical models with parameters of physical–mechanical properties have been set aside along with the forecast of tunnel construction conditions.

Tunnel is passing directly through "Strazevica" mount and linking the valleys of Topciderska river and Rakovica stream.

Wider area is made of three geochronological units: on terrain base there are sedimentary rocks of Cretaceous flysch ($K_{1,2}F$), over which there are deposits of Miocene reef limestone set transgressively with layers of conglomerates (M_3K, Kg) or even marls (M_3Kl). On terrain surface there is rock waste of diluvial and diluvial-proluvial origin (d, d-pr), (Fig. 1).

Pre-Quaternary rock masses have tectonic properties and are divided by numerous fractures and faults into blocks of differing dimensions, thus making the forecast of tunnel construction conditions even more complex.

The assessment of physical–mechanical parameters of rock masses, necessary for dimensioning of structures, was made on the basis of analysis and synthesis of the results pertaining to: laboratory testing of rock samples, level of degradation, homogeneity, anisotropy, structural – texture properties, measurement of propagation speed of seismic elastic waves, and current empirical correlations between physical–mechanical properties and ratings of rock masses (Q, RMR), etc.

Forecast values of parameters of physical–mechanical properties of rock masses for quasi-homogeneous zones (geotechnical milieus), have been

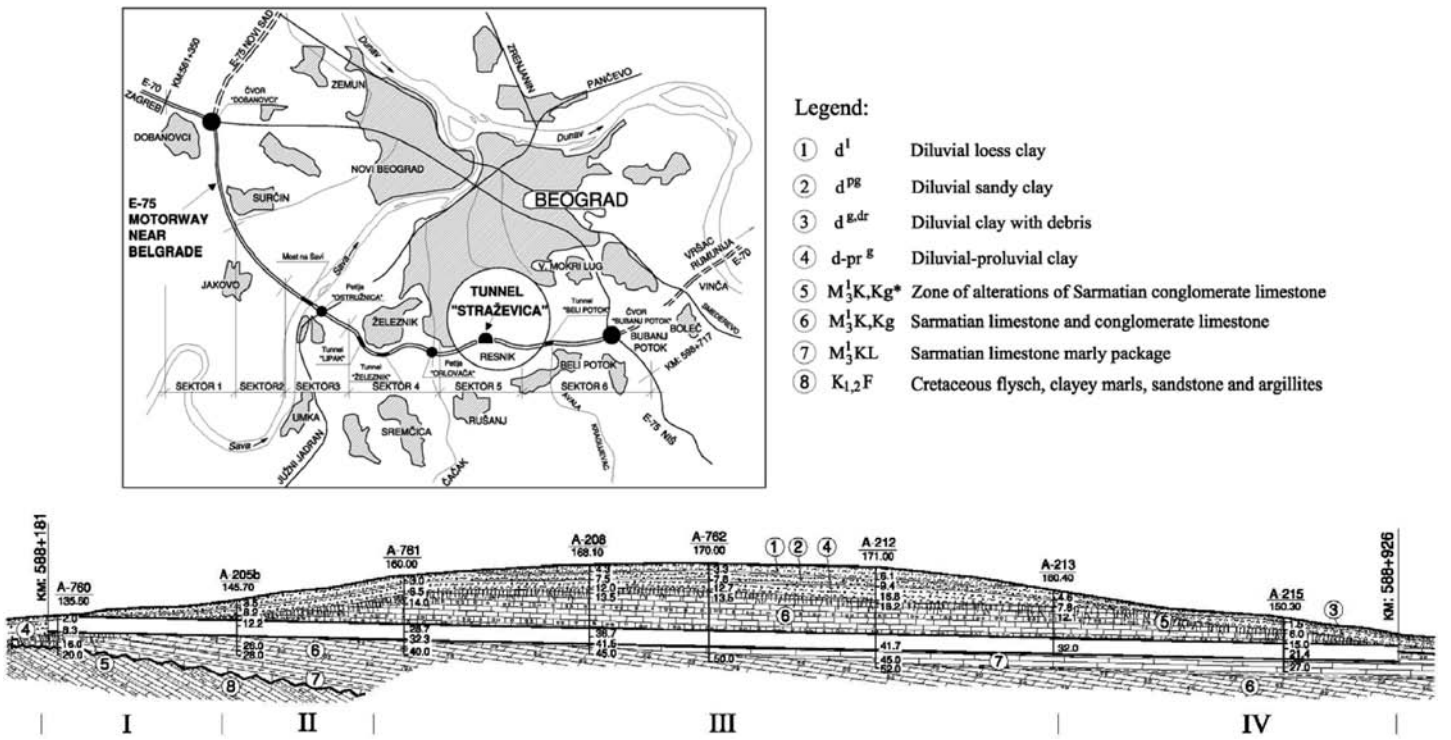

Figure 1. Engineering-geologic cross-section of terrain along the “Strazevica” tunnel route.

singled out along the profile of tunnel according to table 1 and geotechnical models (Figures 2, 3, 4 & 5).

Ground water as permanent aquifer has not been ascertained through investigation works, yet with the exception of entry portal, within the framework of surface alterations of limestone conglomerate deposits (M_3K,Kg^*), where ground water is gravitating towards the river Topciderska. There are some potentials of local and seasonal seepage of ground water on the contact of Quaternary and Tertiary deposits, as well as on the interface of marl interlayers with limestone layers within the limestone and marly deposits.

Table 1. Ruling physical–mechanical properties.

Milieu	γ (kN/m^3)	φ (o)	c (kPa)	Ms (MPa)	D (MPa)	μ
d^{pg},d-pr^g	19	20	25	7	–	–
$M_3{}^1K,Kg^*$	20	25	15	10	–	–
$M_3{}^1K,Kg$	22.5	40	100	–	2500	0.25
$M_3{}^1KL$	20	25	50	–	300	0.3

In view of continuous spreading out of Quaternary clayey deposits on terrain surface (elevated hydrogeologic insulator), there are considerably less possibilities of surface water infiltration into deeper terrain parts, yet no one is asking questions regarding essential collector function of limestone in the bedrock. Therefore, depending on seasonal conditions, there are potentials of diffuse aquifer occurrence within the deposits of limestone and conglomerates. Surface and ground water prevailingly gravitate towards the respective valleys of Topciderska river and Rakovica stream.

3 ANALYSIS OF GEOTECHNICAL CONDITIONS FOR THE TUNNEL CONSTRUCTION

Geotechnical zoning of rock masses along future tunnel excavation has been carried out in regard of complex geologic composition of terrain, with the purpose to define the tunnel construction conditions. Four quasi-homogeneous zones of similar properties, relevant in establishing the conditions of tunnel

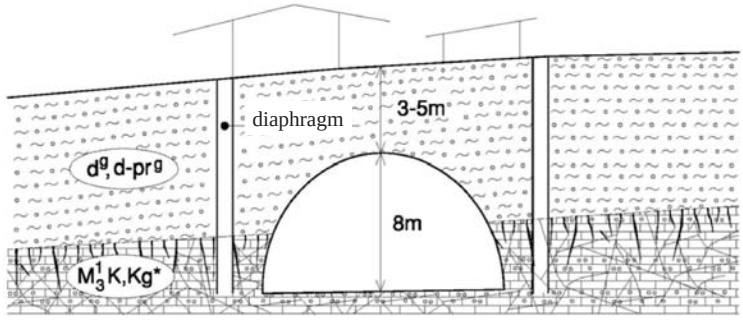

Figure 2. Geotechnical model of quasi-homogeneous zone I.

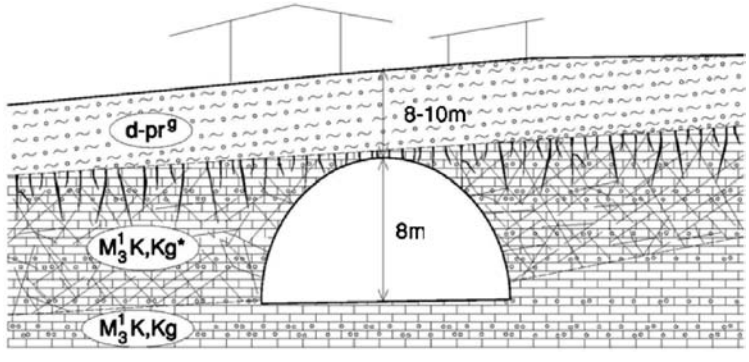

Figure 3. Geotechnical model of quasi-homogeneous zone II.

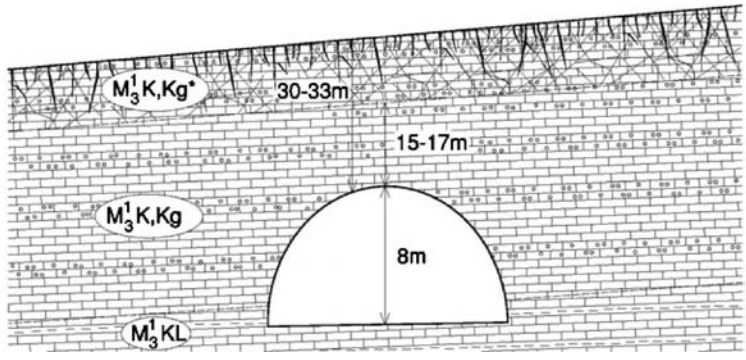

Figure 4. Geotechnical model of quasi-homogeneous zone III.

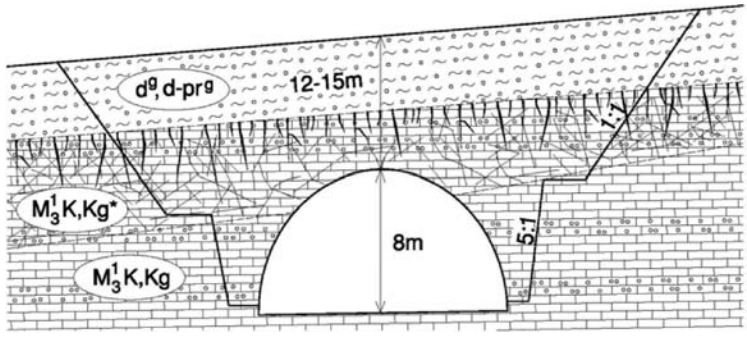

Figure 5. Geotechnical model of quasi-homogeneous zone IV.

construction, have been singled out. Zoning criteria have been as follows:

- lithologic composition in the excavation zone and interactions,
- surcharge thickness,
- structural, physical–mechanical and technological properties of rock masses,
- presence of ground water.

By taking into account the criteria thereof, the zones have been singled out within whose frame-work it has been made possible to implement uniform excavation technology and provide for tunnel profile stability.

3.1 *Quasi-homogeneous zone I/km 588 + 181 – 588 + 263*

Basic characteristics of this quasi-homogeneous zone are as follows: unfavorable physical–mechanical properties of rock masses within the excavation zone, unfavorable orientation of interfaces amongst lithologic members, small height of surcharge (3–5 m), high population density on the terrain above tunnel tube, etc. In the excavation vault there are occurrences of silty–clayey Quaternary deposits (d^g,d-pr^g), settled over degraded limestone (M_3K,Kg*). Interface of Quaternary and Miocene sediments, at the gradient of 30 degrees, is directed towards the entry portal, i.e. front of excavation. On this particular excavation stretch, in addition to unfavorable conditions, excavation categories III and IV, one cannot avoid the problem of deformations on terrain surface. Namely, a calmed down landslide has been recorded in the zone of portal.

A proposal has been made of resorting to open cut excavation in view of indicated properties of the zone thereof, with compulsory immediate protection of both excavation slopes and housing facilities located on the terrain surface. Stability of housing facilities must be provided prior to the commencement of works, for example, with diaphragms, by sinking of Larssen piles or with some other procedure.

3.2 *Quasi-homogeneous zone II/km 588 + 263 – 588 + 315*

In view of surcharge height and surface properties, geotechnical conditions for the tunnel construction in this specific zone are somewhat more favorable. It is prevailingly composed of rock masses ensuing from

the weathering of limestone being either clastic or even marly (M_3K,Kg* and M_3Kl*). There are potentials of local occurrence of alternating series of limestone and interlayers of marls. The appearance of ground water is possible in entire excavation zone. Average surcharge thickness amounts to 10 m, whereas the substratum above tunnel tube is densely populated.

Excavation conditions in this zone are very difficult and unfavorable, with excavation categories III and locally IV, so that it is required to build the profile with the provision of immediate stability of both excavation operations and facilities located on the terrain surface. In the course of excavation there are potentials that excess profile might occur on entire bulk of excavation.

3.3 *Quasi-homogeneous zone III/km 588 + 315 – 588 + 760*

This quasi-homogeneous zone is 450 m long and is typified by uniform lithologic composition with rather high surcharge (30–35 m). It is made of limestone with conglomerates and marls (M_3K,Kg and M_3Kl). They feature sub-horizontal interface and fall into excavation category V. Limestone materials appear prevailingly in the vault and flank, while marl and marly clays (excavation category III) are present in the underlying stratum of excavation.

Construction conditions assessments pertaining to procedure of excavation and bracing, temporary and permanent stability of excavation, subterranean pressures etc. have been made in accordance with: Bieniawsky (RMR), Barton et al. (Q), Louis and National civil-engineering norms GN-200. Classification results as per first two procedures have been presented on Tables 2 & 3.

This quasi-homogeneous zone can be typified as a suitable milieu as regards the stability of excavation, yet for the provision of permanent stability, it is required to provide a certain volume of bracing with the application of systematic anchors and sprayed concrete (gunite) with wire mesh. The appearance of interlayers of marl and marly clay in the flooring, on the foundation spot for abutments, is unfavorable. Therefore, in the process of founding the ground abutments, it is required to foresee eventual substitution of materials or deepening of foundation spot level, down to the first limestone layer. Interlayer thickness of marls is in the range from several cm to 3 m. One should not expect relevant occurrences of ground water, except for some minor wetting and seepage, at the interface of limestone and marl.

3.4 *Quasi I-homogeneous zone IV/km 588 + 760 – 588 + 926*

Rather thick surface weathering crust up to 18 m which is made of limestone and limestone – marly package has been ascertained on this tunnel section. Quaternary clayey deposits are thick up to 4 m. Surcharge height from 5 to 20 m, as well as absence of facilities on terrain surface, provide for open cut excavation with subsequent backfilling. Temporary slopes of cuts, of gradient 1:1, in clayey deposits and in zone of limestone surface alteration, are feasible with compulsory protection by wire mesh and gunite. It is possible to pursue to the excavation through younger lots of limestone under gradient 5:1 with the berm interfacing with the zone of limestone alteration, with minimum width of 3 m. Temporary slopes are considered as such provided that they shall not last longer than one building season.

4 INSTEAD OF CONCLUSION

Geotechnical conditions forecast as regards the construction of "Strazevica" tunnel, as presented in this paper, could have been either confirmed or not in the course of construction carried out so far. Authors of the project thereof are satisfied with the achievements attained in the previous activities of

building the prevailing tunnel's stretch 500 m long, in quasi-homogeneous zones III & IV, since the geotechnical supervision confirmed almost completely the forecast as regards the construction conditions.

Taking into account that these geotechnical conditions may refer also for some other areas, the investigation results during design and construction of tunnel "Strazevica", allow adequate professional generalization and geotechnical conditions forecast of building subterranean facilities in similar geologic milieus.

The construction of tunnel "Lipak" within the framework of E-75 motorway on Belgrade city bypass stretch

S.Jotic, S.Savic, M.Jotic & V.Vujanic
The Highway Institute, Serbia

ABSTRACT: The tunnel "Lipak" is located on the fourth sector of Belgrade city by-pass. The right tube of the tunnel thereof is 665 m long, whereas its left tube is 660 m long. Structure of the tunnel is a double – frame construction with common party wall. It has separate carriageways with three driving lanes for every single driving direction. The lane width for one single driving direction is 11.50 m. The construction of tunnel was carried out in open cut excavation including also the part under the railroad line which was out of service due to the bridge tearing down during the bombing in 1999. The excavation was carried out through differing geologic milieus: in the peak parts there were silty – clayey rock masses, whereas in the deeper parts there were both thick – bedded, and thinly stratified rock masses of differing hardness (sandstone, clayey marls, argillites), and levels of damage (separated by fractures and folded). The greatest problems encountered referred to the provision of stability of temporary operating slopes, protection from ground water, excavation for foundation and backfilling of excavation over which the railroad line was set again.

1 INTRODUCTION

The tunnel "Lipak" is under construction within the framework of E-75 motorway on section Dobanovci – Bubanj Potok (Belgrade by-pass). It is located on the fourth sector, wherein the motorway alignment is in the transition from Sava river alluvion zone (Makis colony) into the rolling backing of Sumadija region, passing under triple track railroad for goods traffic. The right tube of the tunnel is 665 m long, whereas its left tube is 660 m long, thus the tunnel is staggered due to topographic feature of terrain.

Preparation of the design documentation for this facility began in 1987 and was completed in 1991. Framework of civil engineering design was composed by adequate geotechnical data base. From a series of variants taken into consideration, one variant was adopted which was affiliated with a problem of passing through two tunnel tubes directly under the railroad tracks on railroad station plateau, with a condition not to disrupt the railroad traffic. Due to exiguous thickness of surcharge it was anticipated to build the tunnel as open cut excavation except for the passage under the railroad tracks. Execution technique on this specific part included implicitly the operations under traffic and driving of three pilot shafts according to New Austrian Method (NATAM). They provide for the construction of tunnel abutments from the foundation up to the vault's beginning, as presented on Fig 2.

Operation with pilot shafts was made very difficult, primarily due to the fact that they are partly located within the railroad embankment with rather thin surcharge and with abundant inflow of ground water.

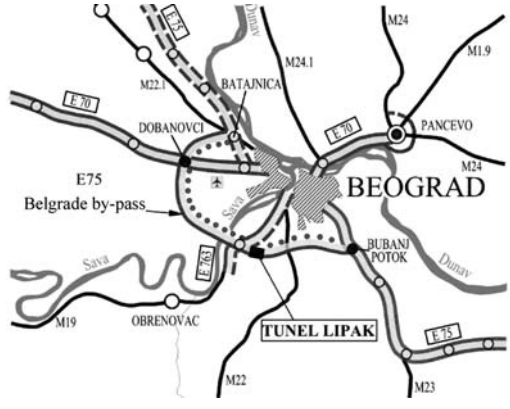

Figure 1. Belgrade city by-pass with the location of tunnel "Lipak".

The works on the construction of "Lipak" tunnel were carried out in the period 1991–1993, when they were interrupted due to the U.N. sanctions imposed to our country. In the latter period a number of activities have been undertaken on the approach cutting of exit portal towards Zeleznik colony and on entry approach cutting, i.e. on portal in the immediate zone of railroad station. Pilot shafts of midrange and left wall of tunnel tube were built on a short stretch within the scope of

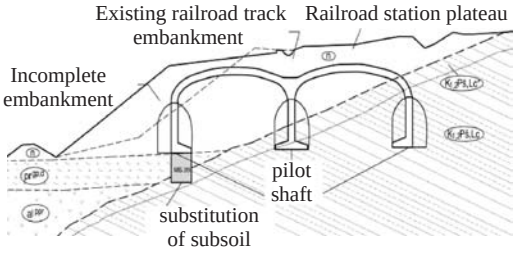

Figure 2. Pilot shafts on the stretch foreseen for tunneling.

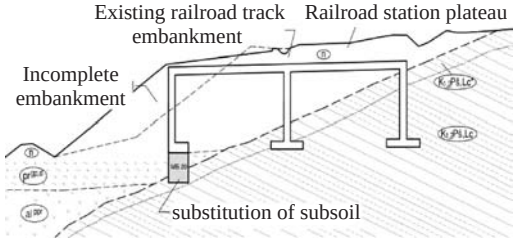

Figure 3. Tunnel's final solution.

these works. The substitution of silty – sandy (marshy) highly compressible alluvial deposit was carried out in the pilot shafts, under the foundations, down to the rock bed with good bearing capacity. This operation was carried out with the concrete grade MB 20.

Railroad bridge across the river Sava was demolished in 1999 during the aerial bombardment. Railroad line was put out of service for quite some time, thus providing the prerequisites to build the tunnel with an open cut excavation.

Arched tunnel profile was substituted by box-type construction through the rationalization process of the design itself as per Fig. 3. Final solution for building tunnel thereof is in fact referring to double-frame construction with common party wall with separate carriageways for respective driving directions. Pavement width for one driving direction is 11.5 m (three lanes for a single driving direction).

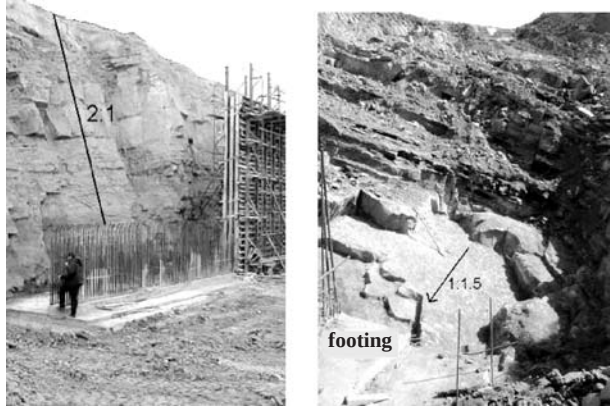
The subject matter of this paper is referring to geotechnical problem area of performing the open cut excavation and construction techniques for tunnel tubes.

2 BRIEF REVIEW OF TERRAIN'S GEOLOGIC STRUCTURE AND GEOTECHNICAL PROBLEM AREA

Geologic structure of terrain under study is made of flysch-like sediments of Cretaceous age represented by sandstones, marls and subordinately by argillites. Indicated rock masses are found in the tunnel zone at uneven depths, with outcrops on terrain surface down to the depth of 13 m. Their distinctive features are referring to layered and somewhat thick-bedded texture, yet the series in askance monocline is set towards SW under the angle of 20–25 degrees, which is suitable for major cutting (right side of open cut excavation). Cretaceous flysch-like products are divided by fractures and fissures into monoliths of cm-dm dimensions, physically and chemically altered and partly folded. They are covered by older Quaternary alluvial–lacustrine sediments of heterogeneous clayey, clayey–sandy and sandy–gravel composition. Surface terrain parts are made of the youngest Quaternary deposits, prevailingly of sandy–silty–clayey composition. From geotechnical point of view, these deposits present unfavorable resistance–deformation properties and as such are prone to landslides and erosion, particularly in the event of inadequate side-cutting.

From hydro-geologic aspect they also feature considerable heterogeneity. In this connection main problems are expected to occur at the appearance of free ground water within the framework of sandy-gravel deposits or seepage water through fractures in flysch-like sediments.

Complex geologic structure requires various geotechnical measures to be undertaken. This is referring primarily in providing the stability of temporary slopes of open cut excavation.



The appearance of several calmed down landslides with average depths of approximately 3.5–5.5 m has been recorded in the tunnel zone. There was a potential of activating the sliding process by every single side-cutting, thus requiring the necessity of undertaking a whole variety of repair measures in the tunnel zone.

The performance of works required the dismantling of existing railroad tracks, stripping of railroad embankment and excavation in phases up to the designed spot level. The design generally anticipated three phases, yet the same had to be broken down right on the spot into a series of sub-phases in accordance with geologic conditions and lythologic composition of terrain.

Part of the tunnel in railroad track zone is the most favorable for slope stability, since the hard rock base is present from the surface or is located at the minor depth. That part of widespread excavation served as *"trial section"* for remaining part of open cut excavation, which from stability considerations was far more risky, either due to the depth, or due to terrain structure. However, with the construction in phases and permanent professional monitoring of works, whereby prescribed sequence and schedule terms had to be strictly held on to, which provided for successful implementation of open cut excavation along the entire tunnel without structural protection. Labile parts of terrain were brought under control by resorting to the

Figure 4. Open cut excavation.

(a) right side of excavation; (b) left side of excavation;

Figure 5. Open cut excavation in hard rock mass.

experience attained in the previous tunnel liner for the subsequent one.

Open cut excavation was carried out within the scope of following conditions:

- excavation was carried out in the slope gradient 1:2 starting from terrain surface, through diluvial and diluvial-proluvial silty-sandy clay and alluvial lacustrine sands and sandy clays down to the contact with hard rock mass – Fig. 4.
- then the berm was built 2–3 m wide with the cross-fall of 4% towards the hill and with control grade meant for drainage of surface water catchment from slopes onto the berm – Fig. 4.

Through hard rock masses, i.e. sandstones, marls and argillites with the slope gradient 2(3):1 at the full excavation height, starting from the foundation engineering spot level. The right side of excavation was carried out with success due to the drop of layered structure (into the hill), whereas the left side, although at lesser depth, had to be carried out along with some alterations of originally designed slope gradient. Namely, the slope gradient 2(3):1 on the left side due to drop of layered structure (towards the excavation – Fig. 6) could not have been maintained under the conditions of required stability. Motions of blocks of major proportions were carried out along the surfaces of layered structure at the slope gradients 1:1.5 to 1:2. The only repair measures to be undertaken referred to permanent follow-up of excavation slope gradient with the progress at restricted scale and subsequent closure.

In the alluvial plain of Sava river there is a presence of ground water as permanently compacted aquifer. Its level is reaching almost the terrain surface. In the rolling zone of terrain there were frequent occurrence of ground water along the fractures as moisture, rather weak leakage or effluent seepage in a form of short-term springs of variable discharge linked with hydrological conditions.

Deadline schedule of operations was strictly complied with in regard to the excavation geometry thereof. The excavation was carried out in tunnel liners

Figure 6. Open cut excavation ring.

50 m long out of which 20 m referred to full profile, and 30 m in preparatory phase at higher spot levels – Fig. 6.

Every progression shift of excavation in an almost full profile meant also the building of tunnel construction in full profile with the closure of wide excavation in complete height of walls in the zone of both tunnel tubes.

Members of design and geotechnical supervision staff monitored the excavation on daily basis (harmonization with the Design of foundation pit protection and Design of tunnel construction).

3 REVIEW OF TUNNEL CONSTRUCTION AND PERFORMANCE OF WORKS

Tunnel construction has been carried out completely in a wide excavation, and later backfilled up to the designed spot level. The height of backfilling of the construction thereof is variable and is ranging from 1.80 m in the intersection zone with the railroad to 5.0 m in the deepest cut zone.

Operations regarding the tunnel construction have been carried out in semi-prefabricated manner, in view of the fact that some parts of the tunnel have been made by standard procedure (excavation, footing concrete works and walls), and then prefabricated reinforced concrete sheeting rails have been exposed to the process of obtaining monolithic properties. Aforementioned processed sheeting rails have been finally set upon hardened walls into proper designed position.

Performance of works has been carried out in phases as follows:

- Phase I – Concrete works – footing
  Reinforcement of the footing ceded for the length of anchorage (splicing for overlap), in order to link with the wall's reinforcement. Footing was made of impervious concrete MB 35, WDP6. Taking into account the terrain's structure, respective footings of the left and intermediate wall, within the zone of soft and highly compressible river load, have been driven into the incompressible rock bed (sandstones, marls) with the substitution made of "lean concrete", Thereby the prerequisite has been fulfilled that footings must be founded on incompressible rock bed.
- Phase 2 – Concrete works – walls
  Link of adjacent walls has been carried out according to the system "Tongue & Groove". Reinforcement has been drawn out and set aside in order to be processed to attain monolithic features for sheeting rails and walls. Concrete grade for walls – MB 30.
- Phase 3 – Setting of sheeting rails
  Setting of sheeting rails into the designed position is carried out after the attainment of 75% of hardness as specified by the design. Sheeting rails are prefabricated elements and they have to pass all required quality controls within their manufacturing facility, and only afterwards they are transported to the tunnel building site. Sheeting rails are delivered to the building site with drawn out bars meant to obtain monolithic features with walls. Quality of sheeting rails has reference to MB35, R.A.400–500.

  Sheeting rail has "T" shaped cross-section and is 160 cm high, with stem thickness of 18 cm. Upper flange width amounts to 90 cm, while lower flange has dimensions 35×26–36 cm, as presented on Fig. 10.

  Some five different types of sheeting rails have been installed in the tunnel thereof with various

a)

Figure 9. Setting of sheeting rails

Figure 10. P.C.C. – Prefabrication of sheeting rails.

Figure 11. External drainage.

quantities of reinforcement thus to take into account the static impacts (train impact, height of potential backfilling, seismic impacts).

- Phase 4 – Monolithic properties of sheeting rails
  Monolithic properties of sheeting rails and walls both in longitudinal and transverse sense are obtained through reinforced concrete slab 10 cm thick. The latter also serves for laying of waterproofing elements.
- Phase 5 – Setting of external drainage pipes
  Pipes are made of PVC and perforated on upper side. Pipe diameter amounts to ϕ 250 and these pipes are laid in the MB20 lean concrete bed, 10–15 cm thick. Layer of coarse – grained gravel 1.2 m high is set above the pipes. This material with such particle-size distribution fills out the entire space from the wall's edge to the dug – out slope, while from outer side it is covered with geotextile. These pipes have chambers on every 25 m and from chambers thereof the water is overflown transversely into the collector which was designed to be on the interior tunnel's side, along with pavement's edge. Collector has also inspection chambers on every 25 m. Polyethylene pipe of high density HDPE ϕ 300 is set between

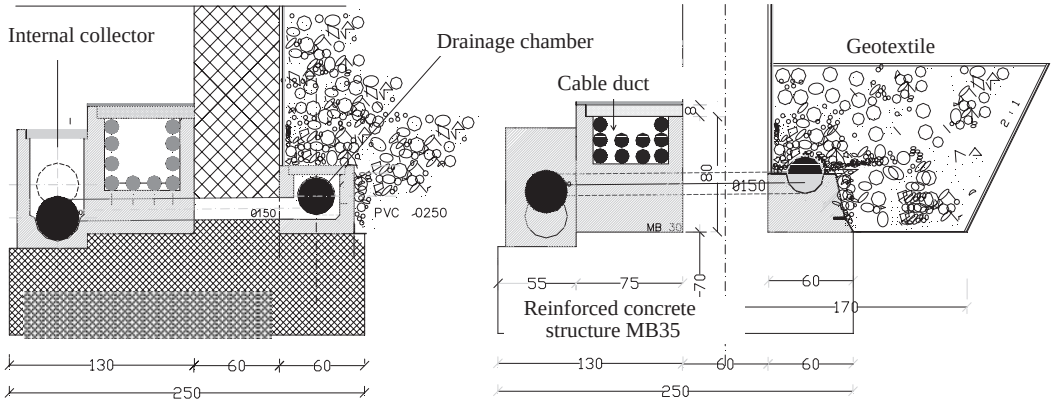

Figure 12. Canal details

inspection chambers, while the space around the pipe is filled with concrete MB300 and reinforced with wire-mesh reinforcement M.A.500–560.

- Phase 6 – Performance of waterproofing works Waterproofing foil was continually stuck to monolithic slab of sheeting rails. Waterproofing was carried out by polymer – bitumen tape hardened with non-woven fabric knitted with polyester fibers. Tape thickness amounts to 4 mm, denominated "Testudo 3" manufactured in Italy by the firm "Index". This tape has EU authoritative certificates of its quality, which was reconfirmed in Serbia by competent authorities (I.M.S., The Highway Institute, Department for building materials).
- Phase 7 – Protection of waterproofing foil Reinforced concrete slab 8 cm thick is cast horizontally over waterproofing. The latter is protected on the horizontal surface from sharp edges of backfilled material with bricking, and partly with proteflon foil.
- Phase 8 – Tunnel construction backfilling This was carried out symmetrically and on both sides up to the design spot level.
- Phase 9 – Performance of works on internal ducts for electrical and mechanical installations
  The tunnel "Lipak" was built by contractor "Planum" from Belgrade, while waterproofing works were carried out by the firm "Hidroizolacija", Belgrade as subcontractor. Prefabrication of sheeting rails was performed by the contractor "Ratko Mitrovic", Belgrade.

4 CONCLUSION

The works as regards "Lipak" tunnel facility was carried out successfully although in a series of several phases.

During the works it turned out that engineering-geologic and geotechnical investigations in all design phases provided sufficient and relevant data with high level of reliability in forecasting, which was confirmed in the operation of open cut excavation.

Thanks to full collaboration amongst the contractors, supervising agents and designers, wherein agreed deadline schedule and sequence of works were strictly held on to, thus providing great savings since the deep open cut excavation over 30 m was carried out without structural measures of protection which were considered as an alternative within the scope of design stage.

Despite all difficulties encountered in the performance of works, the tunnel was built with implementation of the most advanced techniques and materials utilized for protection.

One has to emphasize the operations carried out within the operating activities of two groups which are very sensitive (with unforeseeable negative consequences in case of error), which are specific for this methodology as follows:

– group of activities pertaining to the obtainment of monolithic features of sheeting walls and walls;
– group of activities as regards the protection of waterproofing in the backfilling process of tunnel construction.

Settlement control during the construction of urban tunnels by NATM construction of Kitayama Tunnel on national highway 455

Toshihiko Komatsu, Hideyuki Kitamura, Ken Matsubara & Takaomi Sakurai
Maeda/Hazama/Nashi/Kitayama tunnel construction joint venture

ABSTRACT: The Kitayama Tunnel is constructed by the New Austrian Tunneling Method (NATM) through urban hills. The earth cover is thin throughout the tunnel alignment. It is necessary to control surface settlements according to the type of land use above the tunnel. The tunnel is stabilized by reinforcing the excavation face, tunnel crown and the foot of top heading, and giving priority to early closing of the ring. Ground stabilization ahead of the excavation face and the early reinforcement at the foot of top heading in particular were found to help control surface settlements.

1 INTRODUCTION

NATM, a way of excavating tunnels, has increasingly been applied in urban districts as well as in mountainous areas because it is an effective and economical tunneling method. Numerous issues, however, remain unsolved such as controlling surface settlements when adopting the method in urban areas.

In the Kitayama Tunnel, sections with an earth cover of less than the tunnel diameter occupy 50% of tunnel length. The tunnel penetrates hills with thin earth cover (refer to the earth cover shown in Figure 1 Longitudinal profile of the tunnel.)

The land over the tunnel is used for various purposes from houses to roads, fields and forests. Effective control of surface settlements and adverse effects of tunneling on structures is required. Geology at the site mainly consists of melange mainly composed of mudstones and melange composed of greenstones. Difficulty in geological prediction in melange and outstanding loosening of rock mass due to stress release during excavation make the control of surface settlements and adverse effects on structures even more difficult.

2 PROJECT OUTLINE

The Kitayama Tunnel is located in the north of the central part of Morioka with a population of 300,000 in Iwate Prefecture. It is an urban bypass planned to alleviate chronic congestion caused by commuter traffic from bedroom suburbs of Morioka. The tunnel has a length of approximately 1 km and be composed of two tunnels carrying bidirectional traffic. The tunnels are mechanically excavated and the muck is removed in dump trucks. The upbound and downbound tunnels have cross sections of 100 m^2 and 80 m^2, respectively.

Excavation was started in August 2004. The downbound tunnel was excavated throughout in July 2006. The excavation of the upbound tunnel will be over in December 2006 and the lining will be completed in July 2007.

3 GEOLOGICAL CONDITIONS AT THE SITE

The geology at the tunneling site belongs to one of the oldest zones composed of accretionary prisms on the islands of Japan, and mainly consists of melange mainly composed of mudstones and melange composed of greenstones. The majority of the rock mass at the site has been highly fractured and weathered into sand.

Melange is likely to suffer loosening along cleavage planes owing to stress release during tunnel excavation, and cause large-scale deformation. In preliminary surveys, seismic velocity is frequently measured to be relatively high because earth pressure acts. Rocks are distributed without forming layers, so geologic structure is difficult to grasp and the condition during tunnel excavation can hardly been identified. No serious deformations may occur during tunnel excavation in melange. Remedial measures are therefore sometimes taken only belatedly while economic construction

is given priority. As a result, deformation may be aggravated.

4 CHARACTERISTICS AND PROBLEMS OF CONSTRUCTION WORK

The tunnel is constructed in highly weathered rock mass with a thin earth cover with structures on the ground surface. Cut-and-cover construction is considered most reliable in view of the site conditions. The method, however, cannot be selected because the site is in a scenic area and because of the mode of land use. Excavation using shields is impracticable because of the existence of semi-hard rocks in tunnel cross section. That leaves NATM. The method, however, has the following problems.

(i) Tunnel excavation increases loosening, so no working face is freestanding.
(ii) The soil lacks sufficient bearing capacity at the foot of top heading to temporarily support the tunnel.
(iii) With a thin earth cover, excavation has direct impact on the ground surface.
(iv) Construction should be carried out without adversely affecting land use above the tunnel.

5 REQUIREMENTS FOR CONSTRUCTION

Requirements for tunnel construction in the project are listed below in descending order of priority.

(i) Safe construction work
  – The ground should be stabilized before the start of tunneling to create homogeneous conditions.
(ii) Consideration of effects and the environment
  – Adverse effects on the users of land, roads and water supply systems should be eliminated.
(iii) Economical construction
  – Rational remedial measures should be taken.

6 CONSTRUCTION

Reinforcement from the surface is generally effective during the construction of a tunnel with thin earth cover. In a 40-m section with an extremely thin earth cover of 2.5 m at a point 230 m from the portal, the tunnel was excavated after the ground was stabilized by applying mechanically agitated cement from the surface around the sidewalk (zone A in Figure 1).

In other sections, reinforcement was installed at the working face because the land above the tunnel was used for specific purposes and because no remedial measures could be taken from the surface.

6.1 *Division of cross section and increment of bench advance*

In tunnel construction in weak soils, division of the cross section and the increment of bench advance are important factors. In urban areas, attempts have been made to avoid danger by dividing tunnel cross section into numerous segments.

There were, however, concerns about high cost relative to the effectiveness for controlling adverse effects of excavation. At present, automation and mechanization of construction and use of general-purpose equipment are considered important. Heading and bench is therefore the most common approach, which has also been adopted in this project. The method requires appropriate reinforcement.

6.2 *Construction*

The increment of bench advance was set at 30 to 40 m for simultaneous construction of top heading and bench. Face collapsed frequently at the face of the heading. Settlement occurred 40 m from the portal with sectional cracks in shotcrete at the boundary between the heading and bench (zone B in Figure 1 and Figure 2.) Beyond the point, the increment of bench advance was shortened to 10 to 20 m, and the heading and bench were excavated alternately every 10 m. In the downbound tunnel, the top heading settled 1.5 m over a length of 20 m at a point 350 m from the portal (zone C in Figure 1 and Figure 3.) Prediction of the deformation was difficult because measured displacement satisfied the control levels. Reactive measures resulted in the aggravation of loosening. At the point, a technical review committee composed of experts was launched, and additional geological surveys were conducted to investigate the distribution and fracture of the melange of mudstones.

The committee confirmed that

(a) Tunnel cross section should be completed as early as possible including the invert by minimizing the increment of bench advance,
(b) Appropriate reinforcement should be installed at the face, tunnel crown and at the foot of the heading to ensure construction safety and control the progress of loosening, and
(c) Supports should have sufficient strength to carry overburden pressure.

The road administrator decided not to construct an emergency parking place that was initially planned at the midpoint of the tunnel alignment in view of the construction cost relative to the service function provided.

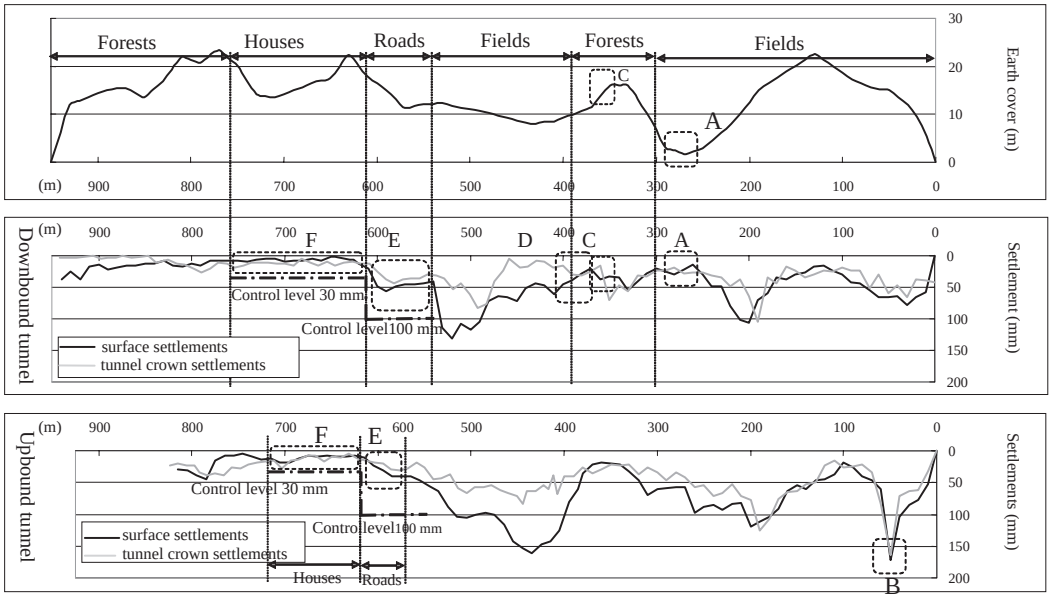

Figure 1. Longitudinal profile of the tunnel (earth cover, surface settlements and tunnel crown settlements).

Figure 2. Fall in a face.

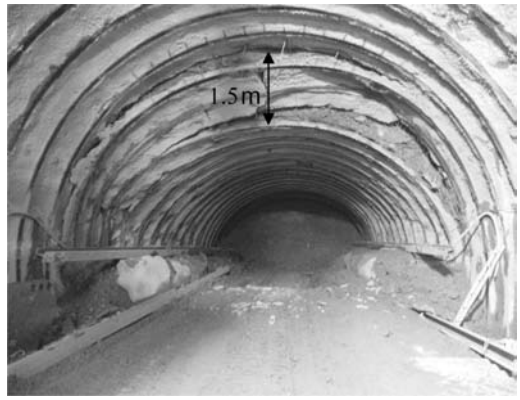

Figure 3. Deformation due to settlement.

The Road Structure Ordinance required no installation of parking places at the site.

7 APPROPRIATE INCREMENT OF BENCH ADVANCE AND REINFORCEMENT

With frequent collapses of the top heading, shortening the increment of bench advance and enlarging the cross section of the face were of concern from a viewpoint of safety. Actively stabilizing the ground and closing the ring early were expected to ensure the safety of work, keep the surrounding ground in sound conditions and increase the total quality of the tunnel.

7.1 *Early closing of the ring*

The increment of bench advance in the top heading was set at 3 to 6 m. The top heading, bench and invert were constructed alternately every 3 m. The distance from the face of the top heading to the point where the ring was closed by constructing the invert was set at 11 m or less (Figure 4.)

7.2 *Crown reinforcement*

The injection-type long forepoling method (umbrella AGF) was adopted. Steel pipes with a length of 12.9 m, a diameter of 114.3 mm and a thickness of 6.0 mm were driven at the tunnel crown. Urethane grouts were used that were expected to prevent the loosening on the cleavage plane (Figure 5.)

7.3 *Face reinforcement*

Injection-type long bolts were driven through the face. Steel pipes with a length of 12.5 m, a diameter of 76.3 mm and a thickness of 5.2 mm were driven at spacings of 1.5 m on the face (Figure 5.) Steel pipes were designed to have slits at spacings of 50 cm and cut by the boring machine and collected to separate them from the muck. Mortar grouts were generally injected. Where urethane grouts were employed, the muck had to be disposed of elsewhere.

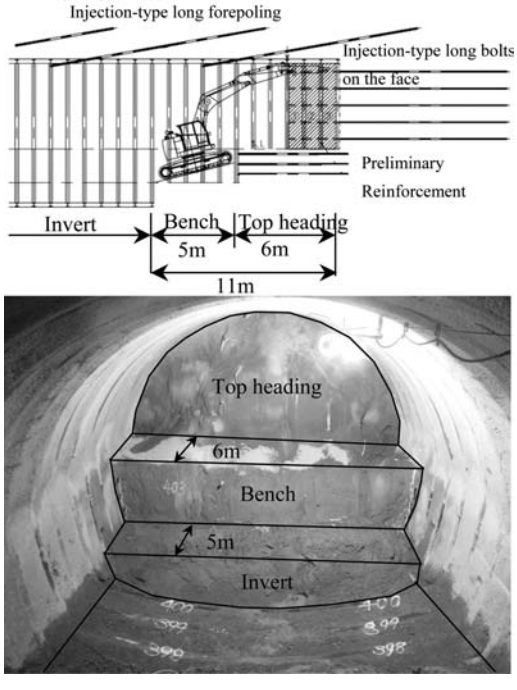

Figure 4. Outline of early closing of the ring.

7.4 *Preliminary reinforcement at the foot of the top heading*

Piles used to be driven from the top heading for reinforcement. Then, construction was delayed and it was doubtful whether they were actually effective or not. A method was therefore proposed and applied to install reinforcement at the foot prior to the excavation of the top heading.

Settlement of the top heading was expected to occur before the closing of the ring after the construction in the bench and at the invert. Closing of the ring was given priority wherever allowable. Whenever the settlement was determined to exceed the allowable level, reinforcement was installed. When the increment of bench advance in the heading was 3 m, the minimum level, 6-m-long steel pipes were driven from the outer circumference of the face in the bench to the foot of the top heading as in tunnel crown reinforcement (AGF). Thus, reinforcement could be installed at the foot of the top heading over a length of 3 m prior to excavation. Instability during the excavation of the bench could be avoided until the installation of supports (Figures 5 and 6.)

8 CONTROLLING OF SETTLEMENTS

No control levels were specified in areas with forests or fields as long as land was used without any problem. Water supply pipes that supply water to twenty thousand people were under the roads. The pipes were replaced with those resistant to settlement and the

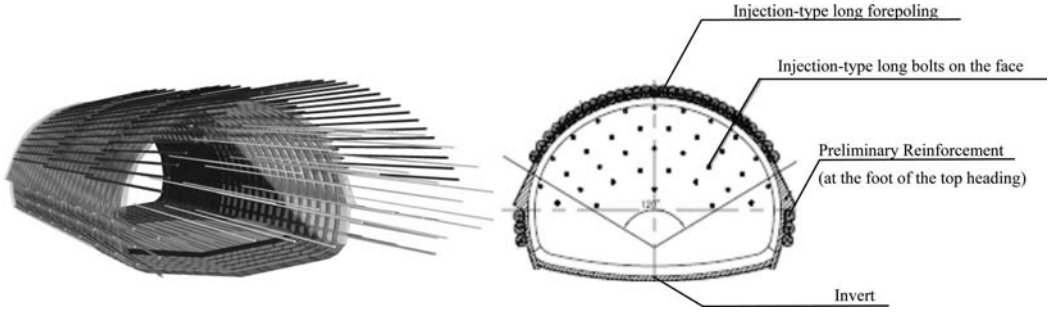

Figure 5. Outline of reinforcement.

control level was set at 100 mm. In sections with houses, generally 30 mm and 1/1000 were specified for settlement and slope of the ground that settled as generally applied.

Fortunately, the control level increased as the tunnel advanced from the areas with forests and fields to those with roads and houses. A few cases of surface settlements were found in the sections where the areas ahead of the face were stabilized with urethane grouts, based on the past construction data (zone D in Figure 1.) Urethane injection in some of the injection-type long bolts on the face resulted in satisfactory reinforcement (zone E in Figure 1.)

In sections with houses, the most strict control level was specified. Injecting urethane grouts for reinforcement contributed to the achievement of the control level (zone F in Figure 1 and Figure 7.)

9 RESULTS OF CONSTRUCTION

The findings obtained during construction are described below.

9.1 *Safe construction*

Appropriate reinforcement can help avoid the risk of face collapse due to early closing of the ring. Proper shotcrete application to the face and subsequent monitoring can ensure the establishment of a safe construction environment.

9.2 *Consideration of effects on surrounding areas and the environment*

Measurement revealed that control levels for settlement were satisfied according to the mode of land use: 100 to 160 mm for settlements under fields (no control levels specified), 30 to 55 mm for settlements under roads (control level: 100 mm), 3 to 19 mm for settlements under houses (control level: 30 mm) and 0.4/1000 to 0.7/1000 for the slope of ground that settled under houses (control level: 1/1000).

9.3 *Economical construction*

It has been determined based on the construction condition (9.1) and measurements (9.2) that rational reinforcement was installed.

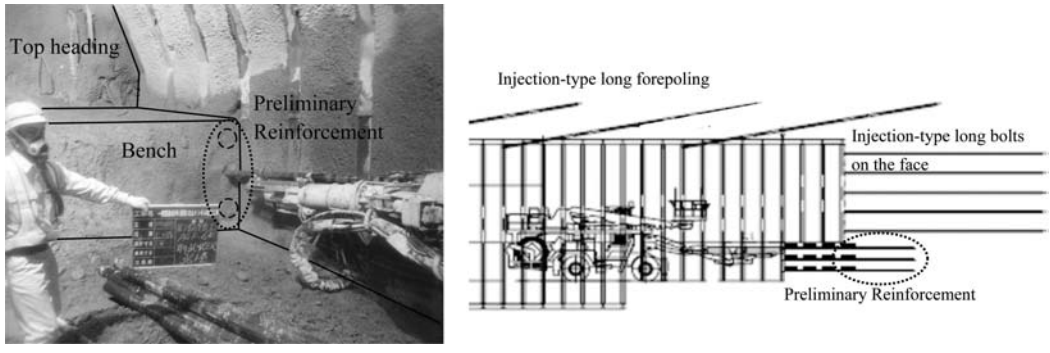

Figure 6. Preliminary reinforcement at the foot of the top heading.

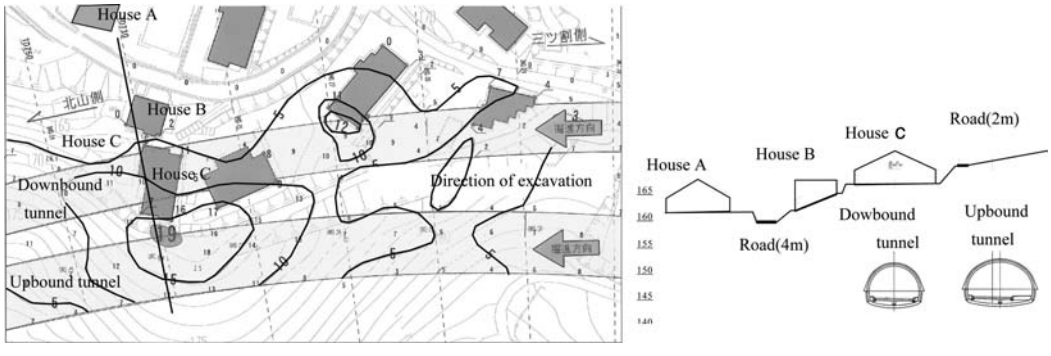

Figure 7. Ontour line of settlement under houses and cross section.

10 CLOSING REMARK

The basic idea that “Nothing is more important than early closing of the ring.” proved right when constructing tunnels in unconsolidated ground as in this project. Trouble can be prevented and high-quality tunnels can be constructed by actively installing reinforcement ahead of the face to keep surrounding ground in sound conditions and closing the ring early to stabilize the tunnel. This is ultimately a highly cost-effective choice in terms of maintenance after the tunnel is placed in service as well. It is hoped that this paper will be of some help in future implementation of NATM in urban areas.

Highways in the Czech Republic in terms of tunnel construction

Ing. Petr Laušman
Ředitelství silnic a dálnic ČR, Prague, The Czech Republic

ABSTRACT: The tunnel constructions are designed for new highways in 2006 and 2007 years. There are highways on route D3/R3 PRAGUE – Tábor – České Budějovice – state boundary, D11/R11 Prague – Poděbrady – Hradec Králové – Jaroměř – Trutnov – state boundary Czech Rep. / Poland, Route D8 Prague – Lovosice – Ústí nad Labem – state boundary Czech Rep. / Germany prepared.

1 ROUTE D3/R3 PRAGUE – TÁBOR – ČESKÉ BUDĚJOVICE – STATE BOUNDARY

Total length of route D3 + R3 between Prague and the Austrian border line is 171.40 km. The route is divided into 12 construction passages 0301 through 0312.

The tunnel constructions are designed just at the first construction passages, i.e. at construction sites 0301 and 0302 within the region of Middle Bohemia. The other construction passages feature no tunnel construction.

Let's have a look at the freeway project in terms of tunnel constructions. From big elevated crossing of the Prague Circle, where stationing of D3 starts off, the route is turning right, west of the town of Libeø. Here, between milestones of about 5.0–6.2 km, the first tunnel "Libeř" is proposed. Its technical solution and way of construction will be decided as late as in more detailed phase of project documentation, after precise level setting of the road. The tunnel will primarily serve as a protection of Libře's residents against adverse impact of the traffic and is to reduce the barrier effect between Libeř and Libeň, where hosing development is planned. The need of this tunnel construction itself will be verified through the EIA process and area management. Further on, another tunnel "Kamenná vrata" is placed at about 7.5 km milestone and being about 300–400 m long. This tunnel will be driven and will have deepened three-portal parts. In order of the stationing direction, third tunnel, "Svatováclavské lázně", about 200 m long is situated at 8.8 km mileage mark and is to preserve the above located forest area. Just after the elevated crossing Jílové, about 100 m long dug tunnel "V Obrázku", follows. Its main purpose will be to allow spreading a bio-corridor over the freeway body as well as recreationally used rural road. At the descending passage towards the river Sázava, driven tunnels "Kopanina" (at 10.8 km, 250 m long) and "Hůrka" (at 11.3 km, 350 m long) are proposed.

After crossing the lower watercourse of Sázava River via an architectonically and technically exceptional arched bridge of about 1000 m in length, the route gets to an area of extended forest complex near Lešany. Here, three short and dug tunnel constructions of length about 200 m are newly proposed. These are to reduce occupation of lands designed for fulfilling forest functions by reducing ground work cubage at trenches while passing through the local broken terrain as well as to allow as easy as possible migration of animals through this area, via given trails.

There is no doubt about realization of the freeway D3 among the professionals. Unfortunately, the progress of investor's preparation status quo in area of the Middle Bohemia region doesn't correspond to this need. In fact, all the preparation work has been stopped, partly due to having the ground plans of large territorial units of the Prague region and Benešovský region still not approved even though their acquisition moved on in 2006, after several years, but also due to a prolonged budget of preparation works at each building passages. Leading the route through a broken terrain south to Prague, with a dominant element – canyon of Sázava's lower watercourse will require a relatively substantial amount of underground passages of various functions, with regard to the high density of inhabitants, permanent and recreational.

In conclusion, it needs to be reminded that the sheer existence of tunnel constructions on route of the freeway D3 or only the technical data and characteristics of each tunnel are entirely orientating in that investor preparation status quo. The final status will be given after the final land order, preceded by environmental impact assessment as well as assessment of building impact on Natura2000 system. This and the wireline

loggings and analysis within the frame of area management documentation compiling, will lead to additional requirements of touched bodies of state administration and autonomy which may considerably affect the final technical solution of the freeway and thus even parameters of all proposed tunnel constructions.

2 ROUTE D11/R11 PRAGUE – PODĚBRADY – HRADEC KRÁLOVÉ - JAROMĚŘ – TRUTNOV – STATE BOUNDARY CZECH REP./POLAND

The total length of route D11, R11 between Prague and the state boundary with Poland, is 112.10 km divided into 9 construction passages 1101 through 1109.

Tunnel constructions are proposed at the last construction passage i.e. the building site 1109 within the are spread between Trutnov and the state border with Poland. The other building passages have no tunnel construction on them.

Route of the building site 1109 enters area of Východní Krkonoše Mts. after Trutnov and passing over so called Poříčský ridge. Here, the topographical and partly even ecological condition require two-tunnel proposal within locality of Poříčí and Zlatá Olejnice. In either case, building of two separated tubes in distance of 21 m is assumed.

The tunnel "Poříčí", 540 m long is proposed with longitudinal gradient 3.5%; in terms of direction, the tunnel is shaped in clockwise curve of 1000 m in radius.

The tunnel "Zlatá Olešnice", 375 m long is proposed with longitudinal gradient 3.2% and straight, in terms of direction.

Width arrangement equal in both tunnels – 2×3.5 m for lanes, 0.25 m for edge lines and servicing footpaths of width 1 m are assumed.

Tunnelling of both tunnels is assumed to occur in gneiss, stable rock setting.

The above stated data is drawn from a technical study and unfinished documentation of EIA, used as the groundwork of the Ground Plan of VÚC Trutnovsko – Náchodsko regions, approved by the region administration of Královéhradecký region in 10/2004. In term of Investor preparation, a point of crossing the state boundary was set at negotiations, held in 05/2004 in Warsaw and in 10/2004 in Český Těšín, at ministerial level, about interconnection of R11 and S3 within area of Královec-Lubawka. A proposition of "Agreement between Governments of Czech Republic and Poland about Interconnection of Czech Freeway R11 with Polish Freeway S3 on Czech/Polish State Boundary" was made and ratified. Subsequently, the "Agreement between Governments of Czech Republic and Poland about Interconnection of Czech Freeway R11 with Polish Freeway S3 on Czech/Polish State Boundary", was ratified on March 18 2005 in area between municipalities Královec-Lubawka with term of putting into service after year 2010.

Further preparation, admittedly, depends on amount of financial resources granted to this building. In the budget of SFDI for 2005, an amount of 0.00 CZK was reserved, for 2006 0.00 CZK was reserved. For those reasons, any investor preparation has been put on hold.

On the Polish side, situation is similar. A report on Polish preparation status was given away by director of the General Management of Routes and by director of Regional Development department in Wroclaw at international talks in Jaroměř, held on May 15 2006. From that report, it was made clear, that a programme of route building in years 2006–20013 was approved by Polish government in January 2006.

It contains building of S3 in direction towards Štětín with realization term set to year 2013. They pointed out that this program will not allow them to build up all routes as planned.

They confirmed the realization term of S3 at point of connection to R11 in 2013 and added, that the term depends on amount of granted financial resources. Further, they noted, 2-lane road has been prepared in the meantime, in regard to the current traffic intensity of 5,000 vehicles a day but will be adjusted as needed.

3 ROUTE D8 PRAGUE – LOVOSICE – ÚSTÍ NAD LABEM – STATE BOUNDARY CZECH REP. / GERMANY

Total length of route D8 between Prague and state boundary with Germany reaches 112.10 km, divided into 7 building passages 0801 through 0807.

3.1 *Building 0805 E tunnel Prackovice*

It is about a newly-built highway tunnel between mileage marks 58.280 km– 58.550 km. It goes through ridge massif of Debus hill (eastern hillside) at peak passage of Prackovický stonepit above municipality of Prackovice and comes out at the opposite hillside above the valley "Uhelné strouhy". The tunnel construction consists of tunnel tubes themselves, LTT (left tunnel tube) 270 m long and RTT (right tunnel tube) 260 m long, with maximal axis distance of 14 m, subcontrol office object and approach retaining wall. The tunnel tubes are proposed with inner clearance to allow for the highway surface inside the tunnel having width 9.5 m ($0.5 + 3.75 + 3.75 + 0.25 + 1.25$) with two footpaths on sides of width 1 m for passing profile according to norm ČSN 73 75 07 "Road Tunnel Design". The basic height of passing section

is 4.5 m – tunnel category T 9.5 (two-lane, one-way tunnel).

3.2 *Building 0805 F tunnel Radejčín*

It consists of a highway tunnel, newly built between mileage marks 58.760 km–59.380 km, highway bridge between tunnels and complex body of the highway of length 1080 m. Within the frame of the building, object required by the building itself are also realized. The highway tunnel Radejčín undergoes flat Radejčínský ridge of Českého středohoří (Czech Central Mountains) east to railway station in Radejčín. The tunnel construction includes tunnel tubes themselves, LTT (left tunnel tube) 600 m long and RTT (right tunnel tube) 620 m long, with maximal axial distance of 14 m. The tunnel tubes are proposed with inner clearance to allow for the highway surface inside the tunnel having width 9.5 m $(0.5 + 3.75 + 3.75 + 0.25 + 1.25)$ with two footpaths on sides of width 1 m for passing profile according to norm ČSN 73 75 07 "Road Tunnel Design". The basic height of passing section is 4.5 m – tunnel category T 9.5 (two-lane, one-way tunnel). The inside dimension also allows for placing of technological equipment of the tunnel (ventilation system, lighting, drainage system, cables, road signs, etc.). The highway bridge, of which support construction is designed as a beam, sandwiched steel-and-concrete continuous structure of 3 fields, has span of 132 m.

3.3 *Building 0805 G*

This project is a separate building of highway D8. It is a capacity traffic solution, connected to traffic of the current road network. It is a pilot work, required for safe base setting of the highway tunnel Prackovice, the main object of building 0805 E.

Control gallery deep goes through the ridge massif of Debus hill (eastern hillside) at peak passage of Prackovický stonepit above municipality of Prackovice and comes out at the opposite hillside above the valley "Uhelné strouhy". Access is proposed on current roads, requiring their modification, from Prackovický stonepit. As a reason of this construction is specifying detailed geologic-engineering probe, verification of factual geological and hydro-geological conditions, proving suitability and efficiency of construction elements used for securing the driven tunnels. The control gallery deep will be realized inside the right abutment of the left tunnel tube in length of 175 m.

Urban tunneling under existing structure

H.S. Lee, K.S. Jue, D.Y. Kim, W.H. Jung & Y.N. Lee
Hyundai Engineering & Construction Co., LTD, Seoul, Korea

ABSTRACT: This paper presents a design and construction case of an urban tunneling construction section carried out in the Seoul Metropolitan Subway. In this section, the tunnel was excavated under an existing overpass thus encountering a pile foundation of the overpass where cutting was unavoidable. In order to ensure the stability of both tunnel and overpass, the ground was reinforced using jet grouting from the surface. The steel pile reinforced step grouting was employed for inside tunnel reinforcement method. The total of 67 piles were exposed during excavation and all of them were properly cut, maintaining the stability of the overpass. The tunnel excavation was successfully complete without any problems for the area under the overpass.

1 INTRODUCTION

One of the major issues in urban tunneling is an underground excavation adjacent to existing structures in poor ground condition. In urban tunneling, unlike mountain tunnels, comprehensive and systematic evaluation and analysis on design, construction, and monitoring are required to ensure the stability of existing structures as well as that of tunnels. This paper presents a case of urban tunneling in Seoul, Korea where the tunnel passes under an overpass. Pre-investigation revealed that a total of 67 piles of the overpass foundation were located in the ground to be excavated. In this paper, the construction process and results of monitoring are presented as well as results of the numerical analysis on the stability of the tunnel.

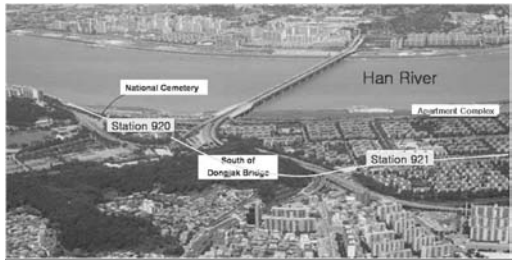

Figure 1. Overview of subway section 912.

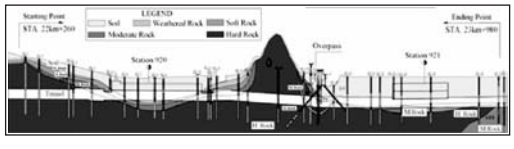

Figure 2. Geological map of section 912.

2 OVERVIEW OF CONSTRUCTION SITE

2.1 *General description of construction site*

Seoul metropolitan subway Line No. 9 (L = 38 km, total 37 stations) runs on the west-east axis of the southern part of Seoul, below Han River. The construction of Line 9 is divided into two stages. The 1st stage is between Gimpo airport and Gangnam (L = 25.5 km). The 2nd stage between Gangnam and Bangi(L = 12.5 km). The 1st stage is to be finished in 2008 while the construction of 2nd stage has not started yet. The 12th work section of the 1st stage, denoted as Section 912, will be discussed in this paper. The total length of Section 912 is 1,720 m (open cut 258.45 m, tunnel 1131.55 m, and 2 stations 330 m), and is excavated by NATM. Figure 1 displays the aerial photo of Section 912.

2.2 *Geological condition*

Banded biotite gneiss in Precambrian period is well developed as bedrock and alluvial soils in the Quaternary period are placed unconformably on top of the bedrock. The alluvial soils widely found in the area show characteristics of bed sediments of the Han River which consists of mainly silty sands with gravels. Figure 2 shows the geological map of Section 912.

2.3 *Overview of overpass area*

A 12-lane overpass consists of 3 bridges and one concrete covered structure. This overpass crosses over the E-Soo crossroad as shown in Figure 3. In this crossroad, the tunnel underpasses the overpass at a

Figure 3. Overpass on E-Soo crossroad.

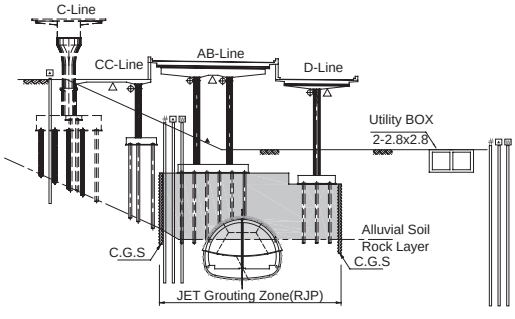

Figure 4. Cross section view of tunnel and overpass.

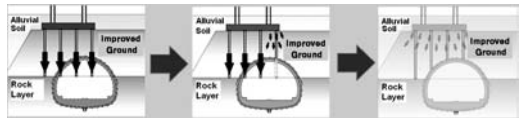
depth of $10 \sim 20$ m below the ground level at an angle of $30 \sim 45°$. This tunnel would contact the pile foundation of the overpasses along the length of 50 m.

As shown in Figure 4, the pile foundation of the existing structures is located near or inside the tunnel excavation section. The number of piles that would fall into the excavation section were expected to be a total of 67.

Table 1 shows the major structures near the excavation area, types of foundation, and each number of piles to be cut. The C-Line is a 4-span continuous steel composite box girder bridge and CC-Line is a 8-span continuous R.C. structure. Four-span continuous R.C. slab bridge is denoted as AB-Line while 8-span continuous R.C. lahmen structure is denoted as D-Line.



3 DESIGN OF TUNNEL

3.1 *Excavation and ground reinforcement*

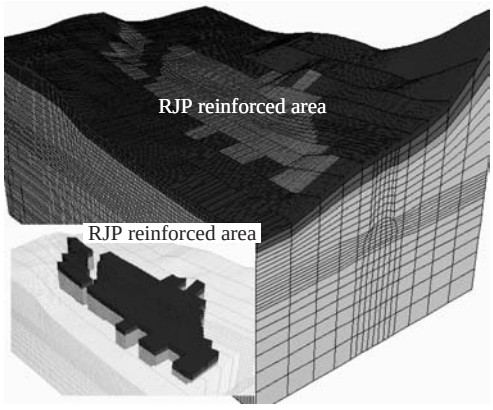
As previously stated, the depth of the tunnel is $10 \sim 20$ m below the ground level. At this depth, the tunnel is to contact the pile foundation during excavation thus cutting of the piles that are exposed to the excavation section is unavoidable. In order to ensure the stability of the superstructure due to pile cutting,

Table 1. Major structures on E-Soo crossroad and foundations.

Structure number	Foundation type	Number of piles to be cut
C-Line	PHC pile (dia. = 500 mm, L = 11.0 m)	0
CC-Line	Steel pile (dia. = 406 mm, L = 11.0 m)	14
AB-Line	PHC pile (dia. = 400 mm, L = 11.0 m)	38
D-Line	PHC pile (dia. = 400 mm, L = 9.0 m)	15

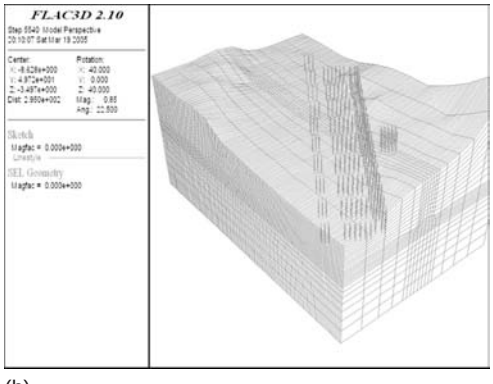
End-bearing piles | Pile cutting Gradual load transfer to improved ground | Load transferred to block footing foundation

Figure 5. Load transfer mechanism due to ground reinforcement.



the ground reinforcement should precede prior to tunnel excavation. Jet grouting and enlargement of the pier foundation section have been carried out in the surface while steel pipe step grouting and forepolling have been employed for reinforcement inside the tunnel. Total length of the reinforcement area is 110 m along the tunnel.

RJP method (D2000 mm, C.T.C 1.8 m), employed for ground reinforcement, reinforces the ground by injecting the cement suspension of high pressure ($300 \sim 700$ kg/cm^2) using the triple rod. Basic concept of the ground reinforcement is transformation of foundation type. Since piles are trimmed step by step as the excavation proceeds, the load acting on the piles would be gradually transferred to the reinforced ground. Through this process, end-bearing pile foundation of the bridges would be changed to block-footing foundation eventually. Figure 5 shows the schematic diagram of the load transfer mechanism.



The reinforcement range has been decided to be two times of pier foundation width based on the result of stability analysis as illustrated in Figure 4.

3.2 *Analysis on stability of tunnel and overpass*

The numerical analysis has been performed to evaluate the stability of the tunnel and overpass for the range of excavation adjacent to pile foundation. Since numerous piles are located at the tunnel depth and ground reinforcements have been applied in this range, a careful consideration has been taken to appropriately

(a)

(b)

Figure 6. Analysis modeling of (a) the reinforced ground and (b) overpass piers.

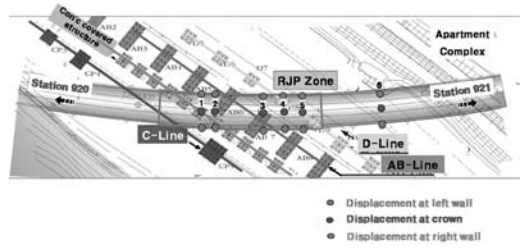


Figure 7. Measuring points for numerical analysis.

simulate the in-situ condition such as the characteristics of the reinforced ground and neighboring ground condition. Another numerical analysis on the superstructure (the overpass) has also been conducted. Both numerical analysis have been conducted using FLAC 3D. Figure 6 shows the analysis modeling of the reinforced ground and overpass piers.

Table 2 shows the material properties used in the analysis. Increased material properties have been used for the reinforced ground to simulate the effect of RJP. The pile elements in the reinforced ground are simulated to be eliminated in the appropriate step of excavation.

3.3 *Results of the numerical analysis*

The results of the numerical analysis are presented in this section. The displacements are investigated along three lines, which are the crown, the left wall, and the right wall of the tunnel. Six measuring points for each measuring line are displayed in Figure 7. Five points for each line are located inside the RJP reinforced zone while one point for each line is outside the RJP zone.

Table 2. Material properties.

								Reinforced ground with RJP			
	Landfill layer	Sand	Gravel	Weathered rock	Soft rock	Moderate rock	Hard rock	Land fill layer	Sand	Gravel	Steel pipe step grouting
Friction angle (°)	31	33	40	35	35	40	45	31	38	37	37
Cohesion (ton/m^2)	0	0	0	5	20	60	140	23	50	80	80
Unit weight (ton/m^3)	1.8	1.8	1.9	2.1	2.3	2.5	2.6	1.8	1.8	1.9	2.1
Modulus of deformation ($\times 10^3$ ton/m^2)	1.0	1.3	3.0	20	90	300	1200	36	47	48	50
Poisson's ratio (ν)	0.33	0.32	0.3	0.3	0.26	0.24	0.22	0.33	0.32	0.3	0.28

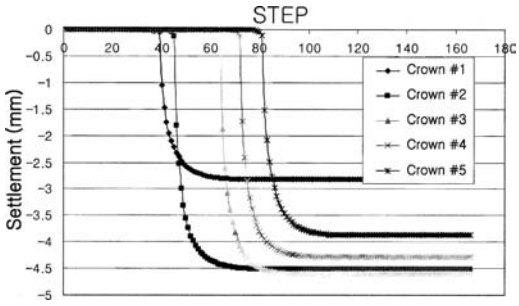

Figure 8. Settlement at tunnel crown.

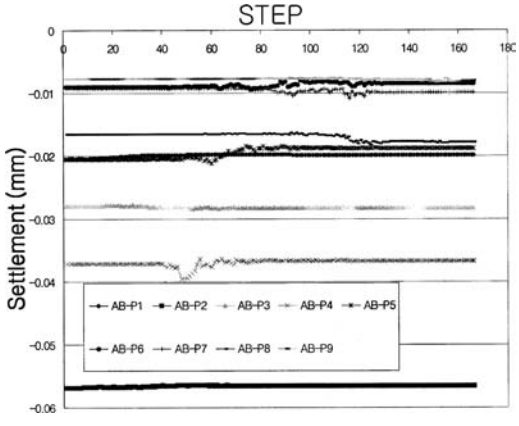

Figure 9. Settlement at overpass foundation (AB-Line).

The analysis results show that the maximum displacements are 4.6 mm for the crown, 0.04 mm for the left wall, and 0.02 mm for the right wall. It was observed that all the values are within the allowance thus was expected that the tunnel would be stable.

It was also observed that the settlements of the overpass foundation ranged from 0.01 mm to 0.19 mm, which were all within the allowance of 25 mm; influence on the foundation by tunneling would be very small. Figure 8 and Figure 9 show the settlement at tunnel crown and at overpass foundation, respectively.

4 TUNNEL EXCAVATION AND MONITORING

4.1 *Tunneling*

As previously stated, cutting of the piles that were exposed to the excavation section was unavoidable. As shown in Table 1, the total number of piles to be cut was expected to be 67. It was observed during tunneling that the location of piles agreed well with the expected location. It was notable, however, that several unexpected piles and different material type of piles also

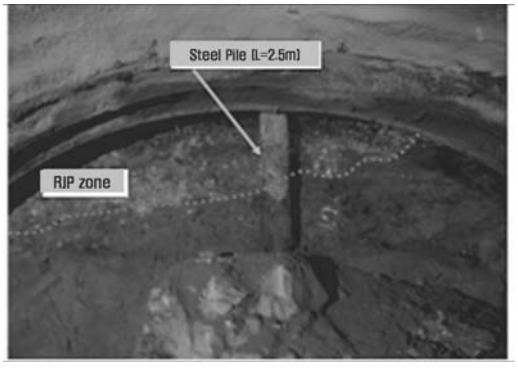

Figure 10. Exposed steel pile during tunneling.

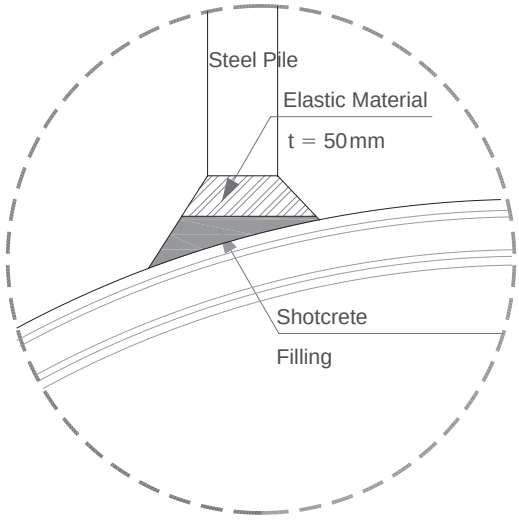

Figure 11. Pile cutting work.

appeared during tunneling, resulting in difficulties in excavation.

The tunnel was excavated as explained in Section 3.1; the ground was first reinforced by means of RJP and the width and height of the foundation were enlarged then tune tunnel was excavated. The sequence of the pile cutting was as follows; (1) once the pile was exposed as shown in Figure 10, the ground around the pile was excavated and the steel rib and shotcrete were installed, (2) pile was cut, (3) elastic material was installed between the pile end the shotcrete layer as in Figure 11, and (4) shotcrete was again installed at the cutting section, and the excavation was repeated.

4.2 *Monitoring and results*

In order to ensure the stability of the overpass and tunnel during both excavation and operation, a total of 98

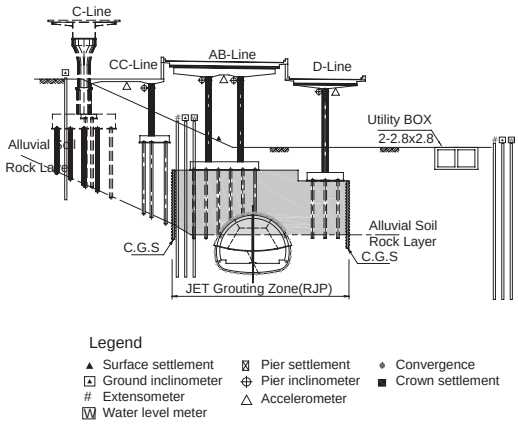

Figure 12. Monitoring plan.

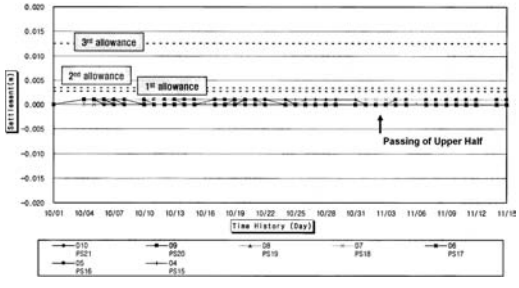

Figure 13. Monitoring result – pier inclinometer.

instruments were installed to determine the stability of the overpass, and to investigate the ground behavior. It included settlement for the ground and the overpass, inclinometer for the ground and the pier, extensometer, water level meter and so on. Inside the tunnel, crown settlement and convergence were measured at a spacing of 5 m, and ground movement and support stresses were measured at 5 points. Figure 12 shows the types of monitoring and location of the instruments.

The results of monitoring show that all the measured values fall within the allowance thus stability of both the overpass and the tunnel was obtained. Figure 13 shows a result of pier inclinometer.

5 CONCLUSIONS

A case study of urban tunneling under the existing structure was presented in this paper. Preliminary investigation showed that pile foundation of the overpass would fall into the tunnel excavation area. Therefore, ground reinforcement was applied to the neighboring ground and around the tunnel to ensure the stability of the overpass and tunnel. Jet grouting (RJP) was applied from the surface of the ground and the width and height of the foundation was enlarged. Steel pipe step grouting was also employed for reinforcement of the ground inside the tunnel. The reinforcement design was verified to be appropriate by the numerical analysis. Excavation of the tunnel was successfully performed without any problem. Monitoring results showed that all the measured values satisfied the allowance.

Civil Engineering Division, Taisei Corporation, Tokyo, Japan

ABSTRACT: Large double adjoined binocular tunnels, which consist of four-linked tunnel system, are implemented in shallow and soft ground at densely populated area in Japan. From a view point of efficiency and safety, the tunnels are planed to be constructed by NATM method using machine excavation in combination with auxiliary methods such as diaphragm wall, soil improvement and AGF (All Ground Fasten) method. First of all, the soil improvement to surrounding soft ground is adopted to support the center pillar and to ensure the stability of the tunnel face in advance. Next, the diaphragm wall is constructed prior to the tunnel excavation not only for the site-work efficiency, but also for the environmental protection. Finally, the secondary linings of tunnels are designed with the following features; (1) center pillars are separated from secondary linings to ensure the structural stability. (2) secondary linings are designed as reinforced concretes to resist earthquakes and to endure external water pressure.

1 INTRODUCTION

1.1 *Outline of project*

Keihan No.2 Road is a expressway connecting Kyoto and Osaka as a bypass for National Road Route 1 to relieve the congestion of traffic on the existing roads, as well as to form a part of the area trunk road network in Kinki region. Figure 1 shows the network of the Arterial High-Standard Roadway in Kinki region.

This paper describes the construction planning and the design for Shoji Tunnel, located on the hillside in a dense residential district between Neyagawa-Kita IC an Neyagawa-Minami IC on Keihan No.2 Road, where an unprecedented construction method in the country is employed, i.e. the Large double adjoined binocular tunnels constructed by NATM in shallow and soft ground.

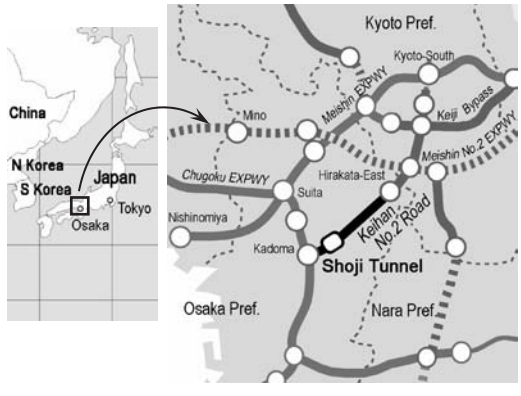

Figure 1. Network of the Arterial High-Standard Roadway in Kinki region and the tunnel position.

1.2 *Structural features of the tunnel*

Figure 2 shows a typical cross section of Shoji tunnel. The tunnel cross-section forms with four main tunnels (expressway: 2 tubes, $A = 170\,m^2$/national road: 2 tubes, $A = 85\,m^2$) connected with each other. The three center pillars placed between the main tunnels are to be built as SRC (steel framed reinforced concrete) structures in the drifts (3 tubes, $A = 40\,m^2$) that are to be excavated prior to the main tunnel excavations. The center pillars structurally bear only the primary

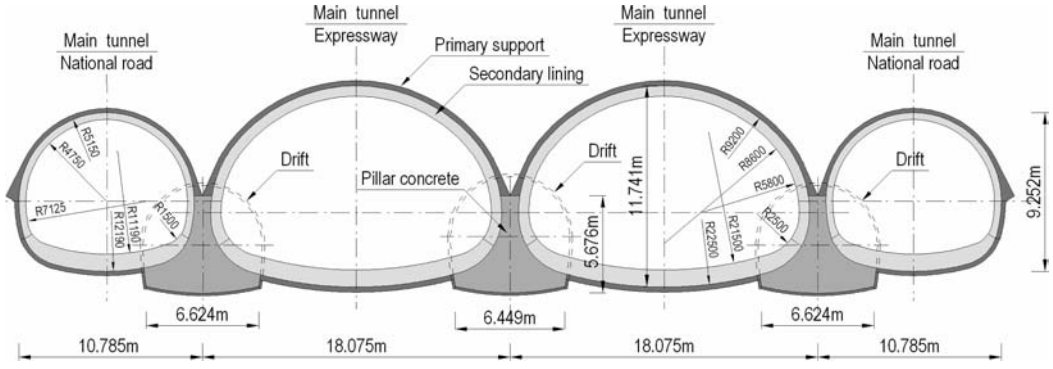

Figure 2. Typical cross section of Shoji tunnel.

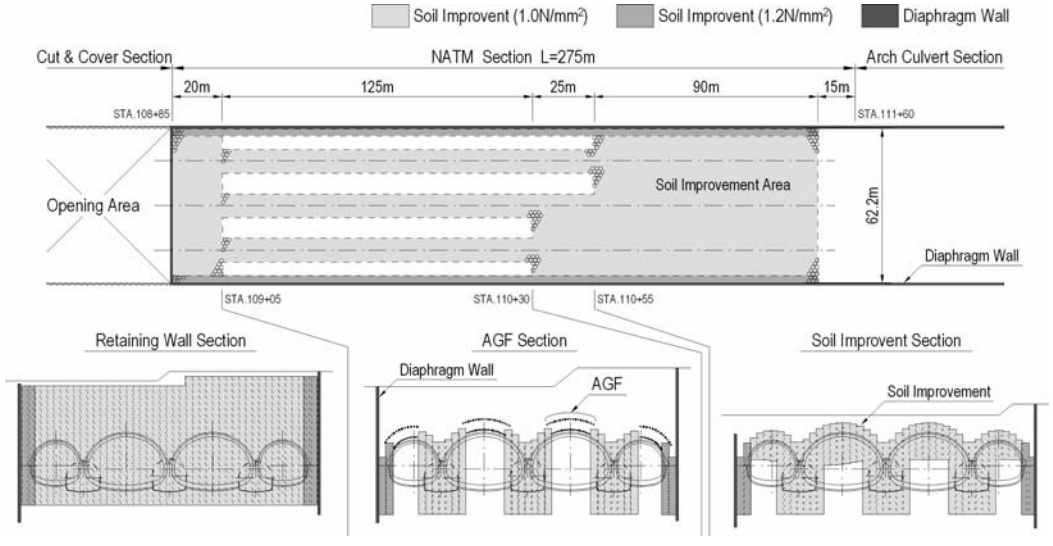

Figure 3. Schematic illustration for works of construction methods for countermeasures against ground surface settlement.

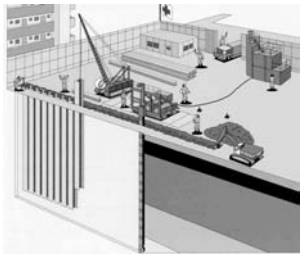
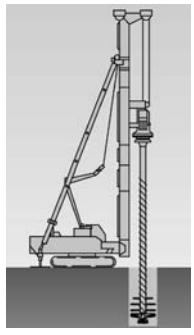
supports of the main tunnels, and are separated from the secondary lining. This is a measure for securing structural safety, and the secondary lining is designed to satisfy adequate safety for surrounding earth pressure, ground water pressure, and seismic loads.



2 CONSTRUCTION PLANNING

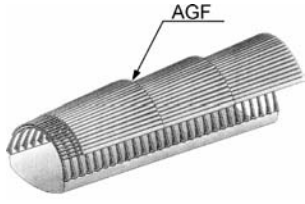
2.1 *Outline of tunnel*

The tunnel is located in the Osaka Layer group consisting of alternate layers of unconsolidated sediment with cohesive layers, sandy layers, and gravel layers, and the overburden height is as small as 10 m at maximum with houses in close proximity. With these severe conditions, it has been determined to reinforce the surrounding ground using the following construction methods before excavating the tunnel, so that ground surface settlement in the private land area should remain as small as possible.



- Underground diaphragm wall
- Soil improvement
- Long pile fore pilling (so-called AGF method)

Figure 3 shows locations and bounds of the above described construction methods. The overall tunnel is roughly divided into three sections, i.e. (1) Soil improvement section, (2) AGF section, and (3) Retaining wall section adjacent to the Cut & Cover section, from the portal side, respectively.



Specification
– Design strength
0.5N/mm^2
– Width of DW
550mm
– Steel rib
H400×200 ctc 1m

Figure 4. Schematic figure of construction of diaphragm wall.

Specification
– Design strength

– Improvement diameter
ϕ 1.6 or 2.0m
– Number
5227

Figure 5. Schematic figure of construction of soil improvement.

Specification
– Diameter of steel pipe
ϕ114.3mm (t=6.0mm)
– Injection diameter
ϕ450mm
– Number
19 (Expressway)
13 (National road)

Figure 6. Schematic figure of AGF method for tunnel.

First, the soil improvement section is the section where the soil improvement is applied to the upper half of the tunnel since the overburden height is very small and soft alluvial soil appears in the tunnel cross-section. Next, AGF section is the section that injection type long steel pipe fore piling at the tunnel crown is adopted instead of soil improvement, to prevent falling in at the tunnel crown during tunnel excavation. Lastly, retaining wall section adjacent to the Cut & Cover section is the section where the soil improvement is applied reaching the bottom of the tunnel for the purpose of reinforcing the retaining wall between the NATM section and the Cut & Cover section at which the tunnel arrives.

2.2 *Diaphragm wall*

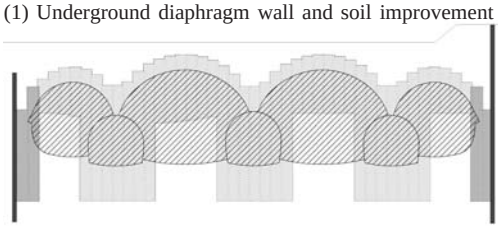
Since the excavation is performed in the Osaka Layer group with high ground water level, it has been decided to build up an underground diaphragm wall prior to excavation, considering ease of works and attention for surrounding environment (noise, vibration, etc.). It is expected that the prior diaphragm wall have an effect to reduce ground surface settlement due to the tunnel excavation. Further more, it is also expected that the diaphragm walls prevent the tunnel itself from expanding in horizontal direction and also contribute to secure the tunnel stability as a whole. Figure 4 shows the outline of the diaphragm wall construction. In constructing the diaphragm wall, the following method has been adopted where the ground is cut toward lateral direction by a chainsaw-shaped cutter and both the cement milk and the in-situ soil are mixed and agitated.

2.3 *Soil improvement*

Soil improvement conducted from the ground surface has been applied, and its main purposes are as follows.

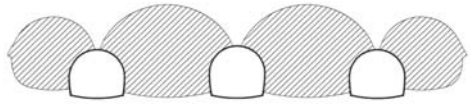
– Improving the face stability during excavation
– Bearing capacity of the center pillars
– Securing long-term permanence and aseismic safety of the secondary lining

As Figure 3 shows, three sections with different improvement methods are set up according to overburden heights and geological conditions. Required strength of the improved body has been determined basing on analyses and the like. Meanwhile in the adopted construction method, the in-situ soil and caking material are mechanically forced to be mixed and agitated with slurry like caking material that is pumped out into the in-situ ground, and after the bore hole reached the designed depth, the mixing and agitating device is pulled out, agitating soil and caking material once again, and thus the improved ground body are formed.



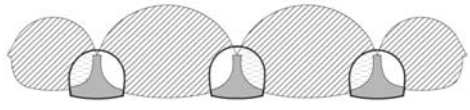
2.4 *AGF method*

For the main tunnel excavation in the section without soil improvement at the tunnel crown, it has been determined to carry out injection type long steel pipe fore piling to protect from falling in at the crown during tunnel excavation. It is a stressed point of this method that fore piling about 12 m beyond the face can be performed by placing steel pipes and grouting with a drill jumbo that is ordinarily used at tunneling works.

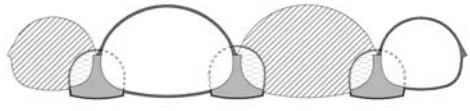


2.5 *Construction procedure*

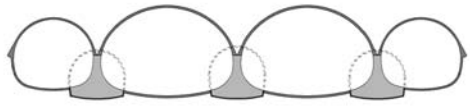
Construction procedures in the soil improvement section are the followings.



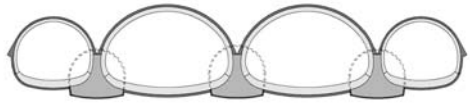
(1) Underground diaphragm wall and soil improvement



(2) Excavation of drift



(3) Placing pillar concrete and air mortar



(4) Excavation of advance tunnel

(5) Excavation of following tunnel

(6) Placing lining concrete

3 TUNNEL DESIGN AND ANALYSIS

3.1 *Outline of design*

In general, it is required for tunnel excavation to make sure the surrounding ground stability and the tunnel deformation behavior associated with excavation before starting execution control. In this tunnel, excavation should be performed under difficult conditions such as small overburden height or neighboring private houses located close to the tunnel, and therefore it has been considered necessary to accurately predict deformation behavior of the tunnel and the like. For these reasons, three-dimensional excavation analyses have been carried out representing relative influences of face positions of the four tunnels or effects of three-dimensional geological and topographical structures. It has been decided to set the following specified control parameters necessary for excavation works on the basis of the results of three-dimensional analyses.

(1) Induced deformation in the private land area
This is an important control item for tunnel construction. Specified control parameters are determined through comparing predicted analysis results with allowable limits for the surrounding private land.

(2) Ground surface settlement above the tunnel and the tunnel deformation
Since these predicted deformations are considered to have a strong correlation with deformation in the private land area, the specified control limits are set up using the relative correlation obtained through the prediction analyses.

(3) Displacement of the pillar concrete
The pillar concrete is considered to play a very significant role in reducing ground surface settlement and securing the tunnel stability on the whole. Hence the deformation modes or displacements of the pillars shall be analytically predicted, and these should be determined to conduct the execution control during construction basing on these predictions.

3.2 *Three dimensional excavation analysis*

Three-dimensional excavation analysis is performed under the following conditions.

(1) Analysis code
FLAC3D version2.1

(2) Three-dimensional FDM (Finite Difference Method) analysis model
Figure 7 is an illustration for the three-dimensional FDM analysis model, which is prepared taking specifications of topography and strata, and structural conditions of the tunnel into account. In modeling, three-dimensional geological structures, such as ground surface, boundary of stratum, distribution of soft strata (alluvial clay) and others, have been faithfully represented basing on the boring survey results ($n = 12$), and also mutual positions of the tunnel, retaining wall, and soil improvement area are three-dimensionally incorporated.

(3) Ground model
A Mohr-Coulomb type perfect elasto-plastic model is assumed for the ground, by using solid elements. Ground physical properties in each layer are set through geological survey.

(4) Support system model
For the underground diaphragm walls, characteristics of bending and axial rigidity of soil cement and core material are taken into consideration, and it is decided to model the walls as solid elements composing those materials together.

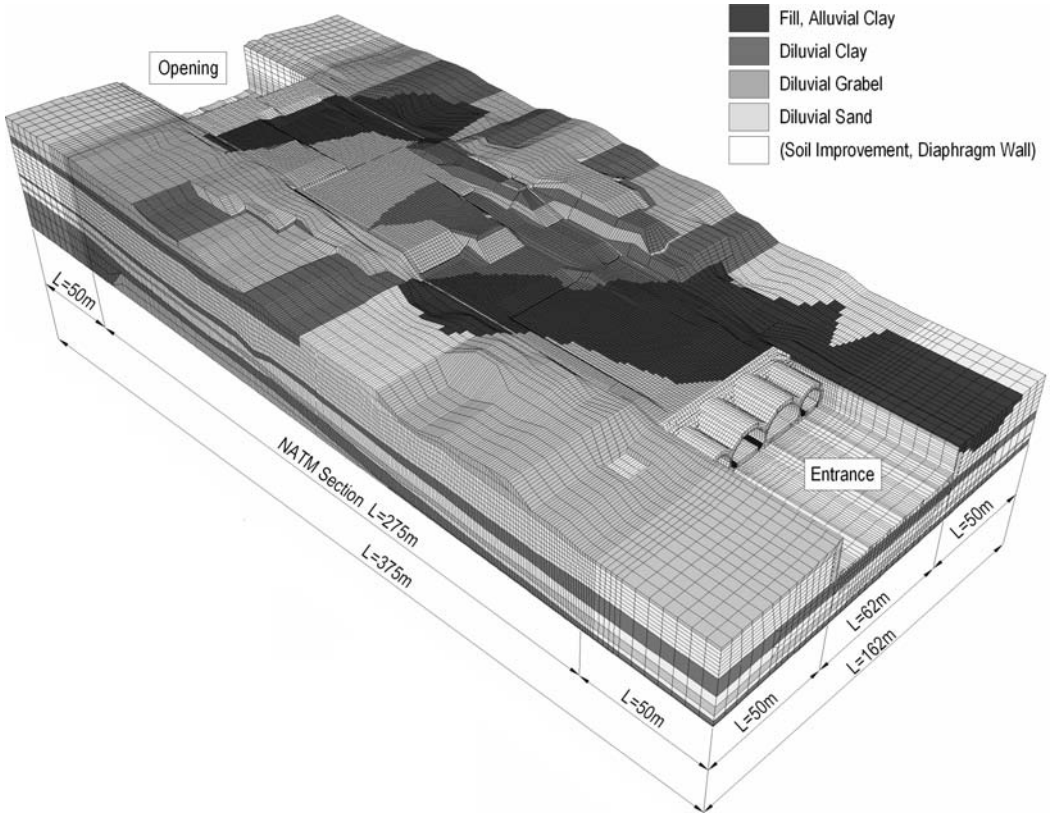


Figure 7. Analysis model.

Support members of the drifts are modeled to be shell elements where characteristics of bending and axial rigidity of shotcrete and steel supports are considered. Bending rigidity is set to be equivalent to that of steel supports, as bending rigidity of concrete has been neglected. While for axial rigidity, axial rigidity of shotcrete and axial rigidity of steel supports were added together.

Support members of the main tunnels consisted of shotcrete and steel supports, and shotcretes are modeled as solid elements and steel ribs are modeled as beam elements.

Figure 8 is an illustration for analysis steps.

3.3 *Distribution of ground surface settlement*

Figure 9 shows settlement distribution at the time of completion of excavation. Ground surface settlement directly above the tunnel is 20 mm at the soil improvement section and about 45 mm at the AGF section. Meanwhile, settlement at the border of the private land area, which is significant for execution control, is around 3 mm in the soil improvement section and 5 mm in the AGF section. On the basis of these predictions, it is planned to carry out an execution control during construction.

3.4 *Behavior and structure of the center pillars*

Figure 10 shows an example of deformation of the center pillars at the central part. The figure shows the result that horizontal displacement of 13 mm at the maximum appears at the top end of the center pillar with excavation of the pilot drift. The center pillars behave in a complicated manner during the following excavations, and displace about 10 mm in the reverse direction due to excavation of the following tunnel. On the other hand, reinforcements for the center pillar have been determined according to the following concepts.

(1) It is assumed to reinforce with steel material only for zone where tensile stress appears during construction, and the bottom of center pillars, where the analysis results for ordinary state show an appearance of tensile stress, has been decided to be reinforced by steel rib (H250 ctc 1.0 m).

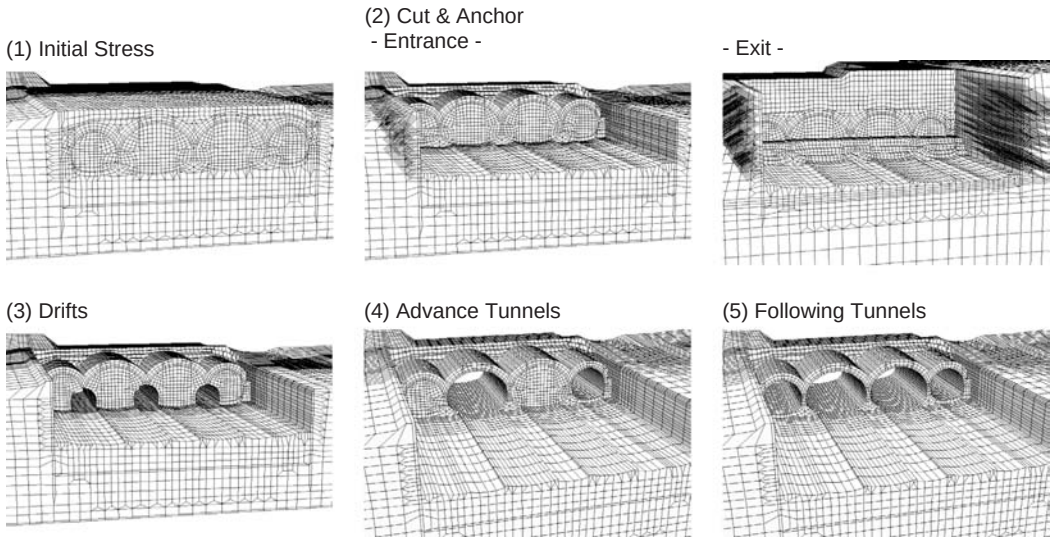

Figure 8. Analysis step.

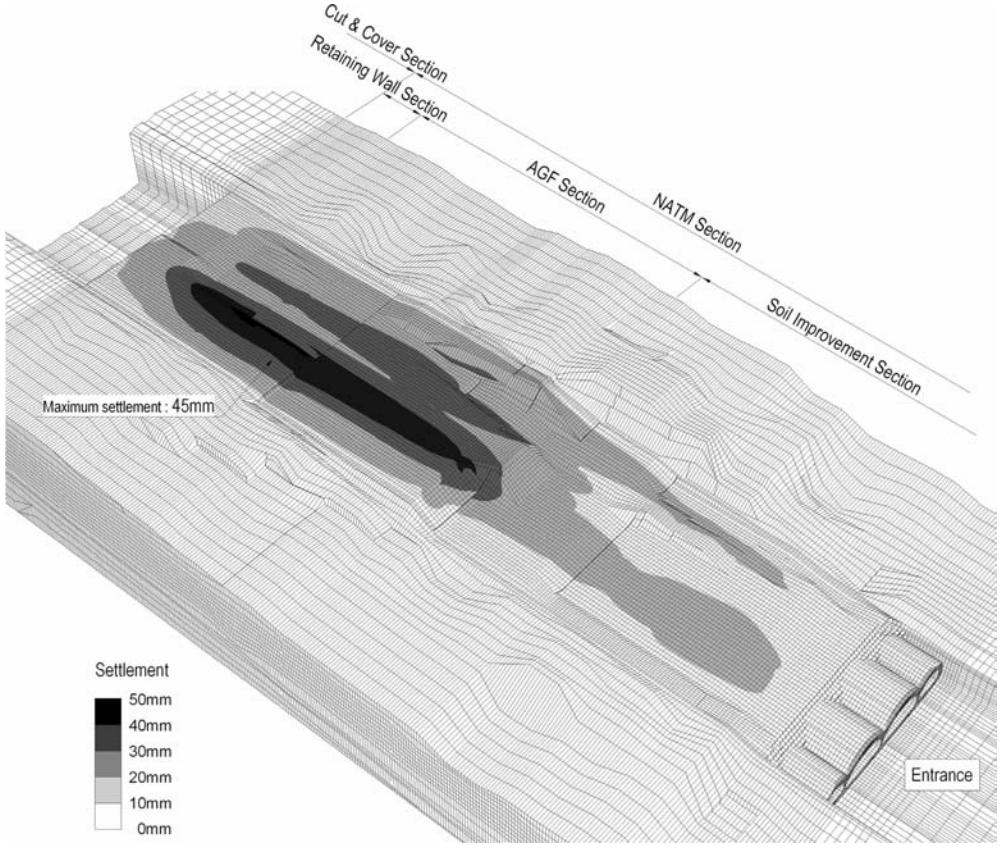

Figure 9. Settlement distribution diagram.

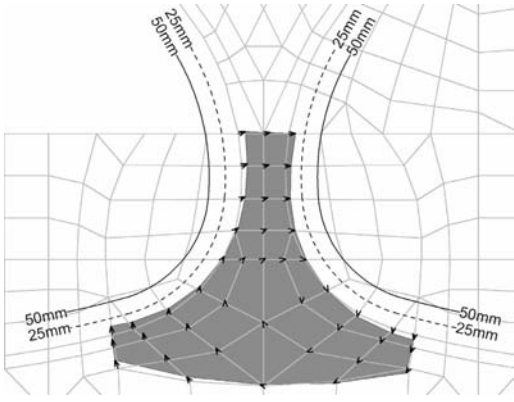

Figure 10. Deformation diagram for pillar concrete (at the time of completion of the upper half of the advance tunnel).

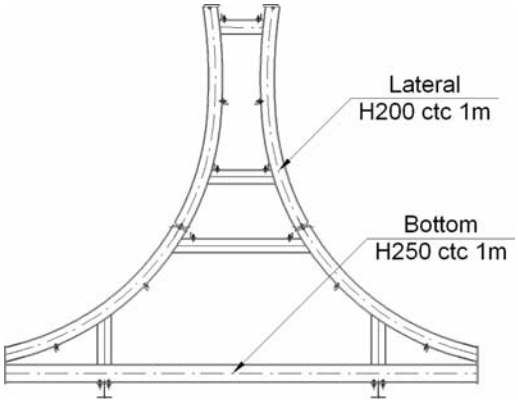

Figure 11. Schematic illustration for reinforcing steel frame layout.

(2) Considering the continuity with primary supports which contain steel rib with the spacing of 1 m, the reinforcements have been decided to execute by equivalent steel supports with the spacing of 1 m, and those effectiveness have been ascertained by both the seismic analysis and the three-dimensional excavation analysis.

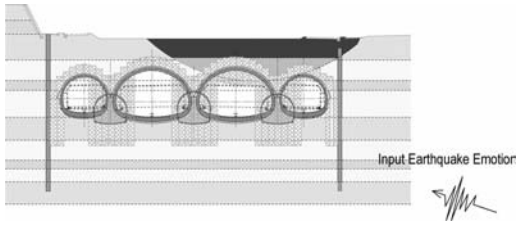

Figure 12. Schematic figure of dynamic analysis during earthquakes.

4 ASEISMIC DESIGN

Regarding seismic stability of secondary lining, it is designed basing on seismic dynamic analyses to secure the safety against the seismic movement in the level equivalent to the actual earthquake motions recorded at the famous Hyogoken-Nambu earthquake occurred in Japan in 1995. Figure 12 shows a schematic figure of dynamic analyses during earthquakes. The Japanese aseismic design codes require the addition reinforcements standing against the induced shear forces for arch and invert concrete.

ACKNOWLEDGEMENTS

Authors express here our deep gratitude to the committee members of the Construction Study Committee, which are organized by West Nippon Expressway Company Limited, who have cooperated with us in this project.

ABSTRACT: Recently, even though designing the twin tunnel is getting more common considering prevention of disasters and environmental disruption, research papers on the twin tunnel are not enough to examine it. Concentration of the vertical stresses and relaxation of the horizontal stresses in the pillar located in the twin tunnel gradually increase by deviation stresses, which causes instability of base rocks. This instability increases according to a decrease in the width of the pillar. In this study, the numerical analysis was carried out on the various conditions to analyze interference effects and behaviors of the stress variation in the pillar according to excavation of the twin tunnel. The induced stress estimation equation of the pillar through the regression analysis on the results of the numerical analysis was proposed. In addition, the quantitative method to estimate the stability of the pillar was proposed by application of Hoek-Brown failure criterion and the proposed equation. In order to enlarge the application of the proposed method, the analysis method was suggested considering reinforcement methods. Lastly, the efficiency of the proposed method was proved by the analysis of various variables.

1 INTRODUCTION

Recently, even though designing the twin tunnel is getting more common considering prevention of disasters and environmental disruption, research papers on the twin tunnel are not enough to ideally examine it. As stated above, the examination of causing stresses of the pillar considering the distance between the tubes and estimation of stability considering the strength of the pillar are very essential when the twin tunnel is designed because the twin tunnel has a progressive failure risk of the pillar by concentration of stresses. When the twin tunnel is designed, things that should be considered first are whether the failure of peripheral rocks comes out or not.

The in-situ ground before excavation balances in stresses, however deviation stresses gradually increase by concentration of vertical stresses and deliverance of horizontal stresses in the pillar between the tubes. As stated, increase in deviation stresses of the pillar by excavation causes the unstable condition of a peripheral rock consisting of the pillar. Hence, the distance of the pillar in behavior estimation of the twin tunnel is a very important factor. In this study, the analysis method to estimate the safety factor of the pillar without reinforcement considering strength parameters, the diameter of the tunnel, the distance from the surface to the crown and the distance between the tubes of peripheral rocks around the tunnel is proposed, and the method to consider a case applying the reinforcement method for the application enlargement of the proposed analysis method on the pillar without reinforcement is proposed.

2 ESTIMATING EQUATION OF THE PILLAR THROUGH THE REGRESSION ANALYSIS

The equation of the regression analysis is the equation 1 using non-linear fitting with the exponential function as the generating function. The estimating equation of the stress ratio (SR_{yp} & SR_{xp}) was determined to the function satisfying that in case strength was better than soft rock, an average square root error was under 5%, and in case strength was worse than weathered rock, an average square root error was under 10%.

$$SR_{ip} = a_i + b_i \cdot \exp[-c_i \cdot (P/D)] \quad (\text{where}, \quad i = x \ or \ y) \qquad (1)$$

Where, represents the stress ratio, and a_i, b_i, c_i represent constants according to the types of base rocks through the regression analysis. Furthermore, if i is equal to x, the equation 1 represents the horizontal direction, and if i is equal to y, the equation 1 represents the vertical direction. The values of constants by the regression analysis are summarized in table 1,

Table 1. The values of a_i, b_i, c_i applied to estimate stress ratio.

Section of base rock Types/Classification	Vertical stress ratio			Horizontal stress ratio		
	a_y	b_y	c_y	a_x	b_x	c_x
Hard / RMR II	1.79	3.18	2.68			
Medium / RMR III	1.79	3.30	2.94	0.93	0.49	1.34
Soft / RMR IV	1.68	2.57	2.65			
Weathered / RMR V	1.48	1.78	2.68	1.10	0.52	1.42
Com. Weatrd. / –	1.29	0.82	1.93	1.30	0.55	1.50

and the relation between stress ratio and regression curves of hard rock and weathered rock. In addition, the constant of horizontal stress ratio in table 1 was determined under the condition that the same constant values were applied to the estimation of stress ratio because the constant values according to the types of base rocks were similar in case strength was better than soft rock. Hence, in case of excavation of the tunnel, the stress ratio considering the types of base rocks, the width of the pillar and the distance from the surface to the crown can be determined by use of the equation 1 and table 1.

The applied stresses of the pillar changed in case of excavation of the twin tunnel are determined by the equation 2 and 3 based on the stress ratio of the equation 1.

$$\sigma_{1p} = SR_{yp} \cdot \gamma \cdot (H + D/2)] \tag{2}$$

$$\sigma_{3p} = SR_{xp} \cdot k_0 \cdot \gamma \cdot (H + D/2)] \tag{3}$$

(In case of $p \geq 2D$, in case of estimating SR_{xp}, $p = 2D$)

Where, σ_{1p} and σ_{3p} are maximum and minimum principle stresses of the pillar. The strength of the pillar that is minimum principle stress (σ_{1p}) of Hoek-Brown failure criterion corresponding to minimum principle stress (σ_{3p}) of the pillar is determined by the equation 4. Hence, the safety factor of the pillar considering the variation of stresses derived by excavation of the twin tunnel in the ground is determined by the equation 5 as the ratio between maximum principle stress (σ_{1p}) derived to the pillar and maximum principle stress estimated by the equation 5 from the Hoek-Brown failure envelope.

$$S_p = \sigma_1 = \sigma_{3p} + \sigma_c (m_b \cdot \sigma_{3p} / \sigma_c + s)^a \tag{4}$$

$$F_s = \frac{S_p}{\sigma_{1p}} = [\sigma_{3p} + \sigma_c (m_b \cdot \sigma_{3p} / \sigma_c + s)^a] / [SR_{yp} \cdot \gamma \cdot (H + D/2)] \tag{5}$$

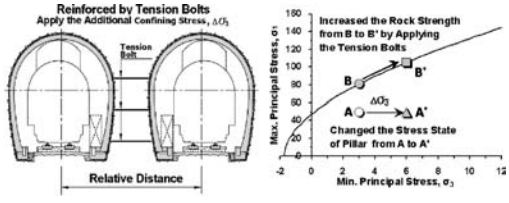
Where, m_b is a Hoek-Brown quota considering the condition of in-situ ground and the types of rocks, s and a are constants depending on the condition of in-situ ground, and σ_c is the unconfined compressive strength of intact rocks. In this study, the strength of base rocks was estimated by use of initial Hoek-Brown failure criterion assuming that it was assumed that $m_b = m$, a = 1/2 because the strength characteristic estimation of base rocks was not a main purpose.

3 THE ESTIMATION METHOD OF STABILITY CONSIDERING THE REINFORCEMENT METHOD OF THE PILLAR

3.1 *Profile on the reinforcement of the pillar*

Overall, in case that obtaining the stability is difficult, the modification of the lines or the reinforcement of the pillar can be used for stability of the tunnel. However, in case of the linear structures like a railroad, road, etc., the modification of the lines is not easy. Generally, the modification of the lines designed first with economical efficiency derives a lot of construction expenses. Hence, the reinforcement method is required to obtain the stability of the tunnel. In this study, in order to increase application of stability estimation method on the pillar proposed, the analysis considering application of reinforcement method is proposed as follows.

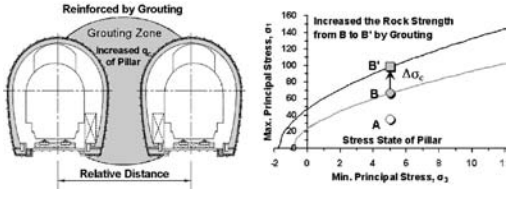
3.2 *Estimation of stability in case of the reinforced method of the pillar*



Of the reinforcement methods of the pillar proposed so far, the tension bolt and grouting method are available in administrative work, and then the profile and principle of reinforcement are illustrated in figure 1 and 2. In case of tension bolt to reinforce the pillar like a figure 1(a), the additional confined pressure causes by installation of tension bolt in the pillar. Therefore, as illustrated in figure 1(b), the additional confined pressure ($\Delta\sigma_3$) derived by the installation of the tension bolts has changed the strength of the pillar ($B \rightarrow B'$) and induced stresses ($A \rightarrow A'$), which increases stability of the pillar. The figure 2(a) describes the instance of grouting for reinforcement in the pillar. In case of grouting for reinforcement, the overall magnitude of the Hoek-Brown failure envelope increases according to an increase in unconfined compressive strength. Eventually, the safety factor of the pillar increases.

In addition, the estimation of the safety factor on the pillar with the reinforcement method can be estimated to the equation 7 based on the equation 5 and 6.

$$\Delta\sigma_3 = q_{tb} / (S_h \cdot S_v) \tag{6}$$



$$F_s = \{(\sigma_{3p} + \Delta\sigma_3) + (n \cdot \sigma_c)[m_b(\sigma_{3p} + \Delta\sigma_3)/(n \cdot \sigma_c) + s]^a\} / \sigma_{1f} \tag{7}$$

Where, q_{tb} is the strength of tension bolt, S_h is the vertical installation distance, S_v is the horizontal installation distance. And n is a quota that represents the degree of increase in unconfined compressive pressure of the pillar by grouting. Generally, it is reported that in case of soft rock, n increases up to 2 times, and in case of weathered rock, n increases up to 4 times,

(a) Tension bolt (b) Principle of reinforcement

Figure 1. The principle and profile of reinforcement by tension bolts.

(a) Grouting reinforcement (b) Principle of reinforcement

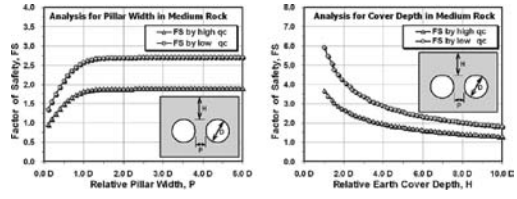
Figure 2. The principle and profile of reinforcement by grouting.

and in case of worse than strength of weathered rock, n increases up to 40 times. In this study, in case of application of proposed reinforcement methods, tension bolt can be applied in the condition of better than the strength of soft rock, and tension bolt + grouting or grouting method is more effective method in the condition of worse than the strength of weathered rock.

4 ANALYSIS AND CONSIDERATION

In this study, the trend of the variation on the safety factor of the pillar was analyzed according to the variation of unconfined compressive strength on the types of base rocks, the width of the pillar, and intact rock except hard rock by using the proposed methods.

When analyzing, unconfined compressive strength of intact rock was applied by use of the values proposed by Bieniawski(1979). The strength of base rocks was applied by use of initial Hoek-Brown failure criterion assuming that $a = 1/2$. m_b and s determined by the types and conditions of base rocks were applied by use of the proposed values on pelite, and the representative values proposed to the analysis are summarized in table 2.



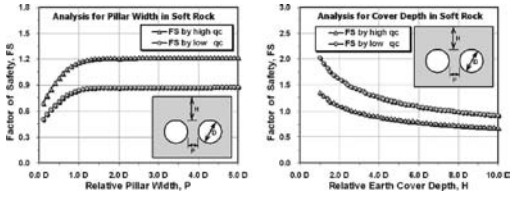
4.1 *Analysis according to the variation on the width of the pillar and the distance from the surface to the crown*

This analysis is about the variation of the safety factor on the pillar according to the variation on the width of the pillar and the distance from the surface to the crown. When analyzing, the compressive strength of intact rock was applied by use of the maximum value and minimum value in the range proposed in table 5. As a result, in case the width of the pillar is over 0.5D and the height of the shaded area is over 10D in hard rock, it is possible to secure the safety factor over 4.0 on the proposed strength of base rocks. However, in case of the completely weathered condition, the trend of the safety factor on analysis was almost same as weathered rock, so it wasn't stated in this study.

Table 2. Representative value proposed to the variable analysis.

Rock types	Compressive strength range (MPa)	H-B constant (pelite, 1980) m_b	s	H (m)	Unit weight (kPa)	Width pillar (P)
Medium	25∼50	1.0	0.004	7.5D	24.8	0.5D
Soft	10∼25	0.2	0.0001	5.0D	22.9	1.0D
Weatrd.	2∼10	0.05	0.00001	2.5D	20.5	1.0D
Com. W.	1∼2	0.01	0	1.25D	18.8	2.0D

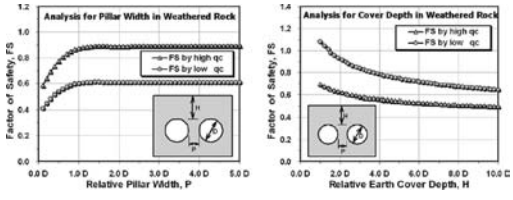
Remark. (1) H: Distance from the surface to the crown; (2) D: Diameter of the tunnel (8.0 m); (3) k_0: 0.5; (4) q_{tb}: 98.0 KPa; (5) Compressive strength: refer to the Bieiawski, 1979.



(a) Width of the pillar (b) Distance from the surface to the crown

Figure 3. The safety factor on the medium rock.

4.1.1 *Results of analysis on the rock*



The results of the analysis are illustrated according to the width of the pillar, the distance from the surface to the crown and the strength of base rocks on the rock in figure 3. As a result of the analysis on the rock according to the unconfined compressive strength of intact rock proposed by Bieniawski, even though the strength of base rocks is 25 MPa that is under the given values, the safety factor according that the width of the pillar is 0.5D and the height of shaded area is 7.5D is 1.487 (Fig. 3(a)).

And even though the height of the shaded area increased up to 10.0D, the safety factor was calculated over 1.0 (Fig. 3(b)). Hence, it is turned out that the security of the safety factor on the pillar in the ground conditions of the rock was comparative easy. In addition, it is turned out that the safety factor was gradually convergent over 1.0D of the width of the pillar.

(a) Width of the pillar (b) Distance from the surface to the crown

Figure 4. The safety factor on the soft rock.

(a) Width of the pillar (b) Distance from the surface to the crown

Figure 5. The safety factor on the weathered rock.

4.1.2 *Results of analysis on soft rock*

The results of the analysis on soft rock were illustrated with figure 4.

As a results of the analysis on the rock by use of the unconfined compressive strength of intact rock proposed by Bieniawski, in case the strength of base rocks was under the given values (10 MPa), it is turned out that the safety factor of the pillar was under 1.0 (Fig. 4 (a)). Moreover, In case the height of shaded area increased up to 10.0D, it is turned out that all safety factors were under 1.0 (Fig. 4 (b)). Hence, it is turned out that the meticulous examination on the security of the safety factor on the pillar was required in the conditions of soft rock.

4.1.3 *Results of analysis on weathered rock*

The results of the analysis on weathered rock were illustrated with figure 5.

In case of weathered rock, it is turned out that all safety factors were under 1.0 on the strength of base rocks proposed (Fig. 5(a)). In addition, in case the strength of base rocks was over the given values (10 MPa), it is turned out that the calculated safety factor was under 1.0 as the safety factor of 1.4D on the distance from the surface to the crown is 1.01 (Fig. 5(b)). Through the results of this analysis, it is reasonable to take into consideration the reinforcement of the pillar on the ground conditions under weathered rock.

5 CONCLUSION

In this study, the regression analysis was carried out on the results of the numerical analysis examined with various variations of the strength of the ground, the width of the pillar and the distance from the surface to crown according to excavation of the twin tunnel. And the quantitatively estimation method of stability on the pillar was proposed by use of Hoek-Brown failure criterion and the induced stress equation of the pillar through the regression analysis. In addition, in order to enlarge application of the proposed estimation method for stability, the estimation method was proposed considering the reinforcement method of the pillar. The results of this study are as follows. First, the various factors influencing security of stability on the pillar were analyzed according to various variations of the strength of the ground, the width of the pillar and the distance from the surface to crown. Through this analysis, it was turned out that the careful examination on security of stability on the pillar was required in case of soft rock, and the reinforcement was required in case of the ground conditions below weathered rock. Then, the variable analysis was carried out according to application of reinforcement methods, and it was turned out that the reinforcement by grouting and tension bolts was effective. Lastly, it is possible for the proposed method to be widely applied to the stability examination of the pillar, application of the reinforcement method and the distance between tunnels in a step for the preliminary design on the twin tunnel. And when considering that the quantitative design method for the configuration of the pillar and reinforcement method is not properly erected, the proposed method in this study is one of the effective methods possible to apply in administrative work.

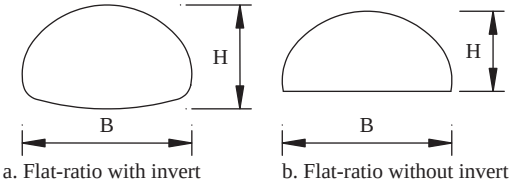
Design and construction of the longest road tunnel with eight-lane in China



H.F. Qu, H.H. Zhu, Y.C. Cai & X.Y. Zhuang
Department of geotechnical Engineering of Tongji University, Shanghai, China

ABSTRACT: Longtoushan Tunnel is a two-way tunnel with eight-lane in either way located in Guangdong province of China. The tunnel has a maximum excavation width of 21.47 m and a maximum height of 13.56 m(including invert arch). Featured by a length of 1010 m one way and a cross-sections area of 230 m^2 in either way, it is the longest and largest tunnel so far in China. Therefore, rational design and construction method is required to assure the stability of surrounding rock and support structure. The paper mainly introduces the successful experience of design and construction on Longtoushan Tunnel. Firstly, the state of design and construction of eight-lane road tunnel in China is summarized. Secondly, design of cross-section, supports, construction, monitoring of Longtoushan Tunnel are presented and discussed in detail. Finally, difficulties and emphases of design and construction, economic benefits during construction are analyzed briefly. According to above experience and methods, the Longtoushan Tunnel has been completed successfully and collapse or accident never happened during the construction.

1 INTRODUCTION

The quick development of economy of China in recent years gave an enormous increase of traffic flow, the usual two-way tunnel with four-lane or six-lane in either way can no longer endure such a heavy traffic burdon. Therefore, eight-lane road tunnels gradually came into being in recent years. The first eight-lane road tunnel named Dageshan Tunnel was built in Guizhou province early in 1999. After that, the second one, Hanjialing Tunnel was built located in Dalian city of Liaoning province. At present, there are two eight-lane road tunnels under construction, one is Yabao Tunnel in Shenzhen city and the other is Longtoushan Tunnel in Guangzhou city. The Table 1 provides the eight-lane road tunnel statistics of China. Here, we defined the flat-ratio β as the ratio of height and span of tunnel ($\beta = H/B$) which is shown in Fig. 1. Height is the distance from the bottom of invert to the crown (if there is no invert, height is the distance from bottom of excavation line to the crown such as right column one of Fig. 1), Width is the longest distance of excavation of cross-section.

Although some experiences are accumulated from the formerly built eight-lane road tunnels, the design and construction of eight-lane road tunnel are still

a. Flat-ratio with invert b. Flat-ratio without invert

Construction method				Double Side Pilot Method
Type	one-way four-lane	one-way four-lane	two-way eight-lane	two-way eight-lane

faced many difficulties because of its characteristic of large-span and low flat-ratio. The paper describes the design and construction of Longtoushan Tunnel which is the longest eight-lane road tunnel in China. The article mentions to provide a reference for the design, construction and study of the extra-large cross-section and span road tunnel.

2 GEOLOGY OF LONGTOUSHAN TUNNEL

Longtoushan Tunnel is located in the eastern section of East-Ring expressway in Guangdong province. It is the longest two-way tunnel with eight-lane in either way ever constructed in China. The tunnel has a maximum excavation width of 21.47 m, a maximum invert arch height of 13.56 m a total length of 1010 m in one direction and a cross-sections area of 230 m^2 in either way. The running speed expected was 100 km/h, traffic flow forecasted was 58710(pcu/d) in 2027. The altitude of tunnel is between 30 m to 166 m along its axis, i.e., 136 m difference in elevation.

Most part of the Longtoushan tunnel crosses the micro-efflorescence monzo- granite. RQD of micro-efflorescence monzo-granite varies between 22% to 88%, ultimate compression strength is from 135.3 MPa to 151.6 MPa. The ground surface of tunnel roof is covered by lush arbuscle and natural grass. At entrance of the tunnel, geological condition is very bad because of serious efflorescence of granite, so it brings some difficulties for construction. In addition, construction is affected by rainfall which reaches 1600–1700 mm/year because of its subtropical marine monsoonal climate.

3 DESIGN OF CROSS-SECTION AND SUPPORTS

Currently, four eight-lane tunnels and tens of six-lane tunnels have been built or are now under construction in China. Usually, a three-centered arch or five-centered arch cross-section was adopted for these road tunnels.

For the first and the second eight-lane road tunnels in China, with reference to the design experience of six-lane road tunnels, three-centered arch cross-section has been adopted because of its well stability. However, a five-centered arch cross-section can reduce the excavation area and is more economic if the stability of tunnel can be assured. Thus, in 2003, five-centered arch cross-section was adopted for the design of Longtoushan tunnel as well as the Yabao tunnel which are the third and fourth eight-lane road tunnel built in China. In addition, the flat-ratio of Longtoushan tunnel is designed less than 0.65 (include the inverted arch) based on the design experience of the large cross-sectional tunnels of Japan(Katushi 2003). Fig. 2 shows the construction cross-section of the

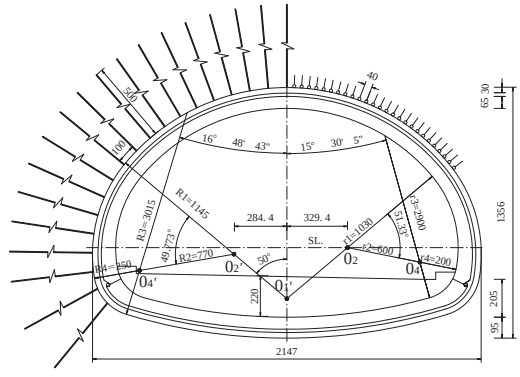

Figure 2. The cross-section of Longtoushan tunnel in V level shallow surrounding rock condition (cm).

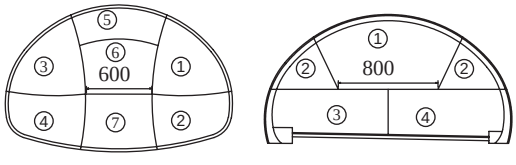
Longtoushan tunnel in V level shallow surrounding rock condition. (Rock mass classification is based on *code for design of road tunnel of china*, it becomes worse from level I to VI.)

Support system of tunnel is composed of bolt, steel arch support, plain shotcrete and concrete lining. Hollow injected bolt is used in this tunnel to improve the tunnel stability. H-steel is adopted in steel arch support with the space of 0.75 m in V level shallow surrounding rock condition. C25 plain shotcrete is used during the construction. The C30 reinforced concrete is used to obtain a reducd design thickness of concrete lining. The parameters of support of Longtoushan tunnel are shown in Table 2.



4 CONSTRUCTION AND MONITORING

NATM(New Austrian Tunneling Method) is used for Longtoushan tunnel construction. Two excavation methods have been adopted considering different ground conditions, which have been divided by *Code for Design of Road Tunnel of china* as shown in Fig. 3. The left one(a) of Fig. 3 was called *Double Side Pilot* excavation method which was used at the portal department or for poor surrounding rock condition such as V and IV levels, and the right one(b) was applied at the comparatively good ground conditions such as II and III levels. The Longtoushan tunnel was designed to minimize the damage to nature environment because it passes through the longtoushan-Mountain Park. Fig. 4 is the photo of excavation in entrance.

Huang Hailun (2005) discussed the rationality of excavation methods mentioned above. He studied the excavation method of eight-lane tunnels of poor conditions based on the physical model experiment and the two-dimensional FEM simulation. The scale of model is 1:5 and three excavation methods (Fig. 5) have been studied in the experiment. The experiment carried by *Integrated Test System for Surrounding Rock Mass of*

(a) (b)

Figure 3. Construction sequence of Longtoushan tunnel (cm).

Road Tunnel which is based on the idea of first loading and second excavation. The system adopts the inlay-jack and high accuracy displacement device in order to simulate and record stress response and change of displacement, and by using it, objective and true simulation of excavation of tunnel can be realized. The results of model experiment and numerical simulation show that *Double Side Pilot* excavation method has the minimum displacement and surrounding rock pressure among three methods, particularly in roof part of tunnel. Therefore, in poor ground conditions, the *Double Side Pilot* excavation is regarded as the most suitable method in China. If there is special poor conditions or urgency, temporary inverted arch can be used in side pilots as Fig. 4 and Fig. 5(b).

Monitoring, the essence of the NATM, was quite extensive after the designer's program. As there are some differences between the eight-lane tunnels and the conventional two-lane tunnels, therefore, monitoring scheme should be improved and perfected gradually in order to adapt to the eight-lane tunnels during the construction. Monitoring of Longtoushan tunnel consists of two parts, conventional monitoring and special monitoring.

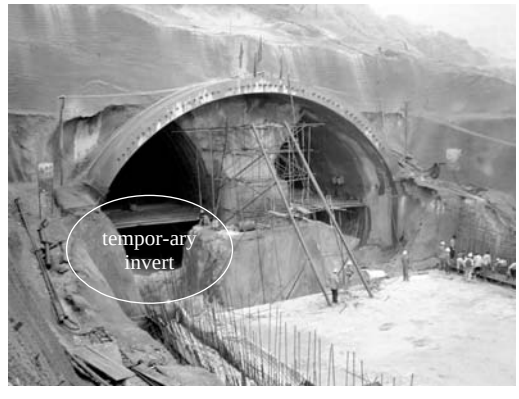

Figure 4. The photo of construction in entrance of Longtoushan tunnel.

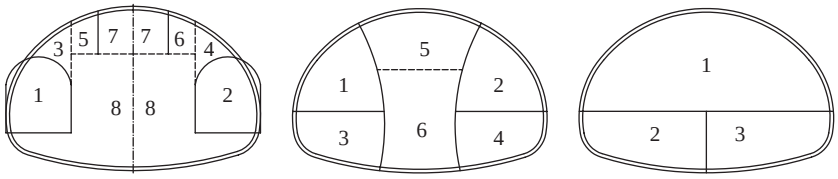
Conventional monitoring includes the convergence and the crown settlement measurements. The purpose of conventional monitoring is to monitor the stability of surrounding rock and primary lining and to provide the guidance for construction of tunnel. Usually it is enough that there are three observation points of displacements and three lines of convergence measure per each measuring section in the primary lining of two-lane tunnels. However, as for Longtoushan tunnel, we disposed a lot of measure points and lines in order to seek the best optimum scheme. Through a lot of tests, we determined monitoring scheme of five points and five lines in which two of them monitor side pilots and three of them monitor the whole tunnel in V and IV levels, three points and three lines in II and III levels. Monitoring schemes are shown in Fig. 6.



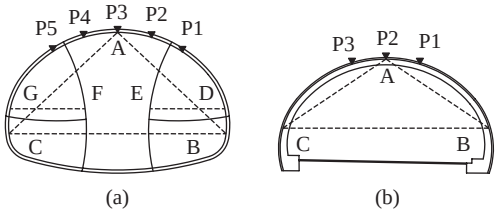


Figure 5. Three excavation schemes.

a. In poor ground condition b. In good ground condition

Figure 6. Monitoring schemes in different ground condition.

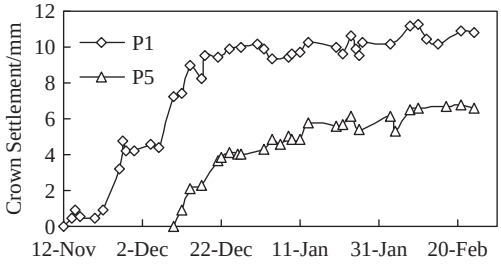

Figure 7. Crown settlement monitoring record of k5 + 859 in left lane in poor ground condition.

Fig. 7 and Fig. 8 are part measure results of crown settlement and convergence in k5 + 859 which is in poor ground condition. In Fig. 7 and Fig. 8, the maximum settlement of crown is only 11.8 mm, and the maximum deformation of convergence is only 22.5 mm. Both of them are less than the allowable value 55 mm. Measure results indicate that the *Double Side Pilot* excavation method is rational.

Special monitoring can provide the data for research topics such as structure optimization design of large cross-section, information construction, information-integration, structure durability and so on. It includes settlement of surface ground, contact pressure, axial forces acting on the steel ribs, axial force acting on the rock bolt, internal force of lining, multi point borehole extensometers(MPBX) as shown in Table. 3. In Longtoushan tunnel, according to the result of MPBX, the dimension of loose zone of V surrounding rock levels is about 10 m.

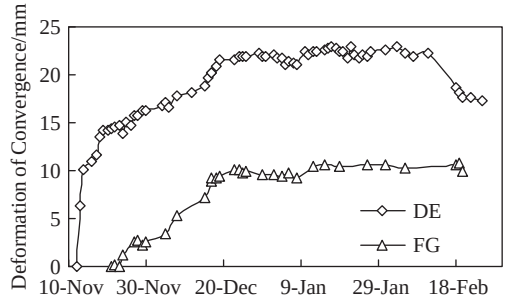

Figure 8. Convergence monitoring record of k5 + 859 in left lane in poor ground condition.

5 DIFFICULTIES AND EMPHASES OF DESIGN AND CONSTRUCTION

During the design and construction of Longtoushan tunnel, there are two distinct characteristics differed from other tunnels. One is adjacent design of oil store. The other is design and construction of unsymmetrical pressure of entrance in shallow ground condition.

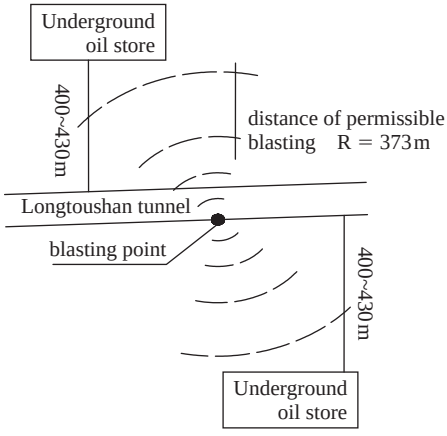

Figure 9. Plane figure of tunnel and underground oil store.

5.1 *Adjacent design and construction of oil store*

Along axes of tunnel, there are two large-scale underground oil stores 400 m distant from the tunnel respectively, which brings us challenge of technology construction. Controlled distance of permissible blasting is the key point in order to avoid the influence on oil stores as shown in Fig. 9. Therefore, techniques of smooth blasting and presplitting blasting are adopted during the construction so that safety shock velocity can be controlled within 1.2 cm/s which is equivalent to IV level earthquake intensity. The equation (1) is used to design parameters of blasting.

$$R = \left(\frac{K}{v}\right)^{\frac{1}{a}} Q^m \tag{1}$$

Where Q is the volume dynamite (kg), v is the safety shock velocity ($v <= 1.2$ cm/s), m is the factor of volume dynamite ($m = 0.5$), K and a are the parameter and decaying exponential which are decided by landform, ground condition and blasting layout and they can be acquired by looking up the table in *Data Ordinary Manual of Engineering Blast* (Yuan 2002).

Three macroseismographs of ALTUS-K2 produced by KINEMETRICS Co. of U.S.A. are adopted to monitor the blasting shock velocity. Table. 4 is the monitoring result of axial line of tunnel direction, vertical ground surface direction and vertical axial line of tunnel direction. In this testing, the volume dynamite is 180 kg, the distances between blasting point and monitoring points are 100 m, 200 m, 300 m separately. From the Table. 4 we can find that the maximum velocity is 1.184 cm/s, it is less than the allowable value 1.2 cm/s.

Table 4. Maximum shock velocity in different direction cm/s.

Distances of monitoring points from blasting point	Axial line of tunnel direction	Vertical ground surface direction	Vertical axial line of tunnel direction
300 m	0.374	0.047	0.609
200 m	1.090	0.209	1.054
100 m	1.184	0.594	0.874

Figure 10. The photo of unsymmetrical pressure in entrance.

5.2 *Design and construction in unsymmetrical pressure ground condition*

As we know that the effect of unsymmetrical pressure ground condition should be properly treated, especially for such a large cross-section tunnel. It usually affects the stability of tunnel directly and brings the potential danger to construction. The unsymmetrical pressure landform of Longtoushan tunnel is shown in Fig. 10. Three measures were applied consequently to avoid development of unsymmetrical pressure. The first one is reinforcement of ground surface injection and backpressure backfill. And then, concrete lining of unsymmetrical form is designed in order to adapt unsymmetrical inner force of lining structure by unsymmetrical pressure landform as shown in Fig. 11. Finally, length of 36 m Concrete lining is built outside mountain after excavation of 10 m distance to enhance the stability of tunnel entrance. Experience proves that above three methods are effectual to control the stability of tunnel entrance, and it ensures the trouble-free operation of construction.

6 ECONOMIC BENEFITS

6.1 *Parameter of support modification*

Steel fiber reinforced shotcrete (*SFRS*) is used in the initial design, however, it is difficult to be carried out

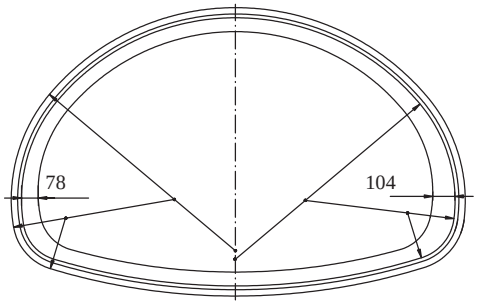

Figure 11. The cross-section of unsymmetrical pressure (mm).

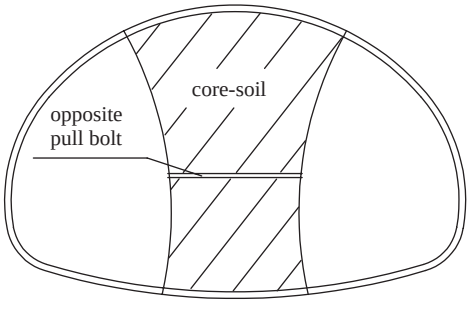

Figure 12. The technology of opposite pull bolt.

during the construction of tunnel because of high technology. Through field tests of 50 m, the plain shotcrete was adopted instead of *SFRS*. Experience proves that plain shotcrete not only meets the strength of design but brings about obvious economical efficiency.

6.2 *Opposite pull bolt instead of temporary inverted arch*

Without question, temporary inverted arch is very effective to control the stability of core-soil and side pilot, however, it also brings some negative effects such as limiting the vehicle running. Therefore, the technology of opposite pull bolt was put forward instead of temporary inverted arch in relative little deformation according to result of monitoring by 5.5 m length and Φ22 reinforcing steel bar in order to restrain the deformation of core-soil as shown in Fig. 12. The technology of opposite pull bolt not only curtails expenditures but shortens construction period.

7 CONCLUSIONS

The paper summarizes the status quo of design and construction of eight-lane road tunnel construction in China. Furthermore, design of cross-section, supports, construction, monitoring and economic benefits are analyzed and discussed in detail based on the Longtoushan tunnel. The building of extra-large cross-section tunnel is just threshold in China, however, with the acceleration of building of infrastructure, the eight-lane road tunnel must be the main design form and instead of four-lane or six-lane road tunnels. For example, a 300 m long eight-lane road multi-arch tunnel will be built in this year in Fujian province. Therefore, we hope that our efforts for the Longtoushan tunnel construction may contribute to the extra-large cross-section and span road tunnel technology in China.

Experiences from driving dual-rail tunnels on Prague metro's IV.C2 route

J. Růžička, M. Kochánek & V. Valeš
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: Two driven route sections with lengths of 977 m and 1,410 m have been carried out as part of building up the 2nd stage of the IV.C route to the Prosek and Letňany area. The paper describes the process of building the route tunnels and the evaluation of the effect of driving the tunnels on the existing structures situated on the ground. Attention will be paid to the spot where the Metro tunnel was driven under two prestressed road bridges traversing a high-speed road, and to the area where the tunnel was driven shallowly, under small residential buildings. To minimise the squeezing of the roof, driving the tunnel using vertical structuring of the stope, makeshift props when the stope was being extended and fixing the head by a system of long laminate fasteners was designed. The results of geotechnical monitoring prove that these measures were efficient.

1 METRO LINE IV.C2

In 2004, the phase 1 of the operational section of the metro line C was put into operation – from Nádraží Holešovice (railway) station to Ládví station. This section is followed by the 4.6 km long phase 2 of the construction IV.C to the area of Prosek and Letňany that will be completed in 2008 and include three new excavated stations Střížkov, Prosek and Letňany, a single excavated inter-station section, excavated manoeuvring rails behind Ládví station and two route sections, driven for their most part. These are sections between Ládví – Střížkov and Prosek – Letňany stations.

The first driven double-track tunnel joins from the west side the excavated manoeuvring rails behind Ládví station, it is 975 m long with a short section of a 80.7 long excavated tunnel, and leads to Střížkov station on the east side. Raising the double-rail tunnel was carried out from the excavation pit of manoeuvring rails, and underhand driving in the opposite direction from the east portal at Střížkov station was performed concurrently.

The second running double-rail tunnel is connected to Prosek station through a short excavated tunnel of 141.7 m. It is 1,287 m long and leads to Letňany station through two running single-rail tunnels of 63.3 m. The development of the running double-rail tunnel was realised from the construction site Klíčov. The access to the double-rail tunnel was provided by descend ramp and short access gallery. The raising to both sides was carried out from the inset point. The double-rail tunnel in the direction of Letňany station is 494 m long, and in the direction of Prosek station 793 m long.

2 GEOLOGICAL CONDITIONS OF THE LINE IV.C2

The bed sequence of the rock environment is similar for both driven lines of running tunnels on the line IV.C2, and it is formed from its top by quaternary sediments and landfills with thickness from 5 to 12 m. These are mostly loess, loess loams and clay-silt-sand loams with detritus (S, D+E). In addition, they are followed by cretaceous formations. The top layer is formed by marlstones (marls) with total thickness from 5 to 10 m. Marlstones (SL) are of various level of consolidation and variable strength. The rock is characterised by tabular and rectangular jointing. Under the marlstone layer, there is a layer of light grey clays (J), which merge into yellow-brown to yellow-grey mudstones. This layer is practically impermeable, it follows the undulating base of marls, and its stable thickness is ca 4 to 6 m. Below, there is a thin layer of glauconitic argillaceous sandstone (GL) with thickness from 1 to 2 m. Its strength is relatively low. Under the layer of soft glauconitic sandstone, there is a formation of quartz Cenomanian sandstones (P), mostly fine-grained. Locally softer layers are crumbly and slack easily into sand. The rock is characterised by tabular and rectangular jointing, with two main systems of fissures, almost perpendicular to each other. Basal chalk formation of clays and mudstones altered with sandstones is located in the sandstone bedrock. These are black chalks with local small coal beds that occur under tunnel bottoms.

In terms hydrogeology, this is an environment with 2 horizons of underground water. There is a turonian

groundwater body based on marlstones with the thickness up to several meters that in some places negatively affected stability of the extraction. This body at some points slightly declines into the layer of impermeable mudstones. In addition to this upper level of underground water, there is also a second (lower) level of underground water in sandstone layers above the grey-black mudstone level. This lower level of underground water revealed itself occasionally by minor outbursts at the bottom of tunnels.

Cenomanian sandstones (P) represented the best geological environment for metro line tunnels on IV.C2 construction. Extractions showed minimum distortion, and also subsidence was low. Increased distortion of extractions and subsidence occurred at the moment, when the tunnel profile started "emerging" from sandstones to the layer of soft mudstones, which tend to press into the extraction profile (confirmed by inclinometer). Problems increased as soon as water tightness of mudstones was disturbed and underground water from lower layers of saturated mudstones started leaking into the extraction. Mudstone layers located in the upper bed of the tunnel have one more negative feature – they create relatively very narrow sunken cauldron. As compared with driving of the same tunnel profile, for example in the environment of less strong Ordovician shalestones, subsidence in the extraction tunnel axis is comparable, but distortion in marlstones disappears quickly at extraction edges. This causes increased frequency of defects in buildings of the aboveground development, in particular when the building reaches above the tunnel extraction only partially.

3 DOUBLE-TRACK TUNNEL LINING

All cross-sections of the double-track tunnel have a shape of a closed flat oval, the dimensions of which respect metro's structure gauges, the arrangement of technical facilities of line tunnels, or eventual suspension of the rail body to reduce the noise and vibration effects on the aboveground development in sections with a low overdburden. Basic profile of the double-track tunnel is designed for the distance between line axes of 3.7 m, with the stope area of 62.20 m^2. For sections where continuous increase of the distance between line axes takes place, other increased profiles of the double-rail tunnel have been designed: 3.9 m, 4.4 m, 5.0 m, 5.8 m and 6.5 m. Jump increase of the tunnel profile is always carried out in these sections.

The double-rail tunnel lining is double-skin lining with closed intermediate foil water-proofing. The outside primary lining is made of shotcrete SB 25 with variable thickness from 200 mm to 350 mm, depending on the actual geological conditions. Water-proofing foil and the inside lining were carried out after a long time interval, after completion of the entire tunnel. The inside lining is made from the monolithic reinforced concrete C 25/30 with the minimum thickness of 400 mm.

4 DOUBLE-TRACK TUNNEL IN THE ROUTE SECTION LÁDVÍ-STŘÍŽKOV

In the most part of the driven tunnel, the distance between line axes is 3.70 m. Only before the portal of manoeuvring rails at Ládví station, the distance of tracks increases gradually up to 4.66 m. The tunnel was driven using a new Austrian tunnelling method (NRTM). Rock disintegration from the west portal was made by a jib cutter Eickhoff 380 with a cross-head. Driving was made in chalk siliceous sandstones with the upper bed of glauconitic sandstone, which with the progressive driving intervene with the extraction. The face of heading was mostly dry without underground water effects. Rock disintegration in driving process in the opposite direction from the east portal was made using a tunnel excavator Schaeff ITC 312. Blasting operations were used for stronger rock layers to a limited extent. Driving was carried out in complicated geological conditions, with rotten and fissured marlstones in the upper bed and the top section of the tunnel profile, and soft mudstones at the tunnel bottom. With respect to underhand driving, the face of heading was affected by underground water due to relatively permeable upper bed. In spite of that, distortions of the extraction were minimal, and also subsidence was small.

Tunnelling in the location, where the double-rail tunnel passes in the close proximity under foundations of bridges for the multilevel junction of Liberecká a Střelničná street was technically the most demanding and also the most interesting section. Within the driven double-rail tunnel, underpinning of medium bridge supports to minimise subsidence caused by tunnel driving, and a method of subsidence levelling at abutments were realised.

5 DESCRIPTION OF BRIDGE STRUCTURES

The bridge structure consists of two independent bridges. Each bridge contains two traffic lanes, 2×3.5 m of width, and a sidewalk, 3.5 m of width. In Liberecká street located under these bridges, there is a four-lane motorway with a central strip and slip lanes with total width of 25 m. The bridge in its longitudinal direction consists of three indeterminate structures of three fields with pairs of medium jugglers with split hinges in base footings. The bridge deck is embedded simply on steel friction bearings of arch abutments. The bridge deck span is $10.80 + 24.60 + 10.80$ m. Its

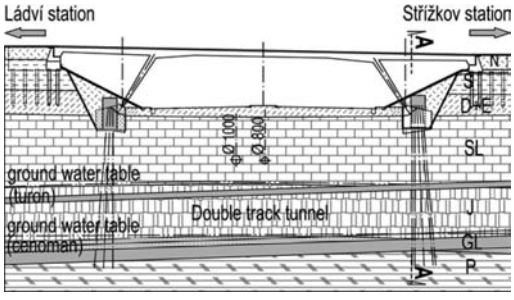

Figure 1. Longitudinal sections of bridges in Liberecká street.

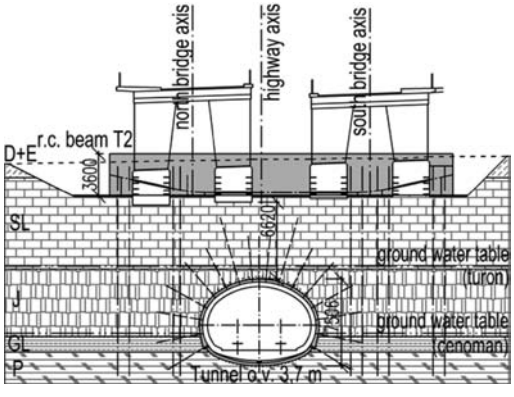

Figure 2. Cross sections of bridges in Liberecká street.

span at the level of base slabs of frame legs is 31.40 m. Arch abutments and bridge wings are embedded on 4.5 m long reinforced concrete piles.

6 TUNNELLING UNDER BRIDGE STRUCTURES

When driving the tunnel under these bridges without taking additional technical measures, subsidence up to 40 mm may occur according to results of mathematical modelling. Based on geo-monitoring results in the driving section outside bridge structures, we can retroactively state that actual subsidence would be up to 30 mm, the existing bridge structure is however not capable to transfer these distortions. To minimise this subsidence, the project designer have proposed underpinning of base slabs of central supports using two teaming pre-stressed reinforced concrete beams embedded on injected micro-piles, the base of which reaches under the bottom level of the metro tunnel. The coupled reinforced concrete beam, 1,600 mm of width and 3,600 mm of height, has connected all 4 base slabs of both parallel bridges. With the proposed method of bridges underpinning, the settlement of central supports has been calculated up to 8 mm at the most.

Subsidence of arch abutments have been levelled using hydraulic presses fitted between abutments and the lower face of the bridge deck. Base slabs plates inserted between the lower and upper bearing section have been used for adjustment.

Other measures have been taken in order to reduce subsidence of bridge structures when driving the tunnel under bridges in 80 m long section. Procedures and outfitting means have been selected so that there is minimum occurrence of distortions of the ambient rock environment. This applies in particular to the max. length of unfitted 1 m attack, the use of self drilling anchoring bolts, densification of 4 m long piles, increasing the thickness of consolidation coating of the extraction, providing the heading face with shot-concrete after each attack, etc. Bottom removal and closing the shell of primary lining was carried out in the distance of 4–6 m from the extraction head. Behaviour of the head in the course of tunnelling in mudstone layers was verified by monitoring before driving under base slabs of the bridge. When driving under sewer collectors in the middle of Liberecká street, it was necessary to proceed with shortened arch anchorage in the top section to avoid drilling in gullies. The entire section was driven using restricted blasting operations, while blasting was completely banned under sewers.

It was unconditionally necessary in the course of tunnel driving to monitor disruptions of the bridge structure by accurate differential levelling. Based on this measuring, it was then decided on subsidence levelling. At the point of arch abutments, subsidence up to 14 mm was observed. Since the limit differences of subsidence determined by the structural engineer were exceeded (max. 5 mm), rectification and levelling of the difference in elevation has been subsequently carried out.

Maximum subsidence measured on supports was 7.5 mm; maximum irregular settlement at the level of supports was 1:1064.

In conclusion, we can state that the measures taken to reduce the extent and irregularity of subsidence of pre-stressed reinforced concrete bridges of the multilevel junction of Liberecká and Střelničná streets were very effective. Project designer's assumptions corresponded well with the reality, and the proposed technical solution of bridge securing when driving the tunnel underneath was correct.

7 DOUBLE-TRACK TUNNEL IN PROSEK-LETŇANY ROUTE SECTION

Basic axial distance between lines of the running double-rail tunnel is 3.70 m and increases gradually in the direction towards stations up to the value of 3.931 m at Prosek station, and 6.559 m at Letňany station.

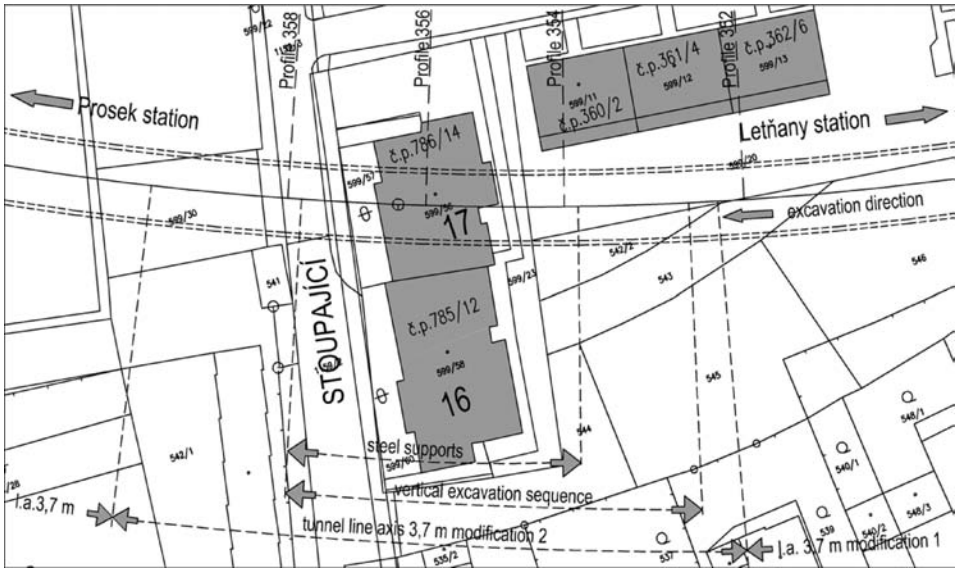

Figure 3. Situation of the metro tunnel under the development in Stoupající street.

The tunnel was driven also by NRTM. Disintegration of rock from the inset point towards Letňany station was carried out using a tunnel excavator Liebher with the assistance of blasting operations. Driving was carried out without difficulties, with minor inflows of underground water. Increased inflows into the underground work occurred at the end of the section, where part of the calotte reached the boundary between mudstones and marlstones. The extraction from driving showed minimum distortion and there was just minor terrain subsidence.

Driving in the direction of Prosek station was also carried out using a tunnel excavator, but without blasting operations. Except for the first 200 m of the tunnel, the driving was carried out in very difficult geological conditions, shallowly under the residential development. Increased disruptions of the extraction and terrain subsidence started occurring when shallow mudstones began to reach the calotte of the extraction. Passing under residential buildings in Stoupající street proved to be the most difficult section in terms of driving, where the horizontal arrangement of the extraction was changed to vertical arrangement. Driving was carried out in complicated geological conditions.

8 ABOVEGROUND DEVELOPMENT IN STOUPAJÍCÍ STREET

The tunnel route passes almost vertically under the building no.17 (č.p.786/14), with adjacent building no.16 (č.p. 785/12), see Fig. 3. The upper bed of the tunnel before the buildings mentioned is ca 12 m thick, and it is reduced to ca 10 m behind these buildings, where ca 3 m are formed by backfills and quaternary soils, and the rest by chalk marlstones (cretaceous marls). The tunnel route continues almost vertically under the local road in Stoupající street, where a sewer gully of 1,300 × 2,100 mm is located. The elevation of the upper bed up to the road level is ca 10 m, ca 6 m of which are formed by marlstones, and the rest upper layer by deluvial soils and sands covered with a loess layer.

Construction works in Stoupající street show many deficiencies. Although in terms of their layout these are two detached residential buildings, their structure is not separated. These are brick buildings with reinforced concrete ceiling panels. Buildings have 4 and 5 aboveground storeys; the floor of the lowest storey is with respect to the ground slope divided into several elevation levels. Buildings are founded on benched wall footings made of mass concrete. Soon after the final building approval, particularly the building no.16 encountered many defects of its structure. It was the case of breaks in building walls caused by movement of the lower building section down the slope. The following causes have been determined: inappropriate foundation method, inappropriate supporting construction, and inappropriate building layout. In 1999, the foundation of the building no. 16 was redeveloped using jet-grouting piles under wall footings. Redevelopment also included installation of linkages connecting both sections. After completion of this redevelopment, control measuring of subsidence was carried out showing stabilised condition of the building.

Table 1. Review of calculated values and actual values measured during tunnelling.

	Mathematical model		Real state	
Arrangement	Horizontal	Vertical	Horizontal	Vertical
Subsidence in tunnel axis [mm]	41.8	16.9	37	18
Max. cross gradient of the valley	1:170	1:800	∼1:300	∼1:600
Extraction arch crown decline measured [mm]	43.3*	18.7*	12–14	6–8

*Total subsidence of the point, incl. subsidence before completing the primary lining and fitting measuring points.

Figure 6. Driving the left partial extraction.

9 TUNNELLING CONCEPT UNDER BUILDINGS ON STOUPAJÍCÍ STREET

During preparation of the building permit documentation (DSP), and in particular the documentation for the contractor selection procedure (DZS), the party preparing the construction-technical survey of the aboveground development warned about poor technical condition of buildings on Stoupající street. For these reasons, a 2D mathematical model (program MISES 3) was created at the beginning of 2003 using the Finite Element Method, where 2 methods of tunnelling were simulated in given geological environment. It is divided between regularly anticipated driving with horizontal arrangement and driving with vertical arrangement of the extraction. The purpose of this model was to compare the extent of maximum distortion of the terrain above the tunnel, synclinal valley width, and maximum cross gradient in the valley. Based on results of this mathematical model, technical condition of buildings and geo-monitoring results from previous sections of the driven tunnel, it was decided on driving with vertical arrangement of the extraction of 60 m in the area of Stoupající street. The table 1 contains a review of calculated values and actual values measured during tunnelling.

10 DRIVING PROCEDURE UNDER BUILDINGS IN STOUPAJÍCÍ STREET

For the primary lining design of the tunnel driven shallowly under the development, minimisation of rock mass distortions and thus maximum subsidence reduction of the terrain, incl. the aboveground development, is necessary. In our case, the lining was designed from reinforced shot-concrete SB 25 with 300 mm thickness. The temporary middle wall in case of vertical arrangement was 250 mm thick. Other outfitting elements include 9 m long piles from steel self-drilling bolts, and up to 6 m long rock anchors from steel self-drilling bolts. Piles and anchors that reached to the second partial extraction were made of laminated self-drilling bolts. Drilling from the access gallery towards Prosek station was carried out with horizontal arrangement. At the distance of ca 30 m before the building no. 17 (Fig. 3), drilling with vertical arrangement was applied, i.e. the left partial extraction was driven first.

Figure 7. Driving the right partial extraction.

Upon completion of ca 20 m long extraction, 35 m long longitudinal laminated anchors with grout were built in the upper section of the heading, where mudstones were encountered (ca 1 anchor/1.5 m^2 of the heading area, total of 11 anchors). This additional measure was to prevent against extrusion of mudstones into the extraction heading. Subsequently, it was followed by driving the remaining left partial extraction of ca 40 m with the maximum 1 m advance per attack. With respect to the size of driving mechanisms, it would not be possible to maintain the temporary middle partition wall during subsequent driving of the right partial extraction. Therefore another additional measure was proposed under the building no.17 in the length of 40 m to reduce building subsidence.

In the left partial extraction, a temporary wall footing was concreted at the bottom of the primary lining that was fitted with iron props (tubes with Ø279/8 mm) in the interval of 2 m. They were activated by filling the contact of the prop head and the primary lining with shot-concrete. When driving the right partial

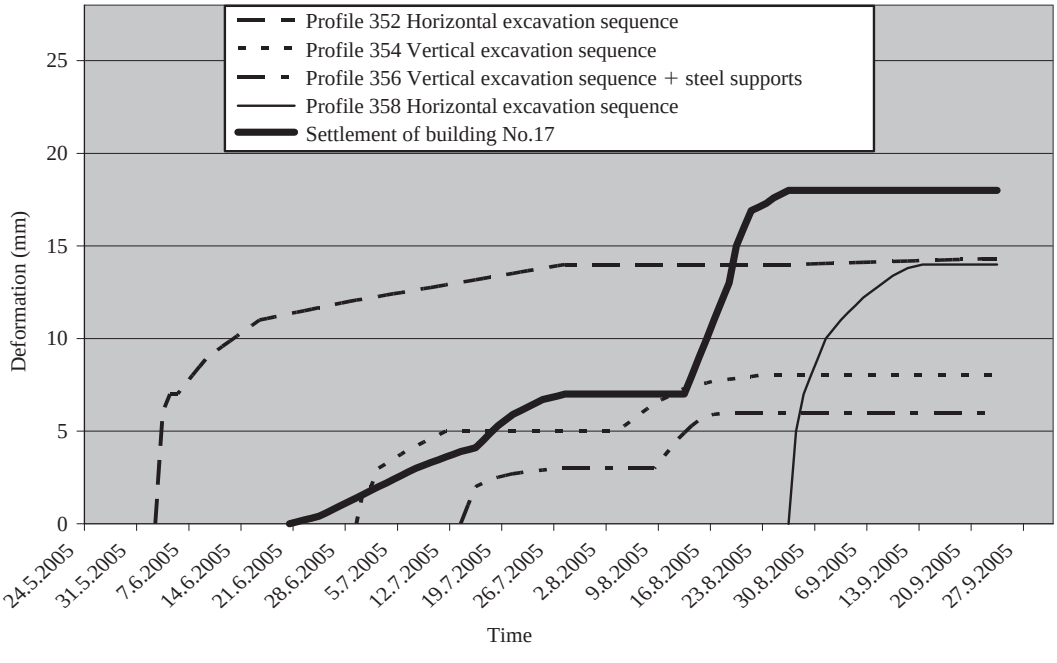

Figure 8. Diagram of the course of distortion of the tunnel extraction arch and settlement of the building no.17.

extraction, the temporary middle wall was gradually demolished and vertical load was transferred to metal props.

These were removed after the shot-concrete of the primary lining of the right tunnel side hardened to its required strength. Efficiency of this measure was verified by measuring of temporary props load. It ranged between 800 to 1000 kN, which corresponded very well with the static calculation. Distortions of the primary lining after props removal ranged between 1 to 2 mm, at the very border of measurability. This also indicates efficiency of this supplementary measure.

11 EVALUATION OF CONVERGENT MEASURING AND SETTLEMENT OF THE BUILDING NO.17

In that situation (Fig. 3), selected convergent profiles with measured extraction distortions are indicated. The diagram in Fig. 8 shows time-dependent vertical displacements of the tunnel arch top. For comparison, there are measured values of the maximum settlement of the building no. 17 stated in the diagram that correspond with respective convergent profile 356, installed in the same place. It is apparent that the measured vertical displacement of the top of the tunnel arch amounts to ca 30 to 40% of the total terrain settlement. Profiles 352 and 358 are in sections, where driving with horizontal arrangement is applied, profiles 354 and 356 are in sections, where driving with vertical arrangement is applied.

12 CONCLUSION

The measures taken to reduce subsidence of the critical building no.17 in Stoupající street were very efficient. They were however very demanding in terms of time and finances. Removing statically unimportant defects in the residential development in sections with horizontal arrangement of the tunnel extraction is naturally considerably easier. It is therefore necessary to always consider use of these procedures and to select them in urgent cases only, in particular if the static function of the building passed under is jeopardised, or eventual faults removal in the building would be unacceptable for financial or other reasons.

ABSTRACT: A technique of building structures that traverse under existing railways or roads has been developed to construct small section grade separation structures such as footpaths and channel boxes without using an open-cut method. This method allows construction of a structure with a rational section under a road or track protection composed of steel plates and steel supports. This paper outlines this method and reports on the series of verification tests conducted prior to practical application.

1 INTRODUCTION

In recent years, more cases have been seen in Japan of non-open-cut methods used for building structures that cross under roads or railway tracks.

Non-open-cut methods include several techniques. Crossing structures under roads and railway tracks that use conventional non-open-cut methods are intended mainly for large section roadway boxes and their direct application to small section structures such as footpaths and channel boxes may end up with disproportionately large protection (including auxiliary methods) for the scale of the structure. As has been pointed out, this method results in protective measures occupying an excessively large proportion of the construction costs. In element methods that do not require special road or track protection, the sizes of elements are limited by workability requirements, which results in construction work that is disproportionately large for small-scale structures and comparatively high prices. To address these issues, a method called COMPASS (COMPAct Support Structure) has been developed as a method of construction of small section grade separation structures that allows rational structural sections and is more economical than the conventional methods. In this method, a structure with a rational section is built under a road or track protection composed of steel plates and steel supports. Steel plates are pulled and inserted along the circumference of the planned structure that has been previously cut with an earth cutting wire. The steel supports are installed when the inside of the steel plates has been excavated with a cutting unit. These components function as part of the road or railway track protection and the plates and supports respectively provide the outer form for the building of the structure and part of the structure. This paper reports on the results of the series of construction tests conducted prior to practical application of the COMPASS method.

2 OVERVIEW AND CHALLENGES OF COMPASS METHOD

2.1 *Overview of COMPASS method*

Figure 1 shows the construction processes of the COMPASS method. In this method, two earth cutting wires (11 mm in diameter) are provided, with one over the other, to first cut the ground, steel plates (22 mm thick) for protection are inserted in the cut ground and the structure is built inside the steel plates. The supports erected when the inside of the steel plates has been excavated (the lower slab and sidewalls are wide-flange beam supports and the upper slab a truss support) are not removed and embedded in concrete, forming inside the steel plates an SRC (steel plus reinforced concrete) structure.

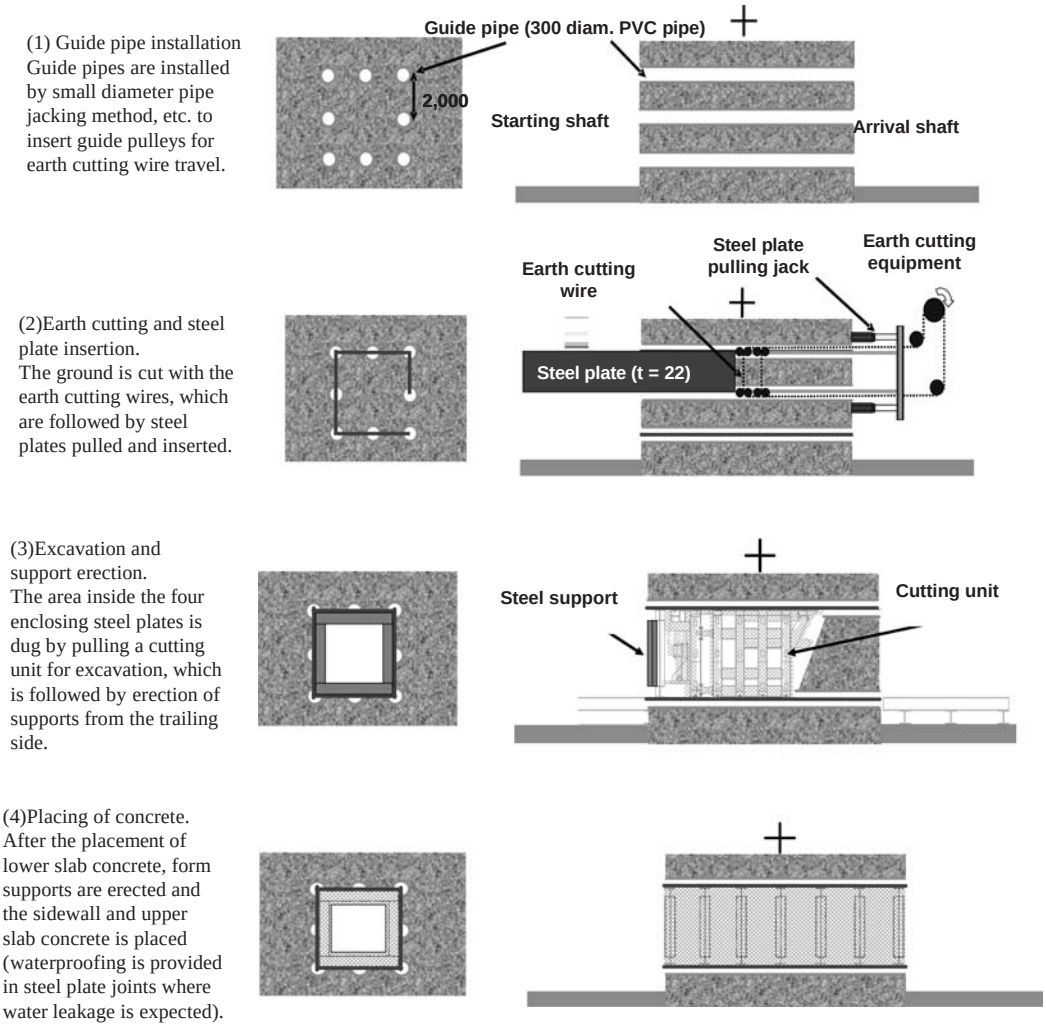

Figure 1. Construction procedure of COMPASS method.

2.2 *Challenges*

For the method to be put into practical use, the following issues have been found to require solutions:

(1) The friction between the ground and steel plates generated during the insertion of the plates may move the soil above horizontally.
(2) Because steel plates with lower rigidity than conventional pipe roofs (steel pipes) are used as protection, excessive vertical displacement may be generated.
(3) Insertion of steel plates must be possible in the ground with obstacles such as large gravel and cobble stones.

To address these issues, tests for earth cutting/inserting steel plate, for excavation of the inside of the steel plates with a cutting unit and for placing upper slab concrete have been conducted for verifying the practicability of the method.

3 TEST FOR EARTH CUTTING AND INSERTING STEEL PLATES

3.1 *Test overview*

Figure 2 shows an overview of the test and Figures 3 and 4 illustrate test conditions. For the test, simulated

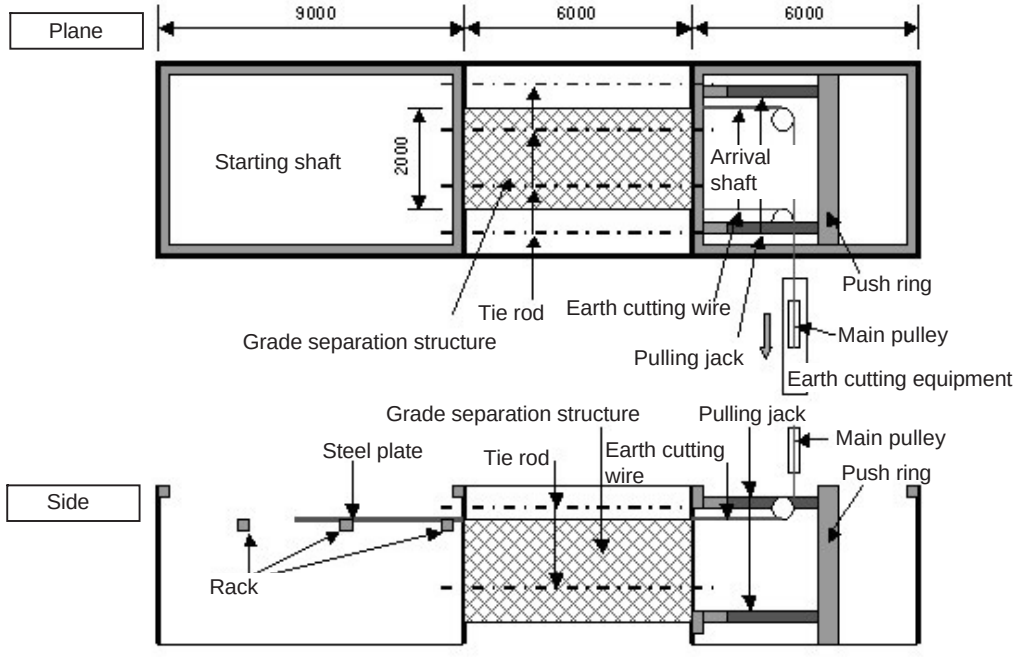

Figure 2. Overview of earth cutting and steel plate insertion test.

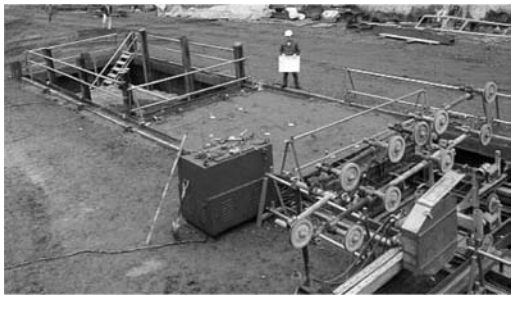

Figure 3. Test for earth cutting and inserting steel plates (full view).

Figure 4. Test for earth cutting and inserting steel plates (starting shaft).

ground of sandy soil was made by mixing 20 percent gravel of 80–350 mm diameter between the starting and arrival shafts (6.0 m in length). This sandy soil was cut by pulling the earth cutting wires with the earth cutting equipment installed beside the arrival shaft while a steel plate was pulled with a traction apparatus composed of a pulling jack and push ring. The steel plates measured 2.0 m in width and 22 mm in thickness. The plates were inserted starting with the upper slab and then the lower slab and vertical walls (left and right) in that order to form a square section of 2.0 m by 2.0 m. The simulated ground made was found to have an N value of approximately 5 as determined by a rapid dynamic cone penetration test. The N value distribution in the simulated ground is shown in Figure 5.

In addition to the vertical and horizontal displacements of the simulated ground, behavior of the wire drive unit was measured. Table 1 lists the items measured in this test, where the axial torque of main pulley refers to the torque of the hydraulic pulley that runs the earth cutting wires, and the value increases when gravel is cut or the pulling speed is rapidly increased[1)]. Figure 6 shows the plan of measurement points for vertical and horizontal displacements. The vertical and horizontal displacements are measured at positions of 0.3 m earth covering.

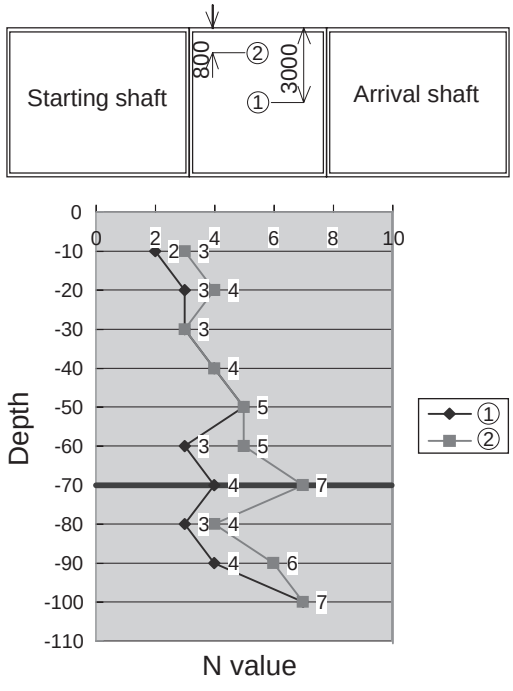

Figure 5. N value distribution in the simulated ground.

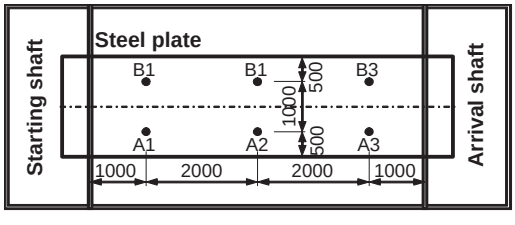

Figure 6. Plan of displacement measurement points.

3.2 *Test results*

3.2.1 *Steel plate insertion*

The appearance of the steel plates as their insertion is complete is shown in Figure 7. The plates were inserted as planned without being hampered by gravel and a square section was successfully formed. No rupture of the earth cutting wires occurred. Figure 8 shows gravel cut with an earth cutting wire.

3.2.2 *Vertical and horizontal displacements of the ground*

Figures 9 and 10 show vertical and horizontal displacements of the ground during the insertion of the upper slab. Horizontal displacement toward the arrival shaft is taken as positive and that toward the starting shaft as negative. While some variation was observed for either case depending on the point of measurement,

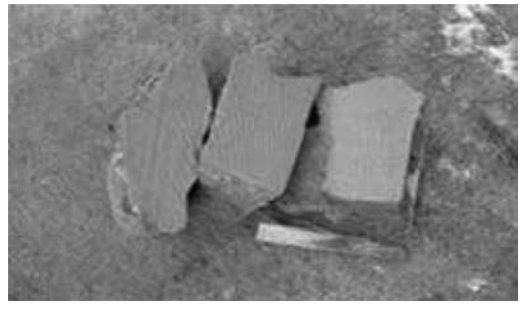

Figure 8. Cut gravel.

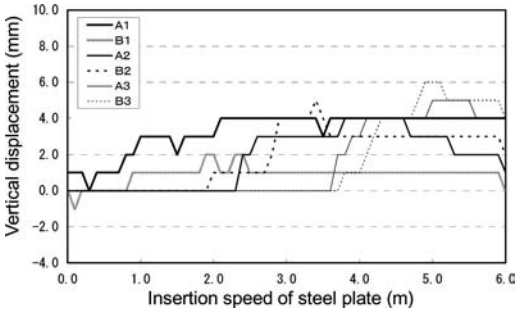

Figure 9. Vertical displacement (during insertion of upper steel slab).

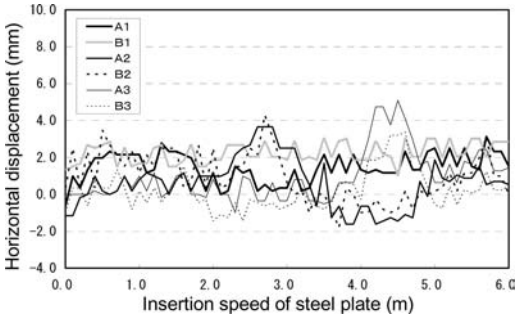

Figure 10. Horizontal displacement (during insertion of upper steel slab).

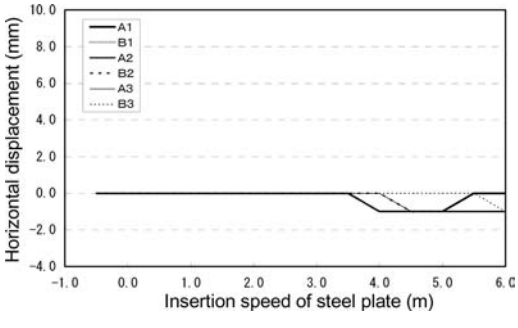

Figure 11. Vertical displacement (during insertion of lower steel slab).

vertical displacement of up to 6 mm was induced with an average of 3 to 4 mm and horizontal displacement toward the arrival shaft of up to 5 mm with an average displacement of 2 to 3 mm.

Almost no vertical or horizontal displacements were observed during the insertion of the sidewalls and lower slab. Figure 11 shows the vertical displacement during the insertion of the lower slab.

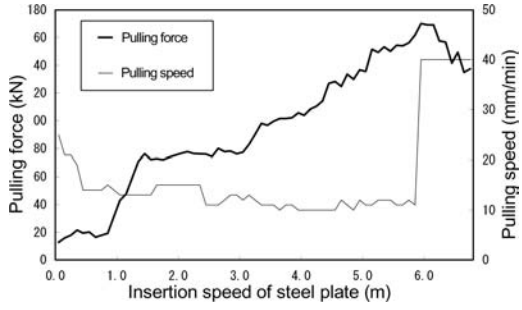

Figure 12. Pulling force vs. pulling speed (during insertion of lower steel slab).

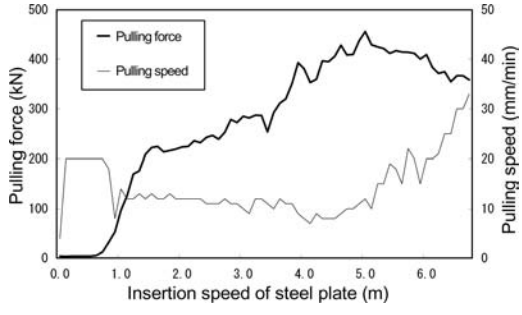

Figure 13. Pulling force vs. pulling speed (during insertion of vertical steel plate).

3.2.3 *Pulling speed and pulling force*

Figures 12 and 13 show the results of the measurements of the pulling speed and force during the insertion of the lower slab and vertical steel plate (on the right side as seen from the starting shaft). These figures indicate that, with a constant pulling speed maintained, the pulling force increases as the friction area between the steel plate and natural ground becomes larger.

The pulling force during the insertion of the vertical steel plate is larger in value than during the insertion of the lower slab. This is presumed to be because, for this test, the vertical steel plate was inserted as engaged via joints with the upper and lower slabs inserted earlier, which generated engaging friction.

4 TEST FOR EXCAVATION OF THE AREA INSIDE OF THE STEEL PLATES WITH A CUTTING UNIT

4.1 *Test overview*

The procedure of this test is shown in Figure 14 and the excavation conditions inside the steel plates in Figure 15. For this test, the inside of the steel plates which had been inserted in the test for earth cutting

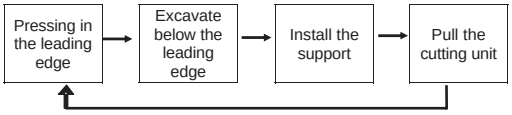

Figure 14. Test procedure.

Figure 15. Test (during excavation).

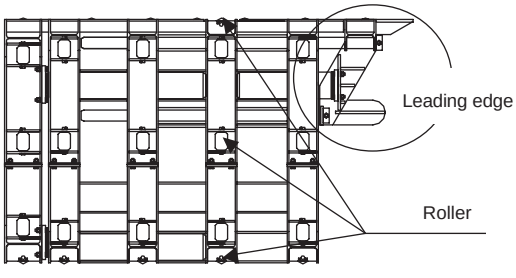

Figure 16. Cutting unit overview.

and inserting steel plates, was cut with the cutting unit specifically designed for excavation of the area inside the plates, and steel supports (H-250 ×250, 1.0 m spacing) were installed. Figure 16 and Figure 17 show the overview of the cutting unit. This unit has a leading edge that is extendable from the unit by means of hydraulic jacks, which makes it capable of being pressed into the ground first. The four sides of the unit that come in contact with the steel plates have rollers, which support the plates as the cutting unit moves forward, and contribute to the reduction of friction between the unit and steel plates. The cutting unit was pulled by pulling prestressing steel bars using the four hydraulic jacks installed on the arrival shaft. As with the test for earth cutting and inserting steel plates, vertical displacement was measured at positions of 0.3 m of earth covering on the upper slab for this test. Figure 18 shows the plan of measurement points.

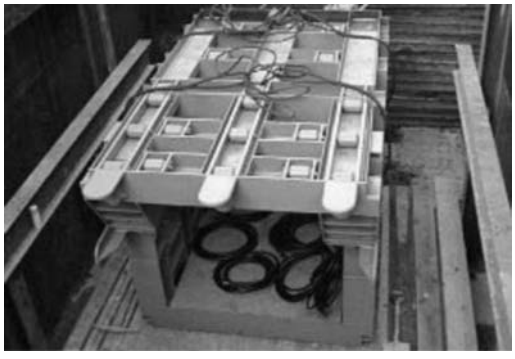

Figure 17. Full view of cutting unit.

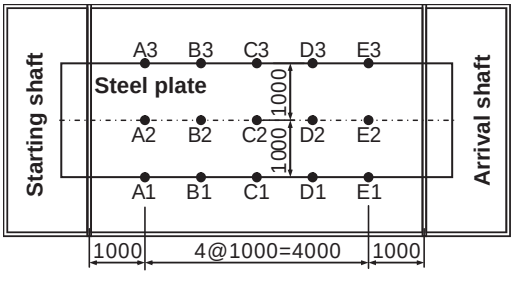

Figure 18. Plan of vertical displacement measurement points.

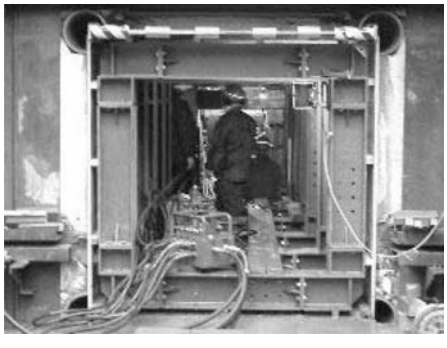

Figure 19. Test completed.

4.2 *Other results*

Figure 19 shows the view at the completion of the test and Figure 20 the results of the vertical displacement measurement at the end of the test. Settlement of up to 23 mm was observed in this test. Study of the settlement of the individual stages of the work reveals that there was a certain tendency toward heaving during the pressing in of the leading edge and erection of supports but almost no displacement was generated during the pulling of the cutting unit, which indicates that the settlement occurred during the excavation.

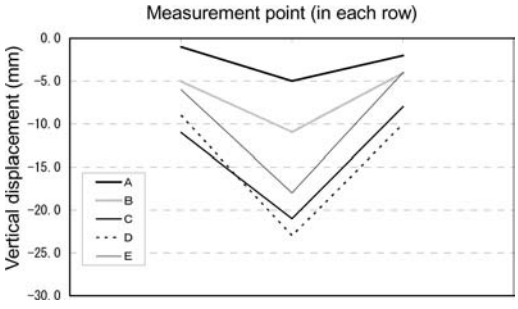

Figure 20. Results of vertical displacement measurements (at completion of test).

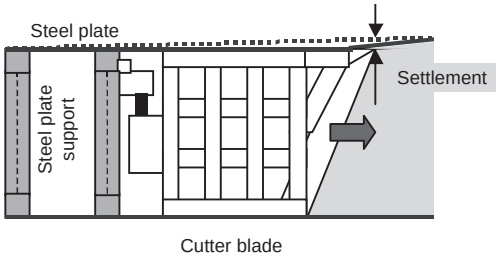

Figure 21. Schematic diagram of cause of settlement during excavation.

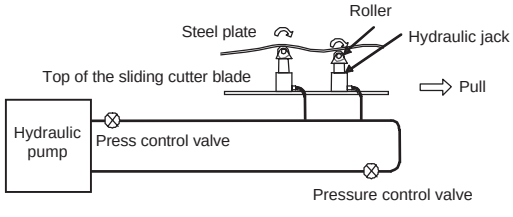

Figure 22. Overview of the adjustable height roller.

A possible cause of the settlement during the excavation is the slightly upward insertion of the steel plate that generated a gap between the plate and the cutting unit, which was horizontally pulled for digging, resulting in the settlement as large as the gap. Figure 21 is a schematic diagram of the cause of settlement during excavation. Regarding this problem, settlement is presumed to be controllable by replacing the roller mounted on the cutting unit with adjustable height units. Adjustable height rollers have also been tested and their ability to support flexibly according to the irregularity of steel plates has been verified. Figure 22 shows an overview of the adjustable height roller.

5 CONCLUSIONS

A series of tests of construction using the COMPASS method have been completed and the following conclusions have been reached. In addition, practicability of the technique has been verified:

(1) The mechanism of earth cutting and steel plate insertion used in this test allows insertion of a steel plate of 2.0 m in width and 22 mm in thickness into ground that contains gravel.
(2) During insertion of a steel plate, no displacement that is large enough to affect the track is generated.
(3) Although settlement of about 23 mm occurred during excavation inside the steel plates, settlement can be controlled by using adjustable height rollers on the cutting unit.

Civil tunnelling with electronic blasting systems – Early experience from Korea

Young-Suk Song
Hanwha Corporation, Commercial Explosives Division, Korea

Dave Kay
Orica Mining Services, Australia

ABSTRACT: To meet the needs of South Korea's rapidly expanding economy, a large number of infrastructure project are under way to improve transportation efficiency within the nation. These projects include high speed rail links between major population centres and improvements to the road network. Being densely populated and geographically mountainous, infrastructure development in Korea requires a significant amount of tunnelling. Owing to the predominantly hard granitic nature of rock, Drill and Blast is the preferred method of tunnel advance. The Korean tunneller, however, faces the same pressures as those of his international counterpart; that both cost and production targets need to be achieved whilst meeting expectations of both community and regulator. The growing acceptance of electronic blasting systems now presents a number of opportunities to the civil tunnelling sector. Conventional initiation systems used for full face firing of large tunnels are hampered by limitation of delay periods and their firing accuracy. The availability of fully programmable and accurate delay systems now open a number of possibilities to the civil tunneller, opposite advance rate, excavation efficiency, perimeter control and environmental conformance. This paper details a series of blasts undertaken at the Kang Chon 1 Tunnel on the 7th Zone of the Kyung – Chun Railway Line Construction. A blast measurement program was undertaken to firstly benchmark two conventional blasts followed by three blasts fired with the i-kon™ Electronic blasting system. Key parameters were measured including rock mass evaluation, tunnel advance, blast fragmentation, perimeter control and vibration. The paper concludes with indications of improvements to perimeter control and a higher confidence level in vibration predication. It then points to further possibilities for electronic blasting systems in civil tunnel applications.

1 INTRODUCTION

South Korea is said to be one of the most mountainous countries in the world with 70% of land mass occupied by rugged terrain. It also has one of the highest population densities in the world. To meet the needs of growing population and industrial development, infrastructure projects are underway to improve transportation links between major population centres. Given the predominant terrain and populous nature of the nation, preference is given to a 'straight line' method requiring significant use of tunnel and bridge for both road and rail construction. Granite and limestone rock are dominant, thereby making drill and blast the preferred method for tunnel advance. Korean civil engineers and tunnellers are therefore faced by a number of challenges, not uncommon to their international counterparts – to complete projects on time, within budget whilst meeting the environmental expectations of both community and regulator. One such project is the Kyung-Chun Railway Line Construction which is providing a complete double track link between the South Korean city of Chunheon and the capital of Seoul.

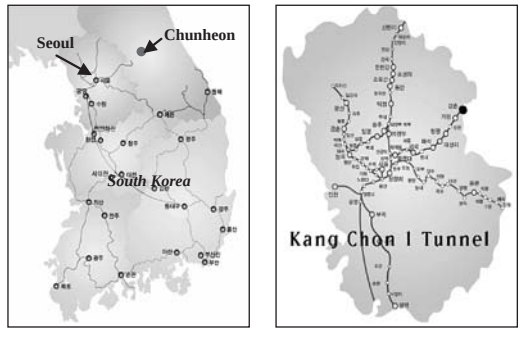

Figure 1. Rail network map of South Korea.

Opportunity arose to fire 3 'full face' tunnel rounds in the Kang Chon 1 Tunnel of the 7th Zone of the Kyung-Chun Line construction using the i-kon™ Digital Energy Control System and perform some preliminary assessment verses conventional pyrotechnic signal tube initiation. It also allowed for a fresh look at initiation timing possibilities for large civil tunnels. This paper is a summary of the results obtained from a series of 5 firings in the Kang Chon 1 Tunnel – 2 preliminary bench marking blasts using conventional non-electric (NE) initiation followed by 3 firings by electronic blasting system (EBS) and modified timings. It should be noted that the results were obtained under 'production conditions' whereby data collection and trial quality were dictated by operational needs. This paper will describe these limitations and attempts made to normalise the results to give performance indicators opposite key aspects of the tunnel cycle including: perimeter control, advance, fragmentation and vibration.

2 THE KANG CHON 1 TUNNEL

The Kang Chon 1 Tunnel is one of several on the 7th Section of the Kyang-Chun Line. It's completed length will be of 2500 m (8197 ft) with cross sectional dimensions of 10.6 m (34.6 ft) wide by 8.4 m (27.6ft) high and a face area of 88 m^2 (946 ft^2). The major rocks present are granite gneiss or banded gneiss with sporadic quartz dykes and scattered cubic jointing observed. A rock mass rating (RMR) gives a result of 66 indicating a medium hardness rock. A 12 hour cycle is worked which includes the following elements : mark-up, drill, charge, fire, excavate, scale, bolt and shotcrete. Typical blasting parameters give 116 (45 mm diameter – 13/4″) shotholes drilled with a V Cut (wedge), with a centre stab hole, for 3.5 m (11.5ft) round depth. Shotholes are charged with 32 mm (11/4″) dia. MegaMITE cartridge explosives and stemmed with wet sand plugs. Perimeter holes are charged with NewFINEX 17 mm (0.7″) pipe charge. Initiation uses a range of millisecond (20 ms) and long period (100 ms) HiNEL, non-electric (NE) detonators. To off-set the timings the face is fired in 4 bunches with the bunches fired with 0 to 42 ms trunkline delays. A conventional face timing is shown in Figure 2.

3 ELECTRONIC INITIATION DESIGN

Given the accuracy and flexibility of the electronic blasting system (EBS) it was decided to redesign the face timing based on a number of good blasting principles. The V Cut timing was left the same as conventional, thus to minimise risk related to cut failure, giving 3 holes firing at any one instant. Once outside the V Cut, timing was set to give single hole firing

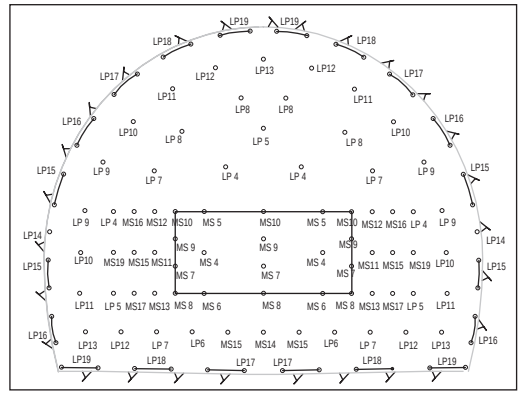

Figure 2. Conventional non-electric timings with MS and LP series detonators.

Figure 3. Change of rock quality in tunnel face.

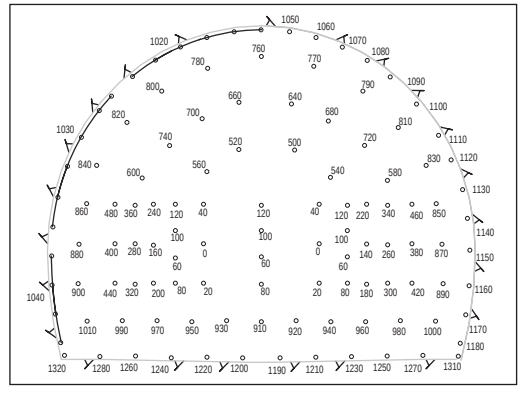

Figure 4. Generic electronic timing used in the blasts.

within a 20 ms window, working direct opposites from the initial cut. With the cut extension removed the face holes were set at 10 ms, off-setting either side of centre. The perimeter was to be fired in 2 halves. One

half was fired in instantaneous batches of 6 holes to gauge the effect of post-split perimeter control, whilst the other half was fired on 10ms delay interval. The delay verses batch firing sides were swapped on alternate firings to negate the effect of geology. The lifter holes were designed to fire on 10ms delay off-set either side of centre. Total blast duration was reduced from 3.2 seconds to 1.3 seconds.

4 TUNNEL CONDITION

During the trialing period a phorphory intrusion entered the left hand side of the tunnel face. This caused a number of poor rounds both with the two non-electric blasts and the first electronic blast. The tunnel contractor decided to increase the number of shot-holes drilled from 116 to 132. This change may have masked some results, however attempts were made to normalise the outcomes by swapping perimeter technique left and right and to compare results only in similar ground. Following is a summary of the results obtained.

5 VIBRATION ANALYSIS

All blasts were monitored for vibration and airblast. Up to 4 monitors were used for each blast spaced along the tunnel at distances of 131 m to 604 m from the tunnel face. To give statistical credibility a further two non-electric blasts were included that were monitored the week previous.

A regression analysis on the above data revealed the following

Furthermore a comparison of the near field vibration traces was conducted. The available vibration recording time was only 2 seconds therefore latter stages of the non-electric blast is missing.

The following conclusions can be drawn from the above data:

1. Comparison of the regression analysis shows that both systems gave similar results for the K (geological constant) and n (reduction level). This is expected in that all the results are taken in the same rock mass with similar explosive weight per delay and indicates that rock mass is not a significant factor for the difference in result. It can however be seen that regression line for the electronic blasts gives an r^2 value of 0.953 compared to 0.653 for the non-electric system. This indicates that the vibration prediction will be far more reliable with electronic blasting.
2. Comparing the vibration traces; it can be seen that the ppv generated in the Cut was slightly higher for the electronic blasting system. This is not surprising as the design allowed for 3 shotholes firing same delay and the accuracy of the EBS would guarantee

	219	1.38	2.67	2.56	2.92	102.0	
	299	1.41	1.17	1.75	1.87	98.0	
	529	0.476	0.540	0.873	0.905	101.0	
EBS 3	137	8.26	2.16	2.92	8.37	97.2	6.375
	222	1.51	3.02	2.49	3.13	103.0	
	302	1.48	1.13	1.21	1.94	99.8	
	532	0.460	0.381	0.667	0.730	99.6	

instantaneous firing of these holes. The non-electric system gave higher ppv in the cut extension, due to the fact of more shotholes firing within a tight time window, and the EBS now operating on true single hole firing at 20 ms interval. This is similar with the face where the EBS has true single hole firing and the NE system now operating with multiple holes firing at the upper end of the delay range. The EBS gave higher readings in the perimeter, probably due to multiple holes firing in batches on same delay compared to the NE system. The highest vibration came from the EBS lifter area firing on 10ms delay. The reason for this is not fully understood and needs more work to assess if this is related to reinforcement due to a tight time window. Opportunity exists to refine this in future tests.

6 FRAGMENTATION SIZE ANALYSIS

Fragmentation analysis was conducted for all five blasts using photographic image analysis. An example is shown in Figure 7. The non-electric detonator showed the average (P_{50}) fragmentation size of 34.9 cm verses 31.2 cm for the EBS, indicating a size reduction of 11% with the overall results showing a uniform distribution. No direct conclusion can be draw here.

7 PERIMETER CONTROL

A series of photo's were taken of the perimeter at the completion of each blast for digital analysis, by

EBS				

assessment of Half Cast Factor (H.C.F). An example of the technique is shown in Figure 8.

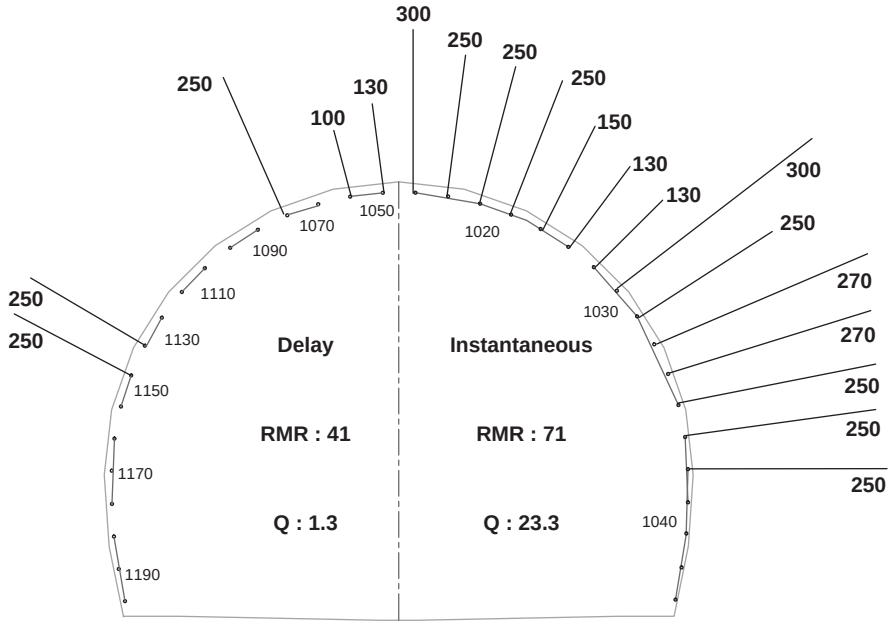
Owing to the change in rock type between left hand and right hand side, the results are presented as a series of comparisons between non-electric vs. electronic, simultaneous vs. delay, and the difference between simultaneous vs. delay in each side of the tunnel face.

The following comparisons were obtained using the above analysis technique.

Table 5. HCF of EBS Instantaneous batch vs delay fired perimeter.

H.C.F	0∼25 V.P	25∼50 P	50∼75 G	75∼100 V.G
EBS Instantaneous				
EBS Delay				

Table 6. HCF of EBS Instantaneous batch vs delay fired perimeter.



H.C.F	0∼25 V.P	25∼50 P	50∼75 G	75∼100 V.G
EBS Instantaneous				
EBS Delayed				

Table 7. Instantaneous firing vs delay firing in excellent ground (RMR:71).

H.C.F	0∼25 V.P	25∼50 P	50∼75 G	75∼100 V.G
EBS Instantaneous				
EBS Delayed				

Table 4 shows that all non-electric perimeters gave a HCF of 49.7% verses all electronic perimeters with 57.6%. This result is taken in both the left and right side of the tunnel face and with delayed and instantaneous firing. Table 5. compares EBS instantaneous firing with EBS delayed firing of perimeter in both sides of the tunnel. Overall instantaneous firing gave a HCF of 68.85% verses delay firing of 44.75%. Table 6. gives a comparison of instantaneous verses delayed firing in the right hand side of the tunnel where the RMR was 71 (classified as 'excellent' rock). Instantaneous firing gave 82.6% HCF verses 63.1% HCF with delay firing. Table 7. shows the difference between instantaneous and delay firing in the left hand side of the tunnel where the RMR was 41 (classified as 'good'). Instantaneous firing gave 55.1% HCF verses delay firing with 26.4% HCF.

From these results it can be concluded that EBS firing has a positive influence on perimeter control compared to NE firing. It is also concluded that instantaneous firing of perimeter yields better result than delayed firing. The HCF analysis technique confirmed

H.C.F (Half Cast Factor)

H.C.F = 1030/(300×13 holes) = 26.4%

H.C.F = 3220/(300×13 holes) = 82.6%

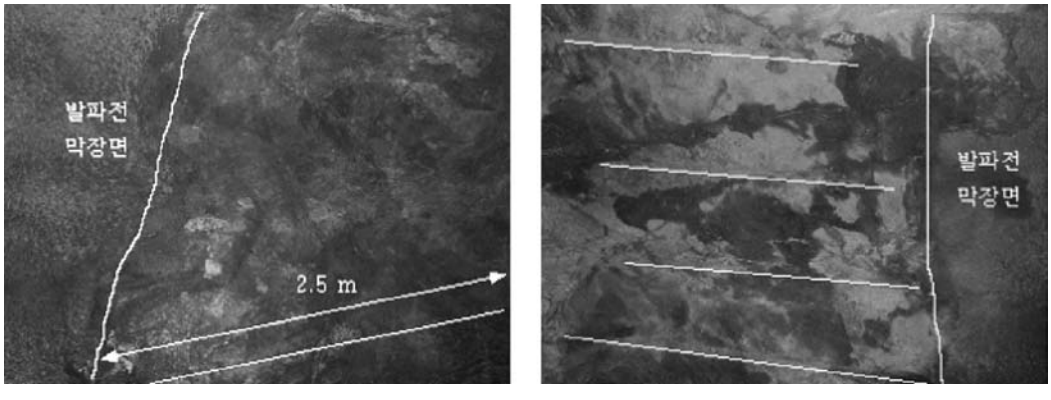


Figure 9. Example of Half Cast Factor analysis.

those observations made in the field where an obvious difference between system was noticed.

8 TUNNEL ADVANCE

Measurements were taken of tunnel advance for each firing. Unfortunately, after some disappointing result due to a change in geology, for both the bench mark blasts and the first electronic blast, more shotholes were added to the round. No direct conclusions can be drawn here, other than the addition of more shotholes is significant to face advance.

CONCLUSIONS

Whilst some of the measurements have yielded no positive result, there are a couple of good pointers to where Electronic Blasting Systems may offer some value to

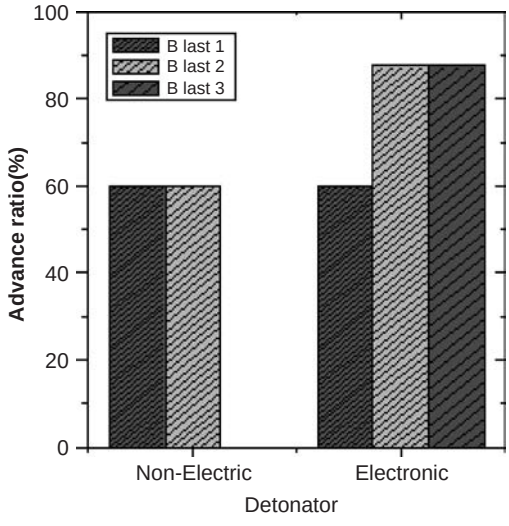

Figure 10. Advance ratio.

the Civil Tunneller. The firing and measurements were taken in a production environment. This meant that no special controls were taken opposite drill accuracy and charging. It could be said that the positive results are most powerful in that the sole change was initiation timing and accuracy.

Most obvious was the improvement to perimeter control. This is a critical aspect of civil tunnel in that the perimeter must conform to specification. Underbreak results in re-work and overbreak is at the expense of the project is terms of additional support material placement.

The fact that vibration prediction proved to be more reliable will have value to tunnellers operating in environmentally challenging locations. Often cautious limits are set for maximum charge weight to overcome variability in vibration results. Charge weight limitation usually results in shorter drill length and therefore reduced advance per cut. Being able to maximise advance for a given set of criteria is of enormous value.

The electronic timing designs were not optimised for vibration control. Opportunities exist to further refine these designs to give true single hole firing to minimise charge weight per delay.

Blanka tunnel complex in Prague

P. Šourek, L. Šajtar, F. Polák, J. Dvořák & A. Butovič
SATRA, Prague, The Czech Republic

M. Hadrava
METROSTAV, Prague, The Czech Republic

ABSTRACT: The largest underground construction being built at present in the Czech Republic is Blanka tunnel complex in Prague. This extensive construction is being realized within the construction of the north-west part of Prague City Ring the whole length of which is 6,382 km and the length of the tunnel part is 5,5 km. After completion of Blanka complex the operating lenght of the City Ring will be approximately 17 km including Zlíchov, Mrázovka and Strahov tunnels.

1 INTRODUCTION

The route of Prague City Ring goes through central part of the City, bordering the historic core and through the area of preserved natural monument Královská obora Park. The first studies, which were made at the beginning of 90 s in the last century, showed necessity for the most part of the route to go under the ground either in cut and cover or driven tunnels. The reason was to minimize the influence of the tunnel construction and then the traffic operation on to the environment. And thus continuous Blanka tunnel complex was created. It includes three tunnel sections which concur fluently from Malovanka intersection at the north portal of Strahov tunnel to Trója intersection by new Trója bridge across the Vltava River. The already operating western part of the City Ring Road continues in:

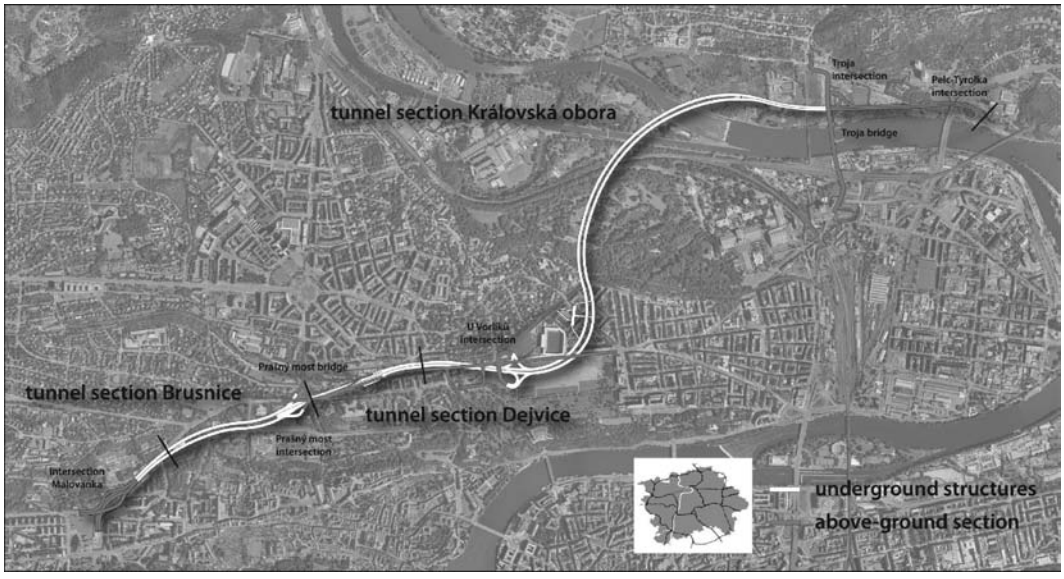
- Brusnice tunnel section goes from northern portal of Strahov tunnel under Patočkova Street at first through cut and cover tunnels. Behind the crossing Myslbek street the driven part of the route begins and ends in front of Prašný most intersection. There the cut nad cover tunnels route again continue. The aggregated length of this section is 1,4 km, out of which 550 m are driven.
- Dejvice tunnel section starts at Prašný most intersection and continues by the cut and cover tunnels under Milada Horáková Avenue up to the area of the future intersection U Vorlíků. The aggregated length of the section is 0,6 km.
- Královská obora tunnel section begins at the intersection U Vorlíků at first by short cut and cover section in Letná area. The adjoining driven section underpasses block of flats, Královská obora Park, a shipping canal, Císařský Ostrov, the Vltava River and then through other cut and cover section up to Trója portal. The aggregated length of the section is 3,43 km out of which 2230 m are driven. The length of the whole tunnel complex is 5502,20 m in the northern tunnel tube and 5489,14 m in the southern tube. The aggregated length of all driven tunnel tubes is 5,54 km, the aggregated length of all cut and cover tunnel tubes is 6,60 km. The opening of the tunnel complex is expected in 2011. This tunnel will be twice longer then the existing longest one in the Czech Republic.

2 HORIZONTAL AND SLOPE ALIGNMENT

The whole City Ring route is always divided in to two or three-lane tubes in both directions. The tunnels descend from Malovanka crossing upto under the Vltava River where they start to ascend to Trója portal. The maximum longitudinal gradient amounts to 5%. The level difference between the highest and the lowest point in the tunnel is 113,5 m. The minimal horizontal curve radius value is 300 m. The traffic lane width in the whole section is 3,5 m, the gauge limit height is 4,8 m. The designed speed is 70 km/h.

3 GEOLOGICAL CONDITIONS

Complex Blanka construction will be driven in a rock massif formed by sediments, which settled at the bottom of the cold Ordovician sea (lower Paleozoic)



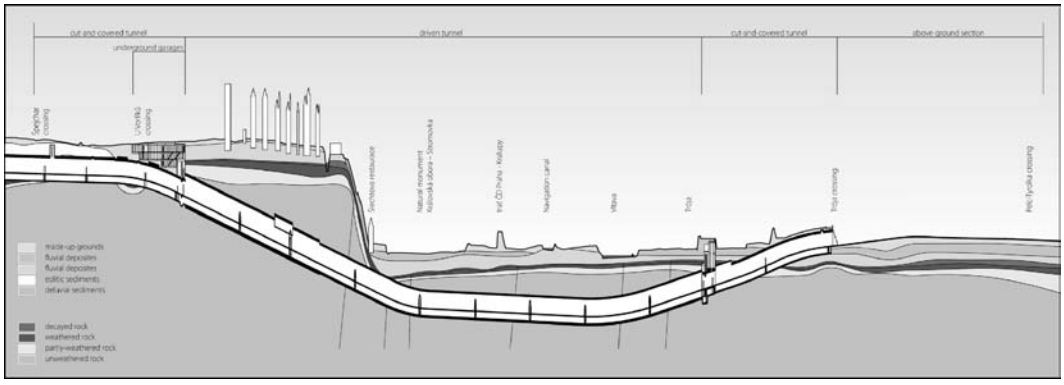


Figure 1. Situation of the Blanka tunnel complex.

in Prague basin, which is a part of the Barrandiene (a characteristic sedimentation basin of the Proterozoic Eon, reaching up to the Paleozoic Era, named in honour of a renowned French palaeontologist). Successively, those sediments were first folded during the Variscan orogeny (the Carboniferous, i.e. upper the Paleozoic), which manifested itself by pronounced synclinal or anticlinal structures (e.g. a quartzite anticline. Later on, these sediments were fractured along faults or local tectonic weaknesses into individual tectonic blocks.

The rock environment of Malovanka–Pelc Tyrolka package is very variable. It consists of Ordovician rock types represented, in the direction of chainage, from the starting point of the construction up to the foot of the slope from Letná by sandy shales of Letná Member (both monotonous and flysh types of sedimentation), which are replaced by clay-silty shales of Libeň Member at the slope from Letná (at a length approximately of 170 m).

A 60 m wide zone of Řevnice Quartzite of Libeň Member begins in the area of the Šlechta restaurant. Further on, in the section passing under Královská obora Park, there are sandy – silty shales of Dobrotiv member, which change to Skalec quartzite of Dobrotiv Member. The remaining section from Trója embankment on is found in clay-silty shales of Dobrotiv Member.

– monotonous development of Letna series
  sandy shales exhibiting an uniaxial compression strength of 20 to 35 MPa in a sound horizon, thus, medium strength (defined by σc within an interval 15 to 50 MPa). Thickness of weathered rock can be about 4–5 m, and sometimes higher (at one bore it was over 14,0 m).
– flysch development of Letna series
  sandy to greywacke shales prevail with a strength of 25 to 55 MPa which are mostly classified as medium strong rock. In a small extent, they come to the lower part with high strength. Quartzite and sandstone inter-beds have an average strength between 80 and 130 MPa. The above mentioned results refer to the difficulty in the rocks disintegration, and they are one of the input values rendering the assessment of suitability of particular types of possible driving equipment.
– Liben shales
  are in non – weathered state dark grey or black grey shales with silt admixture, in terms of excavation, a very important formation, as they are the worst rock material in the route of the tunnels. The clay-silty shales encountered have the strength of 10 to 15 MPa, and they are classified as the rock with low strength.
– Revnice quartzites excavating of the exploratory gallery. This face is created by dark to yellow–brown quartzites with tabular to bench bedding. The thickness of detailed layers is about 7–100 cm. It contains 96–99% quartz which creates slightly oblong corns of 0,06–0,02 mm size. In some places layers of clay siltstone shales with thickness up to 2,0 m can be found. The strength on average of the prevailing fine-grained quartzites is of 100 to 150 MPa, which means that this is the high-strength rock.

fibres on 1 m^3 with fibre length of 6 mm and 0,018 mm diameter) in the upper vault will be used as a protection against entrance contraction and above all against influence of fire over the loss of capacity.

Cut and cover tunnel sections are according to their technical solution divided into classical tunnels and tunnels realized by frontal excavation by means of so-called "Milan method". The classical cut and cover tunnels are always designed into open excavation pit secured by either underground rider or micropile walls, eventually by sloping or anchored rock walls. Suporting structures of the tunnel are made from bottom slab with walls and roof or with upper vault. All constructions are monolithic reinforce concreted from the concrete C30/37 and C25/30. Polypropylene fibres are also designed in the construction of walls and roofs, eventually upper vaults. The classical cut and cover tunnel method is used above all in sections with complicated space layout. Waterproof isolation of these sections is supposed on the base of isolating bentonite mattres always with additional elements to make construction and daywork joints tight.

"Milan method" of the construction of the cut and cover tunnels is designed in the places with very narrow space conditions or where it is necessary to minimize traffic restraint time. Sequence of construction consists in the building of the underground monolitic walls from the surface or secured exavation pit. The finished roof construction will be concreted on the pit bottom. It will be filled up again after hardening and final finishing and traffic renewal can be made. Excavation of the proper tunnel profile is made after finishing the whole tunnel section . Cut and cover tunnels have common central wall for southern and northern tunnel tubes and roof floor will funcionate as continous one with two sections. The cross section of the tunnel tube consists of the bottom angle reiforce concrete board, underground walls 800 mm thick are fixed into hard floor and reinforced concrete roof. Roof and walls are designed from concrete C30/37 with adding PP fibers and hard floor is from concrete C25/30. The roof board is 1300 mm thick. The tunnel waterproofing is created by watertight bearing concrete constructions, with additional elements to make construction and daywork joints tight.

A lot of technical and constructional interesting solutions in demanding section are in Blanka complex. The most interesting ones are as follow:

- The portal tunnel part connecting intersection Malovanka is the first of them. It is made form reinforced conrete monolith two tunnel tubes and technological equipmet center between them. All this section (ground plan about 120×100 m) was divided into several dilatation elements, according to sequence of construction and with the influence of the necessity of keeping the public transport on the streets.
- More difficult conditions for design and construction are in three lane driven tunnel tubes between Myslbekova and Prašný most intersection. In the places where the geological conditions are worse the horizontal jet grouting column are designed to be made in advance over the upper tunnel vault.
- The intersection ramps, technological center and undeground garages (for 463 parking places) are situated in the open construction pit (Prašný most). The coordination of the sequence of construction, keeping the public transport on the streets mainly trams and maintaining excess to the construction of driven tunnels is a demanding task. This asks for special attitude for design of the reinforce concrete construction of the building.
- The situation of cut and cover tunnels near vestibule of the metro station and raliway station in Dejvice is other very complicated probelm, which demands special design. It will be necessary to reconstruct one part of the metro vestibul and build and new railway underpass.

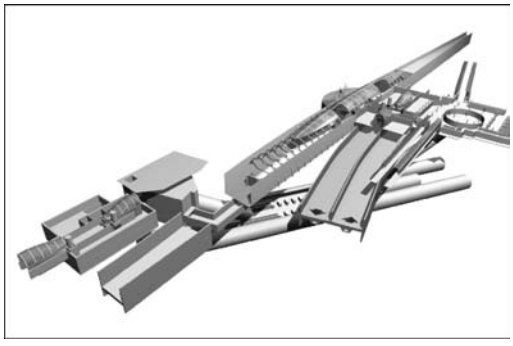

Figure 6. 3D animation of the Dejvice tunnel section in the area of metro station Hradčanská and railway station Dejvice.

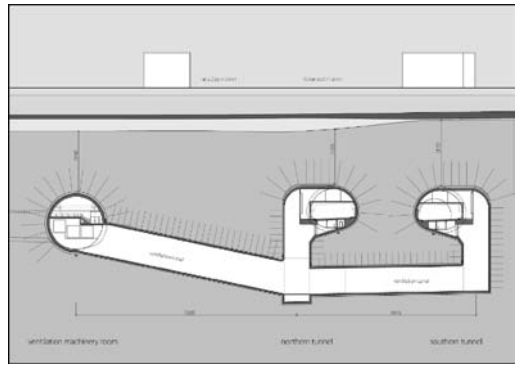

Figure 7. Longitudinal section through the ventilation duct.

– The construction coordination of cut and cover tunnels with individual and public transport is also necessary in Dejvice city district. The route is mostly situated in the track of Milada Horáková Avenue, which is in fact the only connecting road between west and east in all northen city segment. The construction cut and cover tunnels according to "Milan method" was used to minimize the partial closing of the street. The additional sectioning of some of bearing constructions in longitudinal direction is necessary to minimize the area of the closing. Complicated joning details of roof reinforcement construction above middle wall in the place of the maximum banding moment arises from this. The height of the filling above roof construction is extraordinarily even 7 m. It was not possible to make use of vault roof construction because the sanitary sewer was placed on the roof. That is why the horizontal roof slab is bearing all height of the filling. This asked for making the filling from light-weight concrete 3,5 m high with 600 kg.m^{-3} bulk density.
– Cut and covered tunnels end at Letná, where they continue three lane driven tunnels. Open construction pit (25 m deep) houses undergorund intersection, proper tunnel tubes, underground technological center and car park for 863 cars. The interesting solution is roofing of the place where three lane tunnels are widening by two merging or turning lanes lead into intersection U Vorlíků. The biggest span of the roof construction in this place is 26,4 m. The composite construction concrete/concrete prestressed bridge beam VSTI 2000 with reinforced concrete slab 300 mm thick was used.
– The driven tunnels begin in the construction pit at Letná go under Královská Obora Park and the Vltava river ending at the oposite bank in Trója. More dificult place from the point of driving will be at the bottom of the hill from Letná to Stromovka in the vicinity of the hisorical building Šlechta restaurant. Both tunnel tubes go through the lowest overburden on the border of the poor quality Liben shales and Řevnice quartzites layers.

  The overburden consists of 1,5 m high rock and 11 m high sandy gravel. This situation will be solved by jet and press grouting from the explorartory gallery. The driving will be realized afterwards under the protection of microplilot umbrellas with horizontal sequntions and temporal floor vault. This underpassing (120 m^2) the Vltava river will be the biggest ever done in the City of Prague.
– The underground ventilation machinery room at Letná consists of several paralel tunnels. The biggest of these have cross section cca 300 m^2 and length 125 m. The machinery room is conected with the tunnels by ventialtion ducts for fresh and exhust air. This sofisticated underground junction was designed only because of very good geological conditions in this area. The results of the final element method analysis confirm viability of the design solution of the machinery room and gave the information about supposed settlements, which should not be over 35 mm in the overhead built-up area.
– The last part of Blanka tunnel complex is cut and cover section on Trója bank. The influence of floods was one of the criteria for the design of it.

5 TECHNOLOGICAL EQUIPMENT

Technological and safety tunnel equipment of Blanka complex meets and in many cases is above minimal safety demands given by European Directive from 2004. The kind of equipment of Blanka complex is compatible with other Prague road tunnels because it will be controlled from the same Control Centers as it is now. One is for traffic control and the other one for monitoring, control and mainatnence of technological tunnel equipment. The great importance of all tunnel section, from the point of traffic in Prague

Figure 8. Vizualization of northern portal in Trója.

Figure 9. Vizualization of final driven tunnel.

and supposed high traffic intensity, specified demands on high reliability of design of technological systems with minimal operational and maintanence cost. Price of eletrical energy was one of the reasons why a great attention was given to the design of ventialtion system. Operational ventilation system makes use of piston effect of driving vehicles and combines longitudinal and semitransver ventilation systems with local exhaust and fresh air supply in one direction tunnels. Fresh air is mostly supplied by driving vehicles in entrance portals in combination with several hole air supplies. Polluted air is exhausted in a controlled way by ventilation machinery rooms into the chimneys and at the same time the portals are protected as much as possible against the polutant exhaust. Fire ventilation system in driven tunnel sections is designed as a smoke control exhaust into holes in the tunnel vault with remote control dampers each after 80 m. The smoke and heat from the fire will be exhausted in a controlled way by local ventilation machinery and by help of jet-fans to the portals.

6 SEQUENCE OF CONSTRUCTION

The elaborated coordination documentation was prepared for coordination. It solves sequence of construction from individual realignment underground services, individual and public traffic organization and time schedule up to trail run of the system. The construction is divided into 20 basic time periods, which are time and place connected. Three temporary bus lines and 1km long tram line will be opened to ensure public transport in the same way. The tunnel construction will be realized from five main construction sites. The construction of the driven tunnels will be realized always from both portals. Machinery or blast driving are supposed to be used according to the geological conditions. Waterproofing and secondary lining will be realized by flow-line process.

Part of Blanka tunnel construction besides the tunnels will be other adjoining city comunication e.g. new surface section of City Ring in Trója, new road bridges, one across the railway (Prašný most) and the other across the Vltava River (Trojský most).

The scope, number and type of the geotechnical monitoring is very large because of the place of the construction, which is found in these block of flats. It can not be compared with any other tunnel construction in the Czech Republic. To ensure safety sequence of the undeground construction and trail run, twenty six kinds of basic measuring are designed including proposal of the observation method.

7 CONCLUSION

The range of the whole Blanka tunnel complex construction is unique. The time of the design preparation and construction, number of other city investments and realignment underground services, temporal public nad individual transport restrictions and coordination and organization all construction are unique too. The preparation design works started in 1998 and the construction began in 2007. The improvement of the environment and traffic situation in the area of the boundry of historical center of the City of Prague, listed in the cultural and histotical UNESCO heritage will be reached after completion of it.

Study on the behavior of an ultra-large section tunnel project in unconsolidated ground-design and construction of the Minoh toll road tunnel

K. Taketomo
Osaka Prefectural Road Public Corporation, Minoh Site Office, Osaka, Japan

Y. Mitarashi, H. Shiokawa, S. Nishimura & K. Konishi
Kumagai Gumi Co., Ltd., Tokyo, Japan

ABSTRACT: This paper discusses the Minoh tunnel construction. The geology at its south portal is unconsolidated soil, with a high groundwater level. A significant amount of water inflow was therefore anticipated. In such adverse ground, this tunnel with a maximum excavation section of 313 m^2, which is one of the largest sections in Japan, was successively constructed using the side-drift advance method with various new techniques. During tunneling, informatics technologies were fully utilized, by feeding back various measurement results to design and construction, thereby enabling selection of suitable auxiliary stabilizing techniques and excavation methods. The auxiliary methods involved were pipe roof (812.8 mm in diameter, 90 m long), long steel pipe forepiling, and long face bolts. In addition, "quasi-high fluidity concrete" was used to place high quality lining.

1 INTRODUCTION

The Minoh toll road is an expressway about 7.3 km long extending north from Shin-Midosuji Avenue, providing a bypass of Route 423 linking central Osaka to northern Osaka and the city of Kameoka, Kyoto Prefecture, as well as providing an access to the Second Meishin Expressway (Fig. 1).

The Minoh toll road mountain tunnel construction project (south sector construction) covers 2.2 km on the south of the tunnel extending over about 5.6 km (main and evacuation tunnels). Its most significant feature is that the maximum excavation area reaches as large as 313 m^2 at the southern portal of the main tunnel, and is one of Japan's greatest ultra-large section tunnels in unconsolidated ground.

Prior to the excavation of the main tunnel, the construction project started with the work for a working tunnel (having an excavation section area of 41 m^2 and a length of 347 m) that would run in parallel with the main tunnel. In the course of this construction work, the project team encountered difficult problems on the heavily fractured shale bed in the Tanba belt, including extrusion, collapse and large deformation of the face. The construction team excavated the main tunnel by utilizing the data obtained during construction of this working tunnel; and they gradually enlarged the excavation section area from the back toward the portal.

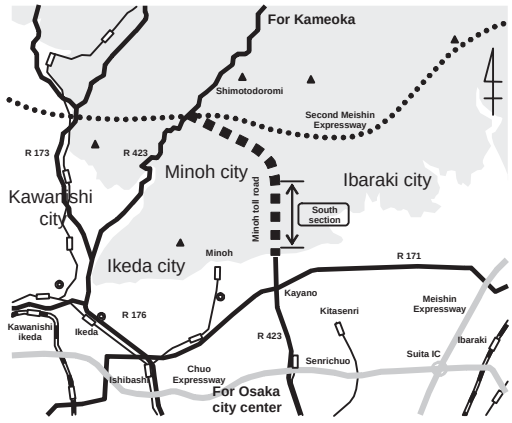

Figure 1. Site location map.

The tunneling team prepared for construction involving an ultra-large section area while re-examining the design and construction method and referring to the measurement results on the working tunnel and the construction results of the sections already excavated in the main tunnel.

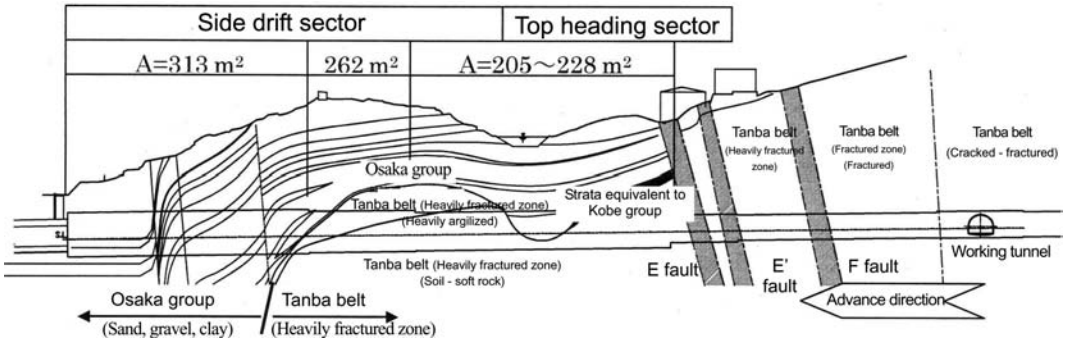

Figure 2. Longitudinal profile of the south portal.

2 GEOLOGICAL OVERVIEW

As shown in Figure 2, the soil around the southern portal contains distributed segments of the Mesozoic or Paleozoic Tanba belt (largely composed of shale) forming the Hokusetsu Mountains, covered with the Osaka group (of sand, conglomerates and clay).

In this construction section, the ground is vulnerable with high clay content as a result of heavily fractured shale beds while a number of branch layers of the Arima-Takatsuiki tectonic line.

The deformation modulus of ground at the southern portal was generally 80–100 MPa for the Osaka group and 55–70 MPa for the Tanba belt (fractured shale bed), according to simulation analyses involving data from various geological surveys and tests as well as measurements on tunnels under construction.

3 CONSTRUCTION OF A PORTION WITH AN ULTRA-LARGE SECTION

3.1 *Tunnel support pattern*

The support structures and section specifications are as shown in Figure 3 and Table 1, which do not include any special specifications but combinations of standard support members.

3.2 *Construction procedure*

Figure 4 shows a flow of construction work for a portion with an ultra-large section.

First, drifts were constructed on the right and the left, and then sidewall concrete was placed. Next, an arch section was excavated and arch concrete was placed.

This construction method succeeded in restricting settlement at the tunnel foot.

Last, the invert was closed to ensure permanent safety.

3.3 *Construction overview*

3.3.1 *Drift excavation*

As each of the sidewall drifts was vertically long with an excavation section area of 74 m^2 and a height of 11 m, the heading was divided into four sections: upper, middle, lower and invert sections.

One excavation round consists of consecutive driving of upper and middle sections, followed by cutting of lower half and invert, with early closure by shotcreting the invert.

Injection pattern forepoling was adopted as an auxiliary method.

Measures to control water inflow included drainage boring with long pipes in sandy aquifers that had been anticipated through the drift faces.

These drainage operations and the application of the auxiliary method enabled excavation of sandy soil (Fig. 5).

3.3.2 *Concrete placement on sidewalls*

Construction of 7.7 m-high sidewalls was divided into two segments: the foundation and the wall.

The bar arrangement specifications included two-tier using internal main reinforcement of D35 at intervals of 125 mm.

Moreover, considering the high density of corner-reinforcing bars and stirrups, the construction plan was streamlined, including [1] preassembly of main and distribution reinforcement bars into modules, [2] simplification of stirrup assembly work through adoption of wedge press-in type joints, [3] adoption of the screw-squeeze type joint (mechanical joint) for sections where the arch section was jointed to invert (Fig. 6).

3.3.3 *Main tunnel arch excavation work*

After the completion of concrete placement on sidewalls, arch excavation was started.

Efficient excavation was conducted using a large-scale breaker (with the long reach) with several back hoes (Fig. 7).

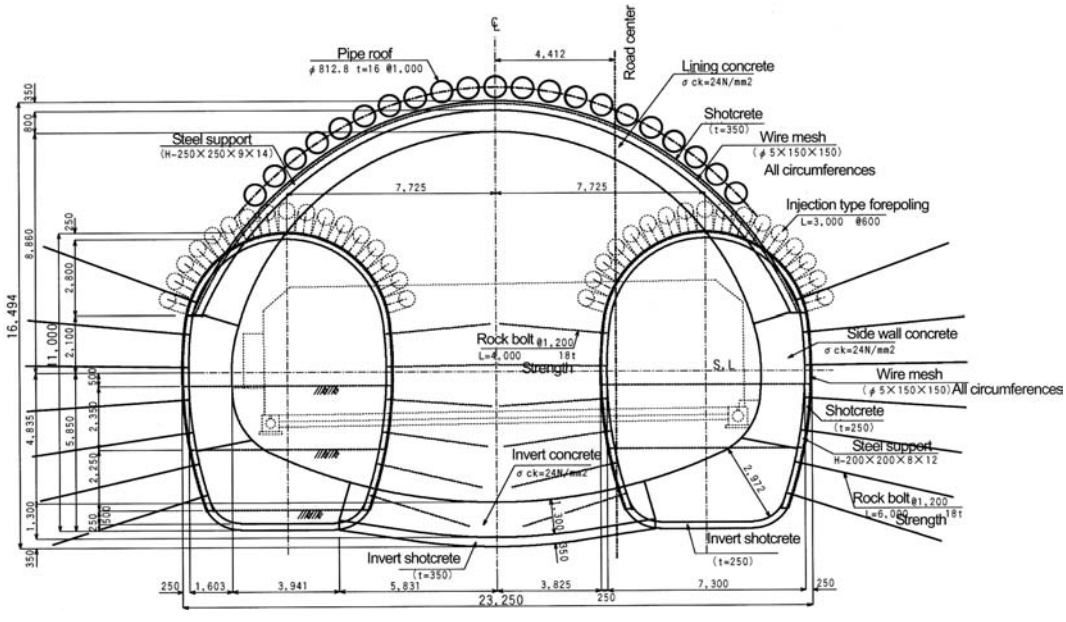

Figure 3. Support pattern.

Table 1. Support structure and section specifications.

Name	Division of heading: Drift	Division of heading: Main tunnel	Remarks
Shotcrete	t = 250	t = 350	σck = 18 N/mm^2
Steel arch support	H – 200	H – 250	SS 400
Rock bolt	L = 6 m / L = 4 m	Not provided	Ground side n = 7 / Cavity side n = 6
Excavation section area (designed)	Total cross section (m^2)		313
	Drift excavation (m^2)		74 (on each side)

Since the steel arch supports extend as long as 14 m on one side, four supports (two each) were jointed at the temporary storage to form two sets of supports for the left and the right sides and were installed using a support erector.

The pipe-roof protection method (ø812.8, about 90 m long) was adopted as an auxiliary method for the section with the maximum section area (313 m^2), considering the fact that the construction was in unconsolidated ground in the Osaka group.

Meanwhile, in the section with the second largest section area (262 m^2) in ground of heavily fractured rocks in the Tanba belt, the improved-type steel pipe forepiling not enlarging the cut section was used.

3.3.4 *Pipe roof*

When selecting a method for pipe-roof work, the following construction conditions were considered; [1] a long-distance (about 90 m) excavation was involved, [2] the ground contained soils with significantly different properties like sand with a low self-sustainability and hard clay, [3] groundwater inflow was likely to occur, [4] the working space was cramped, [5] reaction force generated from propulsion must be borne by an existing structure, [6] it would be impossible to recover the foregoing device (boring machine) on the arrival side and [7] high-precision propulsion was essential. Given those conditions, the sludge pressure type propulsion method (Fig. 8) was adopted, which enables recovery of the cutter and driving unit through the excavator duct.

When construction began, shafts were created on the portal side, from which boring proceeded toward the back of the tunnel. This method enabled us to maintain construction precision to about 1/2000.

3.3.5 *Arch lining concrete*

Concerning arch lining for the section in question, the following problems and challenges were anticipated:

[1] Occurrence of honeycombs, segregation and poorly filled portions with reinforcing bars arranged densely
[2] Poor filling in the crown of the arch, and
[3] Occurrences of thermal cracks associated with very large spans and very thick lining as well as cracks accompanying drying shrinkage.

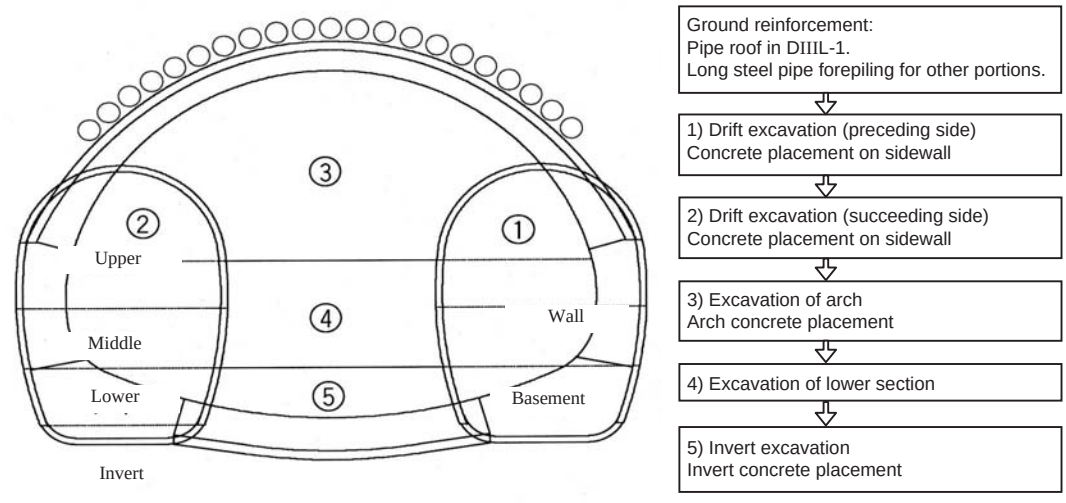

Figure 4. Construction sequence.

Figure 5. Drift portal.

In dealing with the above problems, high-fluidity concrete has been applied in a growing number of cases lately, but not without the following possible drawbacks:

[1] Insufficient strength relative to increases of side pressures,
[2] Concrete running out through the bulkhead,
[3] Higher unit cost of concrete.

For the above reasons, we judged high-fluidity was not an appropriate solution and opted to develop a new type of concrete.

In the development effort, various studies, mix design and trial mixing were repeated from two viewpoints: property improvement of fresh concrete such as workability and that of hardened concrete such as crack control.

Finally, a model was constructed using part of arch forms to verify the adaptability to actual construction.

Figure 6. Bar arrangement in the drift (for the foundation).

Thermal stress analysis of cracks using the three-dimensional finite element method confirmed that the minimum crack index for the crown, which was previously 0.7, was improved to about 1.3 as a result of addition of an expansive admixture, which we decided to use in our development project.

The properties and mix of the developed concrete are summarized in Table 2 and also actually achieved satisfactory construction results.

For reference, the construction span length of the lining concrete was basically 6 m so that one concrete

placement at a time could be controlled at a volume no more than 200 m^3.

3.3.6 *Construction of the lower and invert sections*
The lower section was excavated en masse while breaking the drift. The invert section was excavated and shotcrete was applied in sequence to close the section early.

Lastly, reinforcing bars were arranged and invert concrete was placed.

4 MEASUREMENT RESULTS

4.1 *In-tunnel measurements*

As a result of convergence and settlement measurements shown in Figure 10, the following observations were confirmed:

[1] The maximum crown settlement exceeded 100 mm for the preceding portion of the upper section. However, the settlement of the crown of the main tunnel's arch was no more than 30 mm or so in the preceding portion of the sidewall drifts. The distance over which the main tunnel arch converged was in the range from 35 m to 40 m in the preceding section of the sidewall drifts. This is equivalent to 1.5–2 times of the tunnel diameter.

[2] In the preceding portion of the upper section, settlement at the foot occurred in conjunction with crown settlement, also showing some correlation with the overburden. Meanwhile, in the sidewall drift sections, the settlement of the main tunnel's arch at the foot was contained within the ratio of an average 55% against the crown settlement. Moreover, no correlation with the overburden was recognized.

4.2 *Measurements outside the tunnel*

Figure 11 shows results of follow-up surveys on ground settlement at a point 2.5 m above the tunnel arch. According to this figure, the convergence displacement was 101.7 mm including bench excavation, indicating that the drift excavation brought about 50% displacement. The preceding displacement ratio for the upper arch excavation alone was about 27% relative to the initial value, i.e., the pre-excavation value for the upper arch.

Figure 12 shows an overall view of outside-tunnel measurements. In the working tunnel, a phenomenon

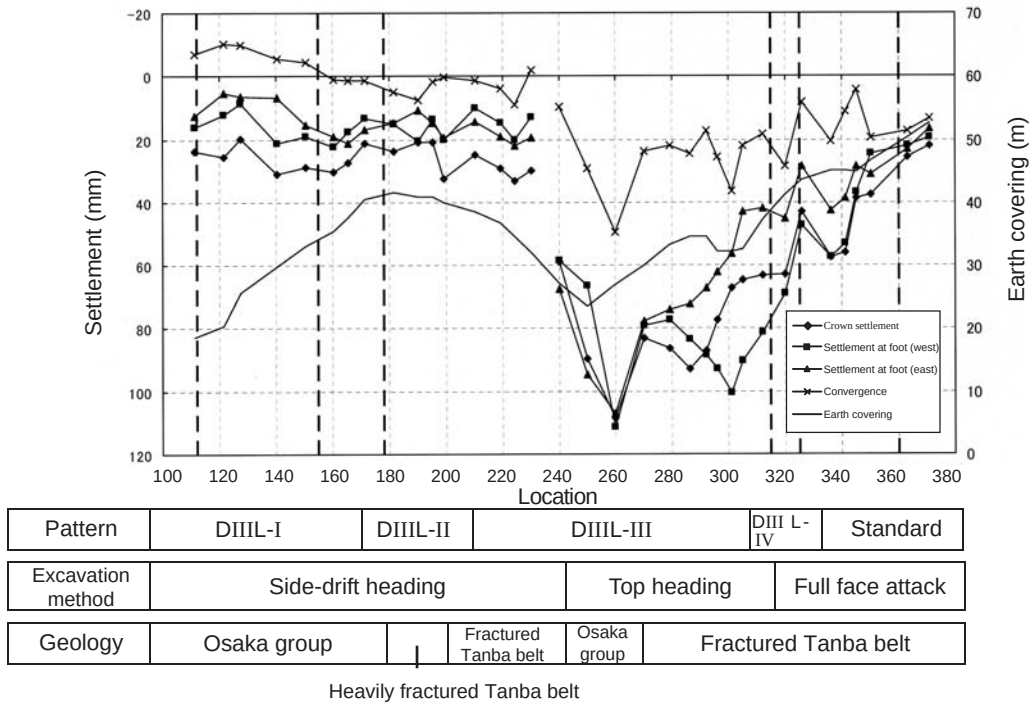

Figure 10. Longitudinal distribution of convergence and settlement measurement results (Data for drift sections represent measurements from excavation of the upper arch sections).

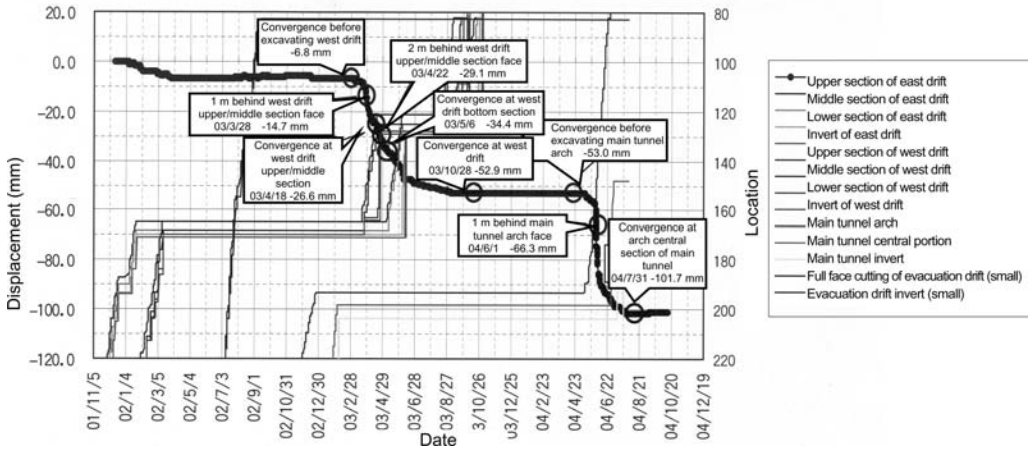

Figure 11. Change in ground displacement.

referred to as "accompanying settlement" was observed, in which settlement occurred across the entire scope from the tunnel arch to the ground surface. In the main tunnel, however, the surface settlement ratio against the underground settlement directly above the tunnel was about 60%, showing some reduction, and no accompanying settlement occurred. This can be attributed to the effect of restricting settlement at the foot that might have arisen from the presence of sidewall drifts.

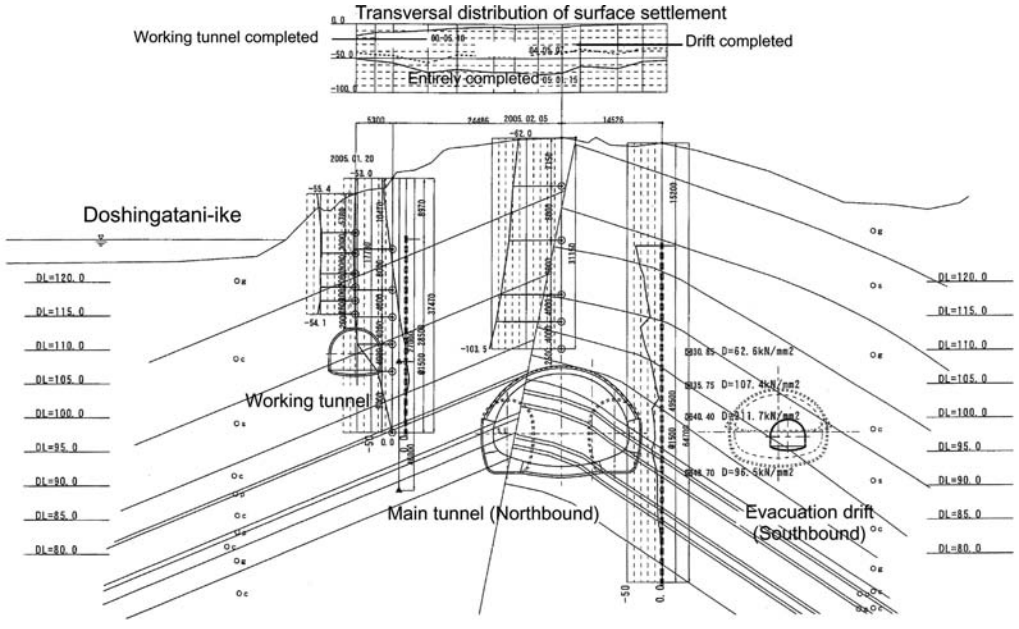

Figure 12. Overall view of outside-tunnel measurements.

5 CONCLUSIONS

This construction project was started in May 1999 with its invert closure for the portion with an ultra-large section completed in February 2005. During the course of construction, we faced numerous problems, for which solutions were sought and utilized in the subsequent construction stages. The following is a summary of findings and related comments.

- One of the challenges was to provide face stabilization measures during arch excavation the width of which reached 23 m. The solution made it clear that effective reinforcement ahead of the face including long face bolts enabled stable excavation.
- Settlement at the foot of the large-span arch was significantly limited by the presence of the side drift. This solution contributed to the prevention of accompanying settlement as well as to restriction of loosening.
- While a control criterion surface strain (1.2%), various measurement results and reproduction analysis results proved that excavation advance was stable with strain below the control criterion.

The project successfully completed an ultra-large section tunnel with the maximum excavation section reaching as large as 313 m^2 in unconsolidated ground.

This success should be attributed to the feedback of measurement results by the construction management based on information technology to the design and construction processes as well as to appropriate selections of auxiliary construction methods and excavation methods.

Large deformations in squeezing ground in the Saint-Martin La Porte gallery along the Lyon-Turin Base Tunnel

J. Triclot
Scetauroute DTTS, Pringy, France

M. Rettighieri
LTF-SAS, Torino, Italy

G. Barla
Politecnico di Torino, DISTR, Torino, Italy

ABSTRACT: Within the context of the Lyon-Turin railway project, the excavation of the *Saint-Martin La Porte* inclined gallery (section 80 m^2 – length 2000 m) has encountered a highly fractured Carboniferous rock mass. Different ground support systems were implemented and convergence measurements confirmed the squeezing behaviour of the rock mass. Convergences of approximately two meters were observed as soon as the cover reached three hundred meters. As a result significant changes in the excavation and ground support systems were required. After setting up a ground support system adapted to the squeezing ground, the rate of convergence reached 40 mm per day in the zone of the face and 2 to 4 mm per day at a distance of approximately 60 metres from the face. Due to the difficulties encountered and with consideration given to the exploratory nature of the work, new support systems and organisation works were implemented, combined with an extensive monitoring programme.

1 INTRODUCTION

The Lyon-Turin railway programme requires the excavation of a 53 km long Base Tunnel. The dual national company Lyon Turin Ferroviaire (LTF), a subsidiary company of RFF and RFI, has been appointed to carry out preliminary studies and works involving the excavation of inclined galleries and exploration adits.

The Saint-Martin La Porte inclined gallery is the closest drive to the West portal of the base tunnel. It is to reach the level of the Base Tunnel situated at a distance of 2300 meters from the portal. The cross sectional area of the gallery ranges between 80 and 100 m^2.

The gallery is situated near an important zone of difficult ground and is designed to fulfil several objectives:

- provide additional geological and geotechnical data on the rock mass conditions to be encountered during the excavation of the main tunnel;
- quantify the uncertainties associated with the difficult ground to be excavated;
- provide access for the future tunnelling work.

When the tunnel will be in operation, this inclined gallery will be used for access by emergency teams and also for maintenance and ventilation purposes.

Participants in the programme are:

- Owner: LTF – Lyon Turin Ferroviaire SAS;
- Project management: Group Scetauroute (agent), Antea and Alpina;
- Contractor: Razel inter-company group (agent), Pizzarotti, Bilfinger Berger, Granulats Rhone-Alpes;
- Sub-contractor: Fondazioni Speciali/GD Test.

2 GEOLOGICAL AND GEOTECHNICAL CONDITIONS

The Saint-Martin La Porte gallery is situated near the contact between the Briançonnaise zone, composed of limestone, marl and dolomite, and the Briançonnaise Carboniferous zone, composed of schists, Carboniferous schist and coal (Fig. 1).

Between the two zones a transition zone is present comprising anhydrites (Fig. 1). The contact area between the Carboniferous and the Briançonnaise zone was found after excavating a tunnel length of 800 m and presented characteristics in line with predictions. Also encountered during excavation was a zone with fluvio – glacial alluvium under a cover of

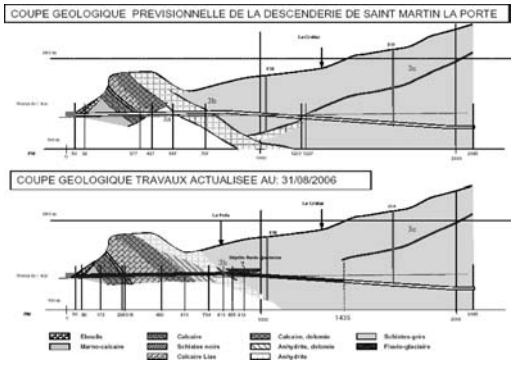

Figure 1. Geological profile.

Figure 2. Appearance of the Carboniferous rock mass at the face. Chainage 1414 m.

150 to 200 meters. This required staged excavation (top heading and bench) and pre-treatment of the ground.

Once the excavation of this latter zone was completed, the gallery encountered the Productive Carboniferous Formation, composed of schists, clays, highly tectonised sandstone and coal. A characteristic feature of the ground in this zone is the highly heterogeneous, disrupted and fractured condition of the rock mass, which exhibits extremely to very severe squeezing problems, Hoek, 2001, Barla, 2001 (see Figs. 2 and 3). As a crude approximation, the GSI (Geological Strength Index, Hoek and Marinos, 2000) is in the range 20–30 (short term conditions) down to 10–20 (long term conditions).

The conditions encountered made the different parties involved in the work to define first a support system based on heavy steel sets (HEB 180) with invert, combined with fibreglass dowel pre-reinforcement at the face, together with a concrete ring approximately 50 cm thick.

Under these conditions, the excavation resumed at a rate of 2 to 3 meters per day and was associated

Figure 3. Appearance of the Carboniferous rock mass during excavation. Chainage 1350 m.

with a specific monitoring programme. As the gallery became deeper, leading away from the valley (Fig. 1), the overburden increased. The tests carried out have confirmed the limitations of the support system adopted when subjected to the high stress conditions expected with an overburden depth in excess of 250 m.

3 SUPPORT SYSTEMS AND GROUND BEHAVIOUR

3.1 *Adoption of the yielding support system*

Several support systems were used following the initial application of a stiff support, as underlined above. It soon became apparent that a stiff support would not be feasible in the severe squeezing conditions encountered, with very high stresses developing in the concrete lining as the overburden increased.

Finally, the design concept chosen was to allow the support to yield in a controlled manner, with the following pre-reinforcement, full face excavation, and support sequence being adopted:

1. fibreglass dowel face pre-reinforcement;
2. full face excavation (1 m face advance);
3. use of yielding steel ribs with sliding joints (TH, Toussaint-Heintzmann type);
4. installation of rock bolts along the excavation perimeter, including the invert, requiring 400 linear meters of rock bolts per meter excavation.

3.2 *Considerations on the observed behaviour*

The excavation-support system, adopted over a length of approximately 100 metres, was marked by high convergences of up to 2 metres, with the radial strains of the tunnel wall ranging between 8% and 16% at a distance of 20 m behind the face. More specifically, with a progress rate of 1 m per day, convergence rates of

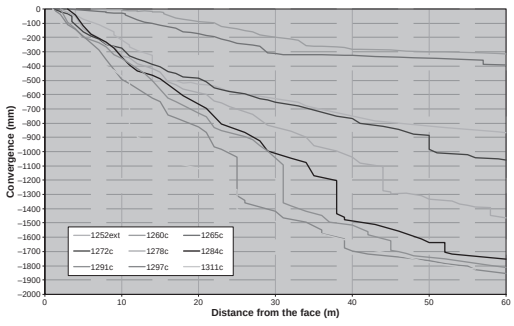

Figure 4. Tunnel convergences measured along the horizontal between chainage 1260 and 1320 m.

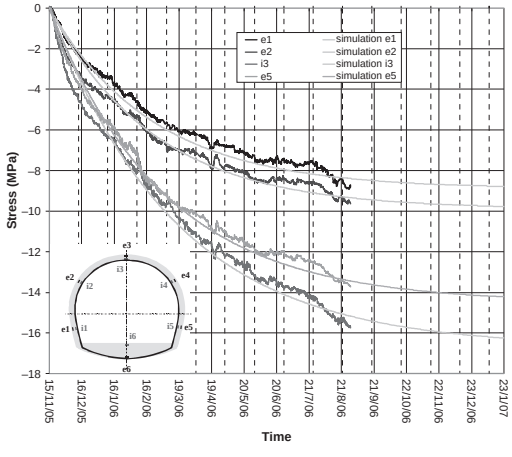

Figure 5. Stress distribution in the lining at chainage 1229 m.

approximately 40 to 50 mm per day were observed. These decreased when moving away from the face and resulted in values of 2 to 4 mm/day at distances between 80 m and 100 m from the face (Fig. 4).

In order to gain in the understanding of the deformational behaviour of the rock mass along the tunnel length, it is of interest to pay attention to the extensometer measurements carried out at chainage 1330 m. It is shown that the zone characterised by a significant strain gradient (say where the strain value is in excess of 0.5%) is un-symmetrically distributed around the opening, with the maximum extent (18 m) being attained at the right rib, in line with the rock mass anisotropic structure (Figs. 2 and 3).

Also to be emphasised, as a means for appreciating the severity of the squeezing conditions being encountered, is the state of stress in the concrete lining at chainage 1229 m as shown in Fig. 5. The vibrating wire strain-meters embedded in the concrete give tangential stresses in the lining, that are still increasing

Figure 6. Re-profiling operations of the opening to the original tunnel profile followed by concrete placing behind steel plates.

8 months following installation with a maximum long term value estimated up to 16 MPa.

The mechanical behaviour of the Carboniferous zone has been shown to be significantly less favourable than anticipated in the design documents. Based on the information gained so far through performance monitoring and back analysis (Barla and Panet, 2006) the ground was found to exhibit a unique deformational response distinguishing between a “short term” and a “long term” behaviour.

In the short term (just behind the face), if the face advance does not stop, the rock mass exhibits a negligible time-dependent behaviour. The tunnel and face deformation can be computed by using an elastic plastic constitutive law. In the long term, the time-dependent behaviour cannot be neglected and an elastic viscous plastic law needs be adopted in order to reproduce the deformational response satisfactorily (Barla and Panet, 2006; Sulem et al, 1987).

3.3 *Improvement of the yielding support system*

Due to the conditions being met, work progress was interrupted for long periods of time, as the reduction in cross section made it necessary to “re-profile” of the opening to the original tunnel profile. With systematic re-profiling operations taking place section by section up to chainage 1325 m, concrete behind the steel plates was placed as soon as possible after completion of the remedial work. Fig. 6 gives a clear view of the re-profiling operations being undertaken with adaptation of the cross section shape.

The observations made, associated with the experience gained during tunnelling in the squeezing ground conditions encountered, made it mandatory to consider a number of possible options for driving the tunnel. The aim was to be able to improve the previous phase of yielding support application, while seeking a different

work organisation in order to adapt to the increased cover and to the necessity to contain the residual deformations at a certain distance from the face.

The main objectives to be achieved were as follows:

- reduce/control, where possible, the amount of convergence in the tunnel and the disturbance of the surrounding rock mass;
- use excavation and support systems compatible with the increased overburden to be experienced in the future (up to 600 m) along the inclined gallery and in the base tunnel;
- optimise the pre-reinforcement, excavation and support sequence, including the distance from the face where to install the concrete lining;
- assess the residual deformations to be expected following support installation and the long term state of stress in the concrete lining.

3.4 *Main adaptations required*

Considering the consequences in terms of the tunnel excavation and support costs, including the time delays in completion of the inclined gallery, the following adaptations were made:

- reorientation of the gallery alignment in order to drive nearly perpendicular to the geological structure;
- change the shape of the opening to a near circular section;
- implementation of a pre-reinforcement, excavation and support sequence leading to avoid the need for important re-profiling to the original tunnel section;
- control of the extent of the disturbed zone around the tunnel, thus reducing the ground time-dependent deformations.

3.5 *Pre-reinforcement, excavation, and support sequence adopted*

The new pre-reinforcement, excavation, and support sequence finally adopted can be summarised as follows (Fig. 7):

Phase 0 – face pre-reinforcement, including a ring of grouted fibreglass dowels around the opening perimeter, designed to reinforce the rock mass over a 2 to 3 metres thickness.

Phase 1 – mechanical excavation carried out in segments of one meter length, with installation of support consisting of systematic bolting (length 8 m) along the perimeter, including the invert, and yielding steel ribs with sliding joints (TH, Toussaint-Heintzmann type).

Phase 2 – application of 20 to 30 cm shotcrete with 8 longitudinal slots fitted with HDC (High Deformable Concrete) elements designed to undergo a total tangential strain of 50%, while maintaining a support pressure of 8.5 MPa with controlled movement (Figs. 8 and 9).

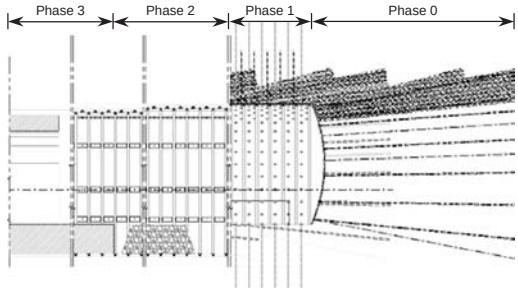

Figure 7. Schematic representation of the adapted pre-reinforcement, excavation, support sequence.

Figure 8. View of the deformable elements installed between the joints of the TH steel ribs.

Figure 9. Photograph taken during Phase 2 implementation.

Phase 3 – installation of a coffered concrete ring when the rate of convergence is low enough to allow this, and outside the zone of influence of the face (Fig. 10).

The guidelines followed for the selection of the excavation-support sequence above were developed

Figure 10. Concrete lining installation.

based on numerical simulations by using both elastic plastic and elastic viscous plastic constitutive laws, with rock mass parameters defined on the basis of performance monitoring. In this context, the support design needs be continuously reassessed according to the results of monitoring and experience feedback from the work site.

It is important to note that the distance from the face at which phase 2 is implemented will depend on the efficiency of the support measures adopted and on the convergence values observed at the face. Diameter reduction for this section is limited to 600 mm. Beyond these values, the shotcrete lining would be overstressed too soon and require repair work on the support structure.

3.6 *First lessons learned*

Use of monitoring equipment during the ongoing work makes it possible to perform back analysis and acquire the experience feedback required for the project. Systematic convergence monitoring takes place continually in both phases 1 and 2. So far also monitored in detail are the strains experienced by the HDC deformable elements installed in phase 2, in conjunction with the tangential stresses induced in shotcrete. The ground response around the excavation in both phases 1 and 2 is being monitored by using multi-point extensometers 24 m long.

Monitoring has shown that the pre-reinforcement and support measures implemented during Phases 0 and 1 have resulted in a better distribution of convergences, while maintaining a tunnel deformation (convergence/diameter ratio) of approximately 2% to 5% at a distance of 20 meters from the face.

Phase 2 (Fig. 9) has been first implemented at a distance of 35 m from the face. The shotcrete ring was rapidly under stress, with a maximum overall deformation being attained in the HDC elements of 20%, i.e. with a reserve for further deformation of up to 25–30% before reaching the limit design value. As a result, phase 2 is being moved closer to the face, to a distance of 15–20 m. Future observations of the overall system behaviour and response will allow one to decide if phase 2 could be implemented at a shorter distance from the face.

A special coffer was designed for the project. It was assembled inside the gallery and served to install the concrete lining in 5-metre long segments, as shown in Fig. 10.

4 CONCLUSIONS

The inclined gallery is currently under construction and is faced with exceptional difficulties over a significant length. This calls for a continuous reflection on the resources and methods to be used. The feedback from experience will be directly used for the excavation of the main tunnel, which is expected to be driven in similar conditions, with a cover close to that to be experienced at the bottom of the inclined gallery.

One of the main challenges ahead lies in the definition of the optimal time for installing the final lining ring, and also in the assessment of the long term state of stress for design. Consequently, particular attention needs to be paid in identifying the long term behaviour and the mechanical properties of the squeezing rock mass. The application of the interactive observational design approach, including design analyses and systematic performance monitoring, become essential for achieving this objective.

Geotechnical conditions, methods, and issues of building the transportation tunnels in the wider area of Belgrade

V.Vujanic, M.Jotic, S.Milenkovic, J.Josipovic & B.Jelisavac
The Highway Institute, Serbia

ABSTRACT: Belgrade is the capital city of Serbia located southwardly from the rivers Sava and Danube on the final part of "Sumadija region crest", i.e. "Belgrade cape". Wider area of Belgrade relief is at the absolute altitude of approximately 70 m above sea level.

Geologic composition of the terrain thereof over basic mountain chain is composed of cohesive clastic sediments and carbonate-limestone, with subordinated presence of metamorphites – serpentinites and with drifts of volcanite – andesites and dacites of Jurassic and Cretaceous age. Almost entire area of Belgrade is covered by Quaternary alluvial, marshy, proluvial-diluvial and eolian sediments. Differing chronsotratographic and lithofacies units are brought into same hypsometric level by numerous faults, thus making even more complex geotechnical conditions for the construction of transportation tunnels.

This paper is presenting briefly spatial distribution of Belgrade area in accordance with geotechnical conditions of previous and forthcoming construction of transportation tunnels, applied methods of excavation and improvement of resistance – deformation properties of rock masses.

1 INTRODUCTION

Belgrade wider area is featuring three geomorphologic units, of higher rank (Figure 4):

- Alluvial plain of rivers Sava and Danube, at absolute altitude of 69–78 m above sea level, whereas the parts of "urban" and "loess" plains are at the altitude ranging from 80 to 115 m above sea level;
- "Sumadija region crest" and its final part – horst-anticline "Belgrade cape" are modified by fluvial erosion and storage, and by proluvial – diluvial processes at the altitude of 25–35 m above sea level, above alluvial plains, i.e. at the absolute altitude of approximately 100 to 200 m above sea level, being bordered by Avala mountain on the city south-side with absolute altitude of approximately 506 m above sea level.
- Neogene basin at Mokri Lug colony, diluvial-proluvial relief covered with loess, locally eroded in the valleys of surface flows. Absolute altitudes of this terrain range from 120 to 190 m above sea level, with certain peaks with absolute altitudes over 250 m above sea level.

Indicated geomorphologic units to the depths relevant for the construction of transportation tunnels are differing as regards the complexity of geologic structure.

Central part of Belgrade wider area in geotectonic sense is falling into the northern part of Central Vardar river sub-zone, i.e. "Sumadija region crest" and its final part denominated as "Belgrade cape".

The oldest discovered rock masses on terrain surface are composed of Jurassic-Cretaceous clastic rocks and limestone of basic mountain chain. Over Jurassic-Cretaceous rock masses, on prevailing part of terrain, there are cohesive, semi-cohesive, and cohesionless clastic (conglomerates, sandstones, clayey marls, argillites, clays, marls, gravels and sands) and carbonate (limestone) rock masses of Neogene. Almost entire area of Belgrade is covered by Quaternary alluvial, marshy, proluvial-diluvial, and eolian sediments. Differing chronostratigraphic and lithofacies units are brought into same hypsometric level by numerous faults with saltation ranging from 20 to 150 m (Figures 1 & 4).

Such lithological composition of terrain thereof predetermined complex, non-homogeneous and anisotropic, geotechnical features of rock masses: grain size distribution of non-cohesive rock masses, origins, and tropism within the system of fissures and fractures of solid rock masses, degradation of rock masses, mode of their interaction with ground waters (differing conditions and regime), as well as resistance – deformation properties of rock masses. Consequently, there is the presence of various

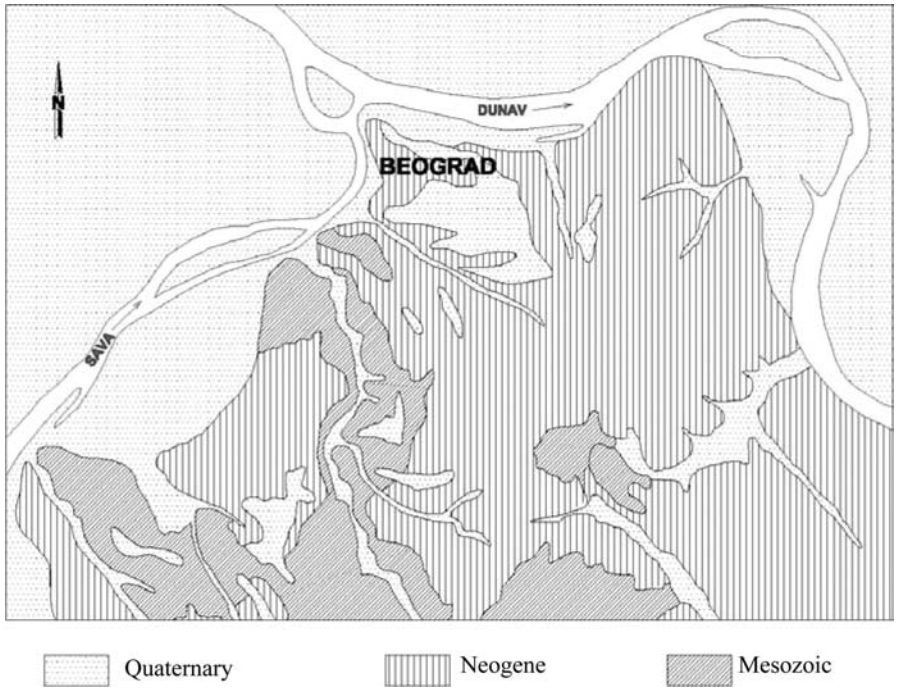

Figure 1. Geologic index map of Belgrade wider area.

geotechnical conditions for the construction and maintenance of transportation tunnels in certain parts of Belgrade wider area.

Until nowadays constructed transportation tunnels in the area thereof, were carried out within the terrains of various lithofacies structure, i.e. differing geotechnical features of rock masses and terrains. In this process, various problems came out which have not been foreseen on time, such as the problems of anchorage, breach of terrain at excavations, protection under ground waters within dusty "fluids", sands, issues of influent seepage of ground waters in already built tunnels, etc.

By analyzing these issues regarding the previous construction of transportation tunnels one came to a conclusion that certain problems occur primarily in terrain parts made of specific lithofacies and chronostratigraphic units. In the text hereinafter, there is a brief presentation of geotechnical features and conditions of transportation tunnels construction in basic lithofacies and chronostratigraphic units in Belgrade wider area, which is in fact the spatial distribution of Belgrade as regards geotechnical requirements, i.e. problems linked with the construction of these facilities. (Fig. 2, 3 & 4). This could be of particular interest for the professional audience, since in the area of Belgrade, there are anticipations for intense construction of transportation tunnels and other underground facilities, such as "LRT-Light Rail Transit" or full-fledged subway, tunnels pertaining "Internal arterial ring", along with the completion of works on tunnels within the framework of Belgrade by-pass motorway E-75.

2 GEOLOGIC COMPOSITION OF BELGRADE WIDER AREA

In geotectonic sense this area is falling into Central Vardar river sub-zone which is ending on this specific terrain with "Sumadia region crest" and "Belgrade cape". The oldest discovered rock masses on terrain surface are made of Jurassic sandstones, with hornstones, clays and marls, and then diabases, melaphyrs, and serpentines. There is a major strike of Jurassic massive and thick-bedded limestone, and Jurassic-Cretaceous flysch. Cretaceous formations, represented in zoogeneous-reef, thick-bedded and massive limestone of Urgon facies. Another lithofacies unit of Cretaceous, with large spreading, is made of Ostruznica flysch, represented by sandstones, marls, and silts in alternating sequence. Locally within their framework there are lenticular beds of breccia limestone and breccia itself. Cretaceous deposits have been ascertained by drilling in the inner urban area of Belgrade. Over Cretaceous and local Jurassic products, there are Neogene deposits set in discordant

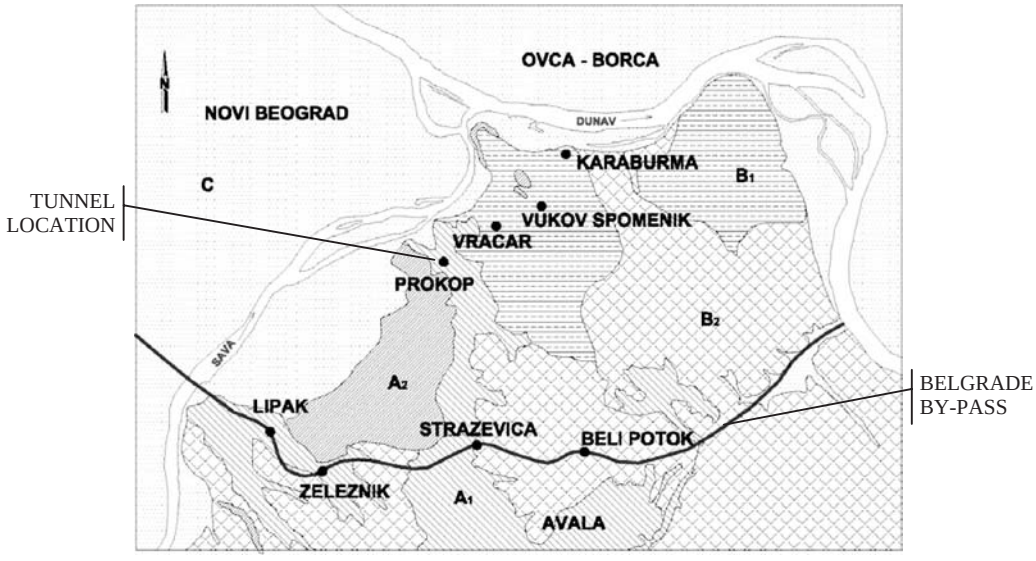

Figure 2. Spatial distribution of terrain as per geotechnical conditions for tunnel construction.

pattern. The oldest Burdigalian products, are represented by schistose, thinly layered clays, bituminous clays and sheet marls with interbeds of tuff and coal. Tortonian and Sarmatian sediments are represented by clays, sandstones, conglomerates and sands, and then by marly limestone, sandy limestone, sandstones and marls in alternating distribution pattern, and zoogeneous reef limestone. Over Sarmatian deposits on almost entire wider area of Belgrade there are Pannonian sediments concordantly set in the facies of marly clays, marls and clayey marls, (Figures 1 & 4).

Pontian sediments, are represented by clays, silts, and fine grained sands with interlayers of weakly cohesive sandstones, conglomerates and limestone.

Pre-Quaternary rock masses are split-up by tectonic motions into numerous faults as blocks set in motion vertically and horizontally, so that differing chronostratigraphic and lithofacies units are brought into same hypsometric level, (Fig. 4).

Quaternary deposits cover almost entire terrain, being represented by fluvial-lacustrine and river sands on the area of alluvial plains of rivers Sava and Danube, loess on the flat of Zemun municipality, diluvial – proluvial silt – clayey deposits on "Sumadia region crest" and Neogene basin in Mokri Lug colony.

3 GEOTECHNICAL CONDITIONS FOR THE CONSTRUCTION OF TRANSPORTATION TUNNELS

Based on previous experience in building transportation tunnels one may draw a conclusion that geotechnical features of rock masses and terrains in Belgrade wider area are very complex in view of heterogeneity and variability of lithofacies composition within the chronostratigraphic units. Thereby, such geotechnical conditions of construction and maintenance of present and future transportation tunnels have been predetermined within the spreading zones of certain lithofacies and chronostratigraphic units.

In the following text, there will be a brief presentation of geotechnical features of lithofacies units, i.e. material composition of terrains and geotechnical conditions for transportation tunnels' construction within their framework, (Fig.2), as per construction requirements, in accordance with following spatial distribution:

- Mesozoic rock masses, area "A_1" are spread out in the western and central part of "Sumadia region crest" and "Belgrade cape", main street Terazije, Tasmajdan park, then in riparian zones of Sava river and in wider area of Cukarica municipality. They are made of flysch sediments, Urgonian reef limestone, layered complex of sandstones, marls and limestone. Generally, these areas consist of highly heterogeneous material composition, differing levels of crystallization and diagenesis, tectonically deformed, with variable and non-uniform physical and mechanical properties along with differing porosity and weathering processes in the presence of water. Within these rock complex packages there are highly consistent and compact milieus, yet likewise with friable parts with undermined physical-mechanical properties which in the presence of water might become extremely unfavorable as operating environment. For such a reason,

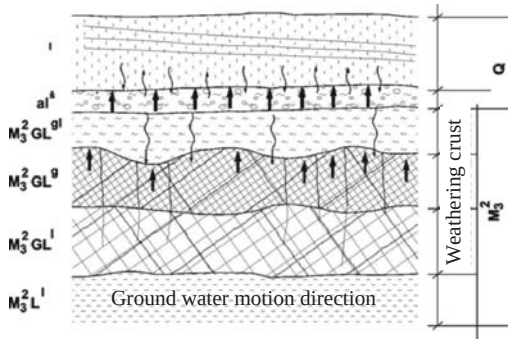

Figure 3. Diagrammatic geologic profile of terrain in narrow urban region.

Mesozoic products can be considered as suitable to restrainedly suitable for tunnel construction. In friable parts there is a possibility of occurrences of ground pressure and falling – in of excavated profile within the overlaying cover and flanks. According to excavation categories GN 200, strong compact parts fall into categories IV to VI, while friable and weathered lithologic units are encompassed by categories II to IV. As regards the conditions for tunnel construction (GN 206), this milieu falls into the category of semi-difficult tunnels with the appearance of minor vertical and lateral pressures. Adequate and thorough bracing is needed for profile heading for these facilities. Prevailing part of railroad tunnel "Dedinje", along with tunnels "Lipak" and "Zeleznik" on Belgrade by-pass motorway were built within these rock masses. New Austrian method (NATAM) can be applied successfully within their framework, with the exception for major distributed faults. This method provides for the excavation with machines or abrasive blasting, and utilization of anchors and prestressed concrete with steel fabric as bracing support. In this process it indispensable to adapt the blasting method to keep the rock mass properties as intact as much as possible and to protect the surrounding facilities.

- Tortonian and Sarmatian carbonate rock masses, area "A_2", are represented by reef limestone and lime- stone, sandstones and marls in an alternating pattern, above ground water level. It is appropriate for transportation tunnel construction. They are rather soft for excavation and stable during construction and maintenance of tunnel facility. In terrain parts where ground water storages are formed in these rock masses one may encounter major problems due to relevant inflow into the tunnel excavations. According to norms GN200, they fall into the category ranging from III to V, whereas regarding the tunnel construction GN 206 these fall into the category of medium difficult tunnels. Although, they provide for somewhat easier excavation conditions, generally speaking they are similar or same as previously described ones, which was proven in the construction of railroad tunnel "Vracar" and motorway tunnel "Strazevica" on Belgrade by-pass.
- Tortonian and Sarmatian marly rock masses, area "B_1", represent the milieus which after the excavation break-up and pulverize into debris and clayey material, thus having unsuitable properties as milieus for tunnel construction. The excavation within their framework must be carried out with particular caution, and excavated profile should be braced immediately, in order to prevent the surface weathering due to the relaxation of rock massif. According to GN 200, they fall into the category IV, while according to tunnel construction requirements GN 206, these fall into the category of difficult tunnels, where one might expect extensive pressures and scattered major falling out of materials above anticipated and required profile. The presence of ground water exerts a great influence onto the quality of rock mass. Adequate and thorough bracing is needed along with tight casing and cautious operations. The most efficient excavation in these milieus is carried out with cutting and milling machines (it can be performed with pneumatic tools), while for permanent bracing in these rock masses, one can utilize prefabricated concrete elements, standard cast reinforced concrete bedding, yet the advantage is obviously awarded to shotcrete, combined with anchors, steel centres and reinforced wire fabric.
- Pannonian marly rocks, area "B_2", represent the least suitable milieu for building transportation tunnels in "Sumadia region crest", i.e. "Belgrade cape", and within "Neogene basin" at Mokri Lug colony. Pannonian products are prone to fast weathering, particularly with the presence of ground water and formation of weathering crust with thickness over 20 m (Figures 3 & 4). In terrains made of Pannonian marls and clayey marls the construction of tunnels is followed by difficulties due to swelling, settlement and ground pressure occurrence, and not only in overlaying soil, but also in invert arch, which requires the construction of purpose-made structures. As regards the tunnel excavation, this milieu is featuring the same characteristics as Sarmatian marly sediments. Techniques of excavation and bracing is the same as in previously described milieus. Underground structures were built in these milieus such as: underground railroad station "Vukov spomenik", exit part of tunnel "Karaburma", whereas the future tunnel "Beli potok" will be built on E-75 motorway by-pass of Belgrade.
- Quaternary rock masses, area "C", represent the package of extremely differing geotechnical features and are made from:

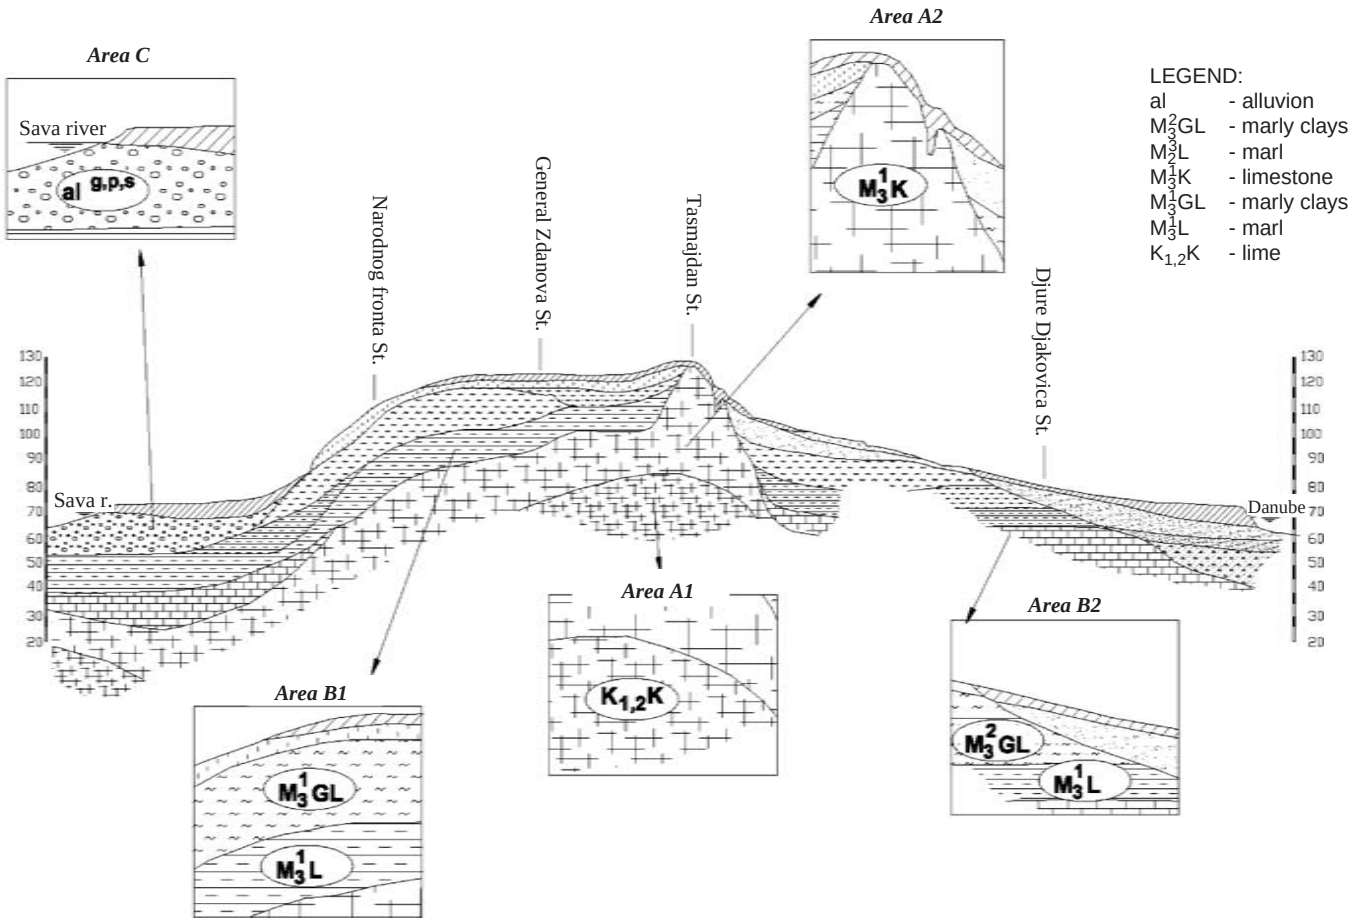

Figure 4. Geologic profile of narrow urban region with areas set apart.

– Diluvial-proluvial, silty-clayey deposits on "Sumadija region crest" and "Neogene basin" at Mokri Lug colony, with high to medium shrinkage, prone to alteration depending on the ground water presence. As regards the excavation (GN 206) they fall into the category of very difficult tunnels to make, with expected strong pressures, extensive overtopping of anticipated profile. Complex and strong bracing is required. Similar geotechnical features are found in boggy basin.
– On-shore loess, in parts above ground water level, as regards the excavation is placed in category I. According to GN 206, tunnels in loess are considered easy to build. Within the zone of ground water oscillations, loess is degrading itself and losing the typical tubular porosity and is becoming very shrinkable with potential breach of soil. In view of that, in the case of minor surcharge, it is advisable to build the tunnel as open cut mining.
– Fluvial-lacustrine and river sandy – gravel deposits, in the area of alluvial plains of rivers Sava and Danube, represent the milieu wherein the excavation can be classified in categories II and III and can be carried out with sophisticated protection from ground water by building watertight membranes, absorbing wells, etc. Tunnels in the area of alluvial plains of rivers Sava and Danube are classified in the category of very difficult facilities to build. Otherwise, conditions for tunnel construction within all these rock masses, are more or less identical, since anticipated severity of geotechnical issues is similar or identical.

4 CONCLUSION

Some of the conclusions should be drawn from the presented issues which are referring to the construction conditions, that is the excavation methods and solution of other problems to be tackled with during the construction of transportation tunnels in Belgrade wider area. The conclusions are as follows:

1. Belgrade wider area is specific by its geologic composition of terrain being highly diversified and complex, either on surface (locations) or deep down. Due to that, geotechnical requirements for the construction of underground facilities also vary within the range from highly suitable to very complex and difficult ones. Hence, the acquaintance with them in the project implementation of underground facility construction is having very high technical and economic relevance, among other things, because based on the results of geotechnical investigations, strategic decisions are being made as regards the viability of underground facility construction;
2. In addition, the construction of underground facility in such conditions must be controlled in view of its impact onto the environment, structures, buildings, streets, utilities, and installations as well. Consequently, one must provide for all necessary requirements meant for it, so that during its operation it can withstand all impacts;
3. Such a complex problem area, requires the creation of information system, and setting up of monitoring pertaining to parameters relevant for determining the construction requirements to which until nowadays insufficient attention has been awarded with;
4. In our view it is important to have at hand the permanent presence of design geologic-geotechnical supervision during the construction of underground facilities, since it has provided for very good results, particularly with reference to costs and target dates of construction.

Construction of major trunk road tunnels in Moscow

B.I. Yatskov

A.M. Zemelman
Metrogiprotrans OJSC, Moscow, Russia

S.N. Vlasov & I.S. Bubman
Russian Tunnelling Association, Moscow, Russia

ABSTRACT: Last years are characteristic with intensive growth of construction of major trunk road tunnels in Moscow. Data on ten largest tunnels are presented in table form. Detailed description is given to challenging Lefortovo and Serebryanoborski tunnels, the latter currently under construction. The Serebryanoborski tunnel system consists of two 2473 m long 14.2 m diameter transport bore barrels with 2060 long approach cut-and-cover sections, one 6.5 m diameter service bore barrel and five connection drifts built in mine techniques. Particular attention is given to safety and surface settlement issues.

During last ten years, general transport situation in Moscow has drastically aggravated. First of all, the streets of Moscow have got saturated with vehicles. From 1991 to 2005, car growth rate exceeded similar indices for previous periods 10 times.

The trend of previous Moscow Development General Pans to presumably develop the public transport modes, first of all metro systems, has resulted in the scope of road construction to lag far behind the city actual needs.

Three quarters of the city trunk roads and transport knots, particularly those in the central part of the city, are overloaded and operate at the upper capacity level.

Traffic jams and increased traffic intervals of surface public transport means have become common. The situation thus formed has considerably worsened the transport service and passenger travel comfort standards immediate solution of the problem was needed. This is why, in order to solve the transport problem and to rehabilitate the city central part, the "Third Transport Ring" program was adopted by the Government of Moscow in 1997–1998. The program stipulated creation of a new multi-purpose transport system as well as rehabilitation and development of areas adjacent thereto.

In order to provide for continuous traffic flows, interchanges must be built at the trunk road.

With this end in view, many structures of various types (bridges over the Moskva River, flyovers, tunnels under the trunk roads and under tracks Moscow Railway) are built along the alignment.

Implementation of this major project of Moscow is actively participated by Organizator Ltd., Corporation "Transstroy" OJSC, Moskapstroy OJSC, Misinzhstroy JSC, Mosmetrostroy OJSC, Moskomarkhitektura as well as Mosinzhproekt, Soyuzdorproyekt and Mosguiprotrans design institutes and many specialized design and construction companies.

While developing designs of the interchanges, it is always a matter of choice between the bridge and the tunnel options to be made with due account of site-specific city development, transport and environment considerations as well as of the availability and location of utilities. Quite often, in spite of higher costs and considerable underground utility rearrangement work, tunnels prove to be more preferable than flyovers, particularly in case of rolling relief.

Tunnel-type interchanges occupy relatively small areas. Their structural elements do not project above the surface, do not hamper visibility at intersections and do not destroy the previously formed architectural ensembles. Contrary to flyovers, tunnels are protected against adverse atmospheric impacts.

Road tunnels equipped with forced ventilation systems lower gas and dust contents in the tunnel environment; in case architectural/acoustic facing facilities (noise-dispersing barriers, hung-up ceilings, wall panels) are provided by the design, city environment will

be less subject to the noise. Vibration absorbing tunnel components and other facilities of similar action minimize the transition of vibrations to adjacent buildings and structures.

The transport infrastructure of Moscow has lately got enriched with several major road tunnels built the largest trunk road crossing sites and designed to separate road traffic flows using several levels. This resulted in higher traffic speeds, increased traffic capacity of the crossings, better traffic safety.

Among projects built by the end of 2007 there are:

- Kutuzovskaya Interchange representing a unique system of structures composed of 6 tunnels, total length 3065 m, flyovers, total length 758 m, and surface ramps, the five-level complex having made it possible to provide for the light-free traffic flows at the crossing; besides, the tunnel complex includes commercial/pedestrian zone, area 7000 m^2, and parking lots, area 5000 m^2;
- enormous interchange at Gagarin Square: 8-lane 900 m long road tunnel with exits towards Andreevski Bridge and Leninski Avenue; this major construction complex integrates 920 m long railway tunnel with transition center to Leninski Prospect metro station and two-level parking lots for 640 cars;
- 509 m long road tunnel for five traffic lanes at Volokolamskoye Chaussee under the Moscow Channel including one lane for trolley-buses; 160 m of this tunnel run immediately under the channel.

The largest underground project at the 3rd Ring optimally solving a set of transportation, ecological, architectural and historical problems is a tunnel in the area of Lefortovo designed for traffic intensity up to almost 4000 vehicles per hour in one direction at 60 km/h tunnel traffic design speed.

Main data on the largest Moscow tunnels are presented in Tables 1 and 2.

At present, construction of Serebryanoborski tunnels, one of most challenging and technically interesting tunnel complexes, is underway; the article is devoted mainly to these tunnels.

Serebryanoborski tunnels being built in the northwest part of Moscow make part of a section of Krasnopresnenski Avenue stretching from MKAD to Marshal Zhukov Avenue to join the central part of Moscow.

The tunnels were called “Serebryanoborski” since the route passes under Serebryanoborsk forestry, an ecologically protected region of Moscow.

The Moscow – Riga (“Baltiya”) up-to-date highway completed by the end of nineties ended at MKAD because it was not possible to directly join it with Marshal Zhukov Avenue and thus with the central part of Moscow. According to terms and conditions imposed by Serebryanoborsk Forestry, any highway surface route option was ruled out owing to ecology considerations.

This is why it was decided by the Government of Moscow to build Serebryanoborski tunnels using TBM with active face support purchased some years ago from Herrenknecht company (Germany) and available after completion of the deep Lefortovo tunnel.

Tunnel complex built by the closed methods consists of 3 tunnels and some drifts:

- two transport tunnels, excavation diameter 14.2 m, length 1514 m each;
- one service tunnel, excavation diameter 6.3 m, length 1514 m, located between the transport tunnels;
- the tunnels are interlinked with five drifts, length 21 m, excavation cross-section 6.5 m (span) × 9.0 m (height), spaced at 250 m.

In the transport tunnels structurally executed in two levels, combined traffic is arranged with road traffic at the upper level on three lanes each direction and trains of the Stroguinsko-Mitinskaya metro line at the lower level. This solution is as interesting from engineering viewpoint as sophisticated in execution, this is why it is seldom used in practice.

Given site specific climatic and ground conditions, it was decided to drive the tunnels using the active bentonite face support technology providing for minimum settlement of the surface, buildings, structures and utilities.

Bentonite slurry and compressed air based hydraulic face support technology was chosen since it makes possible to smoothly adjust hydraulic pressure values depending on changing geological conditions and technological parameters as well as to carry out objective instrumental control. These advantages were many times verified and successfully used while driving the Lefortovo tunnels using the same Herrenknecht TBM. TBM shield assemblage moment is fixed in Figure 1, while the moment of placing the machine into the dismantling chamber is shown in Figure 2.

By the moment, the left and the service tunnels are successfully driven; currently they are being equipped including construction of reinforced concrete carriageway slab and metro line compartment, application of fire-resistant coatings and installation of smoke-removing ducts and all utilities; the right tunnel is being driven.

The following results were attained while driving the above tunnels:

- maximum progress: 16 m/day (8 rings as wide as 2.0 m for the transport tunnel and 13 rings as wide as 1.2 m for the service tunnel);
- surface settlements fixed instrumentally in the course of monitoring made 8 – 12 mm;
- maximal connection accuracy: 8 mm for axis, 12 mm for stationing, 4 mm for height;

Table 1. Main data on road tunnels built in Moscow by end 2007.

– all rings were assembled within the tolerance (±50 mm).

Ground-cutting instruments were controlled, examined and changed under compressed air (caisson conditions) from the chamber adjacent to the face during shield operation stops.

Owing to perfected technological operations and high professional level of the personnel, no particular problems arose in the course of driving, excepting bentonite slurry separation in the course of simultaneous driving of the main and the service tunnels combined with operation under caisson conditions.

Connecting drifts, five in number, are spaced at 250 m station distance; they are multifunctional and destined to help effectively solve the following major tasks related to operation of main tunnels:

– supplying fresh air through service tunnel sections and its subsequent distribution over transportation zones of the main tunnels through the drifts;
– laying the required utilities (cables, pipelines, etc.);
– in case emergency situation occurs in any of the transportation tunnels, evacuating the passengers, drivers and operation personnel through emergency

corridors in the service tunnel and providing for the flow of fresh ventilation air.

250 m distance was chosen proceeding from the condition that a person can stand fire and smoke no longer than for 1.0–1.5 minutes. Any person caught with emergency situation at maximal distance of 125 m from the nearest drift and moving at a speed of 6 km/h will escape within 1.0–1.25 minutes.

Most difficult was mine driving of drifts between the tunnels. The drifts pass in different ground conditions and the driving required various different special construction techniques to be used. Figures 3 and 4 demonstrate preliminary stabilization of the soil and driving of drifts between the tunnels respectively.

To drive the first (on move) drift passing through relatively dry sand below ground water table, horizontal jet techniques were used to stabilize the soil massive.

The second (on move) drift passes through water-saturated sand. Owing to this, two soil massive stabilization techniques were combined: injection of Microdur particularly fine mineral binder and horizontal jetting.

The third and the fourth drifts pass in most unfavorable natural conditions (ground water head approximately 1.6 bars, permeability coefficient from

1 to 2 m/day). This is why it was decided to use horizontal freezing techniques, freezing station being installed in the left transport tunnel.

The fifth drift is built in relatively stable clay, protective screen of pipes driven above the tunnel vault being used.

All the five drifts are driven by means of partial excavation of the cross-section using the wall-supported vault techniques and temporary arch concrete supports.

Figure 3. Soil preliminary stabilization operations while driving drifts between tunnels.

Figure 4. Driving drifts between tunnels.

While executing every soil massive preliminary soil stabilization operation in each drift, thorough fulfillment of technological schedule requirements was observed and first of all, permanent multi-factor control and operation-vise acceptance.

Technological facilities as well as with life-supporting and project operation safety systems.

As soon as driving the transport tunnel whose general view is presented in Figure 5 is completed, the tunnel itself and drifts between its barrels will be equipped with permanent technological structures, life support and safe project operation systems.

Resulting from the tender and competitive bidding, the following main organizations were established:

- Client: Organizator Ltd.;
- General Contractor: consortium headed by Mosmetrostroy OJSC;
- Scientific and technical support: Tunnels and Metro Scientific Research Center, TsNIIS OJSC, and Russian Tunnelling Association;

Figure 5. General view of transport tunnel in the course of driving.

– Consultants: VINCI (France) and Herrenknecht (Germany).

In compliance with a decree of the Government of Moscow, the Serebryanoborski tunnel project is scheduled for completion and putting into operation along with the Stroguinsko-Mininskaya metro line at the end of 2007.

Construction of long tunnels demands that the following sophisticated operation systems absolutely reliable under emergency conditions be developed to provide for the safety of transportation flows: stable power supply systems; ventilation systems providing both for fresh air supply and for smoke evacuation in case of fire; water- and heat supply systems; systems of communication, signaling, information, telemonitoring, etc. Operation of various technological facilities must be concentrated in a single control post. Such systems do operate in the Kutuzovski, Gagarinski and Lefortovo tunnels.

Road tunnels are attributed to structures of increased responsibility level whose failure may result in serious economic, social and ecological consequences. Tunnel design and construction specifications stipulate that stain-stress condition of the tunnel lining be monitored both in the course of construction and during initial operation period. While driving the Serebryanoborski tunnels, special monitoring is being carried out including detailed control of surface deformation and condition of buildings and structures available within the tunnel driving possible influence area.

Selecting auxiliary construction methods for NATM tunnel excavation in urban areas

J. Yorita & Sasaki

N. Yamaki & M. Okamura
Toda Co., Ltd., Chuo-ku, Tokyo, Japan

ABSTRACT: The Takaoka Tunnel on the Hokuriku Shinkansen Line is a tunnel 6,938 m long (north sector: 3,990 m, south sector: 2,948 m) under construction by the NATM in an urban area in northern Nagano Prefecture. The geology of the south sector is fractured cohesive soil (N-value 10 to 20) and silt (N-value 10 to 30) intercalating sand aquifer. Excavation is performed at small depths (tunnel diameter multiplied by about 2 to 3) directly below many existing structures. This paper discusses a technique for selecting auxiliary methods by statistical and FEM analyses, newly introduced for minimizing adverse impact of tunneling work upon nearby structures.

1 INTRODUCTION

The Takaoka Tunnel on the Hokuriku Shinkansen Line is a NATM tunnel 6,938 m long, longitudinally traversing the Nagaoka Hills on the right bank of the Chikumagawa River running in northern Nagano Prefecture, located at the Fossa Magna. The construction alignment is divided into two parts, north (3,990 m long) and south (2,948 m long) sectors. The south sector of this tunnel is located in the southern Nagaoka Hills, running just below many residences and other neighboring structures (Fig. 1). To minimize adverse impact of tunneling upon these structures, the primary requirement is to limit surface settlement. A technique was established for selecting auxiliary methods for limiting surface settlement. Statistical analysis was conducted as the first step, involving data obtained during the construction, to evaluate the auxiliary methods. Based on the results of the statistical analysis, auxiliary methods for numerical modeling were selected. Then, a numerical analysis model was created to mechanically evaluate the auxiliary methods.

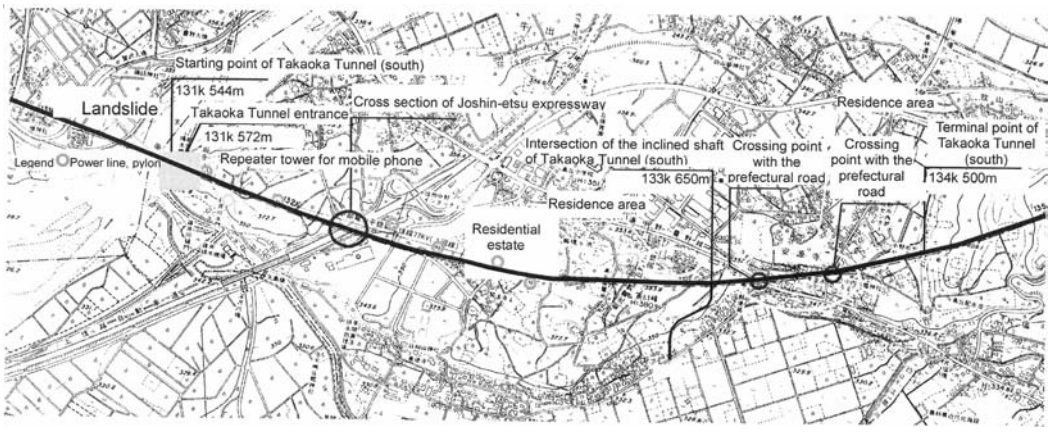

Figure 1. Plan.

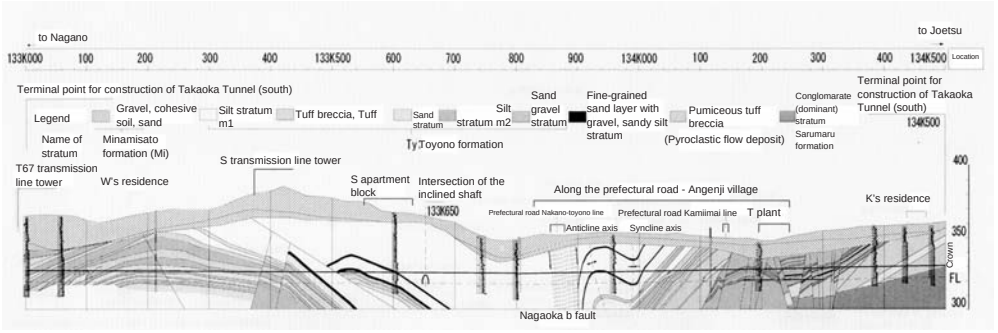

Figure 2. Longitudinal profile.

2 GEOLOGICAL OVERVIEW

The geology of the south sector is weak and unconsolidated. The tunnel is to be constructed at shallow depths just below many residences and important infrastructure. The Toyono stratum forming a large part of the ground of this sector is mainly composed of silt of 1.0 MPa in unconfined compressive strength. Settlement at the support foot and other parts is anticipated due to decrease of bearing capacity of the ground. The silt stratum contains intercalating or alternating sand and gravel layers. Where the ground contains water, there is fear of ground collapse because of water inflow with the soil. The geology is very complex with noticeable folds, dips and faults generated by active tectonic movements (Fig. 2).

3 EVALUATION OF THE AUXILIARY METHODS BY STATISTICAL ANALYSIS (MULTIVARIATE ANALYSIS)

Different auxiliary methods were evaluated in terms of their effect in limiting settlement by means of statistical analysis (multivariate analysis). Since the ground conditions of the tunnel (geology, existence of fault, folding, overburden, etc.) vary from section to section, it is difficult to evaluate each auxiliary method in a generic manner. However, the authors attempted generalized evaluation by multivariate analysis with plural samples of quantifiable data. By involving samples of multiple sections, it is possible to assess the effect of each auxiliary method in limiting settlement in typical geology in the south sector of the Takaoka Tunnel.

3.1 *Evaluation by regression analysis*

Ground surface settlement was taken as an objective variable, and ground condition, supports and auxiliary methods as explanatory variables, to quantitatively evaluate by means of regression analysis. Scarcity of available numerical data of tunnel excavation sometimes makes it difficult to develop a suitable model. Nevertheless, data were quantified as much as possible for analysis. The results of the regression analysis are summarized in Table 1.

Table 2 shows the effect each auxiliary method had in limiting settlement when used alone. This table demonstrates that each auxiliary method is similar in surface settlement effect. However, X(5) (closure with struts), X(3) (AGF: injection type long forepiling) and X(7) (sidewall pre-grouting) are comparatively more effective. Hence these variables should be involved in the modeling to develop an accurate FEM model.

3.2 *Correlation analysis*

Multicollinearity among variables (among different auxiliary methods) is found in the results of correlation analysis shown in Table 3. This is attributable to the fact that multiple auxiliary methods work in concurrence with each other to restrain surface settlement, that is to say, auxiliary methods combine to limit settlement.

Although the analysis used all the explanatory variables that could be quantitatively given, t-value (test of hypothesis concerning mean) is small for the variables, showing that they are not reliable as explanatory variables, except for closure with struts, foot reinforcement pile and sidewall pre-grouting (Table 3). This can be assumed to be due to multicollinearity among variables. The same holds for F-value (variance test).

3.3 *Evaluation by the statistical analysis*

The statistical analysis was capable of quantitatively analyzing the effects of the auxiliary methods. As shown by the analytical results, the effects of X(3) (AGF: injection type long forepiling) and X(7) (sidewall pre-grouting) are more effective for surface settlement. Hence these variables should be modeled for creating an accurate FEM model. In addition, the analysis on correlation among the different

variables quantitatively revealed the fact that they exhibit expected effects by dependency on each other.

4 CREATING A NUMERICAL ANALYSIS MODEL

4.1 *Selection of an analysis model*

Referring to the results of statistical analysis, an FEM model was created, which is capable of accurately simulating the surface settlement aimed at curbing impact on structures in the vicinity.

Through study on the surface settlements in the sector already constructed, elastic analysis, nonlinear elastic analysis and elasto-plastic analysis were conducted, to select a prediction model capable of closely simulating the actual situation.

The geology of the section considered in the analysis was comparatively uniform, mainly composed of silt, located at 133 km 680 m, with modulus of deformation $E = 27\,MN/m^2$, internal friction angle $f = 20$ degrees, cohesion $C = 101\,kN/m^2$ and overburden depth of 35 m.

Comparison was made in the analytical section, between measured surface settlements and those given by direct analysis of each analytical technique, and between surface settlement and tunnel crown settlement at each analysis step (Table 4). In addition, studying the major principal strain distribution diagram of each model, the authors attempted to determine a model that can correctly express the deformation characteristics of the tunneling sector discussed here.

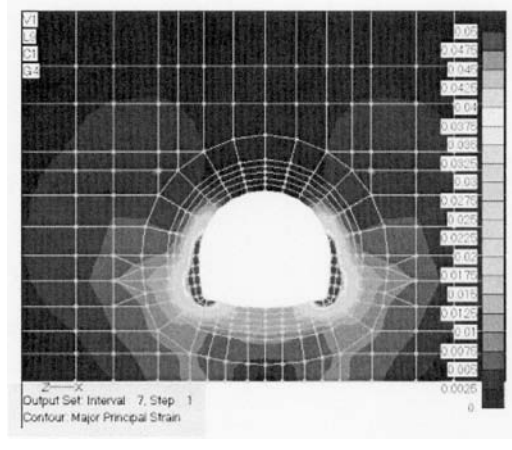

Figure 3. Distribution of major principal strain (nonlinear elastic analysis).

This comparative study confirmed that the nonlinear elastic analysis is capable of simulating the ground deformation characteristics of the tunneling sector in question, providing final surface settlement and crown settlement close to the measured values, and expressing, in the major principal strain distribution diagram, loosened zone in the crown and at the top heading. Consequently, the nonlinear elastic model was selected for analytical study of excavation patterns (Fig. 3).

The silt stratum is the main geology of the tunneling sector. It has a small modulus of deformation,

Result	Surface settlement (mm)	127	87	86	84	76	70
	Crown settlement (mm)	141	103	101	99	87	81

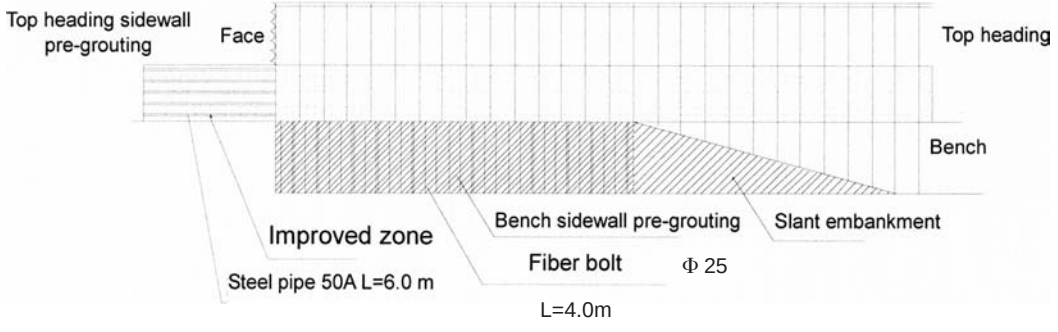

Figure 4. Longitudinal section of sidewall pre-grouting.

where fracture at the sidewall portion was assumed to partially progress along with excavation, causing the whole ground to deteriorate, decreasing the modulus of deformation of the ground around the tunnel, thereby increasing tunnel convergence and surface settlement. The nonlinear elastic analysis gives gradual decrease of modulus of deformation in response to increase in stress. Therefore, this analytical technique well expresses variation in modulus of deformation of ground in a wide range in ground mainly composed of silt.

4.2 *Selection of auxiliary methods using the analytical model*

By the use of the nonlinear elastic FEM model created for the section at 133 km 680 m, assuming the typical overburden depth and geological conditions of the tunneling sector, support patterns and support members were combined, to evaluate their effects in limiting surface settlement. The simulation study involved silt-dominant geology with N-value = 24, modulus of deformation E = 24 MN/m^2, internal friction angle $f = 18$ degrees, cohesion C = 94 kN/m^{2}and overburden depth of 25 m. Table 5 shows the analytically obtained surface and crown settlements with excavation patterns studied.

4.3 *Evaluation of sidewall pre-grouting*

In the tunneling sector, partial development of fractures in the cracked zone at the sidewall was anticipated, leading to deterioration of the whole ground, and resulting in lower modulus of deformation of the whole ground around the tunnel.

For preventing such adverse changes, it is essential to improve the ground strength before the modulus of deformation of ground begins to decrease, or more specifically, before the face arrives at the sidewall portion of top heading and bench, since ground deterioration is induced by fracture in those sections. Therefore, a new auxiliary method, i.e., sidewall pregrouting was adopted (Figs. 4 to 6). To validate the effect of this auxiliary stabilizing practice, numerical analysis was conducted on the preceding improvement with injection rock bolts and the succeeding improvement with injection rock bolts from the excavated cavity (Table 6). Comparison of the results shows that only the preceding improvement achieved surface settlements below control criterion (80 mm), proving the effectiveness of the sidewall pre-grouting. For verifying the improvement effect, sidewall pregrouting was tentatively implemented and bore hole load test was conducted. The test results showed cohesion of the top heading of 181 kN/m^2 and that of the

bench of 185 kN/m^2 achieving the required strength level.

5 VALIDATION OF THE NUMERICAL MODEL

To validate the numerical model, comparison was made between analytical values and measured values of surface settlement with excavation patterns P-5 and M (Table 7). Good agreement was found between analytical and measured values, confirming validity of the numerical model.

6 CONCLUSIONS

Tunneling in the sector discussed in this paper was planned at shallow depths in unconsolidated ground, with many vital infrastructure and residences on the surface just above. For minimizing impact of tunneling upon these structures, it was imperative to select an excavation method well suited to this project. First, various auxiliary methods were quantitatively evaluated in terms of surface limiting effect by means of statistical analysis. This analysis enabled quantitative expression of surface settlement effect. On the basis of the results of the statistical analysis, auxiliary methods to be involved in modeling were appropriately selected, thereby improving simulation accuracy of the numerical analysis model.

Construction update and TBM excavation: Seymour Capilano Twin Tunnels Project, Vancouver, Canada

Dean Brox, Don Phelps & Brian Garrod
Hatch Mott MacDonald, Vancouver, B.C., Mississauga, Ontario, Canada

Tom Morrison
Greater Vancouver Regional District, Burnaby, B.C., Canada

Andy Saltis
Pacific Liaicon & Associates/SNC Lavalin, Vancouver, B.C., Canada

ABSTRACT: The Greater Vancouver Water District (GVWD) is currently constructing the Seymour-Capilano Filtration Project to enhance the quality of water supplied to the Vancouver area from the Seymour and Capilano reservoirs in North Vancouver. The project, designed by Hatch Mott Macdonald, includes major underground works comprising twin 3.8-m diameter, 7.1-km bored tunnels, the 11 m diameter, 180-m deep Seymour Shaft as the main construction access shaft, and the twin 4-m diameter, 275-m deep Capilano raisebored shafts. This work was tendered as a single contract, which was awarded to Bilfinger Berger (Canada) Inc. Construction started in early 2005 with the excavation of the Seymour Shaft by conventional shaft sinking methods through 30 m of dense glacial deposits followed by 150 m of granitic bedrock. Bilfinger Berger used lattice ring girders, mesh and dry-mix shotcrete for shaft support while sinking through the glacial deposits. Shaft support for the bedrock portion followed the Engineer's design, comprising pattern rock bolts, mesh and shotcrete. Shaft sinking was completed in early November 2005. Ancillary shaft-base excavations and structural, electrical and mechanical work were completed in May 2006. TBM excavation commenced in mid-2006 with the first TBM followed by the second TBM in September 2006. TBM excavation is scheduled to be completed in late 2007.

1 INTRODUCTION

The Greater Vancouver Water District (GVWD) is currently constructing the Seymour-Capilano Filtration Project (SCFP) to enhance the quality of water supplied to the Greater Vancouver area from the Seymour and Capilano reservoirs in North Vancouver. The main element of the SCFP is a 1,800-megalitre per day filtration plant, currently being constructed in the Seymour Valley. This plant, when built, will be the largest in Canada. Considerations of cost, community impacts and environmental issues resulted in the decision to build a single filtration plant in the Seymour Valley, connected to the Capilano reservoir by twin tunnels, rather than two separate plants adjacent to each water source. Raw water will be drawn from the Capilano reservoir and pumped through the Raw Water Shaft, Raw Water Tunnel and Seymour Shaft raw water riser pipe to the head of the Seymour Filtration Plant. Treated water will return by gravity through the Seymour Shaft treated water riser pipe, the Treated Water Tunnel and the Treated Water Shaft through an Energy-Recovery Facility and pressure-balancing tank to the Capilano distribution mains.

The Twin Tunnels component of the project comprises the 11 m diameter, 180-m deep Seymour Shaft as the main construction access shaft, twin, 3.8-m diameter, 7.1-km bored tunnels (the Twin Tunnels), and two 4-m diameter, 275-m deep raisebored shafts connecting the tunnels to surface at Capilano. Figure 1 shows the Laydown area of the Seymour Shaft in May 2006.

Investigations and preliminary design work for the SCFP date back nearly ten years. The GVWD selected Hatch Mott Macdonald (HMM) to participate in the preliminary design of the Twin Tunnels and awarded the detailed design to HMM in 2002.

The GVWD awarded the construction of the Twin Tunnels as a single contract, with lump sum and unit price components, to Bilfinger Berger (Canada) Inc. in August 2004. Pacific Liaicon and Associates/SNC Lavalin are responsible for construction management

and HMM are providing resident engineering services. The project is scheduled for completion in early 2009. The GVWD appointed a Technical Advisory Board in late 2004. Tenderers were provided with a Geotechnical Data Report and Geotechnical Baseline Report. The contract makes provision for Escrow Bid Documents and a Dispute Review Board.

Figure 1. Seymour Shaft laydown area.

2 PROJECT LOCATION

The GVWD decided early in the design process to connect the Capilano and Seymour sites entirely by tunnels, rather than by combinations of tunnels and surface pipelines. Length, routing and community impacts made this the best option.

Tunnelling, however, was affected by the existence of deep buried valleys at both ends of the tunnel alignment, eroded from the bedrock by glaciers and filled with mixed, water-bearing glacial materials. The horizontal and vertical alignments of the tunnels were both reached after considering many possible options.

The tunnels will be driven westwards from the Seymour Shaft, beneath the Lynn buried valley, passing beneath the slopes of Grouse Mountain and Mount Fromme and under the Capilano buried valley to a western terminus 275 m from surface immediately south of Cleveland Dam. There, the tunnels will be connected to surface by twin 4-m diameter raisebored shafts. Figure 2 shows the overall project layout.

The location initially selected for the Seymour Shaft was at the west side of the Filtration Plant. Drilling revealed water-bearing glacial materials to 100 m from surface with shattered bedrock conditions beneath.

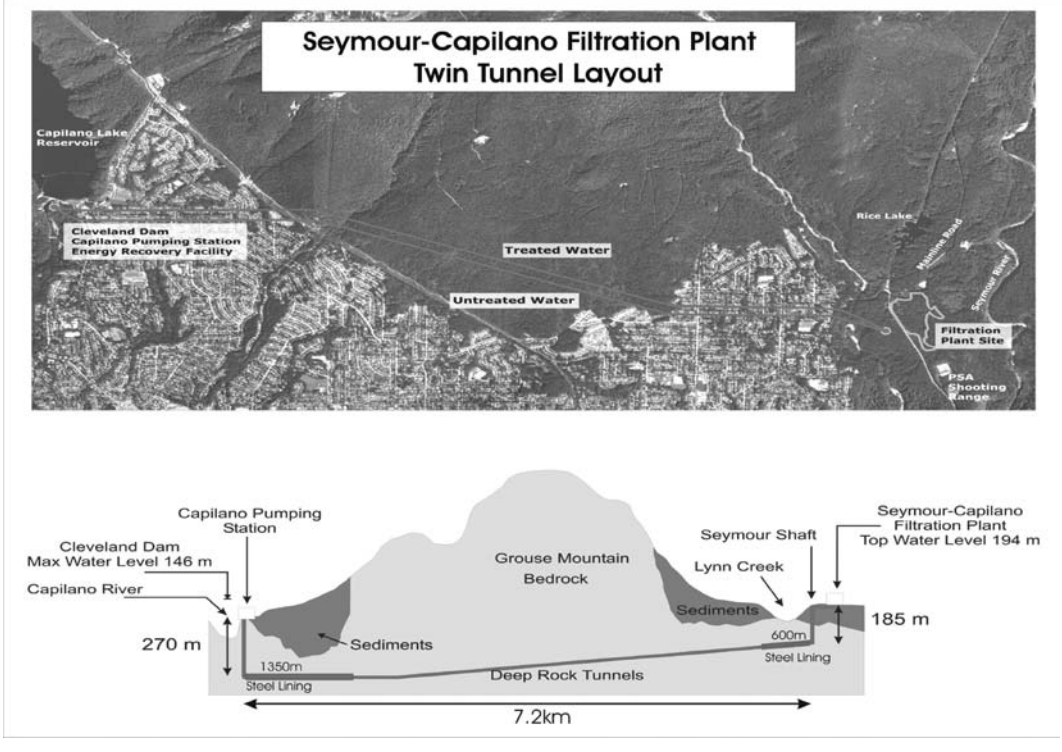

Figure 2. Project layout.

The GVWD and its consultants considered ten alternative shaft sites, taking into account technical, financial, social and environmental considerations. The site finally selected was about 200 m southwest of the original site, where seismic surveys and drilling proved the existence of a buried bedrock hump rising to within 30 m of surface. The Twin Tunnels contractor was provided with a cleared, leveled, drained and graded site; site operations began in the autumn of 2004.

3 SEYMOUR SHAFT CONSTRUCTION

3.1 *Shaft Excavation and Support in Overburden*

Bilfinger Berger Canada commenced construction of the project with the excavation of the 11 m diameter, 180 deep, Seymour Shaft in January 2005. The 30 m deep overburden portion of the Seymour shaft was excavated conventionally through dense glacial materials in approximately 1.0 m lifts using a CAT 308 excavator with mucking into 6 m^3 buckets. Shaft excavation was undertaken with two 12-hour shifts with shift changes at 6:00 AM and 6:00 PM daily.

Bilfinger Berger Canada proposed an acceptable alternative support system for sinking through the glacial deposits, consisting of lattice girders, mesh and 250 mm thickness of dry mix shotcrete and shown in Figure 3. The ground support was installed immediately upon completion of excavation of each lift. No raveling or any form of instability occurred during excavation in the overburden and the alternative shaft support system performed well. Sporadic, localized groundwater inflows were encountered during excavation and drainage holes were completed accordingly. The dry-mix shotcrete for the overburden portion mainly comprised a pre-manufactured product that included an accelerator. The strength of dry-mix shotcrete exceeded the project specifications based on results from test panels and from in situ cores.

3.2 *Shaft Excavation and support in bedrock*

The 150-m bedrock portion of the shaft was excavated by conventional drill and blast methods using two Atlas Copco R3 Crawler drill rigs. A typical blast hole production round varied from 1.5 m to 4.0 m deep. The blast design was based on 220 parallel-drilled blast holes with a typical perimeter hole spacing of 0.5 m. The blast design initially comprised a wagon-wheel cut comprising four reamer holes and a single middle blast hole. The blast design was later changed to a nine hole cut comprising five reamer holes with four surrounding blast holes, which produced significantly improved results.

Shaft support for the bedrock portion of the shaft followed the base design and comprised a combination of a pattern of 4.0 m long, 32 mm diameter, fully grouted and hand tensioned rock bolts at a typical 1.5 m square spacing, welded wire mesh and 150 mm minimum thickness of dry-mix shotcrete.

Welded wire mesh was installed around the full shaft perimeter for the full round depth following mucking. Shotcrete was then applied followed by the installation of pattern rock bolts. Shotcrete was applied to each excavation lift using a portable lifting assembly that was designed by Bilfinger Berger Canada and lowered to the shaft floor by a crawler crane. The portable shotcrete lifting assembly comprised 2–1 m^3 hoppers, 2–16 liter Aliva 252 shotcrete machines, and 2–150 liter pumps for injection of accelerator.

Shotcrete application was closely monitored and tested during excavation as per the project specifications with a testing frequency of three cores (from panels and/or in situ) for every 200 m^2 of applied shotcrete.

Both the pre-mix and on-site batch mix shotcrete provided consistently good strength results from the quality control and quality assurance testing.

Quality assurance testing of the shotcrete was carried out by AMEC of Vancouver on behalf of the GVWD. The quality assurance testing was typically

Figure 3. Shaft support in overburden.

Figure 4. Shotcrete lifting assembly.

Figure 5. Shaft support in bedrock.

Figure 6. Shaftbase excavation, early 2006.

carried out at a frequency of 10% of the quality control testing. The quality assurance testing always comprised in situ core testing.

Figure 5 shows the drilling of rock bolts using a single drill rig. On a few occasions a number of hollow-core self-drilling injection anchors were installed in closely fractured metavolcanic rock that prevented easy insertion of rock bolts following normal drilling. The support system for the bedrock portion of the shaft performed well and no form of any instability manifested along the shaft walls during excavation.

4 SEYMOUR SHAFTBASE CONSTRUCTION

The shaftbase excavation adopted for construction was not significantly dissimilar to the proposed base design. The shaftbase was allowed to be modified by the Contractor and Bilfinger Berger Canada elected to adopt the same excavation width for the starter and back chambers of approximately 14 m and 10 m respectively but extended the length of both the starter and back tunnels as well as the back chamber to facilitate the set up and launching of the TBMs and mucking logistics. The excavated lengths of the starter tunnels, back tunnel, and back chamber were about 35 m, 50 m, and 30 m respectively. The excavated heights of the starter and back chambers are 6 m and about 5 m respectively. Figure 6 shows the start of excavation of the starter tunnels in early 2006.

Excavation of the starter and back chambers were completed by drilling and blasting 1.5 m to 3.0 m full-face rounds. The initial rock support for the starter chamber was modified from the base design by Bilfinger Berger Canada to include lattice girders for the first 6 m. In addition, 6-m long rock bolts were installed for the first 4 m. The length of the rock bolts was subsequently reduced to 4 m for the remainder of the chamber excavations based on inferred good geological conditions and the initial results of the convergence monitoring.

Excavation of the starter and back tunnels were also completed in 1.5 m to 3.0 m full-face rounds. Spot rock bolts and full coverage shotcrete with mesh were applied for support.

The encountered rock conditions within the shaftbase excavation typically comprised mixed granitic and metavolcanic rock of varying quality. Groundwater inflows into the shaftbase excavation have been measured to date to be less than 20 l/min. The final excavation for the shaftbase comprised an 8 m deep pit to receive the mucking buckets and an 8 m deep sump.

5 SEYMOUR SHAFTBASE INSTALLATION

Substantial structural, mechanical and electrical work was needed in the Seymour Shaft and shaftbase chamber in preparation for TBM excavation. This work lasted from March to May 2006. The sidewalls at the heading of starter tunnels have been concreted to facilitate the bearing of the thrust pads of the TBMs. Rails have been laid out for the movement of rolling stock.

A Liebherr modular gantry crane was constructed at the shaft collar, equipped with two hoists, each capable of hoisting 70 tons as can be seen in Figure 1. These are being used for installing the TBMs and, once tunneling begins, will be used to hoist two 28 m^3 mucking buckets built to a Bilfinger Berger patented design. The gantry system is unique and equipped with electronic sensors for automatic muck removal operation.

An Alimak elevator with a capacity of 2,400 kg or 23 people was installed. The electrical facilities were installed to transmit power down the shaft at 12.47 kV for transformation at the shaft base to 4,160 V for supply to each TBM at 600 V. Two 100-kW ventilation fans were installed on surface with ducting down the shaft. In addition, a 400 m^3 capacity sump pit and two muck pits each having a volume of 125 m^3 have been

excavated at the shaft bottom. The pit for the rock buckets was covered with two hydraulically actuated doors. The chamber floor was concreted and track, switches, car dumps and muck chutes were installed. Concrete cradles and gripper walls were installed for the start of TBM excavation.

6 TBM SELECTION AND DESIGN

Bilfinger Berger Canada selected two new 3.8 m diameter, 1,260-kW TBMs that were built new for the project by Robbins at Solon, Ohio. These machines are high-powered, open-shield, hard rock machines with 483 mm (19-inch) cutters and support fingers immediately behind the shield. With trailing gear, each machine will be approximately 250 m long. The trailing gear will include pumping and grouting equipment and will also allow for passing of the mucking trains. Each TBM will be equipped with two drills for forward probing and pre-excavation grouting. A probe-hole will be maintained continuously ahead of the face.

Bilfinger Berger Canada has designed the TBM mucking arrangement such that each 1.5-m push by the TBM will fill a train of six Mühlhauser 5 m^3 side-dumping cars. A GAI diesel locomotive will haul each train from the TBM to the Seymour Shaftbase for tipping. One train will fill one 28 m^3 mucking bucket. The TBM muck will be hoisted to surface and trucked to the GVWD designated disposal site located 4 km away up the Seymour valley.

The Robbins TBMs were trucked from Ohio to Vancouver in 72 tractor-trailer loads, starting in early May 2006. TBM installation and commissioning, with the assistance of Robbins personnel, was carried out in the latter part of May and early June 2006. Figure 7 shows the first TBM assembled in the shaftbase. TBM tunneling is anticipated to begin in mid-June 2006.

7 TBM EXCAVATION PROGRESS

In mid-2006 TBM # 1 was advanced approximately 150 m in the Raw Water Tunnel using an umbilical cord with the back-up for this TBM placed in the Treated Water Tunnel. This procedure was adopted in order to allow for sequential set up of TBM # 2. TBM # 2 was set up in September 2006 and excavated the first 140 m in the Treated Water Tunnel. Figure 8 shows the first part of TBM excavation of the Raw Water Tunnel and Figure 9.

Stress–strain soil behavior during tunneling in soft ground: experimental study on 1g-earth pressure balanced shield model

D. Branque, C. Boutin & H.V. Doan
Ecole Nationale des Travaux Publics de l'Etat, Département Génie Civil et Bâtiment, Rue Maurice Audin, Vaulx-en-Velin cedex, France

ABSTRACT: Since several years, the ENTPE's Geomaterial Laboratory in Lyon (France) has started a large experimental project based on the so-called "Earth Pressure Balanced Shield" (EPBS) method adapted to tunneling in soft ground. Within the framework of the project, a specific reduced-scale physical model of the EPBS (1:10 approximately) was built. A first objective has been to perform a direct rational analysis at the model scale, aimed to understand the different mechanisms occurring during the EPBS method of tunneling. In a second stage, this analysis and the resulting data base will be used to elaborate a numerical modeling of this method. The present paper presents typical test results obtained with the EPBS model for frictional – cohesive material (humid fine silica sand). These results concern the stress-strain soil behavior during ideal tunneling rate. Moreover, the sensitivity of the main control parameters available on the command shield and the action of the cutter head are debated.

1 INTRODUCTION

Tunneling with the earth pressure balance shield (EPBS) originally appeared in Japan during the seventies in fine-grained alluvial soils suitable for this mechanical tunneling procedure. Since that time, several authors had described its theoretical principles in the literature (Kurosawa, 1981, Clough et al, 1983…). The fundamental idea of the EPBS method consists in balancing the hydrodynamic pressure and the earth pressure at the tunnel face by a controlled confinement of the excavated soil contained in a pressure chamber at the front of the shield. In theory, a perfect earth balance is obtained when the weight of discharged soil from the pressure chamber by the screw conveyor is equal to that of soil excavated and entering in the chamber during the same time. This balance between these two weights requires a good synchronisation between the tunnel boring machine (TBM) advancement rate and the screw conveyor rotation speed.

In practice, the EPBS method remains relatively complex. In Europe in particular, the technique is often confronted with very mixed and pervious grounds in which controlling the confinement pressure at the tunnel face remains difficult. Additionally, in some coarse and heterogeneous grounds, it is often observed that the torque required in order to ensure the rotation of the cutter head reaches high values and becomes a non-negligible limiting parameter of the machine advancement speed.

Other practical difficulties of the EPBS technique are revealed on the work site. For example, neither the weight of excavated material nor that extracted from the pressure chamber are usually measured with sufficient accuracy to allow a driving of the TBM uniquely based on the knowledge of these two weights. The definition of additional control parameters appears therefore essential to guarantee the safe driving of the machine.

Feedbacks from work sites also show that a confinement of the working face, though appropriately ensured, does not necessarily prevent large displacements of the ground surface. Other causes of volume loss around the TBM (displacement along the shield tail, ground convergence at its end…) shall be taken into consideration to control the displacement of the ground surface. More generally, it appears in practice that the action of the TBM on the surrounding ground is highly dependent on soil characteristics and tunneling rates. In consequences, the ground volume influenced by TBM during its advancement is generally difficult to define prior to tunneling.

The Geomaterial Laboratory of the "Ecole Nationale des Travaux Publics de l'Etat (ENTPE)" has started in 1998 a large research project devoted to Earth Pressure Balanced Shield method. The project aims to analyze and understand the main physical mechanisms occurring during EPBS method tunneling. The ambition is to provide technical support and guidance to overcome the different difficulties

encountered on work sites. In particular, these studies should lead to the development of an appropriate numerical tool in pressurized tunneling method modeling.

Within the framework of this research project, an experimental study has been carried out in laboratory. For this study, the Laboratory has built an original reduced scale model of earth pressure balanced shield. This model, with a geometric scale between 1/4 and 1/20, allows representing the principal stages of the EPBS tunneling process: excavation of the ground with a cutter head, confinement of the tunnel face with the excavated material, extraction of the material with a screw conveyor and immediate radial support of the excavated ground by means of a sliding cylindrical shield tail.

In a first stage, the analysis of the test is performed at the scale of the model. For this analysis, the excavated ground on the scale model is equipped with both internal stress and displacement sensors. This allows a simultaneous and comparative study on the data collected on the machine and in the ground. Besides, the choice of the material for the scale model and the design of the machine are justified by appropriate similitude laws, which control the transposition to the full-scale model (Mandel, 1962).

So, the present paper presents the details of the experimental set up and the monitoring system. Typical tests results obtained during the digging of frictional-cohesive soils are presented and discussed. These results concern the analysis of stress–strain soil behavior around the TBM during ideal rates of excavation, the identification of pertinent control parameters to guarantee the safe driving of the machine and the analysis of the cutter head action in function of the nature of the ground.

2 THE ENTPE EPBS MODEL

2.1 *Description of the experimental set up*

The ENTPE earth pressure balance shield model is presented Figure 1. The EPBS model consists of a 0.55 m cutter head (A), a conical working chamber (B), a screw conveyor inclined at an angle of 10° (C), a horizontal screw conveyor (D), a cylindrical steel shield tail (E), four thrust hydraulic jacks (F), a frame carrying the whole assembly (G), a stiff steel container placed in front of the TBM frame and containing the ground (H). The test ground dimensions were 2 m long, 1.3 m wide and 1.3 m high. Note that, the ground can be compressed vertically by means of ten air chambers (J) placed under the top of the container (K). This system can maintain a uniform pressure to represent an extra cover above the tunnel, up to four tunnel diameters.

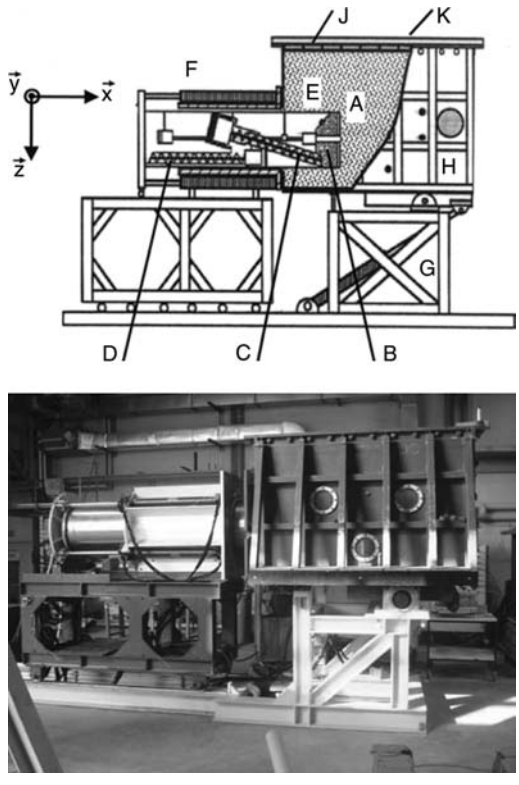

Figure 1. Earth Pressure Balanced Shield model of ENTPE: longitudinal section and photo.

During the test, the TBM enters the ground through a circular port in the container wall. The tunneling maximum length is 1 m. The shield tail forced forward behind the shield itself provides the radial support for the excavated ground. Two alternative cutter heads can be used on the test rig. A low opening ratio head (35%) is usually favored for purely frictional grounds, whilst a high opening ratio head (85%) is retained for cohesive–frictional grounds. To this date, the presence of water table and groundwater flows is not taken into account in our study.

2.2 *Instrumentation*

In our EPBS model, machine parameters alike soils characteristics are directly monitored in real time conditions. For this monitoring procedure, the TBM model is instrumented as follows: three total pressures cells fixed on the working chamber walls measure stresses at sides and roof of the chamber, four dynamometers fixed at the hydraulic jacks extremity measure the thrust cylinder total load, four hydraulic pressure cells provide the measurement of inclined screw conveyor and cutter head torque, an electronic scales deliver real

time measurement of the mass of materials discharged at the rear of the shield, and two precision comparators measure the shield penetration rate.

Simultaneously, the stress–strain ground evolutions are followed during tunnelling with several sensors laid in the excavated ground when the container is filled. The ground monitoring system is made up of:

- 8 internal total stress cells laid at fixed point to measure changes in the state of stress in different directions. During our tests, the measurement of frontal horizontal stresses (σ_{xx}) and vertical stresses (σ_{zz}) in various points of the ground are privileged. (Note that, the subscripts x, y, z relates to the directions $\vec{x}, \vec{y}, \vec{z}$ of the referential given at Figure 1.)
- 10 displacement sensors able to measure real time vertical displacements of the ground free surface.
- 8 internal displacement sensors, laid in the ground to measure internal vertical displacements (u_z), internal horizontal frontal displacement (u_x) and internal horizontal radial displacement (u_y) at the height of tunnel axis.

2.3 *The soil models*

The choice of the materials for the soil models has been led by considering the conditions of similitude (Branque et al, 2006). Cohesive–frictional grounds considered in this paper are made from humid fine ($d50 = 0.35$ mm) silica sand (S28 Hostun RF). Two water contents of the humid sand have been used during our tests: 0.5% and 3%. These are voluntarily taken low with the objective of avoiding gravity drainage and viscosity-driven phenomena.

The sand and water mixture is stirred and poured loosely in the container in uniform layers. Every layer is compacted with an iron roller until the required density is attained. Ultimately, a plastic film, so as to avoid any drying during the tests, covers the whole structured.

In these conditions, the resulting ground apparent cohesions, induced by capillary suction, are less then that 1 kPa for the water content of 0.5%, in the order of 3 kPa for the water content of 3%. If no additional pressure is applied on the ground surface, note that these two cohesions are sufficient to ensure the tunnel face stability without earth pressure acting on this face. However, in some tests, instability of the tunnel face is deliberately induced by means of uniform pressure developed by the chamber placed under the top of the container.

The other mechanical characteristics of the soil model, identified from series of axi-symmetric tri-axial tests performed under low levels of lateral stress ($5\,\text{kPa} \leq \sigma 3 \leq 40\,\text{kPa}$) are given on Table 1.

Table 1. Mechanical characteristics of soils models used on tunnelling tests and deduced from conventional tri-axial tests.

	Total unit weight, γ (kN/m^3)	Void ratio, e	Water content, w (%)	Tangent stiffness, E_t (Mpa)	Apparent cohesion, C (kPa)	Friction angle, φ (°)

Wet sand 2	13.3	1	3	10	3	35

3 STRESS–STRAIN SOIL BEHAVIOR UNDER IDEAL TUNNELING RATES

3.1 *Identification of the ideal tunnelling rates*

Tests carried out with the EPBS model of ENTPE have shown that this last one is able to reproduce different excavation rates observed on work sites, which directly govern the stress–strain behaviour of the ground in front of the shield. In agreement with the theoretical principle of the EPBS method, the tests show that these rates are directly dependent of the ratio (R) between the mass flow of the material discharged from the pressure chamber (Qt) and the theoretical mass flow of excavated material (Qc). Note that in case of homogeneous ground, Qc is calculated on the model as the product of the ground volumetric weight (ρ_{ground}) times the machine advancement speed (v) and the tunnel section (S).

In this context, the ideal tunneling rate, which corresponds to a minimum of strains in front of the shield, is obtained in the model when Qt equals Qc. However, our tests show that this last condition is necessary but not sufficient to guarantee the stability of the tunnel face. In order to obtain and maintain this stability, it is also necessary in function of the geometrical and geotechnical tunneling conditions: (i) to apply a sufficient but not excessive relative pressure on the tunnel face, which limits the volume losses around the machine, (ii) to rotate the cutter head with a minimum rotation speed (dependent of the machine advancement speed) aiming to guarantee the homogeneity of the stresses at the tunnel face and to prevent the apparition of passive earth pressure in the ground which could cause plastic behavior in the soil.

3.2 *Surface Displacements under ideal tunnelling rates*

Under ideal tunnelling rates and for the different cohesive frictional ground tested on the model, the

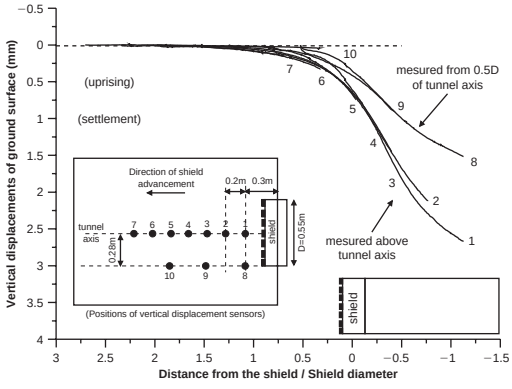

Figure 2. Stationary behavior of surface settlement observed on EPBS model under ideal tunneling rate.

displacement fields measured on the surface of the ground structure reveal a stationary behavior, which depends on the distance to the tunnelling machine. Figure 2 shows this stationary behavior for frictional cohesive material made from wet sand 1: vertical displacements measured at the same distance from the tunnel axis, range in the same zone in the figure. For the different tested materials, the settlements increase as the shield approaches. They are maintained afterwards in result of the friction stresses along the shield tail. Note that, this behavior is in good agreement with observations made on sites (Clough et al. 1993, Kastner et al. 1996).

Concerning the geometry of the settlement basins observed during tests on cohesive frictional material, the cross sections of these basins are consistent with the Gauss distributions usually considered (Fig. 3). The maximal settlements measured on frictional-cohesive grounds are close of 1 mm for a cover height of 1 diameter. By taking into account the displacement scale ratio u^* ($u^* = L^* = u_M/u_P \approx 0.1$), note that settlements measured on EPBS model (u_M) for this material appear in agreement with those observed in practice (u_P) (about 10 mm: Lee and al 1999).

3.3 *Internal Displacements under ideal rates*

As observed for the surface displacements, Figure 4 illustrates the stationary character of the horizontal radial displacements measured in the ground at the tunnel axis height under ideal tunnelling rates. This figure shows that the direction of soil displacements at a fixed point in the ground depends merely on the distance to the shield. Thus, as the shield gets closer, the ground structure is pushed away in the horizontal radial direction. This can probably explain a part of the vertical settlement observed on the ground surface ahead of the machine. Once the shield has passed, an inward movement takes place, driven by the shear

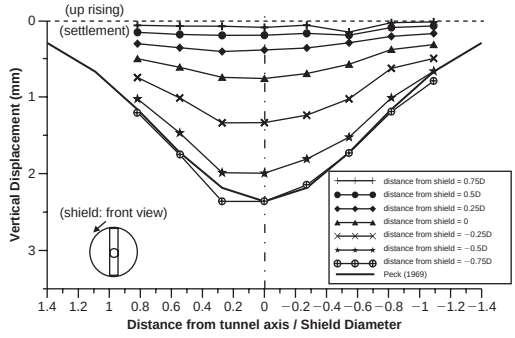

Figure 3. Surface settlement troughs at different distances from tunnel face.

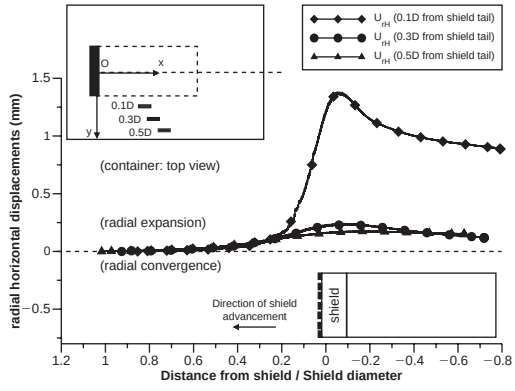

Figure 4. Horizontal radial displacements measured at the tunnel axis height during ideal tunneling rate.

stresses along the shield tail. The horizontal radial displacements revealed on the scale model are consistent with some measurements performed on sites. Those can be found in specific literature (Clough et al 1983, Lee et al 1999).

3.4 *Stress fields under ideal tunnelling rate*

In practice, it may happen that normal stresses on tunnel lining are monitored, but the evolutions of stresses in the soil volume around the machine are generally not well known. These stresses informations are however essential to analyze and to understand the different mechanisms occurring during the EPBS method of tunneling.

In the case of ideal tunneling rate, observations made on the EPBS model in this domain show that, the horizontal frontal and vertical stresses (σ_{xx} and σ_{zz} respectively) measured in the ground unveil a stationary behavior as well, with respect to the tunneling machine. This behavior can be visualised in Figures 5a and 5b, which show the vertical and the horizontal

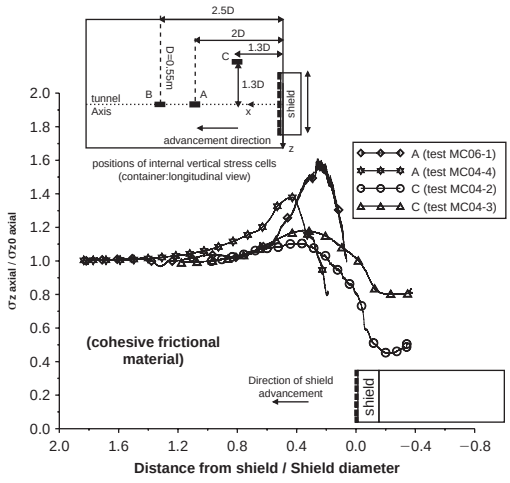

Figure 5a. Stationary behavior and decrease of vertical stresses (σ_{zz}) observed during ideal tunneling rate.

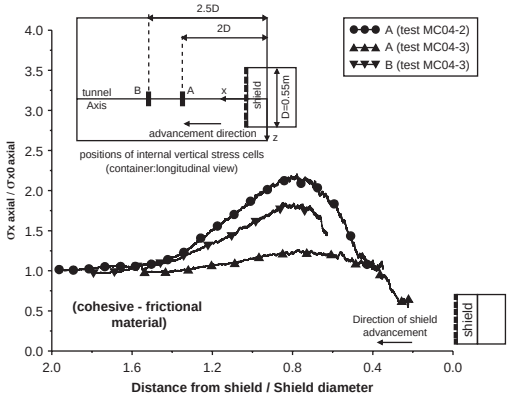

Figure 5b. Stationary behavior of horizontal frontal stresses (σ_{xx}) observed during ideal tunneling rate.

frontal relative stresses obtained in the tunnel axis (A, B) and above the tunnel arch (C). For frictional cohesive materials, the stresses look sensitive to the presence of the TBM up to 1.5 diameters in front of the shield. Moreover, the mean stress measured along the tunnel axes increases in a zone situated between 0.5 to 1.5 diameters ahead the shield, and tends to decrease in the close vicinity of the machine. This can probably illustrate a longitudinal arching effect ahead the machine. The volume of the low-pressure bulb has been partially identified on the scale model in case of frictional – cohesive material. If it is detected up to 0.5 diameters ahead the shield, it seems also spread up to 0.5 diameter above the tunnel crown. Note that, this vertical decompression, which can be associated with a rotation of the principal directions of stresses, remains once the shield has passed, especially above the tunnel crown (C).

4 TUNNEL BORING MACHINE DRIVING: CONTROL PARAMETERS AND ACTION OF THE SHIELD

4.1 *Identification of the "extreme" rates.*

Tests carried out on the ENTPE earth pressure balance shield model have shown that the apparition of large plastic strain in the soil is generally induced by particular conditions of TBM driving. These conditions correspond to the so-called "extreme" rates. These have the particularity to lead to a generalized ground failure if they are maintained for to long. Two kinds of extreme rates can be distinguished in the model:

- under-extraction regimes (in which the rate of material removed is less than the design rate: Qt < Qc) produce excessive confinement of the working face. These regimes involve the passive earth pressure causing plastic behavior in the soil and an upward flow of material in front of the shield.
- in the opposite situation, over-extraction regimes (in which the rate of material removed is greater than the design rate: Qt > Qc) cause a loss of confinement of the working face. In this latter case, the consequences of this extreme rate on the excavated ground vary depending on the soil mechanical characteristics. For purely frictional material, the transition to the over-extraction rates induces instantaneously a flow vertical chimney above the shield, leading progressively to sink holes at ground level. With the presence of cohesion, the apparition of large strains around the shield is delayed and the failure mechanisms imply more a kinematics of block failure rather than a process of soil flow.

4.2 *Sensitivity of driving control parameters*

In this context, tests on the EPBS model have been used to assess the sensitivity and the pertinence of the different control parameters, potentially available on the machine to identify in real time the nature of tunneling rate. As an example, Figure 6 shows the variations of these different control parameters measured on the EPBS model during a tunneling test on frictional cohesive material. The values of ratio R measured in parallel are also given.

Firstly, our tests unveil that the torque applied on the cutter head, the pressures measured at the middle of the working chamber and the horizontal thrust effort developed by the hydraulic jacks present variations that are interdependent and directly in phase with the variations of the ratio R. Thus, in case of homogeneous grounds tested on EPBS model, it can

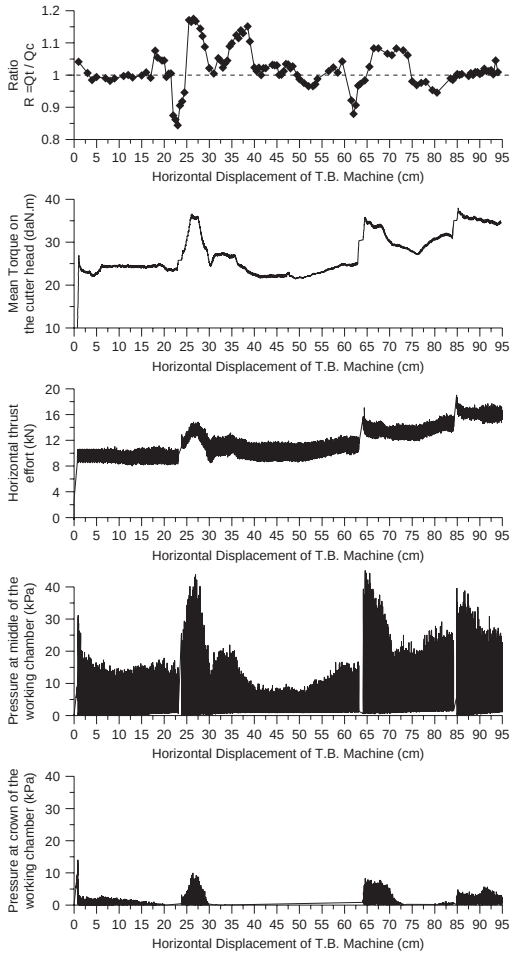

Figure 6. Sensitivity of the principal TBM control parameters to the relative changes in the driving regime.

be widely accepted that a stability of the torque on the cutter head (respectively a stability of the amplitudes of the pressure measured at the middle of the chamber, or a stability of the horizontal thrust effort) is typical of a tunneling phase led with a ratio R equal to 1. In opposite case, increase or decrease in torque on the cutter head (respectively in amplitudes of the pressure measured at the middle of the chamber, or in horizontal thrust effort) characterizes necessarily an extreme tunneling rate.

However, as indicated in paragraph 3.1, the condition of ratio R equal to 1 is not sufficient to guarantee the stability of the tunnel face. This stability depends of the confinement applied at the considered time. For this reason, it appears on EPBS model that informations given by the pressures measured at the crown of the working chamber are essential and complementary of those given by the other control parameters. Thus, if the variations of the torque on the cutter head give indications about the nature of the tunneling rate, pressures measured at the crown of the working chamber give informations about the filling state of the working chamber, and consequently about the quality of the confinement applied on the tunnel face. For example, pressure measured at the crown of the working chamber, and presented Figure 6, show that the tunneling phase occurring between the advancement positions of 30 cm and 64cm has been realized with a working chamber partially full. Note that this condition of tunneling is possible uniquely in case of grounds with a sufficient cohesion.

4.3 *Action of the shield*

It is commonly thought that the torque applied on the cutter head corresponds to the efforts required to cut the ground and to mix the excavated soil contained in the working chamber. Nevertheless, the tests on reduced scale model show that the shield action depends on the mechanical characteristics of the excavated ground. In the case of frictional – cohesive grounds for which the tunnel face is steady, the shield with the large open ratio is used merely for the cutting of the ground. On the contrary, for purely frictional material, the tunneling can be interpreted as a material flow through the wheel and the chamber. In this latter case, the shield with small opening is used as regulator of this flow and its role of mechanical support on the tunnel face cannot be neglected.

Tests on reduced scale model have also shown that the rotational movement of the cutter head appears like an essential parameter to guarantee the stress homogeneity at the tunnel face. Consequently, for the ideal rate ($Qt = Qc$), a reduction of the cutter wheel rotation speed can lead the apparition of passive earth pressures. In the same way, it was observed under extreme extraction rate ($Qt < Qc$) that the appearance of the plastic behavior is strongly accelerated in the case of cutter wheel lock.

5 CONCLUSION

Among the results of the tests carried out at ENTPE on a large 1g reduced scale model of earth pressure balanced shield, the direct rational analysis performed at the model scale has confirmed the existence of different rates of excavation directly governing the stress–strain behavior of the ground in front of the shield. Additionally, an analysis of the sensitivity of the different control parameters has unveiled that a real time control of the excavation rate must consider the complementarities between the different control parameters available on the tunnel-boring machine.

Besides, the same tests have shown that stress profile in front of the shield is directly dependent on the rotational movement of the cutter head.

ABSTRACT: The Arrowhead Tunnels Project represents the final portion of a 70 km (44-mile) long water conveyance facility that will bring up to 28 m^3/sec (1,000 ft^3/sec) of water into Southern California. The 13 km (8-mile) tunnelling project is well underway and consists of two, 5.8 m (19-foot) diameter TBM bores through extremely variable geological conditions. The tunnels lie near the base of the San Bernardino Mountains and several significant faults including branches of the San Andreas Fault that run within one kilometer (0.5 miles) of the tunnel alignment. There are numerous other major active faults that cross the tunnel alignment and water pressures in the tunnel have been recorded as high as 20 bar (300 psi).

This paper will describe some of the problems encountered and the solutions implemented to advance the two hybrid TBMs under conditions that ranged from hard rock with no water inflows to full-face granular material under 10-bar pressure and 32 l/sec (500 gpm) inflows. Due to the range and severity of ground and water conditions actually encountered, the Owner-Contractor-Designer team adjusted the means and methods to be more responsive – virtually on a day-by-day basis – to suit the conditions actually encountered.

1 INTRODUCTION

1.1 *Project description*

The Arrowhead East and Arrowhead West Tunnels, both of which will have a finished inside diameter of 3.65 m (12 ft), will traverse the mountainous terrain north of the City of San Bernardino. The work includes completing the East Tunnel, constructing the West Tunnel, finishing the connections between completed portions of the pipeline and tunnels, and site restoration.

The remaining 6,840 m (22,440 ft) of the East Tunnel excavation must proceed in a down-grade drive from the Strawberry Creek Portal. This tunnel is being excavated beneath ground cover ranging from less than about 15 m (50 ft) to 630 m (2,065 ft). Construction of the 6,062 m (19,890 ft) West Tunnel is an up-grade drive from the Waterman Canyon Portal. This tunnel is being excavated beneath ground cover ranging from less than about 15 m (50 ft) to 335 m (1,100 ft).

1.2 *Purpose and design of the tunnels*

The Arrowhead Tunnels were designed to convey water from the California Aqueduct system to the Diamond Valley reservoir. They were also intended to provide a second source of supply for the Owner.

1.3 *Construction challenges to overcome*

This project required extraordinary cooperation and understanding from all parties and stakeholders involved and required that innovative methods be implemented to deal with the actual ground conditions encountered. The Arrowhead Tunnels Project was not by any measure a routine hard rock tunnel located adjacent to an urban development. It tested the resolve of the project team to meet and succeed in frequently difficult and challenging conditions to successfully pierce the mountain and complete the tunnel that at this stage is 50% complete overall.

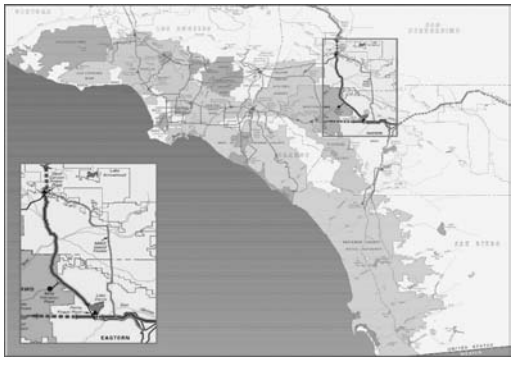

Figure 1. Project location in the San Bernardino National Forest, 100 km (60 mi) east of the city of Los Angeles, California.

2 GEOLOGY AND GROUND CONDITIONS

2.1 *Geological conditions – general*

The geology of the area is very complex and ranges from intact to highly weathered and altered gneiss, marble/calc-silica gneiss and granitic rocks. These conditions required the design of two, one-of-a-kind hard rock TBMs which were modified once experience with tunnelling was gained to better address specific geologic and water inflow conditions.

2.2 *Geological conditions – ground water*

A key construction requirement was to protect the water resources within the strata and neighboring private properties during tunnel construction. In order to protect these water resources, specific limitations on groundwater inflows into the tunnels were established by the U.S. Forest Service in a Special Use Permit. Ground water inflow control measures are mandatory and a key element to the success of the project. The tunnels excavated to date have encountered extremely variable ground conditions and high groundwater inflows due to high hydrostatic pressures. See Figures 2 and 4.

2.3 *Geological conditions – rock mass*

The rock and soil deposits encountered during the excavation of the West and East Tunnels in descending order of abundance include the following:

- Granite rocks including mainly quartz monzonite, quartz diorite, and granodiorite.
- Gneissic rocks including quartzo-feldspathic gneiss with amphibolite and biotite gneiss.
- Marble and calc-silicate gneiss breccia
- Fault gouge, crushed rock and breccia

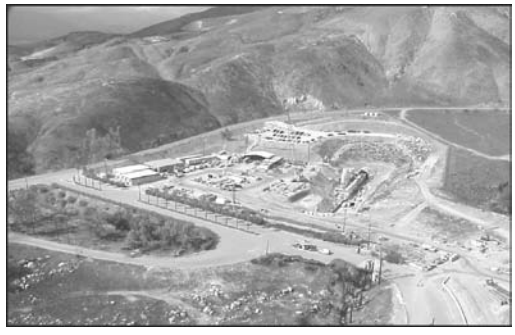

Figure 2. Aerial view of the Waterman Canyon portal (West Tunnel) showing the mountainous terrain and remote access.

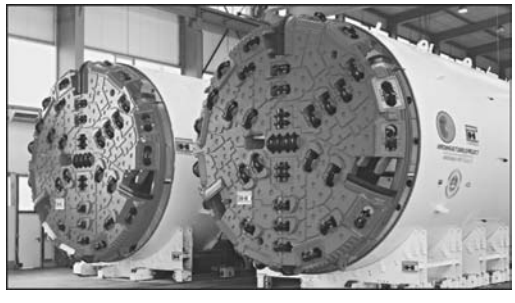

Figure 3. Herrenknecht 5.8 m diameter hard rock TBM undergoing tests in the fabrication shop in Schwanau, Germany.

Both tunnel alignments cross numerous faults that impact tunnel construction. Sixteen separate faults have been mapped and projected across the West Tunnel alignment, and five separate faults have been mapped across the East Tunnel alignment.

3 TUNNELLING PRODUCTION AND IMPACTS

3.1 *Tunnel Boring Machines (TBM)*

This is a unique tunnel that required not only specified tunnel excavation equipment but also a capability to perform repetitive pre-excavation drilling and grouting operations through various geological conditions. Accordingly the TBMs may be generally described as single-shield hard rock machines (cutterhead) with soft ground muck handling and segment erection capabilities. The drilling and grouting equipment included three drills (initially) and several grout plant/pumps. See Figures 3 and 6.

3.2 *Tunnel boring machine advance rates*

The tunnelling advance rates have varied substantially and are dependent on the ground and water conditions.

Figure 4. Aerial view of the Strawberry (East Tunnel) portal area showing the fully-assembled TBM and trailing gear.

Table 1. Tunnel lengths and overall advance rates.

Description	East Tunnel (AET)	West Tunnel (AWT)
Tunnel (total)	6,840 m (22,440 LF)	6,062 m (19,890 LF)
Tunnel (TBM)	6,765 m (22,195 LF)	6,023 m (19,760 LF)
Best month	361 m (1,185 LF)	201 m (660 LF)
Best week	102 m (335 LF)	61 m (200 LF)
Average month	113 m (371 LF)	58 m (189 LF)
Average week	18 m (59 LF)	10 m (33 LF)
Average day	3.6 m (12 LF)	2.0 m (6.6 LF)

Generally, the more water that is encountered at the face, the slower the overall mining advance rates. This is due to the need to perform additional pre-excavation drilling and grouting, water handling as well as the presence of excess quantities of fine material. Fault, gouge and shear zones have also contributed to slower advance rates, in addition to encountering "highly altered" rock that behaves poorly in the presence of ground water and a free face in front of the TBM. See Table 1 and Figure 5 for tunnelling production data.

The tables and charts below will summarize the average productions per month in both tunnels and the distribution of the productions since the start of the work. Overall mining is 50% complete at the time of this writing.

The actual performance of the mining work has averaged the following for both tunnels.

4 PRE-EXCAVATION DRILLING & GROUTING

Probing and grouting ahead of the TBM (probe hole drilling and pre-excavation grouting) was required for both tunnels. The U.S. Forest Service Permit limits groundwater inflows into the tunnel heading behind the advancing face back towards the portal to no more than 32 l/sec (580 gpm) inflow into the tunnel for more

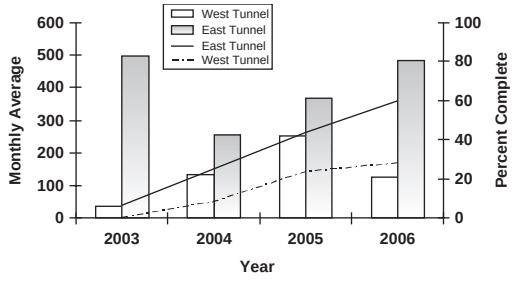

Figure 5. Average annual tunnel advance in the East and West Tunnels – including pre-excavation grouting operations.

than one week. Control of the groundwater inflows to this limit was accomplished by a combination of the following operations;

- Pre-excavation grouting to control water
- Ground improvement grouting
- Filling of discontinuities in the rock mass
- Installation of a watertight segmental lining
- Timely backfill grouting
- Installation of inflatable segment collars
- Installation of drain holes

As an initial criteria, probe hole inflow which exceeds 0.02 l/sec/m (0.3 gpm/ft) or an accumulated 2.0 l/sec (30 gpm) for a 30 m (100-ft) long probe hole represented the threshold at which pre-excavation grouting was considered necessary. Because of the uncertainty of groundwater inflows through a fractured rock mass, probe holes do not necessarily detect all potential groundwater inflows.

A minimum overlap of 6.5 m (20 ft) at the face between successive set-ups of probe/grout holes. Probe holes are limited to a maximum of 45 m (150 ft) in effective length and grout holes are limited to a maximum of 30 m (100 ft) in effective length due to the uncertainty in hole location for longer holes and the reduced effectiveness of grouting long holes.

5 OTHER WATER CONTROL MEASURES

5.1 *Water control grouting & drainage programs*

The Arrowhead Tunnels required the implementation of several grouting programs for the control of water inflows as the TBMs advanced. These included the following as briefly described below;

1. *Stage I Backfill Grouting* – Installed as the TBM advanced and filled the annular void surrounding the segment tunnel lining
2. *Stage II Contact Grouting* – Installed periodically as the TBM advanced and completed the filling of the void surrounding the tunnel

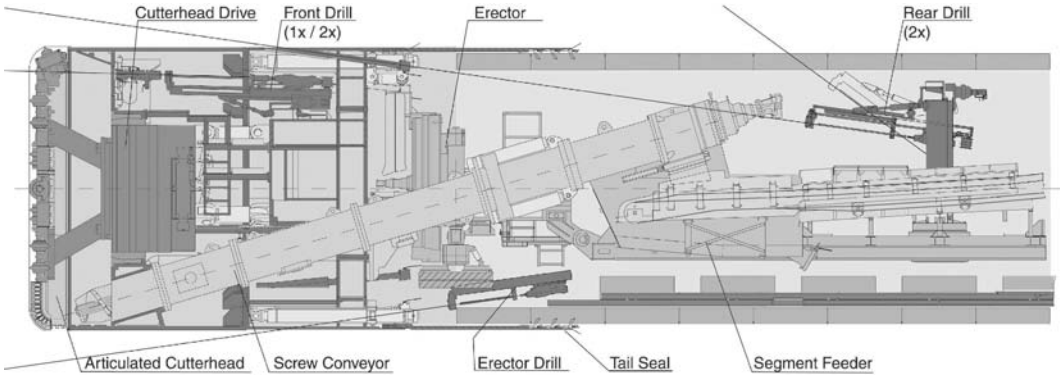

Figure 6. Section through the Herrenknecht TBM showing the principle components, auger and drills for grouting operations.

3. *Drainage Holes:* – Installed at 20° through the segmental tunnel lining to relieve hydrostatic pressure and inflows into the cutterhead.

Several grouting materials have been used with various success for the control of inflows and ground improvement. These have included the following.

- Chemical grout (sodium silicate)
- Polyurethane grouts
- Micro-fine cement
- Colloidal silica grout

A substantial (in excess of 70%) amount of time experienced to date has been consumed with pre-excavation drilling and grouting operations before the TBMs have been advanced. Notwithstanding, this was essential to successfully and safely mine the tunnels through highly variable strata with unknown geological and water bearing features.

5.2 *Segmental tunnel lining with gaskets*

A bolted and gasketed, precast concrete segmental lining is required as the primary support system for the entire length of both tunnels. This construction has been substantially addressed in the referenced papers and will only be briefly described here.

As a baseline for the design of the primary support system the maximum groundwater head during construction for the West Tunnel alignment is 170 m (550 ft) above the tunnel and for the East Tunnel alignment is 275 m (900 ft) above the tunnel.

5.3 *Final tunnel lining – RCCP pipe final lining*

A final lining will be installed in the tunnels to provide a hydraulically efficient system for conveying water, and to prevent infiltration and exfiltration of groundwater. In addition, the final lining must support long-term rock and hydrostatic loads, provide erosion protection, and facilitate dewatering and inspection of the tunnels. Reinforced Concrete Cylinder Pipe (RCCP) was chosen as the final tunnel liner. The annular space around the RCCP will be filled with cellular grout having a density of 330 kg/m^3 (65 lb/ft^3). This will fully envelope the RCCP and is critical to the long-term performance of the final lining. Welded steel pipe will be used also.

Figure 7. Interior of the East Tunnel transition from the starter to the bored tunnel – lined with precast gasketed segments.

6 GROUND BEHAVIOR IN TUNNELLING

6.1 *Actual ground behavior experienced to date*

While the anticipated ground conditions were as generally described in the GBR and variable, we have experienced a wide spectrum of ground types and behaviors. The rate of change from one type to another was very frequent to the extent that extremely hard material could be encountered on the same day as soft and raveling material. Periodically, acute geological features would release flush flows and even flowing ground resulting in the formation of a cavity that

Table 2. TBM basic specifications, weights and measures.

Description	Size or capacity	
1. Design parameters:		
• TBM design	single shield, articulated	
• Static pressure deign	10 bar	145 psi
• Operating pressure	3.0 bar	44 psi
2. Dimensions and weights:		
• Cutterhead diameter	5.820 m	19'-1"
• TBM total length	10.355 m	34'-0"
• TBM & trailing gear	142 m	465 ft
• TBM & trailing gear	820 t	906 tons
3. Power and thrust:		
• Cutterhead power	2,000 kW	2,670 HP
• Cutterhead torque	2,000 kNm	1.5 mil ft-lbs
• Thrust cylinder power	29,270 kN	3,300 tons
• Total installed power	3,600 kW	4,800 HP

required an immediate halt to the mining operations and then backfilling.

Occasionally to date we have encountered decomposed rock acting like sand and silt, blocky ground with large pieces dislodged from the face, both white and gray marble as well as very competent granitic material. High in-situ water pressures and flows have from time to time been enountered and have daunted the pre-excavation grouting program to the extent that this program is adjusted before each mining cycle and constantly assessed during the actual grouting program to be responsive to the conditions.

Shea-Kenny's crews together with the Owner's geological and grouting experts developed a toolbox of flexible means and methods to cope with a wide range of ground and water conditions with the goal to achieve effective pre-excavation grouting and to optimize the TBM advance rates safely.

7 MODIFICATIONS TO THE TBMS

7.1 *TBM design and features*

Two Herrenknecht TBMs were purchased for the project and included a full complement of supporting systems including power, segment handling, ventilation, waste water management, grouting material storage and mixing mounted on the trailing gear. The TBMs had the following specifications that were subsequently adjusted as described below.

7.2 *Unique characteristics of the TBMs*

The TBMs are hybrids in that they need to deal with rock from less than 2.0 MPa to more than 310 MPa (300 to 45,000 psi), in addition to ground water pressures up to 10 bar (145 psi). The TBMs are designed to continuously operate with 3.0 bar (44 psi) pressure based on the cutterhead bearing seal capacity in dynamic mode – in hard rock conditions.

7.3 *Improvements to the TBM and trailing gear*

Based on experience and performance in variable ground conditions and water inflows, several significant modifications were made to the TBM to cope with ground control and ground water inflows.

1. *Cutterhead Shroud*: Installed on the trailing edge of the cutterhead to close-up the gap with the forward shield.
2. *Cutterhead Bucket Closure:* This modification was needed to improve breasting of the face in poor and raveling ground conditions.
3. *Cutterhead Torque Increase:* The original cutterhead torque was 2,000 kNm, (1.5 million ft-lbs) but after several months excavating in variable geological conditions including "soft round", it was determined that the drive gearboxes should be changed resulting in a torque increase by 50% to 3,520 kNm (2.25 million ft-lbs) and cutterhead rotational speed was reduced to 7.5 rpm from 9.75 rpm.
4. *Thrust Pressure Increase:* Thrust was increased to provide improved ability to move the shield forward in squeezing ground conditions.. The total theoretical thrust on the shield was increased by two times from 29,270 kN to 58,540 kN (6,580 tons).
5. *Four-Degree Grout Holes:* An additional 19 grout holes were installed through the forward bulkhead and cutterhead to provide for additional and more effective grouting operations.
6. *Additional Drills – Total of Four:* Three drills were originally installed as per the TBM specifications – one front and two in the rear. One additional probe drill was installed.
7. *Slurry Handling System:* Developed on-site and installed and proved to be a major asset to improve mining production. This will be described below in more in detail.

8 SLURRY HANDLING SYSTEM

8.1 *Slurry handling system*

The Herrenknecht TBMs were not originally equipped with a slurry handling system. The TBMs did, however, have a powerful dewatering system in accordance with the specifications and was designed to pump a high volume of water from the heading out of the tunnel. These TBMs were truly hybrid rock cutting machines designed to operate with a screw auger for muck handling but not in closed mode as an EPBM with a pressurized plenum chamber. They were also not designed to handle high volumes of fines (sand

Table 3. Slurry system design and operating characteristics.

Description	System characteristic or capacity
Peak flow	550 l/sec (850 gpm) Habermann pump
Nominal flow	32 l/sec (500 gpm) Habermann pump
Fines suspension	15% nominal (by volume) 20% maximum and dependent on flows
Slurry medium	Water in a closed re-circulation circuit
Solids separation	Brandt screens, clarifier and centrifuge

and silt-sized particles) that from time to time could be far in excess of 50% of the material excavated from the tunnel face.

In order to cope with the periodic excess fines and water inflows, a slurry handling system was designed by Shea-Kenny in conjunction with Herrenknecht's engineers. The system has the following characteristics in response to the ground and water conditions. See Table 3 above.

This innovative system was integrated into the TBM and trailing operating systems and equipment wherever possible so as to become a seamless function with the overall mining operations.

The water slurry system was working well whenever excess water and fines were encountered at the face. The system flow was regulated to suit the fines and/or water inflows generally to a maximum of 15% fines (by volume). But as the density of the slurry flow increased, resulting flow decreased substantially due to the maximum power available in the system – principally at the Habermann pump.

9 CONCLUSIONS & RECOMMENDATIONS

9.1 *Conclusions from to date performance*

The Arrowhead Tunnels Project could be considered one of the most challenging tunnel projects presently underway in the United States and it has taken considerably longer to excavate than planned. The ground and ground water conditions are extremely variable and could not be well predicted largely due to the extent of the ground cover as well as the degree and frequency of the alterations in the rock mass including the influence from nearby faults. The pre-excavation grouting program was originally intended to address and arrest ground water inflows into the tunnel and is an essential operation to successful mining.

The stout design and high quality manufacture of the precast segmental tunnel liner was also a hidden benefit and especially when it was tested in-situ with as much as 103 mN (23 million pounds) thrust from

the TBM in order to move the machine forward in very difficult squeezing ground conditions.

9.2 *Recommendations from to date performance*

An effective pre-excavation drilling and grouting program was absolutely essential to successfully mine the tunnel in the presence of high ground water pressures and flows. Optimization was a continuous task and just as the ground conditions were variable, the pre-excavation drilling and grouting program was equally flexible and changed frequently. The Owner, designer and Shea-Kenny constantly worked together to discuss and evaluate various means to drill and grout to control water (first) then to improve the ground (second) so as to be able to mine the tunnel faster and reduce risks. Ground water pressures and flows and their effects on the ground behavior became the "enemy" and were eventually treated in a manner that not only provided control of the inflows but improved the safety and production of the overall mining operations too.

ACKNOWLEDGEMENTS

This paper includes key contributions from a number of persons in addition to the co-authors. We would, therefore, like to acknowledge Stuart Warren of Hatch Mott MacDonald, Tom Hibner and Howard Lum of the Metropolitan Water District of Southern California as well as Robert Gordon and Stuart Lipofsky of Shea-Kenny for their assistance.

There have been many recent papers written on the design and development of the Arrowhead Tunnels Project as part of the Inland Feeder Program for the Metropolitan Water District of Southern California. While they generally pre-date to events of the site work described in this paper, they should be considered as useful preconstruction references.

Ground loss control in EPB TBM tunnel excavation

M.C. Gatti & G. Cassani
Rocksoil S.p.A., Milan, Italy

ABSTRACT: In urban tunnelling, EPB TBM excavation is recommended in soft ground and watery conditions, where there is very sensitive interaction between tunnel and surface. Ground loss control is the basic parameter that has to be considered in the design and construction phases for reliable prediction of surface settlement and the consequent risk of damage to buildings. Analyses of ground loss in EPB TBM excavation are presented in this paper and the tools to minimise it, chamber pressure control, soil conditioning and backfill injection pressures, are discussed. One new important aspect concerns the injection of foam or grout through the shields of modern EPB TBMs to control cavity stability until the lining is placed. Numerical approaches to investigate the problem and systems to monitor the operating parameters of EPB TBMs are presented, with particular reference to some new experiences on Italian construction sites.

1 INTRODUCTION

The increasing demand for transport infrastructures in recent decades has resulted in considerable growth in underground works, especially in urban environments where there is less surface space available. Mechanised excavation using EPB type TBM's is particularly recommended in these contexts where "unstable" face behaviour (Lunardi 2000) must be tackled in ground with particularly poor geotechnical characteristics, in order to minimise effects at ground level and to work in hydrostatic conditions when below the water table. The control of deformation induced in the ground by excavation plays a very important role at the design stage for assessing the risk of damage to existing structures, such as buildings and underground utilities, as reliably as possible. An examination of interference between the tunnel and existing structures must be performed by predicting expected deformation and by surveying the geometry and state of conservation of existing structures to define admissible absolute and differential settlement.

Empirical formulations are very useful for evaluating expected subsidence (Peck 1969, Rankin 1987, O'Reilly & New 1982). Developed on the basis of experimental findings taken from a very large number of case histories, these allow Gaussian subsidence curves to be quickly determined from simple parameters such as the geometrical data of the operation (tunnel diameter D and overburden H), the geotechnical characteristics of the ground (by defining a coefficient K, varying between 0.2 and 0.3 for granular soils and between 0.4 and 0.7 for cohesive soils) and the method of excavation (identified by a value for expected ground loss V).

From a comparison of expected values with subsidence considered admissible, determined for example by means of risk analyses by Mair et al. (1996) and damage classes by Boscardin & Cording (1989), it is possible to verify the compatibility of excavation with existing structures, or to identify corrective action such as revising excavation methods (with the assumption of a different value for V) or the adoption of structural ground improvement and reinforcement works to protect existing structures. The value assumed for ground loss in the process described is without doubt the key parameter in the analysis and it is therefore fundamental that it is accurately forecast at the design stage and that it is monitored during the construction stage.

2 GROUND LOSS IN EPB TBM EXCAVATION

The construction of a tunnel determines a change in the stress state of the ground at the face and around the excavation and generates deformation, the size of which depends on the strength and deformability properties of the ground, on the geostatic conditions and on the method of excavation. The development of deformation is governed principally by the stability of the core of ground ahead of the face (Lunardi, 2000): if the core remains in the elastic domain after excavation then modest deformation is to be expected at the face in terms of extrusion and preconvergence, with convergence of the cavity limited by the stiffening action performed by the face. If the strength of the ground

in the core is exceeded then substantial deformation and plasticisation phenomena will occur at the face, which will be followed by relaxation of the terrain and substantial convergence of the cavity. The deformation generated during excavation propagates towards ground level and constitutes the underlying cause of surface subsidence.

The deformation phenomena that occurs in the tunnel determines a value for "ground loss", defined as the volume of ground which on conclusion of tunnel advance is inside the theoretical excavation cylinder and which, given the propagation of the phenomena on the surface, is equal to the volume subtended by the curve for subsidence at ground level. Ground loss is generally expressed as a percentage of the area of the tunnel excavated ($V = V_L \cdot A_{exc}$, for 1 metre of tunnel) and varies greatly as a function of the excavation method employed, up to 2.0–3.0% with conventional excavation methods without adequate confinement and support intervention. The usual values for EPB TBM excavation are in the range of 0.3–0.6%, with maximum values of 1.0% when the operating parameters of the TBM are not regulated properly or in difficult unforeseen situations; the lower values of the range are typical of cohesive soils, while the higher values of 0.4–0.6% are expected for granular grounds, especially when under the water table. The technical specifications of the major Clients in Italy set the standard value for ground loss, for use in designs and monitoring during excavation, at 0.5%.

It is important to consider that given the deformation development described, the volume lost is the sum of various components which cumulate during the construction of a tunnel. As shown in figure 1, in the specific case of excavation using an EPB TBM, three main components can be considered:

- ground loss "at the face" (V_{Lf}) associated with extrusion and preconvergence which occur in the excavation chamber as a consequence of the behaviour of the core ahead of the face, as a function of the stabilisation pressure applied;
- ground loss "around the shield" (V_{Ls}) in the section of tunnel where the EPB TBM is present, associated with the closure of the excavation profile towards the extrados of the steel shield owing to the annular gap that is generally present between the external cutterhead and the TBM;
- ground loss "behind the lining ring" (V_{Ll}), as convergence of the cavity in the tunnel section where the precast segments are placed, in case the backfilling is not properly applied to guarantee a perfect fill behind the lining (e.g. if the injection pressure is too low, slow hardening mortar is used or it is washed away, etc.).

A fourth component associated with long term settlement (V_{Lt}) must then be added. It is a function

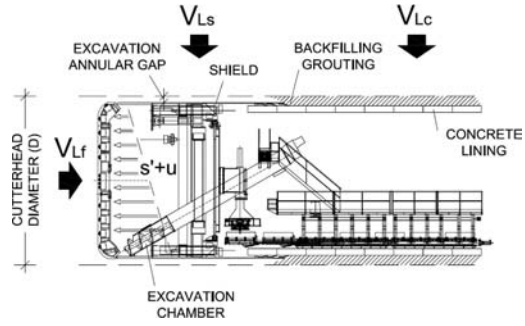

Figure 1. EPB TBM components of ground loss.

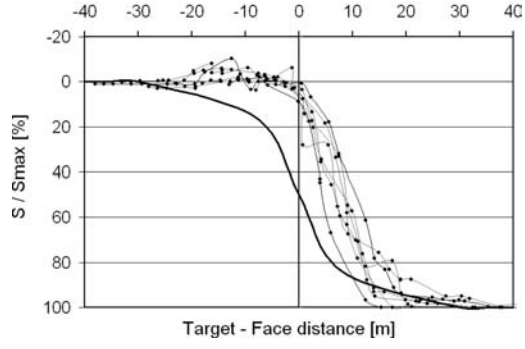

Figure 2. Castellanza railway tunnel – Longitudinal settlements.

of possible ground creep or decay in the strength and deformability characteristics of the ground or of consolidation processes connected with drainage of groundwater which occurred during excavation, especially in clays. Total ground loss can therefore be expressed by the following formulation:

$$V_L = V_{Lf} + V_{Ls} + V_{Ll} + V_{Lt} \quad (1)$$

Longitudinal subsidence curves from some case studies were examined to evaluate the effect of each component. The results obtained on the construction site of the Castellanza tunnel on the Milan-Malpensa railway line are presented in figure 2. In order to superimpose a number of subsidence curves, settlements are expressed as a percentage normalised to the maximum settlement, which is related to ground loss according to the well known equation:

$$S_{max} = (0.31\ V_L \cdot D^2) / (K \cdot (H+D/2)) \quad (2)$$

Figure 2 also contains the longitudinal subsidence curve obtained using Attewell's empirical formulation based on a cumulative probability function (Attewell & Woodman 1982). It can be seen that the settlements that

occurred at the face before the TBM arrival amount on average to 15–25% of total settlements (they are even less than 10% on some curves where ground is actually observed to rise by some millimetres), while the most substantial part accounting for around 60% occurs on the shield section, about 10 m in length, with a final 20% of the settlement occurring along the tail of the machine, during backfill and for long time settlements.

It is significant to observe that because of the stabilisation pressure exerted in the excavation chamber, settlements at the face are much lower than predicted according to Attewell & Woodman's (1982) empirical formulations and are generally less than or close to the value identified by Panet & Guenot (1982) for face convergence in terrains with elastic behaviour, equal to 27% with a stability factor $N = \sigma_o/c_u = 1$. Settlements of more than 27%, up to 50%, would indicate plastic behaviour which it is best avoided.

Furthermore it is important to consider that the problems connected with containing ground loss do not end with proper dimensioning of the stabilisation pressure at the face, but appropriate measures must be adopted for the entire excavation process. For the main components of ground loss, design and control criteria are discussed in the sections that follow.

3 FACE GROUND LOSS CONTROL

Face confinement in EPB TBMs is achieved by using the excavated earth itself (Earth Pressure Balance), which is accumulated through cutterhead openings in the excavation chamber and it is compacted, after additives have been introduced, by the thrust exerted by jacks when the machine advances. The pressure inside the excavation chamber is controlled by regulating the TBM advance rate and the screw conveyor extraction rate (hence the chamber filling rate). When the ground extracted by the screw conveyor is greater in quantity than the volume entering the head, the pressure decreases and vice versa when the quantity extracted is less, the volume increases. The balance is achieved when the conditioned ground reaches maximum density in the excavation chamber, since it can no longer be compacted further, and the volume extracted by the screw conveyor is equal to that excavated by the cutterhead. In these conditions the pressure in the excavation chamber tends towards the "at rest ground pressure", or otherwise it moves towards either an active or passive pressure condition depending on the ratio between the material extracted by the screw conveyor and the ground excavated, (Maidl et al., 1996; Russo, 2003). In order to control the face stability and consequently ground loss at the face, the correct pressure in the excavation chamber must be applied and especially it must remain stable during tunnel drive by controlling the EPB TBM operating parameters and the soil conditioning.

3.1 *Face stability pressure design*

In order to determine the correct excavation chamber pressure, different analysis approaches should be considered. First the minimum pressure needed to guarantee equilibrium in the wedge of ground at the face to avoid failures and collapse of the advance core must be determined. This pressure can be done by applying "limit equilibrium methods", the most indicated of these is that developed by Anagnostou & Kovàri (1996) specifically for excavation with EPB TBMs. The method is based on the silo theory according to the three dimensional failure mechanism proposed by Horn and it allows the effective pressure (s') to be determined in drained conditions by using the following compacted formula:

$$s' = F_0\gamma'D - F_1c + F_2\gamma'\Delta h - F_3c\,\Delta h/D \quad (3)$$

where F_i are dimensionless coefficients, given by normograms, dependent on the soil friction angle, on the overburden H and the diameter of the excavation D, on the ratio $(h_0-D)/D$ and the submerged weight γ'; c is the soil cohesion and

$$\Delta h = h_0 - h_f \quad (4)$$

is the piezometric difference between the level of the water table h_0 and the piezometric height in the excavation chamber h_f, as a function of which filtration forces are generated. Since it is advisable to avoid draining the water table during excavation, the piezometric difference must be nil ($\Delta h = 0$) and consequently the total pressure to be adopted in the excavation chamber to guarantee limit equilibrium conditions s_L, is:

$$s_L = s' + u = (F_0\gamma'D - F_1c) + h_0\,\gamma_w \quad (5)$$

the sum of the effective pressure and the hydrostatic pressure u, with γ_w the water specific weight.

However, the method described cannot be used to assess the face deformation state for the pressure s_L applied and does not therefore allow volume loss to be estimated. Further analysis must be performed to establish a correlation between the pressure in the excavation chamber and values for extrusion and preconvergence. One possible approach is to use axial-symmetric models which, quicker than the more laborious 3D analyses, are able to provide indications of how the stress-strain state is evolving at the face. The calculation is conducted in effective stresses employing finite element or finite difference calculation codes, using the geotechnical characteristics and the constitutive law most appropriate for the grounds concerned and considering the different geostatic conditions along the alignment of the tunnel. To simulate the conditions in the excavation chamber, the

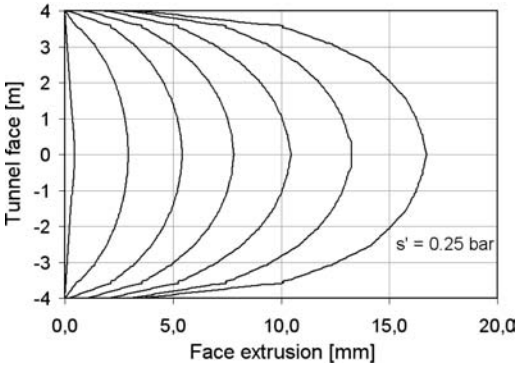

Figure 3. Axial-symmetric analyses – Extrusion vs face-pressure.

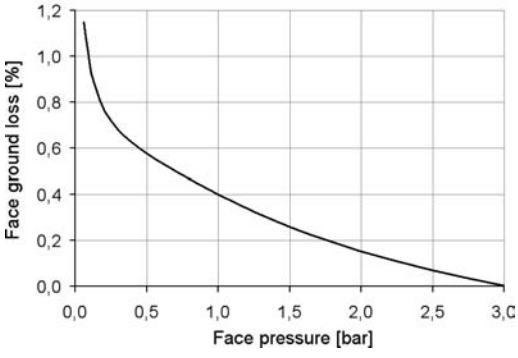

Figure 4. Face ground loss vs face-pressure.

pressure at the face is progressively reduced by the geostatic value to zero in steps of 0.5 bar (0.05 MPa), to thereby evaluate the relative development of extrusion. Figure 3 gives an example of the extrusion graphs calculated for the Castellanza tunnel (with excavation diameter of 8.0 m, in granular soil above the water table, specific weight of 20 kN/m^3, nil cohesion, friction angle of 40° and elastic modulus of 120 MPa), for face pressures varying between 3.0 and 0.25 bar.

Determination of extrusion values at the tunnel axis and at the edges of the face allows the shape of extrusion volumes to be identified (cylindrical, truncated cone, spherical dome) and calculated by using, for example, the formulas reported in Cassani & Mancinelli (2005). It is thus possible to diagram the ground loss at the face as a function of the pressure applied, as shown in figure 4, and select the correct face pressure.

Use of the diagram allows the correct stabilisation pressure to be identified; more specifically it allows to estimate the pressure which constitutes the limit of the core elastic behaviour (s'_E), below which the extrusion-pressure relationship is no longer linear and there is a progressive increase in volume loss as a result of plasticisation that is generated until the face becomes unstable. It should also be observed that the value for extrusion and as a consequence for ground loss is nil for pressures that are equal to the geostatic pressure, which therefore constitutes the upper limit of the pressure range to be applied at the face and can be easily determined with reference to the "thrust at rest" (s'_{ko}) by applying Jaki's formula, corrected in overconsolidated ground:

$$s'_{ko} = \gamma \cdot (H+D/2)\,(1-\sin\phi)\,OCR^{\alpha} \qquad (6)$$

where ϕ is the soil friction angle and OCR the over-consolidation ratio. Additional pressure rate could be considered for loads present on the surface.

In conclusion, the optimum effective pressure in the excavation chamber (s') lies within this range:

$$s'_L < s'_E < s' < s'_{ko} \qquad s = s' + u \qquad (7)$$

To estimate the total pressure (s) the hydrostatic pressure (u) must be added; moreover a linear development along the height of the face has to be taken into account.

3.2 *Soil conditioning*

The broad working range of modern EPB TBMs in terms of the soil granulometry and permeability means that the ground in the excavation chamber must be appropriately conditioned by means of foams and/or polymers. The conditioned ground must present good plastic deformation, soft consistency, low inner friction and low permeability so that it can be employed as a fluid to support the face, especially under the water table, and at the same time it must minimise drive torque and wear of the excavation tools; proper soil conditioning is essential for maintaining the pressure in the excavation chamber "over time". The ratio between the quantity of foam and the ground (FIR, Foam Injection Ratio), the quantity of air and water to be mixed with the foam (FER, Foam Expansion Ratio, and c_F, concentration of foaming solution), see Langmaack (2001), must be established at the design stage together with the chemical composition of the products employed. In granular soil with a low percentage of fines (<5–10%), foams that are capable of increasing the plasticity of the mix and reducing its permeability must be used with high FIR values (>35–45%, usually 10% higher than soil porosity); in cohesive soil, especially in sandy clay and pure clay, the use of dispersing polymers is advisable to prevent clogging of the cutting tools and screw conveyor and also wear resulting from strong adhesion to the cutterhead, with values for FIR of ~25–35%. The values for FER are generally within the 8–15 range, the higher values for granular soils.

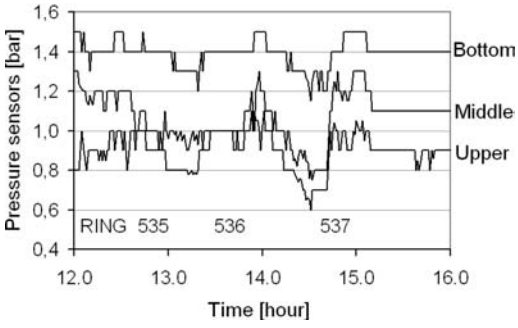

Figure 5. Excavation chamber pressure sensors vs time.

3.3 *Control of EPB TBM drive-parameters*

It is very important to control the operating parameters governing the advance of the EPB TBM, which are the thrust (kN) and the cutterhead torque (MN · m) in relation to the advance rate (mm/min) and penetration (mm/rpm); the control of the screw conveyor torque and rotation is important too.

The drive-parameters must be monitored to make sure that they remain within the specified range without any sharp variations or interruptions. It is also very important to record the length of work cycles and any machine down times. Measurements of pressure in the excavation chamber must be taken using sensors placed at different heights (bottom, middle and upper) to monitor ground loss at the face.

Figure 5 gives an example of tunnel advance, showing reductions in pressure during the installation of the 536 lining ring which it is best to avoid .

4 CAVITY GROUND LOSS CONTROL

The final confinement of the cavity is performed by placing a precasted segment lining in the zone protected by the shield, followed by backfill injections behind the lining performed from the TBM tail; maximum attention must be paid here too, with a view to containing ground loss components pointed out in figure 2.

4.1 *Shield zone*

The annular gap between the excavation diameter and the extrados of the shield, generally employed in TBM construction to reduce friction during tunnel advance (radial 10–15 mm), represents a critical element in controlling convergence of the cavity, especially in cohesionless soils under the water table where the cavity stand-up is negligible. The confinement of the excavation profile relies entirely on the flow behind the shield of the foam injected at the face,

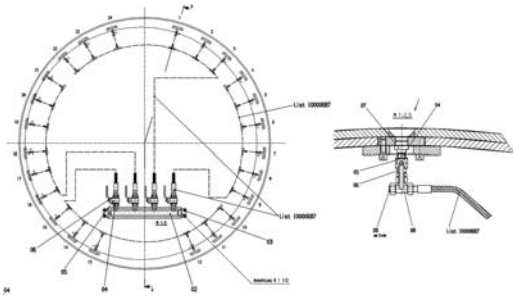

Figure 6. Wirth 816/H shield injection.

often without success. To reduce this problem some modern EPB TBMs have been fitted with systems for injections through the shield to fill the gap using special greases and plastic or expansive mixes capable of preventing the ground from closing around the shield.

The EPB Wirth 816/H TBM employed on excavation of "Channel Tunnel Rail Link" in London and on the Castellanza tunnel is equipped with 24 radial valves connected to a pressure and volume controlled injection system, as shown in Figure 6. Injection of special grouts on some sections of the Castellanza tunnel, where the presence of surface structures was most delicate, resulted in an appreciable reduction in settlements at ground level from 35–40 mm to 10–15 mm, revealing a potential that we feel it is worthwhile developing in future works.

4.2 *Lining placement, backfil and grouting stages*

The ground loss control is performed by defining the injection system and the quantities of grout mix to be injected, where the aim is to completely fill the annular gap between the extrados of the lining and the excavation profile. The EPB must be equipped with a number of injectors along the perimeter of the tail shield to allow good diffusion of the injected grout mix (generally 4–6 injectors fed by different pumping systems so that injections can be performed even if one of them breaks down) and it must also be fitted with a precision balance system to weigh the material excavated in order to calibrate the necessary volume of mix to be injected (V_{gr}) for each stroke by means of the relationship:

$$V_{gr} = (P/\gamma - D_{ext}{}^2 \cdot \pi/4 \cdot L) \qquad (8)$$

where P is the weight of the ground excavated in one boring stroke of length L (equal to the lining ring with diameter of the extrados D_{ext}) and γ is the ground specific weigth to be determined with laboratory tests to also take account of soil conditioning. Monitoring of the real volume excavated, $V = P/\gamma$, with the theoretical volume $V_{exc} = D_{exc}^2 \cdot \pi/4 \cdot L$ allows possible over-excavation or releases of ground to be identified

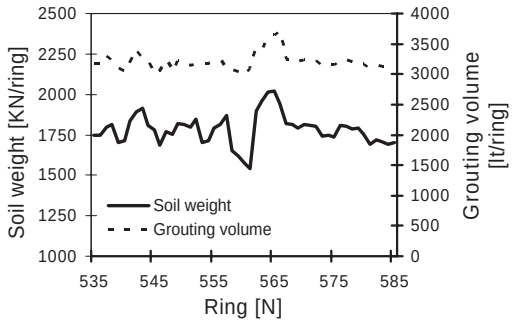

Figure 7. Excavation soil weight/Grouting volume.

so that they can be promptly filled at the injection stage. Figure 7 contains a monitoring graph prepared during tunnel advance, which can be used to "balance" the material excavated with the volume of mix injected.

The injection pressure (p_{gr}) must be a little greater than the geostatic pressure to avoid increasing the convergence of the cavity:

$$p_{gr} > (u + \gamma \cdot (H+D/2) \cdot K) \quad \text{with } K^{O} < K < 1 \qquad (9)$$

The grout mix design must ensure that the mix can be pumped and also that the hardening curve is adequate which avoids compressibility and does not allow it to be washed away. The authors have obtained very positive results using "bi-component" mortars, where a rapid hardening additive is added to a cement mix base in the tail of the shield, through a separate pipe, so that the mix sets immediately after injection but with no risk of clogging the injection systems.

5 CONCLUSIONS

The value for "ground loss" constitutes a key parameter for managing excavation using an EPB shield, because of its importance in assessing surface subsidence phenomena and building damage risk.

It is the sum of different components, which develop during the stages of tunnel advance at the face and around the cavity, in the tail zone and after the precsted segments lining is placed. Account must be taken of the specific aspects of design discussed in this paper for each step of operations: the correct stabilisation pressure to be kept constant in the excavation chamber must be defined (which will leave the core at the face in the elastic range and limit extrusion); the type of soil conditioning; the injection of special greases and mortars through the shield to prevent the cavity from closing in during the delicate stage of shield advance; monitoring the volume of ground excavated and the injection of backfill grout mixes to make sure there are no gaps in the ground.

The design of a monitoring system both in the tunnel by monitoring the operating parameters of the TBM and on the surface by setting up a network of topographical datum points to monitor settlements along the tunnel alignment and across it is an indispensable instrument for verifying and regulating excavation activities.

City-Tunnel Leipzig, a challenge for the shield drive

W. Glitsch
DEGES, Deutsche Einheit Fernstraßenplanungs- und –bau GmbH, Berlin, Germany

T. Maidl
Ingenieurbüro Maidl & Maidl, Bochum, Germany

ABSTRACT: The City-Tunnel Leipzig project is the central part of the reorganization of the railway network within the Leipzig area. The subterranean double-tube connection beneath the centre of Leipzig is divided into six sections, with three interspaced stations, and has a total length of 2.94 km. Following the construction of the stations, the single shell tunnel will be constructed via a Hydroshield with a diameter of 9 m. The biggest challenges for the shield drive are the heterogeneous glacial ground conditions, which already proved challenging in the construction of the sealing blocks, and the very difficult structural boundary conditions.

Natural and non-natural obstacles are to be expected within the tunnel alignment. The tunnel route is below the ground water level, which has a maximum height of approx. 18 m above the tunnel invert. Due to the shallow ground coverage and under-passing of important buildings, a careful tunnelling technology was tendered. Additionally, several ground treatment measures have been executed in order to protect buildings within the settlement trough. Substantial compensatory grouting measures linked to the settlement data will actively counteract detrimental deformations to buildings.

The Hydroshield is designed and constructed based on the tender requirements and the special geotechnical boundary conditions. Innovative monitoring systems are installed to facilitate the excavation of the tunnel in the most sensitive way for adjacent buildings, and simultaneously to monitor at surface level the reaction to the tunnelling process.

1 PROJEKT DESCRIPTION

1.1 *The Projekt*

The City-Tunnel Leipzig project is the central part of the reorganization of the city's railway network, which will run under the city centre from the station Bayerischer Bahnhof via the stations Wilhelm-Leuschner-Platz and Markt to the Central Station.

The tunnel will be used by all suburban and regional train lines and will result in more frequent services and shorter journey times. Spring 2004, the project was put out to tender. On 10th January 2005, the consortium City-Tunnel Leipzig Los B – comprising DYWIDAG Bau GmbH as technical lead, together with ALPINE Bau Deutschland AG, Oevermann GmbH & Co. KG, Universale Grund –und Sonderbau G.m.b.H und STRABAG AG – won the contract to construct the main section between the station Bayerischer Bahnhof and the Central Station.

The total construction costs were estimated at 570 m Euros.

Figure 1. Horizontal alignment.

1.2 *Subsoil*

The City-Tunnel Leipzig will be excavated in glacially-formed, loose quaternary granular soil and a mixture of loose and cohesive tertiary sediments. From south to north, initially quaternary pebble (medium-grain sand and fine gravel) is encountered, then with decreasing alignment, tertiary medium to fine sand and, in places, soft to semi-solid clay in the cross-section of the tunnel. The hydro-geological conditions along the tunnel alignment are determined by two aquifers, which are separated by two aquicludes. The tunnel lies entirely below the ground water level and the maximum height

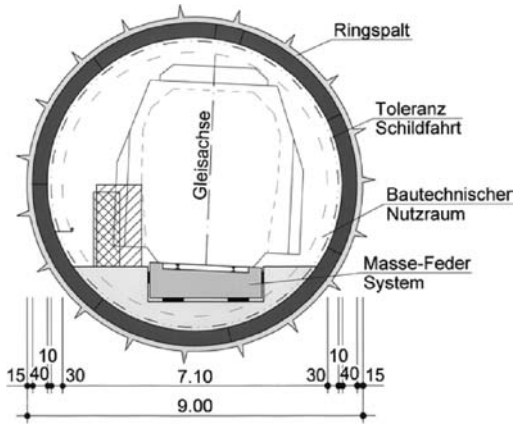

Figure 2. Standard cross-section.

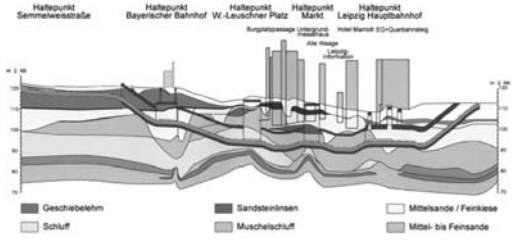

Figure 3. Vertical alignment.

Figure 4. Sandstones in the excavation pit of the Marriott-Hotel.

of the ground water is around 18m above the floor of the tunnel.

In the area of the tunnel tubes, natural and non-natural obstacles are to be expected. Next to the clay or marl deposits, for example, boulders up to 1m in diameter, and sandstone monoliths of up to 15 m^3 and a compression strength of up to 250 N/mm^2 are anticipated.

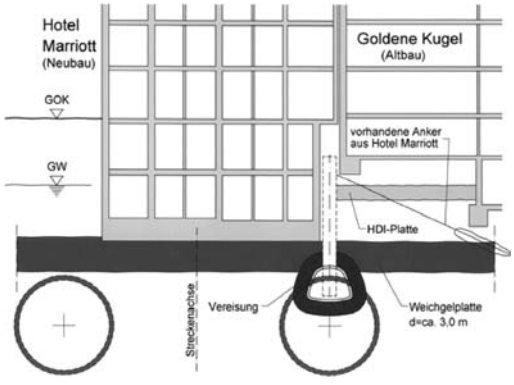

Figure 5. Tender design: salvaging the pile wall by means of mining and soil freezing technology.

Coal deposits are known to be present in the sand and silt, and fossilised tree trunks cannot be ruled out in the layers of gravel.

In this inhomogeneous subsoil, the building contractor must take into consideration the plugging nature of the malleable clay in the shell silt, as well as the abrasive impact of the quartz components of the loose formations.

In the built-up area in particular, non-natural obstacles are to be expected. The ground anchorage in the area of the tunnel between the stations Wilhelm-Leuschner-Platz and Markt was removed with considerable effort. However it cannot be entirely ruled out that further, as yet unknown, anchorages to the working face may have to be removed manually. Over and above this, inadequate or unfilled boreholes cannot be ruled out.

Below the Marriott Hotel, an intersecting bored pile wall remains in the ground, which served as a retaining wall to the adjacent building 'Goldene Kugel'. The partly reinforced piles reach into the roof area of the western tunnel tube and will be salvaged in advance, protected by soil freezing technology.

2 SHIELD ROUTE

Due to the subsoil conditions and the high ground water level, an economically viable under-passing of the centre of Leipzig with minimal settlement is only possible with a TBM with shield.

The excavation of the tunnel begins at the northern end of the station Bayerischer Bahnhof and finishes at the Central Station. It is planned that the machinery will be pulled through the excavations of the intermediate stations (planned in the cut-and-cover method of construction) and, upon reaching the Central Station, the machinery will be dismantled and put back

Figure 6. Moving the portico at the station Bayerischer Bahnhof.

together at the Bayerischer Bahnhof for the excavation of the second tube.

2.1 *Station Bayerischer Bahnhof*

The station Bayerischer Bahnhof is 197 m long. A special proposal from the ARGE suggested moving the 20 m tall, 30 m wide and 2800t heavy listed portico around 30 m to one side, to enable the cut-and-cover construction of the station. Following extensive strengthening of the foundations with HEB-steel girders and a coating of reinforced concrete, the construction was successfully raised and moved by pushing it on a slide bearing on 10th April 2006. Upon completion of the construction of the station, the portico will be returned to its former position.

2.2 *Construction of the stations Markt and Wilhelm-Leuschner-Platz*

The stations will be constructed using the cut-and-cover method (figure 7) with double shell walls. The retaining wall forms a diaphragm wall, which is a retained part of the construction and is attached rigidly to the ceiling. The approximately 26 m high diaphragm wall is embedded, or strengthened, for the duration of the construction, and is embedded in the watertight shell silt. In its finished state, an inner layer made of site-mixed concrete, calculated according to water pressure, guarantees the structure is watertight.

Due to existing constructions directly next to the upper end of the station Markt, the placement of the sealing blocks was only possible using jet grouting. Because the seal of the jet grouting blocks could not be guaranteed, in particular due to the extensive charcoal deposits, the seal is secured with an inner layer of cement blocks, through which the shield drive travels.

The sealing blocks at the other stations, which can be inserted from above without additional effort, take

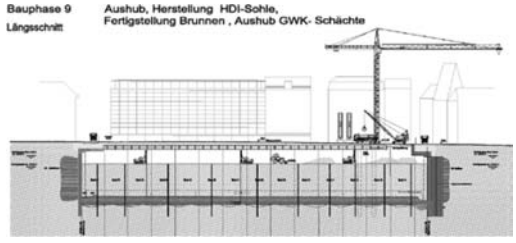

Figure 7. Cut-and-cover method at the station Markt with HDI floor and sealing blocks.

Figure 8. The station Markt on 07.09.06.

the form of a single-layered lamellated diaphragm wall.

2.3 *Sections of tunnel*

In the area of the city centre, numerous buildings and mains have to be under-passed, or are situated in the area affected by the settlement trough, which occurs when the shield drive removes the soil. Settlement of up to 20 mm for a single tube and 30 mm for both tubes were forecast. Under-passing a structure highly sensitive to settlement at a proximity of as little as 4 m requires measures to minimise settlement along the route.

It is planned to use the Compensation Grouting Process (CGV process), which stabilises the ground and – if necessary – with which an elevation is created ahead of the shield drive and occurring settlement can be compensated. The necessary injections of high pressure are delivered by means of valve tubes via shafts and an existing media duct.

The tunnel will be built as a single shell construction. One ring of precast segments consists of seven segments and a capstone with a clam connection where they adjoin. The segments are 40 cm thick and 1.80 m broad. They are prefabricated in a factory of the Max Bögl company and transported by rail to Leipzig.

To avoid the seal tread at the outer edges of the segments 'expanding' during the lifetime of the construction, the front ends and back ends of each section are joined to each other by means of prestressing tendons. The use of ducts for the cables, which run along the inside of the segments, requires an exact ring construction from the outset of the shield's journey.

3 SCHIELD DRIVE

3.1 *The concept of the shield drive*

The use of a Hydroshield with a fluid-supported working face was selected to best cope with the heterogeneous soil conditions and the difficult structural conditions present. With its chamber system, where the extraction and the pressure chamber are connected by a submerged wall opening, a precise, automatic control of the supporting pressure (to 0.1 bar) is possible via the compressible air cushion in the pressure chamber. This enables grain displacement and settlement to be reduced to a minimum. The technical specifications of the shield drive are based on the contractual agreements and the experience of the machine constructor, the Herrenknecht company.

In order to keep the grain displacement in the ground along the shield as minimal as possible, a rigid shield casing with a small shield conicity of 20 mm was chosen and a pressure and volume controlled grouting of the annular space is installed. In addition to this, an excavation control system, i.e. electromagnetic inductive throughput and radiometric density measurement plus a comprehensive operational datacapture, enables the interaction between the ground and machine to be recorded and monitored.

Due to the suspension-supported shield drive technology, the quality of the shield drive correlates, amongst other things, with the separation and bentonite technology, which must be deployed with equally great care and know-how.

Table 1. Technical specifications of the Hydroshield.

Drill diameter	9.0 m
Schield length	9.650 m
Weight	approx. 1,100 t
Total length of machinery	approx. 65.0 m
Max. driving force	65,000 KN
Cutterhead power (8 engines)	880 kW (electric)
Installed total power	2,500 KW
Torque	4,837,000 Nm
Max pressure of the 14 pairs of jacks	65 MN
Cutterhead equipment:	
176 cutters, 42 discs und 16 buckets	

Figure 9. Hydroshield of Herrenknecht.

3.2 *Drill-head area*

The cutterhead was adapted to the heterogeneous foundation conditions in Leipzig: its rim is relatively closed and its equipment includes cutters for areas of soil and rock and discs for boulders, bankings of sandstone and other obstacles. It turns in two directions, is axially moveable up to 400 mm and can be tilted by means of a swing bearing. By tilting the cutterhead, a minimal corrective radius of 300 m can be achieved. Additionally, a hydraulically-operated overcutter can increase the drilling diameter by 60 mm.

Due to the heterogeneous, abrasive ground conditions, the cutterhead is fitted with additional Hardox-wear plates. 6 cutters and 2 buckets are equipped with an electric wear-detection device while the remaining mining equipment can be visually monitored with an endoscope.

The rock discs are 17″ one and two ring rollers 100 mm apart, which can be replaced from the rear. For access to the working compartment, the Hydroshield has a double-chambered channel for people and one material channel, which can withstand a test pressure of 6 bar.

The hydraulically-steered stone crusher, designed for a grain of a maximum edge length of 800 mm, is situated in the floor. Larger boulders are initially broken up by the cutterhead until they fit through its openings. The spaces on the grill in front of the suction flange of the suspension pipe are 180 mm wide.

To avoid blockages in the area of the stone crusher, there is a swivelling suspension jet in the floor area. The extraction and pressure chamber are connected by a communicating vessel which ensures the circulation of the suspension in the event of excessive material deposits between the pressure and submerged wall.

According to the tender document, stone breaking tests took place in the machine constructor's plant to demonstrate its capacity to deal with boulders.

3.3 *Schield peripherie*

In order to be able to carry out ground strengthening measures in difficult construction conditions, for

example within areas of loose gravel or obstacles of any kind, there is an arrangement of 10 test drill channels of a nominal width of 100 mm and an angle of 7° in the roof area of the shield. This enables roof injections to secure the safety of the heading face to allow access to the work compartment. Due to the anticipated obstacles in the soil, the shield's cutting edge was designed to be relatively resilient at 80 mm.

The 2.5 m long carriage drill is mechanically fixed to the erector. Hydraulically-powered Topphammer drive the drill poles via a drill channel through the shield and into the ground.

The pressure grouting at the annular space takes place at the rear of the shield via 6 active pipes, with additional openings fitted with valves and preventer to enable the insertion of a high-pressure hose with rotating jet for cleaning the pilaster strips. To avoid risking settlement by delaying the grouting, a quick unloading of the cement container on the rear carriage is possible, which saves the time it would take to pump through.

To seal the gap between the rear of the shield and the lining, a three-row brush construction is present with 10 pipes per compartment for the sealant. Sealant consumption, flow and pressure are automatically registered.

3.4 *Backup system*

Due to space limitations and entering, transferring across and exiting the stations, the rear carriage is relatively short at 60 m. The rear carriages are designed to accommodate minimal approach and corrective radii. It is an enclosed framework construction set on hydraulically-steered Vulkulan castors.

Figure 10. Station Bayerischer Bahnhof in August 2006.

The key installations to operate the shield drive are situated on the rear carriage. The drill head is electrically powered by 8×110 kW engines.

The transportation and feeding cycle of the bentonite suspension is carried out using pipes of a nominal diameter of 350 and 400 mm with a maximum flow volume of 1844 m^3/h.

3.5 *Innovative measurement and data system*

In accordance with the tender documents, the operational data is centrally captured and made available to the TBM operator, as well as to the construction management above ground and the client in an easily comprehensible form. To guarantee a tunnel-drive with minimal settlement, particularly at the critical points where buildings are under-passed, a continuous cross-checking of the excavation parameters as well as with the actual measured soil displacements are essential.

- **Sonic Soft Ground Probing (SSP)**
  In order to reduce the risk of settlement and the negative implications of geological faults, the seismic pre-assessment system SSP is installed. 4 transmitters, located at the cutterhead, emit acoustic waves which are reflected when density changes or obstacles occur within the ground. By analysing the runtime, a prediction based on the reflection is possible. Specialised 3-D analysis software visualises the reflected signals, which enables a low-impact shield drive to take place, as demanded by the ground conditions.
- **Realtime process controlling system**
  As a result of latest developments, the TBM operator is in the position to directly assess the impact of the shield drive, due to the immediate availability of displacement data.

The recording, collation, evaluation and presentation of data is carried out by the contractor with the process-control system CBP. Closer monitoring,

Figure 11. Controlled Boring Process (CBP) System for low-impact tunnel drive.

within the predetermined boundaries, of data from the machinery directly responsible for settlement, showing, for example, confinement pressure, slurry circuit, bentonite level etc. is thus possible.

In addition to this, measurement data from the immediate surrounding area is fed into the CBP system so that the TBM operator is constantly aware of his exact position in relation to the current geological situation. Additionally a ring-based operational data evaluation takes place during the shield drive.

4 CONCLUSION

The City-Tunnel Leipzig represents an exceptionally demanding challenge in tunnel construction, due to the extremely difficult geo-technical and civil engineering conditions present. Therefore a technique was selected which guarantees low impact tunnel drive. Key to the successful delivery of this project are the collective experience of all people involved in the project, as well as a constructive working partnership and co-operation.

In contrast to the original timetable, the shield drive will not commence in 2006 and therefore information on the actual delivery of the project is unavailable at this time.

Integral studies on mechanical functions of mudding agents and the properties of muddified soils in the EPB shield tunneling technology

T. Hanamura, J. Kurose & Y. Aono
Okayama University, Okayama, Japan

H. Okubo
Taisei Corporation, Tokyo, Japan

ABSTRACT: A key technology of EPB shield tunneling is the mixing of excavated soil with the conditioning agent called "mudding agent" to create the desirable mud state of soil called "muddified soil" having enough flow ability and plastic behavior. In this paper it is clarified the mechanical and chemical functions of mudding agents and the properties of muddified soil. Mudding agents are categorized and classified by the chemical analyses and confirmed by the experiment. The compatibility of mudding agent with soil to be excavated is discussed and clarified also by the experiment.

1 INTRODUCTION

1.1 *EPB shield tunnel and mudding agents*

The EPB shield tunnel is known to be the most economical shield tunnel method used in many parts of the world that was originally developed in Japan, and had been used mostly in Japan until around 1990. Difficulties were existed in the controlling of the excavated soils to keep mud states in order to make the excavated face stable and excavate smoothly in the cutter-head chamber. In the EPB system earth and water pressure can be balanced by the excavated soil pressure through the mechanical thrust from shield machine. One of the most crucial technologies is the method of excavated soils to keep mud states to counteract the earth pressure homogeneously in the face throughout the chamber and excavate smoothly in the cutter-head chamber. In most cases it is necessary to use the conditioning agent to have excavated soils created mud state to keep enough flow ability and plastic behavior. This conditioning agent is mostly the chemical agent of industrially produced or naturally produced and is defined as "mudding agent", for it makes the excavated soil into mud state. Since the soil was not the mud but the mud state soil, the excavated soil mixed with mudding agent can be defined as "muddified soil".

Mechanical functions of mudding agents in the muddified soils are to be required to have first, the bridging effects over soil particles to create mud as plastic and homogeneous and to cope with earth pressure from collapsing, secondly the flow ability to ensure the smooth excavation and to reduce cutting torques during excavation, thirdly the preventing ability of soil from sticking in the chamber by consolidation hardening that cause the stop of cutter-head rotation, fourthly the enough impermeability to ensure the prevention of the muddified soils from leaking into the ground, and fifthly smooth, inseparable and enough cohesive property to prevent muddified soils from gushing through screw conveyor and keep the transporting ability of excavated soils high in the screw conveyor, and on the belt conveyor, in the pipe or on the rail trucks.

1.2 *Purpose of the research*

There are numbers of mudding agents in the EPB shield tunnel market. However there are few explanations and classifications on the mudding agents. It is inevitable to understand the mechanical and chemical properties of mudding agents and muddified soils and to classify them according to the functions. It is also in need to select appropriate mudding agents with the soil conditions to excavate. Therefore the purposes of this study are set up as follows.

(1) Understanding the mechanical functions of the mudding agents in relation to chemical properties.
(2) Proposal of the classification of mudding agents.

(3) Selection of compatible mudding agents to different types of soils.
(4) Evaluation of plastic fluidity of muddified soil.

2 BASIC PROPERTIES OF MUDDING AGENTS

2.1 *Necessary functions of mudding agents*

Existing mudding agents can be roughly divided into two categories as polymer agents and mineral agents. Polymer agents can be also divided into the industrially produced and naturally made agents. The typical mineral type agent is bentonite or clay. These agents are mixed with excavated soils in the cutter-head chamber to modify the excavated soil into the mud state soils called muddified soils.

The required basic properties for the muddified soils are discussed in chapter 2 and can be summarized as "the muddified soils must have the properties of plasticizer, such as appropriate cohesion, inseparability, homogeneousness, impermeability and flow ability". Therefore the basic functions necessary for the mudding agents are as follows.

(1) Appropriate cohesiveness, plasticity and homogeneousness by bridging over the soil particles with polymer chain or by dispersing particles by polymers.
(2) Lubrication by polymers.
(3) Inseparability and impermeability by polymers or grade adjustment materials into the soil particles.

2.2 *Chemical interaction between mudding agents and excavated soils*

Chemical interaction occurs inter-phase between mudding agents and excavated soils. Therefore the mudding agents of high polymer are mostly kinds of surfactants acting on the excavated soil surface in the wide sense. Functions of mudding agents are the bonding, flocculation, dispersion and lubrication between soil particle phase and polymer liquid phase.

Mudding agents of high polymers have molecular weight from 10^5 to 10^7 and make the bridge structures by expanding their molecular chains, thus make the effects of water absorption, flocculation, dispersion and lubrication on the soil particles. Each category of mudding agent will be discussed hereafter. Typical types of industry produced high polymers as mudding agents are a water absorbent polymer, a flocculant polymer, a dispersion polymer and a lubricating surfactant. Furthermore there are other types of mudding agents of high polymer made from natural process. Bentonite is also can be considered as the mineral mudding agent. However bentonite mechanism is somewhat different from high polymer agents as discussed in 2.3.6.

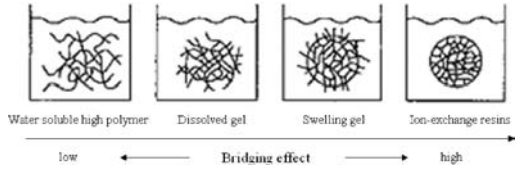

Figure 2.1. Increase of mechanical strength by bridging effect by water absorbent polymer (Revised from Fujimoto 1992).

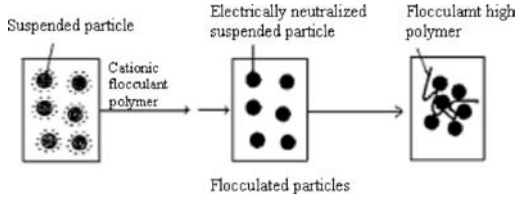

Figure 2.2. Agglomeration processes by the flocculant polymer (Revised from Fujimoto 1992).

2.3 *Typical mudding agent*

2.3.1 *Water absorbent polymer*

Water absorbent polymer absorbs water and swells, and produce the doughty gel. This gel increases in impermeability and inseparability, thus prevents soils from leaking into the ground and gushing in the screw conveyor. Water soluble polymer, especially electrolytic polymer increases the bridging effect with molecular chains. The more bridging effect increases, the more stiffness of gel increases. The mechanical property changes to be strong from a water soluble polymer to semi-soluble gel, swelling gel and ion exchange resin at the end as shown in Figure 2.1. The water absorbent polymer used as mudding agent has the property in-between semi-soluble polymer gel and swelling polymer gel. Water absorbent ability increases by the osmotic pressure and chemical attraction of water, and wraps the large size particles of soil. Typical types of these polymers are polyacrylate, amyloid, etc.

2.3.2 *Flocculant polymer*

The soil particle in the suspension water has an electric charge on the surface, repels each other and suspend without flocculation. Flocculant polymers have strong polymerization reaction, and thus flocculate and cohere to the soil particles by the bridging effect of high polymers. The flocculant polymers build high polymer chain bridges over the soil particles and have them flocculate. The flocculant polymers are effective to cohere to the suspended particles that are relatively small in size. Typical types of these polymers are polyacrylamide, sodium polyacrylate, polymethyl acrylamide, etc.

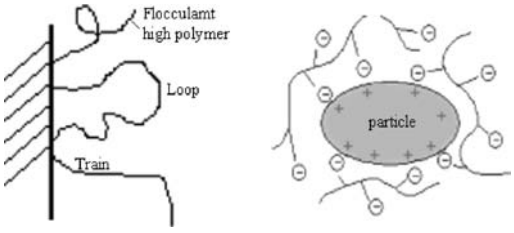

Figure 2.3. Polymer adsorption on the surface of particle (Revised from Fujimoto 1992).

2.3.3 *Dispersant polymer*

Small sized particles such as clay consolidate and have cohesion among them. These soil particles cannot be soluble in the water. By adding the dispersant polymer, the soil particles adsorb polymer on the surface called as the train state as shown in Figure 2.3. The surface of a soil particle is wrapped by the electric charge by polymer adsorption. Since the electric charge of the particle surface is opposite to that of dispersion polymer, each soil particle has the same electric charge and repels each other. The repellent forces enlarge the distance among particles and decrease cohesion of the soil. Therefore the dispersant polymer is effective to separate the cohesive soils like clay and silt. Typical types of these polymers are polycarboxylic acids, melamine sulfonic acid, polyacrylate, etc. Here polyacrylates are primarily used as dispersants and scale inhibitors in a wide range of industrial applications, but they are used as water absorbent polymers when they are used in large amount.

2.3.4 *Surfactant agent*

Surfactants are regarded as wetting agents that lower the surface tension of a liquid, allowing easier spreading, and lower the interfacial tension between two liquids by adsorbing at the liquid-air/liquid interface, thus reduce the interfacial tension at the liquid-soil interface by adsorption. Mudding agents of surfactants in the original meaning are mostly lubricating surfactants. There are two types of lubricating surfactants as follows.

a. Water-soluble type of surfactant
   These mudding agents are used to reduce the cutter torque and smooth excavation or to reduce transporting friction in the pipe flow.
b. Foam type of surfactant
   There is a foam type of EPB shield system. In this system the foam type of mudding agent is used. This agent is a foam type of surfactant agent that is foamed by blowing gas into the polymer liquid. A foam type of surfactant is different phase of high polymer surfactant, and has also same properties as water-soluble type surfactant.

2.3.5 *Natural high polymer*

There are some mudding agents called natural high polymer that are naturally made. They are water-soluble high polymers that increase cohesion, thicken or gelatinize water and wrap soil particles by the polymer bridge. At the same time these polymers are used for lubricating purpose by adjusting the water solution. They are chemically classified as polysaccharides that include starch, glycogen and cellulose. They are nonionic liquids. Typical mudding agents of naturally made polymers are guar gum, alginate, carboxymethyl cellulose (CMC), etc. Guar gum is a natural gum extracted from the guar bean. The alginate such as sodium alginate or alginic acid is a viscous gum extracted from seaweed. The carboxymethyl cellulose (CMC) is a water-soluble high polymer that is made from natural wood pulp and is synthesized by the alkali-catalyzed reaction of cellulose. Though it is produced in the industrial process, it is categorized here as the natural high polymer, for it is originally made from natural wood and is used for food science as a viscosity modifier or thickener.

2.3.6 *Mineral agent as the supplementary mudding agent*

Bentonite and clay can be categorized in the mineral mudding agent. Bentonite is an absorbent aluminium phyllosilicate generally impure clay consisting mostly of montmorillonite. *Swelling bentonite* that is sodium bentonite can be used for mudding agent. Clay is also used for the supplement for the soil. Main purpose of this type of agents is the grade adjustment of particle size of soil. Though bentonite or clay is sometimes used singly for soil additive in the EPB shield excavation, it is used only for soil supplement in order to increase the flow ability and impermeability by filling it into gaps among soil particles. However specially when bentonite is used together with the high polymer agent, the mixed mudding agent works well as good additives for EPB shield tunnelling. Therefore mineral material of bentonite and/or clay can be categorized not as the mudding agent but as the supplement for soils or mudding agents, and can be called as mudding agents supplement. They are categorized as a flocculant agent supplement and a protective colloid supplement.

a. Flocculant agent supplement
   Flocculant agent flocculates and coheres selectively to non-active soil particles such as silt and crushed debris as shown in Figure 2.4. Since the active material of bentonite is not flocculated, bentonite strengthens the bridge effect by polymers, thus increases viscosity and flow ability. These types of selective flocculant agents are polyvinyl acetate, maleic acid copolymer, etc. Since flow ability can be assured by the suspension of bentonite

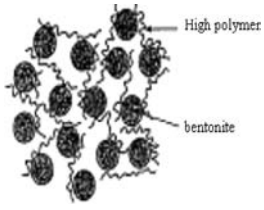

Figure 2.4. Bentonite as flocculant agent supplement (Revised from Fujimoto 1992).

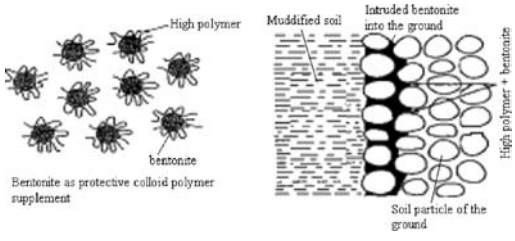

Figure 2.5. Bentonite as protective colloid polymer supplement for sealant (Revised from Fujimoto 1992).

and flocculation of crushed debris, the progress of excavation will increase.

b. Protective colloid polymer supplement Protective colloid polymer itself has hydophillic colloidal property and cover bentonite particles, thus maintains stable colloidal states. This bentonite colloid works as sealant to the soil of surrounding ground together with high polymer. Typical polymer of this type is carboxymethyl cellulose (CMC). CMC keeps the stable bentonite colloid and adsorbs to the calcium ion of soil particle of the ground by the ionic bond. Though the bentonite itself has a sealant ability, the protective colloid polymer accelerates the sealant ability shown in Figure 2.5.

3 EXPERIMENTAL EVALUATION OF MUDDIFIED SOIL

3.1 *Items to be evaluated and be experimented*

3.1.1 *Items to be evaluated*

Before selecting and using mudding agents for excavated soil normally mixing experiments of soil and mudding agents shall be done to evaluate items of mudding agents. The most important experimental item is the plastic flow ability called the plastic fluidity. However at the same time homogeneousness of the mixture; the muddified soil is also evaluated by the sense of touch. Other evaluating items of muddified soil are strength, inseparability. Impermeability of soil is generally not experimented beforehand.

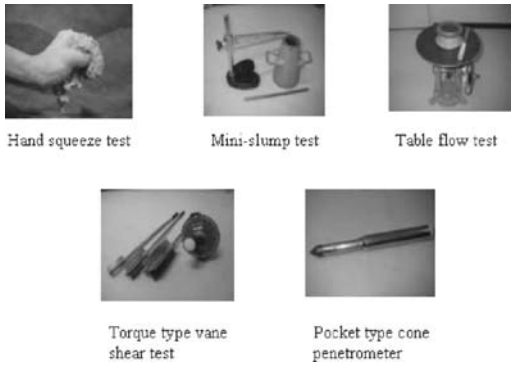

Figure 3.1. Experimental methods to apply.

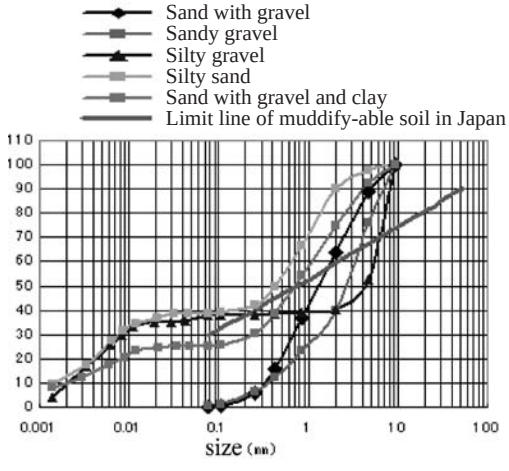

Figure 3.2. Size distribution curves of tested soils (Limit line adapted from Shield T. Assoc. of Japan 2006).

3.1.2 *Test methods to be used*

Conventional experimental test methods employed for the muddified soil are applied by those of fresh concrete. Slump test and table flow test are the most common test methods. Since the plastic fluidity cannot be evaluated directly from the above tests, the direct test of fluidity is evaluated by the hand touch test. The hand squeeze test can evaluate the homogeneousness and inseparability of the muddified soils. Strength of muddified soils is normally evaluated by vane shear test and by cone penetrometer. These test methods are shown in Figure 3.1.

3.2 *Experimental soils to be evaluated and mudding agents to be used*

3.2.1 *Experimental soils to be evaluated*

Five types of soils are tested and their size distribution curves are in Figure 3.2.

Table 3.1. Five types of mudding agents used with different density of agent.

Mudding agent	Density				
A	4 kg/m^3	6 kg/m^3	8 kg/m^3	10 kg/m^3	12 kg/m^3
B	2 kg/m^3	4 kg/m^3	6 kg/m^3	8 kg/m^3	10 kg/m^3
C	500 ml/m^3	1500 ml/m^3	2500 ml/m^3	3500 ml/m^3	4500 ml/m^3
D	10 kg/m^3	12 kg/m^3	14 kg/m^3	16 kg/m^3	18 kg/m^3
E	8 kg/m^3	10 kg/m^3	12 kg/m^3	14 kg/m^3	16 kg/m^3

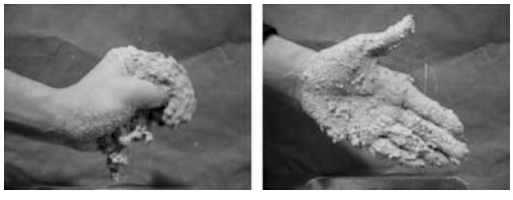

Figure 3.3. Hand squeeze test.

3.2.2 *Experimental mudding agents to be used*

Five types of mudding agents are used as shown in Table 3.1.

Mudding agent A is a complex mix agent of polyacrylamide; a flocculant polymer, and a polyacrylate type of water absorbent polymer. This is recommended to use for sand and gravel soil in the commercial brochure. Mudding agent B is a complex mix agent of a cellulose type of natural high polymer and a polyacrylamide of flocculant polymer, and is recommended to use for sandy soil. Mudding agent C is a dispersant agent of polyacrylate and is recommended to use for clayey soil. Mudding agent D is a natural high polymer of CMC with bentonite as a protective colloid polymer supplement and is recommended to use for sand and gravel soil. Mudding agent E is a natural high polymer of derived mainly from vegetable fiber and is also recommended to use for sand and gravel soil.

3.3 *Mudding agent compatibility with soil*

3.3.1 *Evaluation of plastic fluidity by the hand squeeze test*

Most effective way to understand the property of the muddified soil such as plastic fluidity, homogeneousness and inseparability, is the hand squeeze test with very primitive way as shown in Figure 3.3. The results are shown in Table 3.2 and the circled mudding agents showed good compatibility with the plastic fluidity by the hand squeeze tests.

3.3.2 *Compatibility evaluation of mudding agent with element material of soils*

a. Water absorbent polymer
   This polymer absorbs a large quantity of water and form a gel state. The gel wraps around the soil particle of gravel or sand, and gives the plastic fluidity. This polymer is effective for sand and gravel with high density.
b. Flocculant polymer
   Long chains of high polymers flocculate multiple soil particles with bridge effects and give the cohesion and plastic fluidity. Flocculant polymer is effective for silt and fine sand portion of the sand.
c. Dispersant polymer
   This polymer adsorbs single soil particle and adsorbed particle repels each other. In this way soil particles separate and give the plastic fluidity of the sticky soil of clay. This is effective for sticky type of fine particle of soil such as clay or silt.
d. Natural high polymer
   Natural high polymers of CMC and vegetable fibers in mudding agents D and E have no chemical ingredients to react to soil particles. However the more density of agent increase, the more bridging effect of high polymers increases and wraps soil particles. High density of natural polymer accelerates to be the gel state and gives the plastic fluidity not only for fine particle but also coarse particle of soil such as gravel. In this sense, natural high polymers are considered to be density adjusting agents. These mudding agents can be used for wide range of soil particle size with the quantities to use as additives. Furthermore mudding agent D has bentonite as protective colloid polymer supplement in it and gives good compatibility to large size particle of soil like gravel to increase sealant ability.

3.3.3 *Compatibility result of mudding agents*

Compatibility of mudding agents to excavated soils can be summarized as follows.

(1) For sticky clay or silt, dispersant high polymer agent is good to loosen soil particles.
(2) Flocculant mudding agent represented by polyacrylamide is good to cohere fine and coarse sand particles and easy to handle in mixing process.
(3) Water absorbent polymer increases cohesion to the large size particle of soil such as gravel by making high polymer bridges and wraps gravel particles with high density use of agents.

Table 3.2. Compatibility of mudding agents with four types of soils by hand squeeze tests.

Mudding agents		Sandy soil			Gravel soil	
Type	Density	Salty sand	Sand with clay and gravel	Sand with gravel	Clayey gravel	sandy gravel
A	4 kg/m^3		○			
	8 kg/m^3		○	○		
	12 kg/m^3	○	○	○	○	○
B	2 kg/m^3	○	○			
	6 kg/m^3	○	○			
	10 kg/m^3	○	○			
C	500 ml/m^3	○	○			
	1500 ml/m^3	○	○			
	2500 ml/m^3	○	○			
D	10 kg/m^3	○	○			
	14 kg/m^3	○	○		○	
	18 kg/m^3	○	○		○	
E	8 kg/m^3	○	○		○	
	12 kg/m^3	○	○		○	
	16 kg/m^3	○	○		○	

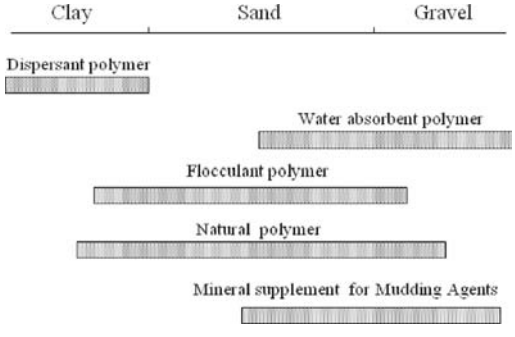

Figure 3.4. Compatibility chart of mudding agents to excavated soils.

(4) Natural high polymers also make other type of bridges over the soil particles with their fibers. Since natural high polymers with high density can wrap not only fine sand particles but also gravel size particles of soil, they can be called density adjusting agents. Above results can be drawn in Figure 3.4 as compatibility diagram of mudding agents to soils.

3.4 *Results of instrumental tests*

3.4.1 *Mini slump tests*

Mini slump cone is the half size of normal concrete slump cone and has a dimension of 150 mm in height, 50 mm of upper inner diameter and 100 mm of lower inner diameter. Results are shown in Figure 3.5. Slump values with the good plastic fluidity are diversified in no particular orders. Therefore mini slump cone values cannot be the evaluating indexes of good plastic fluidity.

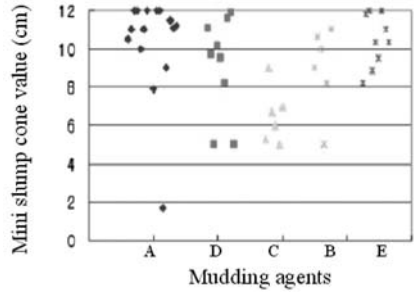

Figure 3.5. Mini-slump values of different mudding agents.

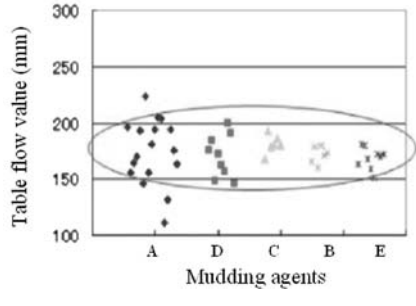

Figure 3.6. Table flow values of different mudding agents.

3.4.2 *Table flow tests*

Table flow test is the same testing method used in concrete test. Table flow values of good compatibility values with good plastic fluidity are between 150 mm and 200 mm and can be good indexes for the good plastic fluidity as shown in Figure 3.6.

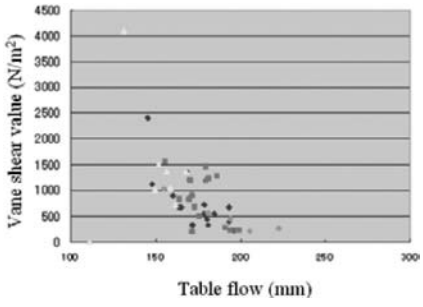

Figure 3.7. Relation between vane shear and table flow test.

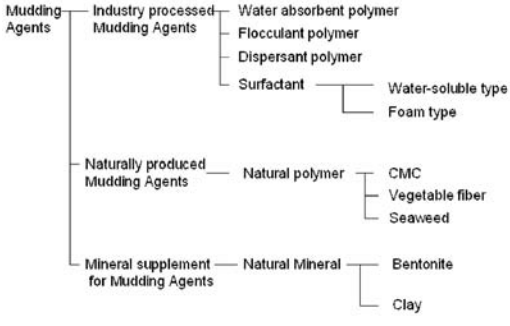

Figure 3.8. Classification of mudding agent.

3.4.3 Relation between Vane shear test and table flow test

Vane shear test and table flow test has some relation. Two groups of values have a hyperbolic relation as in Figure 3.7.

3.4.4 *Cone penetrometer evaluation*

All the penetrating values showed zero, thus pocket type of cone penetrometer cannot be used for evaluation of muddified soils.

4 CLASSIFICATION OF MUDDING AGENTS AND DESIGN MIX EVALUATION

4.1 *Classification of mudding agents and soil conformity*

Through the chemical and physical analyses in Chapter 2 and experimental results of Chapter 3, the mudding agents can be classified as follows.

5 CONCLUSION

(1) Mudding agents for EPB shield tunneling were categorized and classified. Mudding agents could be classified as three types of industry produced high polymers and naturally made high polymer.
(2) Compatibility of mudding agents with the soils was roughly evaluated. Furthermore detailed evaluation of compatibility should be studied in the near future.
(3) Most reliable way of evaluating mudding agents and muddified soils were hand squeeze test. However it is necessary to find good way and to evaluate mudding agents by the digital way.
(4) Table flow values can be a good index for evaluating the good plastic fluidity.

North-South Urban Light Railway Cologne – a challenge for planning and construction – technical solutions for the accomplishment of the upcoming tasks concerning the tunnels

Dr.-Ing. Dieter Handke
Maidl & Maidl Consulting Engineers, IMM, Bochum, Germany

Dipl.-Ing. Lutz Tempel
Kölner Verkehrs-Betriebe AG (KVB), Cologne, Germany

ABSTRACT: The building of the North-South Urban Light Railway Cologne takes place in an extremely sensitive environment; extensive requirements have to be met in order to construct the tunnels. The main part of the 2×3860 m long tunnel route is being built underneath the densely populated city of Cologne parallel to the river Rhine, using slurry shield tunnelling machines. The single shell lining is installed ring by ring covered by the shield of the tunnelling machines. Exemplary for the challenging environment are the building structures in the area of the central station, which are highly sensitive to surface subsidence damages (roofs, railroad embankments, abutment structures), the tunnelling underneath an existing metro tunnel, the philharmonic concert hall, museums, historical buildings and numerous up to four-storey buildings, both business and residential. The tunnels are mainly located in the water bearing quaternary Rhine deposits consisting of sands, gravel sands and gravels. In the northern section the fills of a Roman port have to be passed, and historical relicts can be encountered. The overall project consists of seven underground and one over ground station. Three shield tunnelling machines with a diameter of 6.80 m and 8.40 m are used. The machines, complying with the newest state-of-the-art, have systems to investigate the geological conditions in front of the cutting wheel and to detect unknown wells or relicts of buildings. In addition, equipment is used, which allows the grouting of soil in front of the cutting wheel and the identification of abrasions. Computer data logging systems deliver continuous information about the stability of the heading face, the stabilisation of the lining ring and the deformation of the subsoil. On the basis of failure analyses extensive soil improvements and stabilisations of the buildings have been performed in the run-up of the shield drive in order to minimise the risk. The tunnelling will be accompanied by a permanent supervision of the building structures, the subsoil and the machine data. The determination of boundary and warn values as well as technical failure notifications for the machine allows an early reaction in the case of unexpected failure situations. After starting the tunnelling with all three machines in the middle of 2006, the main report at the conference will be about the experiences of the shield drives – after a short overview of the planning phase. A comparison is made to determine whether the machines and the concept of tunnelling were adequate to cope with the numerous challenges.

1 INTRODUCTION

The beginning of the shield drive in summer 2006 has marked a decisive step for the realisation of the project Urban Light Railway Cologne. After completion the overall building project includes seven underground and one over ground stop and its total length is 2×3860 m. The predominant part will be excavated as tunnel tube in shield advance mode. Thus, after finishing the project, the central station will be connected to the Southern city.

The project is divided into two contract sections. The consortium of the companies Bilfinger Berger AG, Wayss & Freytag Ingenieurbau AG and Ed. Züblin AG (joint venture contract section South) has been assigned with the execution of the southern section in November 2003 and the consortium of the companies Hochtief Construction AG, Bauer Spezialtiefbau GmbH, Keller Grundbau GmbH und Brückner Grundbau GmbH (joint venture contract section North) with the execution of the northern section.

Special requirements will not only demand a thorough technical implementation of the project underneath a, over centuries historically evolved, major city, but will also focus on the logistics within a city centre with high traffic density. Because of the two

thousand years of history in Cologne, special attention is put on the archaeological land conservation, as numerous discoveries from Roman, medieval and Prussian times are expected. The available knowledge had already been considered in the documents of the planning approval. Furthermore, in coordination with the Romano-Germanic Museum of Cologne, timeframes had been agreed upon in the run-up, which then had been integrated in the various construction phases.

Shield machines with slurry-supported face of heading excavate the two, one-track, parallel tubes of the southern section. They both start in the southern part at the starting shaft at Bonner Wall and end in the reception shaft at Kurt-Hackenberg-Platz, south of the philharmonic concert hall.

The two tubes will be excavated parallel to each other, but delayed in time, by two shield machines which are identical in construction. During their course they cross under large parts of the old Roman town and abut on the ancient Roman harbour.

The East tube, which runs away from city, has a length of approximately 2462 m and the West tube, which runs into the city, a length of approximately 2456 m. The internal diameter of the tubes has a value of 7.30 m. The start of the first shield machine for section South (East machine) was on 6 June 2006, the West machine has started early on 2 August 2006.

For the tunnel tubes of the northern section, which will be excavated in opposite direction from the stop Breslauer Platz to the North side of the philharmonic concert hall, only one shield machine is in use. Because of the eminently shorter tunnel, 2×260 m, one machine is sufficient to keep to the timetable. After the machine has excavated the first of the two tubes, the internal machine technology will be dismantled and transported back through the completed tunnel. The shield skin remains in the subsoil. After that, the parallel tube will be excavated from the second starting shaft at Breslauer Platz in the same way. The internal diameter of these tubes has a value of 5.85 m. The tunnelling works have started on 10 July 2006 with the excavation of the eastern tube.

In the run-up extensive requirements had been determined for the logistics of the shield drive in order not to strain the inner city too much. Therefore, an area at the goods station Bonntor has been rented for the building site equipment of the southern section, from which the ground excavations can be taken away via rail. The lining segments can also be delivered via rail, so that the number of heavy goods vehicle transports in the heart of the city can be reduced immensely.

The building site equipment of the northern section is located in the area of the Central Station, also on premises of the German Railway. For this reason old buildings of the Railway had been knocked down. After finishing the procedures, the square Breslauer Platz in front of the station will be completely renewed with regard to urban development.

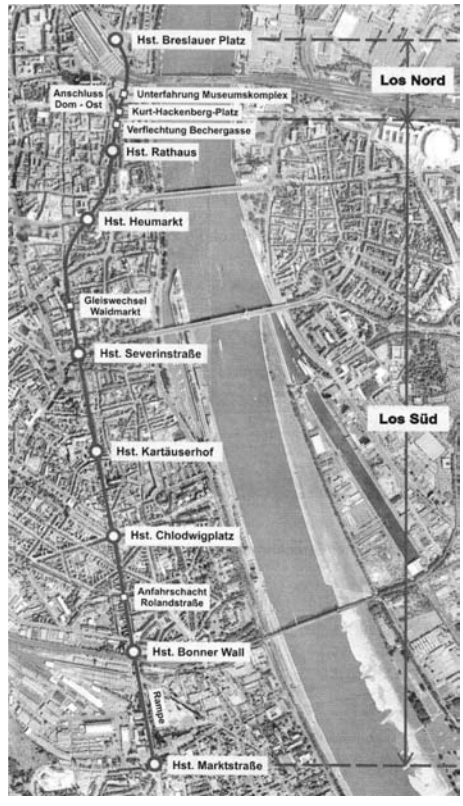

Figure 1. Alignment and special buildings of the North-South Urban Light Rail (Thon, Spohr 2003).

For further information on the total project it is exemplarily referred to the publications (Reinarz 2005), (Thon, Spohr 2003) & (Trier, Tempel 2005).

2 GEOLOGY

The predicted soil conditions, which are located in the sphere of influence of the shield drive are characterised as follows:

Near the surface level, approximately 1 to 2 m of massive filling is encountered. The fillings are either of natural or of anthropogenic type.

Below the fillings, the quaternary Rhine sediments are situated, which are under influence of ground water – here the main parts of the tunnels are being excavated. The sediments consist of sands and gravels in which benches of stone exist. The bedding of these layers varies between loose and dense, whereas medium-dense bedding dominates.

The quaternary layers are located below the tertiary layers. They are characterised as silty fine to middle-grained sands, clayey silt and brown coal.

The tertiary layers are bedded densely and nearly impermeable.

The tunnel cross-sections are located mainly in the water bearing Rhine sediments consisting of sands, gravel sands and gravels. Over a short distance they are crossing the fillings of the Roman port basin.

The tunnel has, in the main part of the alignment, an overburden of 15 to 20 m to surface level. In the area of buildings, foundation distances are minimal in parts.

3 MECHANICAL ENGINEERING AND PROCEDURAL REQUIREMENT PROFILE OF THE SHIELD DRIVE OF THE SECTIONS

Primarily, the planned urban drive requires an advance procedure that guarantees a minimum of subsidence to avoid the damaging of buildings. The total construction method including machine technology has to be suited to this. Simultaneously, the geological conditions have to be mastered with the machine concept.

The mechanical engineering and procedural requirement profile of the shield drive of the sections will be determined basically by the following main demands:

- Maintenance of urban infrastructure (road traffic, public transport), restrictions, respectively partial barring, is conceded only in areas of cut-and-cover methods.
- Conservation of the substance of the buildings, bridges, or rail tracks, which are directly affected by the shield drive.
- Securing of working order of cables and other supply systems installed underground, which have to be crossed under.

These highly difficult infrastructural conditions are overshadowed by the, in parts, extremely unfavourable in-situ subsoil conditions with regard to the advance works and stability and usability of the tunnels.

In addition to the passage of the Roman port basin, where subsoil layers with low load-carrying capacity and deposited obstacles can be found, other obstacles can be expected in the subsoil due to former construction activities: old wells, rests of buildings, anchors, sheet pile walls or piles.

There is no expected arching in the subsurface for the buildings that are crossed under with little foundation distance. Therefore, in many parts of the project, subsoil and foundations of buildings have been improved (jet grouting walls, compensation injections, holdings, shorings, stiffenings) as additional building protection before starting the shield drive. Further details to the forerunning protection measures see publication (Trier, Tempel 2005).

While excavating the tunnel track brown coal layers can furthermore be found in the tertiary layers. Granular structure, compactness or texture could be very diverse in the alignment, which requires precautions as to guarantee the stability of the face of heading.

In the alignment a maximum water pressure of up to 2.5 bar can be expected in the shield invert. Such heights of water pressure are, quoting references, controllable without difficulties using present-day technology.

In order to satisfy the requirements of the sensitive environment within the city, a shield advance procedure is the method of choice for excavating the tunnel tubes.

The most important requirements for the machine as stated in the invitation of tenders are described as follows. The consideration of standard equipment of a shield is obvious and will not be extended further.

- Means to create a grouting area in the top section for preceding stability of subsoil, e.g. as additional security while inspecting the face of heading or for interception and reduction of subsidence of the buildings, which have to be crossed under.
- Development of cutting head with the possibility of giving access to the complete area of the face of heading to remove existing and non-sliceable obstacles.
- Integration of a stone crusher for fragmentation of boulders and building remains to a transportable size for minimisation of inspection states under compressed air.
- Possibility for complete sealing of the face of heading, in order to guarantee the stability of the face of heading during a stop and to avoid postfailures with the consequence of harmful subsidence at surface level.
- Integration of systems for pre-investigation of the expected obstacles in the subsoil, in order to manage necessary procedures on time.
- Possibility of longitudinal displacement of cutter head in order to create a limited area in front of the shield, in which preparatory measures can be taken for removing obstacles.
- Integration of systems for control of mass balance, which are especially important in the lower steady soils for control of volume constancy, therefore for the limitation of subsidence.
- Limitation of conicity of the shield machines and over-cut for minimisation of settlements.
- Possibility for change of main bearing from within the shield for areas in which the construction of caverns for the change of main bearing from the surface level is not possible, e.g. underneath buildings.
- Continuous registration of data of grouting pressures and grouting amounts for the backfilling, to get a nearly cavity-free grouting, which reduces subsidence.

– Systems for automatic registration of annular gap in order to guarantee the building of an ideal ring and to avoid bending of the ring, which could result in damages.
– Distribution of semi-trailer loads for minimization of bending on the freshly grouted lining segment ring.
– Control of operation for all essential components of the machine by optical and acoustic warning facilities as well as limit switch for observation of flow, liquid levels, developments of pressure and temperatures, e.g. in oil circulation, to clear faults as quickly as possible.
– Installation for data registration to observe all data of the shield drive using on-line transmission to the client as well as the engineering offices involved in the building observation.

Superficially this serves as self-observation for the contractor. Furthermore the foreign observation consciously aims at a psychological effect on the contractor.

Due to a demanded risks – hazards analysis in the invitation of tenders for critical advance situations (e.g. crossing under of objects, failure of machine components, accident situations) the tenders were sensitised to the project's specific problems while constructing the tunnels in order to let that knowledge influence the conception of the shield machine.

The shield concept, which has been commissioned and put into action in the end, will be presented exemplarily for section South, on the basis of the essential technical facilities.

4 TECHNICAL SOLUTION FOR THE SHIELD MACHINES OF CONTRACT SECTION SOUTH

Finally, shield machines using the principle of slurry-supported face of heading (Hydro-shield) had been proposed and commissioned concurring to the conditions of the invitation of tenders. All shield machines have been delivered from producer Herrenknecht AG, Schwanau, Germany.

4.1 *Basic principle of shield machines with slurry supported face of heading*

The principle of shield machines with slurry supported face of heading is based on the fact that a pressurized liquid, in this case bentonite suspension, counteracts the extrinsic forces of subsurface, ground water and surrounding buildings to hold the balance of pressure. The liquid is located in a special chamber of the shield machine, in which the cutter head, which excavated the soil, is also situated.

The excavated material at the face of heading is mixed with the supporting liquid in the chamber and extracted to the surface through pipes. The liquid is then separated from the soil and, in a cycle, conveyed to the chamber again.

Only in special situations – e.g. when the tools, which are assembled on the cutter head for excavating the soil, have to be changed – the supporting liquid will be released and substituted by compressed air to render possible the lock in of personnel.

The structurally complete tunnel tube is constructed under the cover of the shield skin behind the chamber. For building the tunnel, lining segments (single re-enforced concrete segments) will be connected to one ring using special bolting and sealing.

While moving forward the shield machine, the annular gap between shield skin and lining segment is grouted with a special mortar, so that no cavities remain in the soil in order to avoid damages to buildings.

The machine moves forward with jacks that press hydraulically against the lining segments. This way, lining segment for lining segment, meter for meter, the final tunnel is constructed.

The complete process using Hydro-shield machines corresponds to the current state of technology. It represents a procedure that is, on the basis of application for more than 30 years, extremely secure, environmentally beneficial, and to the highest degree safe for the personnel involved.

The control of the supporting pressure using a compressed air bubble allows a very sensitive reaction to possible pressure fluctuations at the face of heading, resulting from irregularities in the subsoil in order to reduce subsidence to a procedural technical minimum. Alternative advance methods using compressed air or the EPB-principle are not suitable in the subsoil conditions.

4.2 *Technical data of the shield machines*

Some facts and figures of the machines give an insight into the dimensions and the technical construction of the shield machines.

Shield machines contract section South:

Length of advance machine:	76000 mm
Total weight including semi-trailer:	11000 KN
Length of shield:	9500 mm
Weight of shield machine:	6200 KN
Excavation diameter:	8430 mm
Thickness shield skin front section/middle section/shield tail:	80/50/50 mm
Number of double jacks:	14 pairs
Maximum thrust:	60300 KN
Installed total power:	2800 KW

Figure 2. Shield machine – southern section.

Figure 3. Longitudinal displacement of cutting wheel of shield machine southern section.

Figure 4. Tools equipment cutting wheel of shield machine southern section.

4.3 *Constructive features of the shield machines*

In the design phase of the machines the contractor had been actively accompanied by the client and his consultants. In addition to the technical construction of the shield machines according to the contract, the client proposed, supported by his consultants, recommendations, many of which have been included and put into action by the contractor.

One of the essential requirements was to implement the demand of minimal subsidence.

The closed cutter head is equipped with a total of 174 cutting knives, 19 disk chisels and 16 reamers, whereas the cutting knives are used primarily for the excavation of sands and gravels and the disks for tackling grouted areas and obstacles.

The open parts of the cutting wheel provide enough space to reach all places of the face of heading in order to remove possible obstacles manually if required.

A skew at the flanks of the cutting wheel has a positive effect to the material flow to the back. Four hydraulic extensible over-cuts with copy-cutter function are integrated in the cutting wheel in order to enable the capacity to navigate curves.

In order to control possible signs of agglutination and optimising the material flow, the cutting area has been equipped with an extensive wash-up system. For that purpose, four nozzles and one additional nozzle in the centre have been installed at the cutter head. Separate flushing facilities have been installed in the area of the stone crusher to keep it clear and also to the left and right of the opening in the diving plate for supporting the material flow at the exhaustion.

The power transmission of the cutting wheel works longitudinally moveable as centre-free ring drive. Displacement cylinders support themselves axially at the supporting frame in the middle section. In order to minimise subsidence the cutting wheel can move back within the cutter head. In order to excavate the grouted areas, the cutting edge has a massive design of 80 mm.

In the upper area of the circumference of the shield skin, seven conductors with a nominal diameter of NW 100 for the boring rods are welded to facilitate forward drillings and injection bodies.

The middle section has injection canals in the upper area at the circumference of the shield skin, so that, when required, bentonite suspension can be injected for reduction of skin friction.

An additional gap in the diving plate renders possible the inspection of the face of heading, respectively of the cutter head by means of an endoscope or a camera.

A pressure sealed diving plate gate valve allows working under atmospheric conditions between diving plate and pressure bulkhead when closed.

The machine is equipped with a total of fourteen pressure pairs on the circumference. The jack pairs are divided into six groups. Each group has a cylinder for determining the amount of stroke, using a position measuring system.

The shield tail at the end of the shield skin is equipped with a two chamber brush sealing to counteract the ground water pressure.

The pipes for grouting the annular gap and for the sealing mass of the brush sealing are also integrated in the shield tail skin.

The pressure and volume controlled back-filling is carried out using grouting pipes. Pressure sensors measure the pressure of the grouting pipes. The grouting amount is recorded by the piston stroke of the grouting pumps as well as an ultrasound sensor at the mortar tank. Now the system is switched over to load cells in order to register continuously the temporal change of weight of the grouting amount.

The erector, which is steered from a user interface, places the single lining segments. The air gap (distance outer edge lining segment to inner edgeshield skin) is measured semi-automatically using so-called distometers (measurement of distance through laser beam and wireless data transmission to the data registration plant), which will be installed manually at the relevant place.

The semi-trailers are situated behind the machine. They consist of one bridge and four semi-trailers, which are closed-platform carriages, equipped with steerable wheels. The wheel loads of the semitrailers are distributed evenly on the lining segment rings, so that concentrations of load are avoided.

The data registration is synchronised. The data is visualised and saved for each advance, including ring number, date and time.

The control system determines the position and height of the machine at any time. This laser controlled navigation system shows the shield driver the actual position of the machine in graphical and numerical form on a monitor in the control cabin.

The observation of the bentonite level is carried out using two independent systems. The suction gate valve can close the suction pipe over the first level measuring point automatically. The second level measuring point activates the feed gate valve for automatic closing of the feeding line.

For mass control, a comparison of the flow measurement in the pipes of the feeding line and the transport line is used.

The seismic pre-investigation is carried out by the help of the SSP-System (Sonic Soft Ground Probing) for mechanised shield tunnelling with bentonite supported face of heading. In order to do so, 4 transmitters and 1 receiver are installed at the cutter head. Geological in-homogeneities and obstacles up to a distance of approximately 40 m in front of the cutter head reveal themselves using a seismic reflection method. Cross-hole measurements at the beginning of the tunnelling served as an early calibration of the system.

The direct wear observation, parallel to the excavations, is carried out through conductor loops integrated into six excavation tools. The cut gives information about wear of tools. The other tools are checked visually using an endoscope. The material flow from the face of heading into the excavation chamber is unhindered due to, in parts, conic gaps and due to the cutter head that is 34% open.

5 STATE OF PROJECT AT DATE OF DRAWING UP THE REPORT AT THE END OF SEPTEMBER 2006

5.1 *Contract section south*

The first shield machine under the Bonner Straße has started the advance of the East tube on 6 June 2006.

At date of preparing this report (end of September 2006), approximately 700 m of the East tube and 350 m of the West tube of section South had been excavated.

The average rate of advance was approximately 6 m/day and the maximum rate was 14 m/day.

The subsidence that occurred largely corresponded to the prediction of total subsidence. Continuous supervision and optimisation of confinement pressure in the upper third of the sphere of tolerance, as defined according to static calculation, resulted in a considerable reduction of predicted forerunning subsidence. The forerunning settlements had an average value of 5 mm. The medium total settlements were approximately 15–20 mm, whereas, caused by the procedure, the predominant share of subsidence occurred at the length of the shield. The subsequent settlements were approximately 15–20%, which indicates that the back-filling was adapted ideally to the subsurface conditions.

The advance is accompanied by an extensive measuring system. With this innovative system, a demand in the invitation of tenders, the shield driver has, at any time, an extensive view at:

- Machine data, e. g. jack forces, confinement pressures,
- Functional disorders in the machine system, e.g. leakages, failure of components
- Survey and control system of machine, e.g. position of machine at nominal axis
- Deformations of subsoil (e.g. measuring points in the soil, extensometers), building bolts, hydrostatic tube balance measuring system.

At regular distances measuring points in the soil and so-called main measurement cross-sections (fitting with soil-points and extensometer points in cross and longitudinal direction of advance) are installed at surface level. Additionally, measurement bolts have been installed at every building for which, before the start of the advance, warning and alarm values had been determined.

The segmental lining completely fulfils the requirements of the invitation of tenders with regard to the density. Wet places and spallings have appeared only secondarily at single places. At the same time, this documents the perfect interaction of machine technology and lining segment design regarding the underground conditions.

5.2 *Contract section north*

The shield machine for the northern section has started the advance for the East tube on 7 July 2006 and reached the final position on 9 September 2006.

While excavating the approximately 260 m long section, several buildings had to be crossed under, partly with very low distances.

The average rate of advance in this section was 4.5 m/day and had been characterised especially by the reduced rates of the advance while driving through the Jet grouting walls.

The measured average settlements were 10 mm and can be interpreted as a confirmation of the prediction.

6 CONCLUSION

The systems used for tunnelling have proved successful. They met all requirements. For the future we hope that the accident-free advance continues and situations will be mastered as securely as before.

The latest technology in mechanized tunnelling – the design of the world's largest EPB and slurry shield TBMs

Dr.-Ing. E.h.Martin Herrenknecht & Dr.-Ing. K.Bäppler
Herrenknecht AG, Germany

ABSTRACT: The general increase in growth is a result of a worldwide growing need for an efficient infrastructure in the areas of transport, supply and disposal services. Topographical conditions in large cities and towns encourage tunnelling solutions, particularly by mechanized methods. The mechanized tunnelling process has captured the attention of the public sector. As a safe, settlement controlled tunnelling process it offers a beneficial alternative to other tunnel excavation methods. Innovative solutions are increasingly required for tunnelling projects with a high level of difficulty in terms of construction, such as large diameter inner-city tunnels in heterogeneous grounds with high water pressures or the construction of long-distance tunnels integrating combined traffic systems in the tunnel cross section. Mechanized tunnel excavation moves into new dimensions especially regarding complexity of ground conditions, diameter, length and depth of underground constructions where the feasibility of other tunnelling methods is limited. This paper focuses on the design and technical challenges of the three largest soft ground tunnel boring machines, two Slurry Shields (ø15.4 m) for the Shanghai River Crossing project and one Earth Pressure Balance Shield (ø15.2 m) used for a road tunnel project in Madrid in Spain.

1 INTRODUCTION

The tendency of the tunnel projects of today show the innovative move of using full-face TBMs with diameters larger than 14 metres.

The resulting larger effective tunnel cross sections enable the possibilities of integrating more than 2 lanes of traffic or more than one traffic system in the tunnel or as shown with the example of the Storm Water Management and Road Tunnel project in Kuala Lumpur in Malaysia that the tunnel can take over more complex service functions.

With the example of the two largest soft ground tunnel projects in the world the latest technology in mechanised tunnelling will be described. The current largest Earth Pressure Balance Shield (Ø15.2 m) was in use for a road tunnel project in Madrid. The tunnel takes three lanes of traffic side by side on one level in the tunnel cross section. The two largest Mixshields (Ø15.4 m) designed for the Shanghai River Crossing Project in Asia are in use for the construction of a road tunnel carrying three lanes of traffic on one level and a safety passage and a rescue lane in the bottom of the tunnel cross section.

2 LARGEST EARTH PRESSURE BALANCE SHIELD (Ø15.2 M) USED FOR THE M30 ROAD TUNNEL PROJECT IN MADRID

Within the framework of the project Calle M30, the largest Earth Pressure Balance Shield (EPB) was in use for the construction of the north tunnel of the south bypass on Madrid's highway M30.

The tunnel route passes through a densely populated area and crosses beneath several structures such as three metro lines and railway tracks with minimal cover. The lowest distance from the tunnel crown to the structure is only 6.5 meters and this with an inside diameter of the tunnel of 13.37 m.

The tunnel is constructed with reinforced concrete segments. One tunnel ring is composed of $9 + 1$ segments and has a length of 2.0 m.

The EPB-Shield with a diameter of 15.2 m has been designed to suit the prevailing cohesive soil conditions, which have been predicted along the designed tunnel alignment. Clay and gypsum of stiff to hard consistency are characteristic of the geological conditions at tunnel level.

Large diameter EPB machines, and very large diameter EPB machines such as the one used on the south bypass tunnel for M30, require a very high cutting wheel torque compared for example to slurry TBMs.

Machine technical and process technical factors such as drive unit and bearing unit, cutting wheel design and rotational speed have a relevant effect on the torque of the cutting wheel. The EPB-Shield for the Calle M30 project has a very high cutting wheel torque which amounts to 125,000 KNm. Therefore the cutting wheel is equipped with two concentrically arranged cutting wheels.

The inner cutting wheel is installed in the free centre of the outer cutting wheel as a flat disc-type wheel. It is installed in the working surface of the outer cutting wheel and it is longitudinally displaceable relative to the outer cutting wheel.

The rotational drives of both cutting wheels are completely independent with different rotational speeds in both directions of rotation.

Part of the high torque is consumed in the mixing chamber, which is neutral with respect to the rolling of the machine. The torque is consumed between the cutting wheel and the tunnel face, it is the active part regarding the rolling of the TBM and can be resisted in loose soil by means of the skin friction or by transfer into the tunnel lining (reinforced concrete segments). If the torque rises beyond the value which can be resisted by the moment of friction of the shield shell, the machine will show a tendency to roll.

With a diameter of 15.2 m and a torque of 125,000 kNm the Herrenknecht EPB Shield beats all dimensions which have up to now been available on the mechanised shield tunnelling market.

The drive unit of the inner cutting wheel comprises 10 motors with a total power of 2,000 kW. To summon up the required power of 12,000 kW for the outer cutting wheel a new design was conceived. Altogether 50 motors are necessary for the outer cutting wheel drive. They have been distributed around the main drive in two rows of 29 motors and 21 motors.

The double cutting wheel design also improves the excavation process and the soil conditioning. The material excavation in the outer and inner area of the tunnel face can to a large extent be carried out at an optimised cutting tool speed. This is achieved by adjusting the differences in peripheral speeds, which can be applied to the cutter tools.

The design of the outer cutting wheel area facilitates the arrangement of various cutter positions, which is normally not possible at all in the inner area as a favourable opening ratio must be maintained. A great difference in the cutter penetration depth between the outer and the inner area can be avoided by a higher rotational speed in the inner area, which has also the effect of reducing wear on the cutting tools.

With regard to the soil conditioning with the double cutting wheel design and in particular with respect to the material removal and kneading or mixing effect, the mixing chamber can be divided into two zones. Both can be handled independently from each other.

The areas of the inner and outer mixing chamber are in direct contact with each other so that an exchange of material between both zones is possible but not necessary. Because of the individual handling of the outer and inner mixing chamber, a homogenous consistency of the material in the chamber can be achieved.

The cutting wheel is equipped with eight independent injection points at the front face of the centre cutting wheel and with 14 independent foam lances installed in the outer cutting wheel. Thus the injection of plasticizing agents such as foam is possible. Thereby 36% of the total volume will be injected through the injection points, which are provided on the front face of the centre cutting wheel and the remaining 64% will be injected in the outer ring section.

The start-up of the excavation process of the currently largest EPB-Shield begins when the inner cutting wheel starts rotating. The soil will be conditioned with foam through the rotary union, which is attached to the centre cutting wheel and above the stators. The stators are positioned in the centre area behind the cutting wheel in order to reduce the friction on the inside. To increase the mixing effect in the centre area, the displacement cylinders will be slowly extended.

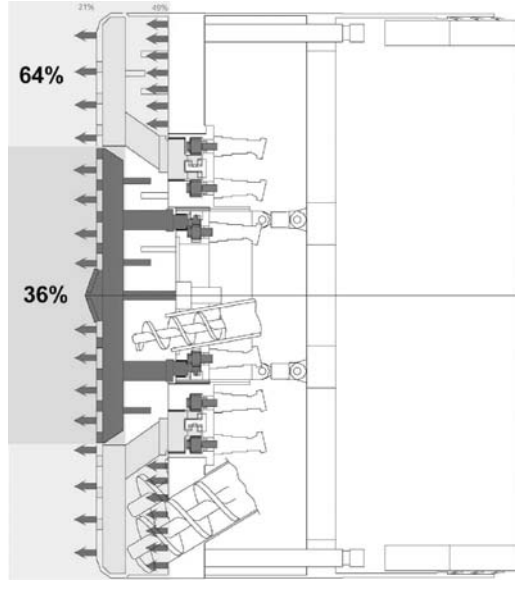

Figure 1. Injection of plasticizing agents through the two concentrically arranged cutting wheels of the EPB-Shield (Ø15.2 m) for M30.

It can be assumed that the soil will be well-conditioned up to a diameter of approximately 9 m and this will considerably reduce the starting torque of the outer cutting wheel.

As soon as the centre area is conditioned, the outer cutting wheel starts turning and simultaneously adding foam. Thus, the complete excavation area will be homogeneously conditioned and the advance process can commence.

The excavated material is transported out of the excavation chamber via three screw conveyors, which are integrated in the shield. They handle an excavated volume of 565 solid cubic meter per ring. There are two parallel screw conveyors (Ø1,250 mm), which are located in the lower part of the shield to remove the excavated material from the outer cutting wheel and to transport it back to the belt conveyor. The third and smallest screw conveyor (Ø600 mm) is arranged in the lower third of the central cutting wheel. It will remove the excavated material from this area and convey it back to the belt conveyor.

The complete transport of the TBM from the manufacturing factory to the jobsite took two months. The main components of the Shield TBM were first transported with a river boat to the port of Rotterdam and then with two ships to Spain. For unloading the components a crawler crane with a capacity of 600 tons was necessary. The transport on the road lasted approximately nine days (50 km per night accompanied by the police).

The excavation of the 3,525 m long north tunnel of the south bypass on Madrid's highway M30 started on November 15, 2005 and could successfully be completed, on July 12, 2006, by the team of the contractors Acciona Infraestructuras S.A. and Ferrovial-Agroman S.A. in cooperation with Herrenknecht AG, after only 8 months of construction time.

During advance the giant boring machine achieved convincing performances, which could be increased week by week and pushed to a best weekly performance of 94 rings or 188 m. The best daily performance amounted to 18 rings or 36 m and the strongest monthly performance could be reached in May 2006 with considerable 758 m.

After the assembly and learning phase, weekly performances, which were clearly higher than 50 rings or 100 m, could be achieved permanently. The tunnelling cycles were 30 minutes and the construction of a ring, consisting of 10 concrete segments, 13.9 tonnes each, could be carried out in approx. 50 minutes. During tunnelling a cycle time of less than 100 minutes could be achieved for the advance and the installation of a 2,000 mm long ring. The TBM supplier's and construction firms' skilled personnel helped to reduce learning curve effects.

After approx. 1,000 m, 2,000 m and 3,000 m of tunnelling, a standstill of approx. 4 days was each scheduled in order to inspect the cutting tools, install tunnel belt boosters and carry out other maintenance operations that could not be done parallel to the advance. The target construction time of 12 months could clearly be underrun, and the 8-month tunnel construction time equals an excellent TBM performance of more than 450 m per month.

3 LARGEST MIXSHIELD (Ø15.4 M) IN OPERATION IN SHANGHAI

With the construction of the gigantic project "Shanghai Changxing Under River Tunnel" the region of the Yangtze delta near Shanghai will be further opened.

The Yangtze is Chinas biggest river. Its yearly flow of 951.3 billion cubic metres of water amounts to approx. 52% of the total yearly quantity of all Chinese rivers.

The greatest challenge of this project is the connection of the two river banks from the Pudong mainland with the island of Chongming. Two parallel motorway tunnels with a length of 8,950 m each will be built between the mainland Pudong and the island of Changxing. A bridge will connect the island of Changxing with the island of Chongming.

Since the waterway between the mainland Pudong and the island Changxing is a very busy main shipping route, the tunnel solution was preferred instead of a bridge construction.

With a length of 80 km and a width of 20 km, Chongming is the third biggest island of China. The island Changxing with a population of about 30,000 is characterised by the establishment of industries with three large shipping services.

The two parallel tunnels will run beneath the largest river of China with the currently largest two tunnel boring machines. The Mixshields have a shield diameter of 15.43 m. Each of the tunnel tubes will integrate two levels, of which the upper level will contain three lanes for motor traffic and the lower level is planned to integrate a rescue lane in the centre and a safety passage.

The planned construction period of the Chongming Yangtze River Crossing Tunnel near Shanghai amounts to four years.

The challenges for the design of the two largest Mixshields for the river crossing were on the one hand the large shield diameter of 15.43 m and on the other hand the predicted geological and hydrological conditions. Each tunnel will have a total length of approx. 7,170 m with a gradient of ±2.9%.

The two Mixshields are adapted to the local geological and hydrological conditions featuring clayey formations and very high groundwater pressures. The entire tunnel will be built in very weak, clayey soils below the groundwater table. Characteristic of the

Figure 2. World's largest Mixshield Ø15.4 m for Shanghai.

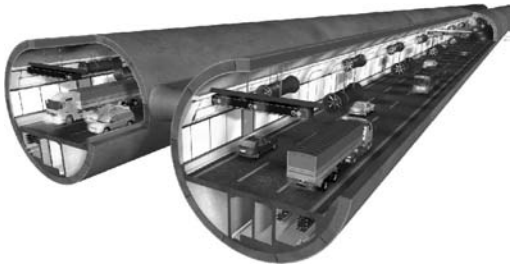

Figure 3. Changjian under River Tunnels, Shanghai.

expected geology are local intercalations of silty and sandy layers and shell residues.

Due to a ground-water level of up to 47 m above the centre of the tunnel, the TBMs are designed for a maximum working pressure of 6.5 bar. At the deepest point the tunnel will run about 65 m below the surface.

The tunnel lining consists of precast reinforced concrete segments with an inside diameter of 13.7 m. One tunnel ring consists of $9 + 1$ segments and has a length of 2 m. For both tunnels altogether 7,500 segment rings are needed. They will be delivered with two special trucks from the segment fabrication yard, which is about 1.5 km away, to the jobsite.

A feature of the cutting wheel design are six accessible main spokes, which are sealed against the water pressure. To avoid adhesion of sticky clay at the cutting wheel, the centre area is equipped with an own slurry circuit. Large openings in the cutting wheel optimise the flow of material and reduce the risk of blockage of material in the centre.

In order to get reliable information about the condition of the soft ground tools and buckets, especially in the loaded outer area of the cutting wheel, ten cutting tools (2 buckets and eight soft ground tools) are equipped with an electronic wear detection system.

The system generates online data on the state of the selected cutting tools and gives early warning of possible wear to the TBM staff.

With this electronic wear detection system maintenance works can be planned and the service life of the tools can be optimised, thereby minimising costly chamber accesses under compressed air.

The heart of the system is a new tool support with integrated sender electronics. This is permanently connected to the soft ground tool through induction loops and "detects" whether the wear limit is reached. For this purpose the sender is electrically connected with a power supply. If the probe is intact a certain current flows but if the probe is destroyed due to wear of the tool this is "sensed" by the sender through a significantly higher fault current. The sender is inductively connected with the receiver and the tool probe through a small gap. A LED informs the machine driver of the wear. With this automatic method of wear detection unnecessary maintenance could be avoided.

The design of the cutting wheel was conceived in order to allow man access to its interior space under atmospheric air pressure, sealed from the ground water pressure outside.

Tool change devices, which are integrated in the cutting wheel, allow the personnel to replace tools under atmospheric conditions from the interior of the cutting wheel.

The tool change device has two functions:

1 To serve as receptacle for the tools.
2 To allow the outward and inward airlock transit of the tools.

In order to flush the devices there are flushing connections installed on the rear case.

This tool change device consists of the following main components:

1 Front casing. This forms the connection to the steel structure of the cutterhead and is circumferentially welded to it.
2 Rear casing. It is flange-mounted to the front casing and assumes in connection with the front casing the guidance of the slider and of the sliding pipe.
3 Slider.
4 Sliding pipe. The sliding pipe receives the cutting tool.

The sliders are opened in the working position. In this position the cutting wheel is made water tight by the front seal. In case of damage of this seal, the circumferential profile seal located around the slider and the rear seal would assure the leak tightness.

A further feature, which has to be mentioned, is the installation of road elements by the back-up of the Mixshield. The back-up is composed of three trailers. The first one contains all necessary equipment and supply material for the functioning of the excavation

process. The second trailer is a bridge construction to allow free space of ±20 m for placing the road elements, which are precast concrete parts of 2 m length in dimension, 4.30 m in width and 4.56 m in height. Each element has a weight of approx. 35 tons.

Supplies will be delivered to the TBM with trucks. They will drive along these rectangular road elements which are placed along the centre of the bottom of the tunnel. The trucks will be unloaded in the back-up trailer number 3.

Back-up number 1 will run on invert slabs. These are placed on the already built segment ring and will be taken out and moved to the front as soon as the first back-up trailer passed this section. Back-up trailer number three runs on auxiliary rails.

The tunnel excavation for the about 7,170 m per tunnel tube is expected to take about 34 months. The commissioning of the BOT-tunnels is planned for 2010.

4 CONCLUSION

The two cited Shield TBM projects are characteristic of demanding conditions like the under river crossing near Shanghai and the inner-city tunnelling for the M30 project in Madrid. Both projects illustrate the feasibility of large diameter tunnels and are pointing the way for future projects regarding the excavation of even larger tunnel cross sections, long-distance bored tunnels and even deeper excavations.

In general, it is important to have a good understanding of all the conditions of a project already in the planning stage. The geological information is of particular interest because the machine design will be adapted to the predicted geological conditions. It is increasingly important to avoid possible risks when tunnelling in urban areas and also in the open country when underpassing existing structures or rivers and to further adapt the technology to make it even more safe and efficient.

Compressed air work with tunnel boring machines

E.h. Martin Herrenknecht & K. Bäppler
Herrenknecht AG, Germany

ABSTRACT: In general diving and compressed air works are associated with works on offshore drill rigs and production platforms in the North Sea and Baltic Sea, national and international recovery operations, refurbishments of dams and works in contaminated waters, e.g. treatment plants. The use of divers in tunnelling first seems to be unusual. For more than one hundred years, however, compressed air works have been carried out on large construction sites during tunnelling works below groundwater level and nowadays, in particular, during river crossings at very high water pressures. The diving techniques employed in conjunction with mechanized tunnelling have included diving to depths of more than 50 m using mixed-gas or saturation diving. The tasks undertaken by the divers have included welding and cutting underwater; or in a bentonite suspension; surveying, welding inspections, removing and replacing tools on the cutting wheel. This report gives detailed information on the use of divers as well as the latest developments in construction and diving technology during very complex tunnelling projects at overpressures of more than 4 bars, referring to tunnelling projects such as the '4th Elbe Tunnel' in Hamburg (Germany), the 'Wesertunnel' (Germany) and the 'Westerscheldetunnel' (the Netherlands).

1 DIVING AND COMPRESSED AIR WORK IN TUNNEL BORING MACHINES

1.1 *General information on TBM design and diving operations*

The use of professional divers in mechanized tunnel excavation is usually limited to those machines that are deployed in very complex heterogeneous geological conditions at high water pressures: Mixshields. They can safely support the tunnel face by using a pressurized liquid. Here water-bentonite suspensions are often used for the support of the tunnel face. The bentonite is used because of its geomechanical characteristics, its plasticity and its swelling capacity in the support liquid. The pressurized suspension penetrates the ground and seals the tunnel face with a possibly thin, impermeable film, the so-called filter cake that is used to generate the support pressure. This process is carried out within a relatively short time span of 1 to 2 seconds. The support pressure balances the encountered ground and water pressure and avoids uncontrolled collapses and stabilizes the tunnel face.

The regulation of the support pressure in the excavation chamber is not directly carried out via the suspension pressure but via an air cushion between bulkhead and submerged wall. Fully automatic circuits, permanently controlling the pressure conditions at the face and generating the relevant counter pressure via the support media, allow for a precise support pressure control. Thus settlement or heave is avoided between the machine and the surface, which is especially important where there is low overburden.

In this operating mode, the bentonite suspension not only serves as a stabilizing support medium but also as a slurry transport medium to remove the material excavated at the tunnel face. The spoil is pumped through a slurry line to a separation plant that is normally located outside the tunnel, where the ground and the suspension are separated and the treated suspension is fed back to the slurry circuit.

Within the protection of the tailskin of the shield, the tunnel lining of precast reinforced concrete segments are put into position by the segment erector. For excavation, the tunnel boring machine is advanced by hydraulic thrust cylinders which push against the last-built segmental ring. The gap between the extrados of the segmental ring and the ground is continuously grouted as the tunnel boring machine advances to secure the ring and to support the surrounding ground.

1.2 *Compressed air works during mechanized excavation*

Work in compressed air (compressed air work) is carried out at an air pressure above atmospheric pressure. The compressed air work at overpressure in the excavation chamber can present serious health hazards to the personnel. Thus medical checks are mandatory prior to the works to ensure that the workers are fit for this type of work. Important health and safety regulations must be observed and complied with.

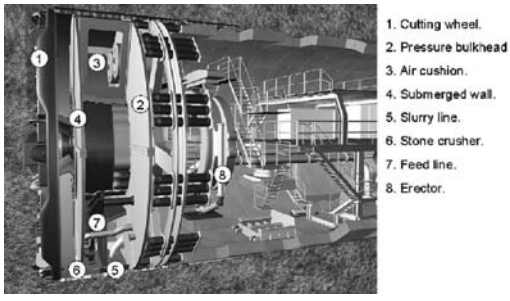

Figure 1. Functional Principle Mixshield (Shield Tunnelling with liquid supported tunnel face).

Divers also work under hyperbaric conditions as soon as they move below the water surface. The exposure to overpressure implies serious health hazards to the personnel even if the compressed air works are appropriately organized and monitored. According to the 'Regulations for Compressed Air Works – ('DruckluftV' of 1972) – the staff must not carry out works at an overpressure of more than 360 kN/m^2 (3.6 bars/52.2 PSI).

From 4.0 bars/58 PSI overpressure (40 m (131 ft) water column) upwards, the extended decompression times for the compressed air personnel and the reduced working time reaches a levels where it is no longer viable to carry out compressed air works in the conventional way. Here the use of divers is required. There is no pressure limit for diving. With compressed air as breathing air, the diving depth is limited to 50 metres (500 kPa or 5.0 bars overpressure). Breathing-gas mixes allow diving depths of more than 100 meters (328 ft) and operation times of several days or weeks using saturation methods.

Based on three prestigious projects, compressed air works and diving, that have become vital for mechanized excavation, will be explained in more detail.

1.3 *Compressed air works and diving during the '4th Tunnel under the River Elbe project'*

During the construction of the '4th Tunnel under the River Elbe', a Mixshield was deployed with a liquid supported tunnel face. The TBM was 14.2 m diameter and the special requirements of the project (an overburden of only 7 m between the top section of the tunnel and the river bed of the 'Elbe' at the most critical point) put the personnel and the technology to the test.

The geological conditions, in particular, the presence of large boulders, required a cutting wheel equipped with mixed cutting tools consisting of cutter discs as well as soft-ground cutting tools. The possibility to excavate boulders with sizes of 0.8 m up to 1 m with groups of cutter discs has been proven in practice.

The cutting wheel consists of five main and five additional spokes and is equipped with 120 soft-ground cutting tools as well as 31 cutter discs.

Due to the low overburden at pressures of up to 5 bars, a conventional access to the working chamber (lowering of the compressed air support) was considered critical. Since a cutting tool change had to be expected, a complete set of cutters was installed on two levels.

The first level comprised soft-ground cutting tools that were arranged correlatively with the cutter discs. The latter could only be exchanged after a conventional access.

The second level was equipped with cutting knives (scrapers) that could be exchanged from within the accessible spokes without lowering the slurry in the excavation chamber. This also applied for the cutter discs.

Additionally, the machine was equipped with all installations required for diving operations in the excavation chamber.

The cutter tools can partially be exchanged under atmospheric pressure from the five accessible main spokes and, in part, from the tunnel face under overpressure conditions.

To allow for a cutting tool change without lowering (fully maintaining the liquid support), another step (cutting tool change in the arm with exchange unit) was inserted between the conventional cutting tool change and the diving.

This was achieved through accessible spaces within the cutting wheel and depressurization valves located behind the cutters. The spaces within the cutting wheel could be accessed via the cutting wheel center, at atmospheric pressure or under hyperbaric conditions. Here the cutting tool change under atmospheric pressure in the cutting wheel arm was carried out as follows:

Each cutting disc is mounted in a pressurized housing with a hydraulically operated gate valve. The cutting disc is held in position by a hydraulic cylinder whilst the mounting bolts are removed. The cutting tool is then withdrawn and the gate valve is closed sealing the housing off from the face.

A crane attachment is then used to remove the worn cutting disc to be replaced with a new disc.

The same method is used for the replacement of scraper tools located in the five main cutting wheel spokes.

This development is part of the safety concept.

The tools on the first level could only be exchanged after a conventional access. Thus a new method for 'works in compressed air' was, for the first time, implemented during the construction of the project '4th Tunnel under the River Elbe'. During the planning phase, the use of divers was already considered for maintenance and repair works to the cutting wheel equipment. An operation program for potential diving

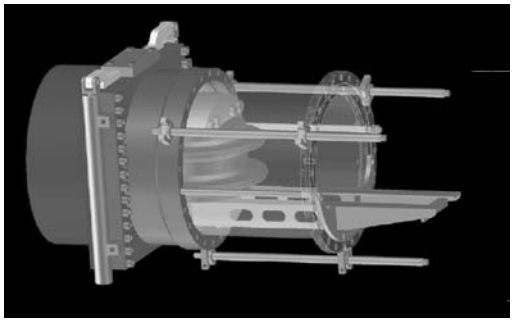

Figure 2. Cutting tool change under atmospheric conditions.

Figure 3. Emergency/Transport chamber to evacuate injured personnel from the pressurized zone to the surface.

works in bentonite as well as compressed air works at overpressures up to 5.5 bar was formulated in cooperation with the joint venture partners: 'Bilfinger + Berger', 'Hochtief AG', 'Wayss & Freytag AG', 'Philipp Holzmann AG', 'Dykerhoff und Widmann AG', 'Züblin AG', 'Heitkamp GmbH' (construction companies), the 'Amt für Arbeitsschutz' (Occupational Health and Safety Authority), the 'TBG' (The Employer's Liability Insurance Association for Underground Works) and the 'Nordseetaucher GmbH' (diving company).

A special team of nine divers was formed and prepared for the diving operations.

The tunnel boring machine was equipped with additional technology and a rescue system for the diving operations specially adapted to the machine. Claus Mayer working with 'Nordseetaucher GmbH' was senior manager in charge of this special operation.

Since the available decompression tables for works under hyperbaric conditions were insufficient, the works were partially based on the 'Druckluftverordnung für die Taucherarbeiten' (Regulations for Diving Operations in Compressed Air) and the French tables 'Air Oxy 12 M'.

For the diving operations, a special container with control and supply units was located on the tunnel boring machine, equipped with an individual air supply and communication system, independent from the Mixshield.

For the first time, a supply flange, specially adapted to the diving operations, was mounted on the bulkhead for:

- the supply of breathing and reserve air,
- the communication and lighting cables,
- the video and depth control units as well as
- the water and hydraulic connections for tools (impact drill, FLEX grinder and split-type drill rigs)

When accessing the excavation chamber for maintenance and repair works, the divers used specially adapted offshore diving helmets (Kerby Morgan 27), fitted with a water flushing system to prevent the breathing membranes of the air regulator from sticking together in the bentonite suspension.

The TBM is equipped with three man locks to pressurize the operating personnel and the divers, two man locks Ø2, 000 mm in the top section of the shield and one man lock in the center Ø1, 640 mm. The man locks consist of two independent chambers that are sequentially arranged (prechamber/main chamber). The prechamber serving all locks provides space for two persons, the main chamber (lock DN1600 mm) is designed for three persons and the main chambers (locks DN 2000 mm) for 5 persons each.

The prechambers are normally not be pressurized to allow additional personnel to access the main lock to assist with the evacuation of injured persons from the working chamber.

A door connects the main chamber to the working chamber in the cutting wheel. Each lock is equipped with a clock, a thermometer and the pressure gauges that display the pressures required for pressurizing and decompression. Each lock chamber can be pressurized or depressurized from the inside or the outside. A full-stroke safety valve limits the pressure to 5.5 bars.

Outside the man lock, additional pressure gauges are installed to display the air pressure measured in the pre- and the main chamber as well as in front of the bulkhead. A multi-band recorder registers the different pressures.

Optionally a transport chamber (with a Nato-connection flange) can be docked on to these locks during the works in compressed air to evacuate injured persons via the transport system (train) on the machine and out of the tunnel in an emergency. Above ground, the transport chamber can then be docked on to a recompression chamber where the necessary measures can be taken that are required for treatment. However, no emergencies occurred during the entire period of

Figure 4. Soft rock tunnel face – tool change at 3.5 bar at the 4th tube Elbe Tunnel (Hamburg, Germany).

the tunnelling works. The emergency chamber is part of the safety concept in order to safely evacuate injured persons from the pressurized zone to the surface.

During the tunnelling works on the site '4th Tunnel under the River Elbe' in Hamburg, a total of 10,920 hours were worked in compressed air, 6,603 of which in the pressure and excavation chamber. A total of 2,738 pressurizations of personnel were carried out, 237 pressurizations of which above 3.6 bars, 21 cases of decompression sickness occurred, all in a pressure range up to 3.6 bars.

Regarding the cutting tool change times, it needs to be mentioned that, approx. 13 hours were initially required for a cutting tool change under atmospheric conditions in the accessible spokes without particular complications. Since this time effort was considered too costly, several options were evaluated to reduce the working time. Through organizational improvements and modifications in terms of the existing cutter exchange design, the assembly time could be reduced from 13 to 6 hours.

With divers conventionally accessing the pressurized working area, approx. 8 cutter discs could be changed within about two hours compared with 2 to 3 hours required for a double disc cutter, depending on the type and volume of the muck to be cleared.

1.4 *Works in compressed air during the crossing of the river 'Weser' project in Mixshield mode*

In Dedesdorf, Germany, a Mixshield ø 11.67 m was deployed during the crossing of the river 'Weser'. Two parallel road tunnels, each with a length of approx. 1,635 m, were driven in very varying ground with heterogeneous formations.

The Wesertunnel is the first onshore traffic link north of Bremen crossing the river 'Weser'. Before, ferries connected the cities 'Nordenham-Blexen' and 'Bremerhaven', 'Kleinsiel' and 'Dedesdorf' as well as 'Brake and Sandsted'.

The shielded tunnel boring machine was designed for an operational pressure of 5.5 bars.

In this tunnelling mode, the support pressure is generated via an air cushion in the working chamber. The pressure communication between the chambers is carried out through the submerged wall opening. Even in case of clogging at the submerged wall opening, the pressure communication can still be maintained. This is achieved by additional compensation lines, connecting the invert area of the working chamber with the excavation chamber. The regulation of the air-cushion pressure is carried out through a redundant compressed-air regulator.

The 'Mixshield concept' allows for a pressure compensation from the atmospheric zone behind the bulkhead or from the working chamber, when the suspension level is lowered for accessing the excavation chamber.

Requirements such as low overburden and high water pressures, during projects with large TBM diameters, led to a situation where the suspension level can often be lowered by only one third in order to access the excavation chamber. In this case, it is mandatory to close the submerged gate valve. By closing the submerged wall gate valve, the principle of 'communicating pipes' is suspended. Additional units in form of pressure basins that are connected separately to the excavation chamber then serve as air cushion to support the tunnel face.

Maintenance and inspection works below the partially lowered bentonite level or at pressures higher than 3.6 bars were carried out by divers. The working chamber could be accessed via two double-chamber manlocks.

Regarding the diving operations, the following difficulties occurred during the compressed air works:

- tide-related pressure variation up to 0.4 bar per tide,
- compressed air works up to 4.5 bars for operations on the cutting wheel,
- compressed air works up to 5.0 bars for operations in the shield invert,
- use of divers up to 5.0 bars for operations in bentonite.

During the construction of the two 'Wesertunnel' tubes, the maximum admissible limit for compressed air works of 3.6 bars was exceeded at the deepest point due to compressed air operations at approx. 5 bars. Since the tunnel had to be driven 4 m below the planned tunnel alignment due to a modification of the operating program, the 'Druckluftverordnung für Arbeiten in Druckluft' (Health and Safety Regulations for Works in Compressed Air) and the H & S regulations 'VBG 39' (now 'BGV C 23') could, at times, no longer be observed. To be able to carry out compressed air works above the maximum admissible working pressure of 3.6 bars, a special authorization was required.

In cooperation with the responsible 'Occupational Health and Safety Authorities' 'TBG' and 'GAA-Oldenburg' as well as the 'Nordseetaucher GmbH' (diving company), a method was developed to comply with H & S regulations during compressed air works or diving operations at overpressure by the JV 'Wesertunnel' consisting of the companies 'HOCHTIEF AG', 'Philipp Holzmann AG', 'Ludwig Freytag GmbH & Co. KG', 'Heinrich Hecker GmbH & Co. KG' and 'Martin Oetken GmbH & Co. KG'.

During works at pressures of up to 5 bars, that had to be faced during this project, the ratio between the efficient working time at overpressure and the required decompression time has already now become uneconomical and borderline, e.g. reaching the physical limits of the personnel. Thus the involved parties ('Nordseetaucher GmbH', 'TBG' and 'GAA-Oldenbug', JV 'Wesertunnel', the hyperbaric doctor) issued the following framework regarding health and safety regulations for staff working at overpressure:

- common charts based on the 'Regulations for Works in Compressed Air' up to 3.6 bars and 'Air Oxy 12 M up to 5.0 bar'.
- in principle, depressurization with oxygen.
- an oxygen break of five minutes after a maximum of 30 minutes in compressed air.
- use of a 'hyperbaric assistant' as link between the personnel and the hyperbaric doctor.
- additional 'trial pressurizations' of the entire staff in the emergency chamber prior to the first operation above 3.6 bars.
- Reduction of the maximum working time at overpressure:
  - for the first exposure
  - after a longer working break
  - for extreme physical works.
- regular training of the tunnelling staff for operations at overpressure up to 5.0 bars.
- training of the doctors on call by the hyperbaric doctor.
- training and test of the personnel as to the appropriate conduct before, during and after pressurization/decompression.
- training of the lock attendant by the hyperbaric assistant and the hyperbaric doctor.
- regular assistance by the hyperbaric doctor of the compressed air works
- extension of the waiting time on site to 2 hours after an operation at an overpressure of more than 3.6 bars.
- a prophylactic 30-minute oxygen treatment at 0.9 bar in the emergency chamber for travel distances of more than 100 km after work.
- alarm system for the operating personnel, the doctors on call as well as the divers.

Figure 5. Special flanged connections installed at the bulkhead to allow manned interventions to be carried out in the bentonite.

Figure 6. Diving helmet for diving in bentonite.

This concept for Works in Compressed Air has been proven in practice and needs to be adapted to the information and conditions determined by the project requirements and the operation. Thus it is possible to safely access the working chamber at overpressure without exposing the 'compressed air personnel' to serious health hazards.

For diving in bentonite, special flange connections are installed at the bulkhead of the tunnel boring machine (figure 5), providing the divers and the personnel under hyperbaric conditions with breathing and reserve air, communication, lighting, video and data transmission as well as drinking water for the air regulators in the diving helmets.

The diving equipment consists of a diving helmet supplied through an 'umbilical'.

With pressures of up to 5 bars, the works were similar to offshore works. Thus a diving helmet (figure 6), comparable to those used during offshore diving, was specially adapted for the operations in bentonite. To make it easier for the divers to breathe in the bentonite suspension, the diving helmet was fitted with a water-flushing unit for the air regulator. The drinking

water prevents the breathing membranes from sticking together. The diving helmet is designed as hard hat that is connected with a diving suit. The air volume within the helmet and suit is constantly flushed with compressed air.

The 'umbilical' (figure 7) is the 'umbilical cord' for divers consisting of hoses and cables for the supply of air, emergency breathing air, drinking water, communication, lighting, video and data transmission.

For works in the working chamber, the diving equipment and the required tools are pressurized via a material lock in the working chamber. Following this, the operating personnel are pressurized. The latter consists of two divers, one 'signal person' and one assistant. Prior to the works, the excavation chamber is inspected for possible overhangs and cloggings at the cutting wheel for risk prevention. The maintenance and repair works then start and the cutting tools are inspected for potential faults or damage. If a cutting tool change becomes necessary the required equipment, tools and auxiliaries are mounted on the submerged wall and the cutting wheel and the worn or defective cutting tools are exchanged and depressurized. Figure 7 shows a diver during a maintenance and inspection operation below the partially lowered bentonite level. After completion of the works, the required tools and auxiliaries are disassembled and the connection door to the excavation chamber is closed. The divers return to the lock, where they are depressurized.

At pressures between 4 and 4.2 bars, a cutter disc was changed within approx. 2 to 3.5 hours. The change of 12 soft-ground cutting tools could be carried out within 2 hours, depending on the type and volume of the clogging.

1.5 *Excavation with saturation diving during the construction of the 'Westerscheldetunnel'*

The most demanding diving operations in tunnelling were carried out during the project 'Westerschelde' in the Netherlands. Here the experiences gained during the projects '4th Tunnel under the River Elbe' and 'Wesertunnel' could be used. While pressures up to 5 bars had to be mastered on the 'Elbtunnel' site and overpressures of up to 5.5 bars during the 'Wesertunnel' project, hyperbaric conditions of up to 8.5 bars were expected on the 'Westerscheldetunnel'. During works at an overpressure of up to 8.5 bar, compressed air can no longer be used, since the nitrogen contained in the breath causes narcosis with increasing depth. The nitrogen is replaced by helium. During the design phase, the use of mixed gases was already planned. Mixed gases consist of oxygen with different inert gases. Depending on the pressure ranges that had to be expected, operation times of several days and weeks (saturation method) are possible. To smoothly carry out saturation diving, the TBM technology and

Figure 7. Use of divers for maintenance and repair work in the working chamber.

logistics needed to be designed in compliance with the requirements for saturation diving and rescue technology, already in the planning phase. The required technology was successfully designed and implemented by the diving company 'Nordseetaucher GmbH'.

Saturation diving is a long-term stay at overpressure. All tissues are 100% saturated with inert gases, i.e. an increase of the diving time leads to a longer decompression phase. This technology makes diving operations at depths of more than 150 m more efficient, since the divers can stay pressurized (depending on the working depth) until the completion of the works.

To allow the divers during the project 'Westerscheldetunnel' a long-term stay under hyperbaric conditions, a chamber system was planned, consisting of two pressurized living chambers outside the tunnel. This chamber system, containing all the necessary facilities such as berths, showers and toilets, can take on a maximum 12 divers and technicians.

Since it was not possible to install the saturation unit in the tunnel and to dock it on to the tunnel boring machine, a mobile transport system (shuttle) was manufactured. The shuttle can transport up to 4 divers under hyperbaric conditions. The shuttle collects the divers at the living chambers outside the tunnel (figure 8, right) prior to their diving operations. It transports the divers into the tunnel and docks on to the left manlock (DN 2000), in direction of advance (figure 9). This lock is equipped with a 'NATO' flange which allows the transport shuttle to dock on and also provides access to the working chamber.

In contrast to the 'Elbtunnel and Wesertunnel' projects, it was impossible to work at pressures of more than 4.5 bars with compressed air. Mixed gases were used instead, consisting of helium, nitrogen and oxygen. The special gas mixes reduce the absorption of the dangerous nitrogen in the blood. The oxygen content of these gas mixes is higher and its nitrogen content lower compared with normal breathing air.

Figure 8. Transport shuttle.

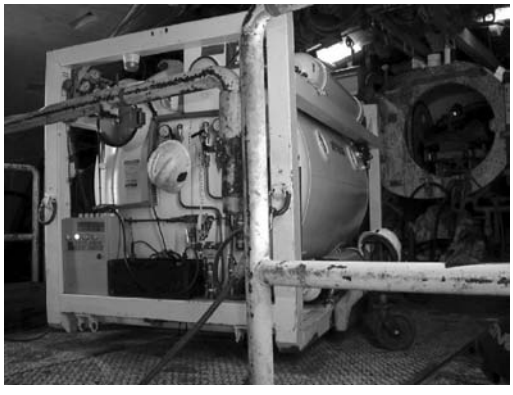

Figure 9. Transport shuttle before docking on the manlock.

The diving equipment is similar to the equipment that has already been successfully used during other tunnelling projects. For the works in the partially lowered conditions under the river 'Westerschelde', lightweight diving helmets used in the chemical industry were provided, specially adapted for this task. The special diving helmet is equipped with two air regulators and a controllable cooling system, since the temperature at the tunnel face can reach up to 60 degrees centigrade. All necessary tests prior to the works, were carried out at the Belgian Navy's Hyperbaric Center in Zeebrugge.

During the operation in the bentonite suspension, about 7 to 10 soft-ground cutting tools could be changed within 3 to 4 hours during one diving shift. The change of a double disc could be carried out in approx. 1.5 diving hours.

In total, five excursions in saturation were performed with a total saturation time of more than 40 days. The decompression time at working pressures

Figure 10. Special diving helmet (hyperbaric helmet) for application in hyperbaric conditions at 6.9 bars.

up to 6.9 bars was 4 days each time. In addition, six excursions were performed with mixed gas and 1,652 hours with compressed air involving 546 transfers. Five cases of decompression sickness (DCS) occurred, all of which could be treated in the on-site emergency chamber.

2 CONCLUSION

The above stated projects are exemplary for diving operations and compressed air works under extremely complex conditions at high pressures. Due to their technical profile, the qualified professional divers are an integral part of the day-to-day operations on a mechanized excavation site. The divers are permanently exposed to dangerous pressurization and depressurization transfers during their work in order to provide a smooth excavation process. State-of-the-art equipment is deployed, in accordance with the latest technologies in construction and diving and in compliance with national as well as international health and safety requirements. Good qualifications of the divers and compressed air workers involved, the permanent training as well as the adaptation of the tunnel boring machines to new requirements, make it possible to carry out technically challenging projects with success.

The experiences, that we have gained up to now, show that new methods for compressed air works in tunnelling were found that pave the way for increasingly complex projects with growing requirements in terms of TBM and diving technology. Only through a close cooperation between all parties involved in such a complex project, we will be able to continue a successful and innovative implementation of difficult projects.

Stormwater management and road tunnel (SMART)

Gusztáv Klados & Yeoh Hin Kok
MMC – Gamuda JV, Kuala Lumpur, Malaysia

David R. Parks & Derek T. Tavender
Mott MacDonald JV, Kuala Lumpur, Malaysia

ABSTRACT: Kuala Lumpur, the business and commercial hub of Malaysia has of late often been inundated by the floods from the Klang River as development has canalized the river. Over the years the intensity of the floods increased with each incidence, causing financial losses and inconvenience to the city folk. With cars submerged and traffic grinding to a standstill, the city was in urgent and immediate need for flood mitigation.

The SMART Project provides a stormwater diversion scheme including floodwater storage and a 10 km, 11.8 m diameter bypass tunnel, sufficient to save the city from flooding in the foreseeable future. With no major flood event most of the year the tunnel a dual use was engineered, with double road decks built into the central three kilometre section, relieving traffic congestion by providing 2×2 traffic lanes for cars connecting the city centre to the southern gateway, the KL – Seremban highway.

The flood water is diverted at the confluence of the Klang and Ampang rivers into a Holding Pond. From there the water passes through the tunnel into the Taman Desa Attenuation Pond and via a box culvert discharges into the Kerayong River.

The government accepted the innovative proposal of two Malaysian companies, MMC and GAMUDA, to reduce the cost of the scheme for the Government. The firms proposed to build the road tunnel section at a cost to be recovered by a toll collection Concession from the Government thus providing a dual purpose usage and offsetting the overall Government costs as a Concession.

1 MAIN PROJECT COMPONENTS

Besides the 9.7 km long, 11.8 m internal diameter stormwater tunnel the project also comprises of a number of other major structures associated with river diversion, intake to the tunnel, road structures and outfalls. The main project components are as follows:-

- River Klang Offtake Structure
- River Klang Diversion Weir
- Holding Pond
- Tunnel Inlet Structure
- 9.7 km, 11.8 m internal dia. bored Tunnel
- Emergency Escape Passages
- North Ingress/Egress Road Box ramps
- North Junction Box
- North Ventilation Shaft
- South Ventilation Shaft
- South Junction Box
- South Ingress/Egress Road Box ramps
- Tunnel Outlet Structure
- Attenuation Pond
- Twin Box Culvert
- River Kerayong Outfall Structure

The overall scheme provides storage for some 3,000,000 m^3 of water and allows water to be transferred through the system whilst utilizing the upper and lower road decks for traffic at the same time. Three operational modes are envisaged.

2 ORGANISATION OF THE SMART PROJECT

The project owner, the Government of Malaysia is represented by JPS the Public Works Department, DID the Drainage and Irrigation Department and by LLM, the Highway Authority.

The project design and supervision Consultants are Sepakat Setia Perunding (SSP) in association with Mott MacDonald of the UK.

The project promoter is the MMC – GAMUDA Joint Venture. MMC – GAMUDA Joint Venture also set up the Concession holder company for the road operation called Syarikat Mengurus Air Banjir & Terowong Sdn Bhd (or SMART Sdn Bhd). The EPC Contractor for the whole project is the MMC – GAMUDA Joint Venture.

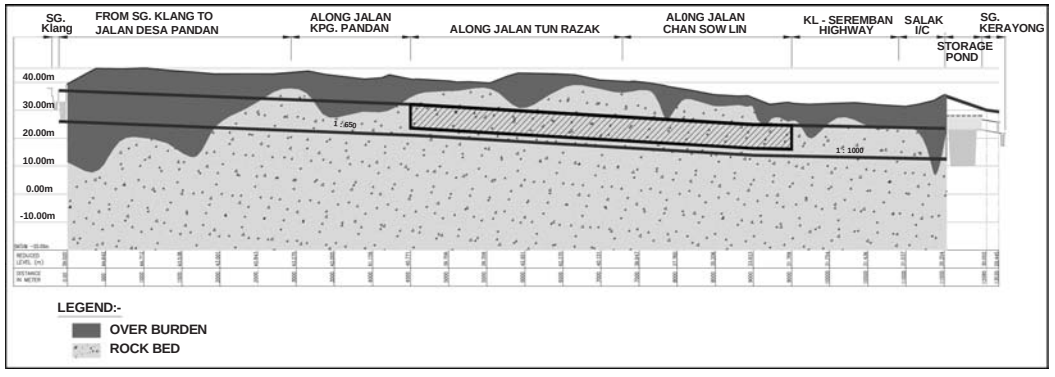

Figure 1. Sub surface conditions for the SMART tunnel.

3 GEOLOGICAL PROFILE

The tunnel traverses the Kuala Lumpur limestone formation at shallow depth (Figure 1). The mature karstic formation is covered by loose silty sand, peat or, at some places, mine tailings, the remnants of the extensive but now historic tin mining in the region.

The quaternary alluvial deposit is generally 4–5 m thick. However in karstic areas and at granitic dykes the unpredictable rockhead may suddenly drop 20–30 m due to eroded solution and cliff formations.

The groundwater table is 1.5–2.0 m below the surface. The permeability of the rock is generally low although groundwater movement through the soft alluvial overlay and karstic features can be extensive and lead to water drawdown hundreds of metres away from a disturbed area.

From north to south the tunnel runs in alluviums, or in mixed face conditions with frequently changing rockhead. The overburden is natural alluvium or mine tailings. The central section is predominantly in limestone with karstic features. The south section being with shallow rockhead, covered by soft alluvium or mine tailings. The last 200 m is in residual soils of the Kenny Hill Formation. Typically, the rock cover is around 3–7 m but in areas of depressed rockhead, a full face of soil or a mixed face of soil and rock were encountered.

The karst is very sensitive to groundwater drawdown. The reduction of groundwater level is known to activate existing sinkholes in karstic areas.

4 TUNNEL AND SHAFT CONSTRUCTION METHOD

Four major shafts were constructed to house ventilation structures and gate house structures for the central 3 km section of the tunnel which accommodates the double road deck. These shafts were at the quarter points along the road section at the North Junction Box, the North Ventilation Shaft, the South Ventilation Shaft and the South Junction Box.

On consideration of having the majority of the tunnel in karstic rock or mixed soil/rock face conditions and the paramount need to control groundwater it was considered appropriate to select slurry TBMs. Two identical Mixshields were purchased from Herrenknecht. The first TBM was delivered within 12 months and the second machine within 15 months of order. The cutterhead was designed for mixed face conditions. The double rotational head had to be able to effectively excavate medium rock and soft soil or mixed face conditions.

The shaft excavation experience has shown that ground treatment including grout curtains, prior to open excavation was essential in controlling ground water lowering which may trigger sinkholes some distance from the works. At the deeper karstic features bored piling with tie-back anchors was necessary to support the excavation. These areas were extensively ground treated to control ground water before excavation by drill and blast methods continued. Overall more than 600,000 m^3 of rock was successfully excavated by controlled blasting in a city environment for the four major shafts and for the egress-ingress ramps construction. The rock surface was secured by rockbolts and shotcrete where necessary.

5 TUNNEL LINING

The tunnel segmental lining consists of an 11.8 m internal diameter precast lining with 500 mm thick segments. The ring is in effect a universal taper of 110 mm, but the rings are used as left and right tapers to keep the keystone above the axis level for ease of erection. The ring is made up of 6 standard plates, 2 counter keys and a keystone. The rings are 1.7 m long and

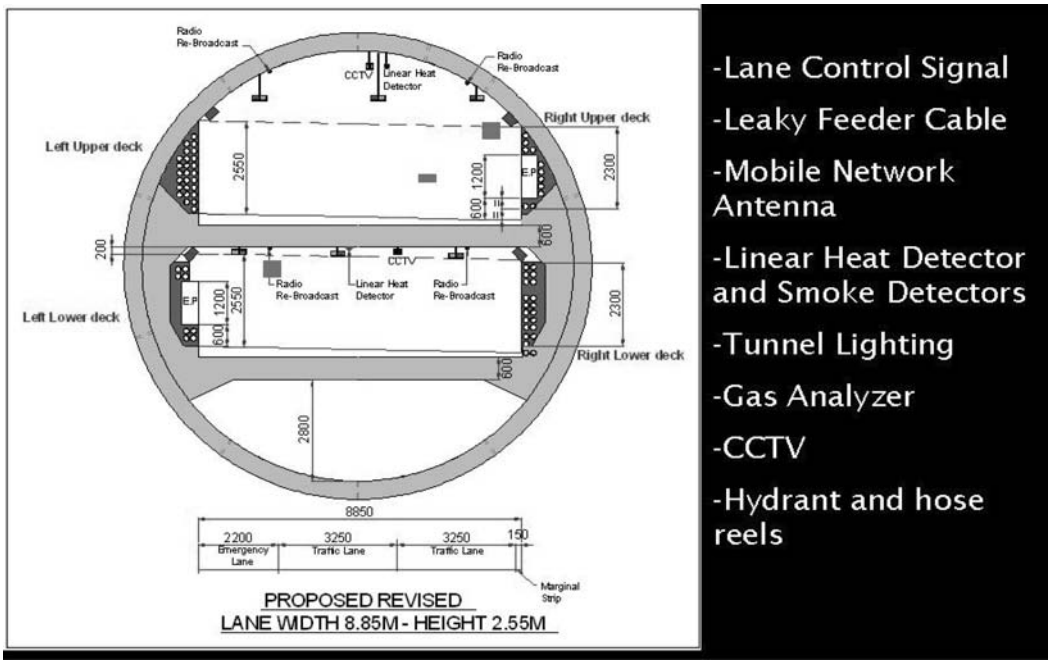

Figure 2. Road Deck Configuration in Tunnel with E&M equipment indicated.

weigh 82 tons each. The segments were produced by local subcontractors at two precast segment factories to the required high quality.

6 ROAD DECK

Within the central 3 km of tunnel the dual purpose facility of double deck roads is included between the North and South Junction Boxes, parallel to an existing notorious traffic bottleneck. These Junction Boxes provide the bifurcation arrangement where the stormwater and road systems merge together with provision of the road and flood gate systems which provide the control and safety of the operation of the scheme.

The road decks were constructed in two pours. Firstly the lower deck and secondly sidewalls and upper deck (Figure 2). The original design and anticipated construction method was modified to that using precast planks, 100 mm thick carrying the lower reinforcement cage, introduced, similar to the 'Omni' system used in bridge decks. To achieve programme the work progressed at the same time that TBM tunnelling continued while deck construction proceeded above the TBM service railway.

Provisions for hydrant, cables and openings to cross passages are provided within the secondary mass concrete placed inside the structural walls.

7 CROSS PASSAGES

Escape staircases are provided at a nominal 250 m spacing along the tunnel to facilitate passenger escape to a 'place of safety' in the event of an emergency. These comprise cross passages connecting the lower and upper road decks and at the ventilation shafts locations, escape staircases and fireman's lifts to grade. The cross-passages are not considered as a 'place of safety' in themselves but provide a passenger escape route to the non-incident road deck. These provisions together with fire detection, alarm and extinguishing equipment, smoke control by the tunnel, ventilation system designed to handle a 10 MW fire and an extensive Emergency Response Plan co-ordination with the Highway Authority and the Fire Brigade, ensures public safety.

Extensive grouting from the surface preceded the construction of the cross passages to prevent groundwater drawdown. Drill & blast method with shotcrete temporary support and spot rockbolting was used. Sprayed on water insulation membrane was followed by the shotcrete permanent lining.

8 M&E COMPONENTS

Integrated within the major structural components detailed above are significant mechanical and

electrical services. These facilities are similar to those incorporated in modern road tunnels but adapted and supplemented to allow for dual usage of the structure, as a road and water tunnel. The design challenge was to enable the road decks to be periodically flooded to facilitate full use of the cross section for flood relief of Kuala Lumpur.

The main mechanical and electrical components comprise:

- HV/LV electrical supply and distribution systems
- Tunnel lighting
- Fire alarm, detection and extinguishing facilities
- Communication and control systems
- Building services for the ancillary structures and buildings
- Tunnel Ventilation
- Pumping
- Flood detection system
- Flood gates, watertight doors and transits

9 HV/LV ELECTRICAL SUPPLY AND DISTRIBUTION SYSTEM

2 No. 33 kV independent incoming supplies are available to supply the SMART project from the TNB grid. Each of the 2 No. 33/11 kV transformers feed one side of a ring mains such that should one source/side of the ring fail, supply can be reinstated via the other. From the load centres the supplies are again transformed and distributed at LV. The essential and very essential loads are backed-up by LV gensets and the very essential loads like the emergency lighting are also backed-up by UPS.

10 TUNNEL LIGHTING

The tunnel lighting is designed to CIE 88:2004 2nd Edition. The ingress/egress tunnels contain the threshold, transition and exit zones boost lighting with the luminiares IP65 rated. The bored tunnel section basically encompasses the interior zone lighting and as this section is flooded all the luminaries are rated at IP 68++ designed and tested to maintain their integrity and withstand a hydrostatic pressure of 2.5 bar with a hydrodynamic force equivalent to a flow of 5 m/s for 24 hours. The IP 68++ luminiare is designed around a 70 W ceramic metal halide lamp. Cable glands were specially designed integral with the body of the luminaire.

11 FIRE ALARM, DETECTION AND EXTINGUISHING FACILITIES

A comprehensive system has been installed throughout the project that is independent of but linked to, the SCADA system and comprises alarm system, detectors, hydrants, hose reels, portable extinguishers and fixed gas extinguishing systems. Within the tunnel an emergency panel is located every 90 m containing a hydrant, hose reel and dry powder portable extinguishes. The cross passages also have a hose reel at each level. There is a fibre optic type, zoned linear heat detector installed throughout the tunnel monitoring temperature and rate of temperature rise with smoke detectors, break-glass points and emergency telephones in the cross passages. All data is fed back via intermediate fire alarm panels to the manned Motorway Control Centre.

12 COMMUNICATION & CONTROL SYSTEMS

The main components comprise:-

- SCADA System for the Tunnel Control System
  The SCADA system incorporates redundancy throughout the whole design. The use of a single fibre provides an acceptable level of redundancy and capability due to the unique arrangement provided by the network supplier.
- Communications Network
  The main communications network is a ring structure using latest techniques from a well known system supplier.
- Radio System
  A leaky feeder is installed within the tunnel to provide for incident, emergency and maintenance communications.
- Closed Circuit Television (CCTV)
  CCTV coverage of the whole tunnel is provided with cameras spaced at every 55 m. Coverage of the cross-passages and escape stairways is also provided.
- Public Address/Telephone System
  A pubic address system is installed in the cross-passages and the escape stairs.
- Access Control and Intruder Detection
  Proximity card readers will be used for access to all controlled areas.
- Variable Message Signs and Lane Control Signs
  Variable message signs are provided at the tunnel approaches to advise and control traffic with lane control signals over the 2 No. traffic lanes spaced between 90 and 135 m according to the curvature of the tunnel.
- Automatic Incident Detection (AID)
  Road tunnel Automatic Incident Detection based on the use of video detection units from fixed camera along the length of the tunnels.
- Video Wall
  The Video Wall is a very comprehensive system being provided by a well known supplier and is installed in the MMC.

- TMCS and FDS Interface
  The Tunnel Management Control System and the Flood Control System are two separate systems. When the FDS notifies the Controller that a flood is imminent, the Controller will check the status and notify the Tunnel Operator accordingly using a secure communication mode.

13 BUILDING SERVICES FOR THE ANCILLARY STRUCTURES AND BUILDINGS

Comprise small lighting and power, ventilation and air conditioning and water supplies and drainage in the ventilation buildings, cross-passages, Motorway Control Centre, Toll Supervision Building, Maintenance Workshop, Stormwater Control Centre and other ancillary buildings.

14 TUNNEL VENTILATION

There are four ventilation shafts covering the bored section each containing axial fans supplying and extracting air. The supply fans deliver air to Saccardo nozzles located in the walls of the lower deck and the roof of the upper deck with adjacent extract ducts. During normal operations, tunnel ventilation is by the piston effect of the vehicles only. During congested operations ventilation is by half the operational axial fans and the ingress/egress jet fans, activated as necessary by air quality monitoring units installed throughout the tunnel. For incident operations, smoke control is provided by the manual operation of all fans serving the incident deck, in response to input from the linear heat detector, CCTV, comms., etc.

15 PUMPING

Sumps and pumps are provided for road tunnel drainage during normal operations.

Following flooding of the tunnel the water will be gravity drained as far as possible and then the tunnel gates will be lowered and a considerable amount of residual water in the flooded road tunnel will have to be pumped into the water tunnel and then, to maintain the reservoir, from the stormwater tunnel into the attenuation pond.

The pumps at the tunnel outfall are designed to be able to drain the water tunnel within 21 hours.

16 TUNNEL OPERATION MODES

The tunnel can operate in three modes: with the whole tunnel dry (Mode I); with the tunnel upstream and downstream of the highway section flooded, and with water flowing beneath the invert of the lower deck, but with the road decks open for traffic (Mode II); and with the highway decks closed to cars and open to water flow (Mode III) (see Figure 3).

During a flood event (Modes II or III), flood flows are diverted from the Sg. Klang into the SMART system to store the flood water before returning it to the Sg Kerayong when conditions in that river allow.

17 FLOOD DETECTION SYSTEM

At the side of the Sg, Klang within the Holding Pond area is the Stormwater Control Centre which monitors information provided by the Flood Detection System (FDS). This is an early warning system utilizing river level and rainfall information from 28 gauging stations in the Sg. Klang and other catchment areas. If the event is significant enough the Motorway Controller is instructed to close the road and a shutdown sequence is initiated.

18 ROAD AND FLOOD GATES

The Junction Boxes are configured to allow bifurcation between the tunnel road facility and stormwater. Within the stormwater section of the junction box sits the Gate House which houses the service gates separating the road, and thus public, from stormwater section where water will be flowing a number of times per year without the need to close the road section. The service gates which seal each road deck at either end of the tunnel are backed up by an emergency gate.

In the other leg of the junction boxes sits the road gate housing which is built into the road slab. This houses the road gates which rise up radially and seal the ingress/egress ramps from flooding when the tunnel is used for stormwater control.

19 PROGRESS ACHIEVED

The first 0.7 km section of the 5.2 km long North Tunnel drive from the North Ventilation Shaft to the North Junction Box holed through in December 2004. The TBM was relaunched on the 4.5 km long second drive towards the Holding Pond to the north in March 2005. Completion is anticipated in March 2007.

The TBM of the South Tunnel was launched in August 2004, having passed through two shafts, the final breakthrough of the 4 km long drive was in April 2006.

The entire dual use tunnel section including the nine Cross Passages has been completed, including the road decks. The shaft building structures have been completed. M&E installation will be completed in January 2007. Ingress/Egress works are substantially complete

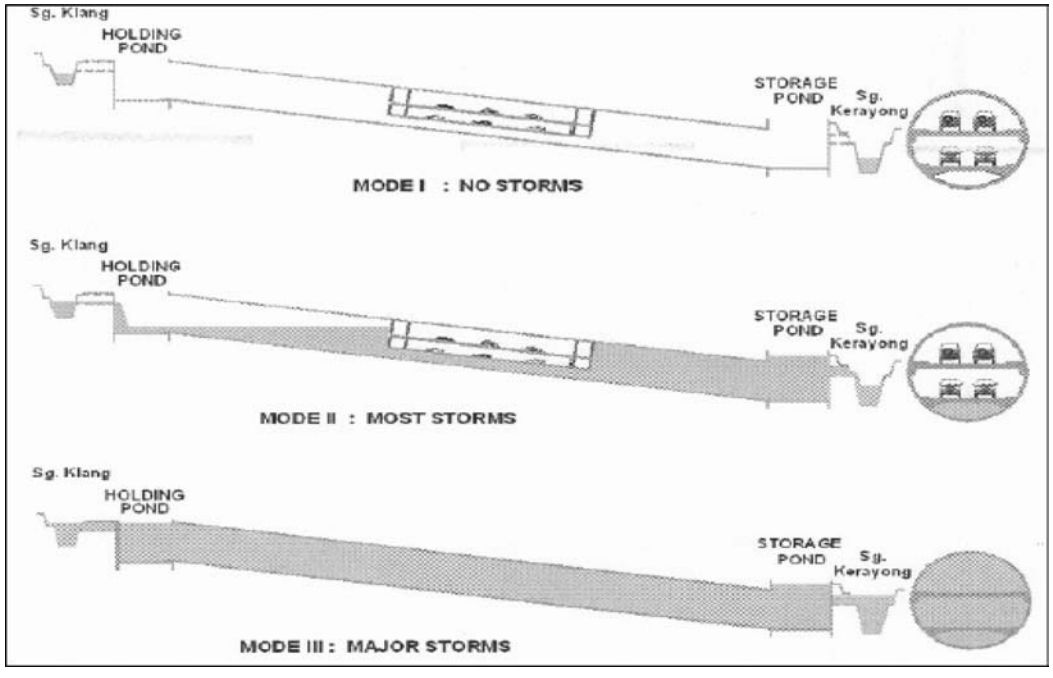

Figure 3. Tunnel operation modes.

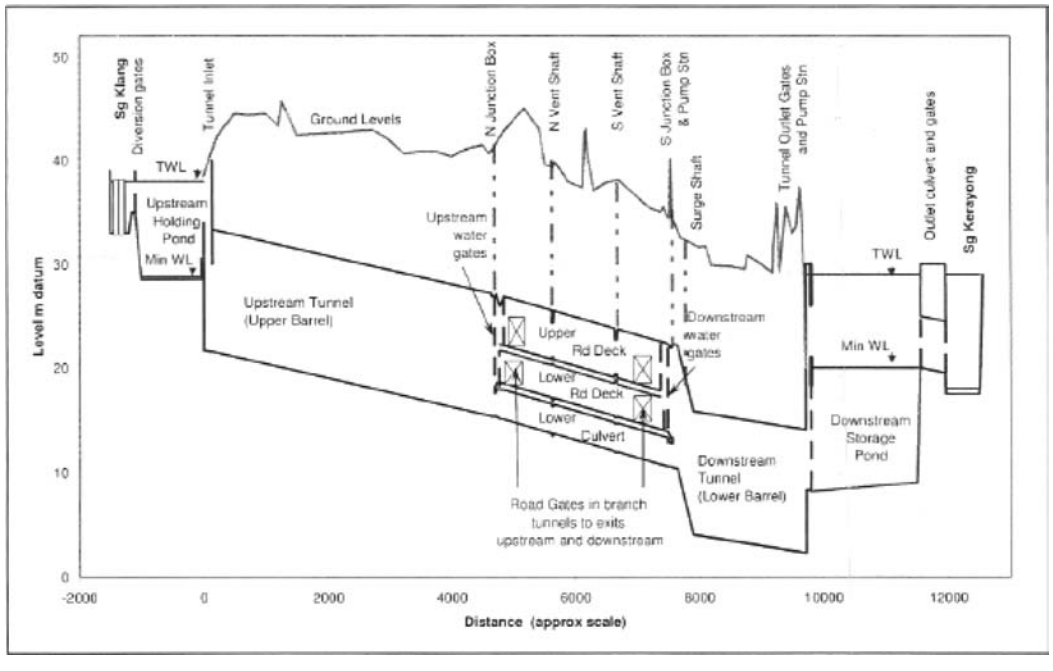

Figure 4. Longitudinal section of SMART system.

with Toll Plaza, Toll Supervision Building, Motorway Control Centre, Maintenance Depot completed.

Overall SMART project progress is on schedule at 92% as of November 2006. The full Stormwater Management facility will be open in July 2007.

20 SUMMARY/CONCLUSION

The Stormwater Management and Road Tunnel scheme is unique but has demonstrated that with some innovative thinking dual usage of major infrastructure works are feasible from an engineering perspective. The submersible road facility is a first of its kind and needed a new level of engineering for the fixtures and fittings within it.

Despite concerns about the variable nature of the karstic limestone in Kuala Lumpur before embarking on the project the choice of TBM type has been vindicated and the project has shown that tunnelling in this type of ground is possible, although considerable care is needed to maintain optimum TBM parameters and slurry properties.

Large scale shaft excavations have also been achieved with minimal settlement using carefully designed ground treatment strategically located to control groundwater in geological features and avoid sinkholes, a common event in this type of ground.

Wienerwaldtunnel – a challenging tunneling project

Hans Köhler
Porr Tunnelbau GmbH, Vienna, Austria

ABSTRACT: Work is under way on the Wienerwald Tunnel contract, which is part of the new railway route between Vienna and St. Pölten, currently Austria's largest tunnel project. By 20012, this new rail link will reduce travel time between Vienna and St. Pölten from 40 to 25 minutes. The technical challenges of the project include conventional tunneling in large cross sections on a length of 2,35 km, as well as the use of two tunnel boring machines with a diameter of 10,68 m on a length of 10,7 km each. Challenging geological conditions call for experienced tunneling crews and immediate reaction to actual conditions. On site segment casting and hauling of large material quantities over major distances need sophisticated logistics.

1 THE PROJECT

The Wienerwald Tunnel, approximately 13,35 km long, will form an important part of the Vienna to St. Pölten high-capacity rail link in eastern Austria and, passing under the Vienna Woods, will connect the Lainz Tunnel at the western border of the city of Vienna with the Tullnerfeld plain in Lower Austria.

The client of this important infrastructural project, ÖBB-Infrastruktur Bau AG awarded the contract to ARGE Wienerwaldtunnel, a joint venture sponsored by Porr Tunnelbau GmbH, in July 2004.

The Wienerwald Tunnel route passes mainly through Molasse and Flysch formations.

The contract sum is app. 340 million Euros at 2004 prices. The contract period is from July 2004 to August 2009, the project is scheduled to be put into service in 20012.

The project (figure 1) is composed of four different sections, each of which presents a number of technical challenges:

- Section "East", 2,35 km long, driven by conventional tunneling.
- Section "West", with two tubes, 10,7 km each, driven by two tunnel boring machines.
- Taglesberg landfill and mucking gallery.
- A 10,5 km long above ground section west of the tunnel, involving earth- and concrete works.

The paper concentrates on the main tunnel works in section east and west.

2 SECTION "EAST"

The East Drive starts underground from its eastern end, in the Hadersdorf-Weidlingau shunting hall.

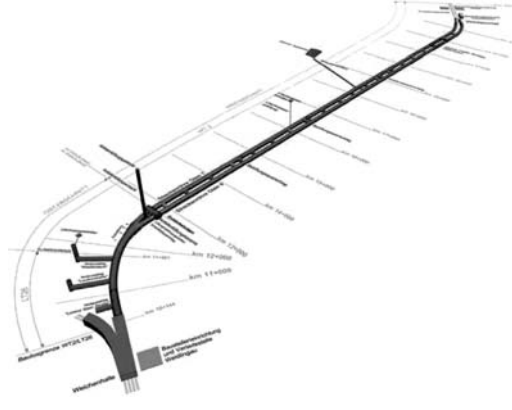

Figure 1. Project overview.

A length of some 2,35 km is being driven by conventional excavator and drill&blast tunneling, passing through the changing flysch sequences of the Vienna Woods, thus resulting in frequent changes of rock support classes.

The drive starts with a cross section of app. 120 m^2 for the twin track tunnel, is then enlarged to a maximum of 250 m^2 in several steps and continues in two single track tubes to the emergency ventilation chamber, where the east drive ends. This chamber will as well be the disassembly chamber for the two TBM's of the west drives.

The East Drive includes several special features, which are "firsts" at least for Austria.

- The site installations are, except offices, completely situated underground (figure 2) to avoid causing nuisance to residents in the densely populated area.

Figure 2. Underground site installations.

Figure 3. Top heading and bench.

- The wet mix for the shotcrete is produced according to the so called mixed-in-car system. Aggregates, cement, plasticizer, water and retarder are loaded into the drum of the remixers by a fully automatic filling station, the mixing is done in the remixer drum while driving into the tunnel. The availability of shotcrete in the tunnel at any time on short notice is essential for this drive with shallow overburden and buildings above the tunnel.
- The entire muck of the tunnel is removed by train, the train loading station is located underground and presently two mucking trains are loaded with 800 tonnes of excavated material each per day.
- The top heading as well as bench- and invert drifts proceed simultaneously at a distance of 80 to 130 m, by use of the "island" system, which means there is no connection to the top heading by a ramp (figure 3). All material supply to the top heading is to be reloaded at the bench, all top heading equipment stays up there for the whole drive and has to be serviced and repaired there.

The secondary lining will be installed after completion of the tunnel driving operations and will be made of a special fire resistant concrete. The part beneath existing buildings will be equipped with a reinforced inner lining combined with a heavy mass- and spring system in the invert.

3 SECTION "WEST"

The Section "West" is a twin tube tunnel with 10,75 km in length and an excavation diameter of 10,68 m. The drives proceed slightly uphill with a gradient of 2,8 ‰, a 2000 m long molasse section is followed by varying formations of flysch.

The tubes are driven by two single shield tunnel boring machines, rock support is provided by reinforced concrete segments, which are erected under protection of the tail shield. All necessary equipment, invert erection and logistics for the drives are provided on the 240 m long back up trains. Material to the machines is provided by rail bound equipment, muck transport is handled by continuous conveyors.

The two single track tunnels are connected by 23 cross cuts at an average distance of 500 m. These connection galleries are constructed behind the main drives by drill and blast method.

3.1 *Site installations*

The site installations are located app. 700 m west of the tunnel portals. The main parts are the segment factory, concrete mixing plant, filling station for mortar, cement and pea gravel, workshops, storage facilities, muck handling and intermediate storage as well as offices.

The segments are produced in a field factory. One segment ring is 2,25 m long, 35 cm thick, and consists of 5 large segments and one small key stone which is always situated in the invert. The segment reinforcement is a welded steel cage, which is completed in the field factory. After pouring, the segments are left to set in the heating tunnel for 6 hours. Following a 24-hour intermediate storage within the factory hall, the segments are stored in the open. The rail bound segment cars are loaded by two gantry cranes which are covering the entire open-air storage area.

The batching plant is during tunnel excavation needed mainly for filling concrete for the invert, the full capacity will be required later on for the inner lining of the tunnel.

The logistics for material supply to the TBM's is set up to transport all material for two segment rings on one train and a cycle time of two hours, therefore an automatic filling station for pea gravel, sand and cement has been installed.

The intermediate muck storage is capable to store 38000 m^3 of muck from each tunnel and to separate different quality of material to be used for different

Figure 4. Site installations at the west portal.

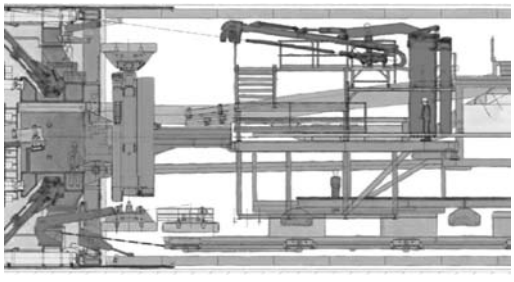

Figure 5. TBM and back up.

purposes on the above ground section of the new railroad line.

3.2 *The tunnel boring machines*

The two tunnel boring machines and their back up trains have been newly built by Herrenknecht for this project to fulfill the specific demands for these particular drives.

The single shield machines are equipped with a closed hard rock cutter head with 64 disc cutters. The cutter head has an electrical drive with 14 motors with 350 kW each, the cutter head speed from 0 to 5 rpm is controlled by frequency converters.

In the shield, just behind the cutter head there are two feeds mounted, capable to bore in an angle of 45 degree upwards for bolting or grouting, behind the shield there is one more feed installed with which exploration holes or grouting holes in an angle of 8 degree off the tunnel axes can be bored to a maximum depth of up to 80 m.

The segment erector is designed to set up one complete ring in app. 15 minutes. The segments for one complete ring are stored in the segment feeder behind the TBM in the invert of the front part of the back up, from where they are picked up by the erector and installed in the tail shield. Simultaneously to boring operation the annular gap is filled with mortar through

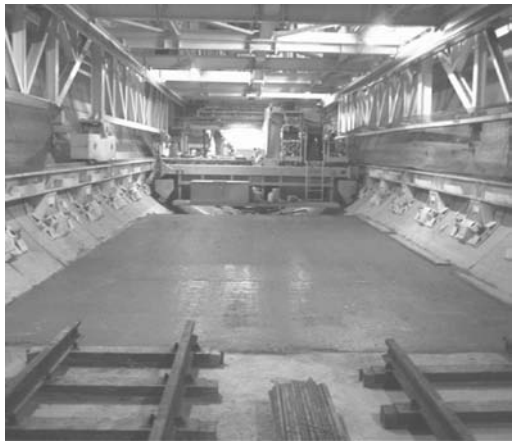

Figure 6. Invert concrete in the back up.

channels in the tail shield in the invert (app. 120°), the upper part is filled with pea gravel through openings in the segments.

Technical data of the tunnel boring machines:

Length of shield:	10,40 m
Total length incl. back up:	248 m
Total weight:	1750 to
Excavation diameter:	10,68 m
Cutter head power:	4900 kW
Cutter head speed:	0–5 rpm
Torque:	29532 kNm
Installed thrust:	156260 kN
Total installed power:	8400 kVA
Number of cutters:	64 pcs
Size of cutters:	17 inch

The capacity of the back up train is designed for a complete cycle time of one hour.

In the front part of the back up all necessary electrical and hydraulic equipment and components which are needed to operate the TBM are placed. Furthermore there are the silos for pea gravel, sand and cement storage, as well as mortar batching plant, mortar pumps and shotcrete pumps for filling the annular gap with pea gravel.

Behind these decks there is the invert concrete installation area which is designed to pour the invert of one daily production within the four hours maintenance shift with the aid of a concrete finisher which is installed in the back up.

In the rear part of the back up there is the train unloading station. The supply train is parked there and a fully automatic crane transports the segments and other material to the point of destination in the front part of the back up.

At the rear end of the back up, ventilation tube magazine, high voltage cable reel and installation area for the structure of the continuous conveyor are placed.

Figure 7. Train unloading station.

3.3 *Assembly of tunnel boring machines*

The two machines have been completely installed at the west portal before they have been moved into the 20 m long starting chamber, which had been constructed by conventional means before.

Since there was space enough available we took advantage of the possibility to start with completely ready units without the necessity to interrupt tunneling operations for additional assembly stages.

The biggest parts to be handled had a weight of 280 to, accordingly heavy cranes were needed.

For start of boring the thrust cylinders of the TBM pushed against a steel ring which transferred the forces into the rock via 16 heavy pretensioned rock bolts.

The second TBM was erected 3 months after the first one. So the same assembly crews could work on both machines. To have a certain distance is required by the project for geotechnical reasons and the advantage for the contractor is, that experience from start of the first unit can be utilized for the second start.

3.4 *Tunneling and cross cuts*

Tunneling works are done in two shifts 10 hours each per day and a 4 hours maintenance shift, seven days per week.

Both tunnels are equipped with a double track rail system in order to secure continuous supply to the tunnel boring machines and to construct the cross cuts parallel to boring operations.

A total number of 23 connection galleries between the two tunnels have to be constructed, most of them parallel to boring the main drives due to the fairly short overall construction period.

There are works for at least four cross cuts simultaneously in operation. First the segments of the main tunnels are secured by bolting them into the rock and the rings are connected to each other to transfer the forces from the opening to the neighbor rings before cutting the opening with diamond saws. The second stage is excavation works by drill and blast, and then the invert concrete is installed. The final stage is the inner lining of the connection gallery.

The supply to all four worksites of the connection galleries has to be arranged so that the supply to the tunnel boring machines is not interrupted.

Figure 8. Mounting of the cutter head.

Figure 9. TBM assembly at the west portal.

Figure 10. Mucking installation connection gallery.

4 CONCLUSION

The tunneling works, currently in full swing both at the east and the west drives present substantial logistical and technical challenges. The drives will meet in the emergency ventilation cavern towards the end of 2007.

At the time of the world tunnel congress app. 70% of the excavation should be completed, the presentation at the congress will include more details about performance and progress rates of excavation works.

End of 2007 the concrete works for the permanent lining are scheduled to start, to be completed by summer 2009.

The total high-capacity rail link project between Vienna and St. Pölten is scheduled to be put into service in 2012.

The construction of shield tunnel crossing right under Shinkansen station

Atsushi Kojima[1], Takashi Inoue[2], Atsushi Sano[3], Mitsuru Shimizu[4] &
Shiroh Suematsu[5]
[1,2,3]*East Japan Railway Company Tohoku Construction Office, Sendai, Japan*
[4,5] *East Japan Railway Company, Tokyo, Japan*

ABSTRACT: AKITA-CHUO road is a road only for the high standard car from the center part of Akita City to express highway interchange of AKITA-CHUO. Among these, extend about 178 meters sections of the part where the East Japan Railway company Akita Shinkansen line Akita Station premises right under are crossed is a part that East Japan Railway was received the consignment from Akita Prefecture and constructed with the shield method because it is necessary to cross the station building and 11 lines in the railroad line. In this paper, we describe the result of the obstacle paling removal by the JC&R method of construction, and the railroad line right under crossing of the shield machine.

1 INTRODUCTION

This construction was the one to cross the shield machine right under the railroad line after the obstacle things such as the foundation piles of Akita station building were removed and to construct the underpass tunnel as for the underpass where the Akita Station east to west was connected. Especially, the JC&R (Just Cut and Reduce) method of construction that was able to cut and remove the obstacle part foundation piles to the shield section by operating on the ground was developed to achieve the construction time saving and cost reduction, and the station building obstacle pile removal was applied to the practice construction. Moreover, the pipe roofing was executed as the track guard method because it was large section shield tunnel in soft ground construction for the railroad line right under crossing of the shield machine, and construction was executed while quantitatively managing the influence on the railroad line. In this paper, we describe the result of the obstacle paling removal by the JC&R method of construction, and the railroad line right under crossing of the shield machine.

2 OBSTACLE THING REMOVAL CONSTRUCTION ACCORDING TO SHIELD TUNNEL CONSTRUCTION

The problem of this construction was to be going to exclude the factor that might become the trouble of construction surely by the time the shield machine reached because it constructed the shield tunnel by the shortest days.

The pile in this construction for the removal was four of the following.

CASE I : The cast in place RC pile. (The foundation pile of present station building)
CASE II : The cast in place RC pile. (The foundation pile of Akita Station escalator pit)
CASE III : The timber pile. (The foundation pile of Shinksen platform)
CASE IV : The hollow PC pile. (The foundation pile of old station building)

In this paper, we describe the case I (The cast in place pile. (The foundation pile of present station building)) that applied JC&R method of construction.

2.1 *JC&R method of construction*

The construction space is limited because there is an existing structure on the removed pile when the pile is removed, and in general, there is a lot of strict construction conditions, and the construction method is limited. The conventional method is Chicago method. This method were attended by many risks due to removal works by manpower excavation and manpower demolishing. Moreover, the soil improvement work for water stops is needed and a high cost generally. Another method is that pile of full length is pulled out after cutting the skin friction of the pile with steel casing. Where the overhead clearance is very small, the pile of full length cannot be pulled out. Thus it is necessary to cut the pile short enough for the clearance and connect

each short casings many time. This method required a long period of time.

Therefore, we have developed a new method, cutting a pile horizontally below the existing structure by operating wire sawing system on the ground and pulling up only the upper pile to the ground above the cutting depth. As for the application of this method, the length of the obstacle pile is long, and the range of the removal targets the case only in the top of the pile to cross section of shield tunnel.

The order of constructing JC&R method

1. The CD machine(the machine of overall casing method) inserts the casing to the removal pile. (In this case, the casing shaves off the removal pile to 1000 mm in diameter.
2. The cutting device of the JC&R method is descended. (photograph-1)
3. The removal pile is horizontally cut with Wire saw by the ground operation at the position.
4. Inserting steel bar for pulling up the pile and the power jack for the pile lifting up, and the pile in the ground part is cut and removed with wire saw.

The advantage of the JC&R method to the conventional method (Chicago method) is as follows so far.

Photograph 1. The cutting device of the JC&R method.

Photograph 2. The CD machine inserts the casing.

1. It is possible to cut it by the operation from the ground.
2. The soil improvement work for water stops is no necessity.

The advantage of the JC&R method to the conventional method (the casing as for the total length of the pile) is as follows so far.

1. The frequency of casing build and pull off casings pile decreases because building of the casing is by the cutting position.
2. The cutting removal frequency of pile decrease in the ground part.
3. To break off top of pile is unnecessary.

Safe and time saving construction became possible compared with the conventional method by JC&R method on the above mentioned reasons.

2.2 *Construction condition*

Objects of removal piles were foundation pile of station building. The removal pile received design load 275 t per pile. The bearing layer of foundation piles of station building were siltstone. This work took the isolation of 2.0 m from the bottom of the shield tunnel for the pile of eight obstacle of the existing pile that receive a present Akita station building, cuts in the ground. Then only the upper part is removed from the cutting plane. The underground cutting position is G.L.-30.8 m. The pile cutting length is 20.5 m. The plane and the cross section are shown in Figures-1 and 2.

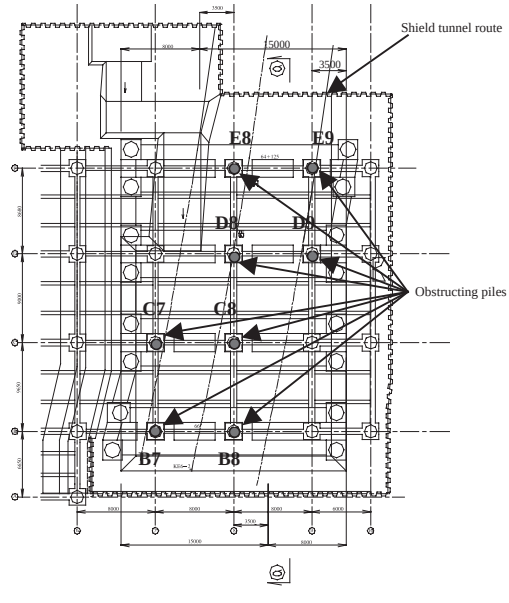

Figure 1. Ground Plan of AKITA station building.

The load of the station building that operated on eight existing piles was received with the beam and the pile of new built by the underpinning process. Before this work, the relation between the station building and the existing pile was cut. The construction environment was an underground plane space 19 m × 30 m, and the overhead clearance was 4.3 m above the excavation bottom. The existing pile removed by this work was the cast in place pile pf earth drill of 1000∼1300 mm in diameter. The construction accuracy of the amount of eccentricity and the shape of drilling, etc. was not able to be understood though parameters such as the lengths of the pile and the arrangement of bar were able to be understood beforehand.

2.3 *Problem and verification in construction*

2.3.1 *Casing built and shaving of existing pile*

The problem of this work shaved the existing paling without twisting off the pile, and built the casing. There was a possibility that reaming cutter cuts a main reinforcement of the pile when the pile has inclined, and the pile was twisted off when falling below the torque reading of CD machine that the endurance force on the twist of the pile was transmitted from the casing to the pile. Therefore, we managed to setting the upper bound value of the shaving torque to be 400 kN · m from the result of the examination construction, and so as not to cause a rapid torque rise.

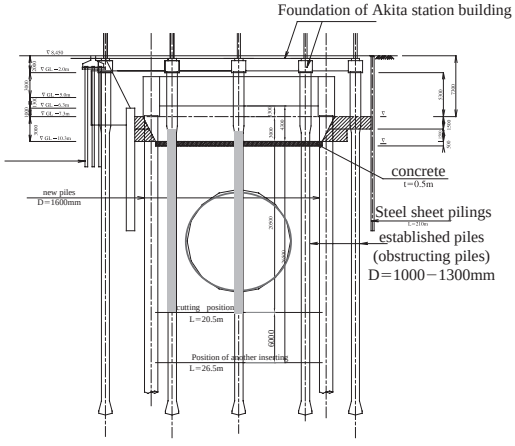

Figure 2. Section of AKITA station building.

The construction result at built of the casing is shown in Table-1. B-7 and B-8 were upper bound values 400 kN · m or less, cannot twist off the pile though were bad vertical accuracy, and were big compared with another the shaving torque, and built of the casing ended safely. The time that had been required to cut 1 m for the pile other than B-7, B-8, and D-8 became 130∼160 minute. Be able it to cut well, and it to be built though it took some time the much more before this construction than as a result of the full-scale shaving examination done beforehand (about 120 minutes).

2.3.2 *Cutting of pile and built of cutting device*

The problem of this work was to avoid an impossible cutting by the wire saw moving intensely. Therefore, when the full-scale cutting was examined, we arranged the pulley for the wire saw was prevented from intensely moving, and improved cutting device. Then we adopted an endless wire on a no edge without connection parts so that prevented the wire saw from breaking while cutting it.

The construction result when the pile was cut is shown in Table-2.

The cutting position was changed once in E-9 for cutting. This reason was because cutting became impossible on the way. The cutting plane had hoop ties, main reinforcements, and the reinforced ring when the removed pile was seen, and it tried just to cut the part in the top of the reinforced ring (photograph-3).

Table 1. The result of construction (The building the casing).

		The building the casing			
Pile no.	The order of constructing	The length of excavation (m)	The time of excavation (min)	Time a meter in excavating length (min)	The maximum cutting torque (kN · m)
B-7	1	23.5	5439	231	371
B-8	6	22.5	5827	259	371
C-7	7	24.5	3732	152	202
C-8	4	22.6	3313	147	202
D-8	5	22.5	6503	289	202
D-9	8	20.5	3320	162	202
E-8	2	24.5	3698	151	202
E-9	3	22.5	2942	131	168
Average		22.9	4347	190	

Table 2. The result of construction (The cutting pile).

Pile no.	The order of constructing	The cutting pile: The time of building the cutting device (min)	The cutting pile: The time of cutting (min)
B-7	1	285	45
B-8	6	550	31
C-7	7	330	35
C-8	4	225	39
D-8	5	290	75
D-9	8	400	41
E-8	2	250	51
E-9	3	240	45
Average		321	45

Photograph 3. Cutting plane of pile.

Therefore, we guessed that the wire saw was not able to cut the pile because it tried to run away to the weakness or more and the side that the reinforced ring was no and the cutting plane lost planarity on the way. Then, about 200 mm was cut again in the lower side.

Cutting when the cutting position was changed ended without trouble. A steady cutting was able to be done about other pile both building the cutting device and cutting in the ground. Wire speed was low, about 4∼5 m/sec, and we could not confirm the moving of wire intensely. It took about 45 minute on the average to cut the pile.

3 RAILROAD LINE RIGHT UNDER CROSSING OF SHIELD MACHINE

Right under the railroad line, besides, the construction results of the large section shield with the soft ground are little. This large section shield tunnel was rare construction also in Japan. The shield machine adopted the closed type shield machine of slurry from the construction of the soft ground. We adopted inside concrete placing type ductile segment from the necessity for supporting the train load. (12.2 m in diameter, 1200 mm in width, and beam height 400 mm, when inside concrete is included, it is 500 mm.)

Photograph 4. The shield machine.

The earth covering in the range of our construction was about 13.0 m. The sandy clay of soft alluvial deposit and the cohesive soil were distributed in the alternation of strata, and the cohesive soil formed the soft ground of the subject, and the surface layer was the humus, and the groundwater level was high with about G.L.-2.0 m. Moreover, the bedrock layer decreased rapidly from the vicinity of west area of Akita station, and was a drowned valley of about 40 m in depth.

3.1 *Technical feature*

3.1.1 *Track guard method*

As for this construction, for the soft ground and the large section shield, the generation of the track displacement because of loosening of the forward ground of proceeding to excavate the shield was feared.

Therefore, the result of comparing the chemical grouting method, the pipe roofing method, and the high-pressure jet stir mixing method as the track guard method, we adopted the pipe roofing that indicated the value with the smallest amount of the track displacement We placed the pipe roof to be gate type arrangement by 1.2 m in diameter and 70.5 m in length. (Figure-3) We adopted the excavator of closed type that the chemical grouting method used an unnecessary so that construction might prevent groundwater from flowing in the pipe roof that became the factor of the track displacement (photograph-5). As for the yard that constructed the attainment shaft, securing the yard was difficult because it was adjacent to the station building, and overlapped with construction yard of the underpinning of the station building. Therefore, we adopted that the excavator was pulled to the start shaft after construction, and the excavator of the return type that was able to be collected. The water stop of 3 m in total thickness and protective layer was formed by the soil improvement, and about the face stop of the pipe roof in the attainment part, the pipe roof was intrusive and fixed to this part. The pipe roofing was aiming at another of the track defense and the investigation of the obstacle of underground laying thing moreover, the obstacle thing did not exist from among this when there was an obstacle thing by any chance though it was scheduled to remove it.

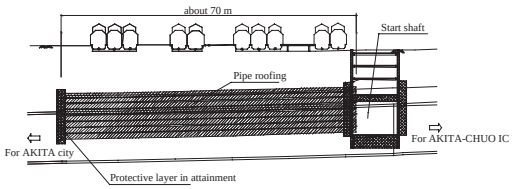

Figure 3. Longitudinal section of the pipe roofing.

Photograph 5. Track guard method.

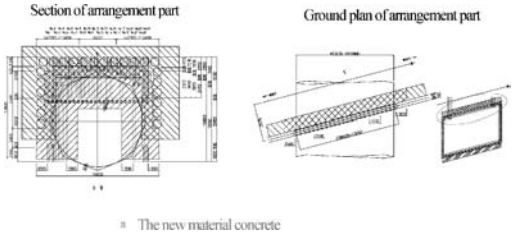

Figure 4. Arrangement part of the new material concrete.

3.1.2 *The new material concrete (improvement type of the NOMST material) is adopted for the pipe roof start shaft of earth retaining structure*

In this construction, we adopted the new material concrete that the coarse aggregate was the lime aggregate that can be cut with cutter of shield, and the reinforcement was high strength and the big carbon fiber reinforced plastic of the modulus elasticity, so that the pipe roofing start shaft of earth retaining structure of soldier piles were obstacle to the shield proceeding to excavate. This new material concrete was the NOMST method. (NOMST : Novel Material Shield cuttable Tunnel-wall System) (Figure-4) In a past construction case, it transmitted of soldier piles (H steel) set up in the NOMST section by shield passing over the NOMST section, and the vibration in the ground level was confirmed. Therefore, the vibration when the shield machine passed over the NOMST section was feared. This time, we adopted the new material concrete that was improvement type of past NOMST method. This type improved the shape of the grid reinforced that made from the carbon fiber reinforcement.

3.2 *Problem and verification in construction*

3.2.1 *Influence on track according to shield machine proceeding to excavate*

The problem of this work was to understand the influence on the track by proceeding to excavate the shield machine by the track measurement. We adopted the track measurement by the hand because there was no passing train in the station premise, and constructed the track guard of pipe roofing. As the management value, the maintenance standard value was adopted to be a limit value, and the 70% was adopted to be a construction discontinuance value. Moreover, to prevent the ground level from subsiding along with excavating, a simultaneous filling injection method was adopted for the shield machine to reduce the influence on the track as much as possible. The simultaneous filling injection method was a method of inject beginning at the same time as excavating beginning from the injection tube set up by the shield machine. Therefore, the possibility of loosening the ground while proceeding to excavate even if it was the ground that collapsed was high was small. In this construction, necessary filling quantity was calculated from the proceeding to excavate data of the shield machine automatically, and the injection material was injected from the hole in four places in the machine upper part at the same time as generating tail void.

The construction management of the filling injection executed it using the injection pressure management together with the injection quantity management. The target value of the injection pressure set the face slurry pressure from past construction results in the lower bound, and the upper bound value added face slurry pressure to 200 kPa. Moreover, the target value of the quantity of the injection was adopted to be 100～150% of the quantity of the calculation void.

The relation between the track displacement and the top position of the shield machine in the vicinity of the section of the crossing under the railway track beginning position is shown in Figure-5. The amount of the maximum track subsidence on the shield center became 3 mm. This amount of the subsidence was a value that was smaller than 5.94 mm that was the amount of the assumption subsidence requested beforehand by two dimension FEM analysis. The change in the amount of the track subsidence on the shield center showed the subsidence tendency immediately after proceeding to excavate, and showed the tendency to the rise after passing the shield machine. When the distance from the measurement part to the top of shield machine exceeded about 30 m, the upside converged. Moreover, all were below the construction discontinuance value as for track measurement by the hand.

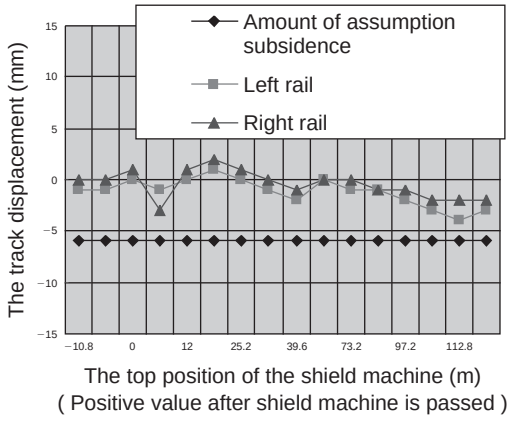

Figure 5. The relation between the track displacement and the top position of the shield machine in the vicinity of the section of the crossing under the railway track beginning position.

3.2.2 *Vibration and noise measurement when new material concrete was proceeded to excavate of shield machine*

We measured the vibration that generated cutting the new material concrete so that cutting the new material concrete that adopted the new NOMST material for the wick material with the shield machine of the prototype became the first construction this time.

The feature of this measurement management was a point to set the vibration acceleration level of the convertible acceleration to the management value. The purpose of this was to prevent the emergency's stopping of elevator (ELV) set up in the station premises. The vibrograph was set up in ELV set up at Akita Station, and when 10 gal (correspond the vibration acceleration level 80 dB) were measured, ELV was stopped. Therefore, when the vibration measurement member was arranged in the shinkansen platform, and the vibration acceleration level exceeded 75 dB, we adopted by lowering the proceeding to excavate speed. The plan proceeding to excavate speed was usually adopted 20 mm/min, but the plan proceeding to excavate speed of the new material concrete section was 2 mm/min.

The relation between the shield proceeding to excavate time above the new material concrete and the vibration acceleration level was shown in Figure-6. Proceeding to excavate the new material concrete section began proceeding to dig at first according to schedule of 2 mm per minute. The value of the vibrograph showed 30∼40 dB. This measurement value showed the tendency to the value similar to before it began to proceed to excavate. Moreover, before it began to proceed to excavate and after it began to proceed to excavate, the tendency to a similar value was shown about the noise meter set up in the Shinkansen

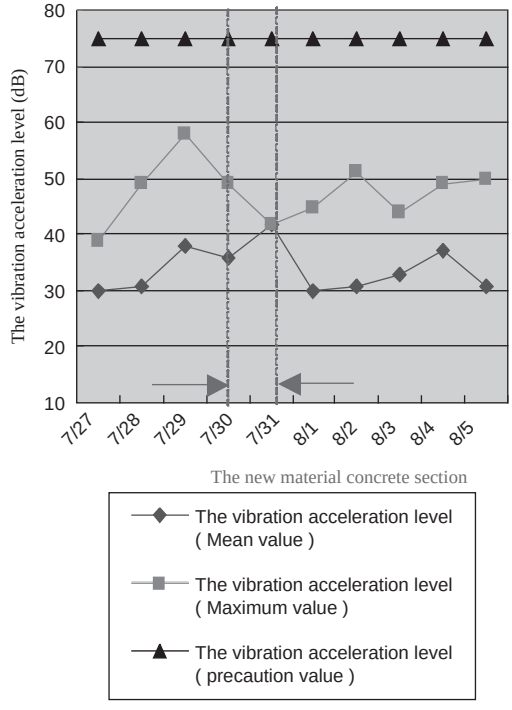

Figure 6. The relation between the shield proceeding to excavate time above the new material concrete and the vibration acceleration level.

platform. We managed the proceeding to excavate speed while confirming the value such as vibrograph by the result of the above-mentioned measurement, and the proceeding to excavate speed was executed up to 13 mm maximum per minute. The value of the vibrograph became 40∼55 dB along with proceeding to excavate. It became a result with room enough for 75 dB set as a precaution value. Moreover, the rounds were executed at Shinkansen platform, therefore there were no swing of the overhead wires, and the vibration that became unpleasant of the customer was not generated.

We considered the reason why the value of vibration in the NOMST section that compared with the case cut in the all sections of the cutter face was small so that the new material concrete was cut by part of cutter face because a new material concrete wall was diagonally arranged for the shield machine. The problem that the NOMST material blockaded the sludge pipe was assumed about cutting the NOMST material along with proceeding to excavate a new material concrete section. However, the result of excavating the new NOMST material (GRM), the NOMST material discharged from the low head screen was cut by the size of about 100 mm. (photograph-6) Therefore, the blockage of the sludge pipe that depended on the NOMST

Photograph 6. A piece of the reinforcement of the new material concrete.

Photograph 7. Tunnel interior of completion.

material was not caused. We considered that it was one of the factors to decrease the vibration and the noise that cutting improved like this.

4 SUMMARY

This construction was extremely rare construction that passed the large section shield in the section of the crossing under the railway track in the soft ground for an intense heat period after removing the various obstacle things to the shield section.

We stopped the minimum influence on the station building, and completed proceeding to excavate that not causing spurts of slurry neither the track subsidence nor the road subsidence.

Non-circular full face tunnel boring machines –21st century challenge

M. Krčík
Geotechnical Design Office, Bojnice, Slovak Republic

ABSTRACT: Rapid development of Full Face Tunnel Boring Machines admits using very large units, often more than 14 metres in diameter. However, only two thirds of those excessive cross-sections are utilised efficiently. Therefore, development of Tunnel Boring Machines is focused to excavating ideal cross-section works, similar to cross-section typical for the New Austrian Tunnelling Method (NATM). The mentioned development takes place mostly in countries such as Japan, Germany but also in Slovakia supported by private resources. Several concepts of these machines are introduced herein describing both their advantages and disadvantages.

1 INTRODUCTION

Tunnel boring machines in excess of 14 metres in diameter are commonplace. In Madrid there is a machine with a 15.2 m diameter. This is an EPB SHIELD manufactured by Herrenknecht. In Niagara Falls there is a machine with a 14.4 m diameter; this is HARD ROCK TBM, produced by the ROBINS Company. In Switzerland there is a machine with a 14.4 m diameter made by WIRTH, whilst in the Netherlands is a machine with a 14.87 m diameter from the French manufacturer NFM.

A disadvantage of such big tunnel boring machines for traffic tunnels, road, railway or subway tunnels with two or three lanes is that the excavation in the bottom part of the profile is not utilised and often filled with material again (see Fig. 1 and Fig. 2).

In different tunnels driven by means of tunnel boring machines the road pavement is supported by piers in the full length, similarly to the bridge deck (see Fig. 3 and Fig. 4).

Concepts of non-circular full face tunnel boring machines with the cross section aiming at the profile

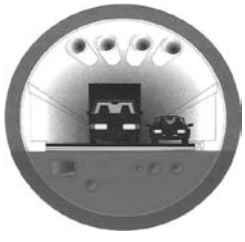

Figure 1. Cross section of 14,2 m diameter motor way TBM.

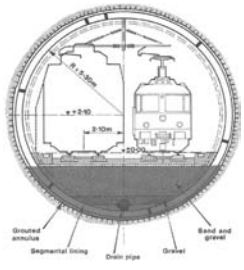

Figure 2. Cross section of 11,62 m diameter railway TBM.

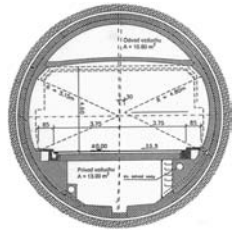

Figure 3. Cross section of 11,8 m diameter.

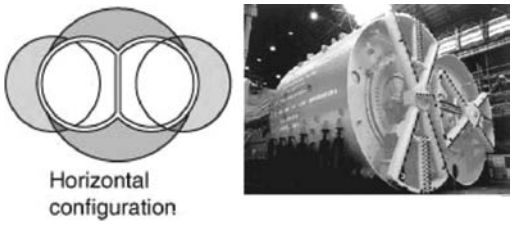

Figure 5. Cross section and DOT (Double-O-Tube) shield.

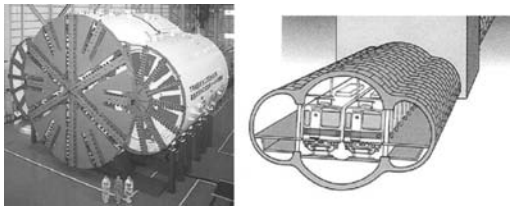

Figure 6. A horizontal triple-circular shield tunnelling machine excavated two railways and a platform.

used in the drill and blast method, and the NATM method, solve the above disadvantage.

2 MANUFACTURED AND SUCCESSFULLY USED NON-CIRCULAR TUNNEL MACHINES

The Japanese are well advanced with the concept of tunnel boring machines with non-circular profile.

Nevertheless, these are generally machines designed for soft sedimentary ground. It is probably due to the fact that all big industrial cities in Japan are situated along the Japanese shore, which is the typical location for this type of sedimentary rocks.

An advantage of DOT (Double-O-Tube) tunnel boring machines consisting of circular cross sections is that they cover less space than two tunnel tubes next to each other as to the width, but also less space as to the height, with low overburden, than one circular tunnel tube, especially in the rural built-up areas (see Fig. 5).

Their disadvantage is that the pillars must be supported in the place in which the circles are interconnected due to the static reasons.

It is similar with the multi-circular Shield machine, which was successfully used for subway stations. (see Fig. 6)

Various cross-sectional shapes (Fig. 7) is Shield machine with a circular disc cutter at the center of the face and multiple planetary cutters, as shown in Figure 8.

The orbit of planetary cutters can be changed freely by adjusting the angle of swing arms attached to them.

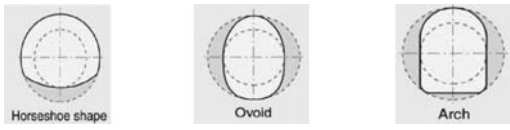

Figure 7. Variations of cross section.

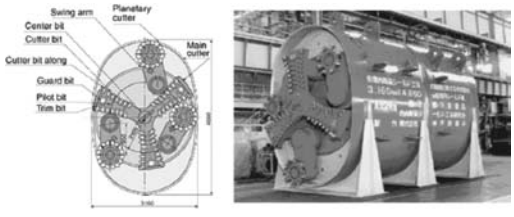

Figure 8. Three – part articulated OK (muddy soil pressure) shield.

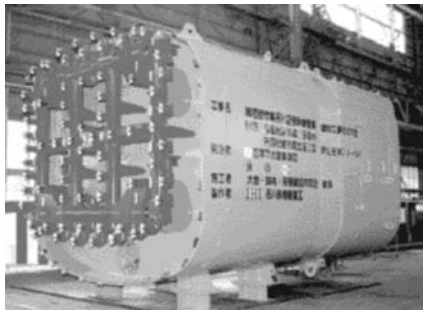

Figure 9. DPLEX shield: 4 m wide in Narashino City.

Thus, various cross sections can be created easily such as a rectangle, oval and arch.

DPLEX (Developing Parallel Link Excavation) shield method is used in Japan by the HITACHI Company for the construction of Subway line No. 11 in Tokyo.

3 PLANNED NEW CONCEPTS OF NON-CIRCULAR TUNNEL MACHINES FOR SOFT GROUND

3.1 For SOFT GROUND there are two interesting concepts of shields designed for full face. It is the DPLEX shield for a three-lane motorway tunnel with economy cross section being 17.2 m wide and with the total length of 12.8 m. (Fig. 10)

Four division cutter head – has for stabillity the face pre EPB with rotational speed of the screw conveyoe.

The TMB concept with combination of the rotation cutter method and the sliding cutter method is also interesting. The TBM is of the slurry shield type.

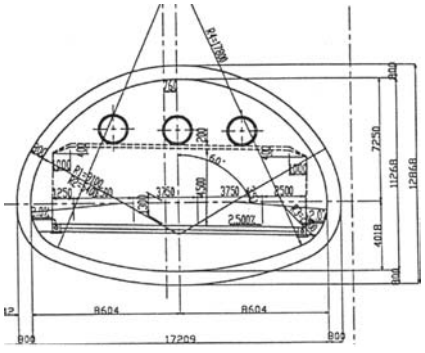

Figure 10. Cross section of the three-lane motorway tunnel in soft ground.

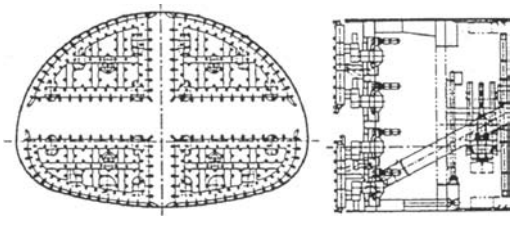

Figure 11. Developing parallel link excavating 4-division type.

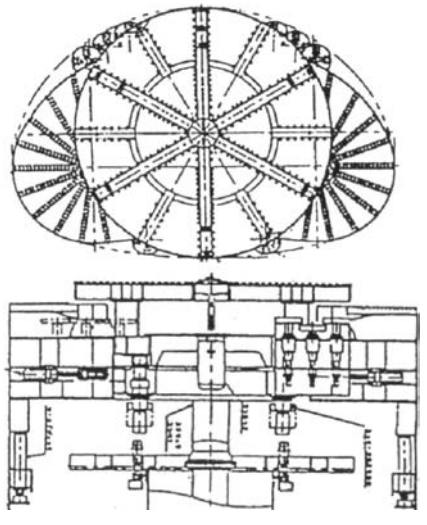

Figure 12. Combination of the rotation cutter method and the sliding cutter method.

4 SUCCESSFULLY USED NON-CIRCULAR TUNNEL MACHINES FOR HARD ROCKS

This area has been the main focus of the WIRTH for the past 15 years and of the ROBBINS Company for the past 20 years. Since 1991 WIRTH has developed and manufactured the Continuous Miner Machine successfully used in Canada. Profiting hereof the undercutting technique distinctly increases the excavating performance per cutter, whilst this technology was applied for a Continuous Miner. (Fig. 13)

Figure 13. Continuous undercutting miner.

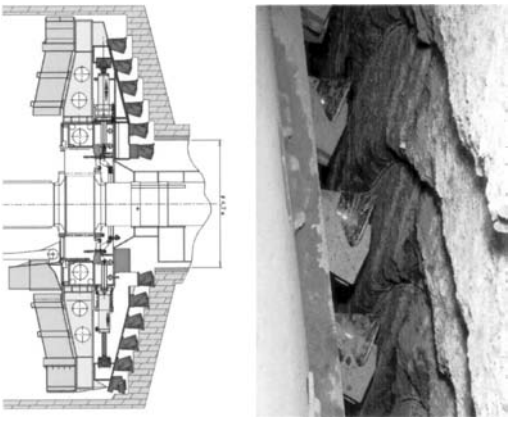

Figure 14. Reaming tunnel boring machine.

This technical development has now been applied for the first time for teaming principle. The WIRTH TBE 500/1440 H-HST is a Reaming Tunnel Boring Machine (Fig. 14)capable of boring diameters up to 14.4 m.

It was used with success to drive the UETLIBERG Tunnel in Zurich, Switzerland last year. Its profile is slightly elliptical being 14.4 m wide and 14.2 m high.

The American tunnelling machine – a mechanical hard rock excavator (Fig. 15) manufactured by the ROBBINS Company, and which belongs to the machines with conventional radial chisels, was used with success.

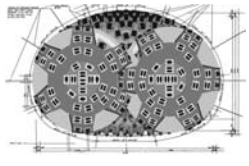

Figure 17. Profile driven by means of NATM with the use of the "two plus two face" TBM.

5 SOME PLANNED CONCEPTS OF NON-CIRCULAR HARD ROCK TBMs

The idea of developing such technology which would enable us to excavate the economical profile in a rapid manner is based on the fact that the construction of more than 50 km of motorway tunnels is necessary in Slovakia. As there is no need for the invert in the majority of long Slovak tunnels the horse-shoe shaped economical profile seems reasonable enough and advantageous indeed.

The "Two plus two face TBM" concept consists of four rotary cutting heads. (Fig. 17) The front two of them have the same circular shape. Behind them two other cutting heads are situated. The upper of them, barrel shaped, excavates the crown and the lower one, which may have barrel or drum shape according to quality of rock, excavates the invert of the tunnel. Such configuration enables to excavate full economy cross section at the same time.

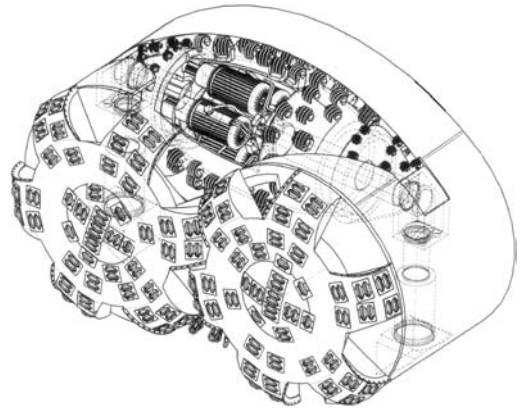

Figure 18. View 3D of the TBM with partial section throught upper barrel shaped cutting head.

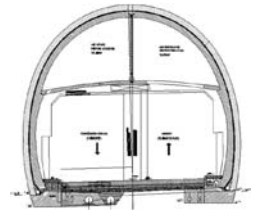

Figure 19. Cross section of the Planneed motorway 7 km Višňové Tunnel for the NATM 7 km long for NATM.

The additional advantage of the "Two plus two face TBM" concept, comparing with circular one, is possibility to lower the upper head by means of mighty hydraulic jacks in case of geological dislocation. (Fig. 18) This feature enables access to the space "over the barel heads" without necessity to make additional excavations. Two possible tandems can be attached behind the "Two plus two face TBM" cutting head system:

a) TBM with expanding hydraulic jacks leaning against tubing lining
b) TBM with extruded concrete lining system, enabling rapid tunnelling, well-known mainly from Japan.

The concept of TBM consists of one non-circular head only which has two additional finishing cutting pear-shaped heads (Fig. 20) to excavate the horse shoe-shaped profile well-known from the NATM.(Fig. 19)

Power supply of the finishing cutting head is situated inside the barrel which provides for electricity and cooling by means of a non-rotating shaft.

In soft rocks it is possible to use the version TBM with the shield and the tubbing lining.(Fig. 22)

The concept of TBM which has only one non-circular head and two finishing cutting pear-shaped

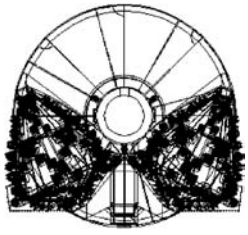

Figure 20. Profile of NATM driven with use the full face TMB with the finishing pear-shaped cutters.

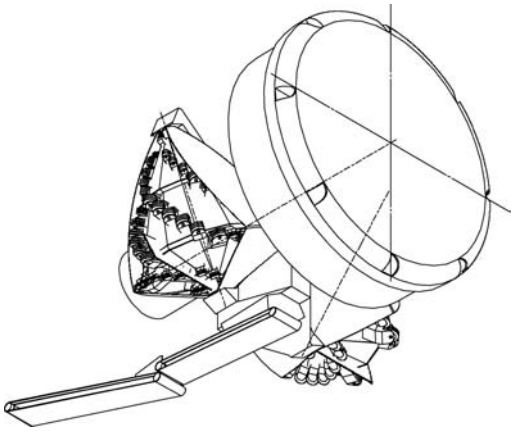

Figure 21. Undersight of the TBM principle with the finishing cutters.

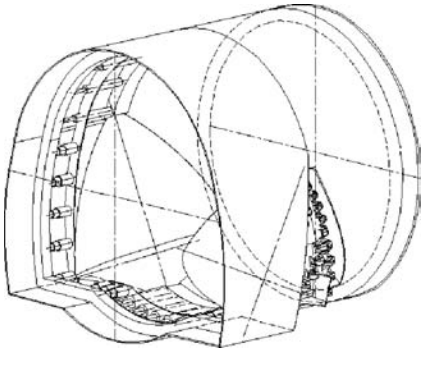

Figure 22. Rear view of the shield type TBM with the finishing pear-shaped cutters.

heads behind which excavate a horse-shoe shaped profile well-known from the NATM.

The power supply of the finishing cutting head is inside a barrel in which electricity and cooling is provided by means of non-rotating shaft. Both TBM concepts have patent protection.

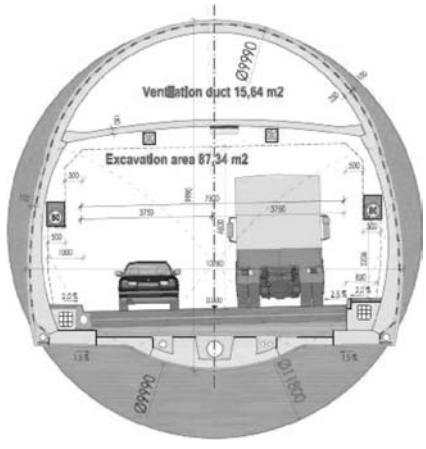

Figure 23. Sample cross section of the motorway tunnel by means of the non-circular TBM with a smaller area compared to the circular TBM.

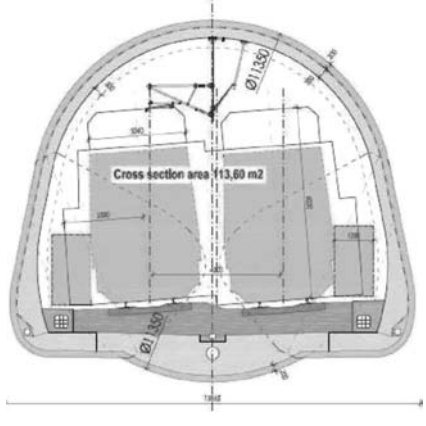

Figure 24. Sample cross section of the railway tunnel driven by means of the TBM.

In softer rocks it is possible to use the concept with a shield and tübing lining. Apart from the use of pear-shaped cutters for the TMB gripper it is possible to use the finishing cutters for the shield type TBM. Hydraulic jacks for pressing of tubings, adjacent to the finishing cutting heads have telescopic design. (Fig. 22)

6 CONCLUSION

The economical advantage of non-circular TBM with horse-shoe profile is especially convenient from long full face traffic tunnels.(Fig. 23 and Fig. 24) The cost

of a tunnel excavated by means of a non-circular TBM is lower if compared with a circular TBM, namely:

- cost of rock excavation is lower by 20% to 30% due to the smaller profile, i.e. lower costs for electric energy and exchange of cutting discs
- construction of lining with the tunnel circumference smaller by15% to 20%
- backfilling and compacting of the space beneath the road pavement or railway yard which increases the speed of driving.

The disadvantages of the non-circular TMB are as follows:

– initial higher cost for the manufacturing of a complicated TBM
– higher number of tübings for the tübing lining.

In case of tunnels which are longer than 3 km the above disadvantages are minor and the advantages of non-circular TBM prevail.

Toulouse Metro Lot 2: soil conditioning in difficult ground conditions

Alban Martinotto
Campenon Bernard SA (Group Vinci), Paris, France

Dipl.-Ing. Lars Langmaack
BASF Construction Chemicals (Europe), Zürich, Switzerland

ABSTRACT: The JV of Campenon Bernard TP (VINCI Group) & Eiffage TP was working on the Metro Line B, Lot 2 Project in Toulouse, together with BASF Constructions Chemicals for the soil conditioning and annulus grout admixtures. The machine used was the Herrenknecht S-208 7,75 m diameter EPB TBM. The TBM was driven under a housing area leaving the TBM launch shaft, continuing under a railway and houses with foundations lower than the tunnel alignment, coming then under the «Canal du Midi» and crossing old archaeological sites and sewers that were in a poor condition. Therefore the correct and stable face pressure was a prerequisite in order to prevent surface settlements and uncontrolled water & soil ingress. In addition, the clogging risk at the cutterhead and in the working chamber of the TBM caused by the tertiary molasses was fairly high, especially taking into account that the molasses were disturbed by sand lenses and large sections of the tunnel were below ground water level.

1 THE PROJECT

In June 1997, SMAT (Societé du Métro de l'Agglomération Toulousaine) got the task to construct the metro extension Line B from north to south through the city centre (Figure 1), a natural complement to Line A with the common station being Jean Jaurès.

Line B consists of 20 stations and a total length of 15.000 m, where 2.000 m represent cut and cover sections and 13.000 m bored tunnel.

The main Lots were:

- Lot 2: Herrenknecht EPB TBM, 4.731 m
- Lot 3: CSM Bessac compressed air TBM, 1.000 m
- Lot 4: FCB Slurry TBM, 3.700 m
- Lot 5: FCB EPB TBM, 3.400 m

Campenon Bernard TP & Eiffage TP were responsible for Lot 2, using a Herrenknecht EPB TBM S-208 named «Carlos Gardel». The TBM had a shield length of 8,50 m; a shield diameter of 7,750 m and a cutterhead diameter of 7,785 m. About 200 excavation tools were installed on the cutterhead and its rotation speed was adjustable from 1–3 RPM. The TBM speed was designed to reach 80 mm/minute with and EPB pressure of up to 3 bar. The installed power was 2.000 kW, resulting in a driving force of 55,75 kN and a jack force of 6.000 tons.

The tunnel inner diameter was designed reach 6,80 m with a $5 + 1$ Segment structure of 1,40 m length and 340 mm thickness. The total number of placed segments reached 26.000 and the muck excavation of 225.000 m^3 or 517.000 tons.

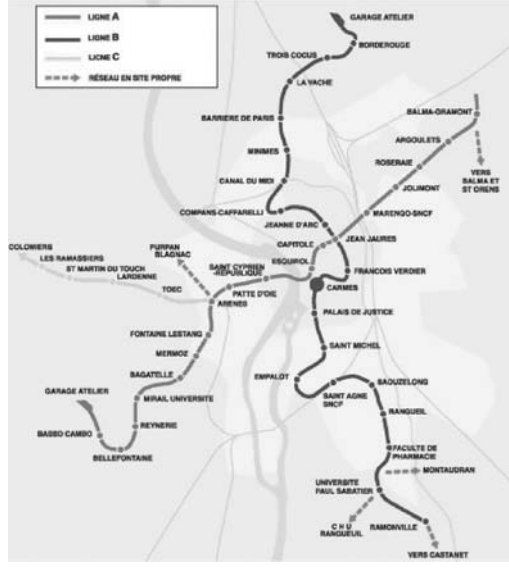

Figure 1. Metro plan Toulouse.

The tunnel alignment was placed under a housing area just leaving the launch shaft «Trois Cocus», continuing under a railway and houses with foundations lower than the tunnel, coming then under the

«Canal du Midi» and crossing old archaeological sites and sewers in a poor condition. Therefore correct and stable face pressures were a must in order to prevent surface settlements and uncontrolled water & soil ingress. In addition, the cutterhead clogging risk of the tertiary molasses was fairly high, especially taking into account that large sections of the tunnel were below ground water level. Furthermore, sand strata were present at the TBM crown level.

2 SOIL CONDITIONING BACKGROUND

EPB tunnelling is used in homogeneous as well as heterogeneous ground conditions. Famous examples for EPB drives in very heterogeneous geological formation are BPNL Lyon with a 10,98 m diameter NFM machine (Bentz et al 1997) and Barcelona Metro L9 with a 12,06 m diameter Herrenknecht machine (Gabarró et al 2003). The soil distribution of these two projects is indicated in.

As a consequence of the soil heterogeneity, the TBMs cannot be designed for the optimum of a specific geology, but for the overall optimum (Rehm 2004). This implicates a compromise from the machine technology point of view which has to be optimized by using different soil conditioning agents. The 3 most important factors for soft ground tunnelling – apart from the hard rock geology – are the

- Soil permeability
- Ground water pressure
- Risk of clogging and adhesion

The soil permeability for EPB drives can reach values of up to $k = 10^{-3}$ for the most porous soils (BPNL Lyon, Turin) and comes down to practically impermeable clay (Heathrow T5).

The TBM drives in clay soil – either full face or mixed face – often face clogging and adhesion problems. In porous soils, the faced problems are very instable tunnel face, uncontrolled soil and water income as well as loss of face pressure through the soil. These problems were lately described for the Milan Metro project (Grandori et al 2003). Important for a successful TBM drive is the mechanical adaptation of the TBM itself including shield opening factor, number and choice of tools and finally the right soil conditioning with foams and polymers combined with a complete filled working chamber. The use of pure foams will not be successful.

Another important influence for the EPB drives in soft ground is the ground water pressure. The higher the water pressure, the more difficult to handle will be uncontrolled water ingress and subsequent settlement risk. From the machine technique point of view only few things can be done like very long screw conveyors, dual screws with intermediate water release or the installation of piston pumps after the screw conveyor. The most important and successful factor to control the water and the soil income is to fill the TBM working chamber completely with a homogeneous and impermeable soil paste by help of Foams and Polymers. Site examples are Botlek Tunnel and Aviles Sewage Tunnel as described in the literature (Fernandez et al 2002).

Figure 2. Clay clogging in Toulouse Line B Lot 2.

EPB drives in clay formations – either full face or mixed face – often run into clogging and adhesion problems: as it was the case in Toulouse. Even working in dry mode with compressed air in the working chamber resulted in huge problems.

Figure 2 shows how easily the cutterhead centre can be plugged, openings can be closed and cutterhead tools can be turned ineffective by clogging clay. The problem of clay clogging and adhesion will always lead to difficult TBM guiding, slow advance rates and extensive cleaning. From the machine technique point of view few things can be done like the design of an open cutterhead – especially in the centre – and well placed mixing devices in the working chamber. Again one of the most important factors to reduce successfully the clay clogging and adhesion is the use of highly effective Foams and/or special anti-clay Polymers. Site examples are Madrid MetroSur (MBT Online) and Roma 4 Venti (MBT Online) or Toulouse Metro as described in chapter 3.

2.1 *Foam*

The main demand of foam as a conditioning additive is to obtain the suitable rheology of the soil in order to build up and to maintain the necessary support pressure in the working chamber and to prevent high pressure variations. Foam incorporated in the earth paste has got the same effect as the big air bubble in slurry machines. The reduction of torque and abrasion are very important additional effects too. Foam is produced by turbulent mixing of a surfactant solution with air (Langmaack 2000).

Figure 3. Clay behaviour without and with anti-clay polymer.

The main surfactant properties are:

- fluidising effect on soils because of the decrease of surface tension. Soil particles are no longer bound to each other by linked water.
- electrostatic repulsion effect which can separate two particles attracting each other by electrostatic forces.

Laboratory tests as well as the site experience show, that often each soil type, from stiff clay to sandy gravel, requires more or less an own type of foam to reach its best effectiveness. The reduction of the angle of internal friction as well as the cohesion is important. In clay soil, the reduction of cohesion is one of the main tasks of foam. The type of surfactant used for a specific site has to be determined by preliminary laboratory tests with the original in situ type of soil.

Generally, the use of only foam reaches its limits when it comes to clay containing soil as well as soil with high porosity and low cohesion. In these cases, the dual use of foam and polymers is necessary, as described in chapter 2.2 and 2.3.

2.2 *Polymer for clay soils*

As indicated already in chapter 2.1, soil conditioning additives shall decrease the clogging and adhesion characteristics of clay soil. Therefore anti-clay polymers have to adsorb on the clay particle surface. They have to carry a high charge density to separate the soil particles and they should furthermore be able to create a steric barrier in order to avoid reagglomeration effects. These demands can be fulfilled by surfactants and anti-clay polymers, but anti-clay polymers are much more efficient.

Anti-clay agents are mainly used to support the destructuring properties of the foam, but they might be introduced without foam, too. Figure 3 illustrates the effect of those polymers in clay soil.

Using only foam and water, the clay particles agglomerate immediately and show extensive adhesion to metal surfaces (figure 3 left part or figure 2). Using a TBM in this mode, the cutterhead as well as the working chamber will get plugged. Only the additional use of anti-clay polymer results in separated clay lumps and decreases to a minimum their adhesion (figure 3 right part). A proper EPB mode with a reasonable TBM speed and regular maintenance work is only possible under these conditions.

Figure 4. Comparison of original pure dry porous soil and as homogeneous paste after mixing with foam and polymer.

2.3 *Polymer for porous soils*

In contrast to the anti-clay polymers, the polymers for porous soil have to create cohesion in order to obtain a pasty soil rheology. This was important for the partially existing sand strata at the TBM crown, preventing an uncontrolled inflow of sand or uncontrolled squeeze-out of foam.

A couple of polymers can be used in porous soils:

- water binding polymers
  to dry out (liquid) soils.
- soil structuring polymers
  which are useful in loose, coarse soils to change the soil rheology and which prevent sedimentation.
- foam stabilising polymers.

Some polymer developments are based on hydrocarbon chains and are produced by bacterial fermentation. These polymers are water soluble, biodegradable and compatible to the foam surfactants. Well designed, both of them are safe for the foaming generator and consequently they can be mixed with the foaming solution and pass through the foam generator. Polymers also induce a more stable support pressure in the working chamber during boring and when stopping the machine.

All polymers should preferably be in liquid form to avoid dosing problems and additional installation to get a solution or suspension out of the powder.

3 PROJECT TOULOUSE LINE B LOT 2

After the start on 5th August 2002, the TBM advanced slowly in the initial face. With in average 10 m of cover, the TBM had no general problems in zones of pure (full face) stiff & dry clay, but the numerous encountered sand lenses with pressurized water made the machine advance quite difficult. Despite the air pressurized working chamber, water and fine soil came into the TBM in an uncontrolled way, causing clogging & adhesion problems on the cutterhead (see figure 5), huge

Figure 5. Problems working in dry compressed air mode.

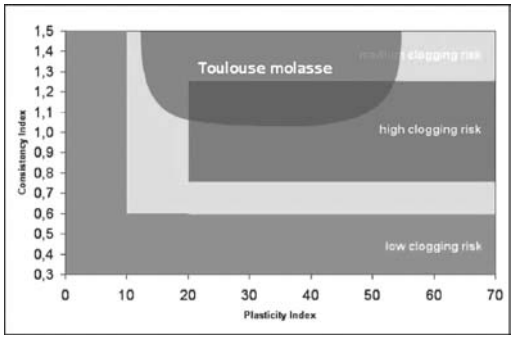

Figure 6. EPB mode (Babendererde 2003).

cleaning problems and last but not least causing doubts on abrasion, face stability and surface settlements.

The only way to successfully counterbalance the soil and water pressure on the tunnel face is a completely filled and pressurized TBM working chamber (Herrenknecht et al 2003, Steiner et al 1994). Therefore the soil must be treated during excavation with soil conditioning agents either separately or in combination:

- Foams
- Polymers for porous soil
- Polymers for clay soil

Their use enables filling of the TBM working chamber with excavated soil and reducing simultaneously the TBM torque and abrasion. No other modes of advance are suitable for instable, water bearing ground and sensitive surface areas as Babendererde 2003 has shown in figure 6.

In order to advance the TBM quickly and safely, the in-situ soil must be transformed into a non-adhesive and non-clogging soil paste in order to completely fill the working chamber and work in EPB mode.

This soil transformation called «soil conditioning» has to be pre-tested in laboratory scale in order to determine suitable products and their quantity.

Figure 7. Clogging soil in the laboratory.

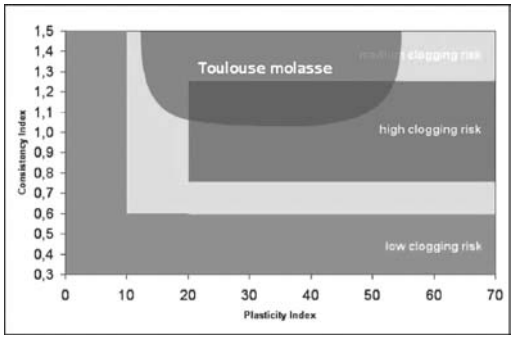

Figure 8. Clogging soil in the laboratory.

3.1 *Laboratory tests*

The first step in the laboratory is to reproduce the difficulties encountered on site. Therefore, original soil was used together with the soil conditioning systems originally used. The result is shown in figure 7, indicating quite well the difficulties encountered on site.

Scientifically, the clogging and adhesion capacity of the Toulouse molasses can be explained by their atterberg limits, showing a wide plasticity index between 15–55 combined with a high consistency index of >1 as indicated in figure 8 after Thewes 2004. In order to achieve the desired pasty and nonclogging soil rheology, numerous trials had been carried out. The best results were achieved with simultaneous addition of water, foam and Rheosoil® anti-clay agent. The result is shown in figure 9.

3.2 *EPB mode using SLF30 and Rheosoil®*

The soil conditioning concept determined in the laboratory had to be translated into the site system with a 6 line foam generator, serving 5 injection points on the cutterhead, 2 in the working chamber and 2 into the screw conveyor. An example of the TBM setting is shown in figure 10, demonstrating full EPB advance with 54 mm per minute and 2,6 bar medium earth pressure.

Figure 9. Correct EPB conditioning in the laboratory.

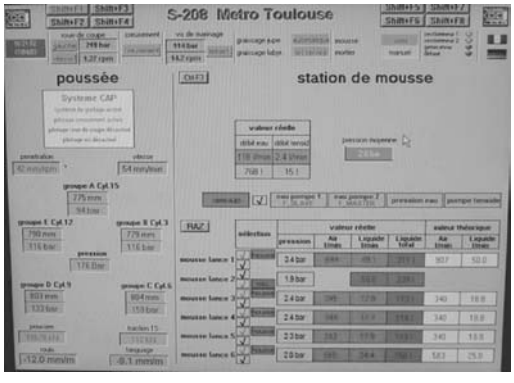

Figure 10. Foam generator screenshot.

The setting details were the following:

- Foam concentration SLF 30: 2–3%
- Expansion Ratio FER: 8
- Foam Injection Ratio FIR: 70% (+30% for the chamber)
- Rheosoil® 211: 0,8–1,0 kg/m^3 soil in situ
- Water (in case of dry soil): 5–20 m^3/ring

This soil conditioning system could be handled in a very flexible way:

- advancing with low torque and low abrasion values in compressed air mode, in case of homogeneous dry soil
- quick change to EPB advance with completely filled working chamber within minutes, in case of geology change

Figure 11 indicates the TBM parameters just after switching from air to earth pressure, mainly decreasing the pressure of the cutterhead centre (reducing the clogging risk). Graphs show also an increasing TBM speed with simultaneous decrease of torque values, indicating a highly efficient soil treatment. Figure 12 illustrates the soil conditioning quality, creating a plastic and non-clogging earth paste.

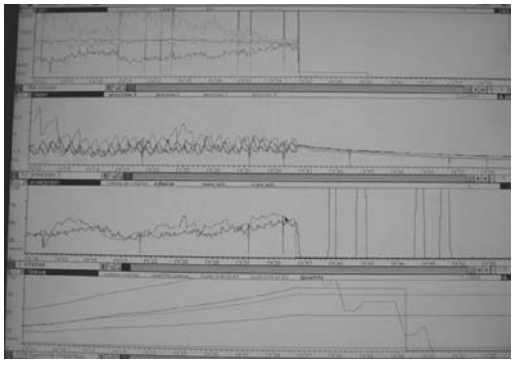

Figure 11. TBM data working EPB mode.

Figure 12. Plastic & non clogging excavated soil.

Once this soil conditioning concept was established, the TBM showed reasonable advance rates of 40– 50 mm/min also in the EPB mode, no water ingress occurred any more and the face support could be secured. Figure 13 shows the clean cutterhead after the TBM breakthrough.

3.3 *Sand strata above TBM*

From ring number 2758 onwards, a sand strata was located in the crown of the TBM and on top of it. In order to avoid uncontrolled sand flow-in, a polymer (MEYCO Fix SLF P2) enriched foam with structuring effects was injected into the TBM crown. This system turned out to be quite effective, but due to increasing sand strata and collapse risk it was decided to undertake surface injection with cement and silica gel in order to stabilize this geology (ring 3095–3120).

3.4 *Ecotoxicology*

In the beginning of the project, also ecotoxicological questions were raised concerning the landfill of the excavated soil (see figure 14).

Figure 13. Clean cutterhead after breakthrough.

Figure 14. Landfill of conditioned soil.

After switching to the BASF soil conditioning concept, all additives used including the anti-clay polymer passed a strict risk assessment study to ensure minimum impact on the workers and the environment. Neither during construction nor on the disposal sites negative influence of the soil conditioning additives could be observed.

The lixiviation data (1×24h, DIN 38-414 4) and following acute toxicity tests on Daphnids (NF EN ISO 6341) showed no dangerous potential of the treated soil from day 1 on. This enabled the contractor to avoid costly pre-stocking of the soil and to achieve a low general cost level for the landfill disposal.

4 CONCLUSION

As demonstrated by various site examples including Toulouse Metro Lot 2, it is possible to drive a TBM successfully and quickly through difficult geologies. In addition to the choice of a well adapted TBM machine, the use of the right soil conditioning additives is vital – for very permeable soil under ground water table as well as for clay rich soils with high clogging and adhesion potentials.

With an average daily TBM speed of 16,20 m and a significant best day advance of 37,80 m, the tunnel Lot 2 in Toulouse was finished within the foreseen time schedule with the final breakthrough on the 30th August 2004, 25 months after the start.

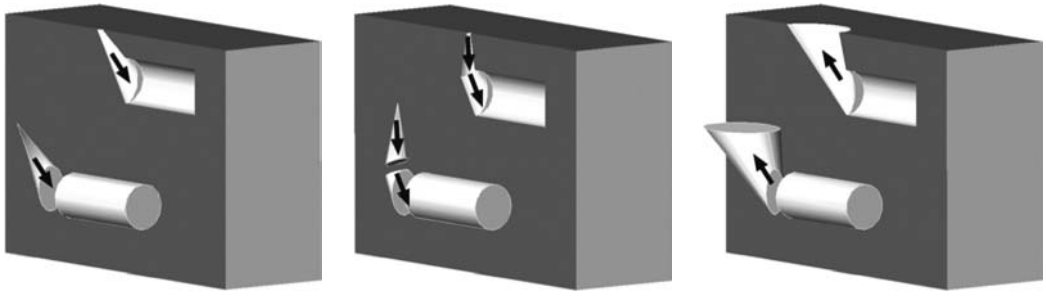
Upper bound solutions for tunnel face stability considering seepage and strength increase with depth

Jun Kyung Park, J. Tanner Blackburn, & Jae-Hun Ahn
Zachry Department of Civil Engineering, Texas A&M University, College Station, TX, USA



ABSTRACT: The upper bound method of limit analysis theory can be employed to calculate the active and passive limit pressures for maintaining tunnel face stability when using pressurized shield methods. The influence of seepage forces and depth-dependent effective cohesion was investigated for a dual-cone failure mechanism (MII, as defined by Leca et al., 1990), using the upper-bound method implemented by numerical analysis. The upper bound analytical derivation for depth-dependent effective cohesion and corresponding numerical results are presented and compared to those presented by previous authors. The analysis illustrated that the required face supporting pressure decreases when the depth-dependent rate in increase of effective cohesion increases. In addition, the numerical analysis demonstrated the influence of tunnel diameter on required face supporting pressure. Lastly, the upper bound limit analysis was employed to compare the relative importance of seepage force on cohesive and cohesionless materials, illustrating that the effect of seepage force is less prominent for cohesive materials.

1 INTRODUCTION

Face stability analyses are required to determine the proper pressure to be used for pressurized shield construction of shallow circular tunnels. Analytical, limit based methods have been developed (Atkinson et al., 1977; Davis et al., 1980) to calculate the optimum supporting pressure, which avoids face collapse (active failure) and surface 'blow-out' (passive failure).

Active failure of the tunnel face is caused by surcharge and self weight exceeding the frictional resistance and tunnel face pressure. Under passive conditions, the roles are reversed and the face pressure causes blow-out with resistance being provided by the surcharge, frictional resistance, and self-weight. Three failure mechanisms which involve the movement of solid conical blocks with circular cross sections, proposed by Leca et al. (1990), are shown in Figure 1. MI and MII failure mechanisms are single-cone and dual-cone systems, respectively; where the cones move into the excavation. An MIII failure mechanism is a single-cone, passive mechanism, where the cone moves outward to the surface.

In this paper, the MII collapse failure mechanism, which is most common failure pattern in shield tunneling (Chambon et al., 1994), is investigated by the upper-bound theorem. Recently, Lee et al. (2001) proposed that the seepage forces acting on the tunnel face under steady-state flow conditions should be considered if the tunnel is located under the groundwater table. However, general solutions which combine the

Figure 1. Failure mechanisms.

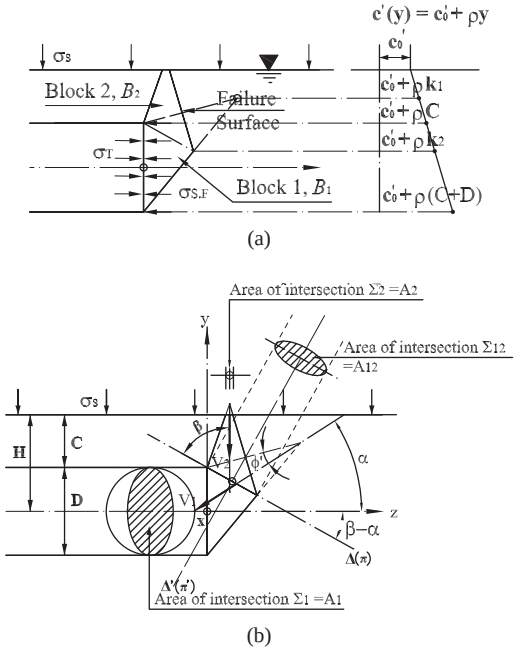

Figure 2. Collapse mechanism of tunnel face by the two conical blocks (modified from Lee et al., 2001).

depth-dependence of the effective cohesion (c′) of NC clays and the influence of seepage have not been reported.

In this paper, the influence of seepage forces and changes in shear strength with depth will be investigated for a Mohr-Coulomb material (c′, ϕ') based on the upper-bound method.

2 KINEMATIC APPROACH TO FACE STABILITY ANALYSIS BASED ON UPPER BOUND THEOREM

2.1 *MII failure mechanism geometry*

The MII active failure state can be idealized by considering a circular rigid tunnel of diameter (D) driven under a depth of cover (C) in soil with an effective cohesion (c′) increasing at rate, ρ with depth. A surcharge (σ_s) is applied at the ground surface and a constant retaining pressure (σ_T) is applied to the tunnel face.

Figure 2(a) shows a schematic cross-section of the MII failure mechanism geometry. Kinematically admissible failure mechanisms must be considered to obtain upper-bound solutions, initially developed by Leca et al. (1990). An MII failure occurs as two conical blocks move vertically and into the tunnel face, as shown in Figure 2(b). The two conical blocks consist of:

- **B_1**, a cone truncated by plane π, which is perpendicular to the page and represented as line $\Delta(\pi)$ in Figure 2(b)
- **B_2**, a cone corresponding to the removed, upper section of the cone B_1, mirrored about a plane π', such that the axis of B_2 is vertical. The mirror plane, π', is also perpendicular to the page and passes through the center of the ellipse created by the intersection between B1 and B2.

As such, the orientation of initial plane, π, is defined by the requirement that the axis of B_2 be oriented vertically and that π' pass through the center of the ellipse formed by the intersection of B_1 and B_2. Therefore, the MII failure mechanism geometry can be characterized by the angle of the axis of B_1 from horizontal, α, as shown in Figure 2(b).

For all three failure mechanisms, the intersection of the tunnel face and the adjacent block forms an ellipse, Σ_1, with a major axis length equal to $D/2$. For the MII failure mechanism, the intersection between blocks B_1 and B_2 is an ellipse, Σ_{12}, in plane π.

2.2 *Derivation of upper bound solutions*

This section summarizes the kinematic upper bound solutions to the MII failure mechanism, as originally reported by Leca, et al. (1990) and modified by Lee, et al. (2001). However, a new solution is derived to account for an increasing effective cohesion with depth.

The upper bound limit analysis solution is found by comparing the power of external applied loads, P_e, to the dissipation power caused by system movement, P_V. When the external power exceeds the dissipation power, an upper bound state exists. The following sections describe the derivations of the upper bound solution, as introduced by Leca et al. (1990), along with the modifications for increasing soil strength. The reader is referred to Leca et al. (1990) for additional geometric derivations.

2.2.1 *Dissipation power*

The dissipation power associated with the MII failure is calculated from the integration of plastic energy dissipation per unit area along block interfaces,

$$P_V = P_{1V} + P_{2V} + P_{12V}, \tag{1}$$

where P_{1V} is the contribution of the surface between B_1 and the surrounding soil, P_{2V} is the contribution of the surface between B_2 and surrounding soil and P_{12V} is the contribution of the interface between B_1 and B_2, represented as Σ_{12}. The dissipation is a function of the resistance along the interface surface and the block

velocity, therefore the dissipation power of the three interfaces are given as:

$$P_{1V} = \left(c_0{}' + [\rho y]_{y=k_1}^{y=C+D}\right) V_1 \cos\phi' \cdot S_{B1}, \tag{2}$$

$$P_{2V} = \left(c_0{}' + [\rho y]_{y=0}^{y=k_2}\right) V_2 \cos\phi' \cdot S_{B2}, \tag{3}$$

and

$$P_{12V} = \left(c_0{}' + [\rho y]_{y=c}^{y=k_2}\right) V_{12} \cos\phi' \cdot A_{12}, \tag{4}$$

where S_{B1} and S_{B2} are the perimeter surface areas of B_1 and B_2, respectively, A_{12} is the area of Σ_{12}, V_1 and V_2 are the velocities of B_1 and B_2, and V_{12} is the relative velocity between B_1 and B_2. Leca et al. (1990) derives the geometry of the surface areas and the velocity fields with the following equations:

$$S_{B1} = \frac{\pi D^2}{4}\left(R_A \frac{\cos\alpha}{\sin\phi'} - R_C R_D \cos(\alpha+\phi')\right), \tag{5}$$

$$S_{B2} = \frac{\pi D^2}{4}\left[R_C R_D \cos(\alpha+\phi') - \frac{\sin\phi'}{\cos^2\phi'} \cdot \left(\frac{\cos^2\phi'}{\sin\phi'}\frac{R_C{}^2}{\cos(\alpha+\phi')} - \frac{2C}{D}\right)^2\right], \tag{6}$$

$$A_{12} = \frac{\pi D^2}{4}\frac{\cos^2(\alpha+\phi')}{\cos\phi'}\frac{\sqrt{\sin(\beta-\phi')}}{[\sin(\beta+\phi')]^{3/2}}, \tag{7}$$

$$V_1 = \frac{\sin(\beta+\phi')}{\sin(\beta-\phi')}V_2, \tag{8}$$

$$V_{12} = \frac{\cos\alpha}{\sin(\beta-\phi')}V_2. \tag{9}$$

where R_A, R_C, and R_D are simplified geometric coefficients, introduced by Leca et al. (1990):

$$R_A = \frac{[\cos(\alpha-\phi')\cos(\alpha+\phi')]^{\frac{1}{2}}}{\cos\phi'}, \tag{10}$$

$$R_C = \frac{\cos(\alpha+\phi')}{\cos\phi'}\left[\frac{\sin(\beta-\phi')}{\sin(\beta+\phi')}\right]^{\frac{1}{2}}, \tag{11}$$

$$R_D = \frac{\sin\beta}{\sin\phi'\sin(\beta+\phi')}. \tag{12}$$

β is the angle between the intersection of B_1 and B_2 and vertical, and can be shown as:

$$\beta = 45° + \frac{\alpha}{2}, \tag{13}$$

2.2.2 *Power of external loads*

The power of the external loads, P_e, can be calculated as

$$P_e = P_T + P_S + P_\gamma + P_{S.F.}, \tag{14}$$

where,

$$P_T = -\sigma_T V_1 \cos\alpha A_1, \tag{15}$$

$$P_S = \sigma_S V_2 A_2, \tag{16}$$

$$P_\gamma = \gamma V_1 \sin\alpha V_{B1} + \gamma V_2 V_{B2}, \text{ and} \tag{17}$$

$$P_{S.F.} = \sigma_{S.F.}\frac{\pi D^2}{4}\frac{R_A}{R_C{}^2}\frac{\cos\alpha\cos^2(\alpha+\phi')}{\cos^2\phi'}. \tag{18}$$

P_T is the power of the tunnel face pressure(σ_T), P_S is the power of the surcharge(σ_s), P_γ is the power of the soil unit weight(γ), and $P_{S.F.}$ is the power of seepage force. The contact areas A_1 and A_2 correspond to the surface Σ_1 and the area of the intersection between the B_2 and the ground surface, respectively. The areas are defined as:

$$A_1 = \frac{\pi D^2}{4}\frac{\sqrt{\cos(\alpha-\phi')\cos(\alpha+\phi')}}{\cos\phi'}, \tag{19}$$

$$A_2 = \frac{\pi D^2}{4}\left[\frac{\sin\beta\cos\alpha}{\sin\phi'\sin(\beta+\phi')} - \left(\frac{2C}{D}+1\right)\right]^2 \tan^2\phi'. \tag{20}$$

The soil unit weight component of the external power depends on the volume of the failure blocks, V_{B1} and V_{B2}, which are given as:

$$V_{B1} = \frac{\pi D^3}{12}\left(R_A R_B - R_C{}^3\frac{\cos\phi'}{2\sin\phi'}\right), \tag{21}$$

$$V_{B2} = \frac{\pi D^3}{12}\left[R_C{}^3\frac{\cos\phi'}{2\sin\phi'} - \frac{\sin^2\phi'}{2\cos^2\phi'} \cdot \left(\frac{\cos^2\phi'}{\sin\phi'}\frac{R_C{}^2}{\cos(\alpha+\phi')} - \frac{2C}{D}\right)^3\right], \tag{22}$$

where R_A and R_C are given in equations (10) and (11) and R_B is defined as:

$$R_B = \frac{\cos(\alpha-\phi')\cos(\alpha+\phi')}{\sin(2\phi')}. \tag{23}$$

2.2.3 *Upper bound theorem*

Using the upper bound theorem, an MII failure mechanism will be avoided if the external power is below the dissipative power, shown as:

$$P_e \leq P_V \tag{24}$$

Substitution of equations (1) through (23) into equation (24) will give an upper bound solution in the following form:

$$N_S Q_S + N_\gamma Q_\gamma \le Q_T + \frac{\sin\phi'}{\cos\alpha}\frac{R_F \cdot R_c^2}{R_A}. \quad (25)$$

The three loading parameters (Q_S,Q_T,Q_γ) and the coefficients (N_S,N_γ) are given in equations (26)–(30) as defined by Leca et al. (1990) and Lee et al. (2001). A new parameter (R_F) is introduced which accounts for the increase in soil effective cohesion, and is given in equation (32):

$$Q_S = (K_p - 1)\frac{\sigma_S}{\sigma_C} + 1, \quad (26)$$

$$Q_T = (K_p - 1)\frac{\sigma_T - \sigma_{S.F}}{\sigma_C} + 1, \quad (27)$$

$$Q_\gamma = (K_p - 1)\frac{\gamma D}{\sigma_C}, \quad (28)$$

$$N_S = \frac{1}{\cos\alpha\cos^2\phi'}\frac{\sin(\beta-\phi')}{\sin(\beta+\phi')}\frac{{R_E}^2}{R_A}, \quad (29)$$

$$N_\gamma = \frac{1}{3}\left[\begin{array}{l}\tan\alpha R_B + \dfrac{\cos\phi'\cos(\beta+\phi')}{2\sin\phi'\sin(\beta+\phi')}\dfrac{{R_C}^3}{R_A} \\ -\dfrac{1}{2\sin\phi'\cos\alpha\cos^2\phi'}\dfrac{\sin(\beta-\phi')}{\sin(\beta+\phi')}\dfrac{{R_E}^3}{R_A}\end{array}\right], \quad (30)$$

$$R_E = \frac{\cos^2\phi'}{\cos(\alpha+\varphi')}R_C - \frac{2C}{D}\sin\phi', \quad (31)$$

$$R_F = \cos\phi'\cdot\left\{\begin{array}{l}\left[\dfrac{\cos\alpha}{\sin\phi'}\dfrac{R_A}{{R_C}^2} - \cos(\alpha+\phi')\dfrac{R_D}{R_C}\right]\rho(C+D-k_1)+ \\ \left[\dfrac{\cos^2\phi' R_C R_D}{\cos(\alpha+\phi')} - \dfrac{{R_E}^2}{\sin\phi'\cos^2(\alpha+\phi')}\right]\rho(k_2)+ \\ \left[\dfrac{2\cos\beta\sin 2\phi'\cos(\alpha+\phi')}{\sin\beta}\cdot\dfrac{{R_D}^2}{R_C}\right]\rho(k_2-C)\end{array}\right\}, \quad (32)$$

where, σ_c is the unconfined compression strength, K_p is the Rankine passive earth pressure coefficient, $\sigma_{S.F.}$ is the seepage pressure acting on the tunnel face, γ is the unit weight of the soil, D is the tunnel diameter, k_1 is the apex of block 1 (B_1), and k_2 is the lowest point of the intersection between B_1 and B_2.

Relation (32) provides the best upper bound associated with an MII failure mechanism when N_s and N_γ are maximized by optimizing α.

The parameters Q_S and Q_γ are imposed geometric and loading conditions, and the supporting pressure σ_T should be chosen such that failure of the tunnel during construction is prevented. The selection of supporting pressure corresponds to:

$$Q_T = N_S Q_S + N_\gamma Q_\gamma - \frac{\sin\phi'}{\cos\alpha}\frac{R_F \cdot R_c^2}{R_A}. \quad (33)$$

which can be rewritten, after substitution, as:

$$\left[(K_P - 1)\frac{\sigma_T - \sigma_{S.F.}}{\sigma_C}\right] = N_S Q_S + N_\gamma Q_\gamma - \frac{\sin\phi'}{\cos\alpha}\frac{R_F {R_C}^2}{R_A} - 1, \quad (34)$$

$$\sigma_T = \frac{\left[N_S Q_S + N_\gamma Q_\gamma - \dfrac{\sin\phi'}{\cos\alpha}\dfrac{R_F {R_C}^2}{R_A} - 1\right]\sigma_C + \sigma_{S.F.}}{(K_P - 1)}. \quad (35)$$

The parameters in equations (33)–(35) correspond to geometry and Mohr-Coulomb soil properties except for the seepage pressure acting on the tunnel face. To calculate the seepage pressures acting on the tunnel face, the failure surface must be pre-determined from the limit analysis. Given this failure surface, seepage pressures acting on the tunnel face can be obtained from the difference of total head between the tunnel face and the failure surface. The average predicted seepage pressure has been calculated using numerical analyses by Lee et al. (2003). The analysis conducted by Lee et al. (2003) demonstrated that seepage force seriously affects tunnel face stability, but effective overburden pressure is reduced slightly by the arching effect during tunnel excavation, the seepage pressure remains the same.

The variation of the effective cohesion (c′) of NC clays with depth has not been included in previous numerical analyses and model tests. However, the seepage analysis results will not change due to added cohesion, because the hydraulic head will be the same. Therefore, the seepage analysis results reported by Lee et al. (2003) were employed for the calculation of upper bound supporting pressure (σ_T) in this research.

3 CASE STUDY OF TUNNEL FACE STABILITY

The optimal upper bound solution that accounted for the influence of seepage force and the depth-dependence of effective cohesion (c′) of NC clays was calculated using a spread sheet program created for this research.
