As shown in Figure 3, when the depth-dependent rate of change (represented as ρ) of effective cohesion increases, the required face supporting pressure decreases. A value of $\rho = 0$ corresponds to a homogenous soil, with constant cohesion. In Figure 3, negative supporting pressure values indicate that additional face supporting pressure is unnecessary. In this case, the surcharge (σ_s) will have very little influence on face collapse because the tunnel is deep enough ($C/D = 2$). This is because the results of failure shape and support pressure have the same values when the depth ratio (C/D) was greater than 0.2 as shown in Figure 4.

Figure 5 shows the required face supporting pressure as a function of tunnel diameter and effective cohesion. As the tunnel diameter increases, the

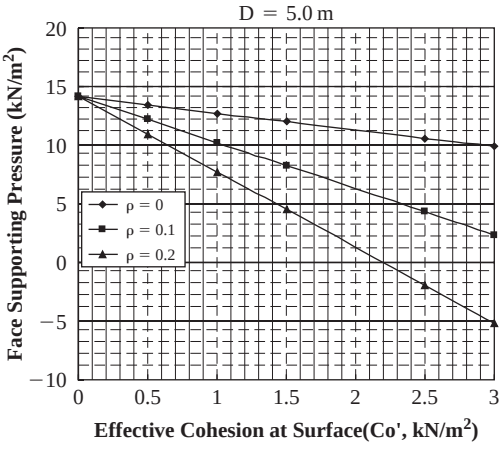

Figure 3. Change of support pressure with variation of the rate of change of c′ with depth (In case of $\phi' = 35°$, $\gamma = 15.2(\text{kN/m}^3)$, C = 10 m, Water Level (Hw = 5 m), D = 5 m).

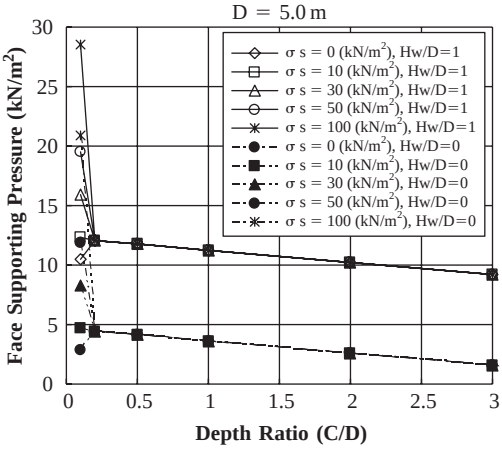

Figure 4. Change of support pressure with variation of surcharge (σ_s) and depth ratio (C/D) (In case of $\phi' = 35°$, $\gamma = 15.2(\text{kN/m}^3)$, $\rho = 0.1$ (kN/m^2/m), $c'_o = 1$ (kN/m^2)).

required face supporting pressure will also increase. Even if the failure happens in the very shallow depth when depth ratio is larger than 0.2, the effect of surcharge (σ_S) is very small compared to the changes in the required supporting pressure by other parameters such as tunnel diameter, cover depth, effective cohesion as previously shown in Figure 4.

4 COMPARISON WITH OTHER PREVIOUS RESEARCH RESULTS

The relationship between groundwater depth, tunnel depth, tunnel diameter, and required tunnel support

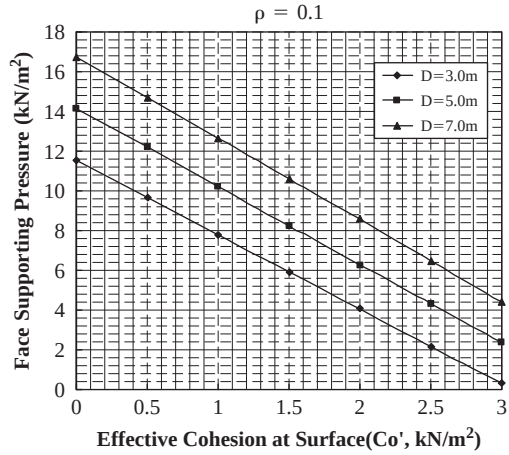

Figure 5. Change of support pressure with variation of tunnel diameter (D) (In case of $\phi' = 35°$, $\gamma = 15.2(\text{kN/m}^3)$, C = 10 m, Water Level (Hw = 5 m), $\rho = 0.1$ (kN/m^2/m)).

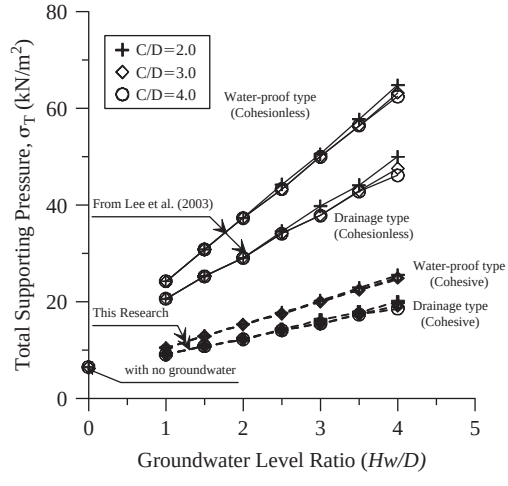

Figure 6. Change of support pressure with variation of the Hw/D.

pressure for a sand and an NC clay material is shown in Figure 6. The cohesionless sand results are those reported by Lee et al. (2003) ($\phi' = 35°$, $c' = 0$). The cohesive material results were computed using the spreadsheet, based on the derivation described herein ($c'_o = 10\,\text{kN/m}^2$, $\phi' = 35°$, $\rho = 0.5\,\text{kN/m}^2\text{/m}$).

Figure 6 illustrates the large influence of groundwater conditions on required tunnel face supporting pressure for both soil types and for drained and waterproof tunnel construction methods. Although, the influence of seepage pressure on the upper bound required supporting pressure is less for an NC clay material, this effect must be considered for this material type.

5 CONCLUSIONS

In this study, an upper bound solution that will address both the influence of seepage forces in front of tunnel face and the depth-dependence of effective cohesion was derived for the collapse failure mechanism (MII). A spreadsheet program was developed to investigate the influence of seepage forces and changes in cohesion for a general Mohr-Coulomb material (c', ϕ') based on the upper-bound method with an assumed seepage pressure. The new upper bound solution was used to calculate the effective support pressure in steady-state groundwater flow condition. The results of this study lead to the following conclusions.

- When the depth-dependent rate (ρ) of change of effective cohesion (c') increases, the required face supporting pressure will decrease. Negative supporting pressures indicated that, in some cases, no additional face support pressure is necessary.
- As the tunnel diameter increases, the required face supporting pressure will also increase.
- The surcharge (σ_S) will have very little influence on face collapse when the depth ratio (C/D) is larger than 0.2. Even if the failure happens in the very shallow depth, the effect of surcharge (σ_S) is very small compared to the changes in the required supporting pressure by other parameters such as tunnel diameter, cover depth, effective cohesion.
- Seepage force is a key factor for maintaining stability of the tunnel face in non-cohesive material as mentioned by Lee et al. (2001). However, the effect of seepage pressures on the upper bound supporting pressure (σ_T) is decreased in a cohesive material. This difference implies that this effect should be considered in weathered soil having both c' and ϕ' properties.

Gotthard Base Tunnel: Work progress at the five construction sections

M. Rehbock-Sander & A. Gerdes
Amberg Engineering Ltd., Regensdorf-Watt, Switzerland

ABSTRACT: The 57 km long Gotthard Base Tunnel (GBT) is scheduled to be opened in the year 2015, the preparatory work started in 1996. When completed the GBT will be the longest railway tunnel in the world. This paper gives an overview on the five construction sections of the tunnel and shows the status of work of each. The overcome of the problems with the blocked tunnel boring machine (TBM) in Amsteg, the successfully applied yielding rock support in Sedrun and Faido and the occurred rock burst phenomena in Faido are described in more detail.

1 GOTTHARD BASE TUNNEL – OVERVIEW

1.1 *General*

Today modern traffic infrastructures have to ensure faster and more reliable connections. Switzerland's New Alpine Transversal (NEAT) will provide a high-speed rail link for passenger and freight trains passing through the Alps between northern and southern Europe. It will enable much of the traffic to be shifted from road to rail. There are two NEAT lines: the Lötschberg axis in the west and the Gotthard axis in the east.

The heart of the Gotthard axis is the 57 km long GBT. The initial preparatory work for the Base Tunnel started in 1996, it is scheduled to be opened in the year 2015. After completion, the GBT will be the world's longest railway tunnel.

1.2 *Design*

The GBT is designed to handle high speed passenger trains travelling at speeds of up to 250 km/h and freight trains travelling at up to 160 km/h. This will be achieved with an alignment with a minimum radius of 5,000 m and a maximum slope of 1%. It will have an elevation of approx. 500–550 meters above sea level and a maximum overburden of approx. 2,300 m.

The GBT stretches from Erstfeld in the north to Bodio in the south. It consists of two parallel single track tubes with a diameter varying from 9.0–9.5 m, which are linked by cross-passages every approx. 300 m. Multifunction stations (MFS) are located at two locations one-third and two-thirds along the length of the tunnel. These will be utilized for the diversion of trains to the other tube via crossover tunnels, to house technical – infrastructure and equipment, and as a emergencystation for the evacuation of passengers.

To shorten construction time and for ventilation purposes, the tunnel has been devided into five sections and will be excavated from several sites simultaneously. Excavation will take place from the portals as well as from three intermediate attacks, by access tunnels in Amsteg and Faido and by two vertical shafts in Sedrun (Fig. 1).

1.3 *Geological conditions*

From north to south, the Gotthard Base Tunnel passes through mostly crystalline rock, the massifs which are interrupted by narrow sedimentary tectonic zones. The three crystalline rock sections include the Aare massif to the north, the Gotthard massif and the Pennine gneiss zone to the south (Fig. 2). These massifs consist mainly of high strength igneous and metamorphic rock. More than 90% of the total tunnel length consists of these types of rock.

The most difficult section of the new tunnel from the viewpoint of geology is expected to be the (old crystalline) Tavetsch intermediate sub-massif (TZM) in the Sedrun section, located between the Aar-massif and the Gotthard-massif. Beneath this section there are about 90 different isolated short fault zones along the 57 km.

The Tavetsch intermediate massif consists of a steeply-inclined, sandwich-like sequence of soft and hard rock.

The initial planning phases concentrated – beneath other aspects – on aligning the tunnel through the various fractured zones at their narrowest points wherever possible.

The high mountain overburden of up to 2,300 m means that rock temperatures in the tunnel can reach

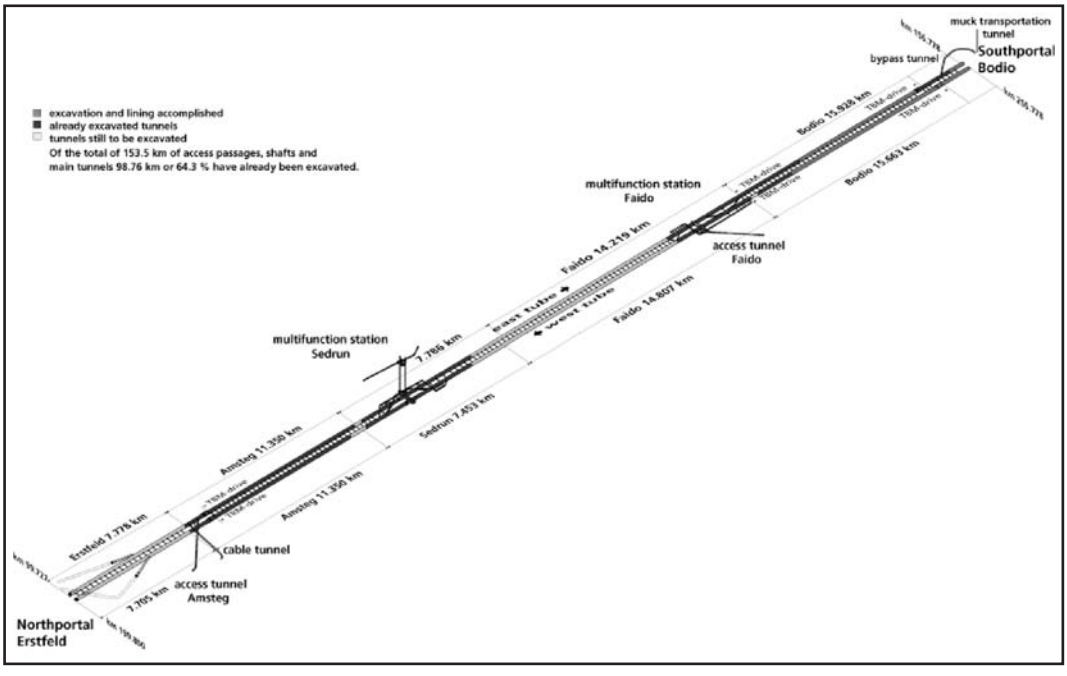

Figure 1. System of the GBt and construction status as of September 2006.

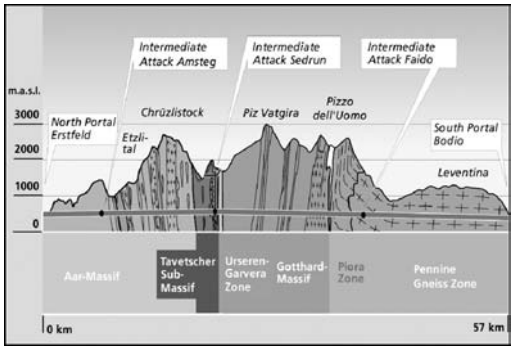

Figure 2. Longitudinal geological profile of the GBT.

more than 50–55°C. In order to maintain the required air temperature in the various working areas, an air conditioning system is required.

2 THE FIVE CONSTRUCTION SECTIONS

2.1 *Erstfeld*

Preparatory work started at the north portal at Erstfeld in July 2004.

The works for the construction lot Erstfeld contain the driving of the two single-track tubes of the 7.8 km long section from Erstfeld to Amsteg, the excavation of the 23 connecting galleries and the construction of an underground fork. The work contract is not yet awarded. This will happen in 2007.

2.2 *Amsteg*

In Amsteg, the heading of a 2 km long horizontal access adit to the GBT along with construction of the processing plant and conveyor belt equipment for muck removal began in December 1999.

In autumn 2003, the two tunnel boring machines (TBM) in the Amsteg section with a diameter of 9.58 meters each, were installed in underground assembly caverns. In April 2004, the first zone predicted to contain difficult geological conditions (Intschi Zone) was penetrated successfully and without the expected time delays.

The muck is transported with conveyor belts from the back-up of the TBM to the material processing plant on the construction site, where a part of it is recycled to produce concrete aggregates. Tunnel trains only provide transportation of rock support materials, concrete, miners, staff members, and some visitors. The rest of the muck from the Amsteg and Erstfeld sections will be transported by rail and boat to the nearby Reuss river mouth , where it will be used for restoration of the natural conditions of the river delta.

Figure 3. Restart of Gabi II.

In June 2005, the Amsteg tunnellers came across a fault zone with hydrothermally influenced rock below the Chrüzlistock mountain. The TBM in the eastern tube, Gabi I, penetrated this roughly 50 m long zone without any problem. The TBM Gabi II in the western tube, however, was brought to a halt, as a mix of loosened rock and groundwater flooded the cutterhead. In order to ensure Gabi II could function properly again, the soft area in front of the machine's cutterhead was consolidated with cement via a 15 m long grouting gallery from the parallel running eastern tube. At the same time, a 50 m long gallery leading to the western tube was excavated from the eastern tube, and the TBM's cutterhead subsequently exposed by November 15th, 2005. Thanks to the counter-drive, it was possible for Gabi II to resume excavation in the western tube towards Sedrun (Fig. 3).

In mid-June 2006, Gabi I reached the Sedrun section in the eastern tube nine months ahead of schedule. The tunnellers of Amsteg and of Sedrun are separated by only 700 m of rock mass. This rock, where in some places highly squeezing conditions prevail, will be excavated mainly from the Sedrun side. Breakthrough is expected by summer 2008. The TBM Gabi II is expected to reach Sedrun by the end of 2006.

In the coming months, Gabi I will be completely dismantled underground, and its individual parts then transported out of the tunnel by the service train.

2.3 *Sedrun*

Sedrun is the most complex section of the base tunnel due to logistical and geological reasons. The adit (1 km), the inclined ventilation shaft (450 m), the cavern at the top of the first shaft and the 835 m-deep vertical access shaft were completed in several preparatory construction lots since 1996. The entire logistic supply for the heading of a total tunnel length of 2×6.8 km (four simultaneous tunnel drives, together with others minor drives) has to be conducted through the access tunnel and the double shaft system. Up to 6,000 tonnes of excavated material have to be handled every day. Shaft drives were installed for a double floor hoisting cage with a 5 MW rating, providing a 60 km/h hoisting speed for an 80 t load.

Because of the complex geological conditions, different auxiliary support measures are to be applied during excavation, e.g. investigations ahead of the tunnel face with geophysical systems and/or percussion and core probe drillings. The drillings must be preventer-protected against water inflow and debris under high pressure. In the GBT Sedrun, for example, the core drilling rigs must be equipped to water pressure strikes as high as 200 bar. The triple preventer systems used offer three independent systems. If water under high pressure is struck unexpectedly, the drilling rod can be clamped (pipe ram) or even cut off (shear preventer). The third system, Roto Pac, makes it possible to keep on drilling even in zones with high water pressure. This preventer technology was developed for the oil and gas drilling industry.

In the TZM since May 2005 both tubes were driven in squeezing rock. With regard to deformations, the geotechnical behaviour of the kakiritic gneisses and slates encountered turned out to match the forecast. Some 30 m behind the face the deformations converge. Here the first shotcrete lining is applied and the flexible lining changes to the resitance principle. The friability is extremely high in some areas. In this regard, the influence of the strike of the layers vis-à-vis the tunnel axis is of major significance. In the case of vertical and perpendicular layers towards the tunnel axis there is a higher need for supporting the face (shotcrete with net reinforcement, excavation in stages, and installation of spiles), whereas in the case of flat lying layers, the danger at the edge of the excavation is increased. All situations occurring so far have been mastered by adapting the means of support and the length of advance.

The deformations in squeezing rock occur radially at the anticipated average magnitudes of 20 to 80 cm. The deformations in the cross section can occur in a very different manner (asymmetrical deformations). These asymmetrical deformations are reacted by corresponding additional supports (grouted anchors).

Rates of advance in TZM North have increased since the start of drives after the learning phase of the contractor had set in relation to the various excavation phases and the optimisation of construction measures. Apart from these phases, optimisations also concerned project aspects such as adapting the length of advance, the spacing between steel arches and the application of spiles.

To counter the immense rock pressure, Alp Transit Gotthard Ltd. and the Engineering Joint Venture have pioneered a new method of tunnel construction for this kind of deep tunnels. Two steel rings are

installed, one inside the other. Each of the two rings is composed of eight segments which are connected together by slightly compressible joints. When the rock pressure starts to take effect, the rings slowly close in on themselves until the maximum supporting force is reached.

This technology is used in German coal mines, but nowhere in the world has it ever before been applied with these dimensions. The system has proved itself in recent months: driving is within budget and on schedule from the clients point of view.

The cross section of the single tubes increases from about 80 m^2 up to more than 130 m^2. The installed steel mining arches have the capacity to deform to the permissible 80 cm radial deformations as planned. The large -in some cases asymmetrical -deformations that occur have so far been mastered thanks to the proposed supporting measures.

The southern drives in both tunnel tubes in the Gotthard Massif gneisses have been undertaken by means of highly mechanized excavation and transport installations with drill and blast since spring 2005. The driving operations for both single-track tunnels are more than 6 months ahead of schedule as compared with the contract construction program. This is due to the technically easier penetration of the Urseren Garvera Zone, which was tackled prior to entering the Gotthard Massif in summer 2005. Further driving operations will run until the middle/end of 2008 towards the north and south. Starting in the second half of 2006, vault supporting work in the core area of the MFS will commence in the tunnel change-over enlargements followed by the lining operations for the adjoining single-track tubes. Emergency stations follow in the first quarter of 2007.

An interesting project to be mentioned for the section Sedrun is the project "Porta Alpina". During the operation of the Gotthard Tunnel the Porta Alpina intends to use the MFS Sedun as an underground train station which allows passengers to leave the train. From there the passengers can reach the 800 higher village Sedrun and the Gotthard region by using lifts. The Alp Transit Gotthard has awarded the order for the preparatory construction works. The costs of this project are estimated to be about 50 Million CHF.

2.4 *Faido*

In Faido, the GBT is accessed up via a 2.7 km long sloped tunnel (declination of 12.7%). Construction of this tunnel began in December 1999 and was constructed by conventional drill and blast methods. Close to the access tunnel portal, extensive material processing plants for recycling of a part of the muck and for the production of concrete aggregates as well as conveyor belt systems for the transportation of debris were installed. A 5 km long conveyor belt transports the muck for permanent disposal in an old quarry.

Figure 4. Breakthrough MFS Faido, September 2006.

The contract for the main lot has been awarded in combination with the southern Bodio section at a sum of 1.1 billion US$.

The first tunnel boring machine (TBM) in the Gotthard Base Tunnel started out in the east single-track tunnel from Bodio in November 2002. Two months later, the second TBM started driving in the west tunnel. A number of different geological zones had to be overcome along the approximately 15 km route to the multifunction station at Faido.

In September an important milestone was reached in Faido: the first breakthrough by a tunnel boring machine was done (Fig. 4).

It took place with the expected precision. Continuous measurements showed that the specified accuracy was maintained along the entire length of the drive. At breakthrough, the deviation of the TBM was only 2 cm vertically and 5 cm horizontally.

2.4.1 *Fault zones in the MFS Faido*

The MFS Faido lies at the end of the Faido access tunnel. It consists of the two tunnel tubes that are connected with each other by two tunnel crossovers in the MFS, the cross cavern for housing the railway infrastructure equipment, the cross-cuts required for construction operations, the cavern for handling logistics in the construction phase, the two emergency train stops that are connected by side galleries, and a ventilation tunnel system.

Altogether there are about 6 km of tunnels and galleries with cross-sectional areas ranging from 40 m^2 to more than 300 m^2.

The MFS Faido was planned according to the geological prediction of favourable rock conditions. The different types of galleries, tunnels and caverns are excavated by drill and blast.

In summer 2002 an intensive fault zone was tunnelled into unexpectedly. It passes through the large caverns of the multifunctional station at a very acute angle. An intensive investigation program was carried

out to define the best location of the large cross over caverns with cross sections up to 260 m^2. An intensive investigation program was carried out. The risk of constructing the large cross-section in the middle of a fault zone was judged to be too high. Based on the results of these investigations, it was decided to adapt the layout of the MFS Faido with the aim of placing the large caverns in good rock conditions in the southern part.

Besides the layout of the MFS the geology encountered also made it necessary to carry out a critical review of excavation support means to be applied in the relevant cross-sections.

In the meantime in the MFS Faido a yielding support system with steel arches with friction clutches and convergency slits is being used successfully (Fig. 5). This yielding arches allow deformations of the ground (principle of yielding). Depending on the result of deformation the slits are filled with shotcrete and the support system becomes rigid (principle of resistance). Additionally to the steel arches different other support elements are applied and they are adapted according to the requirements of the heading. At the MFS Faido the yielding steel arches in addition with staggered anchoring and shotcrete are being applied. The launched task force interpreted the geological conditions encountered as a combination of loosening and squeezing behaviour. Currently the overall rock support system is always adapted and optimised based on the geotechnical computations, the continuous observations of geology on site and the experiences (observations, measurements) from the last excavation steps.

Figure 5. Yielding steel support with convergency slits.

Figure 6. Rock burst in the MFS Faido, June 2005.

2.4.2 *Rock burst phenomena in the MFS Faido*

The excavation of cavities associated with mining and tunneling works lead to the disturbance of the primary stress conditions of rock. Redistributions of stress result in some cases to stress concentrations which exceed the material strength. A rock burst is the immediate failure of the rock under which large amount of stored energy is released. In hard rock tunnelling and mining as a rule, as the compactness of rock and overburden increases, the probability of rock bursts increases. Rock bursts are extremely difficult to predict or to prevent. In order to ensure occupational safety at tunnelling sites, steps must be taken to predict as much as possible the probability of rock bursts and to minimize their effects upon workers and the structure.

During construction of the Faido MFS frequent and often massive rock bursts or rock burst phenomena have occurred since March 2004. According to geologic prognosis and the above described phenomena of rock bursts in hard rock tunnels, rock bursts are to be expected in the massive gneiss of the Gotthard Massif. In the layered, highly faulted gneiss of the MFS Faido, these phenomena were not expected.

An extremely heterogeneous geology is present and could be regarded as a possible cause. Hard, brittle Leventina gneisses are situated next to more ductile Lucomagno gneisses. Through the nearly parallel orientation of the tunnel axis and the fragmented Lucomagno-gneisses, narrow rock wedges of Leventina-gneiss are locally formed. These competent wedges take on loads from the Lucomagno-gneiss which causes local stress concentrations that increase as excavation proceeds. At the same time the incompetent sections of Lucomagno-gneiss are prevented from unhindered pressure relief by the competent Leventina-gneiss. Stress concentrations in the Leventina-gneiss can lead to loads which exceed the rock strength accompanied by rock burst-type pressure release.

A prognosis of the rock burst risk was undertaken along with the envisioned measures for the entire MFS Faido. A rock burst information sheet and lists of progressive measures have been prepared. Specific dangers and the necessary actions are being determined in advance and are continually adapted as new knowledge is obtained during tunnelling operations.

In addition, excavation support measures are altered to meet the different levels of rock burst risk. Special yielding support elements are used to absorb dynamic loading, such as rock bolts (Swellex or Yielding Swellex bolts) and flexible steel arches.

The most powerful rock burst experienced at that time occurred on June 1, 2005 north of the cross-cavern. At the same time, instruments at the ETH Zurich Earthquake Service registered seismic activities that were not perceptible on the surface. This prompted efforts to investigate the correlation between the construction of the GBT and the resulting rock bursts as well as mini-tremors.

A work group "Mini-tremor" was formed. The goal of the work group is to develop measures for the tunnel to address the risks associated with mini-tremors.

A seismic monitoring programme with a total of ten seismometers around the MFS including one station on the surface above the MFS and one in the MFS is now attempting to determine whether there is a correlation between the MFS Faido tunnelling operations, pressure relief phenomena in the rock and the weak earth tremors in the Leventina. On March 25, 2006 an earthquake with a magnitude of 2.4 was recorded and at the same time a very heavy rockburst occurred in the MFS.

Important is to determine which dynamic and static loads are to be expected for the tunnel from the seismic events. The goal is to maintain the highest possible safety for tunnel construction and tunnel operations.

Based on the available results and the strength of previous tremors, the specialists believe that until now it was not possible to justify whether further reaching actions are necessary or not.

2.5 *Bodio*

Extensive construction work was realized at the southern Portal in Bodio before autumn 2002 in preparation for the heading of the main tunnel section. These were e.g. a bypass-tunnel (1.2 km) to bypass the very delicate and time-consuming loose rock zone at the portal, a 3.2 km long mucking tunnel and processing plants that recycle muck into concrete aggregates.

The past year was marked by good rates of advance. The lining operations are also forging ahead parallel to the excavations. In 2003 the roughly 600 m of equipment for the rear "inner vault" construction site assembled at the Bodio yard in front of the tunnel. The concreting of the lining support and of the lining itself was started in the west tube in April 2004. A specially designed vault formwork, which possesses some degree of adaptability, is being utilized. It is used to optimize the support taking into account any TBM deviations and the actually installed supporting elements.

After driving some 13.5 km and almost four years after starting out from Bodio the first TBM reached the MFS Faido in September 2006.

3 CONCLUSIONS

Construction of the GBT is preceding full speed ahead. Up to now all challenges were successfully managed. The unpredicted fault zones in Faido and Amsteg caused delays in the schedule but in the meantime they were overcome by applying suitable rock support systems.

As things stand today the GBT should be completed on schedule in the year 2015 and it will be a milestone for the realization of the New Alpine Transverse in Switzerland.

Amberg Engineering is member of the Engineering joint venture Gotthard Base Tunnel South with the partners Pöyry Infra Ltd. and Lombardi SA. We like to thank the AlpTransit Gotthard AG for the allowance to present this paper and to use some pictures from their homepage.

Innovative design and construction in Sydney's newest underground rail line

J. J. Rozek
Parsons Brinckerhoff, Sydney, Australia

ABSTRACT: The new Epping to Chatswood rail line will consist of 12.5 km of fully underground rail, constructed between 15 and 60 meters below the ground, and include four new underground stations. The project is the largest publicly funded infrastructure project to be built in New South Wales, Australia. The project represents an important precedent in Australia for underground rail and station design and construction in an urban environment. All four stations were excavated as mined station, three of them, Macquarie Par Station, Macquarie University Station and the Delhi Road station were excavated as caverns. The cavern stations were constructed with unique architecturally established asymmetrical arched roofs, with one side flatter than the other. This paper discusses many of the design and construction challenges and innovative solutions that were utilised to perform the excavation of this complex urban project enroute to meeting the project requirements and a 2008 opening.

1 INTRODUCTION

Sydney is the largest city in Australia, with a population of some five million people. Today, there are 1,000 people coming to Sydney every week. The need for transportation mobility is an ongoing challenge. There have been a number of underground transportation projects since the early nineties. The Epping to Chatswood is one of the most significant and is the first new rail start in Sydney in 80 years.

The 12.5 km AU$880 million (civil works) Chatswood to Epping underground rail link is the largest publicly funded projects in New South Wales history. The project is significant for its shear size and the rate at which design and construction was required to be performed. There was a need for close control of settlement and groundwater as the rail line excavation passed under residential, commercial, public areas and water bodies. Three of the most notable features are the underground stations at Macquarie Park, Macquarie University and Delhi Road. Each of these stations is excavated as caverns below significant urban activities at the surface. The excavated spans are amongst the largest performed to date in Sydney and probably internationally, and despite excellent Sydney Basin geology, posed significant challenges to the detailed design, including significant bedding and subvertical features in the sandstone, high insitu stresses up to 6 MPa, a lack of precedence of near surface wide span arch excavation in high stresses, a tight schedule and stringent surface settlement criteria.

2 GEOLOGY

The new rail line is located within the Sydney Basin. The majority of the route lies within well known Sydney geological formations – the Mid Triassic Ashfield Shale, Mittagong Formation and Hawkesbury (Sydney) Sandstone. Ashfield Shale is a dark grey to black shale and siltstone, which weathers to produce high plasticity clays. The Mittagong Formation marks the transition between the marine sequence of Ashfield Shale and the fluvial sequence of the Hawkesbury Sandstone. This formation is characterised by interbedded shale, laminite and medium-grained quartz sandstone. Hawkesbury Sandstone is a medium to coarse grained quartz-rich sandstone, typically with a strength of 35 MPa, with occasional minor shale and laminite lenses. The Hawkesbury Sandstone comprises massive, thick-bedded and cross-bedded strata in near horizontal layers. Most of the tunnelling occurred in Hawkesbury Sandstone, while the dive structures will be excavated predominantly in Ashfield Shale.

3 RUNNING TUNNELS

The tunnel TBM excavation works for the project were completed in July of 2005. It took almost two years to complete the excavation of the 12.5 km long, 7.2 m diameter twin tunnels, during which time over two and a half million tones of Hawkesbury sandstone were

excavated. One of the TBMs set a world record by excavating 92 meters in one day.

Design of the tunnel support system considered the risks of potential variations in geology in the development of the range of tunnel support systems. One of the most significant parameters providing an impact on design was the pre-existing in situ stress fields which influence tunneling conditions, and post excavation induced ground movements. Rock mass and rock defects, including shear strength, cohesion and friction values were developed on the basis of geotechnical information, data and testing. Published information and geological experience in the Sydney Basin were also used to develop rational design parameters.

The running tunnel support consisted of initial or temporary support. An array of six 2.7 meter long, 310 kN capacity, temporary full-resin-encapsulated rock bolts generally made up the temporary support. They were installed approximately 6 metres back from the face directly behind the TBM cutting head. About 110,000 bolts were used in the excavation of the two running tunnels. Sets were used as the excavation crossed the North Ryde fault zone, as very poor ground conditions were encountered. Ground support did not change from TBM No. 1 to TBM No. 2. However, from the detailed information of the geologic structures encountered by TBM No. 1, the geotechnical team was able to provide TBM No. 2 crew an accurate forecast on impending ground conditions.

The permanent lining for TBM excavation, was a circular formed, unreinforced concrete, nominally 200 mm thick, with a design strength of 32 MPa at 28 days. The concrete lining was the same for drained and undrained tunnels. The formwork consisted of six shutters, 15 metres long.

Waterproofing was achieved by installing hydrophilic waterstops in the joints. The long term steady state condition of the ground water was established by investigation and analysis, to meet the maximum inflow criteria of 0.1 L/sec/100 m of running tunnel and no visible water spotting on the interior of the lining. About 75% of the tunnel was constructed as drained. As the three creeks and the Lane Cove River were approached, forward probing was required to determine if grouting was required. The effects on ground water and settlement were monitored.

4 STATIONS

The distinctive station configuration for Macquarie Park, Macquarie University and Delhi Rd stations consists of an asymmetrical arched roof defined by the architects, with one side having a flatter arc than the other. It was designed to not only meet functional requirements, but also to enhance aesthetic qualities. The stations consist of 190 m long platform caverns that were 14 m high and 20 m wide. For these cavern stations, there is also a 50 meter long concourse caverns excavated adjacent to the platform caverns, also excavated as a arch. At either end of the Mac Park and Mac University stations, there is a 32 by 18 meter large service shaft about 30 meters below the ground. See Figure 1. The Delhi Road station has a slightly different configuration. The stations were located as close as 15 m below the existing ground surface.

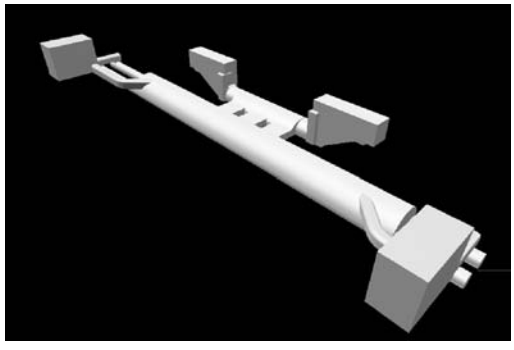

Figure 1. Isometric view of Macquarie Park station.

Each of the station cavern detailed design was developed which included excavation layout and dimensions, excavation sequencing, as well as permanent and temporary support of cavern excavations, shafts and related tunnels. Permanent waterproofing was performed for the caverns, shafts and related tunnels, including associated drainage was developed. Permanent lining of the station caverns, shafts and related tunnels, was also developed, including provisions for fixing points for subsequent works.

4.1 *Cavern design*

The design methodology for the principal components of the station caverns at Macquarie Park, Macquarie University and Delhi Road included an initial study of cavern shapes to determine the feasibility of large span arched caverns in these geologic conditions, and the relative costs when compared with the precedent practice of flat roof or trapezoidal sections. The study indicated that despite no precedence for long span arched construction in the Hawksbury sandstone, the architectural arch shape was technically and economically feasible. Numerical modeling was performed to investigate the rock mass response. The modelling was performed for the platform cavern alone, for typical and adverse rock conditions, and included excavation and support sequencing. Numerical modelling of the adjacent cavern configuration was performed to measure overall cavern stability and compliance with all relevant criteria. Analytical and numerical studies of secondary openings, junctions, passageways and service shafts were also undertaken. Permanent anchor

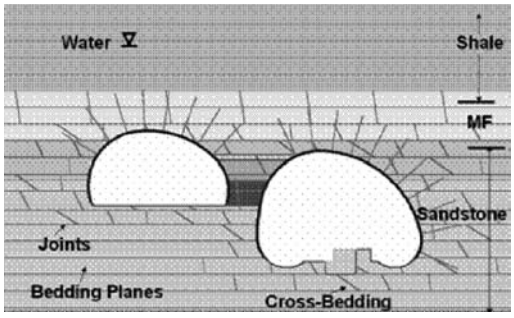

Figure 2. Simplified cross section of caverns in geology.

support and passive shotcrete arch construction were compared.

Preservation and utilisation of inherent rock strength were explicitly considered while analysing the cavern arches, the cavern and shaft interactions, the pillars, the excavation sequence with 3DEC and Phase2 software. Staged top heading excavation and timely installation of temporary and permanent rock reinforcement bolts combined with the observation and monitoring were the core principles of the design strategy for establishing a stable crown arch and haunch. Extensive numerical modelling was performed during the detailed design using state of the art practice 2D and 3D finite element and discrete element programs to evaluate rockbolt loads, bedding shear displacements, crown displacements, surface subsidence and shotcrete loads under various combinations of rockbolt types, (end anchored versus grouted), horizontal stresses, local bedding geology, and excavation sequence.

4.2 *Insitu stresses*

The natural insitu stress state of the rock mass had a significant impact on both tunnelling conditions and induced ground movements in the immediate area of the tunnelling works. The existence of significant and variable virgin stress field within relatively shallow rock is well established in Sydney.

A strategy was developed to deal with the potential for high loads and shearing stresses. The risk could best be managed through an observation approach, by establishing sufficient instrumentation from the surface and within the tunnel (in addition to normal convergence and surface monitoring), and to closely monitor the ground behaviour as the excavation progressed. The designers defined criteria upon which additional ground support would be triggered.

4.3 *Rock support*

In general, the station caverns were excavated in mainly competent, horizontally bedded sandstone and shales, although weaker weathered sandstone, and some shale, occurred above the crowns of the caverns at MP and MU Stations.

Precedent international and local practice indicated that large-span excavations in these conditions could be permanently supported using composite linings consisting of specified rock reinforcement in the form of rock bolts and shotcrete. The particular cavern geometries required the architectural arched profile be followed in order to minimise excavation. The proximity of adjacent major caverns required the station caverns to have specific detailed designs. See Figure 2, for a simplified cross section of the excavation. The bedding characteristics of the sandstone, and the potentially high local insitu horizontal stresses could be expected to lead to a rock mass response that developed predominantly horizontal crown beams, rather than conventional arching action. The crown beam response was strengthened where high horizontal stresses existed. Consequently, where large curved haunches were formed, the haunch rock and sidewalls could potentially experience significant shearing on the bedding planes, and fallout of blocks and wedge-shaped corbels released by the bedding planes and sub-vertical jointing. The roof support concept began with the basic assumption that the horizontal crown beam response was developed within the rock mass above the caverns. To retain the rock haunches, early support was required to sustain self-weight loading. The primary crown beam acts over the top of the haunches.

4.4 *Permanent lining, drainage and waterproofing*

The caverns were fully lined, as the internal surfaces of the permanent linings were required to be essentially dry. Since the caverns long term structural support was provided by permanent rockbolts, there was very little transfer of rock load to the linings. The permanent lining of the station caverns could therefore be of minimum thickness, consistent with constructability requirements, support of its own self-weight, the hydrostatic head of less than a 100% efficient drainage system and other considerations such as cover to rock bolt face plates and nuts. From consideration of the scale of the cavern roofs, the profiles, and programme requirements, the final cavern linings were determined to be shotcrete. The thickness was established at 120 mm thick for the platform caverns. The lining was integrated with the rock support elements by means of mechanical connections ('spiders') and which provided long-term security against minor rock fall from between the elements. The caverns were designed as drained structures, *i.e.* not subject to significant groundwater pressure. This was accomplished by a drainage system, which includes continuous

waterproofing membrane on the extrados of the lining so the internal surface of the lining remains dry throughout the design life. A sprayed membrane was selected over sheet membranes due to the requirement for architectural penetrations. The approach adopted for the caverns included a drainage fleece over the full excavated area supplemented by vertical strip drains at regular close spacings.

4.5 *Macquarie Park station*

The Macquarie Park station cavern design began in September 2002. It was carefully studied and was the proto type for the subsequent Mac University and Delhi Rd stations. Its design was based on modeling moderate and worst case geotechnical scenarios both as bedded and joined ground types, typical and adverse conditions. Results of insitu stress testing received January 2003 indicated stresses some 50% greater than had been anticipated at tender preparation time. Following careful consideration by the design team and external experts and specialists, it was determined that these unusually high results could not be ignored, and the design had to be adapted to accommodate the stresses and to investigate their impact. The higher stresses resulted in higher predicted ground displacements, particularly along thin beds of clay and other weaknesses in the rock which acted as shear planes. Of critical concern was the timing of the installation of the permanent rock bolt support. As the platform cavern was some 14 meters high, the cavern was excavated in a series of levels stating from the top. Installation of the permanent bolts was preferred from the top heading as the roof was easily accessible, however, there was the significant risk of having to rebolt the roof at a later date, as shear movements could occur during the subsequent lower bench excavation, or from the excavation of the significant service shafts or entry shafts adjacent to the caverns. As a result, the issue of rock bolt design and the timing of permanent rock bolt installation was a critical issue.

Permanent, corrosion-protected, fully grouted end anchored two stage and single stage rock anchors were the primary support mechanism for the MP cavern design. Over 1000 permanent rock anchors were installed in the platform area including some 340 two stage rock anchors. The array of rock anchors comprised 310 kN and 600 kN anchors. The approach taken for the MP cavern support design incorporated local precedence for example rockbolt lengths, and used a combination of numerical modelling, observation and monitoring, field adjustment as required and mandatory excavation and support sequence to arrive at the overall construction solution. See Figures 3, 4 and 5 for the excavation sequence at Macquarie Park station.

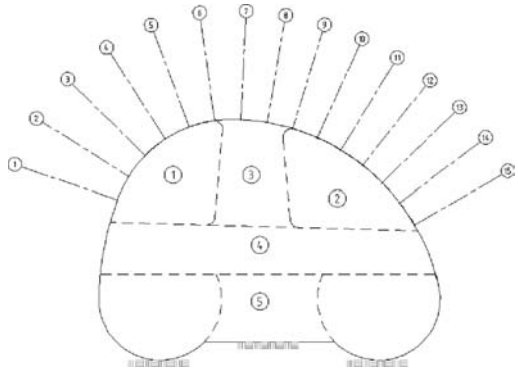

Figure 3. Sequence of exaction of platform cavern.

Figure 4. Excavation of first top heading drift.

Figure 5. Excavated top heading and intermediate bench.

4.6 *Macquarie University*

The initial design of the excavation sequence and ground support at Macquarie University station, was carried out using a geotechnical model developed in the light of geotechnical information available in the early stages of design. Further geotechnical investigations were conducted during the detailed design. There

were significant differences between Macquarie Park and Macquarie University stations, including the presence of significant clay beds in adverse locations in relation to the cavern crown and the permanent support at Macquarie University. These beds, in conjunction with the inferred high insitu principal stress across the caverns, were identified as shear movement concentrators which had the potential to either rupture the rock anchor anchorages or shear the anchors in the free length and to develop large extensional loads within the anchors themselves. The numerical modelling indicated that the primary agent mobilising these shear movements was bedding plane displacement associated with the stress relief induced from sinking of the shafts and the concourse excavation adjacent to the platform cavern after installation of the permanent support.

Because of the concern over the impacts on the cavern support, from both stability and anchor durability standpoints, there was a design prerequisite to dissipate stress relief if the shafts were sunk before the platform cavern excavation was supported with permanent anchors. The permanent rock support could be designed to take advantage of the reduced shears and anchor demands. However, based on schedule and access factors, and in order to avoid schedule delays to the cavern construction (which was driven by the need to have excavated and supported the crown before the TBMs came through), the decision whether to sink the shafts first was important. Equally important, the experience at the adjacent Macquarie Park station suggested that the ground behaviour might be more "benign" than the modelling had indicated and the support design had assumed. A relatively large amount of data had been collected from ground movement monitoring at Macquarie Park and it was considered appropriate to reassess the geotechnical design parameters used for the Macquarie University station modelling based on back-analysis of that data. Further to these considerations, the shafts were excavated first to minimise the risks.

The material costs of the rock bolts for the Macquarie University and Delhi Road station were reduced as the 2-stage bolts were replaced with single stage bolts as the service shaft excavation was performed before the cavern excavation so the permanent bolts did not experience the shaft excavations shear. As such, a "most probable" ground model was developed. This predicted lesser shear which allowed simpler anchors but required closer observation to ensure that corrective action could be taken if movements greater than predicted actually occurred.

4.7 *Delhi Road station*

Delhi Rd design was based on analysis of further stress testing (in late July, early August 2003), a re-assessment of the stress regime, an incorporation of observed movements, and a detailed geological mapping from 'exploratory' adits.

Although the Delhi Road station geology had the highest insitu stresses of the three stations, its geology was massive. The pervasive clay beds in Mac Uni station were not present at Delhi Road. As such the high stresses were locked in as they had no defined shear planes. Single stage bolts were also used pervasively as the permanent support.

4.8 *Monitoring*

The complexity of the geology and the possibility of higher insitu stresses than have been allowed for in the design led to the adoption of an observational approach to the construction and support of the works. An essential part of this process was the feedback, assessment and possible re-analysis based on monitoring the performance of the works as the station is constructed. Elements of the performance monitoring included:

- geological mapping to confirm the nature of the ground, i.e. exposed rock type, quality, prevailing jointing, shears and discontinuities;
- endoscopic inspections of proposed permanent bolt anchor zones in those areas where the design predicts significant localised shear displacements;
- ground movement monitoring in the form of convergence monitoring within the excavations, multipoint borehole extensometer monitoring in the crown, inclinometers and extensometers in the rock pillars and surrounding the shaft and cavern excavations, to monitor horizontal shear and vertical ground movements, and surface settlement monitoring;
- rock bolt load cells and/or strain gauges;
- endoscopic, up-borehole inspections to assess crown geology and to determine the locations and magnitudes of bedding shear movements in the rock anchor zones; and
- piezometers and groundwater inflow measurements to monitor groundwater drawdown and compliance with Deed requirements.

5 STATION DESIGN POSTSCRIPT

The three 'brain' caverns, although similar in appearance, were significantly different in the aspects that affect rock support.

The design of the three underground cavern stations was based on precedent design, factual geotechnical data, 2 and 3 dimensional computer modelling, empirical design, as well as the knowledge obtained from the ongoing construction, which allowed back analysis and refinement of design elements. The results

show that the work was highly successful. The surface settlement has been within the allowable levels permitted by the Deed and there was close correlation between the predicted movements and the actual movements. A key component of the design was the use of the observational method. It enabled the design to be implemented rapidly but required specific action, when pre-set trigger values were exceeded.

There was some appropriate conservatism in the Mac Park design, as exampled by the design of the rock bolts to accommodate the ground movement through any of four possible scenarios (moderate case, worst case, bedded and jointed) even though only one of which could occur at any one location. This approach was modified for Macquarie University station, based, based on back analysis of ground behaviour at Macquarie Park station. Instead, the design was based on a most probable scenario but with distinct clay beds, there was the higher risk of re-bolting. As the ground was behaving better than anticipated, the risk taking was successful. The observational method allowed the designers to specify bolts that would be lower in cost than ones that would be required to fully take the modelled loads and shears. Importantly, the allowable trigger levels for rock bolts were exceeded at both Mac Park and Mac Uni Station, which resulted in 108 temporary rock bolts were replaced in Mac Park, and a lesser number of permanent bolts in Macquarie University station. There were about 1500 temporary rock bolts installed in each of the three cavern stations, and about 2500 permanent rock bolts installed. In all, an appropriate design was provided at each of the cavern station. Adjustments were made based on the geologic conditions of the exposed rock, additional borehole data, back-analysis of measured deformations and movements observed during the initial works.

The Macquarie Park station design was successful. The measured settlement at the surface was 10 mm, well within the maximum allowable settlement of 40 mm. The maximum shear displacement was 14 mm. Macquarie University Station had a maximum measured shear of 29.5 mm. The largest shear seen by bolts was 16 mm. Delhi Rd. Station has had a maximum measured shear of 5 mm.

6 CONCLUSIONS

The design was successfully completed for the very large multiple arched profile spans of up to 20 metres and with relatively low covers which have never before been attempted in the jointed and bedded rock of Sydney Sandstone. The designs had to cope with the high horizontal residual rock stresses and planning consents which required minimal surface settlements and strict constraints on ground water ingress to the structures. As of July 2006, the concrete work was complete at Macquarie University Station. The station M&E is being outfitted. Concreting works at Macquarie Park and Delhi Road stations will be complete in early 2007 for the platforms, escalator shafts and stairwells, and work is progressing at the interchange station at Chatswood and at Epping to meet the 2008 opening.

In 2008, the Epping to Chatswood rail project will move more than 250,000 people a week and bring public transport to new suburbs housing 1 million people.

As a reflection of the success of the project, and the need for more rail service, the New South Wales Government announced it would invest $8 billion between 2005 and 2020, for the biggest expansion in Sydney's rail network since the 1930's. 25 kilometers of the 38 km expansion will be in tunnel, including stations.

ABSTRACT: Sio-Se-Pol bridge, built 500 years ago in Esfahan, is one of the most popular and historical bridges in the world. Due to this important fact the effects induced by probable subway tunneling during the passage of the tunnels under the bridge are studied in this paper. In Esfahan's jobsite two parallel tunnels with the diameter of 6.88 is under the process of excavation with two earth pressure balance TBM machines. Settlement is one of the most important effects that occur during underground excavation that may cause sever damage to the construction. In this study the tunnels and the bridge will be simulated by a two and three dimensional Finite element package (Plaxis 7.2 and 3D Tunnel) and then the effects of shield tunneling on Sio-Se-Pol bridge piles will be discussed.

1 INTRODUCTION

Esfahan is one of the historical cities of the world. Several historical monuments such as the ChaharBagh School and the Sio-Se-Pol Bridge are located in the centre of it where Esfahan's metro North-South line passes through. Esfahan's North-South line consisting of 21.2-km of twin tunnels is subdivided into two main tunnel sections namely the east tunnel (S-228) and the west tunnel section (S-227). There have been serious discussions between the City officials and the Cultural Heritage Organization on the tunnels alignment. The Cultural Heritage Organization is concerned about the tunnel's construction under the ChaharBagh Street and the Sio-Se-Pol Bridge. In this paper the effects of shield tunneling on the Sio-Se-Pol foundation are discussed using a three dimensional Finite analysis.

Many innovations have been introduced to improve tunneling in soft ground. At Present, the earth pressure balance (EPB) shield tunneling Method, which first was developed in Japan (Stack 1982; Maidl et al.1996), has become one of the most popular methods for soft ground tunneling. With this tunneling technique, ground movement can be, in theory controlled by balancing the pressure inside the earth pressure chamber relative to the outside ground pressure during excavation.

Two Herrenknecht Earth Pressure Balanced Shields are used for twin tunnel drives. The excavation diameter is 6.88 m (without over cut). The lining is pre cast concrete, composed of six segments plus one key

Figure 1. Esfahan Metro line network.

element. The inner diameter is 6.00 m and the exterior diameter is 6.60 m.

In order to analyses the stability of the overburden and to determine confinement pressures, model presented by (Mohkam 1989) has been used, the model considers a three dimensional potential failure surface. The phenomenon of arching effect, soil's mechanical parameters and physical characteristics, as well as muck conditioning in the working chamber have been taken into account.

2 GEOMETRICAL, GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

The overburden is more or less uniform and has about 8 to 8.7 m thickness. The soil formation is:

Fill; on top composed of fine materials with some coarse particles and building waste. The fill thickness lies in the range of 1.5 to 2.5 meters.

Fine Grained Alluvium; comprised of clay and silt of low to high plasticity. These deposits have brown to light brown color, and are mostly homogeneous and firm in place. Among the fine grained deposits, there are some lenses of coarse grained gravely deposits, which may be encountered at the tunnel face.

Coarse Grained Alluvium; predominately consisting of clean well graded/poorly graded (gap graded), very sandy gravel and/or very gravely sand. The soil particles are mostly rounded with 60 mm maximum grain size. These deposits are water bearing and dense in place.

According to the geotechnical investigation results, the following design data of the soil layers have been considered in designing of the tunneling parameters. In the section studied, tunnel's heading would run in the Coarse Alluviums.

The groundwater elevation is mainly related to the Zayandeh-Rud River. Records, since 1997, show the highest level on April and May of 1998 and lowest level at January 2002. The recent level (August 2006) is situated at some 2 meters above the surface.

3 SHIELD OPERATION FACTORS AFFECTING SURFACE SETTLEMENTS

Based upon case history reviews (Clough and Leca, 1993; Finno and clough, 1985; and Matsushita et al., 1995) and extensive observations in Esfahan Project, the shield operation factors causing settlements can be listed as bellow:

- Face Pressure
- Penetration rate
- Pitching Angle
- Tail void Grouting Pressure
- Percent Tail void Grout Filing
- Thrust Forces
- Soil Conditioning Agent
- Foam Expansion Ratio
- Foam Injection Ratio
- Polymer Presence in Foam

In this paper only the Tail void grouting pressure and the percent tail void grout filing is discussed.

4 TAIL VOID GROUTING

Quality of tail void grouting contributes to the extent of the ground settlement. As the shield is jacked forward, a tail void around the outside of the lining is created. Tail void grouting is necessary in order to prevent ground moving towards the void. In general practice, grouting pressure should be sufficient enough to guarantee the flow of grout material and to resist the ground moving into the void. Another criterion to check the grouting performance is percent grout filling that has

Table 1. Esfahan's Soil Parameters.

Soil type	Total unit weight KN/m^3	Horizontal coefficient of permeability m/s	Mohr-Coulomb shear strength parameters*	
			Cohesion KN/m^2	Angle of internal friction deg
Fill	18	10–5	15	23
Fine grained alluvium	19	10–8	30	25
Coarse grained alluvium	20	10–3	0	35

* Strength parameters are in terms of effective stress.

to be maintained at a level higher than the theoretical void. Another parameter is the grout mix. The grout mix should be given according to the geometrical, geological and Hydro geological Conditions of the region. Tunneling operation with an appropriate grouting pressure and sufficient percent of grout filling and also an appropriate grouting mix can considerably reduce settlements developed after the shield passing (examples: the WMTA project; Leca 1989; MRTA project; Suwansawat, 2002 and Esfahan project). Figure 2, shows an example of the actual grout pressure and executed grout pressure applied in Esfahan jobsite.

5 INSTRUMENTATION AND SURFACE SETTLEMENTS

Few surface settlement markers and extensometers were installed to measure settlements during excavation. The primary objective of the measurements with extensometers is to measure surface and subsurface settlements above the tunnel axes. Additionally, since readings were taken over time covering a period between shields approaching and after shield passing, extensometers also allow one to observe longitudinal sub surface settlement profiles and to study how they develop during shield passing.

From ring number 860 in the tunneling direction, arrays of settlement markers were installed to measure settlement troughs developing during and after shield passing. The layouts of arrays on one hand, concentrates the instrumentation above the tunnel alignment because this is where shield operators wanted to check on settlements, and on the other hand, place instrumentation adequately distant from the alignment to determine a zone of influence.

Thus, the main objectives of surface settlement array measurements are (1) to measure the extent of settlement during excavation, (2) to observe the shape of settlement troughs and the magnitudes of the displacements. Therefore, results from the instrumentation provide engineers with useful information to design appropriate measures for preventing damage to existing structures induced by EPB tunneling. Note that monitoring frequencies adopted in Esfahan project depended on the shield position. For example readings were taken everyday before and after shield passing but increased to higher frequency (i.e. every 2–4 h) during shield passing in order to capture the development of surface and sub-surface settlements. Note that large settlements occurred over the shield body behind the face. Subsequently, beyond this point, the settlement showed a small change after shield passing.

On ring number 866 (4147.2 kilometer of the alignment) a sewage pipe was observed at the depth of 6 meters. The sewage system of Esfahan was built 40 years ago by the Russians. Due to this critical situation for monitoring the settlements an eight meter long extensometer was installed before the sewage pipe. The extensometer has 4 rods that are in the depth of 1, 4.76, 6.76 and 7.76. Figure 3, shows the settlement recorded by the extensometer during the tunnels construction.

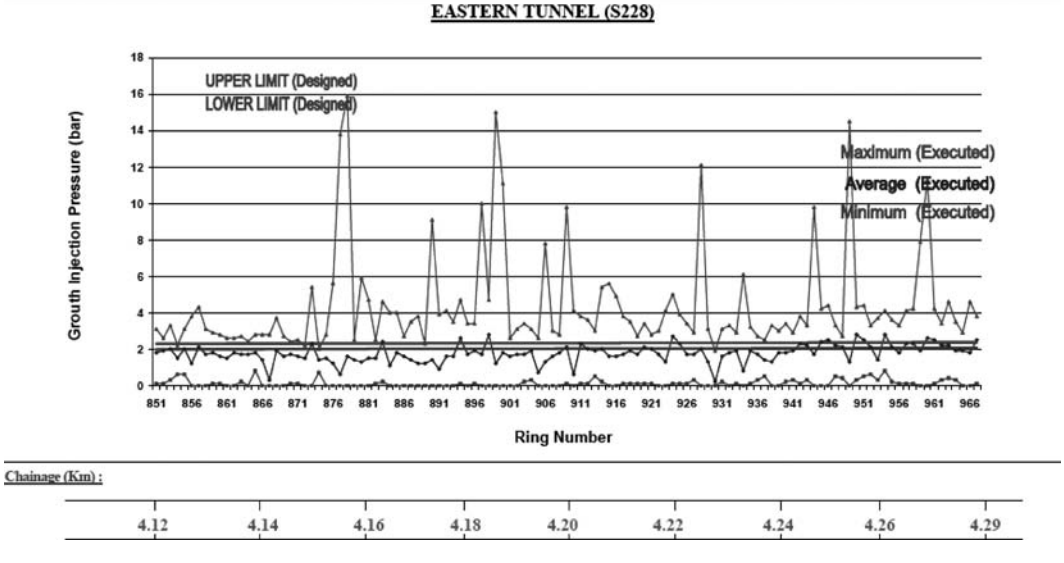

Figure 2. The Designed and executed grout pressures group 2.

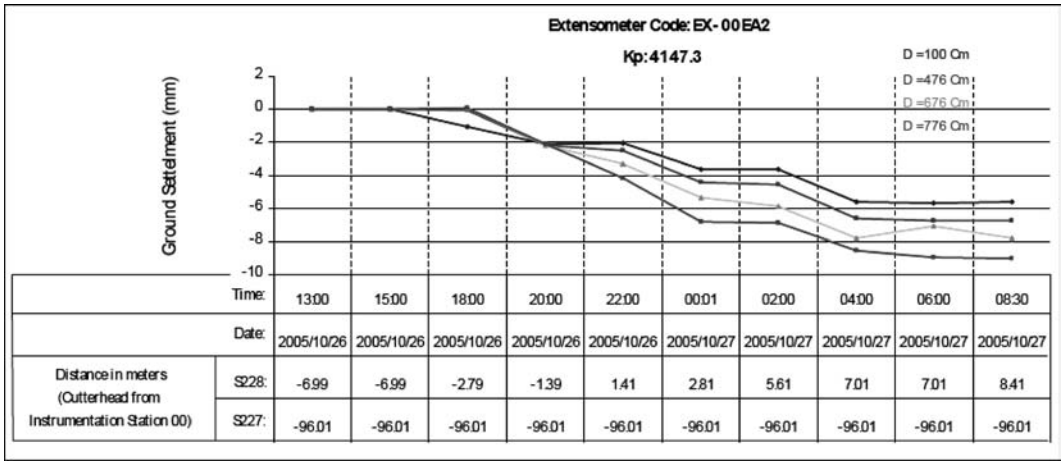

Figure 3. Settlment recorded by the extensometer.

Table 2. TBM properties used in 3D model.

Axial stiffness	Flexural rigidity	Equivalent thickness	Weight	Poisson ratio
KN/m	KNm^2/m	m	KN/m/m	–
8.2×106	6.17×104	0.3	32.7	0

Table 3. Segment properties used in 3D model.

Axial stiffness	Flexural rigidity	Equivalent thickness	Weight	Poisson ratio
KN/m	KNm^2/m	m	KN/m/m	–
9.4×106	7.06×104	0.3	7.2	0.15

6 SIMULATION OF EPB TUNNELING IN 3D TUNNEL PLAXIS

This model takes into account the following parameters: geometry, geology, the hydrological conditions, the TBM machine, the lining, excavation of the tunnels, applying the Tail void (Contraction), And the face support pressure. The TBM and Segment properties used in 3D Tunnel Plaxis are listed in Table 2 and Table 3.

7 BACK ANALYSIS ON THE MODEL

To calibrate the parameters of the calculations on the main model and to have an outlook of what exactly is happening in practice, a primary model was made based on the location where the extensometer was installed on ring number 866 (4147.2 kilometer of the alignment).

Several values of contraction are applied to the model and the settlement results are then compared to the settlement results obtained from the extensometer. The face pressure applied is exactly the same as the value used for excavation. Also a sensitive analysis was made on the soil strength parameters, cohesion and the frictional angle(C and Φ). Figure 4, shows the designed and executed face support pressure in the Instrumentation region.

7.1 *Back analysis results*

Due to the back analysis results the value of contraction should be near zero. This is achieved with an appropriate grout pressure injection and sufficient grout quantity for the tail void. Also it is shown that the strength parameters of the soil are in acceptable ranges.

8 SIMULATION OF SIO-SE-POL BRIDGE IN 3D TUNNEL PLAXIS

The Sio-Se-Pol Bridge built on the Zayandeh-Rud River is a 295 meter long 14 meter wide structure. It is constructed on a $295 \times 35 \times 2$ meters foundation. According to some resources it is built on a shallow foundation while due to some other resources it is possible that some kind of well foundation has been used for its construction .However the nature of the Sio-Se-Pol Bridge foundation is not clear. The bridge is made of stones and old bricks. It has been repaired several times.

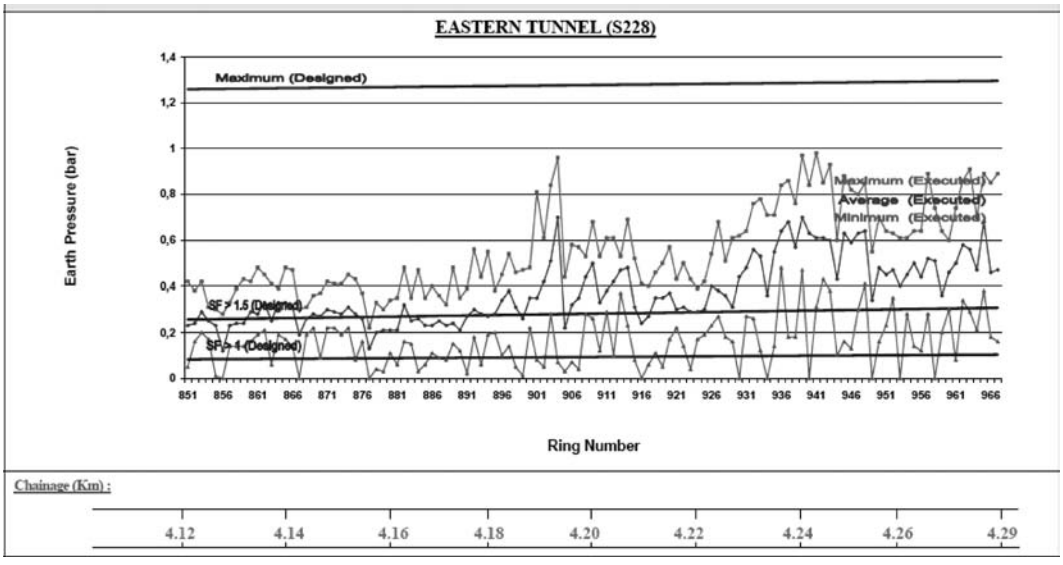

Figure 4. The designed and executed face support.

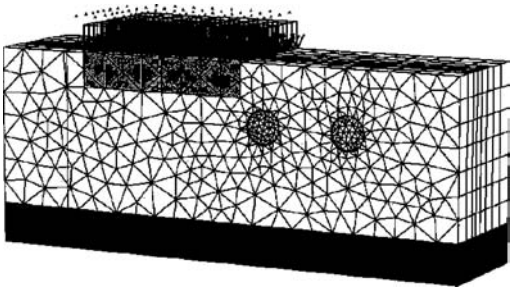

Figure 5. Sio-Se-Pol Bridge designed with a rigid foundation.

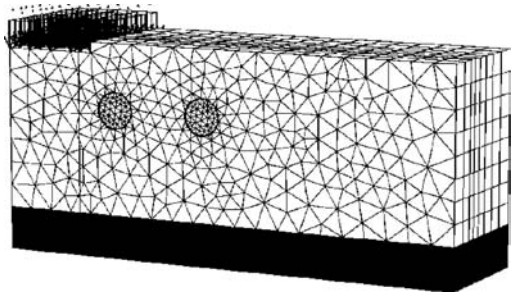

Figure 6. Sio-Se-Pol Bridge designed with a shallow foundation.

According to the above argument two different model of foundation has been used. First a rigid foundation with 7 meters depth Figure 5. And second a shallow foundation with two meters depth Figure 6. A 75 KN/m^2 force is applied on the rivers surface as the structures weight. The actual designed distance between the tunnel's axes and the bridge is 93.5 meters. This distance is reduced to the point where the settlements under the foundation are allowable. According to Iran's Heritage organization's principles for historical monuments the maximum allowable settlement amount for historical monuments is 2.5 mm. Also the contraction applied to the front plane is 1%. As mentioned before this amount could be reduced to near zero with an appropriate grout injection pressure and a sufficient amount of grout quantity. The earth pressure applied to the face for the crown of the tunnel in this section is 110 KN/m^2. The soil model used is Mohr-Coulomb Elasto-Plastic. The distance between the two tunnels axes is 17 meters.

It should be mentioned that all the parameters used for the modeling are selected in high ranges of conservative senses. Therefore the results achieved can be compromised.

After applying all the parameters to the model the distance between the foundation and the eastern tunnel axes is decreased each 10 meters from 93.5 meters (the actual designed distance) to 5 meters where the settlements exceed allowable values.

Four points are selected under the foundation. Point D is the nearest point to the tunnel axes. And point A is the most far. The settlement of these points is monitored in the software.

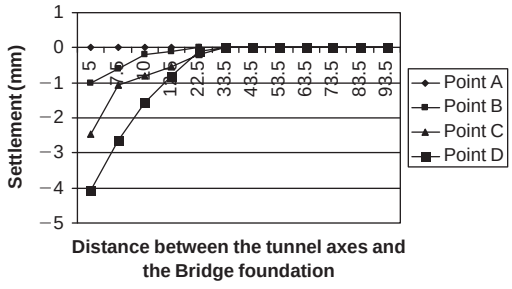

Figure 7. Settlement results of the rigid foundation.

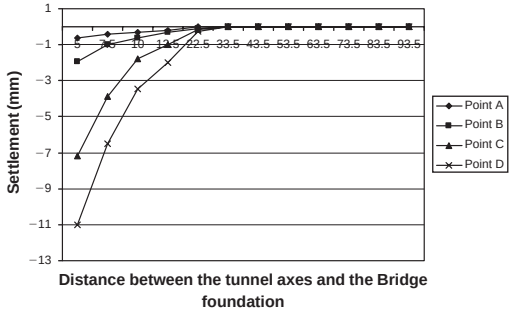

Figure 8. Settlement results of the shallow foundation.

9 RESULTS

9.1 *Settlement results of the rigid foundation*

In this case the results show that there is no significant settlement until the distance of the Eastern tunnel axes and the Bridge's foundation is 22.5 meter. From this point the settlements start to show up but they are in the allowable range until the distance is decreased to 7.5 meters. On this point, point D shows -2.629 mm of settlement which according to the limits is out of range and is not acceptable.

9.2 *Settlement results of the shallow foundation*

In this case as predicted before, the settlements are more intensities than the first case. The results show there is no significant settlement until the distance of the Eastern tunnel axes and the Bridge's foundation is 27.5 meter. From this point the settlements start to show up but they are in the allowable range until the distance is decreased to 12.5 meters. On this point, point D shows -2.5 mm of settlement which according to the limits is out of range and is not acceptable.

10 CONCLUSION

The back analysis method shows its capabilities to provide some vital parameters such as the contraction for evaluating the damage risks due to the excavation process by shield tunneling. As shown in this paper using a prediction and correction method based on a finite element method during the excavation makes a safe tunnel construction possible in very sensible and critical conditions. Also the closest safe distance of excavation near Sio-Se-Pol Bridge is determined.

Review of the project Uetliberg Tunnel

A. Sala
CEO Amberg Engineering Ltd. and Deputy Overall Project Manager Uetliberg Tunnel,
Civil Engineer FH, Amberg Engineering Ltd., Regensdorf-Watt, Switzerland

ABSTRACT: On May 18, 2006 the tunnel bore extender (TBE) finished successfully the enlargement of the second pilot tunnel. This signified that all excavation work had been successfully concluded for the Uetliberg Tunnel. Also the interior lining work has already been finished by now. At the moment all the electromechanical equipment is being installed. This is an ideal point of time for a review, first of all about the TBE driving.

1 PROJECT OVERVIEW AND GEOLOGY

1.1 *Project overview*

The Uetliberg Tunnel in Switzerland is the longest tunnel in Zurich's new Western Bypass Expressway.

The project comprises two parallel tubes, each about 4.4 km long. The two tunnel tubes are connected every 300 m by a transverse walkway and every 900 m by a transverse roadway. The SOS niches are spaced 150 m apart. The total cost will be about CHF 1.12 billion (price basis October 1994).

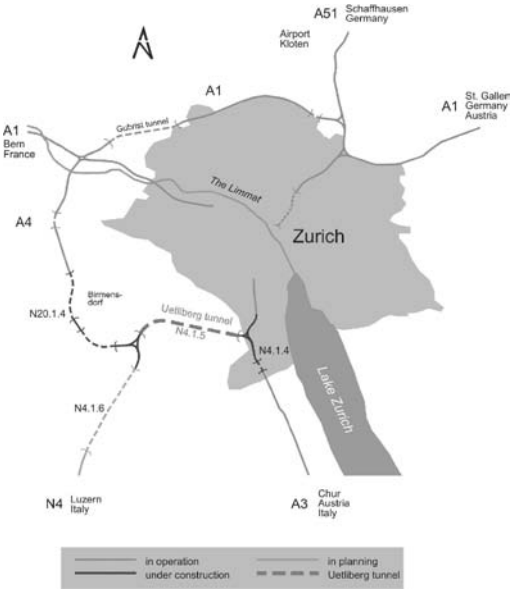

Figure 1. Project overview of the Uetliberg Tunnel.

1.2 *Geology*

From west to east, the Uetliberg Tunnel passes under two parallel ranges of hills (Ettenberg and Uetliberg) with the Reppisch Valley in between. The core of both ranges consists of flat layers of the upper fresh water molasse and alternating deposits of sandstone and soft marl. Maximum overburden of the tunnel under the Uetliberg is about 320 m.

Before the molasse sections of Eichholz (500 m) and Uetliberg (2800 m) were reached, three sections of soft ground (Gjuch, Diebis and Juchegg) had to be driven.

2 CONSTRUCTION PROGRAM AND PROCEDURES

From the Reppisch Valley construction site, the rock tunnel excavation was driven downwards under the Uetliberg to the Zurich-South motorway interchange.

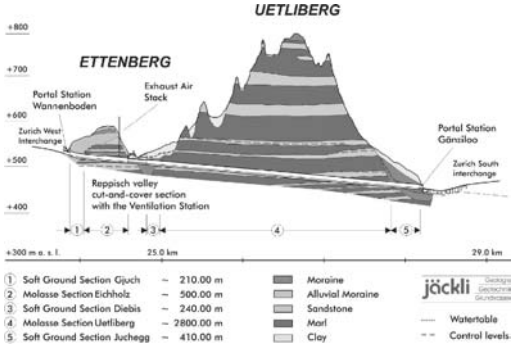

Figure 2. Geologic profile along the Uetliberg tunnel.

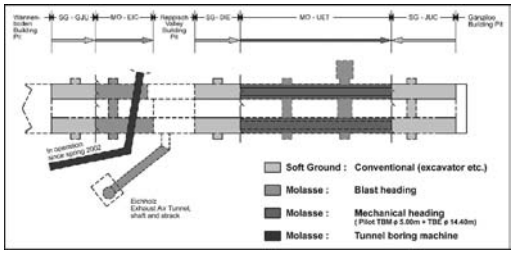

Figure 3. Heading methods of the Uetliberg tunnel.

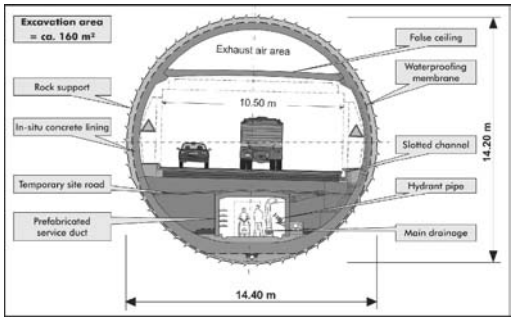

Figure 4. Standard cross-section of the TBE-section.

Figure 5. Core method for all soft ground heading.

This work was preceded by the excavation of soft ground sections using the core construction method in both tubes over distances of 250 m and 350 m from April 2001 to May 2002. At the end of the soft ground excavation at Diebis, starting caverns were excavated in the molasse under the Uetliberg for the tunnelling machine operations to follow in both tubes.

At the beginning of April 2002 an open pilot tunnel boring machine (TBM) Type Wirth TB III 500 E (diameter 5.00 m) was installed in the first tube. After starting in the middle of May 2002, the TBM drove the entire Ueltiberg molasse section. Since the beginning of May 2003, a tunnel bore extender (TBE) Type Wirth TBE 500/1440 using the undercutting technique has been traversing this entire molasse section under the Uetliberg to extend the centered pilot tunnel bore to the final profile of 14.10 to 14.40 m. Simultaneously with this bore extension, work has proceeded on driving the other pilot tunnel in the second tube untill the end of 2003. Afterwards this pilot tunnel was enlarged to its final profile by the same bore extension procedure.

Starting from the Gänziloo pit, excavation has been proceeding since February 2002 in the two 450 m long rising tubes through the soft ground of the Juchegg section. In both tubes, the first 50 m were driven through Uetliberg loam with pipe screen protection, likewise using the core construction method.

Since the beginning of April 2002, work has also proceeded on the downward tunnel starting at the west portal (Wannenboden) and leading under the Ettenberg towards the Reppisch Valley excavation site. The first hurdle here was the Gjuch soft ground section with a length of 220 m. It is followed by the 500 m long Eichholz molasse section, which was excavated by drill and blast and ripping.

3 TUNNEL CROSS-SECTIONS

3.1 *Soft ground sections and Eichholz molasse section*

The horseshoe cross-section used in all of the soft ground sections (SG) and for the drill and blast excavation in the Eichholz molasse section (MO-EIC) is about 14.70 m wide and about 12.70 m high. The face area is roughly 143 to 148 m^2.

3.2 *Uetliberg molasse section (TBE)*

The standard cross-section for the Uetliberg molasse section (MO-UET) is 14.40 m wide and 14.20 m high. The face area is about 160 m^2. Figure 4 shows in detail the elements of the tunnel cross-section.

Waterproofing, concrete invert, service duct (prefabricated elements), a cable conduit block and side backfilling were installed beneath the back-up equipment behind the TBE suspended from rock bolts in the ceiling. The concrete ring of the inner shell and the intermediate ceiling were installed successively later on in the rear areas.

4 SOFT GROUND HEADING WITH THE CORE METHOD

All soft ground sections were driven with the core construction method, shown in Figure 5.

Normally, temporary support measures consisted of steel arches (HEM 180 girders spaced 1 m apart) and a 25 cm thick layer of steel fiber reinforced shotcrete.

Figure 6. Excavation of the Eichholz molasse section.

After about two years of construction and the installation of 10,000 tonnes of steel, it is now possible to issue a positive progress report. During this two year period, about 1800 meters of tunnel has been driven successfully through soft ground. The excavation rate specified in the contractor's bid, 1.2 m advance per day over the entire cross-section was achieved and even exceeded. The systematic installation of steel supports has made it possible to organize efficient and predictable tunnelling progress practically free of unpleasant surprises and complications (first of all without a cave-in) despite these exceptionally heterogeneous geological formations. Overall support at the working face and support of the partial cross-sections was insured at all times with face anchors and cement injections.

5 DETAILED DESCRIPTION OF DRILL AND BLAST AND MECHANICAL HEADING IN THE UETLIBERG TUNNEL

5.1 *Drill and blast excavation of the Eichholz molasse section*

The 500 m long Eichholz molasse section was excavated by drill and blast with round lengths of 3 m, divided into crown, bench and base. Rock support generally consisted of mesh reinforced shotcrete and rock bolts. Initially, the tunnel crown was driven over the entire length of the molasse stretch. As soon as breakthrough of the crown was achieved, work started on excavation of the core and the base (by pneumatic pick and roadheader).

5.2 *Pilot tunnel in the Uetliberg molasse section*

The TBM for the pilot tunnel bored two 5.00 m diameter tunnels in both tubes.

Rock support used consisted of steel fiber reinforced shotcrete and glassfiber reinforced rock bolts

Figure 7. TBM-excavation of the pilot tunnel.

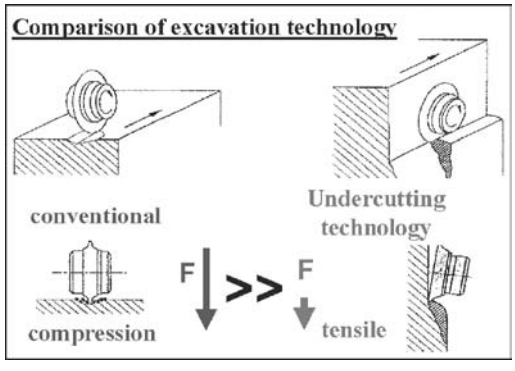

Figure 8. Principle of the undercutting technique.

2.5 m long. The peak rate of advance was 42.6 m/workday in three shifts. The average rate over the entire section was 20 m/workday.

5.3 *Tunnel bore extender (TBE) in the Uetliberg molasse section*

Starting in November 2002, the TBE was assembled in the Diebis soft ground section and in the starting pit. The rock was excavated with the undercutting technique, known to be an effective cutting method ever since the early days of tunnel boring machines. With this technique, the cutting rollers worked against the rock's tensile strength, which is much lower than its compressive strength.

The TBE enlarged the pilot tunnel of 5.00 m to a diameter of 14.10 to 14.40 m. The head of the TBE consisted of a two piece cutterhead body with six cutter arms. It rotated on the inner kelly, which was braced and positioned in the pilot tunnel and in the extended tunnel cross-section. The cutters, which were offset both axially and radially from the tunnel axis, were mounted on radially movable slides on the cutter arms.

When the six arm boring head rotated, the rollers were shifted from an inner to an outer boring diameter. When the nominal boring diameter was reached, the

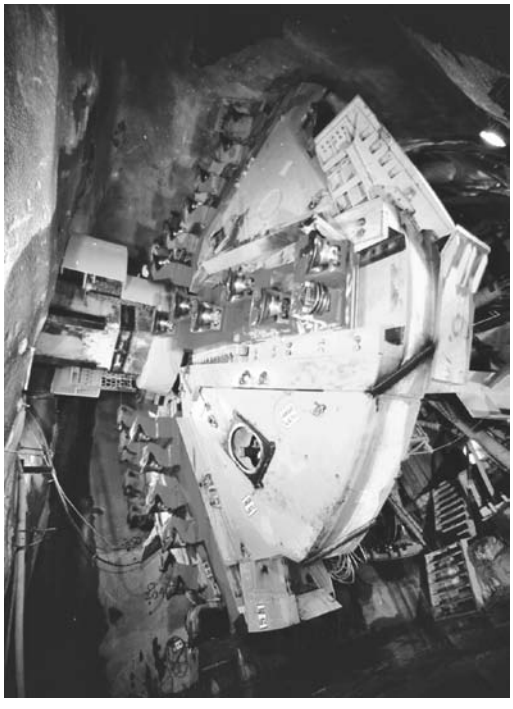

Figure 9. The TBE boring head.

slides were retracted. Then the continuously rotating head was shifted by one 20 cm advance towards the face, and boring of the next round could begin.

Excavation support, comprising cable bolts, Swellex rock bolts, nets and shotcrete, was installed right behind the cutting head.

The erection of the TBE with its back-up equipment had a total length of about 180 m.

6 EXPERIENCES WITH THE TBE-DRIVING

6.1 *Back-cutting technology*

The successful enlargement of the two tubes showed that the back-cutting technology functions well. It was possible to reduce the energy output by some 50% through working against the rock's tensile strength rather than its compressive strength. When passing a previously excavated cross-passage it was possible to observe the back-cutting process (Figure 10).

The offset traces of the cutter rollers could clearly be identified on the face as well as the exact removal of material in accordance with the profile. Dust, vibrations and water meant that the complex electronic control facilities in the cutterhead, which were installed for the back-cutting technology, had to be maintained intensively. Even when individual cutterhead components failed, which meant that only three of

Figure 10. TBE-cutterhead passing an accessible cross-passage.

the six cutter arms could be extended, it was still possible to continue excavating. Through ensuring that the diverse technical components for the cutterhead were set up in a redundant manner for the second tunnel tube, the TBE's availability could be constantly geared to a high level albeit with a substantial maintenance requirement. As the forces in each case act in a diametrically opposed manner when the slides with the roller bits are extended radially and consequently nullify each other, only slight forces are generated from the main bearing. The abolition of the major contact forces (thrust) and the related high torque loads on the tunnel boring machine was also positive.

6.2 *Block-form of the excavated material*

The block-form of the backcut excavated molasse material (flat lying sandstone and marl layers) differed considerably from the chip form of traditional TBM drives. The grading curve of the material is more similar in fact to that of a drill and blast operation. On account of its larger block-form the material had to be reduced at the end of the back-up by means of a crusher in order to adhere to the maximum permissible edge length of 30 cm for conveyor belt transportation. A powerful dedusting plant together with its casing was installed at the crusher to protect the crew's health. The resultant block-form made it possible to reutilise the excavated material for backfilling at both sides of the service duct after sieving and adding a hydraulic binder.

6.3 *Possibility of overcutting*

A circular profile of 7.0 m radius was excavated by the roller bits on the six radially extendable cutterhead slides. Thanks to the three additional extendable roller bits (Figure 11) installed in the cutterhead an overbreak with a maximum radius of 20 cm could be attained in order to provide more room for supporting the

Figure 11. Overbrake roller bit on the TBE cutterhead.

Figure 12. Excavation support in L1 of the TBE (with spalling above the cutterhead).

excavation. The overbreak was only required in the vault area because the completed base invert was placed some 80 m behind the face so that the temporary excavation support there could be reduced. Thanks to targeted overbreak, it was on the one hand possible to save on material transport and on the other on concrete and backfill requirements.

6.4 *Applied supporting media*

The supporting friction bolts that were used for overhead protection could be installed at the earliest some 4 m behind the face slightly inclined forwards and 4.5 m behind the face vertical to the tunnel axis.

In zones with geological overbreak for example on account of the molasse's horizontal bedding, it was possible to react flexibly at local level to spalling thanks to the chosen support system (friction and rope anchors, netting and shotcrete, Figure 12). In this connection, the anchors and netting were placed in the cavities that ensued and subsequently filled with shotcrete. Where potential areas of spalling were identifiable (e.g. coaly base levels) additional anchors with $l = 3.60$ m were placed in addition to the anchorage system ($l = 5.0$ or 6.0 m in a 1.20×1.20 to 1.50×1.50 m grid).They were set up in such a way that they penetrated possible areas prone to spalling that were identified in order to additionally nail the fissured zones. A row of the anchor system was installed every 1.20 tm in such geologically tricky zones and a row of additional anchors offset by 0.60 m placed every 1.20 m.

This flexible system of rock support did stand the test. However it demanded of all the involved a high attention and a professional competence to react correctly and in time to the identified hazard scenarios.

6.5 *Deformations of the rock support*

The deformations measured (3D convergence measurements following installation of the support means

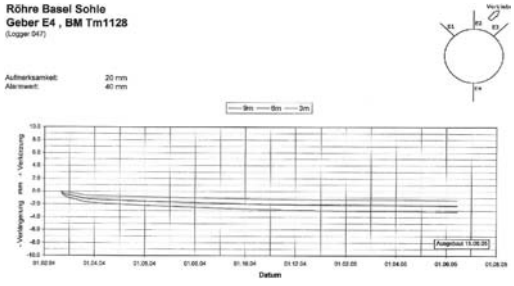

Figure 13. Maximal deformations of the base in the molasse (extensometer).

were of about 1–2 cm. The deformation occurred around the entire vault periphery, mostly radial to the excavated surface towards the cavity.

Extensometers in the base showed normally about 1 mm of enhancement, at most 3 mm because of swelling after contact with water (Figure 13).

6.6 *Ventilation*

As far as the TBE application was concerned the prior production of the centric pilot tunnel represented a prerequisite in order to provide pre-tensioning for the enlargement. Alongside some invaluable geological findings from the pilot tunnel excavation, the pilot tunnel served for surveying purposes during the TBE drive and especially for ventilation. The dust that occurred during the drive or rather during the drilling of the anchors (dry) was suctioned off by fans stationed at the end of the pilot tunnel, cleansed by means of dedusters and released into the open. As a result, it was possible to largely minimize dust nuisance in all TBE working sectors.

6.7 *Rates of advance*

In 2003, the TBE drive was executed by means of a two-shift operation (driving 7.00 a.m. till noon and 1.00 till

Figure 14. Service duct and backfilling behind the TBE.

10.00 p.m.) with residual supporting and maintenance taking place from 11.00 p.m. till 3.00 a.m.) during a five-day week. Weekly rates of some 20 m were attained. The maximum daily rate amounted to 12 m.

Since early 2004, work was carried out on a three-shift basis (for schedule reasons), with supporting and maintenance operations being undertaken during the reduced third shift (driving from 6.00 a.m. till 10.00 p.m. continuously, with residual supporting and maintenance jobs taking place between 10.00 p.m. and 6.00 a.m.). As a result of this measure, average weekly rates of advance of some 40 m were arrived at, with maximum weekly progress of 63.5 m. The maximum daily rate of advance amounted to 16.5 m per work day. At the same time the entire base area was tackled in the back-up zone simultaneously with the drive (base invert, service duct and backfilling).

On the basis of the three-shift operation, the average rate of advance for the entire cross-section amounts to approx. 29 m/week (including the pilot tunnel and the completion of the base area in the back-up zone).

7 OUTLOOK

At the moment all the electromechanical equipment is being installed in the tunnel. Finished this installations the functioning will have to be checked.

It is planed to open the Uetliberg Tunnel for traffic at the end of 2008.

ABSTRACT: The Tokyo Electric Power Company (TEPCO) planned the construction of a gas pipeline connecting a TEPCO LNG base located on the east shore of Tokyo Bay with another on the west shore, in order to supply LNG to its thermal power stations on the Tokyo Bay coast more flexibly and efficiently. As part of this project, a shield tunnel was built to house the 18-km section of the pipeline that crosses Tokyo Bay. The construction of shield tunneling was that each slurry shield machine starts tunneling from each side of shore of Futtsu and the opposite Higashi-Ohgishima, and the two shield machines meet midway beneath the seabed of Tokyo Bay. Each shield machine is required to tunnel a distance of 9.0 km, of world-class long tunnel. This paper reports on the planning and construction of the shield tunnel.

1 INTRODUCTION

The location and cross section of the tunnel are as shown in Figure 1. The internal and external diameters of the shield tunnel are 3.0 m and 3.44 m, respectively.

The following is a chronological summary of the construction of the tunnel:

- In November 2003, shield tunneling from the Chiba side (east side) was started (called the "Futtsu" section).
- In February 2004, shield tunneling from the Kawasaki side (west side) was started (called the "Ohgishima" section).
- The shield machine from the Chiba side completed the excavation of the Futtsu section (9,030 m) and reached the docking point in March 2005, and the shield machine from the Kawasaki side completed the excavation of the Ohgishima section (9,030 m) and reached the docking point in July 2005.
- After 5 months of underground docking work, the tunnel was completed in December 2005.

The most challenging parts of the construction of the tunnel were (1) to ensure that the shield machines could withstand excavation of 9.0 km tunnel, (2) to ensure high-speed tunneling at a steady rate of more than 500 m per month and (3) to successfully complete the mechanical underground docking operation under a high water pressure of 0.6 MPa.

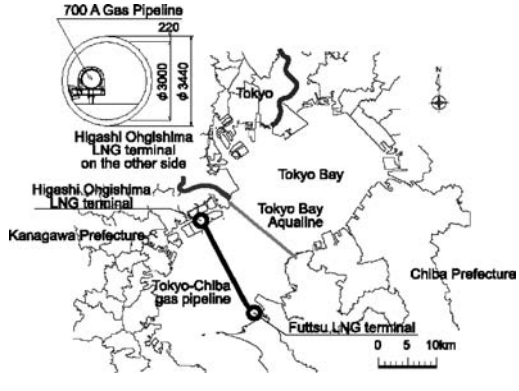

Figure 1. Location and cross section of the tunnel.

The following chapters describe the planning and construction of the shield tunnel in detail, focusing on these three points.

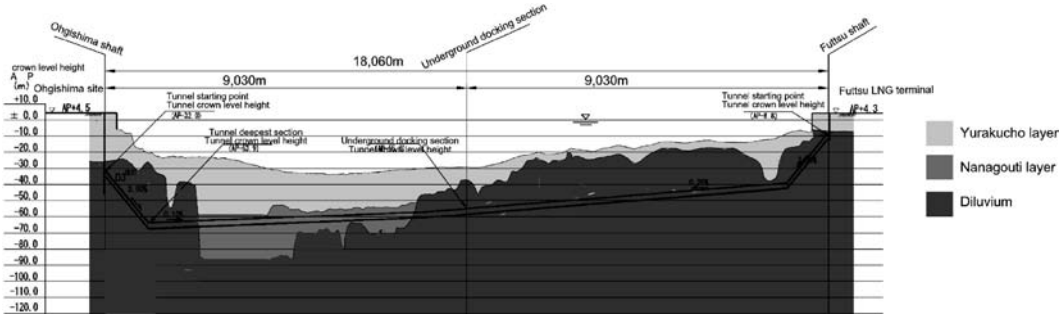

Figure 2. Supposed geological structure of the construction site.

2 OVERVIEW OF THE GEOLOGICAL STRUCTURE AND THE TUNNEL PROFILE

Figure 2 shows the geological structure of the construction site, which was estimated by the past survey records in surrounding areas including "the Tokyo Bay Aqua-Line" and the periphery of this and sonic prospecting conducted in Tokyo Bay. An estimated profile is used because it is difficult to conduct boring surveys in the construction area due to the heavy sea traffic in Tokyo Bay.

To ensure the stability of the tunnel against earthquakes, the tunnel profile was designed so that the tunnel run through the Nanagohchi layer and diluvium and no part of the tunnel is located in the soft Yurakucho layer. As a result tunnel gradients are ranging from 0.1% to 0.3%. In addition, it was expected that this profile design would subject the shield machines to a water pressure of 0.67 MPa at its deepest part. This was a tough environment for shield tunneling. The alignment of the entire tunnel is a straight line, except for one curve with a radius of 4,000 m located in the Futtsu section.

3 PLANNING AND CONSTRUCTION OF THE LONG-DISTANCE SHIELD TUNNEL

It was expected at the outset of the project that the construction of the tunnel would involve many risks, because (1) each of the two shield machines would be required to excavate a 9.0-km section of the tunnel, (2) most of the two sections of the tunnel had to be constructed in a high water pressure condition beneath the seabed, and (3) There would be uncertainties in geological condition. In addition, the specified construction period required high-speed tunneling at a rate of 500 m or more per month.

All possible risks associated with the design and construction phases were identified and measures were taken to minimize or eliminate these risk. In addition, backup measures were prepared in case of a critical problem. The following sections describe the durability enhancement measures taken for the cutter bits, which is easy to be worn away and damaged when used continuously in long-distance tunneling difficult to be repaired or replaced.

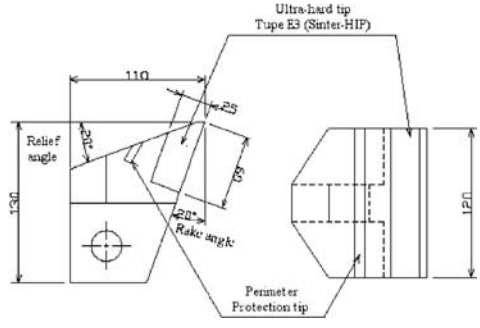

Figure 3. Shape and dimensions of main bit (Futtsu section).

3.1 *Durability design of cutter bits*

Because the shield tunnel is a small-diameter tunnel with an external diameter of 3.6 m, it was practically impossible to equip the shield machines with a cutter bit replacement mechanism. It was therefore decided to plan and implement measures to allow the shield machines to excavate the respective 9-km tunnel sections without bit replacement.

Tips made of a type E3 material (equivalent to Sinter-HIP), which has high abrasion resistance (hardness) and shock resistance (transverse rupture strength), were attached to the cutter bits. Figure 3 shows the shape and dimensions of the main bit for the Futtsu section. The tips were attached to the bits using the plate-style attachment method, which allows a larger surface area as the cutting edge.

The leading bits were deployed on the same path, to reduce the abrasion load on the main bits. Multi-tier shell-type leading bits, which are highly durable and suitable for excavation of hard soils and gravel layers,

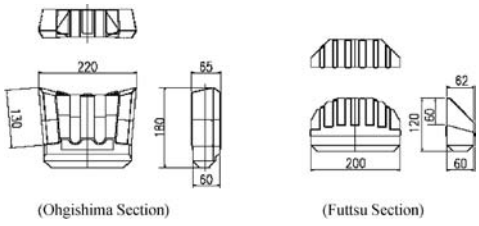

Figure 4. Shape and dimensions of leading bit.

were attached to the shield machine for the Futtsu section, and large-sized leading bits were attached to the shield machine for the Ohgishima section (Fig. 4).

The expected amount of abrasion of a cutter bit can be calculated from the following formula:

$$\delta = k \cdot \pi \cdot D \cdot N \cdot L/V$$

where, δ: expected amount of abrasion (mm), k: abrasion coefficient (mm/km), D: external diameter of the shield machine (mm), N: number of revolutions of the cutter (min^{-1}), L: tunneling distance (km), V: tunneling speed (mm/min).

The abrasion coefficient was determined individually for each soil type from bit shape-specific records of past tunneling projects, taking into account the height difference between the leading bit and the main bit. This resulted in lesser calculated expected amounts of abrasion of the outermost main bits (with the largest sliding length) than the allowable amounts of abrasion (26 mm, 30 mm), which meant that the designs would allow the shield machines to excavate the respective 9-km sections without suffering excessive abrasion.

3.2 *Other measures*

Although the calculated expected amounts of abrasion were based on records of actual past tunneling projects, they were still estimates, and so the actual amounts of abrasion could have turned out to be significantly different from the estimated amounts. It was also possible that unexpected abnormal abrasion might occur. To protect against these risks, the following measures for the bits were taken in addition to backup measures.

To prevent cutter bit abrasion due to excessive sliding, a system was adopted which could automatically adjust the cutter revolution speed to the tunneling speed to keep the bit penetration depth constant.

In addition, the design of the shield machines was modified to allow the excavated material to be taken in more efficiently (including elimination of the cutter perimeter rings), because the amount of abrasion of a bit is closely related to the amount of excavated material that remains on the cutter disk surface. As a result of these modifications, a cutter aperture rate of 42 to 43% was achieved, which was higher than that of existing slurry shield machines.

Table 1. Measured maximum amounts of abrasion of the outermost bits.

		Leading bit		Main bit	
		Expected	Measured	Expected	Measured
Futtsu section	Amount of abrasion (mm)	61.3	31.0	18.6	4.0
	Abrasion coefficient ($\times 10^{-3}$ mm/km)	14.8	6.61	4.48	0.85
Ohgishima section	Amount of abrasion (mm)	80.1	19.0	15.7	0
	Abrasion coefficient ($\times 10^{-3}$ mm/km)	23.2	3.72	4.55	0

3.3 *Results*

After completion of tunneling, the shield machines were disassembled and the bits were inspected to confirm the amounts of abrasion. Table 1 shows the results. The abrasion coefficient values in the table are averages over the tunneling distances. The actual amounts of abrasion of the leading and main bits of both shield machines were significantly smaller than the expected amounts of abrasion. This is due to the fact that considerably larger portions of the lengths of the two sections (than originally estimated) lay in soil layers consisting predominantly of cohesive soils. It is also considered that the main bit protection effect of the large-sized leading bits, as well as the design modifications to allow the excavated material to be taken in more efficiently, helped reduce abrasion by reducing the cutting load.

4 MEASURES TO ENSURE CONSTANT HIGH-SPEED TUNNELING AND RESULTS

To achieve an average tunneling rate of more than 500 m per month, measures were taken to enhance the levels of performance and availability of individual systems and facilities.

4.1 *Performance enhancement measures for the shield machines and individual systems and facilities*

The tunneling capacity of a shield machine is largely determined by its advancing speed. The shield machine for the Ohgishima section was designed to be capable of advancing at a speed of 70 mm/min. and that for the Futtsu section at 90 mm/min. Table 2 shows the specifications of the shield machines.

Measures were also taken to enhance the performance levels of individual systems to help the shield

Table 2. Summary specifications of the shield machines.

		Ohgishima section	Futtsu section
External diameter		ϕ3,590 mm	ϕ3,620 mm
Total length		11,645 mm	12,180 mm
Shield jack	Thrust × Number of jacks	1,680 kN/jack × 20	1,225 kN/jack × 18
	Length	2,550 mm	2,000 mm
Jack extension/contraction speed (when all jacks are in operation)	Pushing	70 mm/min	90 m/min
	Pulling	1,500 mm/min*1	450 mm/min
Cutter torque		560–805 kN•m ($\alpha = 12.1$–17.3)	674–1,013 kN•m ($\alpha = 14.2$–21.4)
Number of revolutions of the cutter		1.93–3.0 rpm	0.6–3.0 rpm
Driving system		Hydraulic	Hydraulic

*1: When 7 jacks are in operation.

machines constantly advance at the design speeds. The system to transport segments through the tunnel was designed to be capable of running three battery-driven trucks coupled together with each truck carrying segments for two rings or six battery-driven trucks coupled together with each truck carrying segments for one ring, at a maximum speed of 11 km/h. In addition, a facility capable of fully loading a train of trucks with segments/slabs at a time and a facility capable of fully unloading a train of trucks of segments/slabs at a time were constructed under the vertical shaft in the Futtsu section and at the face areas, respectively.

The slurry transport and slurry treatment systems were designed to be able to handle both a 100% sandy soil cross section and a 100% cohesive soil cross section, in order to accommodate uncertainties in geological condition of the construction site. In addition, the slurry transport systems were designed to have two or three intermediate bypasses to reduce losses in the event of a start-up failure, etc.

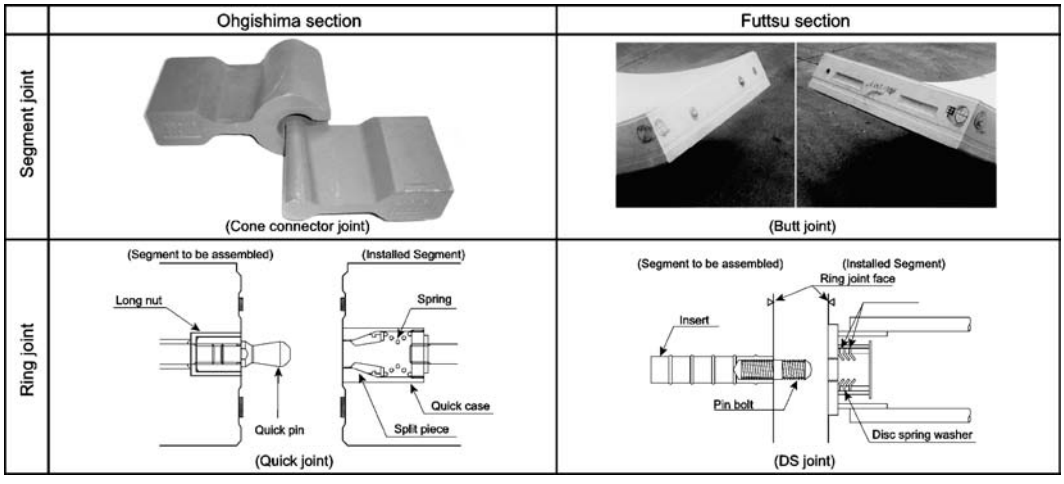
4.2 *Segment type*

Efficient segment assembly is also essential for high-speed tunneling. To achieve a highly efficient segment assembly process, segments for the Futtsu section were designed so that six segments comprise one segment ring with a segment length (along the tunnel axis) of 1.35 m, and the segments for the Ohgishima section were designed so that five segment comprise one segment ring with a segment length (along the tunnel axis) of 1.2 m. Segment joints for both sections were designed such that the segments could be easily joined together just by operating the erecting system. Table 3 shows the shapes of the segment joints.

4.3 *Availability*

Apart from enhancing the capabilities of facilities and systems, ensuring a high level of availability of the shield machines is also essential for high-speed tunneling. The best way is to reduce failures of the shield machines. In this project, maintenance of the shield machines was performed monthly and parts were replaced systematically according to a meticulous replacement plan, to reduce failures. In addition, spare equipment and parts including an ample stock of segments were kept in the tunnel against an unexpected failure or problem.

These availability improvement measures resulted in an availability of higher than 93%, which was much higher than the target availability of 80%.



4.4 *Results*

Figure 5 shows a graph of the distances tunneled by the two shield machines, both on a monthly basis and on a cumulative basis, with the above-mentioned measures implemented. The shield machine for the Futtsu section excavated at an average monthly rate of 665 m and that for the Ohgishima section at 605 m. Although the rates of tunneling varied from month to month because of unexpected encounters with gravel layers, steady high-speed tunneling was achieved overall. The maximum monthly distance was 1,168 m in the Futtsu section and 830 m in the Ohgishima section. The shield machine for the Futtsu section achieved the maximum distance on 23 days in a month, and the average daily distance for that month was approximately 50 m. To sum up, both shield machines performed better than expected, successfully tunneling as long as 9 km at a high tunneling rate of more than 600 m per month without any major failure or safety-related problem. The Ohgishima section was tunneled in three shifts for the entire tunneling period, and the Futtsu section was tunneled in three shifts until July 2004 and in two shifts thereafter.

5 MECHANICAL UNDERGROUND DOCKING

The two shield machines started from opposite sides of Tokyo Bay and docked with each other beneath the seabed of Tokyo Bay after each completing 9 km of tunneling. In this project, a mechanical docking

Table 3. Shapes of joints.

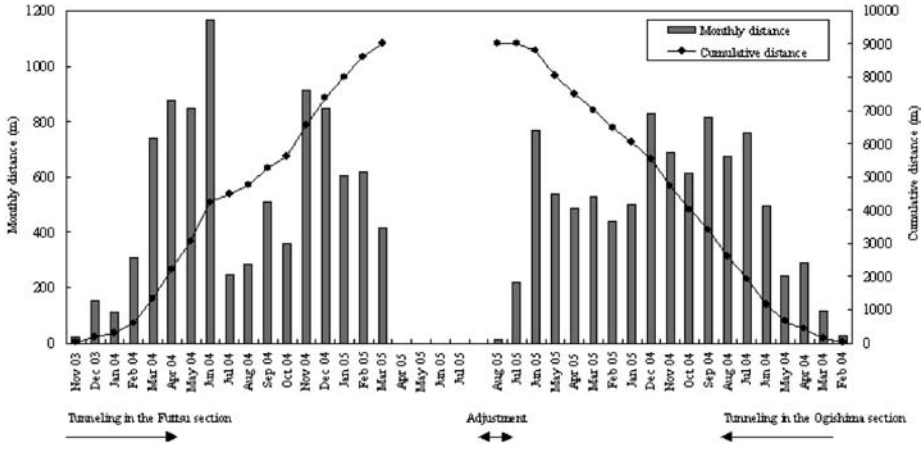


Figure 5. Distances tunneled by the two shield machines.

method was adopted whereby the shield machines were directly docked with each other. This method had been used in more than 10 projects, but never in an environment under a high water pressure of 0.6 MPa anticipated for this project. Therefore, effective sealing of the connection section to prevent infiltration of water was a major challenge.

5.1 *Overview of the underground docking work*

Figure 6 illustrates three steps of the docking work. As can be seen in Step 3, both shield machines have an inner cylinder comprising a cutter head and a bulkhead, which slides in the outer cylinder (i.e. the shield machine body). The shield machines are directly docked by sliding backward the inner cylinder of the receiving shield machine (the Futtsu shield machine) and sliding forward the inner cylinder of the entering shield machine (the Ohgishima shield machine).

5.2 *The three steps of the docking work*

In Step 1, the entering shield machine is advanced until the center bit of the entering shield machine reaches the point exactly 50 mm away from the center bit of the receiving shield machine (the relative positions of the machines are continuously checked throughout the process). After the entering shield machine reached the point exactly 50 m away from the receiving shield machine, the relative positions of the shield machines are confirmed by horizontal boring utilizing magnetic sensors and RI radiation sources. The allowable arrival error for the entering shield machine was $\pm$50 mm and $\pm$1 degree.

In Step 2, the inner cylinder of the receiving shield machine is slid backward using the articulation jacks with its spokes contracted and the face water pressure maintained at the appropriate level. After this, the entering shield machine is advanced using the shield jacks until its hood reaches the point exactly 50 mm away from the hood of the receiving shield machine with the entering shield machine's spokes contracted. Minimizing the distance between the hoods is an effective means of ensuring the stability of the soil surrounding the shield machines.

In Step 3, the inner cylinder of the entering shield machine is slid forward by 510 mm. Then, the tube seal system to prevent infiltration of water is activated to seal the gaps in the connection section. The tube seal system expands the rubber film tubes attached on the inner surface of the outer cylinder of the receiving shield machine by injecting water into the tubes, so that the seal plates are strongly pressed against the outer surface of the inner cylinder of the entering shield machine.

After this, the spaces behind the seal plates are filled with grout material and iron seal plates are welded (all-around welding) to complete the docking.

5.3 *Results of the docking work*

In each of the three steps, all the relevant mechanisms, including the spoke contraction mechanism and the inner cylinder sliding mechanism, functioned as expected. The water leakage rate with the tube seal system in operation was less than 0.1 l/min., indicating that the tube seal system effectively prevented infiltration of water. The mechanical docking operation under the high water pressure of 0.6 MPa was completed successfully despite the fact that it was a highly complex process in terms of both mechanisms and procedures. In addition, no human errors were made during the docking operation, thanks to the constant communications and efforts of the teams of both sections.

6 CONCLUSIONS AND ACKNOWLEDGEMENT

The construction of the 18-km trans-Tokyo Bay undersea tunnel was successfully completed in spite of many tough challenges, including accurately estimating the geological structure by means of sonic prospecting from above the water surface, ensuring that each of the two shield machines would withstand as long as 9.0 km of shield tunneling beneath the seabed of Tokyo Bay, ensuring high-speed tunneling at an average monthly rate of more than 500 m per month and successfully completing mechanical underground docking of the two shield machines under a high water pressure of 0.6 MPa.

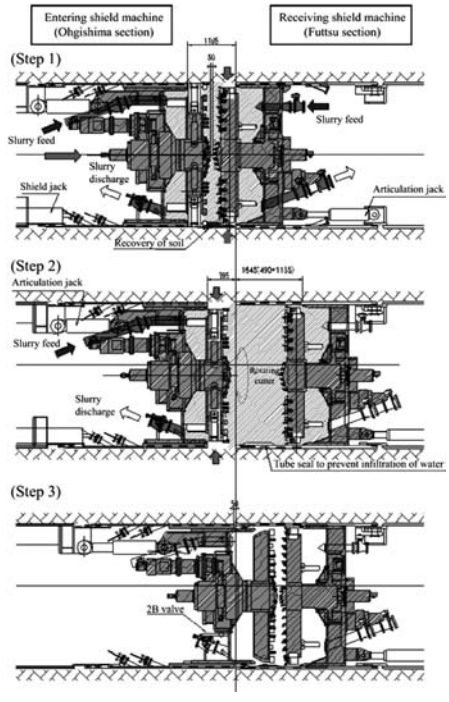

Figure 6. The three steps of mechanical underground docking.

The main reasons for the success of the project were the development of a meticulous construction plan, the rigorous control of construction work and the rigorous implementation of measures to resolve the challenges.

We would like to express our gratitude to many people who supported the project in its design and construction phases by providing valuable guidance and advice, including Emeritus Professor Toru Konda, Professor Atsushi Koizumi and Mr. Yukinori Koyama. The basic plan for the Futtsu section was developed based on a proposal by a joint-venture team comprising engineers from Kajima, Nishimatsu and Obayashi Corporation and the basic plan for the Ohgishima section was developed based on a proposal by a joint-venture team comprising engineers from Taisei, Shimizu and Hazama Corporation (because the project was a "design-and-build" project). We sincerely thank all people who provided great assistance to the project including staff of the above-mentioned construction companies who participated in the project.

ABSTRACT: To predict shield behavior correctly, understanding geological structure around the tunnel is important. Therefore, this paper examines the 3D geological structure using data obtained from boring and investigates the relationships among the 3D geological structure, the shield operation and the shield behavior. Furthermore, the effect of 3D geological structure on the shield behavior was confirmed, comparing the simulation results of the shield behavior with actual observations. As a result, not only macro geological structure but also micro geological structure have an effect on shield behavior and shield operation.

1 INTRODUCTION

Shield behavior depends on geological structure, soil properties, tunnel alignment, tunnel dimensions, shield dimensions, and shield operation. Therefore, understanding geological structure around the tunnel is important to predict shield behavior more precisely (Sugimoto et al. 2003). This paper examines the 3D geological structure using data obtained from boring around the tunnel, and investigates the relationships among the 3D geological structure, the shield operation, and the shield behavior. Finally, the effect of 3D geological structure on the shield behavior is confirmed, based on the results of shield behavior simulation by applying the inferred 3D geological structure to the shield kinematic model (Sugimoto and Sramoon 2002).

For a case study, Hon-chou Tunnel in MM21 Line in Yokohama, Japan was adopted as the test site. Since this tunnel is located along the seashore and the sand spit existed close to this tunnel more than 100 years ago, it is expected that the geological structure around the tunnel is complicated. This tunnel is a twin tunnel, which was excavated by EPB type DPLEX shield. The out bound tunnel and the in bound tunnel are constructed on the seaside and land side respectively by using the same shield machine. The dimensions of the tunnel and shield, and the geological profile around the tunnel are shown in Table 1 and Figure 1 respectively.

Table 1. Dimensions of tunnel and shield.

Item	Component	Value
Tunnel	Horizontal radius	Straight
	Vertical gradient	0.2% up to 1.2% up
	Overburden depth	16.7 m to 15.4 m
	Groundwater level	14.7 m to 12.3 m
	Outer radius of segment	3.5 m
	Width of segment	1.2 m
Shield	Outer radius	3.575 m
	Total length	7.485 m
	Self-weight	3.1 MN
	Open ratio of cutter face	54.4%
	Radius of cutter face	3.583 m

2 GEOLOGICAL STRUCTURE OF GROUND

2.1 *Geological cross section*

Figure 1 shows the geological cross-section along the tunnel. The geological structures drawn in the figure

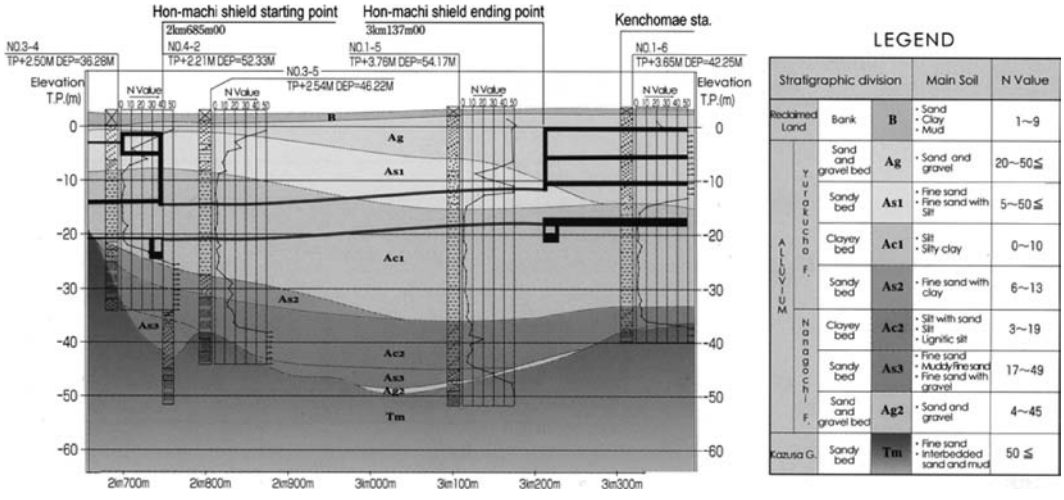

Figure 1. Geological profile at test site location.

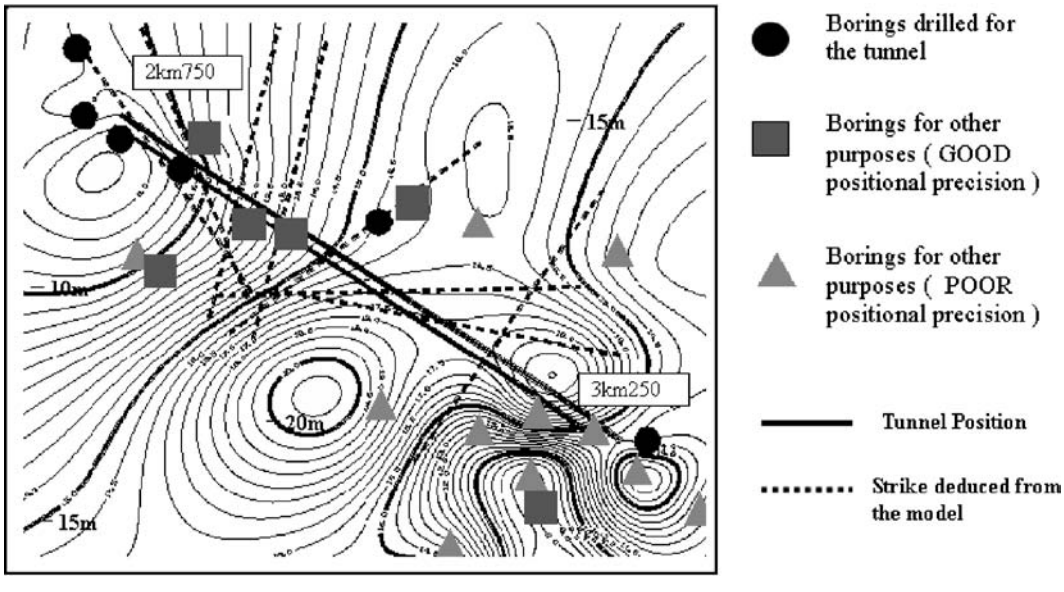

Figure 2. Contour display of Ac1/As1 boundary.

were inferred from data obtained from the four holes drilled along the tunnel. The composite log displays of the data obtained from boring are drawn on the figure. The tunnel position is also shown with two solid lines. The geological structures in this area appear to be simple layered ones in the alluvial formations, As1, Ac1, etc. above the base rock Tm, although the shape of the in boundary of the basement rock is a little rough.

In the simulation of shield behavior, several parameters relating geological structures along the tunnel are used, such as, soil properties, elevations of geological boundaries along the tunnel axis, and dip and strike of the geological boundaries. These parameters, especially strike of geological boundary, are very sensitive to the detailed shape of the geological boundary when the geological boundary has a low angle as is often the case with alluvial formations. To infer these parameters more precisely, the 3D geological structure was investigated utilizing more data obtained from boring nearby the tunnel in addition to those in Figure 1.

2.2 *3D geological structure*

Figure 2 shows 1 m contour lines of Ac1/As1 boundary by the Convergent Gridding method (Schlumberger

Ltd, 2000). In this figure, the circles, the triangles and the squares denote the drilling locations used for modeling this Ac1/As1 boundary. The triangle marks mean slightly less precision of the boring head location, compared with the other borings. The two solid lines in the figure from upper-left (NW) to lower-right (SE) denote the tunnel location.

From this figure, it is obvious that the geological boundary is rough in orthogonal direction to the tunnel axis. This also proves the importance of 3-D geological modeling since it is difficult to grasp such geological boundaries only from geological cross-sections.

3 SITE DATA

In this section, the site data are examined, taking account of the above 3D geological structure. Figure 3 shows the soil component, the horizontal jack moment during tunnelling, and the deviation of the segment in the horizontal direction. The three upper figures show the data along the out bound tunnel, and the three lower figures show the data along the in bound tunnel. The distance between the two tunnel centers is 10.650 m. The horizontal jack moment (here after called as M_{3p}) has a positive sign for right turn in direction of excavation. Therefore, the opposite sign of M_{3p} along the out bound tunnel and the upper one means the same rotation direction, since the excavation direction of each line is reversed. The soil components were obtained by sieving the mucking soil at each ring. The horizontal deviations of segments were surveyed after the completion of the shield tunneling work.

3.1 *Soil component*

The tendency of soil component distribution around the out bound tunnel and the in bound tunnel corresponds in range A, range B, and range C in the figures. Considering the geological profile in Figure 1, the out bound tunnel from 2800 m to range B is located in Ac1 layer, and the sand content in the in bound tunnel is about 10% higher than that around the out bound tunnel. The thickness of As1 layer in the upper part of the tunnel cross section increases in the area between range B and range C, since the sand content in this range is about 60%. In range C, Ag layer almost covers the tunnel cross section gradually, since the gravel content increases from 0% to about 95%. These facts coincide with the above 3D geological structure. On the other hand, in area A, the sand content increases up to about 60%, and in area B, half of the tunnel cross section is in the gravel layer, since the gravel content is about 50%. These ground configurations can not be observed in the above 3D geological structure. It is considered that this comes from the scarcity of information about soil conditions in this area, since data from boring near this area are at the distance 2809 m and 3077 m only. Furthermore, considering that the sand content of As1 and Ac1 layer is about 75% and 16% respectively, it is supposed that the sand layer appears in the tunnel cross section at the range between the distance 2800 m and range B.

3.2 *Horizontal deviation of segment*

Along the out bound tunnel, the segment positions are changed to the sea side near points a and b, to the land side after point c, and to the sea side gradually at the other range. Along the in bound tunnel, the segment positions are changed to the sea side after points d, e, and f. The deviation of segment position usually appears due to the following reasons: 1) shield control is difficult due to a sharp curve; 2) shield operation, such as, jack pattern, copy cutter length and range, and articulated angle, is changed; 3) ground reaction force is not symmetric due to inclined ground layer or twin tunnel; and 4) shield has a special characteristics due to the center of gravity or the manufacturing accuracy. Therefore, it is considered that the deviation at points a and f comes from the tunnelling at the curve alignment, the deviation at points b, c, and d comes from the inclined soil layer, and the deviation at point e is caused by the shield operation so that a taper segment is installed near the distance 2890 m.

3.3 *Horizontal jack moment*

From Figure 3, it is found that the horizontal jack moment M_{3p} is not equal to zero at some range, even if the planned horizontal tunnel alignment is a straight line, and the tendency of the fluctuation of M_{3p} along both tunnels has a certain relation with the distribution of the soil component. Furthermore, M_{3p} in range D except for range A is applied to the land side continuously, M_{3p} in range E is applied toward the opposite tunnel, M_{3p} in range F is applied to the sea side, and M_{3p} in range G shows fluctuation. These shield jack operations were carried out to prevent the wriggle motion of the shield. Taking account of the soil component distribution, these phenomena can be explained as follows: 1) in ranges D and F, the shield excavates the boundary of the inclined soil layer; 2) the soil layer with high gravel content like seam exists in range E, which corresponds to the gravel content in range B; and 3) the shield meets Ag layer in range G.

Assuming that M_{3p} is applied continuously when the shield excavates the boundary of the inclined soil layer in a transverse direction of the tunnel, strike direction angle can be estimated by connecting the points on both tunnel centers where M_{3p} is changed. Figure 4 shows the estimated strike line using the above assumption. Figure 5 shows the strike direction angle along the distance. In this figure, Ag-As1 and As1-Ac1

show the strike direction angle on the planned horizontal alignment of the out bound tunnel, which are obtained from the 3D geological structure as shown in Figure 2, and the black circle points are obtained from the line in Figure 4, of which the number corresponds to the number in Figure 4.

From this figure, it is found that the strike directions at points 2 and 4–7 coincide with that of As1-Ac1. This means that the geological structure affects M_{3p} directly. On the other hand, the strike directions at points 0, 1 and 3 are different from that of As1-Ac1. This fact indicates that a certain 3D geological structure exists around these points, irrespective of the above 3D geological structure, since the above 3D geological structure can not represent the change of the soil component along the tunnel.

4 SIMULATION OF SHIELD BEHAVIOR

4.1 *Analysis conditions*

The dimensions of tunnel and shield have already been described in previous sections. Based on the above examination of the 3D geological structure, the 3D geological structure was inferred as shown in Figure 6. Here the depth of As12 is estimated by calculating the thickness of sand layer at the tunnel cross section based on the soil component in Figure 3. Table 2 shows the ground properties used in the analysis. The values of the dynamic friction were adjusted so as to fit the calculated shield behavior with actual observations.

Figure 7 shows the input measured data, which were measured continuously by the automatic measurement system. Here, observed data were summarized at 20 cm intervals, i.e. one segmental ring is about six excavation steps. The operational control data are the jack thrust F_{3r}, the horizontal jack moment M_{3p} (+: right-turn), the vertical jack moment M_{3q} (+: downward), and the cutter torque CT (+: counter-clockwise direction, view from shield tail). The observed shield behaviors are the yawing angle ϕ_y (+: right-turn), the pitching angle ϕ_p (+: downward), and the rolling angle ϕ_r (+: clockwise direction, view from shield tail). The excavation conditions are the shield velocity v_s, the slurry pressure σ_m, and the slurry density γ_m in the chamber.

The initial excavated area, which is long enough for the whole length of the shield, i.e. from Ring Nos. 72 (Distance 2846.507 m) to 90 (Distance 2868.768 m) was set up by using the observed position and rotation of the shield. The shield behavior was then simulated up to Ring No. 141 (Distance 2929.307 m), based on the operational control data and the excavation conditions in Figure 7, using the shield kinematic model.

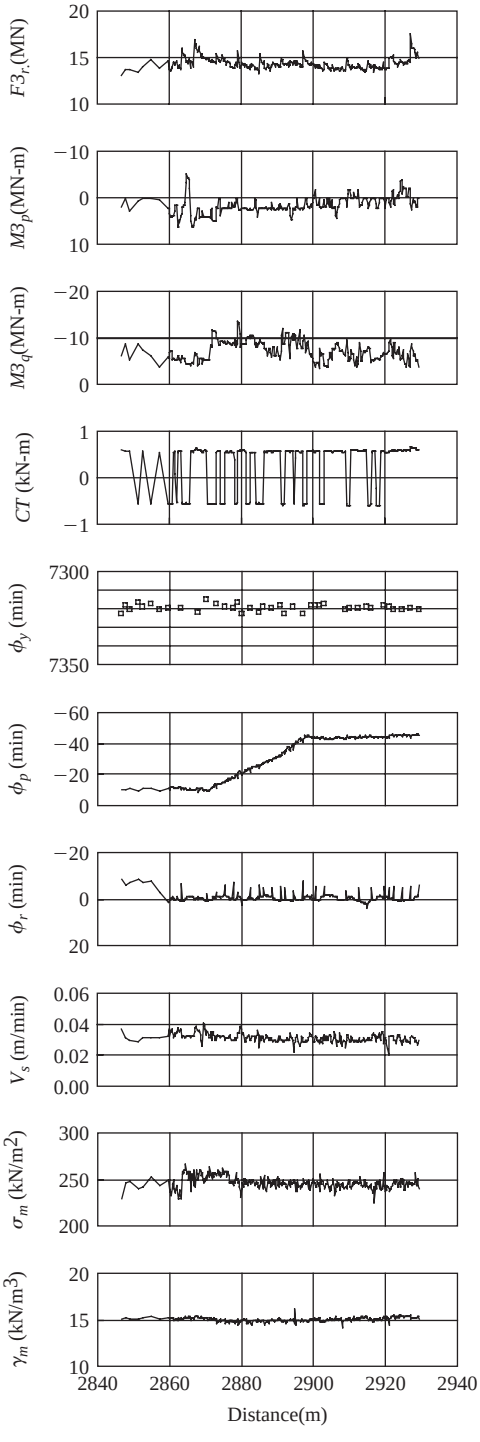

Figure 7. Shield tunnelling measurement.

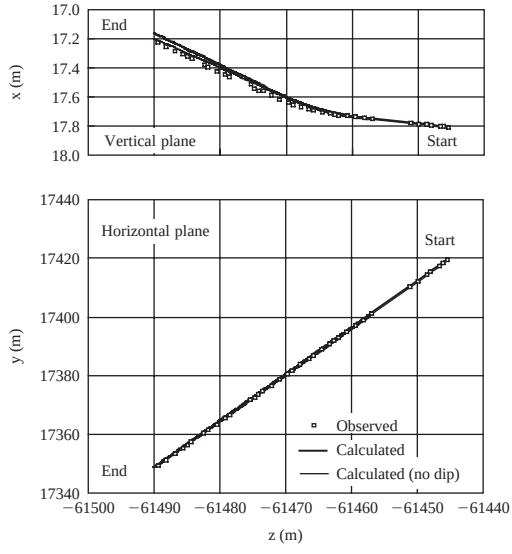

Figure 8. Shield traces.

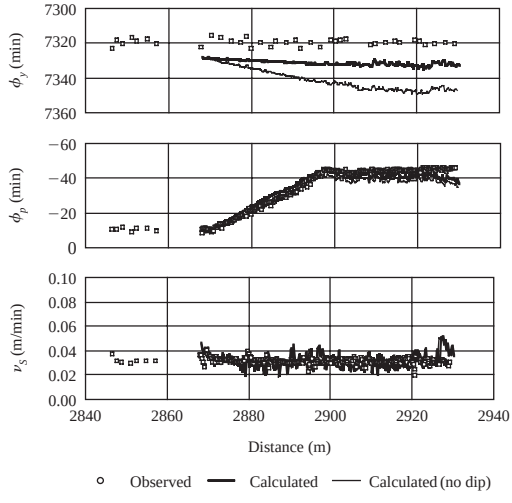

Figure 9. Shield behavior.

4.2 *Analysis results*

Figure 8 shows the shield traces on the vertical and horizontal planes, and the time dependent parameters ϕ_y, ϕ_p and v_s are shown in Figure 9. These figures include the observed data, the calculated data taking account of the 3D geological structure (called Case 1), and the calculated data without the consideration of the 3D geological structure (called Case 2), where the other parameters are the same as those of Case 1. Here, the observed shield position and the observed yawing angle were surveyed after excavation, whereas

the other observed data were measured continuously by the automatic measurement system.

These figures show overall good agreement between the calculated shield behavior of Case 1 and actual observations. As a comparison between calculations and observations, the maximum differences are 3 cm for the vertical position, 12 cm for the horizontal position, 5 min for ϕ_p, and 1 cm/min for v_s. The calculated ϕ_y of Case 1 has a slight parallel shift to the right about 6 min and 12 min from the planned ϕ_y and the observed ϕ_y respectively. This is because the observed ϕ_y were surveyed after the excavation, i.e. after relieving the jack thrust, while the calculated ϕ_y shows ϕ_y during excavation.

On the other hand, the calculated ϕ_y of Case 2 increases up to the distance 2910 m. This is because M_{3p} is applied to the right turn in the excavation direction as shown in Figure 3. This fact indicates that it is important to take account of 3D geological structure to simulate shield behavior precisely.

5 CONCLUSIONS

The 3D geological structure was obtained using the data obtained from boring around the tunnel, the relationship among the 3D geological structure, the shield operation, and the shield behavior was discussed. Finally, the effect of 3D geological structure on the shield behavior was confirmed, comparing the simulation results of the shield behavior with observations. As a result, the following conclusions can be drawn:

1. When geological structure is complicated, 3D geological modeling is important, since geological cross section does not provide adequate information.
2. Horizontal jack moment and shield behavior depends on not only macro geological structure, which is obtained from 3D geological modeling using data obtained from boring, but also micro geological structure due to soil component change, seam etc..
3. The shield kinematic model can simulate the shield behavior in the inclined soil layer in transverse direction.

ACKNOWLEDGEMENTS

The Japan railway construction, transportation and technology agency and Hazama Co. are gratefully acknowledged for providing the test site data.

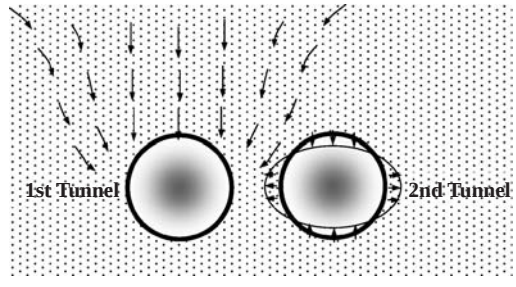
Lining response of twin tunnels affected by EPB shield operation

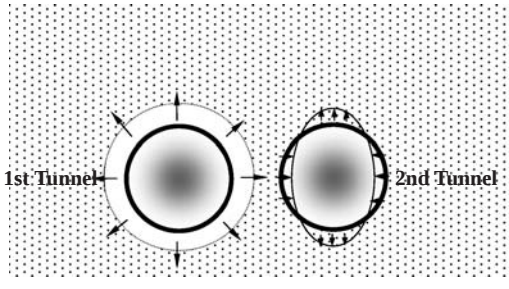
S. Suwansawat
Department of Civil Engineering, Faculty of Engineering
King Mongkut's Institute of Technology Ladkrabang, Thailand

ABSTRACT: In the Bangkok MRTA project, some parts of the tunnels were designed to run close to each other due to the limitation of underground space. To investigate the lining response when an EPB shield was driven very close to another tunnel, convergence bolts were installed to measure changes in the tunnel shape. The convergence bolts were observed relative to the advance of the second shield. Additionally, shield operational parameters were monitored to determine effects of shield operation on tunnel linings. It was found that the first tunnel lining was deformed during the passing of the second shield as the second tunnel can induce stresses acting on the first tunnel. The stresses can cause inward deflections in the tunnel lining particularly at the location between springline and invert. The deflection magnitude of the first tunnel appeared to be proportional to the face pressure and the grouting pressure levels of the second shield. This paper describes the behavior of tunnel lining as affected by the shield operation.



1 INTRODUCTION

In recent years, many tunneling projects have been built in congested urban environments which often involve the tunneling of twin tunnels in close proximity to each other. Furthermore, in many cases, the new tunnel is often excavated adjacent to existing tunnels. Hence, in the design of new tunnels, it is crucial to understand the interaction mechanism of the twin tunnels and their effect on the surrounding ground. Furthermore, from the structural engineering point of view, one needs to ensure that excessive bending moments or displacements are not developed in the lining of the tunnel which is built first.



This research observed the behavior of the tunnel lining of the first tunnel as affected by the construction of the second tunnel in Bangkok MRTA project. Operational parameters applied during excavation of the second tunnel were also recorded and analyzed to study if they have effects on the existing tunnel lining.

2 EFFECTS ON EXISTING TUNNEL

Several authors observed the interaction occurring between closely spaced tunnels. For instance, as reported by Terzaghi (1942) and Ward and Thomas (1965), a set of field instrumentation records on tunnels excavated in Chicago Clay and London Clay indicated that significant lining deformations occurred in the first tunnel as the second tunnel was being excavated causing ground loss toward the tunnel (Figure 1a).

(a) Ground loss toward the 2nd tunnel

(b) Ground pushed out of the 2nd tunnel

Figure 1. Effect of the second tunnel on the first tunnel.

Physical tests were also conducted to investigate the response of the first tunnel's lining on the approaching

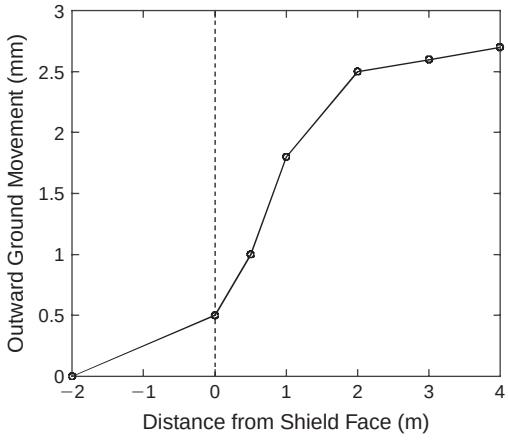


Figure 2. Maximum lateral deformations relative to the shield.

of the second shield. Kim et al. (1996 and 1998) performed laboratory tests using a miniature shield to simulate the effect of tunneling on an existing tunnel. The results of their model tests showed that the interaction effects are greatest in the springline and crown of the existing tunnel. However, the interactions between tunnels are unlikely to be significant unless the spacing between the tunnel centerlines is less than about two tunnel diameters (Kim et al., 1996). Additionally, numerical analyses of this interaction problem were carried out by Leca (1989), Addenbrooke and Potts (1996), Yamaguchi et al. (1998). Their results were similar in that the influence of driving of a second tunnel on the previously installed lining of the first tunnel depends upon relative tunnel position and on the spacing between two tunnels.

Effect of a second tunnel was also found to depend on shield operation. Suwansawat (2004) illustrated that the arrival of the Earth Pressure Balance (EPB) shield used in the construction of twin tunnels in the Bangkok MRTA project can cause outward ground movement during shield passing (Figure 1b). The magnitude of the outward movement depends on distance from the shield face as shown in Figure 2. It was found that the maximum outward movement occurred at the position corresponding to the shield tail. In other words, it was affected by tail void grouting. Additionally, the magnitude of outward deformations also appeared to correspond to the magnitude of the applied grouting pressure and the distance from the shield. This ground response mechanism can affect lining of existing tunnels nearby.

Therefore, it is clear that the problem of interaction between adjacent tunnels is complex, and the interaction depends on the geometry of the tunnels, the shield operation, lining properties, soil

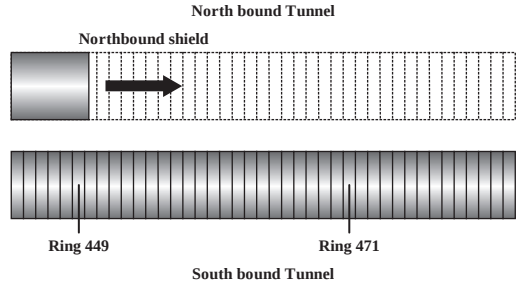

Figure 3. Schematic diagram of the twin tunnels and installed locations of convergence bolts in the Bangkok MRTA project.

characteristics, and relative stiffness of soil and lining. Operational parameters such as face pressure and grouting pressure are among the most significant factors. Nevertheless, although many studies on the interaction between two tunnels excavated side by side were carried out, very few were based upon field instrumentation and operational parameter records.

3 BANGKOK MRTA PROJECT

This research specifically copes with the Bangkok MRTA Project. The project of 20-kilometers of twin tunnels is subdivided into two main tunnel sections namely, the North Tunnel Section and the South Tunnel Section. The tunnel alignment was excavated underneath heavily congested areas of the city. Each of the twin tunnels is 6.3 meters in outer diameter and 5.7 meters in inner diameter. Eight EPB shields were used in total for the entire project.

Bangkok geological profile is quite uniform with soft clay underlain by stiff clay along the tunnel alignment. In most tunneling section, a horizontal-twin tunnel was excavated mostly within the stiff clay layer (i.e. about 15–25 m below ground surface). The tunnels have to be excavated within sand layer only at the mid-point between stations and also in the case of stacked tunnels. Details of the project can be found in Suwansawat (2003).

In the South Tunnel Section, some parts of the tunnels were designed to run close to each other due to the limitation of underground space in Bangkok. The southbound (SB) tunnel was excavated first and followed by the northbound (NB) tunnel approximately one month later. In some locations, the spacing between two tunnels is less than 3 m. To investigate the lining response when an EPB shield was driven very close to another tunnel, convergence bolts were installed (Figure 3) to measure changes in the tunnel shape.

Figure 4. Measuring lining deformation using tape extensometer.

4 CONVERGENCE BOLTS

The tape extensometer (Figure 4) is used to detect and monitor changes in the distance between two reference points. By comparing the current reading to the initial reading, the operator can calculate the change in distance between the two reference points where convergence bolts were installed. In this research, the monitoring was designed to correspond to the position of the second shield in order to study effects of the second shield operation on the first tunnel lining. Results of the monitoring are shown in Figure 5 and Figure 6.

5 LINING RESPONSE

The installed convergence bolts were observed relative to the advance of the second shield and the data were all plotted in the polar graphs (i.e. it is also recommended to look at the plots of lining deflection versus distance from the second shield face). It was found that the first tunnel lining was deformed during the passing of the second shield. It is evident that the second tunnel can induce stresses acting on the first tunnel. The stresses can cause inward deflections in the tunnel lining particularly at the location between springline and invert as clearly shown in Figure 5 and Figure 6. However, the pattern of the lining deflection observed in the MRTA project is not a typical result. Theoretically, the most significant inward deflection was expected to occur at the springline. As the second shield approaches the measurement section, it should induce inward movement at the springline and outward movement at the crown and the invert of the existing tunnel.

If one takes a detailed look at the plots of lining deflection versus distance from the second shield face (Figure 5), it was found that the lining begins to deform about 10 m ahead of the shield. As the second shield face approached the ring equipped with the convergence bolts, the lining deflected. However, the deflection decreases or the lining moves toward its initial shape shortly after the shield face passes the section. Therefore, based on this observation, it was suggested that the first tunnel lining was affected by the approaching second shield. However, this effect only occurred during the second shield passing. The shape of the tunnel lining rebounded back as the second shield passed away about 10 m from the measuring point.

The deflection magnitude of the first tunnel appears to be proportional to the face pressure level and the grouting pressure of the second shield applied during passing. For example, in Figure 5, during the northbound shield (i.e. the second shield) arrival at SB ring 449 where the first series of convergence bolts were installed (see also Figure 3), the shield was operated at high face pressure up to 200 kPa and at high grouting pressure up to 4 bar. As a result, the first tunnel lining deflects significantly (i.e. 11 mm at the 298 degree location or at between springline and invert). Thus, shield operators had to reduce face pressure to 150 kPa and maintain this pressure level until the end of the tunneling drive. Also, the grouting pressure was reduced to 3 bar in order to ensure that no significant deflection takes place at the lining of the southbound or the first tunnel. Accordingly, as the northbound shield continued to excavate to the end of the tunneling drive, other series of convergence bolts installed in the first tunnel measured smaller deflection compared to that installed in ring 449.

For the other section studied in this research, converge bolts were installed at SB ring 471 to measure effects during NB shield passing. There is only 2.5 m spacing between two tunnels. Figure 6 showed plots of lining deflection and also operational parameters recorded at the NB shield. It was found that the first (SB) tunnel lining begin to deform at 5 m ahead of the shield face and continues until the shield passed approximately 10 m away from the measurement point. During the shield passing, the face pressure was applied at earth pressure balance mode (i.e., somewhat equal to external ground pressure). However, the grouting pressure was still high up to 4 bar. This lining behavior recorded at this section is very similar to that of the section measured at SB ring 449. The tunnel lining tends to deform during shield passing but recovers after shield passing.

6 CONCLUSIONS

The behavior of tunnel lining relative to the second shield operation was studied. It was evident that the second shield can induce deflection at the first tunnel lining particularly between springline and invert. The deflection magnitude of the first tunnel appeared to be related to the face pressure and the grouting pressure

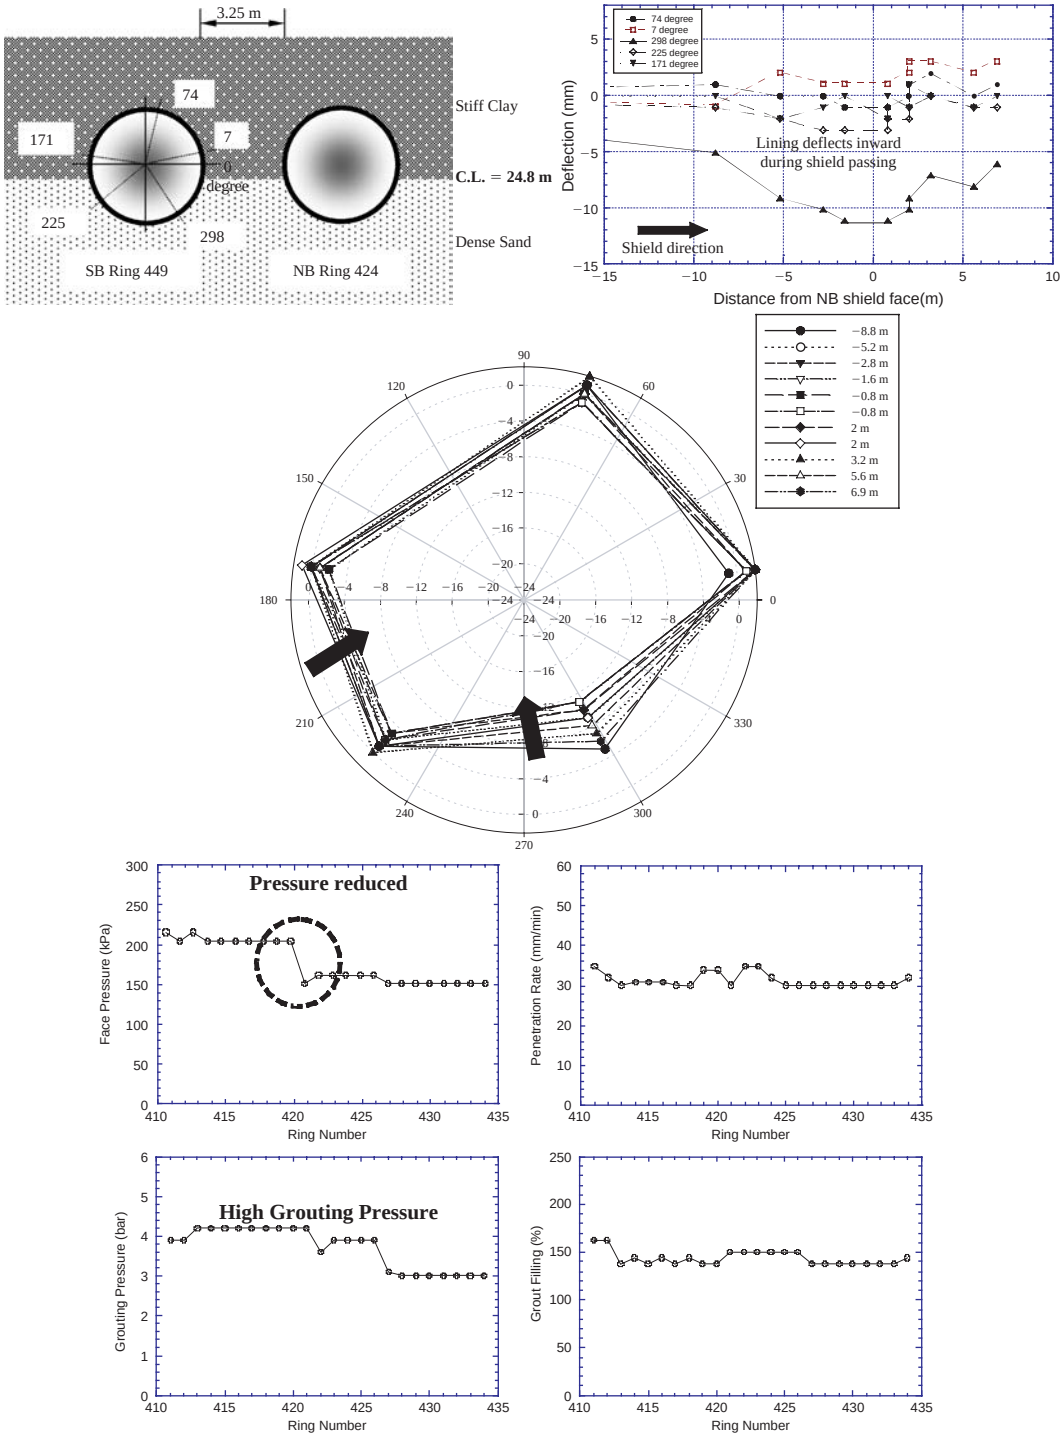

Figure 5. Deflection of SB tunnel Ring 449 during the passing of NB shield and operational parameters recorded in NB shield corresponding to the NB Ring 424.

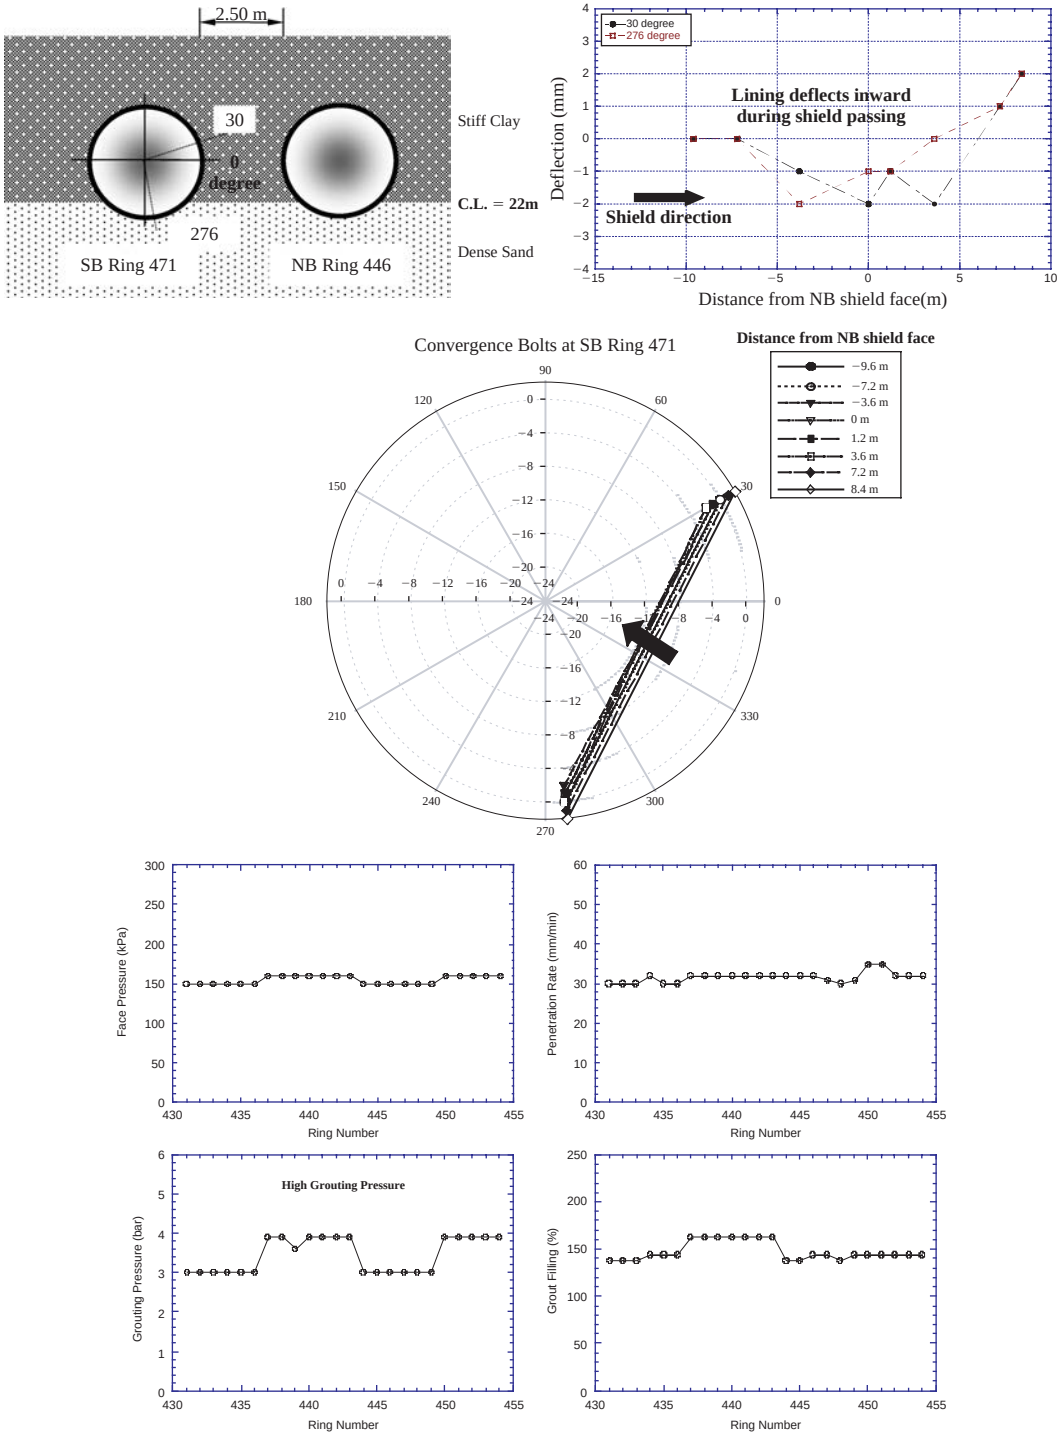

Figure 6. Deflection of SB tunnel Ring 471 during the passing of NB shield and operational parameters recorded in NB shield corresponding to the NB Ring 446.

levels of the second shield. In other words, at close distance, if applied face pressure or grouting pressure is high, the lining of the nearby existing tunnel can be affected. However, the monitoring showed that the effect only occurred during shield passing (i.e. from about 10 m ahead of the shield face to 10 m behind the shield face.

This suggests that to minimize the lining deformation in case of twin tunnels in close proximity to each other, the second shield have to be operated carefully to maintain operational parameters at suitable level. Also, this study showed that tunnel lining should not be only designed to withstand overburden pressure from surrounding ground, but also has to consider the pressure induced by the second shield operation. Safety of the lining should be calculated that excessive bending moments or displacements are not developed. Otherwise, the lining can be exposed to the risk caused by the construction of the second tunnel.

A86-West Paris ring road-a bi-mode TBM

J.L. TORIS
Socatop JV, VINCI Company, Paris, France

ABSTRACT: The East tunnel of the A86 project is a 11.65 m external diameter tunnel, excavated in a very sensitive environment composed of forest parkland, historic sites and residential areas .This tunnel has been bored through thirteen different geological grounds (chalk, clay, limestone, sands . . .), three water sheets with a bi-mode TBM (Slurry and Earthpressure mode). This TBM has been driven with only 10 m below railway tracks and 15 m below a motorway. All the equipments needed by these two excavation modes have been installed on the TBM and only two days were necessary to change the boring mode. The TBM selection, the technical description of all the equipments and the monitoring will be exposed in details.

1 INTRODUCTION

The A86, the outer Parisian ring road has been built mostly in 1990s. Its west section is not complete yet, a ten kilometers section is still in works. This part is located in a very sensitive environment composed of forest parkland, historic sites (Versailles and Petite Malmaison castles) and high residential areas. The current project consists of building the link between Rueil Malmaison and Versailles with a bored tunnel. This tunnel has an innovative design with two superimposed traffic spaces, each level receive one way traffic composed by two traffic lanes of 2.8 m wide and one hard shoulder for emergency lane .It only accommodates vehicles with maximum 2 meters high. Each traffic space is equiped with two ventilation tubes, one for fresh air, the other for emergency/fire ventilation.

The east tunnel of A86 is the largest tunnel ever bored in France with a Tunnel boring machine. It has an external diameter of 11.6 m and an internal one of 10.4 m which allows 2.55 m clearance on each traffic level. Along the tunnel, the overground moves between a minima of 10 m and a maxima of 70 m and two specific areas are encounted. The first one is when the tunnel is located under the railways of Butard with only 10 m of overground and the second one when the tunnel drive beneath the A13 with a cover of 157 m.

2 DESIGN OF THE TBM

The first part of this tunnel, of 4.5 km long, starts near the seine river in Rueil Malmaison and goes up until the plateau of Vaucresson where the interchange with the A13 is located, 150 m higher. During this drive, the TBM crosses almost all the différent geological grounds which can be found in the Parisian area. Only few are missing and we encount successively the following families of grounds:

- Chalk : soft rock with inclusion of flint
- plastic clay : clay with some inclusion of sands
- limestone : the easiest soil to excavate
- marl and gravel layers : ground with mostly marl and some limestone
- Beauchamp sands and sandstone: On this first part of the east tunnel we mainly met sands without water
- the sandwich of marl, sannois limestone and green clay : this is the impermeable layer supporting the water table of the Fontainebleau sands
- marl with inclusion of shells : this is a mixed of limestone and marl with permeable lines where we were in contact with the water table of the Fontainebleau sands under a pressure of 3 bars
- Fontainebleau sands: Thickness of 50 m with 20 to 25 m of water

As we can see we did not have a sole dominant geological formation. We also notice that we had to manage a big diameter tunnel boring machine (excavation diameter of 11.6 m) with several different thin layers of ground (1 to 3 m per layer) and three separate water tables. The behaviours of these sandwiches of different grounds in the front face of the machine always moved during the excavation of the tunnel and needed an adaptable machine.

The TBM had also to manage with the surface settlements to minimize them specifically when the tunnel was bored beneath the building areas, the butard railways and the A13 traffic lanes.

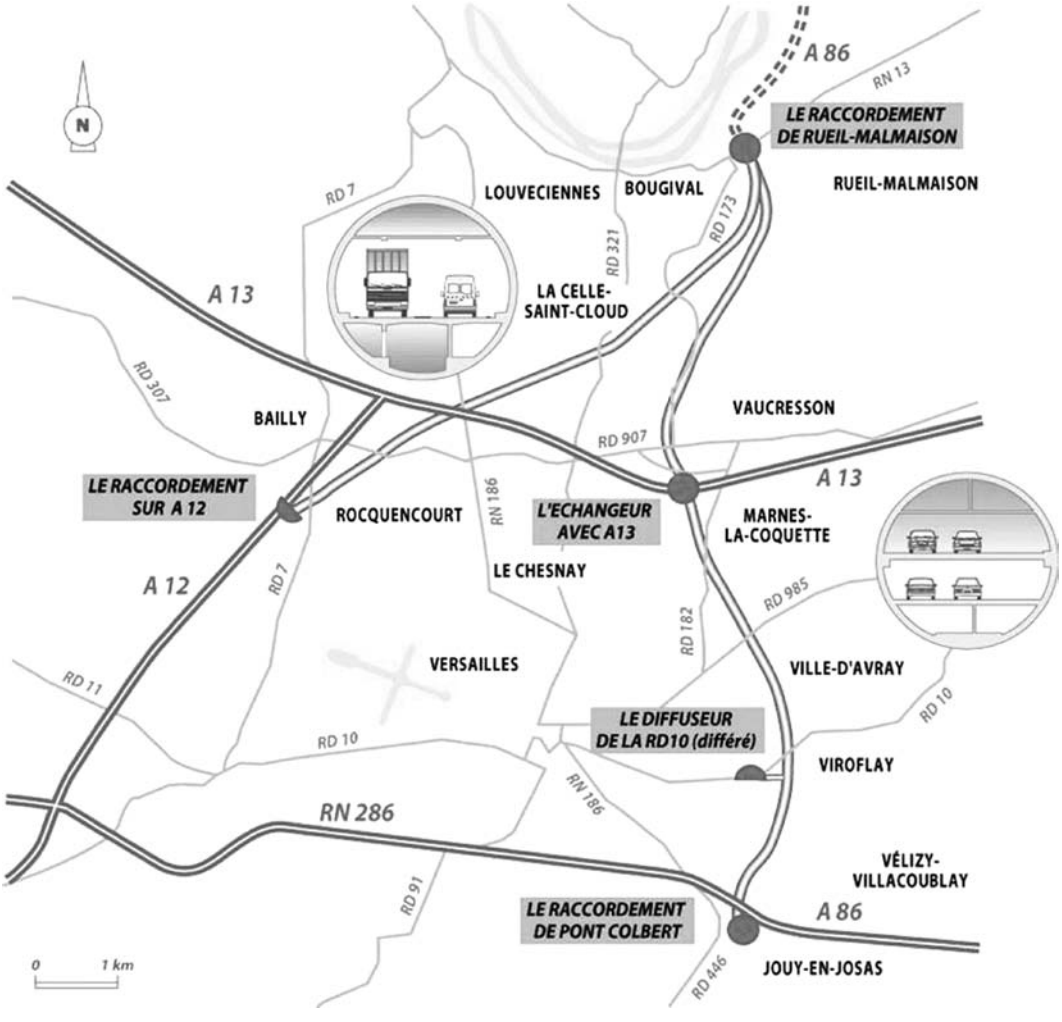

Figure 1. General project layout.

The conception of the tunnel boring machine had also to take into account the general schedule of the project and the target to excavate the first 4.5 kilometers of the east tunnel in 24 months.

To excavate in the cohesive grounds and soft rock, the technical committee of Socatop agreed with a choice of an earth pressure boring machine which permits to work in open mode, compressed air mode and in EPB mode. High speed of excavation can be expected in these grounds with this kind of machine and with the depth of cover available, settlements were managed.

The question was: How did an EPB machine drive in sand layers with or without water table?

To check this point, tests have been done on a reduce model composed with a pressurised tank, a reduce spoil extraction screw and a discharge gate. All these equipments were monitored with pressure captors. The target was to simulate the behaviour of the mucking with a screw in sands, to check the possibility to plug it enough to manage a pressure in the front at a maximum of 3 bars. To be representative, the tank was filled with sands extracted in a shaft near the future project and several tests have been driven with varying pressure, using different additives with varying concentration. These tests have shown that it was not possible to manage in the Fontainebleau sands, a high pressure in the front with a spoil extraction screw. A slurry machine had to be used in this layer which was met on 30% of the length. With this mode of excavation, a better face control was possible in this unstable formation and a higher level of limited settlements could be guaranteed. The problem was that a slurry machine can not

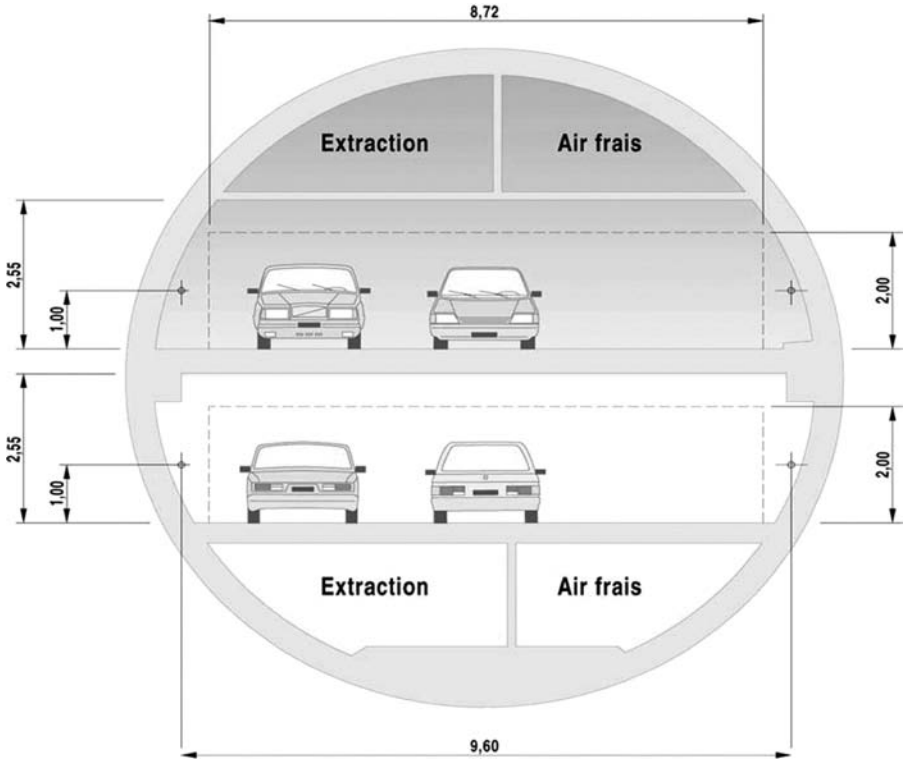

Figure 2. East tunnel – Transverse profile.

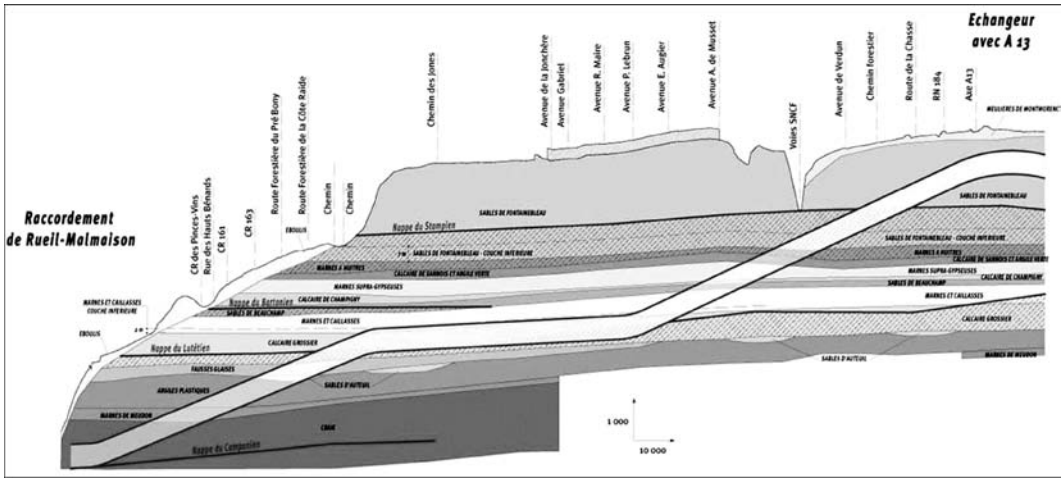

Figure 3. Tunnel East – Geological profile.

be used in grounds with high level of thin particles as clay, chalk, marl (Slurry treatment too long and expensive).

After these studies and tests, Socatop went through a design of a bi-mode tunnel boring machine, able to drive in every mode described above. On the first part of the east tunnel between Rueil-Malmaison and A13, it was foreseen to start the excavation in EPB configuration until the junction with the Fontainebleau sands where the slurry mode had to be used.

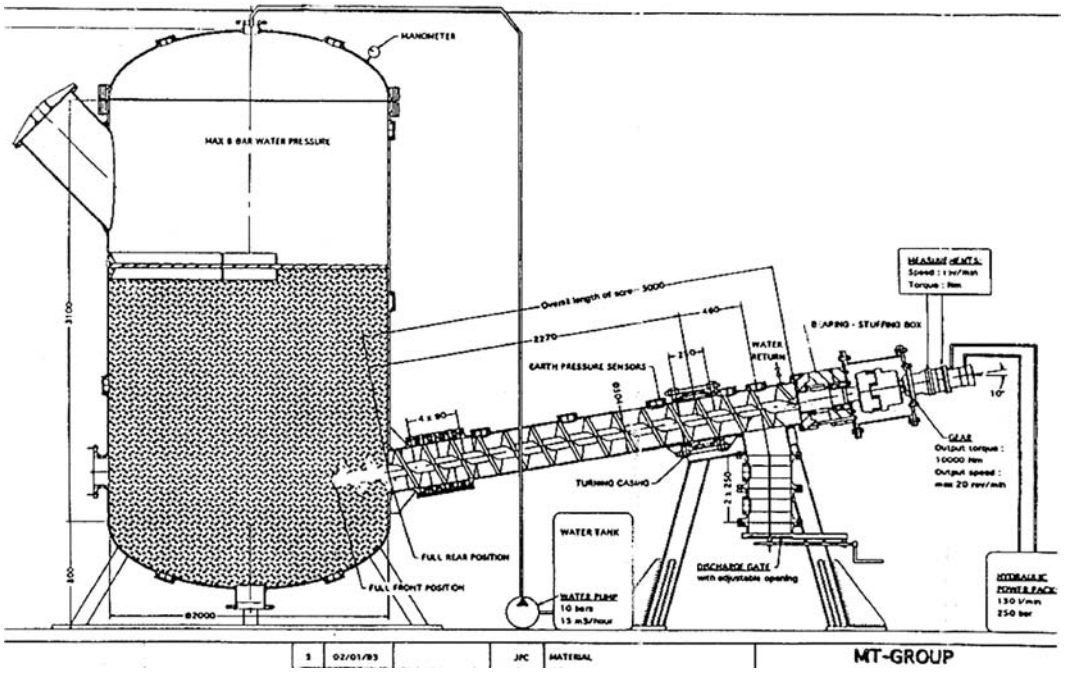

Figure 4. Test layout.

To be able to have a short time modification between these two modes, we design with the supplier, a tunnel boring machine with all the equipments necessary for both modes, installed at the beginning. So only 48 hours were needed for the modification of the configuration of the TBM, and one week for training in the new mode of excavation.

In the different grounds, the excavation modes were the following:

- Fontainebleau Sands : slurry mode – Hydraulic mucking
- Chalk, Limestone, marl and gravel: open mode – mucking with the spoil extraction screw and a belt conveyor
- Clay : compressed air mode – mucking with the spoil extraction screw and a belt conveyor
- Beauchamp and Auteuil sands between clay layers: Earth pressure mode – mucking with the spoil extraction screw and a belt conveyor

3 DESCRIPTION OF THE TBM

The figures 5 & 6 show the configurations of the shield of the TBM in the EPB and the slurry modes.

In the EPB mode a 1.25 m diameter and 22 m long spoil extraction screw takes the excavated material behind the cutter head in the bottom of the excavation chamber. This material is carried by this screw until a discharge gate and then fall on a belt conveyor installed on the TBM. Further, at the back of the back up of the TBM, this conveyor is connected with a belt conveyor installed in the tunnel on the precast concrete segments.

To pass in the slurry mode we had to move back the casing and the screw to liberate the bottom area of the air bubble chamber where we were pumping out the slurry. After this modification, we injected clean slurry in the top of the excavation chamber and we pumped out the heavy slurry (clean slurry + excavated material) in the bottom of the air bubble chamber. These slurries were carried through 450 mm diameter pipes and five 750 kw pumps to go to the slurry plant installed on the outside yard. In this station, the excavated material was separated from the slurry and the cleaned slurry was re-used and sent to the TBM.

The capacity of the slurry circuit was 2 000 m^3/hour.

4 TBM DRIVE BENEATH BUTARD RAILWAY

On the first part of the east tunnel, the TBM had to cross a specific and very sensitive point.

At this point the tunnel is located beneath the butard railways (two traffic lanes) with a cover of 10 meters. At this point the front face is on its upper half in the

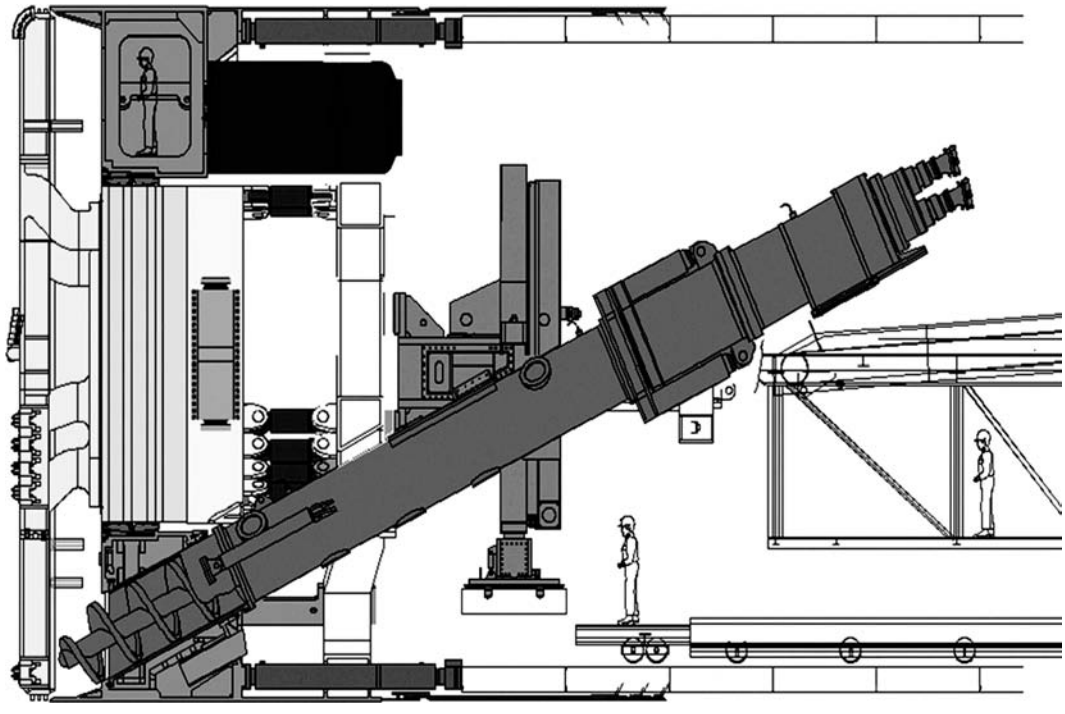

Figure 5. EPB shield configuration.

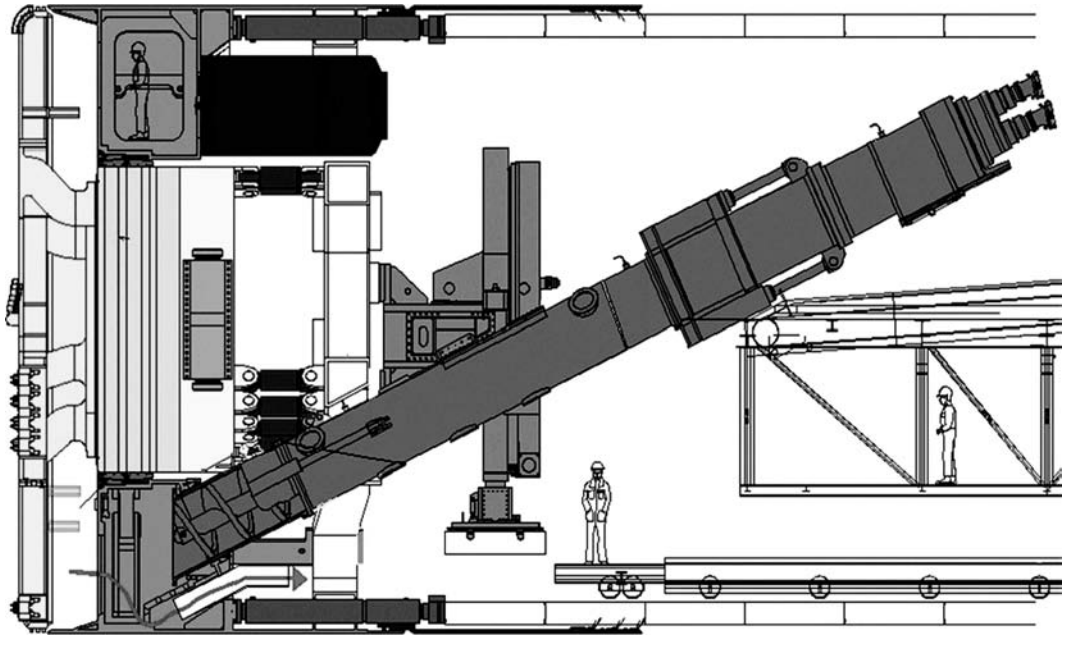

Figure 6. Slurry shield configuration.

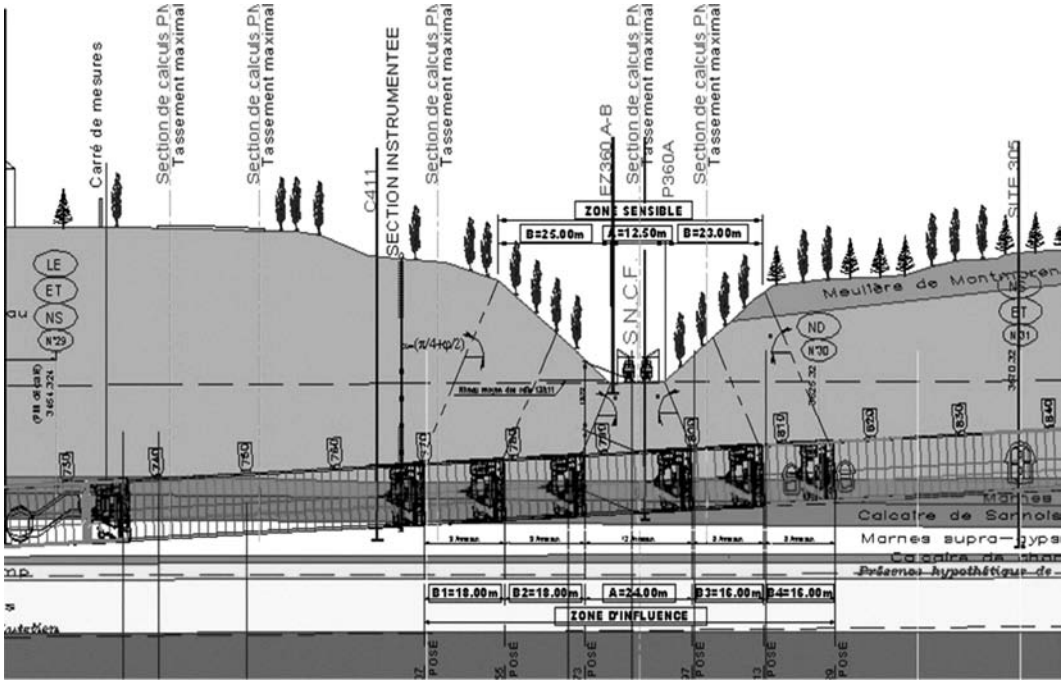

Figure 7. Butard profile.

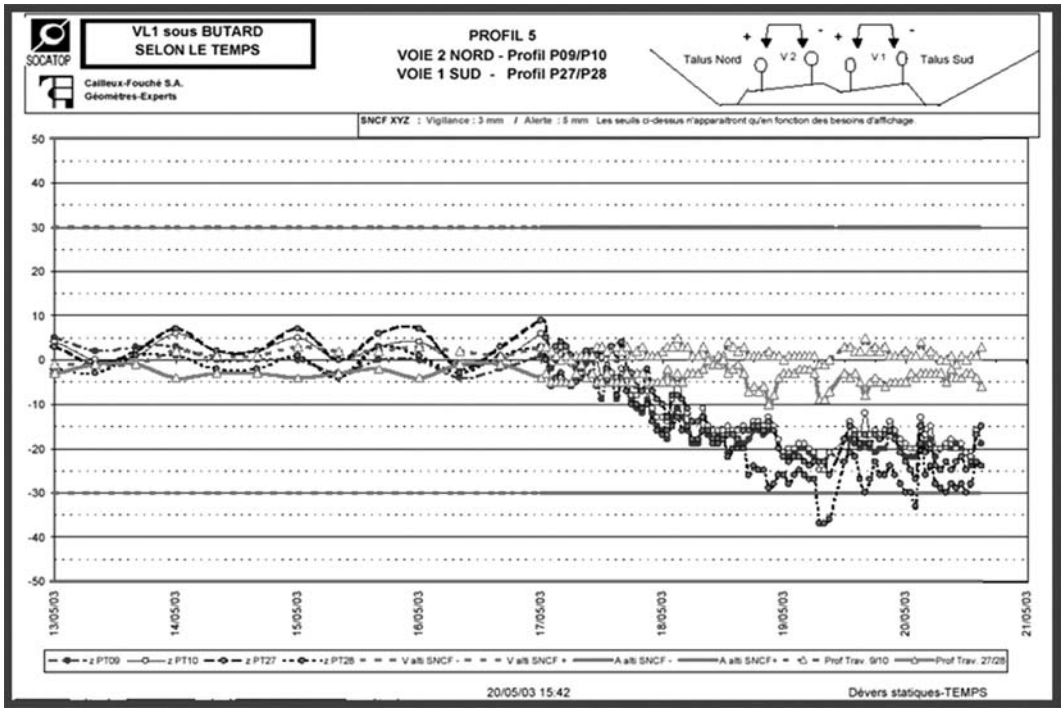

Figure 8. Monitoring results.

Fontainebleau sands and under a water table, and on its bottom half in a sandwich of marl, clay and limestone.

The project had to manage with several other difficulties:

These railways were located in the bottom of a valley and on 60 m of tunnel, the cover first decreased from 40 m to 10 m then grew to 35 m.

- These railways were under a tunnel just 20 meters before crossing the east tunnel.
- The TBM had only a 50 m training period in the slurry mode before this point.
- The traffic of the trains could not be stopped during the crossing of the TBM.

A three dimensions modelisation has been done to define the levels of slurry pressure to use.

A permanent and full automated monitoring has been installed to survey the railways and the settlements in the area. The results were available on a website for the work company and the railway company and a coordinated emergency plan had been done in case of too high settlements.

The TBM drive, in a continuous way, beneath this point during a week end when the train traffic was lower and when it was possible to reduce their speed.

It has been a great success for the project and the highest settlement measured was 3 mm for a maximum authorised of 5 mm.

5 CONCLUSION

On the A86 project, the TBM technology has climbed one more step with a machine able to use all the excavation modes, and therefore be compatible with very different ground formations and a high level of guarantee in the management of settlements.

Engineering department Rotterdam Public Works, The Netherlands

ABSTRACT: RandstadRail is a light-rail link between the cities of Rotterdam, The Hague and Zoetermeer. It connects the local transportation systems in aforementioned cities in such a way that travelling between the inner cities is possible without transfer.

In Rotterdam RandstadRail will be connected to the existing North-South metro line at Rotterdam Central Station. At present time a tunnel of 3 kilometres length is being realised of which 2,4 kilometres is constructed using shield tunnelling for two single track tunnels. Halfway the alignment the underground station Blijdorp is constructed 17 meters below reference level at the transition of soft clay and Pleistocene sand.

The two bored tunnels both have an outer diameter of 6,5 metres. The tunnels are mainly placed in the deep Pleistocene layers. However adjacent to the starting shaft, the receiving shaft as well as the station the tunnels are placed in soft Holocene layers.

When the bored tunnels are placed for more than 50% in the soft Holocene clay additional measures have to be taken as the clay does not support the tunnel lining enough. If possible a ground improvement is used. However instead of a concrete lining with additional ground improvement a steel tunnel lining is used under the railway track near Central Station and adjacent to the station Blijdorp.

The boring process takes place in different ground conditions:

i. Regular ground conditions (clay, sand);
ii. Ground improvement (jet grout, soil deep mixing, gel);
iii. Wooden piles;
iv. Low strength concrete and diaphragm walls with glass fibre reinforcement.

The tunnel boring machine has a length of 68 metres. The shield has a joint for making the curves in the alignment ($R_{min} = 240$ metres). The tunnel boring machine crosses a highway, a channel and a railway line at two locations. Near Central Station over 16 railway tracks have to be crossed.

This article gives an overview of the project and will give insight in the boring process in different ground conditions as well as the boring process at sensitive locations regarding settlement.

1 INTRODUCTION

RandstadRail is a light-rail concept with the aim of realising a high quality public transport system in the southern part of the urban area called "Randstad". RandstadRail connects the local public traffic network of Rotterdam, The Hague and Zoetermeer. In Rotterdam RandstadRail will be linked to the local North-South metro line which now ends at Rotterdam Central Station.

For the connection between Rotterdam and The Hague an already existing railway line, Hofplein line, is used. This heavy railway line has been transformed for light-rail use in 2006. For the connection between Rotterdam Central Station and the Hofplein line the Engineering Department of Rotterdam Public Works has worked out a design using the shield driving method.

This was namely the best method regarding the surrounding conditions. This results out of the crossing

Figure 1. Map of the Netherlands.

Figure 2. Horizontal alignment.

of the different traffic systems, such as railway lines, roads and a channel. Also the shield driving method gave the best results regarding construction time and cost criteria. Now the link between Central Station and the Hofplein line is under construction. In 2008 RandstadRail connects to the North-South metro-line.

Alignment

The alignment has a length of 3 kilometres and is more or less u-shaped (Figure 2). The alignment follows the run of the road Statenweg in north-south-direction. Starting in the northern part the alignment turns west and crosses the "infra bundle", consisting of a railway (Rotterdam-Utrecht), a local tram line, highway between Rotterdam and Utrecht, a channel including the yacht harbour.

In the southern part the alignment turns to the west starting from Rotterdam Central Station crosses a railway embankment consisting of 16 tracks.

Shield tunnelling is used over a total length of 2,4 kilometres which is divided in two sections by "Station Blijdorp". The alignment is constructed as two single-track tubes with an outer diameter of 6,5 m. The thickness of the tunnel lining is 0,35 metres.

2 SOIL CONDITIONS

An extensive soil investigation has been performed along the alignment of the tunnel. Over 60 geotechnical borings and 600 CPT's have been executed to determine the geological build-up of the soil layers. The build-up along the alignment primarily consists of a Holocene overburden and a Pleistocene sand layer underneath. Over 500 laboratory tests regarding strength and stiffness have been done. This intensive research has given detailed insight in the soil parameters.

Directly at the surface, above the Holocene layers a man made sand layer with a varying thickness of 2–5 m is found. Underneath this layer Holocene soil layers, consisting of clay and peat (Hollandveen) are present. The boarder layer to the Pleistocene layer normally consists of a less thick basic peat layer.

Under the Holocene overburdens a 20 metres thick Pleistocene sand layer is present. This layer is the foundation level for the built-up area.

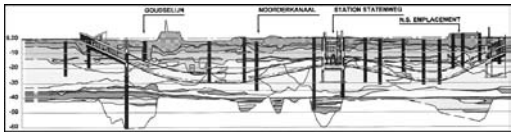

Figure 3. Vertical alignment.

3 VERTICAL ALIGNMENT

The bored tunnels are placed mainly in the Pleistocene sand layers. However adjacent to the building pits the tunnels lie in the Holocene clay which is above the Pleistocene sand layer. Reason for this is that the total building costs of the project reduce when the bored tunnels are placed in clay adjacent to the building pits. So the building pits are made as shallow as possible.

Figure 3 shows the vertical alignment of the tunnel as well as the geological profile.

4 CHALLENGES

For realising the bored tunnels in Rotterdam two aspects are special:

i. Bored tunnel in Holocene clay;
ii. Surrounding conditions.

Bored tunnel in Holocene clay
The Holocene clay does not support the tunnel lining very much. The Holocene soil layers are also effected by extremely strong settlements resulting from consolidating and creep effects (Pachen et. al, 2002). The surface settlements expected for the future are about 1,5 cm per year. The long-term settlement leads to additional loads on the tunnel lining (Zanten et. al, 2002). During the engineering phase it was found out that due to these additional loads it was necessary to use ground improvement techniques when the bored tunnels are placed for more than 50% in the Holocene clay. However on two locations these ground improvement techniques were not desirable as the surface is in use for train and car traffic. On these locations a steel lining is used instead of a concrete tunnel lining.

Surrounding conditions
The surrounding conditions of the project are difficult that is why the goal of driving the TBM is to be able to handle the settlement. As it is necessary to cross the abovementioned railway lines, highway, channel as well as roads. Above this it is necessary to consider obstacles in the tunnel alignment, such as wooden piles with a diameter of 0,2 to 0,3 metres. These pile foundations are not in use as the buildings were already demolished. The design philosophy is that the piles have to be removed before the tunnel boring process. However at the crossing with the railway tracks this was not possible. So the TBM has to pass through the wooden piles. Additional ground deformation due to the presence of the wooden piles has to be avoided. Taking all factors of influence into account the tunnelling conditions are complex.

5 DEALING WITH RISKS

The overall aim of the project was to find out all risks, evaluate them and examine as well as evaluate technical solutions.

The requirements to guarantee a life-span of hundred years have to be regarded with low running costs.

On account of the extremely difficult surrounding conditions Rotterdam Public Works decided to prepare an own design in order to gain an insight in the problems that could occur.

Settlement
With regard to the settlement the performed analyses led to:

- The use of a ground improvement technique (gel) in the railway embankment Rotterdam-Utrecht for realising a crossing with a low risk profile (Zanten et. al, 2003);
- Definition of maximum values for settlements (gradient, torsion angle) for buildings and tracks;
- Insight in sensitivity of settlement in respect to buildings, tracks, pipes and surface level;
- Well defined monitoring program.

Machine-technological aspects:
With regard to machine-technological aspects the analyses led to detailed information on:

- steering of the machine in soft soil;
- stability of the face even while men entering the drilling chamber;
- obstacle removal.

Construction-technological aspects:
With regard to construction-technological aspects the analyses led to:

- use of ground improvement techniques, e.g. jet grouting, mixed in place;
- segmental lining with reinforced concrete elements with a high content of reinforcement;
- segmental lining with steel segments.

6 CONTRACT

To attain in the following steps the best project safety, Rotterdam Public Works decided to take the already worked out technical solution (final design) as basis of the tender documents. Within the final design feasibility results, cost criteria and risk profile studies were

considered. In formulating the technical minimum requirements, which the bidder has to adhere the level of the quality is defined. The danger of receiving "less serious tenders", meaning tenders which carry high risks for the principal is eliminated.

Machine- technological:
The following demands are specially given in respect to the TBM:

- minimum thickness of sheet metal of the shield skin to secure the correct form;
- limitation of the conicity and of the overcut;
- integration of injection possibilities for hood injection and stabilisation of the steering gap;
- alarm secured control for support of the face, annular gap grouting, shield tail seal and mass balance;
- data capture devices with notice of disturbance messages for the most important functions of the shield machine;
- pre-checking systems for the ground;
- wear measure systems.

Segmental lining:
The following demands are specially given in respect to the tunnel lining:

- minimum thickness and minimum reinforcement amount for reinforced segments;
- steel segments for critical sections with permanent prestress to the reinforced segments;
- quality assured fabrication and installing of the segments;
- minimum requirements for the design of the segments;
- performance of tests to cover the limit support behaviour;
- the integration of measuring facilities for the surveillance of load and deformation behaviour.

On the basis of these requirements the contractor has free room for a solution of the technical concept with a manageable risk:

- detailed design tunnel lining;
- design TBM;
- boring parameters.

7 GROUND IMPROVEMENT

The contract was awarded in February 2004 to the contractor Saturn v.o.f. Works started at the starting shaft and the ground improvements near the starting shaft. These ground improvements consist of:

- soil removal for sand;
- mixed in place;
- gel.

Figure 4. Ground improvement mixed in place.

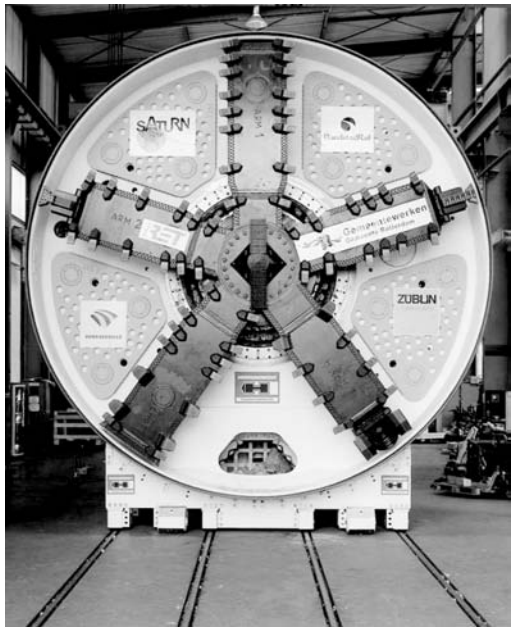

Figure 5. TBM.

The minimum strength of the mixed in place was 0,6 MPa. However testing showed that strength values over 2 MPa were realised as well.

Adjacent to the receiving shafts jet grouting is done. Approximately 2000 columns are made. The strength is varying between 2 and 8 MPa.

8 TBM

The tunnel sections are driven using a shield machine with fluid-supported face. The TBM has a total length of 68 meters. The length of the shield is 9,8 meters. In June 2005, the shield machine was approved at the factory in the presence of the client and consultants. In the process, the functional capacity of the entire machine together with all components was demonstrated and verified. The shield started operating in December 2005. Figure 5 shows the TBM at the factory.

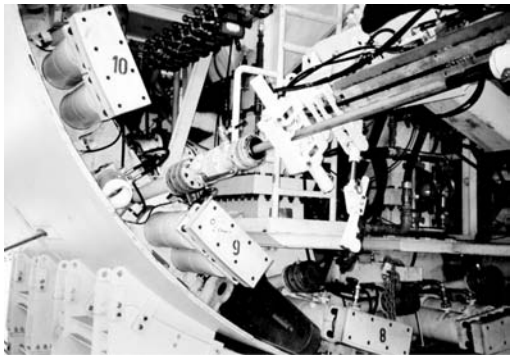

Figure 6. Drilling ports.

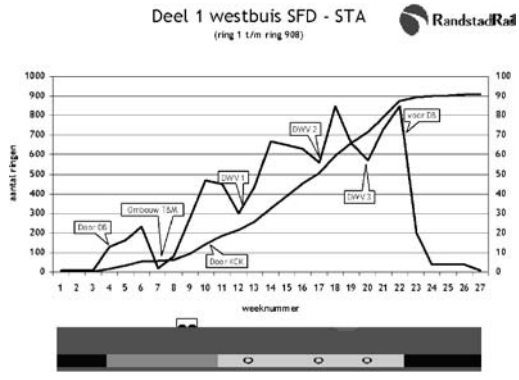

Figure 7. Building speed.

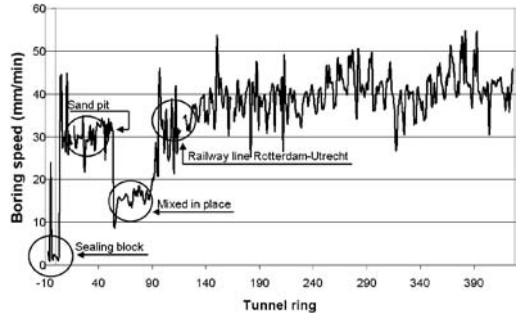

Figure 8. Boring speed.

The machine possesses an external diameter of 6,78 m and a 5-arm cutting wheel.

The curves in the alignment have a small radius (240 meters). So a joint between the middle shield and the tail shield is constructed.

The cutting wheel is equipped with cutters, overcutting tools, a central device and special wear measuring systems. The transmitters and receivers integrated in the cutting wheel serve geological advance exploration purposes. On six cutting tools measurement tools for wear are placed.

A rock crusher is installed in front of the intake screen. Drilling ports integrated in the shield skin facilitate the production of a ground improvement.

The cutting wheel can be shifted in longitudinal way over a length of 0,4 meters. So over cutting is possible. Shifting can be helpful by overcoming a blocking of the cutting wheel as well.

9 BORING PROCESS

In June 2006 the TBM reached the station Blijdorp. For the first section between the starting shaft at the "St. Franciscus Driehoek" and station Blijdorp 908 tunnel rings are placed. Each tunnel ring has a length of 1,50 m. The average speed was approximately 8 m/day. It can be seen that due to building segments for the cross passages the building speed is lower.

The concept using a hydro shield with a 5-arm cutting wheel worked out well. The settlement along the alignment was on average 15 mm. When crossing the railway track Rotterdam-Utrecht surface settlement of 10 mm was registered. This had little influence on the tracks. No influence on train service was encountered. The wooden piles which were in the tunnel alignment were taken care with the cutting wheel without problems. No problems with the bentonite cycle were encountered.

Boring speed

Starting the boring process it was found out that the sealing block adjacent to the starting shaft was very hard. The strength of the concrete was 15 MPa. This led to substantial wear of the cutting tools. So it was necessary to change the cutting tools several times. The type of cutting tools was also changed. A cutting tool with a better cutting behaviour was used. When crossing the ground improvements it was found out the boring speed was somewhat lower than regular speeds.

In August 2006 the boring process restarted from the building pit of the station Blijdorp. In this restart the tunnel had to cross diaphragm walls with glass fibre reinforcement. The strength of the diaphragm wall was on average 45 MPa. The boring speed was very low, approximately 1 mm/minute.

Directly after the building pit the tunnel is placed in Holocene clay for more than 50% of the cross-section. So over a length of 40 meters a steel tunnel lining had to be placed. Figure 9 shows the building of a steel tunnel ring. Due to the many bolts building a tunnel ring takes approximately 12 hours.

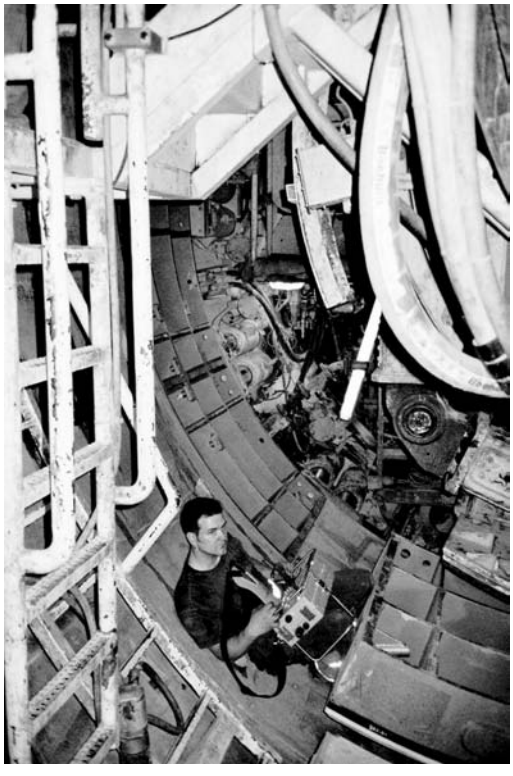

Figure 9. Steel tunnel lining.

Figure 10. Tunnel rough structure.

Tunnel lining
The quality of the tunnel lining until now is good. The tunnel is very dry. The requirements of the contract are met. Only a small amount of damages are encountered (<0.5**%**). The maximum tunnel deformation is 5 mm (measured at radius).

Monitoring
The boring process was accompanied with a extensive monitoring program. With this innovative monitoring system the TBM driver has on line insight on:

- TBM data, e.g. boring pressure;
- Faults in system, e.g. leakage;
- Surveying system tunnel and shield, e.g. position of shield;
- Deformation of sub soil, e.g inclinometer, extensometer.

The actual position of the TBM with respect to the measuring points, the buildings, geology is shown to the TBM driver. Also a sonic system was used (SSP-System). With this system it is possible to "look" in the ground over a length of 40 meters. So large obstacles can be seen in advance.

10 CONCLUSION

The hydro shield has been proved yet totally. The requirements to them were fulfilled. For the future one can hope that the accident-free advance will go on and possible situations will be mastered securely as before.

Analysis of long-term deformations of an earth-covered tunnel

J. Barták
Czech Technical University, Faculty of Civil Engineering, Prague, Czech Republic

ABSTRACT: A road tunnel leading to the active face of a stage-working limestone quarry is being continually covered with an inner dump consisting of inert material, which will restore the landscape to the pre-existing contours once it has been reforested. The final depth of the dump will amount to some 60 m. Continual monitoring of the contact stress on the external surface of lining, of deformations of the tunnel sub-base and deformations of the tunnel lining allows a control analysis of the tunnel lining to be conducted during the course of the tunnel covering.

1 INTRODUCTION

The five-stage Hvížd'alka limestone quarry, which is situated on the south-eastern periphery of Prague on a slope of the Radotín brook valley, forms a distinct "scar" in close proximity to the border of the Český Kras (Czech Karst) Protected Landscape Area. The years shortly after 1990 saw the beginning of the process of searching for environmentally friendly and technically suitable disposing of a significant amount of the spoil and waste cement rock. The system of gradual development of a disposal site inside the quarry, which would not only require no extra land but would even reinstate the ground to its original profile, was adopted as a solution advantageous in all respects. But the excavation of the first quarry stage required a permanent access to the bottom of the quarry. The access was provided by building a horseshoe shaped profile road tunnel with the cross section area of 30 m^2. The tunnel was 332 m long in the first stage and it can be gradually extended up to a length of 400 m.

The tunnel, with a roadway for Terex-type cross-country lorries inside, is continually covered in the waste material forming the inner dump with the depth over the tunnel roof reaching up to 60 m. The depth followed both from the requirements for the volume of the soil and rock to be dumped and from a structural analysis, which was developed within the framework of the dump management using the Finite Element Method.

The dimensions of the final lining with the thickness of 0.85 m allow the thickness of the cover to achieve 60 metres starting from 104 m chainage (measured from the entrance portal). The safe angle of 29° for the front slope of the dump was calculated and verified on a physical model. This slope angle allows the full height of the dump of 60 m to be achieved. At the cover height of 60 m and the tunnel length of 332 m, the Hvizdalka quarry will be able to hold 960,000 cubic metres of the spoil material and unusable stone from the quarry.

The tunnel covering process is continually monitored, with the focus being on deformations of the tunnel sub-base, convergences of the tunnel lining and development of pressures exerted by the dump on the external surface of the lining. Owing to the observation of these quantities it is possible to observe actual stresses in the tunnel structure, to compare them with the design loading capacity of the tunnel lining, and to trigger a timely response to unexpected irregularities in the development of the tunnel deformations and the state of stress.

2 GEOLOGICAL CONDITIONS

In terms of the geological structure, the Hvizdalka location is part of the eastern part of the Silurian-Devonian zone of the Barrandiene formation, a part of the eastern edge of a tectonic-structural unit called the Choteč Syncline. The underlying bed of the deposit consists of the Slivenec Limestone. The cement rock deposit body is a complex of the Dvorec-Prokop limestone, which represent the bulk of the sedimentation complex. The greatest thickness of the deposit that was determined by a survey amounts to 160 m. In terms of hydrology, the massif is characterised by movement of ground water along open fissures and dislocations. The circulation of the water is very irregular and heavily dependent on precipitation.

In terms of tectonics, the area is significantly folded and affected by slip faults. The typical feature of the deposit area is a flat synclinal structure with the wings dipping at 30°–40°. At the south-eastern edge of the deposit, the layers are stretched out at 50°–80° as a result of dip-slip faulting.

The faulting of the rock environment at the bottom of the Hvizdalka shelf quarry is mainly of endogenous origin. It is a result of equalisation of the endogenous pressures and forces that formed the current block faulting and folding system during the geological development of the area. The rock massif can be assessed as mostly significantly broken.

Anthropogenic effects are considered a nonnegligiblecause of disturbance to the rock mass at the quarry bottom level. They comprise the breaking of the deposit block by blasting operations (bench blasting and chamber blasting) and also the discharge of the load acting on the quarry bottom due to the removal of the overburden; the discharge has resulted in opening of fissures within the existing discontinuity systems. The geotechnical characteristics of the rocks (physical-mechanical properties, alterations and intensity of the rock mass disruption by discontinuity surfaces) significantly influence the magnitude of the rock compression (even irregular) in the active zone under the quarry bottom in the course of the placement of the backfill forming the inner dump.

3 THE TUNNEL OBSERVATION MEASUREMENTS

The observation measurements taken on the tunnel leading inside the Hvizdalka quarry have the aim of long-term monitoring the deformational behaviour of the tunnel lining and the tunnel sub-base during the process of the tunnel covering with the spoil. The monitoring allows observation of the relationship between the actual stress state of the lining and the stress values obtained by the design structural analysis (according to the original structural analysis [1] and sizing [2], the tunnel lining can safely carry the loading by the cover up to 60 m thick).

The observation comprises the following tasks:

– To quantify deformations of the sub-base generated by the continual addition of the load acting on the rock massif on which the tunnel structure is founded.
– To follow changes in the shape of the tunnel lining.
– To monitor the distribution of changes in the contact stress on the outer surface of the lining attributable to the growing thickness of the tunnel cover.

The following three methods were utilised to meet the above tasks:

– monitoring of the settlement of the tunnel sidewalls using precision levelling,
– measurement of deformations on the inner surface of the tunnel lining,
– measurement of the contact stress on the outer surface of the lining using hydraulic pressure cells.

3.1 *Vertical survey of the tunnel*

The vertical survey of the side walls of the tunnel during the process of covering with spoil has been performed since 1996; till 2000 at regular 4-month intervals, since 2000 every even year at 6-month intervals [3]. A schematic longitudinal section through the 25 m thick cover existing at the end of 2005 is shown in Fig. 1. The measurement results from the mid 2006 are documented for individual measurement profiles No. 1 to 9 and for both tunnel sidewalls (R-L) in Fig. 2.

The assessment of the vertical survey clearly shows that differential settlement has been affecting the tunnel tube both in the longitudinal and transversal directions. While the differential settlement in the longitudinal direction is not dangerous for the tunnel lining because the individual 5 m long tunnel blocks are not interconnected and do not interact in terms of the structural analysis, the differential settlement of the side walls of the tunnel lining in the transversal direction significantly affects the magnitude of internal forces in the lining of the individual tunnel blocks.

The majority of differences in the settlement values fluctuate under 5 mm; nevertheless, the actual difference in the settlement of side walls at the profile No. 5 amounts to 6.7 mm and the largest value of the

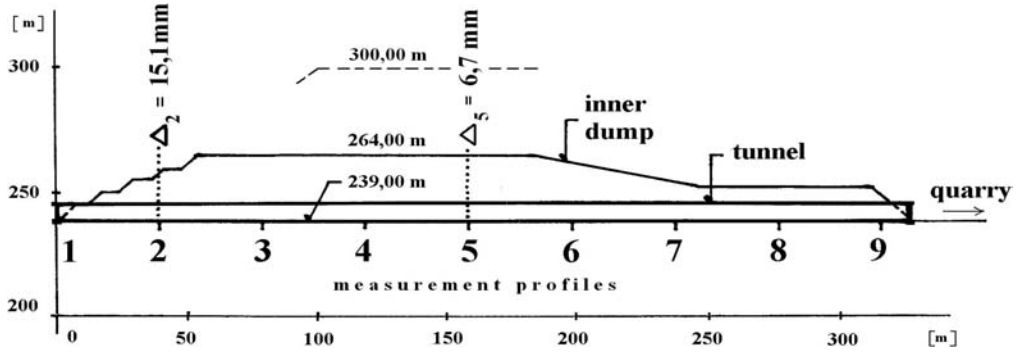

Figure 1. Schematic longitudinal section through the tunnel and earth cover.

differential settlement at the profile No. 2 amounts to 15.1 mm.

3.2 *Measurement of the contact stress*

The measurement of the contact stress on the outer surface of the tunnel lining is carried out at the same intervals as the levelling. Three pressure cells of the 6 installed ceased to measure due to irremovable causes of unclear origin.

It follows from the assessment of the contact stress measurements that the vertical stresses registered by the remaining three cells are nearly identical. They change continually and always closely correlate with the weight of the cover. The conclusion that follows from this fact is that the common theoretical assumption that, in this particular case, the concentration of the loads acting on the relatively rigid tunnel structure found inside a continually built high embankment has not been confirmed by direct measurement of pressures on the outer surface of the tunnel lining. The most probable reason is the fact that the material covering the tunnel was being improved, even if only imperfectly, by waste cement up to the top of the tunnel and roughly up to a distance of 10 m from the outer surface of the side walls. Owing to this treatment, the differences in the subsidence of the rigid reinforced concrete structure and the settlement of the surrounding cover material considered at the level of the tunnel top are insignificant, thus no surcharge is imposed on the structure.

3.3 *Measurement of the tunnel lining convergence*

The measurements of the tunnel lining convergence have been conducted at the same intervals as the

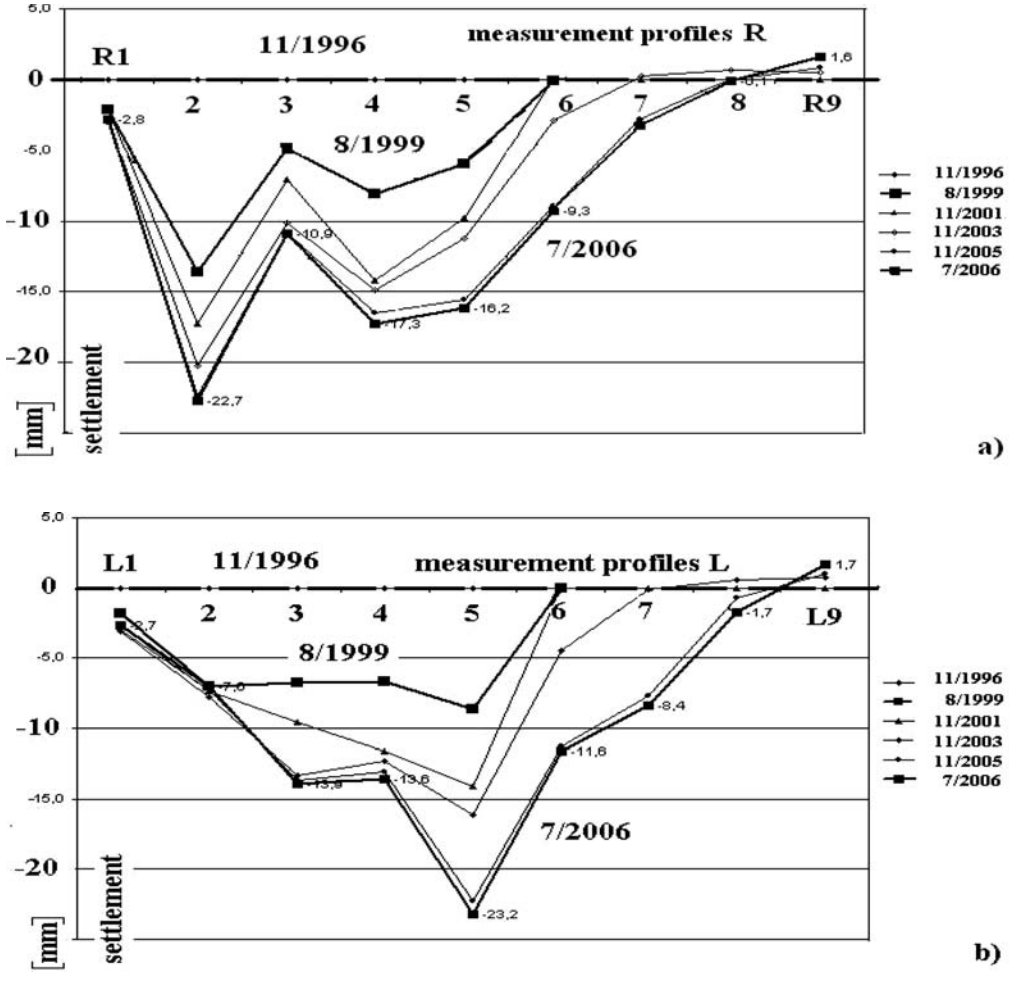

Figure 2. Settlement of the tunnel right (a) and left (b) side walls in the longitudinal direction.

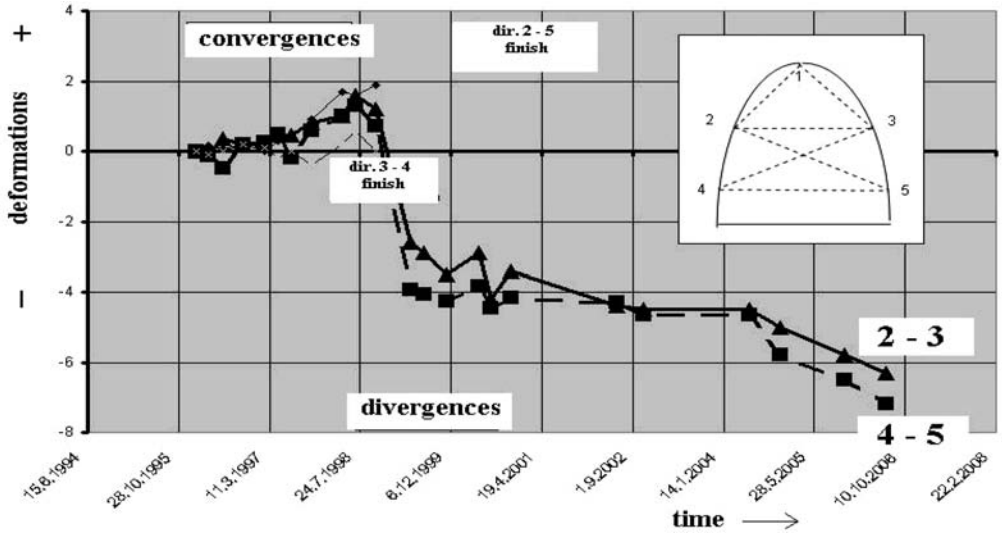

Figure 3. Convergences (divergences) of the tunnel lining at the profile No. 3.

levelling and the measurement of the stress on the outer surface of the tunnel lining. The measurement have been performed by means of a tape extensometer.

The graphical representation (see Fig. 3) shows relatively considerable horizontal divergences of the lining. It is obvious that the cross section of even a relatively rigid tunnel tube formed by the 0.85 m thick reinforced concrete lining is changing under the pressure; the width of the cross section is growing while the height is diminishing. The good structural function of the lining therefore depends on deformational properties of the cover material along the tunnel sides; those properties can be expected to be improving to a certain extent during the course of the continual placement of the cover.

4 MATHEMATICAL MODELLING OF THE DIFFERENTIAL TUNNEL SETTLEMENT

Inhomogeneities in the bedrock of the quarry caused differential settlement of the side walls of the tunnel structure. Differential settlement of supports of a statically indeterminate system of a tunnel liner causes significant increase in the internal forces, primarily the bending moments. These conditions require regular structural back analysis of the lining based on the measured values. The reason is the fact that larger values of transversal differential settlement induce additional stresses in the tunnel liner for which the liner has not been designed and which could cause damage to the structure. If necessary, technical construction measures can be implemented (e.g. grouting under the foundation of the tunnel side walls) which will prevent excessive deformations of the sub-base. Mathematical modelling of the state of stress and deformations of the covering body and its sub-base, but primarily the structural analysis of internal forces and deformations of the tunnel lining are carried out using the Finite Element Method. The PLAXIS program simulates the interaction of the two elements of the system (the lining and the cover) on the basis of a constitutive relationship for the contact zone (the Mohr-Coulomb failure condition for tensile stress in tension cut-off conditions).

The largest value of the differential settlement at the end of 2005, at the actual depth of the cover of 25 m, amounted to 12.4 mm in the exposed profile No. 2 and 6.7 mm in the profile No. 5. In the other profiles, this value is somewhere under 5 mm.

The completed calculations proved that the design loading capacity of the reinforced concrete profile has not been exceeded even in the profile No. 2; however, the final depth of the cover is only of 12 m because the profile position is under the inclined front slope of the cover body. The final state of the thickness and shape of the cover body in the profile No. 2 was reached as long ago as 2000; the differential deformations of the lining slightly grew by 2005 as a result of the increase in the cover thickness in the adjacent parts of the tunnel.

Actual internal forces acting in the profile No. 5: max $M_5 = 726$ kNm, $N_5 = 2780$ kN (see Fig. 4); the corresponding lining failure moment amounts to 1400 kNm, therefore, the cross section is perfectly satisfactory for the time being. Nevertheless, the final depth of the inner dump will grow by 35 m. Because the increase in the differential deformations has a continually growing character, the tunnel cross section must be paid permanent attention.

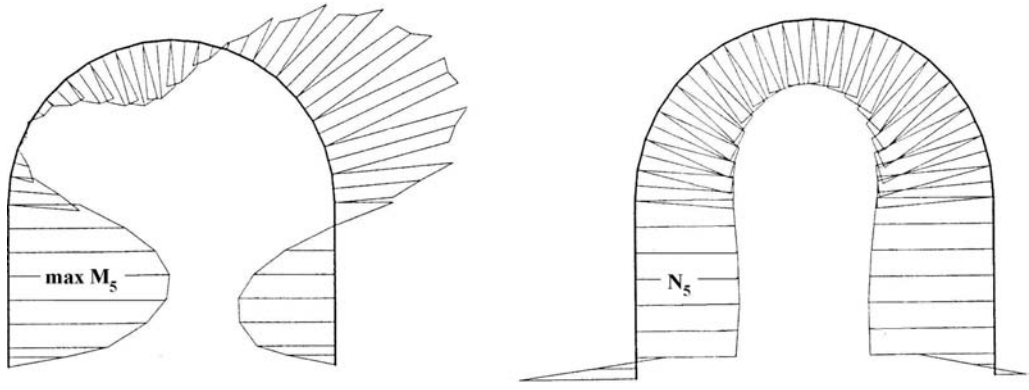

Figure 4. Internal forces in the lining (end of 2005, pr. No. 5 – max $M_5 = 726$ kNm, $N_5 = 2780$ kN).

5 CONCLUSION

The observation measurements conducted on the Hvizdalka covered-over tunnel allow continual checking on the deformation of the rock mass under the tunnel and analysing of the behaviour of the tunnel structure.

The so far obtained results, i.e. results for the years 1996 to 2006, in principle correspond both with the knowledge about the tectonic structure and geotechnical properties of the sub-base and the cover and with the assumptions about the behaviour of a thick-walled vaulted structure in terms of the structural analysis. The situation is, however, complicated by quite significant differential settlement of the tunnel side walls. If the current trend in the differential settlement continues in the course of the increasing of the cover thickness, internal forces acting in the liner that will exhaust the load bearing capacity of the most stressed cross sections will originate at smaller thickness of the cover than assumed. The adverse consequences of this state on the final thickness of the cover are obvious: smaller thickness would mean smaller capacity of the inner quarry dump.

ABSTRACT: The construction of the underground Circle Line Paya Lebar Interchange Station requires two existing viaduct piers of an operating Mass Rapid Transit (MRT) line to be underpinned. The loads from each viaduct pier were transferred from their existing piled foundation to a new support system using hydraulic jacks and a transfer beam supported at both ends on barrette piles. This paper describes the design of the underpinning works, its construction and the monitoring of the nearby existing MRT viaduct structure including the measures that were implemented to minimize movements.

1 INTRODUCTION

The underpinning works described in this paper is the first such operation carried out in Singapore on a live railway viaduct. As land scarce Singapore extends its transit infrastructure, companies and developers will find it commercially attractive to build future projects around the existing MRT structure. Underpinning would be a method that can be employed to incorporate the new developments with the existing MRT. The information in this paper would be useful to the developer and the contractor who undertakes such a project.

The proposed underground Circle Line (CCL) Paya Lebar (PYL) interchange station is situated west of the existing East-West Line (EWL) Paya Lebar Station. It will serve as an interchange station for the new Circle Line and the existing East-West line. CCL PYL station is being constructed under Circle Line Stage 2, comprising five fully underground stations, namely Old Airport Road Station (OAR), Tanjong Katong Station (TKT), Paya Lebar Interchange Station, Macpherson Station (MPS) and Upper Paya Lebar Station (UPL). Figure 1 shows the location of these stations in relation to the whole Circle Line.

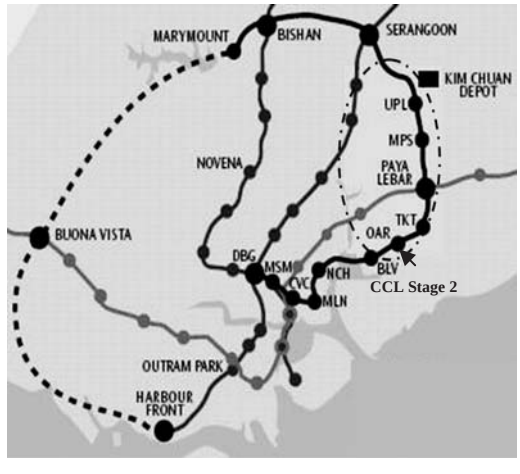

Figure 1. Singapore's circle line stage 2.

Nishimatsu-Lum Chang Joint Venture (NLC) was awarded the Contract 823 to build three of the CCL Stage 2 stations (OAR, TKT and PYL) with 1.66 km of bored tunnels and about 150 m of cut and cover tunnels.

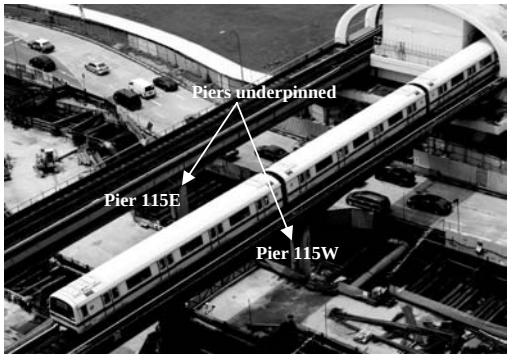

Figure 2. Viaduct Piers underpinned.

At the CCL PYL station two existing viaduct piers (identified as Pier 115E and Pier 115W on Figure 2) were underpinned as its piled foundations were in the way of the new underground station.

The new PYL station is constructed using the conventional cut and cover and bottom-up approach in soft marine clay. The underpinning was carried out by casting a transfer beam beneath the pile cap of each of the piers. Hydraulic jacks were used to transfer the pier load to the new support system before cutting the piles.

The following sections of the paper will describe this underpinning work which highlights the design of the structural elements of the underpinning, the construction, the jacking system and the monitoring of the nearby existing MRT structure. The paper also discusses the risks assessed and the measures that were implemented to minimise movements to the existing Piers 115E and 115W during excavation and underpinning. At the time of writing this paper, the Project had successfully underpinned the piers.

2 DESIGN CONSIDERATIONS

The underpinning is the main risk on this project. Redundancies were intentionally designed into the system to cater for any contingencies. One of these measures was providing 'spider' struts to resist horizontal loads of the piers during the construction stage. A second measure was the provision of six rows of lean concrete walls in the marine clay layer to minimise the deflection of the temporary earth retaining structure. Another measure was to provide additional capacity in the jacking system.

2.1 *Ground conditions*

The site investigation shows the following geological formations:

a) Fill
b) Kallang Formation, comprising F1 (Fluvial Sand), F2 (Fluvial Clay) and M (Marine Clay)

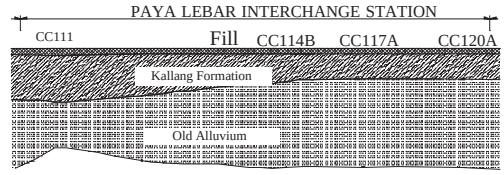

Figure 3. Interpreted longitudinal soil profile.

c) Old Alluvium.

A longitudinal soil profile along the station is shown on Figure 3. The Kallang Formation layer is deeper at the southern side of the station than at the northern side. The depth varies from approximately 25 m below ground level at the southern side to about 13 m at the northern end. An intensive soil investigation with boreholes every 20 m along the rectangular outline of the station box provided a good basis for design.

2.2 *Underpinning design*

The two existing EWL MRT piers were designed to be underpinned by transfer beams spanning between barrette piles. The loads from the existing MRT piers were to be transferred to the new transfer beams using hydraulic jacks. Figure 4(a) shows the cross section of the underpinning area. The 8 m (L) × 1 m (W) barrette piles provide support for the 18 m (L) × 8 m (W) × 3.1 m (D) transfer beams. To allow adequate working space for jacks set-up, the transfer beams were located 1 m below the soffit of the pile caps.

The design intent was to cast in the jacks to mitigate the risk of jack removal. The gap between the soffit of the pile cap and transfer beam will be grouted to ensure structural durability and stability. The bored piles were separated from the new transfer beam by a gap to ensure that they could slide easily during jacking.

At the design stage, an alternative approach of post-tensioning the transfer beam (without jacks) was studied. Finally, the hydraulic jack option was chosen as it allowed the flexibility for adjustment until the station structure is completed. The jacks could also be activated in a configuration that could correct any tilt of the piers.

2.2.1 *Lean concrete walls*

The six rows of lean concrete walls acting as in-ground struts were provided to limit the inward deflections of the temporary retaining system during excavation. These proved to be effective.

2.2.2 *'Spider' struts*

Spider struts were installed between the piers and the temporary earth retaining system to resist the lateral forces of the piers and any additional loads arising during construction.

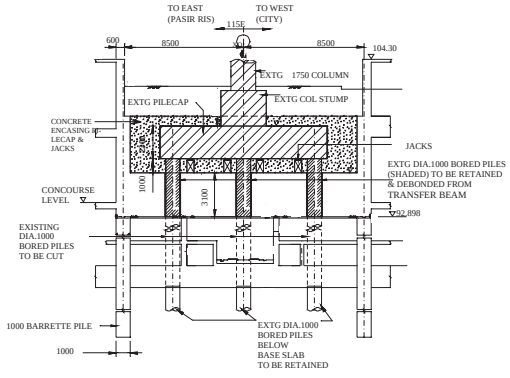

Figure 4(a). Sectional View of Underpinning.

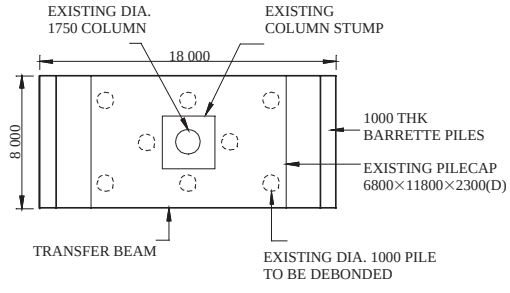

Figure 4(b). Plan View of Underpinning.

To provide sufficient rigidity, a minimum steel section of H350 × 350 × 137 kg/m, was specified. A plan view of spider struts is shown in Figure 5.

2.2.3 *Corbels*

Concrete corbels were introduced as 'guides' at four corners of each pile cap to restrict movement in the:

a) horizontal plane
b) vertical plane during and after pile cutting. Vertical restraint was provided by wedging the top of the corbel using steel plates after jacking.

This mitigates the risk of movement during jacking and the holding period before finally encasing the pile cap and jacks in concrete, i.e. when the piers are being supported off the jacks.

2.3 *Transfer beam and barrette pile design*

The barrette piles and transfer beams were analysed as a 2D sub-frame. The vertical and horizontal stiffness of the barrette pile supports were modeled in the analysis. The effective width of the transfer beam in the design was reduced to 4 m due to the bored piles, although the overall width is 8 m. Depth of the transfer beam (3.1 m) was selected by checking the amount of space available and structural performance to limit deflection during load transfer.

Figure 7 (a) to 7 (c) illustrates the design sequence of load transfer.

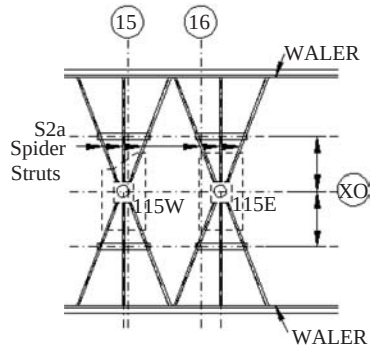

Figure 5. Spider Struts.

Figure 6. Corbel.

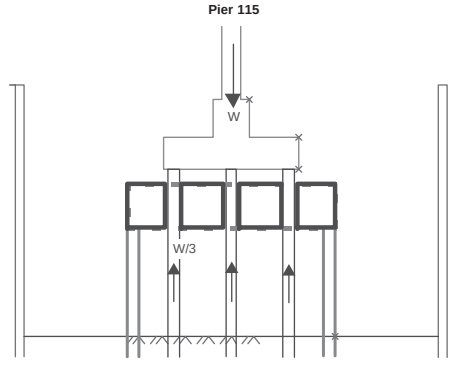

Figure 7(a). Initial condition.

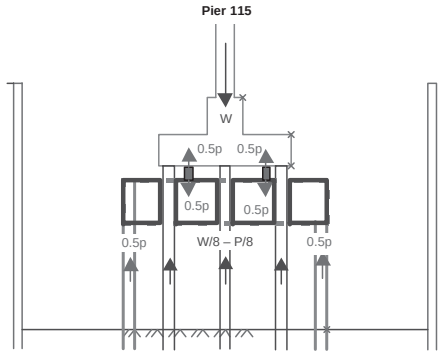

Figure 7(b). Pre-loading of jacks by a total force of "P".

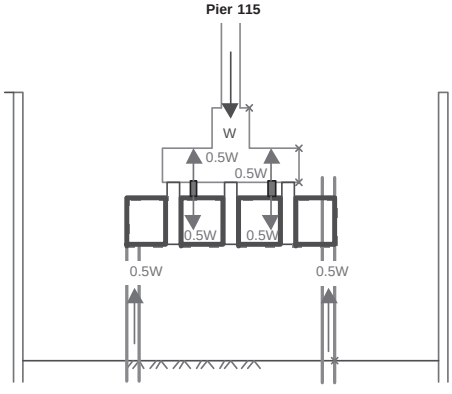

Figure 7(c). After cutting off the existing bored piles.

This construction sequence with pre-loading was chosen as it serves to 'load test' the new support system. At this stage, with the existing bored piles still in place, any unforeseen problems could be detected.

In order to derive the optimum percentage of jack pre-loading, a sensitivity study was carried out using different percentages of pier dead load. The predicted vertical movements of the pier and new transfer beam are plotted on Figure 8 (a) and (b) respectively.

From the sensitivity analysis, a jack pre-loading of 50% of pier dead load is optimal as it limits the vertical movement of piers to <0.5 mm. This also caters for:

a) Minimum effect on the EWL tracks
b) A preview of the effects of load transfer and opportunity to make adjustments, if necessary
c) Adequate buffer to prevent jacking beyond the actual load

Pre-loading of jacks to 50% of the existing pier dead load was then adopted.

The structural analysis of the sub-frame was modelled in 4 stages in the design:

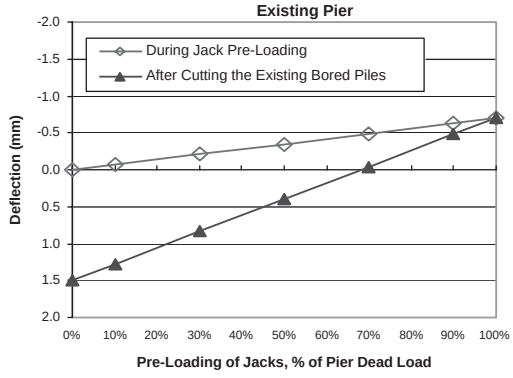

Figure 8(a). Existing piers.

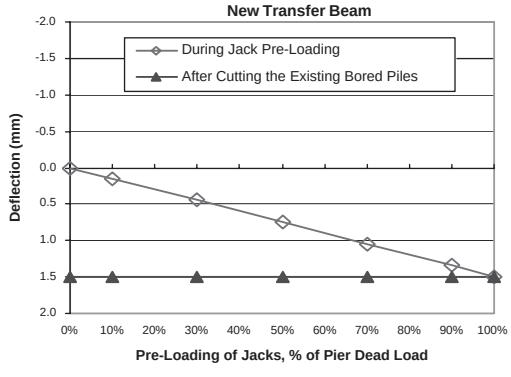

Figure 8(b). Center of transfer beam.

Stage 1 – Casting of the transfer beam (first loads introduced to the barrettes)
Stage 2 – 50% of pier loads (through pre-loading of jacks)
Stage 3 – 100% of pier loads, after cutting the existing bored piles
Stage 4 – Final Stage (when underpinning frame has been integrated with station structure).

2.4 *Predicted movements*

From the results of the sensitivity analysis shown on Figure 8(a), the predicted movement of the pier during jacking is about 0.3 mm (upwards) and 0.4 mm (downwards) after cutting of bored piles.

From Figure 8(b), the predicted movement of the transfer beam during jacking is about 0.75 mm (downwards) and 1.5 mm (downwards) after cutting of bored piles.

The predicted movements are well within the allowable limits imposed by the Code of Practice for Railway Protection (see Table 1) and rail operator (see Table 2).

Table 1. Allowable limit for the movement of structure.

Total movement in any direction	Differential movement in any plane
15 mm	15 mm or 1:1000

Table 2. Operating limits for track.

Twist	Vertical dip or peak
1:500	5 mm (measured over 5 m chord)

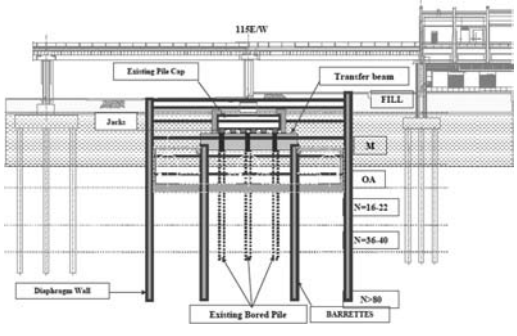

Figure 9. Construction sequence.

3 CONSTRUCTION

3.1 *Construction sequence*

The sequence adopted for underpinning construction is as follows:

a) Installation of barrette piles to about 50 m below ground level
b) Installation of lean concrete walls to about 15 m below ground level
c) Strutted excavation in 4 layers to 10 m below ground level (completed in July 06)
d) Construction of the transfer beams across the barrette piles with de-bonding of the existing piles (completed on 11 Sep 06)
e) Construction of corbels at four corners of each pile cap (completed on 20 Sep 06)
f) Excavation to 2 m below transfer beams to allow deflection by self-weight (completed on 14 Oct 06)
g) Installation of jacks and jacking (completed on 15 Oct 06)
h) Cutting of 8 nos of 1m diameter bored piles at each pier (completed on 29 Oct 06)
i) Continue strutted excavation to formation level (about 5m) (in progress at the time of writing this paper)
j) Cast station base slab and build up structure in stages up to roof level (expected to complete in Aug 07)
k) Encasement of pile cap and jacks (scheduled in Sep 07).

Table 3. Major risks.

Risk	Remedial measures
Pier movement due to uneven excavation	• Controlled excavation in layers not exceeding 2 m
Lateral stability of piers	• Spider strut provided
Soundness of barrette piles	• Confirmed by Pile Integrity Test
Uneven load distribution of existing bored piles due to eccentricity/as-built condition	• Checked as-built condition • Jack arrangement derived with nearly zero center of gravity
Inaccuracy of jack load	• Jacks re-calibrated one month before installation
Uneven movement of pile caps/piers during jacking	• Controlled by adjusting individual jacks • Jacking done during non-revenue hours
Unforeseen deflections during pile cutting	• Symmetrical cutting of piles

3.2 *Risk assessment*

The entire underpinning work is carried out below the operational viaducts of the EWL. Adverse effects of the construction activities could cause significant movements or unforeseen settlements to the piers and viaducts. Thus, risks that could lead to suspension of rail operation were assessed for every construction activity.

Prior to the commencement of underpinning work, a detailed risk assessment was undertaken; the major ones are listed in Table 3.

3.3 *Monitoring plan*

Existing piers, viaducts and pile caps were inspected to assess the condition of bearings and concrete quality.

Monitoring of the piers comprises (see Figure 10):

a) 3D prisms and electrolevels mounted on viaduct beams and piers that provide real time information on three-dimensional behaviour.
b) Weekly monitoring of EWL track twist and dip.
c) Daily monitoring of absolute levels of piers, pile caps and transfer beams.
d) Dial gauge monitoring of relative movement between pile cap and transfer beam (implemented only during jacking and pile cutting).

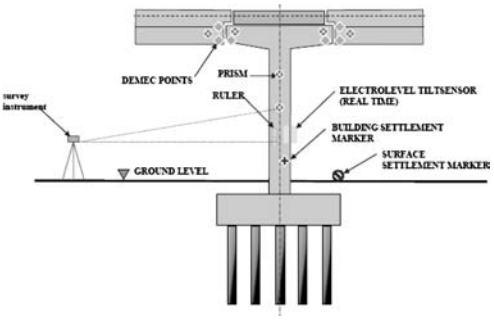

Figure 10. Monitoring schematic.

Figure 11. Installation of Barrette piles.

3.4 *Structural elements*

The biggest challenge was to build the structural elements (viz: barrette piles and lean concrete walls) under the viaduct with headroom less than 6 m. Special low-head equipment was required to carry out the work, especially the barrette piles and lean concrete walls (see Figure 11). Also, mini-excavators were used for all excavation work ensuring little impact on the operating EWL.

3.5 *Jacking*

Based on the calculated loads, a combination of jacks of rated capacities 100T, 150T and 200T were used (see Figure 12).

Typically, a pair of jacks (positioned so as to maintain almost zero centre of gravity) was used to support each pile; thus requiring 16 jacks per pier. Loading of jacks was done using three pumps serving the three jack groups (see Figure 13).

Jacking was carried out during non-revenue hours between 0130 hours and 0430 hours. In order to

Figure 12. Jack installation.

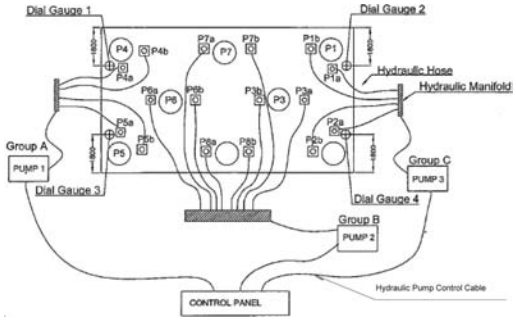

Figure 13. Jack layout schematic.

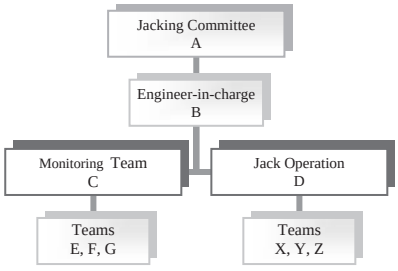
complete the whole jacking sequence in incremental steps within this time frame, it was essential to pre-plan and trial run the command and communication protocol (see Figure 14).



The dial-gauges were monitored at every 10% load increment, other survey readings were taken at 20% load increment.

3.6 *Pile cutting*

Cutting of piles was carried out during non-revenue hours using low-vibration diamond wire-saw cutter in a symmetrical sequence, see Figure 15 (a) to (c). In order to work within the available time of 3 hours, setting-up of the cutting rig and pre-cutting preparation were done in advance during revenue hours. Three cutting machines were deployed to complete the cutting operation in four consecutive nights.

3.7 *Monitoring results*

The same monitoring plan used during jacking was implemented to measure settlements and deflections during pile cutting.

A: Comprised project stake-holders to manage the jacking operation
B: Coordinator of all jacking related activities
C: Coordinator of Monitoring Teams
D: Coordinator of Jacking Teams
E: EWL Track survey team
F: Team to survey transfer beam, pile cap and pier
G: Team to monitor real-time data
X,Y, Z: Teams on individual pumps and dial gauge readings

Figure 14. Jacking operation control.

Figure 15(a). Pile Cutting Set-up.

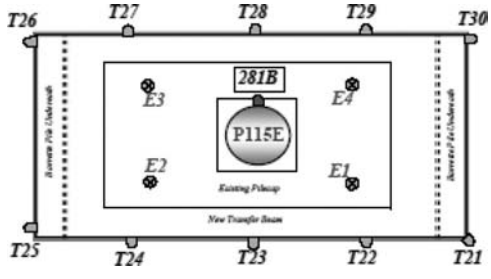


Figure 15(b). Close-up of wire saw set-up.

Figure 15(c). After pile was cut.

Table 4. Settlement values (mm).

Date	T25	E2/ T24	281B/ T23	E1/ T22	T21
15 Oct (aft jacking)	0.0	0.0/ 0.0	0.0/ 0.0	0.0/ 0.0	0.0
Predicted	–	–	−0.75	–	–
01 Nov (aft pile cutting)	−1.0	−2.5/ −1.5	−1.5/ −1.5	−2.0/ −1.0	−0.5
Predicted	–	–	−1.5	–	–

At the end of jacking, no measurable movement was observed on the piers. At the end of pile cutting, 1.4 mm settlement of the pier was recorded. Table 4 graphically presents the settlements observed on the transfer beam (T21 to T25), pile cap (E1 to E2) and pier (281B).

4 CONCLUSION

Based on the monitoring results, the actual performance of the new transfer beam is close to the design analysis. The settlement at mid-span of the transfer beam after pile cutting was measured at 1.5 mm, which is consistent with the design prediction.

The risk mitigation measures implemented to control the pier movements were effective in restricting the pier settlement to 1.5 mm.

The track twist and the pier tilt measurements during underpinning showed very little change and remained well within the operating limits.

Thus the underpinning was carried out successfully and safely without any impact to the EWL operation.

Design and construction of a cofferdam for a sub-sea tunnel on The Palm Jumeirah, Dubai

Nakheel, Dubai, UAE

ABSTRACT: The paper presents design, construction and performance of a sheet piled cofferdam required to construct a 1.4 km long sub-sea vehicular tunnel in dry conditions. An overview of the challenges faced whilst piling and how these were overcome are presented. Measures taken to maintain the cofferdam during tunnel construction are included.

1 INTRODUCTION

The Palm Jumeirah in Dubai, United Arab Emirates, involves the reclamation of land to form the shape of a palm tree comprising of a crescent, 16 Fronds, Spine and Trunk. Reclamation extends some 5.5 km into the Arabian Gulf and the artificial island is protected at the seaward side by a rock armoured semi-closed elliptical Crescent (Figure 1). The resulting development increases the Dubai shoreline by 75 km and when completed will provide for a community of about 100,000 people.

To cross a body of water some 500 m wide a sub-sea vehicular tunnel connects the Spine to the 11.5 km long Crescent. The tunnel cross-section comprises 3 cells, the outer cells carrying 3 lanes of traffic in each direction while the central cell is reserved for services and emergency evacuation.

The construction methodology adopted was cut and cover in dry conditions which required a 2.4 km long sheet piled cofferdam as temporary works, with the sheet piles acting as cut off to reduce seepage into the cofferdam to manageable levels. Offshore and onshore operations were undertaken to install 30 m long steel sheet piles into the crest of temporary dykes and into the recently reclaimed islands where the tunnel portals are located. The construction sequence was to dredge, form dykes, install sheet piles and drain the cofferdam. After draining, the dykes provide construction access to the Crescent, a significant advantage over an immersed tube approach. The cofferdam constitutes some 30% of the total project cost of the tunnel works.

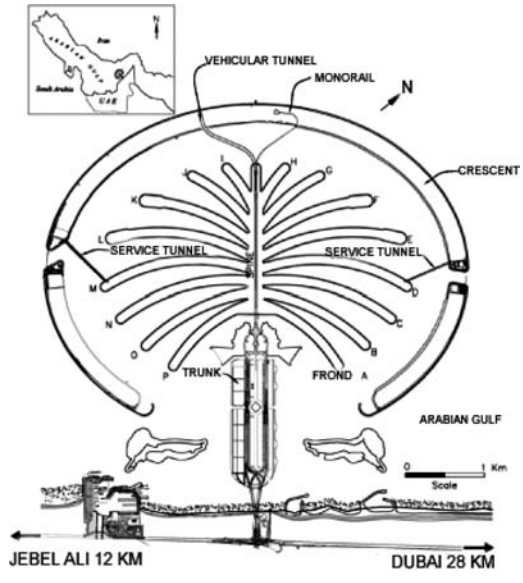

Figure 1. Overall view of The Palm Jumeirah.

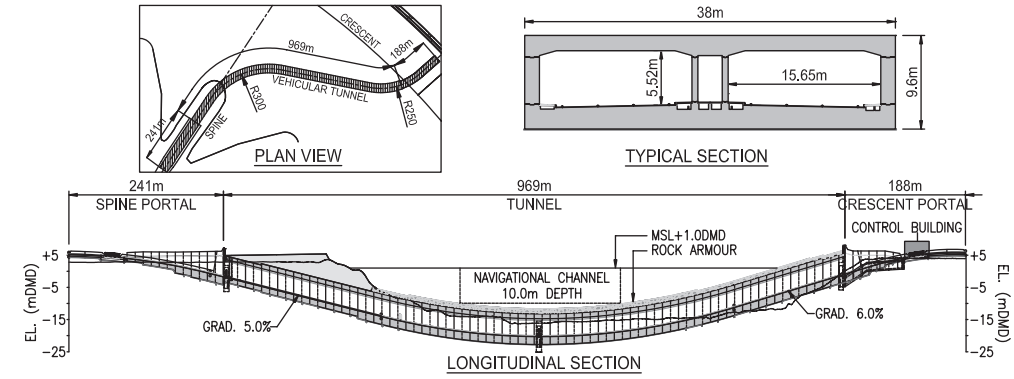

Figure 2. Tunnel alignments.

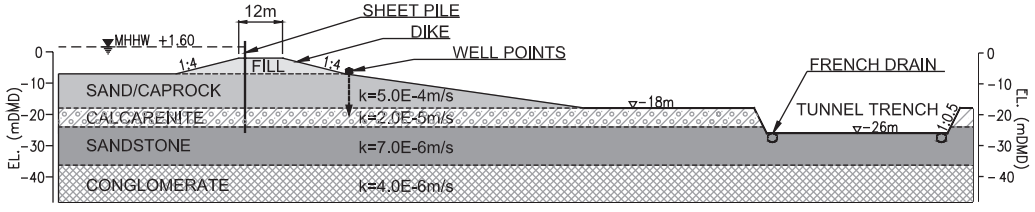

Figure 3. Typical cross section and ground conditions.

2 PROJECT DESCRIPTION

The total length of the tunnel structure is 1398 m and comprises of a 241 m long Spine portal approach, 969 m of reinforced concrete box section and 188 m of Crescent portal approach.

The horizontal and vertical alignments were dictated by a maximum grade of 6% for a 60 kph design speed, in compliance with Dubai Municipality Geometric Design Manual for Dubai Roads (1999), and the need to ensure that the tunnel was sufficiently deep to maintain a 125 m wide arc-shaped navigation channel with a minimum draft of 10 m, above the 1.5 m thick layer of armour protection on the roof slab. The vertical alignment and the horizontal alignment, which is a reverse curve with a central straight section, are shown in Figure 2.

Mean sea level is +1.0 mDMD (Dubai Municipality Datum, which is 0.09 m below Admiralty Chart Datum) with a tidal range of 1.2 m between MHHW and MLLW. The reclaimed islands are at +3 m and +4 mDMD at the Spine and Crescent, respectively. Seabed elevations before The Palm reclamation were in the range −11 m to −12 mDMD. Pre-construction surveys indicated that the minimum seabed elevation along the tunnel alignment and the cofferdam region was −15 m and −19 mDMD respectively, in areas where materials had been won for breakwater construction.

A Design and Build contract was awarded to Taisei Corporation in 2004 for the construction of the vehicular tunnel.

3 GEOLOGY AND GROUND CONDITIONS

The local geology in the vicinity of the project site has been shaped by the current hot arid climate and by fluctuations in sea level and is described by Gahir *et al*. (2006).

Ground conditions were determined by sinking 13 offshore boreholes to a depth of 30 m into the seabed and 3 boreholes up to 30 m depth on the onshore reclamation. The minimum elevation explored is −45 mDMD. The offshore boreholes were drilled along the alignment of the dykes and are offset up to 230 m from the tunnel centre line. All boreholes were grouted after completion.

The boreholes revealed that under a 12 m thick recent fill a 1 m to 2 m thick band of weak caprock is present which in turn is underlain by 2 m to 4 m thick layer of medium dense sand. The sand overlies an 18 m to 22 m thick sequence of very weak to weak interbedded calcarenite and sandstone. A conglomerate layer whose upper horizon is some −35 mDMD is present across the site (Figure 3). The UCS of rock encountered is in the range 1 to 3.5 MPa. In isolated boreholes a thin layer of soft silt was recorded

under the fill, and is suspected to be the original seabed.

In-situ permeability of the rock units, measured using standard Lugeon tests and variable head permeability tests, indicated k values ranging from 4×10^{-6} to 5×10^{-4} m/sec with lower values at depth.

4 DESIGN CONSIDERATIONS

The cofferdam is required for some 17 months and at peak periods a workforce of about 1000 was expected within its confines and thus safety was of paramount consideration in the design process.

The cofferdam outline was dictated by the following considerations (a) the dykes have a 12 m wide crest at −2 mDMD; an elevation adopted after a soil-structure interaction analysis was undertaken for different pile sections and various crest elevations, to provide a balance between the fill available and the structural performance of the piles (b) the sheet piles were planned 2 m from the seaward edge so that a 10 m wide corridor was available for a 2 lane temporary road inside the cofferdam after draining (c) the tunnel trench at its deepest is −26 mDMD and the trench slopes, located in interbedded sandstone and calcarenite, were planned at 1 V:0.5 H (d) a 15 m minimum clearance was maintained from the top of the trench excavation to the toe of the dyke thus avoiding surcharging and undermining the stability of the trench slope and (e) a dyke slope of 1 V:4 H from crest to −10 mDMD and 1 V:7 H thereafter, was adopted from slope stability considerations based on recent experience gained in the construction of The Palm. A 2.4 km long cofferdam outline was thus identified having a plan area of some 300,000 m^2 and a maximum width of about 400 m. This outline involved 1550 m of offshore piles and 850 m of onshore piles. Local filling adjacent to the recently formed islands was undertaken to maximize land based operations.

Both marine and land driven sheet piles are up to 30 m long and the top of the piles were planned at +3.3 mDMD for minimal overtopping under storm surge and wave conditions, and the toe at −26 mDMD based on seepage analyses which required 1 m minimum penetration into the lower less permeable sandstone which underlies the calcarenite. Bending stresses and deflections complying with Technical Standard and Commentary for Port and Harbour Facilities (2001) indicated that pile sections SX27 (section modulus, z = 2700 cm^3/m) for the offshore piles, and PU25 (z = 2500 cm^3/m) for onshore piles were appropriate. The estimated maximum deflections at the top of the marine piles, after draining, was calculated to be about 200 mm and the relative deflection between +3 m and −2 mDMD i.e. the cantilevered section, to be about 150 mm. These estimates are based on a sea level of +2.45 mDMD, to take account of storm surge, and a horizontal modulus of subgrade reaction of 10,000 KN/m^2/m based on an empirical relationship to an SPT-N value of 5.

Seepage analysis using 2D FLOW with an average k value determined for each substrata indicated that some 820 m^3/hr could be expected under the cofferdam once steady state conditions had established. French drains at the base of the tunnel trench, with pits and submersible pumps of sufficient capacity, and lines of well point systems were designed to collect the inflow (Figure 4). The collected inflow was directed to two locations, one either side of the tunnel trench, before being pumped back to the sea over each dyke with due care taken not to erode the outer slope.

5 CONSTRUCTION METHODOLOGY

5.1 *Dyke construction*

Cutter suction dredgers were used to excavate the tunnel trench, one for shallow and one for deep dredging below −15 mDMD, with operations commencing at the end of the alignment i.e. at the newly formed islands and progressing towards the centre where the trench is deepest. The dredgers lowered the seabed elevation by some 2 m in a single step until the desired elevation along the tunnel alignment was achieved within 0.5 m of the invert elevation, with the final grade being achieved using earthworks equipment in dry conditions. Seabed elevations were constantly monitored by surveying equipment on the dredger and from a survey boat.

The dredged material was sucked into the dredger holds and placed at the dyke locations using a spread pontoon positioned by GPS and controlled by anchors and winches. Both dykes were built up concurrently and care was required to achieve the 1 V:4 H slope by considerably reducing the volume discharged through the pipe. Total volume for the two dykes was 920,000 m^3 of which 660,000 m^3 was obtained from the tunnel trench excavation and the balance was obtained from a borrow source nearby, with a small quantity purchased from a supplier. A larger volume than had been estimated at the tender stage was necessary due to the flattening of the dyke slopes from 1 V:4 H to 1 V:7 H below −10 mDMD as already described in Section 4. Bathymetric surveys were carried out after filling to either confirm that the desired dyke profile had been achieved or identify local areas requiring additional fill.

5.2 *Sheet pile procurement and preparation*

Procurement of the 12,500T of sheet piles was a lead item due to a shortage on the world market. Some 9500T of new SX27 sections in 15 m lengths were

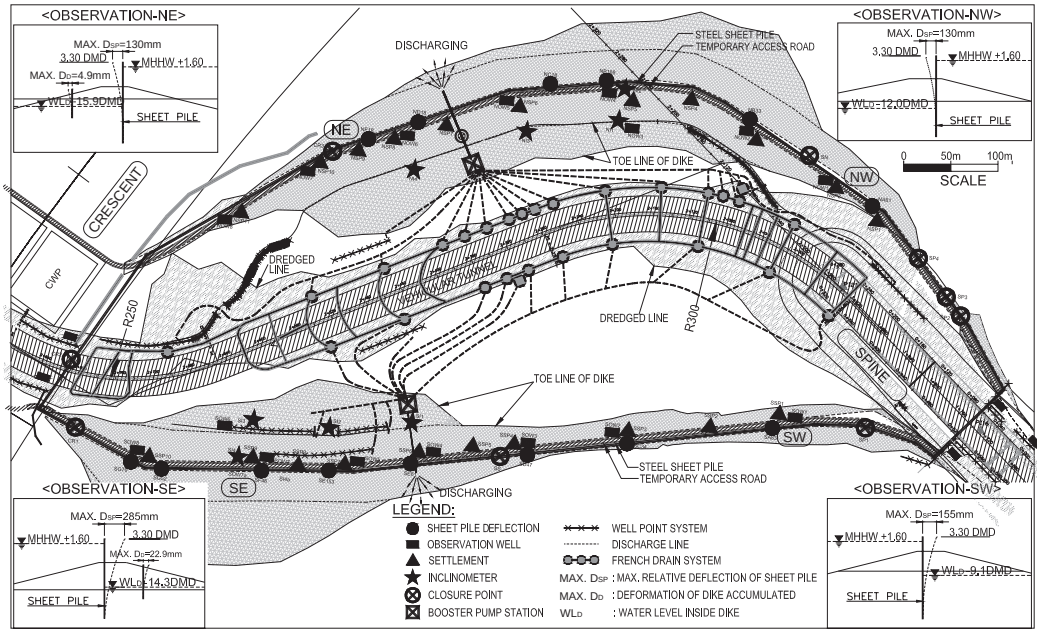

Figure 4. Dewatering regime and cofferdam monitoring points.

procured from Japan and had a 2 to 3 month delivery time. Used PU25 sections of some 10 m length were purchased locally and taken to an onsite yard at the top of the Spine where 20 m lengths were assembled. To determine the sheet pile drivability a trial was undertaken near the Spine portal close to a borehole location using PU series. The piles were spliced and driven to depths of 33 m using vibrohammer ICE815C (1250 kN max centrifugal force) without difficulty.

The newly purchased SX27 sections were taken to Hamriya Port, about 35 km east of the project site, where they were chamfered and welded to form 30 m lengths. Hyperseal DPS-1000 was applied to the pile clutch. This material can expand up to 10 times its original volume in fresh water but its performance offshore is curtailed due to the salinity of sea water and it expands to half the figure. The piles were paired to form 1.2 m wide panels, so that each prepared offshore panel comprised of 4 sheet piles, before being barged to site.

5.3 *Onshore sheet piling*

Sheet pile sections, 20 m long and 0.6 m wide, were pitched into a guide frame capable of accommodating 16 sheet piles and driven one by one with a 1.5 m stick up. Longer sheet piles could not be accommodated due to limitation of the crane boom. Ten metre long pile sections were hooked through the guide frame and spliced to the driven piles. Driving recommenced using vibrohammer ICE815C and progress was slow due to difficult driving. Some hard nodules present within the calcarenite and the wear and tear on the used piles were felt to contribute to difficult driving. Additionally two splices in the desired pile length did not always provide a plumb vertical section and this led to an increase in the frictional force in the pile clutch.

At some locations especially on the Crescent piles were terminated 5m short of the required design penetration due to refusal with the driving system. A reassessment of the seepage inflow into the cofferdam was undertaken using k of calcarenite 2×10^{-5} m/s which indicated that the anticipated inflow in this area increased 9 times locally with the nett effect that the overall infow into the cofferdam after draining increased from 820 m^3/hr to 1600 m^3/hr. To cope with the additional inflow contingency measures were put in place and comprised of (a) drive secondary short length sheet piles in local areas at the top of the tunnel trench excavation (b) increase the number of wells and (c) increase pump capacity.

5.4 *Offshore sheet piling*

Offshore piling was undertaken from 2 barges, each with a 150T crane, and the prepared panels 30 m long and 1.2 m wide, were driven through a guide frame using a double clutch vibrohammer ICE1412 (2300 kN max centrifugal force). The contractor reported difficult driving conditions which required greater effort

in getting the necessary penetration than had been anticipated initially. On average 2 to 3 panels were being achieved in a 12 hour shift. When the second barge, operating a week later on the opposite dyke, also experienced similar difficulties it was recognized that the problem was not local.

Piling records indicated that the penetration rate decreased significantly below −17 mDMD in the second calcarenite layer. A review of the unconfined compressive strength results indicated weak rock and that although the presence of hard nodules may explain some of the driving difficulties, something fundamental had been overlooked. Pairing the piles doubled the area at the cutting edge and also doubled the friction from the fill and underlying rock, and this resistance could not be overcome by simply doubling the hammer capacity required for a single pile section. The decision to pair the piles was taken after discussion with a local piling contractor who had successfully driven paired piles but not to the depth required for this project. An offshore pile driving trial may have revealed the problem earlier, and more work in this area would have been useful.

To overcome the difficulties in the short term predriving was undertaken with a panel connected to a water jetting system to −25 mDMD and withdrawn, and the final 1 m was driven with the permanent pile. Following the initial success with water jetting, a decision was taken to weld four 25 mm diameter steel pipes in the corners of all the sheet piles along its total length and connected to 2 mm diameter jetting nozzles located near the toe of the sheet pile. The pipes were hooked to a high pressure pump capable of delivering 250 l/min at 40 bar pressure. Simultaneous water jetting and driving with the same hammer overcame the driving difficulties. To make up for lost time a third barge was mobilized and a night shift introduced. In 86 working days 1290 paired sheet piles were successfully driven to the desired toe elevation. Towards the end a production rate of 5 to 6 pairs was being achieved in a single shift.

5.5 *Cofferdam closure*

Seven onshore and 2 offshore closures were necessary to complete the perimeter. Sheet pile sections driven from the opposite ends were overlapped so that an open box was formed. A uPVC tube was inserted from the top of the piles to key into the top of the dyke and grouted, thus sealing the open box. After setting, a borehole was drilled through the grout, the dyke and into seabed extending to the same elevation as the toe of the sheet piles. A rapid setting chemical grout, colloidal silica with sodium chloride, was then injected at 0.5 m centres working from the bottom up. The colloidal silica when set has a very low permeability, thus effectively sealing the closure point.

The offshore closure was undertaken during a Neap tide within a 4 hour window. Due to an increased flow velocity some scouring of the dyke, up to 2 m deep over an 8 m long section, was observed by divers deployed periodically during the course of the works. The dyke was repaired after closure.

5.6 *Draining*

Some 4,350,000 m^3 of water inside the cofferdam (excluding seepage) was pumped out in stages to reduce the water level from +1 m to −23 mDMD. This was undertaken using 9 high capacity pumps each fitted with a flow meter, of which 7 were operational at one time, connected via valves and manifolds to the discharge pipes and over the northern cofferdam wall and to sea. The pumps were located on two floating pontoons placed centrally at the deepest section of the trench excavation. Discharge was completed in 45 days and the rate of water level drop was maintained at less than 1 m/day. Some leaks in the sheet piles joints were sealed using underwater welding and sealants.

6 IN-SERVICE PERFORMANCE AND MONITORING

6.1 *Summary of instrumentation installed*

To provide information on sheet pile deflections, the deformation of the dykes, and water levels in the cofferdam 6 total station targets with a mirror attachment, 8 inclinometers, 16 observation wells with ground water loggers, and settlement monitoring stations were installed at strategic locations and depths. Base readings were established on top of the sheet piles before draining and the instruments were installed shortly thereafter. Temporary bench marks were installed at 50 m intervals on the shoulder of the dyke for monitoring settlements. Trigger and action values were identified for each item along with an action plan should the values be exceeded, and to provide an early warning system in the event that unanticipated conditions arise. Typical results are included on Figure 4 and an aerial view of the cofferdam is shown on Figure 5.

6.2 *Strengthening works*

A maximum total deflection of some 1000 mm and a relative deflection of 285 mm was recorded along a 200 m long section at the end of draining, which were in excess of the action values set. The measured deflections, which incorporates pile rotation, is in an area where the original dredged channel was the deepest and the dyke height maximum. CPT testing indicated the presence of very loose material with entrapped silty clay for which a horizontal modulus of subgrade reaction of 2000 $KN/m^2/m$ was appropriate. A best fit analysis using a 2D FEM analysis with

Figure 5. Aerial view, December 2005.

the surveyed dyke geometry and the lower modulus value was undertaken to simulate the actual condition, and indicated that the stresses in the steel piles were within tolerances. As a result, the trigger values for sheet pile deflection were revised up to 1250 mm at the top of the sheet pile as an absolute deflection and 335 mm between +3.0 m and −2.0 mDMD as relative deflection to reflect yield stress situation. Vibrotreatment works on 2.5 m grid spacing and to a depth of 15 m were undertaken in this portion of the dyke fill to densify the material and the crest level was raised by 2 m to 0 mDMD and the dyke widened locally to limit further deflections.

6.3 *Maintenance*

In addition to visual inspections the instruments are monitored daily. Once steady state conditions had established there was no further deformation of the dyke or additional deflections of the sheet piles, other than minor cyclic fluctuations due to tidal variations. The measured discharge averages 1650 m^3/hr and compares very favourably with the calculated inflow estimate of 1600 m^3/hr indicated by the seepage analysis.

Corrosion of the sheet piles due to seawater aggressivity was observed along the perimeter. Ultrasonic testing revealed that the rate of corrosion was 0.8 mm/yr at the upper half, where tidal fluctuations occur, and 0.3 mm/yr at the lower end of the cantilever section. A couple of moist areas were observed on the dyke slope and standpipes were installed in these areas which recorded water level at a depth of 3.5 m below the dike slope. The moist spots are related to the capillary rise in the area and the capillary fringe is consistent with the results reported by Fookes *et al*. (1983) for sandy silts.

7 PROGRAMME

The overall project schedule is shown on Figure 6.

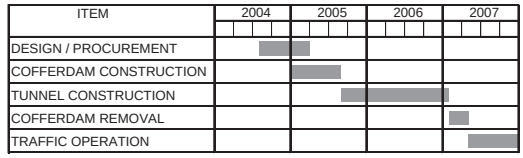

Figure 6. Overall schedule.

8 HEALTH, SAFETY AND ENVIRONMENT

A plan was prepared to evacuate the cofferdam in an emergency and drills undertaken at periodic intervals demonstrated that the work force could be safely evacuated in 8 minutes. Discharge water quality was visually monitored on a daily basis with water quality samples analysed weekly.

Whilst draining the cofferdam local fishermen were engaged to catch fish trapped within its confines using wire net traps of different sizes, up to 2 m in diameter. The trapped fish were removed and placed in oxygenated cool boxes before being returned to sea. Almost 1900 fish comprising 35 species were safely returned to open waters.

9 CONCLUSION

The successful completion and draining of the cofferdam has resulted in a safe environment enabling cut and cover tunnel construction to proceed. At the time of writing in September 2006, 85% of the tunnel structure is complete and the tunnel will be operational in December. Difficulties encountered whilst pile driving were successfully overcome with additional effort and within programme constraints, without compromising safety.

Flood Protection of Prague Metro after the 2002 flood

M. Jakoubek
Metroprojekt Praha, Prague, The Czech Republic

ABSTRACT: About one third of the length of operating lines of the Prague Metro found in the central area of Prague were inundated during the flood in August 2002. The construction of a new flood-protection system commenced immediately, when the damage caused by the flood had been repaired and the metro lines operation had resumed. Analyses and the assessment of the flood impacts showed that the flood wave threatens most of all cut-and-cover structures of the metro lines which are founded near to the surface, namely by increased external hydrostatic pressure and/or the hydrodynamic effects of this pressure. Mined metro sections are virtually unthreatened in these cases. Protection of the cut-and-cover structures is provided by several basic types of traditional construction measures. The structural parts found in the flooded zone are reinforced or thickened, permanently anchored, braced or supercharged. Structures which are selected with respect to their design and local hydrogeological conditions are provided with elements relieving the hydrostatic pressure on the outer surface of stations and concourses. This paper describes the function of the relieving elements in detail.

1 INTRODUCTION

The oldest line of the Prague Metro has been in service since 1974. Since then, 54 stations have brought into service, on three lines. Before 2002, all threatened sections of the Prague Metro had been protected against inundation from the surface up to the level of the Vltava River peak flood calculated in a 100-year cycle. The water surface level exceeded the 100-year flood level by more than 2 metres in the vicinity of some stations during the August 2002 flood. The metro entrance spaces were inundated by surface water; it was impossible then to prevent the water from rushing into the stations. At the same time, the flood wave was running through the metro tunnels. This is how the inundation affected the total of 17 stations (6 stations – primary inundation, 11 stations – subsequent inundation through running tunnels and cross-passages). Even though the flood wave did not affect integrity of structures, it caused extensive damage to the structural parts and equipment of the metro.

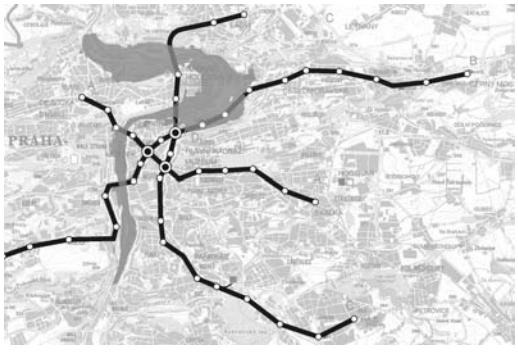

Figure 1. Plan map of the Prague Metro showing the extent of the surface inundation during the 2002 flood.

2 HYDROLOGICAL CAUSES OF THE FLOOD

The flood that passed through Prague in August 2002 had not been recorded before since 1827 when systematic hydrological monitoring started. It was probably the greatest flood in the history starting in 1432, when a flood destroyed five pillars of Charles Bridge, which was at that time the only stable connection between the Vltava River banks in Prague.

The peak flow was assessed statistically as a 500-year recurrence flood. Nearly 3 km^3 of rainwater fell during a single August week in 2002 in southern and south-western Bohemia. The amount of precipitation exceeded the precipitation totals for many months in some locations. The ground, which had been saturated by previous rains, did not receive other water, therefore nearly all this amount flew directly to streams and rivers. Virtually the entire above-mentioned area is part of the Vltava River catchment basin, therefore this amount of water had to flow through Prague in the course of several days.

The volume rate of flow, which is referred to as "100-year flood discharge" in statistical terms (3700 $m^3\,s^{-1}$) was exceeded roughly by 1500 $m^3\,s^{-1}$.

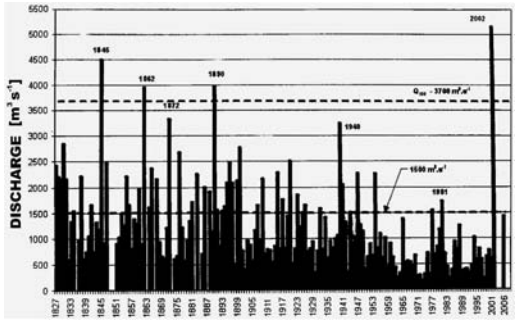

Figure 2. Time series of culmination flow capacity on the Vltava River – maximum annual flow capacity.

3 FLOOD PROTECTION SYSTEM DESIGN

3.1 *Parameters specified for the new flood protection system*

The catastrophic effect of the flood brought about a need for development of a new system of the Prague Metro flood protection. This is why the city authorities subsequently decided that the height of flood barriers be raised up to the level of the inundation experienced in 2002 in the given profiles of the particular stations, with a safety margin of 0.6 m. This level was further considered to correspond to the design protection height $Qn_{2002+0.6\,m}$.

The underground railway protection system is designed as a system independent of the systems protection individual districts of Prague; it protects the underground railway even in the case of the water spilling over barriers installed along the Vltava River. The primary task of the project is to prevent a flood wave from getting inside the metro spaces from the surface, in the case of inundation, to prevent water from spreading into other spaces of the metro, and to provide resistance of load-bearing structures of the metro against hydrostatic and hydrodynamic effects of the flood wave; The load bearing capacity of the metro structures is adequate to the height of all completed barriers.

3.2 *The summary of implemented measures*

The inundation of metro entries is prevented at the surface level by fixed walls and new lines where mobile barriers can be erected are prepared. When the flood wave is stemmed by barriers surrounding a metro station, the hydrostatic pressure on the station envelope will increase. Individual expansion blocks of cut-and-cover structures founded near the surface are, with respect to hydrogeological conditions threatened by heaving due to the buoyancy forces, or by a structural failure due to the hydrostatic pressure. The mined sections of the underground railway are not directly threatened by the flood.

The recently completed system of flood protection of the stations consists of implementation of several basic types of traditional construction measures. The load-bearing structures found in the flooded zone are reinforced or thickened, permanently anchored, braced and supercharged. Elements relieving the hydrostatic pressures on the outer surface of envelopes of stations and concourses are installed in some parts of the structures in the flooded zone, with respect to the design of these parts and local hydrogeological conditions. The construction measures that are implemented either remain hidden from passenger sights or they are incorporated into the architectural design of the stations.

The work on the flood protection system was carried out without any interruption to the underground railway operation. If the design protection height ($Qn_{2002+0.6\,m}$) is exceeded, the internal spaces of the metro stations found in the flooded zone will be automatically inundated. Elements of the civil defence system of the metro, namely pressure-resisting gates and other barriers, are also incorporated into the system preventing a flood wave from spreading.

In two cases (Florenc interchange station and the concourse of Invalidovna station), the implementation of the complete set of protection measures to reach the unified level is so complex and difficult that it will require much longer time than that required at the other stations. In the short run, organised inundation of the internal space of the metro is designed for these stations, to begin when a lower water surface level is reached for which the load-bearing capacity of the structures has been verified. The inundation of the internal space of the protected structure is a simple flood protection method. In this case, the pressures are equalised, thus damage to the structures is prevented. It has been proven that the damage due to the forced organised inundation would be lower by an order of magnitude and significantly faster to be compensated for than the damage resulting from contingent destruction of load-bearing structures.

4 TYPES OF THE CONSTRUCTION MEASURES IMPLEMENTED

4.1 *Permanent fixing of a concourse structure with anchors*

The system of protection against inundation from the surface level was provided for the concourse of Vltavská metro station, which had been originally built in an open trench. A line of permanent walls and mobile barriers up to 1.8 m high as a maximum was erected at the surface level. The barriers were

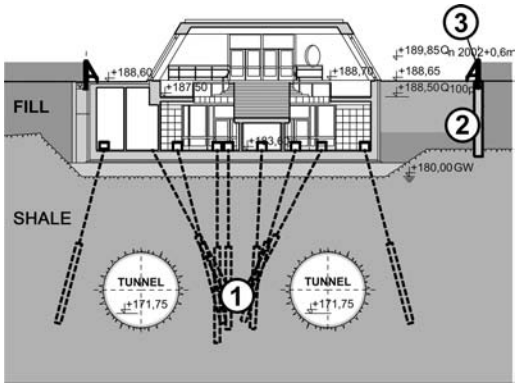

Figure 3. Permanent anchoring of Vltavská station to the bedrock. 1. Permanent anchors, 2. Jet-grouted pillars, 3. Mobile barriers.

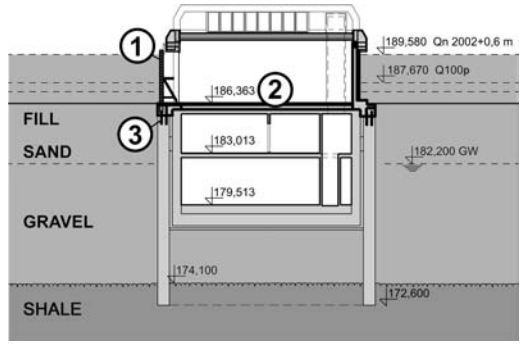

Figure 4. Incorporation of the weight of the diaphragm walls into the weight of concourse structure – Křižíkova metro station. 1. Mobile barriers, 2. Thickening of the roof structure, 3. Sills joining the diaphragm walls to the concourse structure.

founded on newly installed jet-grouted pillars keyed into bedrock consisting of shale.

The protection of the concourse structure against floating was provided by a system of permanent anchors (see Fig. 3). The structural analysis assumed full hydrostatic pressures exerted as a result of the design flood flow; the environment surrounding the concourse structure consists, according to the hydrogeological survey, of permeable man-made ground. The foundation slab of the concourse, which is found at a depth of 5.0 m under the surface, was tied to the bedrock with anchors; in terms of the structural analysis, this system even reduces the span of the slab carrying the hydrostatic forces. The ground plan of the grid of anchors was adjusted to operational requirements. The ends of the 500 (800) kN capacity anchors were provided with steel face plates. The openings where the anchors passed through the slab and the waterproofing layers were made watertight by grouting. The heads of the anchors found on the floor of the public area of the concourse were masked by visible benches. The hinged upper part of the benches allows an easy access to the anchor heads, where the pre-stress can be checked. The benches were incorporated into the architectural design of the concourse.

4.2 *Reinforcing and/or thickening of the structures; incorporation of diaphragm walls weight into the weight of the concourse structure*

The whole height of the original light-weight glazed external walls of the Křížíkova station concourse, from the floor to the roof, are designed to be replaced by 300 mm thick reinforced concrete walls. The walls will be structurally connected with the existing reinforced concrete underground part of the station and tied to the at grade steel structure of the concourse.

The newly constructed reinforced concrete sills are tied to the original diaphragm walls for the purpose of protecting the concourse structure against the buoyancy effects (spliced reinforcement bars). The incorporation of the weight of the diaphragm walls into the weight of the overall structure is shown in Fig. 4. Additional elements of the at-grade part of the concourse structure were built and this part of the structure was extended to cover the entire ground plan area of the underground part within the framework of the flood protection works. Openings and entrances to the concourse are protected up to the height of 3.0 m by means of mobile barriers. The architectural design maintains the features of the original design. The new external walls are a combination of stone cladding with opaque glazing.

4.3 *The drainage system for lowering of the ground water table during a flood emergency*

The technical solution to the flood protection system around Malostranská station is based on the idea of preventing inundation of the underground railway from the ground surface by means of mobile barriers and, at the same time, lowering of the ground water table in the immediate proximity to the concourse structure to a level specified by a structural analysis. The at-grade atrium space will be closed during a flood from all sides: from three sides by means of new lines of mobile barriers; from the west, the barrier is provided by the building of the Waldstein Riding-School built in 1630. The mobile barriers are founded on jet-grouted pillars. There are drainage galleries in the area surrounded by the barriers driven along the external wall of the concourse. Dewatering wells are at the ends of the galleries (see Fig. 5). The gallery houses a DN 250 mm horizontal drainage pipeline installed

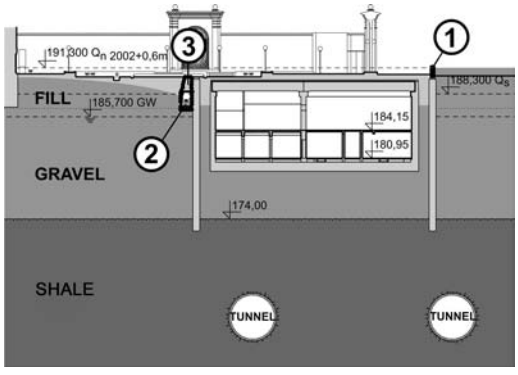

Figure 5. The drainage system along the concourse of Malostranská metro station. 1. Mobile barriers, 2. Drainage gallery, 3. Dewatering pump.

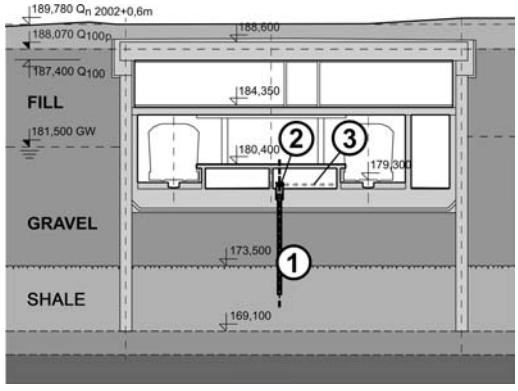

Figure 6. The pressure-control element passing through the foundation slab of Florenc metro station. 1. The cased hydrogeological borehole, 2. The head of the pressure-control element, 3. The pipeline draining water away.

on a 1 per cent gradient falling toward the dewatering well. The remaining space of the gallery around the pipeline is filled with gravel-sand, which guarantees that the stability of the environment being dewatered will remain unimpaired. The ground water that will seep to the galleries during a flood will be collected by the drainage and led to the wells; it will be pumped from the wells behind the barrier line, to the raised Vltava River. Thus the ground water table level in the atrium will be lowered and the hydrostatic pressure on the concourse structure reduced. The design has allowed for requirements for the stability of the Waldstein Riding-School subbase to be secured. The flow of water in the closed atrium space was verified by a hydrogeological survey and mathematical model.

4.4 *Pressure-control elements passing through the foundation slab*

The inventive solution to the problem of protecting the foundation slab against the buoyancy effects is based on pressure-control elements passing through the foundation slab of Florenc interchange station on the Line C (Fig. 6). The station was cut-and-cover top-down box excavation between slurry diaphragm walls. The foundation slab of the station consists of a single 221.0 m long expansion block. The design of the station (diaphragm walls braced with the bottom and roof slabs) does not allow overloading during the design flood.

The original structural analysis from 1970 assumed the 100-year flood level to be lower by 2.38 m than the current design level of the flood wave. This criterion is hard to satisfy by implementation of the above-mentioned traditional measures because of the existing intensity of operation of the interchange station. This is why a non-traditional solution to the problem of protection of the station substructure was adopted.

Figure 7. Drilling of the hydrogeological borehole through the hermetically embedded gate of the pressure-control element, with the seeping water drained away to a branch pipeline. A temporary extension piece is attached to the pressure-control element making it possible to cope with the inflows during the drilling operation.

Two hydrogeological boreholes passing through the foundation slab and reaching the bedrock were carried out inside the station to be used for pumping tests; additional two monitoring boreholes were drilled. As described in detail below, the drilling rods passed through special gates hermetically embedded in the foundation slab, with an intention to use them after the completion of the hydrogeological survey as parts of the pressure-control elements (see Fig. 7).

Based on the results of the hydrogeological survey, the function of the pressure-control elements can be described in the following simplified way: In a flood emergency, the hydrostatic pressure in the closed space under the bottom of the station and in the vicinity will

grow as a result of the rising ground water table level combined with an increased rate of seepage through the external diaphragm walls. The ground water table level around the station is bound to the level of the Vltava River surface. The installed pressure-control elements will allow controlled relieving of the hydrostatic pressure under the foundation slab of the station. When the valves installed on the heads of the pressure-control elements are opened, the pressure ground water will flow to the interior of the station and, at the same time, the hydrostatic pressure will be reduced in a controlled manner to the level verified by the structural analysis. Considering the completed measurements and on the basis of a model calculation, we can expect that the rate of the inflow which will be drained away into the existing sufficiently capacious non-faecal sump found in the metro station and pumped over back to the swollen Vltava River will amount to $5.0\,l.s^{-1}$. The efficiency of the protection of the foundation slab using the pressure-control elements was verified by hydrodynamic pumping tests within the framework of the survey activities, both in normal condition of the ground water table and, subsequently, using a mathematical model, which assumed the flow of the ground water during a flood emergency situation. The results of the model analysis resulted in addition of two elements to the existing four pressure-control elements so that gradual and steady process of reducing the hydrostatic pressure under the entire area of the foundation slab was possible. The filtration stability in the situation of ground water flowing from under the foundation slab of the station to the interior of the station is guaranteed owing to the hydraulically tested perforated casing of the boreholes and the fill around the casing pipes.

5 SOME ASPECTS CONCERNING THE INSTALLATION OF THE PRESSURE RELIEVING ELEMENTS

5.1 *The design*

The additional incorporation of the pressure-control elements into the load-bearing structure is an innovative solution, which has been applied neither in Czech probably nor foreign construction practice. The design followed pre-set requirements to be met by the pressure-control elements, first of all the viability of drilling through the foundation slab, which is exposed to a permanent hydrostatic pressure, and handling the subsequent flow of ground water into the station space. Further, the elements had to allow installation of equipment necessary for the pumping tests to be carried out within the framework of the hydrogeological survey, waterproof embedment into the foundation slab, and had to meet requirements for long-term resistance against pressure.

The work was complicated by the fact that the drilling of the cored boreholes had to be carried out through the reinforced concrete platform slab, during overnight traffic closures. The pressure-control elements were incorporated into the foundation slab using the following procedure (see Fig. 8):

1. Ø500 mm core drilling down to a depth of three quarters of the foundation slab depth (approximately 850 mm),
2. gluing of stainless steel prefabricated head of the pressure-control element into the foundation slab using an epoxy sealant,
3. a check test of hardening of the epoxy sealant,
4. checking on the sealing of the head by means of a pressure test (see below),
5. Ø300 mm core drilling through the remaining portion of the slab and the waterproofing layers, drainage of ground water away to the pumping station,
6. the final hydrogeological borehole extending to the bedrock; a pumping test,

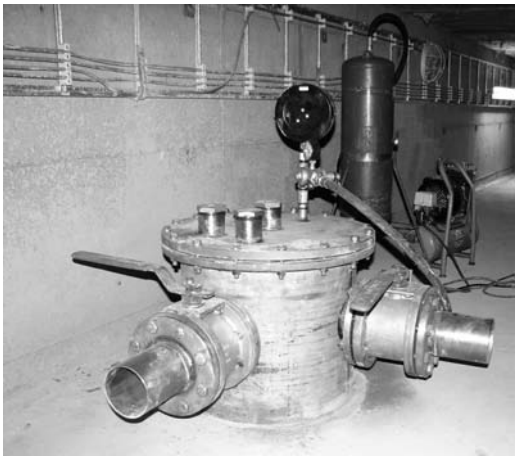

Figure 9. The complete pressure-resistant head embedded in the foundation slab.

7. installation of the equipment of the head, installation of closing ball valves,
8. closing of the pressure-control element

The valves are closed in the condition of common operation. These elements, which interconnect the external and internal environment, even allowcontinuous monitoring of the ground water pressure under the foundation slab.

5.2 *Testing of quality of the gluing and sealing of the heads of the pressure-control elements*

The tests carried out during the installation of the stainless steel heads of the pressure-control elements consisted of pull-out tests performed to verify the process of setting of the epoxy glue and pressure tests checking the tightness of the glued sealing and individual components (the valves, flanges) of the head of the pressure-control element. The testing set is shown in Fig. 9.

6 NOTES

6.1 *Other measures implemented within the framework of the flood prevention system*

The flood protection structures were built concurrently with installing permanent instruments monitoring the hydrostatic pressures in selected structures as a part of the survey operations. The load-bearing capacity of roof decks of the stations was tested using loads corresponding to the expected extent of the surface inundation. The services penetration points were inspected and the openings provided for the services in external walls were protected against leakage.

6.2 *Mined sections of the metro and the flood*

In terms of the condition of tunnel structures, we can say that the mined sections of the Prague metro survived the 2002 flood without any damage. The metro was in full service even during the initial hours of the flood while the water surface level had risen by several metres. No increased leakage was observed, let alone operational safety threatening defects caused by the adequately increased hydrostatic pressure on the tunnel lining. Despite the fact that speculative notions that the inundation happened due to a collapse or holing of the main load-bearing structures which were expected to withstand the water pressure, the inspection carried out after the water pumping had been completed and the condition of the structures checked conclusively proved that the tunnel lining passed this test undamaged.

7 CONCLUSIONS

The solutions described in this paper regarding the problem of protection of load-bearing structures are generally applicable to other structures located in a flooded zone or threatened by increased level of the ground water table.

The above-mentioned method of diminishing the hydrostatic effects by means of additional incorporation of the pressure-control elements can be conveniently utilised in other cases, after a thorough analysis of the condition of the lining and of the potential rate of water inflow from the outer environment. A hydrological survey of the outer environment and subsequent verification of the function of the pressure-control element are advisable.

Regarding the existing underground structures exposed to one-off effects of increased hydrostatic pressures, for instance during a flood, the application of the pressure-control elements is not only a highly effective but also highly economic solution compared with traditional conventional methods.

A catastrophic flood, similar to the flood which hit Prague and inundated the metro, can also affect other cities where underground railway lines are within the reach of a river. We can recommend a responsible solution of the flood protection system to be developed in such a case.

Shinjuku 7-chome work Office of Konoike, Aoki Asunaro, Siraishi Kensetu Joint Venture

ABSTRACT: The Tokyo Metro Line No. 13 of is a north-south line between Kotake-Mukaihara and Shibuya, of which the 8.9 km section from Ikebukuro to Shibuya is currently under construction for scheduled opening in June 2008. (Figure 1). The project includes building the Shinjuku 7-chome Station (tentative name) at an average excavation depth of 37 m and with a length of 373 m immediately below Meiji Street, which has one of the largest traffic volumes in Tokyo. The section discussed is located in the first section on the Ikebukuro side (199 m long). The approximately 20 m length portion of this section, which is under the Okubo Intersection where Meiji Street and Okubo Street cross, has major underground lifelines, including two NTT tunnels, a Tokyo Electric Power tunnel, and a main sewer (Figure 2). As it is difficult to proceed with excavation while protecting these existing buried utilities through suspension, it was decided to employ the cut-and-cover method for each section on Ikebukuro and Shibuya sides from the intersection, except that the section immediately below the intersection was to be excavated according to the non-cut-and-cover construction method. This paper provides a summary of the underpinning method using pipe-roof to protect the intersection structures.

1 SUMMARY OF GEOLOGICAL FEATURE

The geological profile of the section includes, from the top downward, subsurface soil, Kanto loam (with the N-value of around 5), terrace gravel (with the N-value of around 2), Tokyo formation (with the N-value ranging from 10 to 50) and Kazusa group (with the N-value of 50 or more). The clayey soil is hard and the sandy soil is extremely compacted. Figure 4 shows the soil boring log.

Figure 1. Work location map.

2 OUTLINE OF THE WORK PROCEDURE

To avoid impacting the large buried utilities during excavation according to the non-cut-and-cover construction method for the approximately 20 m section

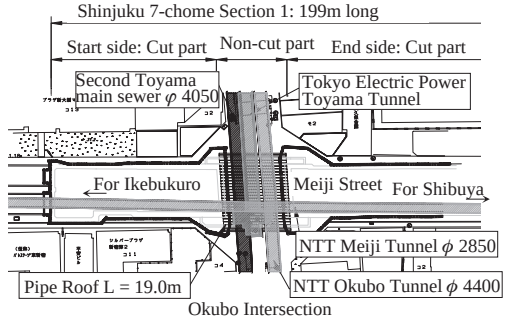

Figure 2. Plane view.

below the Okubo Intersection, the pipe-roof was constructed under the buried utilities, followed by its underpinning with bearing piles and finally by tunnel excavation and construction of tunnel structures. Figure 3 shows a plan view, Figure 4 provides a cross sectional view, and Figure 5 a longitudinal profile.

2.1 *Construction work sequence*

Figure 6 provides an outline of the work.

2.1.1 *Shaft excavation*

Using a cut-and-cover method a shaft was excavated at both ends of the intersection to be used as a base for constructing the pipe roof.

2.1.2 *Pipe-roof*

From inside the shaft, 26 horizontal pipes and 13 vertical pipes were driven to form the pipe-roof for temporary support. Explanation on how this was done will be made later.

2.1.3 *Excavation of the portion protected by pipe roof and driving of bearing piles*

The portion (5.6 m high) protected by the pipe-roof was excavated in steps of every 2.5 m depth. Each time such excavation was completed, bearing piles were driven from inside the shaft, support beams were installed, and jack-up (preloading) was done. By supporting the pipe-roof through sequential steps in this

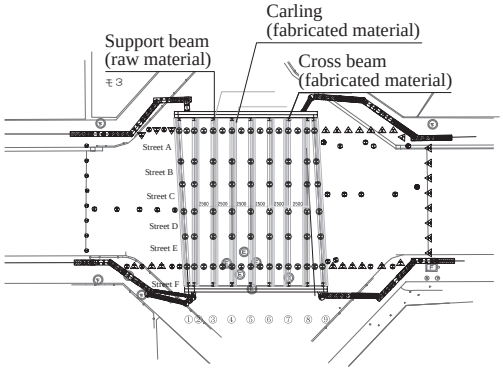

Figure 3. Plane view.

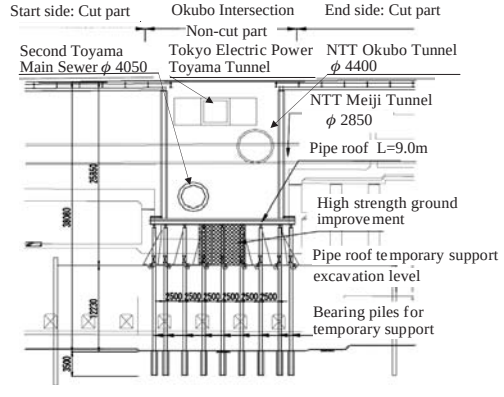

Figure 5. Longitudinal profile.

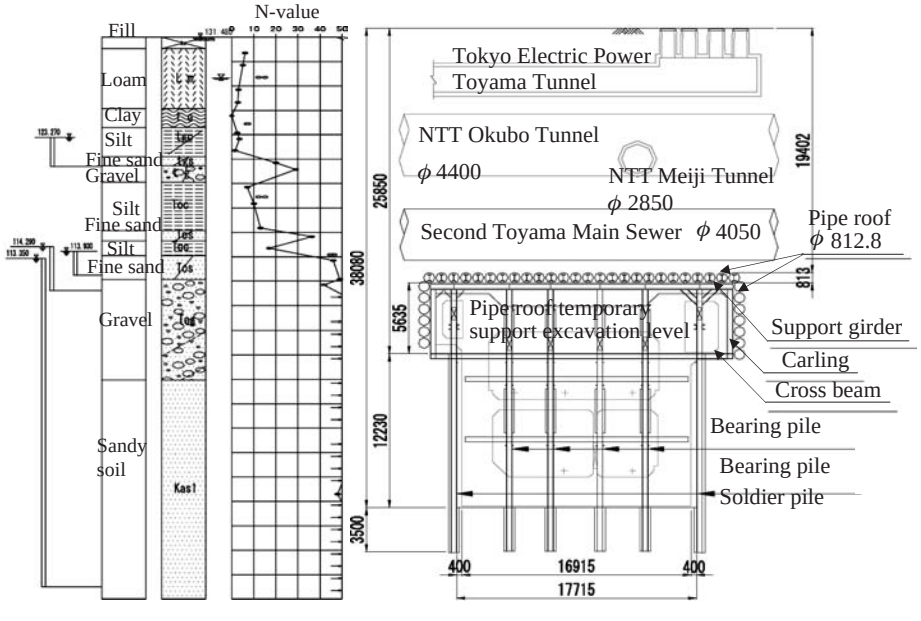

Figure 4. Cross section.

way, temporary underpinning was provided under the intersection. Concurrently, earth-retaining piles were also placed on both sides.

2.1.4 *Excavation of the main tunnel*
Under the protection of the pipe-roof, subgrade excavation of the tunnel was made in two stages (double-deck support).

2.1.5 *Building the tunnel structure and backfilling*
After completion of subgrade excavation, the tunnel structure was constructed.

3 ENGINEERING CHALLENGES

3.1 *Excavation under the pipe-roof protection*

As the pipe-roof was to be provided immediately below the important structures, the superfluidity (??) balance semi-shield method (mud density shield method) was employed, which can prevent ground collapse and groundwater inflow and minimize the extent of the ground loosening during excavation (Photograph 1). To protect launching and arrival of driving under pipe-roof protection, chemical grouting for water cut-off was made in advance from inside the shaft and also for the excavated portions to minimize any impact on the buried utilities from excavation under pipe-roof protection.

3.2 *Pipe-roof members*

Preliminary study was made on the displacement of the pipe-roof, the axial force of the bearing piles and the effects on the buried utilities expected during excavation of portion protected under the pipe-roof. Since the result proved that the initially designed members would exert substantial effects on buried utilities, members were changed to those with higher rigidity.

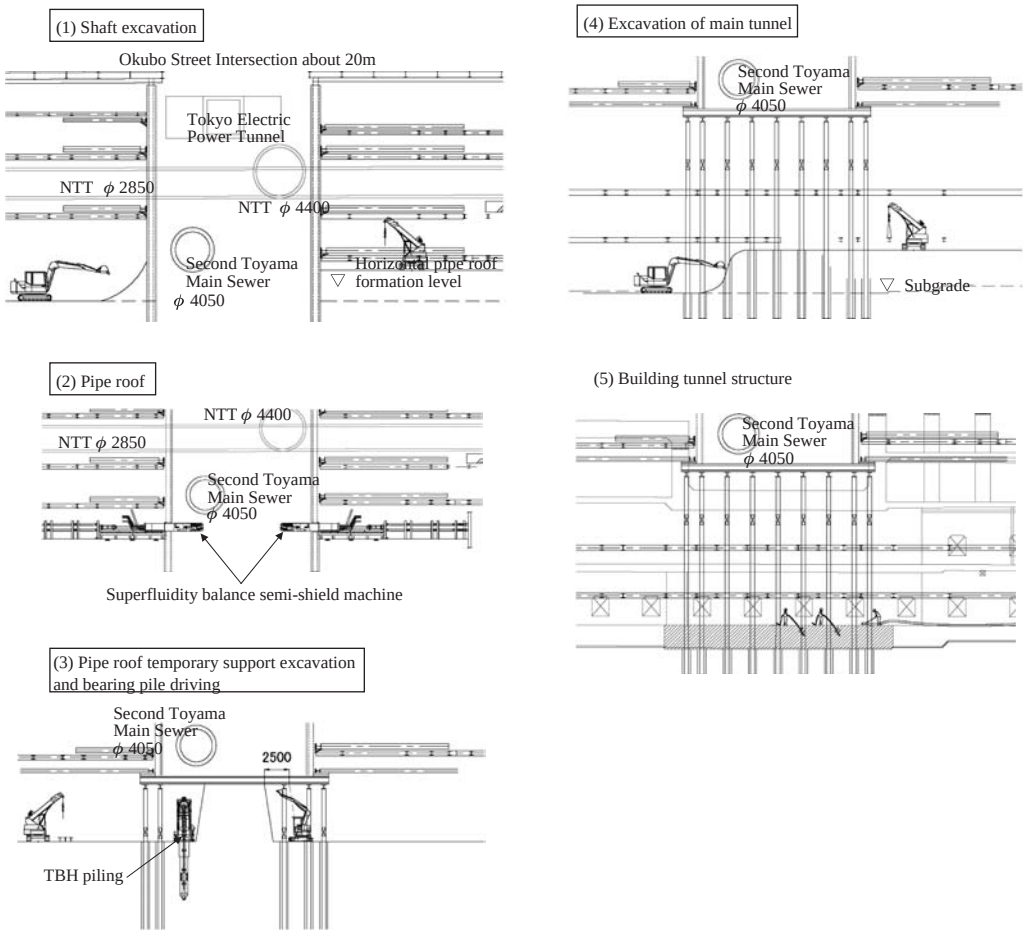

Figure 6. Construction outline.

Photograph 1. Completion of pipe roof protection.

– Before change Horizontal steel pipe φ812.8 mm t = 12 mm (Mortar filled)
– After change Horizontal steel pipe φ812.8 mm t = 22 mm (Mortar filled) Insert a core material H-488 × 300 in a steel pipe

For analysis, the sequential stress analysis method was employed, in which the excavation sequence and ground plasticization were studied by applying the surcharge to the elasto-plastic beam spring model comprising the beam for the pipe-roof, the elastic foundation for the ground, and the elastic support for bearing piles. Figure 7 shows the analysis model.

3.3 *Bearing piles*

The pipe-roof carries the overburden load of about 130,000 kN (13,000 tf). The maximum load burden per pile is 5000 kN in case of temporary support and 3000 kN after completion of the temporary support. Therefore, TBH piles that are advantageous in easy treatment of their edges were used to secure the bearing capacity and to reduce pile settlement under load (Photograph 2).

3.4 *Preloading method*

Initial preloading was done each time one row of support beams had been installed and adjustment preloading was done after completion of temporary support protection (completion of installation of all support beams).

3.4.1 *Initial preloading*

The load of 100% or more of the dead load was introduced during initial preloading after laying the support beams, so as to enable monitoring load measurements during construction without fastening the safety nuts of jacks.

Loading was made as follows: the load expected in the future was applied, as the hysteretic load*1, stepwise in advance, followed by unloading to the preload*2 after confirmation that there was no abnormality in the pile settlement and pipe-roof behavior. Figure 8 shows the initial preloading steps.

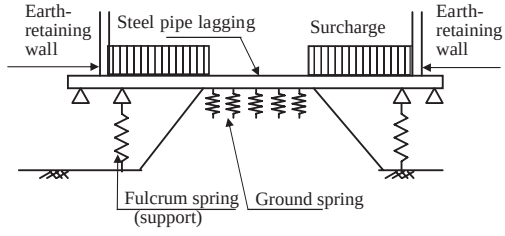

Figure 7. Analysis model.

Photograph 2. Pipe roof temporary support, TBH piles.

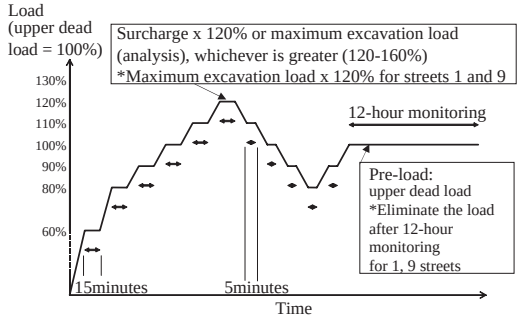

Figure 8. Initial preload loading steps.

*1. *Hysteretic load*

In the preliminary elasto-plastic analysis, the maximum load applied during excavation or the preload (surcharge) × 120%, whichever is larger, is introduced as the hysteretic load. Preliminary loading to provide

hysteresis enables prevention of further settlement of bearing piles.

*2. *Preload*
Unit surcharge x assigned area, which is determined by calculating the overburden load and by taking into account the tare of pipe-roof and the tunnel. Displacement of the pipe-roof is prevented by applying the loads to the bearing piles before excavation.

3.4.2 *Adjusted preload*
It was decided to adjust the load balance when any variation was observed in the load of support beams that had already been subjected to initial preload after installation of all beams.

The adjusted preload to be applied was set as the total of preloads on piles.

3.5 *Subgrade excavation of the main tunnel*

Skin friction resistance that is reduced by excavation is thought to migrate into the pile embedment, causing settlement. Therefore, a vertical load test using the driven piles was made to confirm the distribution state of pile bearing capacity and skin friction resistance and to estimate the increased load migrating to the pile embedment.

3.6 *Measurement control*

Various measuring instruments were installed to identify the conditions of buried utilities and temporary support protection members during construction, so that excavation can be made concurrently while comparing measured values with the predicted values. (Table 1)

3.7 *Bidirectional excavation*

As it was necessary to shorten the construction period to open the tunnel in June 2008, bidirectional excavation was employed, instead of the originally designed unidirectional excavation. As deformation of the pipe-roof in bidirectional excavation was greater than that in unidirectional excavation, attempt was made to achieve high ground strength by grouting chemicals of a design strength of 1.0 N/mm^2 (10.0 kgf/cm^2) in the center of the pipe-roof to restrain deformation of the ground and the pipe-roof.

4 VERTICAL LOAD TEST

4.1 *Bearing capacity*

By multi-cycle tests, maximum 6000 kN was loaded, resulting in observation of some change against a load of 5000 kN or more. It was thought that the value would not reach a first limit resistance . We judged that the ultimate bearing capacity would be 6000 kN or more and the allowable bearing capacity 5000 kN or more (safety factor of 1.2).

Table 1. Measurement control items.

	Subject	Measurement item	Measurement method
Buried utilities	NTT Okubo Tunnel and Meiji Tunnel	Distortion and convergence	Optic fiber strainmeter in the tunnel
	Second Toyama Main Sewer	Settlement	Placed settlement bar in the sewer and surveyed level of the crown of the sewer pipe
	Tokyo Electric Power Toyama Tunnel	Settlement	Entered the tunnel and surveyed level of the lower floor
Temporary support	Horizontal pipe-roof	Settlement	Placed pressure-type settlement gauges in the pipe-roof steel pipes
	Bearing pile jacks	Jack pressure	Placed pressure converters in the hydraulic cables of jacks
	Bearing piles	Axial power	Placed strainmeters on the bearing piles. Converted the measured strain to the axial force
		Settlement	Placed electronic staff in the bearing piles and measured the levels with an automatic level

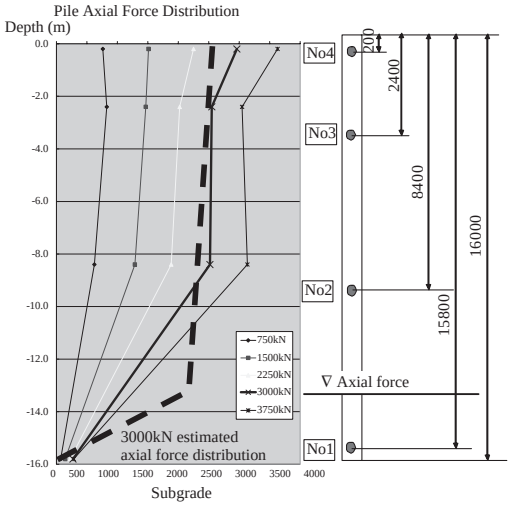
4.2 *Skin friction resistance*

Figure 9 shows the distribution of axial force as measured by strainmeters attached to the piles. The strainmeters were not placed at the subgrade level but, judging from the distribution state (red dotted line), a load of some 2500 kN was carried near the subgrade under the load of 3000 kN after completion of temporary support. It was estimated that the incremental load at the embedment by subgrade excavation would be about 500 kN.

5 MEASUREMENT CONTROL RESULTS

5.1 *Measurement of the buried utilities*

We were able to complete the excavation within the controlled values, although some effects were seen



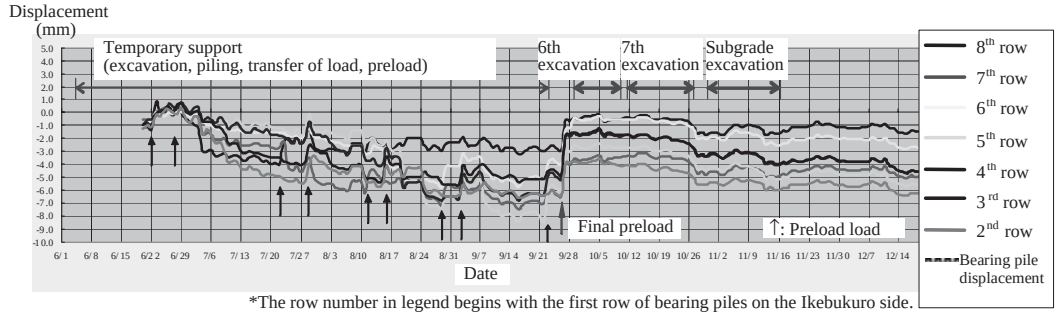


Figure 9. Pile axial force distribution.

Photograph 3. Completed pipe roof temporary support.

Photograph 4. Subgrade excavation upon completion.

*The row number in legend begins with the first row of bearing piles on the Ikebukuro side.

Figure 10. Chronological change in pipe roof pressure-type settlement gauge and bearing pile electronic staff.

during the pipe-roofing. Upon establishing temporary support and subgrade excavation, the protective structures such as the pipe-roof effectively worked and caused no increase in displacement.

5.2 *Pipe-roof settlement*

5.2.1 *When excavating pipe-roof temporary support for temporary support*

The settlement at maximum was 9 mm as compared to the projected value of 8.5 mm, but it was 4 mm at maximum upon final preload (Photograph 3).

5.2.2 *Subgrade excavation*

The settlement increased by about 2 mm as compared to the incremental predicted value of about 5 mm, but the maximum settlement was about 6 mm (Photograph 4).

5.3 *Bearing pile settlement*

Like the pipe-roof settlement, there was an increase of about 2 mm between completion of the final preload and subgrade excavation. Figure 10 shows the chronological changes of the pipe-roof pressure type settlement gauge and the bearing pile electronic staff.

6 CONCLUSION

We conducted non-cut-and-cover construction of a station site for a subway line in an important traffic node in central Tokyo by using a temporary support with pipe-roof underpinning to reduce the effects on large buried utilities. We hope this example can serve as a reference for similar projects.

Czech Technical University, Faculty of Civil Engineering, The Czech Republic

ABSTRACT: This project has completed a thorough review and evaluation of the state of the art in design and construction of large-span corrugated metal and reinforced concrete Arch-Shaped Cut-and-Cover (ASCC) structures. Through full-scale field tests the behaviour of investigated structures was made. Indeed, the extensive computer modelling took an important role within this research to extend the understanding of ASCC structures behaviour under different conditions. Both the corrugated metal and reinforced concrete ASCC structures are the main interest of this work. Two comprehensive computational models were developed using finite element package PLAXIS and validated by field measurements of tunnel profiles at different stages of backfilling procedure. Firstly, the replacement of the soil by two different kinds of plasticity models is conducted. Secondly, the response of the numerical models without and with compaction process is analysed. Finally, several parametric studies are performed by means of the numerical model with the closest results to the field measurements.

1 INTRODUCTION

The general aim of the research presented here is to update the construction specifications for metal and concrete ASCC structures which do not reflect current knowledge. Because large span Arch-Shaped Cut-and-Cover (ASCC) constructions depend on soil support for proper performance, it is imperative that the construction procedures must be carefully specified and implemented.

The main findings of this work are twofold. Firstly, a comparison between the results from the finite element analyses by means of two material models for non-linear soil behaviour; the Mohr-Coulomb model (perfect plasticity) and the Hardening-Soil model (deviatoric and volumetric hardening with plastic strains); and observed field measurements from real arch-shaped corrugated metal as well as reinforced concrete cut-and-cover structures are made. Secondly, parametric studies are carried out using the numerical models with the closest computed results to the real case. Three main objectives are analysed within parametric studies. Namely relevancy of using more sophisticated material models, behaviour of ASCC structures in different geological conditions and behaviour of ASCC structures in extreme unfavourable situations. The results of the parametric studies are used to develop generalised simplified expressions for predicting design forces for both the corrugated metal and reinforced concrete ASCC structures. Factors such as the influence of different types of subsoil, arch structural material, cover depth and extreme situations are reviewed.

2 STATE OF THE ART OF ASCC STRUCTURES

Flexible and rigid ASCC structures, ranging in span from 3 m to occasionally more than 15 m, are often a practical structure for short to intermediate span crossings, especially on local road systems. The use of these structures is growing; however, the available design and construction specifications have not been updated for many years. Current design of metal ASCC structures is largely experience based, and, with the exception of thrust, design forces are not computed. Current design of large-span concrete ASCC structures is less empirical than that of metal constructions. However, several key parameters are still not defined, and the result is that designs may vary because of reasonable interpretations of the code.

Over the past 30 years, the development of ASCC structures in the Czech Republic has been quite significant. The first structures of this type were constructed in the middle of the 1970's these constructions were abandoned in the 1980's. The advantages of ASCC structures and today's more advanced technology concerning the construction process and monitoring as well as a fundamentally different economic approach

to led further substantial development of these constructions in the Czech Republic in the second half of the 1990's.

3 FULL-SCALE FIELD TESTS

The results presented below are related to cases with small heights of backfill cover. The opportunity to compare calculated and measured behaviour of these structures was afforded at two full-scale field tests conducted at the University of Massachusetts at Amherst within the framework of the National Cooperative Highway Program to investigate the structural behaviour of large-span ASCC structures under shallow fills. The test investigated the ASCC structures response to forces resulting from erection, placement and compaction of backfill as well as from live load. During field measurements ASCC structures behaviour, soil behaviour, structure-soil interaction during backfilling and live loading were monitored. The ASCC structures were installed end to end in a single trench, see Figure 1. The span and rise of both test structures were approximately 9,3 and 3,6 m, respectively. The concrete ASCC structure was precast and delivered to the site in 1,8 m segments. The metal ASCC structure was assembled on site from corrugated structural plates. Two sets of tests were carries out. The first installation used a well-graded, clean sand backfill compacted to 92% Proctor Standard. The second test used the same backfill but without compaction. In this second test, the material achieved about 85% Proctor Standard density.

In both tests, the crown continued to rise until earth was placed over the top of the structure, at which point the movement was reversed. In test with the backfill compacted to 95 percent of maximum dry density, crown peaking deformation exceeded the subsequent downward movement during overfilling. Maximum peaking during backfilling was about

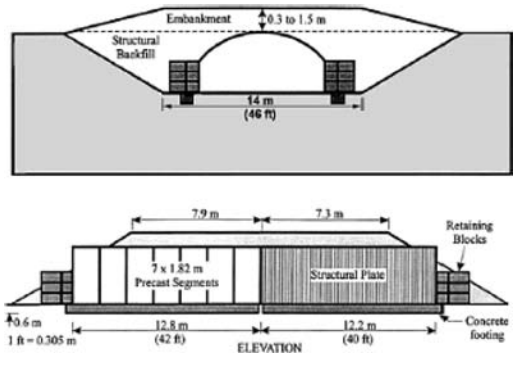

Figure 1. Installation of the arches (McGrath et al., 2002).

80 mm, respectively. Both tests showed fairly similar trends for movements of the curvature points.

Horizontal changes in top chord measurements for both investigated structures during backfilling operation were obtained. The reinforced concrete arch showed very little movement between the curvature points for both tests. The metal arch produced similar changes in top chord measurements during top loading for both tests (inward movement of the curvature points and thus contraction). More over, the concrete arch did not significantly deform during backfilling procedure. Measurements indicate a maximum downward movement of the crown of less than 2 mm at the end of backfilling operation. Also, maximum outward movement (spreading) of the arch legs was less than about 2 mm.

4 NUMERICAL MODELLING

The finite element package PLAXIS v. 7.2 (Plaxis Reference Manual, 1998) was chosen for developing comprehensive computational model of both the corrugated metal and reinforced concrete ASCC structures, presented in this project. In this project the lining of the cut-and-cover construction was assumed to be linear-elastic and for the soil continuum two different soil models were used. Firstly, the soil continuum was assumed as Mohr-Coulomb model (perfect-plasticity) for a quick and simple first analysis of the problem, and secondly Hardening-Soil model (deviatoric and volumetric hardening with plastic strains) was used as a more sophisticated constitutive model.

5 DEVELOPED NUMERICAL MODELS

On the whole eight numerical models were developed and adopted to approximate the actual construction processes as closely as practically feasible. First set (four) of numerical models represent the corrugated metal structure and the rest reinforced concrete structure. Two soil constitutive models (Mohr-Coulomb and Hardening-Soil) are applied into numerical model of each investigated structure. More over, each of used numerical models based on different soil constitutive models was calculated in respect of the construction process without and with compaction procedure.

6 DEVELOPED NUMERICAL MODELS

The database of obtained data from the full-scale field tests was used to compare the response of four constitutive models for both concrete and steel ASCC structures. Selected results of the constitutive models are examined, in order to achieve a better understanding of the cut-and-cover system behaviour. Most

observations refer to horizontal and vertical displacements, internal forces (bending moments and thrust) and the development of earth pressures in time on the contact of tunnel lining and backfill. In additional, the construction phase where the tunnel structure was built up was taken into the comparison as an initial state with zero displacements and/or pressures.

6.1 *Metal ASCC construction*

6.1.1 *Comparison on displacements*

Deformation measurements were made with the laser, digital level, structural extensometers and the manual tape extensometer. The measurement locations are summarised in Figure 2 for the metal structure, respectively. A total of 26 locations around the circumference of the metal construction were selected for detailed laser measurements. A conventional level survey with a digital level was used to obtain level measurements of crown and points of radius change. Structural extensometers were used to measure relative horizontal movement between points of radius change.

Table 1 summarises the calculated and measured response of the crown using values of total uplift movement to the point where the backfill reaches the crown and the subsequent downward movement as the earth is placed up to 0,9 m above the structure. Again, these demonstrate that the values calculated by HS and MC are the most similar ones to demonstrations measured in the tests.

6.1.2 *Comparison of internal forces (bending moment & thrust)*

Sets of four weld able electrical resistance strain gauges were installed at each of 25 locations on the inside wall of the metal lining (circumferential and longitudinal directions on inside crest and valley locations). In Figure 3 is clearly visible the exact locations of strain gauges. However, the thrust strains were small and are believed to be in error. The computed bending moments are believed to be correct and, therefore, only bending moments obtained from the full-scale test are reported here. Wall thrusts were estimated from measured radial pressures. In addition to computing strain thrusts from the measured radial pressures, additional strain gauges were installed just before removal of the backfill at the centroidal axis of the wall section at seven locations around the arch circumference. These locations included the arch springlines, curvature, shoulders and crown. After the centroidal strain gauges were added, the structures were uncovered, and the load on metal arch could thus be obtained from unloading.

Bending moments at the crown and shoulders are summarised in Table 2. Calculations at other locations were also reviewed and yield similar trends. Peak negative moments occur at the crown, as a result of lateral earth pressures and compaction induced deformation during placement.

Results obtained with the compaction models provide conservative bending moments for this shallow buried structure. Bending moments would eventually change sign as the structure was buried further. From that point, the analysis without compaction would yield conservative values of bending moments.

6.2 *Concrete ASCC construction*

6.2.1 *Comparison on displacements*

The same equipment for measure deformations was used as for corrugated steel ASCC structure (the laser, digital level, structural extensometers and the manual tape extensometer). The measurement locations are summarised in Figure 4 for the reinforced concrete structure, respectively. A total of 23 locations

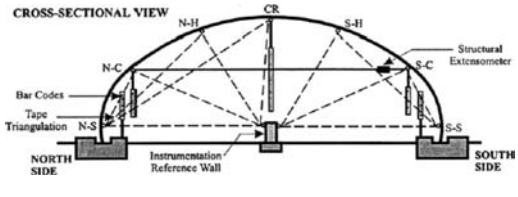

Figure 2. Instrumentation for monitoring deformation in metal structure (McGrath et al., 2002).

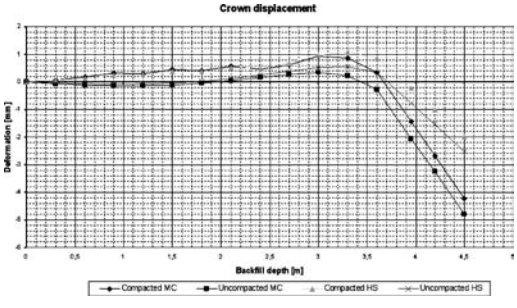

Figure 5. Crown deformations of concrete arch during backfilling procedure.

around the circumference of the metal construction were selected for detailed laser measurements. A conventional level survey with a digital level was used to obtain level measurements of crown and points of radius change.

The reinforced concrete ASCC structure showed very little movement between the curvature points during the test. For the concrete arch, compaction test produced slightly more inward movement (contraction) of the curvature points compare with test without compaction. The concrete arch did not significantly deform for either of the tests during backfilling procedure. Field measurements indicate a maximum downward movement of the crown less than 2 mm at the end of backfilling. Also, maximum outward movement (spreading) of the arch legs was less than about 2 mm. For the reasons mentioned above no results obtained from field measurements were presented. Figure 5 presents crown movement of the concrete arch

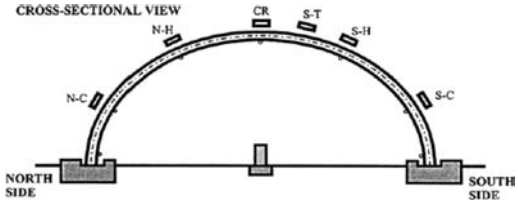

Figure 6. Interface pressure cells for reinforced concrete arch (McGrath et al., 2002).

during backfilling calculated by code PLAXIS. From the plot is visible the upward movement of the crown within all analyses less than 2 mm since the fill reached the top of the arch. Then movement changed direction and at the end of backfilling crown moved downward up to 5 mm, respectively.

6.2.2 *Comparison on displacements*

The transverse locations of installed earth pressure cells around the reinforced concrete ASCC structure are shown in Figure 6, respectively. Sixteen earth pressure cells were installed around the arch.

Analysis of the reinforced concrete field tests focused on the interface pressures, as these pressures are commonly used as a basis for simplified design. As for the metal ASCC structure test, the results were evaluated with two-dimensional computer model.

Table 3 compares field data with mathematical calculations with and without compaction for earth loads. The table shows that calculated pressures by the code PLAXIS at all measured points are somehow slightly lower compare to field measurements and the calculations at the crown are also less than measurements at both locations. In this case, the field data may be in error, as the vertical pressure at the crown should be essentially geostatic, which is consistent with the computer predictions. The field data might be also affected by the low cover and low stress levels.

These comparisons also highlight an important discrepancy between measurement and calculation near the arch crown. The soil at this location likely experiences a vertical earth pressure distribution close to geostatic values. Using a bulk unit weight of 20 kN/m^3 implies vertical stress of 18 kPa at 0,9 m depth. This

Table 3. Comparison of calculated and measured earth pressures.

		Measured	Uncompacted		Compacted	
	Location	[kPa]	MC [kPa]	HS [kPa]	MC [kPa]	HS [kPa]
SC-NC	North	51,93	39,67	42,12	40,19	40,47
	South	48,01	41,42	38,93	41,73	42,11
SH-NH	North	31	27,6	28,58	28,59	29,25
	South	27,85	28,01	29,12	28,64	29,42
ST		26,9	22,29	22,71	23,28	24
CR		23	16,69	16,93	17,18	17,3

is consistent with the finite element calculations and implies that either the stress distribution at the crown of the arch is not geostatic or, more likely, that the stress cells overestimate earth pressures when the stress is low.

7 PARAMETRIC STUDIES

The finite element analysis used the mathematical models with compaction were giving closer results to the field measurements throughout the whole procedure compared to other numerical models without compaction. That is why the analyses using the finite element models with compaction are chosen for further investigation.

A comparison between the results obtained from the finite element analyses by means of two material models for non-linear soil behaviour; the Mohr-Coulomb model (perfect plasticity) and the Hardening-Soil model (deviatoric and volumetric hardening with plastic strains); is made. Moreover, the seven different types of subsoil are used to get comprehensive understanding of investigated constructions and their behaviour during backfilling procedure. The types of subsoil used within individual analysis represented the whole spectrum of geological conditions (from good grained sands through overconsolidated clayey soils to soft clays) where ASCC structures could be constructed on.

The main findings of the parametric studies are threefold:

1. To investigate the relevancy of using more sophisticated material models in the case of mathematical modelling and design of the ASCC structures.
2. Recommendations of the most suitable usage for both metal and concrete ASCC structures within different geological conditions are made.
3. To observe the influence of extreme antisymmetrical earth load as well as the extreme local force load with and without interaction of backfill soil on the behaviour of both the corrugated metal and reinforced concrete ASCC structures.

Table 4. Extreme displacement differences of metal and concrete arches in respect of dissimilar geological conditions. A – Berlin Sand, B – Frankfurt Clay, – Percentage [%].

	Metal			Concrete

Note: All values are in [mm], negative values = inwards and/or downwards movements of the arch. Negative percentage values represent higher deformations reached on Berlin Sand subsoil.

8 SUMMARY AND CONCLUDING REMARKS

Comparative analyses have shown that, although simple models generally provide realistic values of lining movements and distribution of internal forces, only the most complex model accurately predict soil displacements. The first part of parametric studies is aimed to analyse the relevancy of using more sophisticated material model in respect of large span ASCC structures. From results reached within first part is clearly visible that in both cases, corrugated metal and reinforced concrete arch, is recommended to use more sophisticated material model if:

- the quality of subsoil layer is poor (very soft clays),
- the overburden layer is higher than rise of the arch.

The behaviour of ASCC structures built on varied spectrum of different subsoil layers were introduced in the second part of parametric studies. On the whole, seven types of subsoil were analysed. From obtained results can be seen that for worth subsoil layers is suitable to use more flexible constructions in this case corrugated metal arch. Deformations calculated on the reinforced concrete arch built on different subsoil

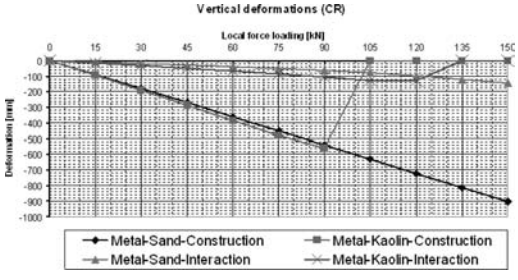

Figure 7. Vertical movement of the top of the metal arch built on different subsoil considering interaction with surrounding soil.

were approximately ten times higher compare to the corrugated metal arch, see Table 4.

Analyses of internal forces showed the same tendency and approve the conclusion remark reached by study of deformations, see Tables 5 and 6. This part of parametric studies demonstrated high sensitivity of stiffer constructions on geological conditions especially on subsoil layer.

As it is mentioned above the third part is focused on behaviour of ASSC structures on extreme unfavourable situations. In the case of antisymmetrical earth loading was the behaviour of the metal arch almost identical within different foundation conditions compare to concrete arch. More over, deformations calculated in the metal arch were significantly higher and had opposite tendency with respect of the concrete arch during antisymmetrical loading.

Second unfavourable situation was concentrated on vertical deformations of the top of both metal and concrete arch loaded by local force. The influence of structural interaction with surrounding soil on construction behaviour was studied. In the case of metal arch considerable effect of displacement occur when the interaction was taken into account, see Figure 7.

ABSTRACT: A case study is presented where the construction of underground structure is expected to interfere with unconfined aquifer: the design of the Metro Line 1 in Turin (Italy), where deep retaining structures have to be built for the stations. A full range of water table monitoring data were collected and analyzed. In addition to this a hydrogeological modelling approach has been developed, to simulate the groundwater-structures interference. A site investigation program provided the model geometry data (geological inputs) and intrinsic hydrogeological properties for the aquifer. Firstly, a regional modeling was performed, to obtain the starting conditions for the local model (works scale). Subsequently, with the local model, the interference between groundwater flow and structures was computed. The results were coupled with the long-term data monitoring and the information on the historical groundwater table level in order to allow the designer to define the appropriate countermeasures and interventions to be taken for both the construction and the exploitation phase.

1 INTRODUCTION

The city of Turin is an urban environment where new infrastructure and transport network (local railway, parking and metro line) are being increasingly developed underground. Such development is increasingly occupying a space never or poorly used before. The first metro line (Line 1) has been designed and constructed in the last five years. The line is crossing the city from east to west passing through a heavily urbanized area where both existing and new underground works are present.

Logistical and functional needs were considered to choose the alignment (in plan), on the other hand (in depth), such choice had to cope with critical constraints that the project design had to properly face and solve. One of these critical issues is the hydrogeological scenario, because the metro works are interfering with an unconfined aquifer.

2 THE LINE 1 OF THE TURIN SUBWAY NETWORK

The Line 1 is the first Metro Line ever constructed in the city of Turin and is divided into two sections (Fig. 1). Section I connects the town of Collegno, on the city's western outskirts, to the Porta Nuova railway station in the city centre. It includes 9.5 km of running tunnels, 15 stations and 15 ventilation and emergency-access shafts in-between stations. Section II runs entirely in the urban area of Turin with 4 km tunnel length and 6 stations.

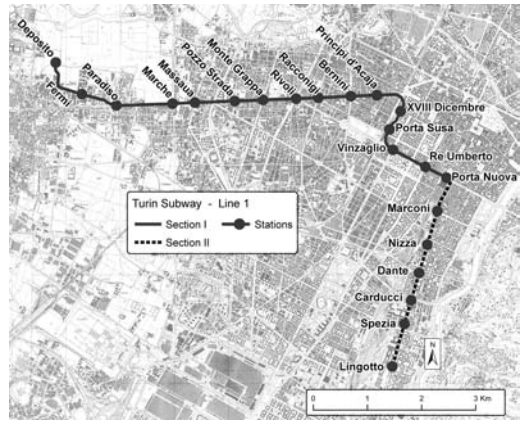

Figure 1. The Turin subway Line 1.

This article will refer to Section II and particularly to the problems due to the interference between the underground works and the unconfined aquifer.

3 GEOLOGICAL AND HYDROGEOLOGICAL SETTING

3.1 *Geology*

The town area of Turin is placed in an alluvial plain built up by numerous contributions of alluvial fans located at the Alpine valley mouths of Dora Riparia and Stura di Lanzo rivers. Alluvial fans are composed by outwash deposits that were partially reshaped by the fluvial activity of the rivers that cross the town area (Po, Stura di Lanzo, Dora Riparia e Sangone).

Geological stratigraphy (Bonsignore et al. 1969) of the area shows the following units described starting from surface:

- outwash and Quaternary fluvial deposit (Riss Glacial Period): gravels, pebbles and sands in a silty matrix. The deposit is from 30 m to 40 m thick and is generally loose except for some cemented lens of conglomerates.
- lacustrine and fluvio-lacustrine deposit of Villafranchiano (Sacco, 1886): clayey silts with sandy gravel lens poorly cohesive. The thickness of the deposit varies from 40 m to 150 m.
- neritic marine deposits from Pliocene: clayey silts, silty sands and fine blue and grey sands moderately cohesive. Maximum thickness is about 40 m–50 m.

While the first Quaternary deposit (outwash and fluvial deposit) is wide-spread and represents the first unit in the town area, both the Villafranchiano and the Pliocene deposits are underlying the Quaternary outwash and fluvial deposit. This is due to local uprising and differential erosion of the Villafranchiano at the beginning the Quaternary Period. As a result, both Villafranchiano lacustrine and fluvio-lacustrine deposits and neritic marine deposits from Pliocene can be found under the outwash and Quaternary fluvial deposits.

3.2 *Hydrogeology*

With reference to tunnel depth, that varies from −12 m to −25 (railway level), the hydrogeological setting shows an unconfined aquifer located in the outwash and fluvial quaternary deposits. This aquifer is confined below by a thick layer of low permeability deposit (clayey silts located at the top of Villafranchiano) and has a saturated thickness from 15 m to 25 m. In the area of the Section II of the Metro Line, depth to water ranges from −12 m to −15 below ground level. The unconfined aquifer is recharged from the west side while direct infiltration (from rainfall) in the urban area is almost totally intercepted by the city water drainage system. In the town area the Po river bed is located at a lower level and acts as a drain to the groundwater of the unconfined aquifer. This role is confirmed by the relationship between the water table contour lines and the river water level, which

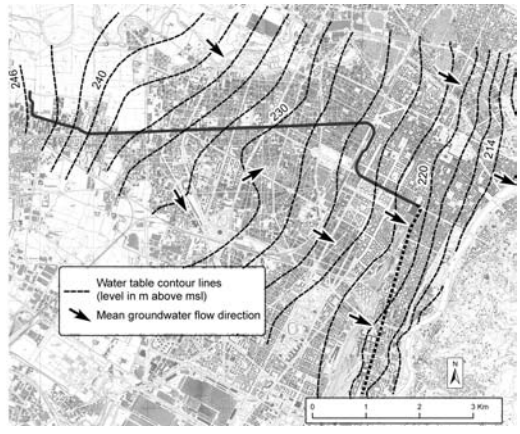

Figure 2. Water table contour in the Turin area (level in m above msl) and mean flow direction.

crosses the town flowing from South to North-East. Groundwater mean flow direction is oriented ESE (120° N) and locally diverges because of permeability anisotropies that creates converging and diverging flow paths. Hydraulic gradient varies from 0.25% (mean value in the centre of the town) to 0.7%–0.8% approaching the Po river bed (Fig. 2). Piezometric level is located at about – 15 m from ground level and the natural phreatic fluctuation is about of ±1.5 m as response to rainfall input.

It must be pointed out that during ancient times (Eighteenth Century) phreatic level was probably about from 4 m to 5 m higher than current level. This fact is confirmed by the presence of ancient adits of the underground defence system of the city (excavated just above water level) and by some historical water well found below the old town building foundations. Moreover, in the last five decades the unconfined aquifer has been exploited for industrial purposes, causing a widespread lowering of the water table. In the last twenty years the displacement of many industrial factories from the town has decreased water extraction rate and, consequently, this fact has allowed the water table to slowly rise back towards the "unexploited" level. Nevertheless, water table monitoring data collected in the last twenty years have clearly shown that the water table uprising rate, due to the cease of industrial exploitation, has notably dropped especially in the last 10–15 years. This evidence suggests that current water table will probably never reach the pristine level referred to the ancient times. An explication to this could be the urbanization of the town area that has practically led to a minimum groundwater recharge from precipitation that is now canalised in the main drain system and discharged in the Po river.

By the way, the design of such an important underground work has to deal with very long time scenarios,

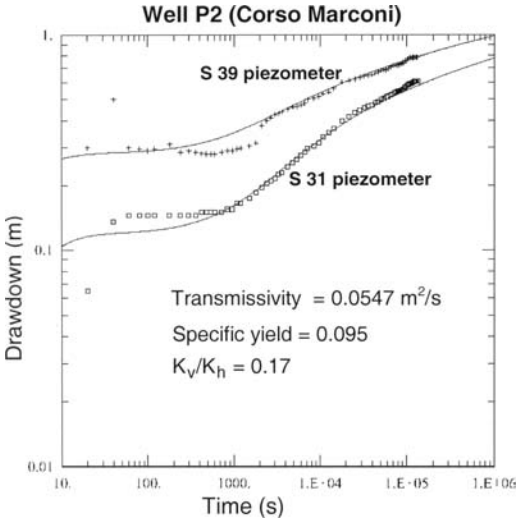

Figure 3. Water pumping test in water well P2 (Corso Marconi). Drawdown vs Time chart with interpolation curve (Neuman, 1975) and hydraulic properties.

therefore the "historical" level of the water table has to be considered and then taken into account in the design of the infrastructure.

4 HYDROGEOLOGY TESTING AND WATER HEAD MONITORING

4.1 *Water test*

A full range of permeability tests were performed during the site investigation campaigns carried out in the design phase of project.

- over 50 Lefranc permeability tests were performed in 25 boreholes (core boring drilling), distributed along the Section II. Water tests were performed at different depths in order to investigate hydraulic properties both in the outwash and fluvial deposits and in the low permeability Villafranchiano deposits.
- n. 2 long-time water pumping tests (Fig. 3) were performed in the outwash and fluvial deposit with ad-hoc excavated wells. Each well had water table drawdown monitoring devices installed in two piezometer located at close distance.

The water test results have showed that the Quaternary deposits have medium to high permeability while the underlying Villafranchiano top layer has low to very low permeability. Table 1 below summarises the permeability range for both units.

These permeability test results clearly show that the aquifer in the Quaternary outwash and fluvial deposits has good permeability while it is confined below the by

Table 1. Hydraulic properties of hydrogeological units.

Unit	Outwash and fluvial Dep. (Quaternary)	Fluvio lacustrine Dep. (Villafranchiano)
k (m/s)	$1.0E^{-05} \div 3.0E^{-03}$	$5.0E^{-06} \div 1.0E^{-08}$
k_v/k_h	$0.1 \div 0.01$	n.d.

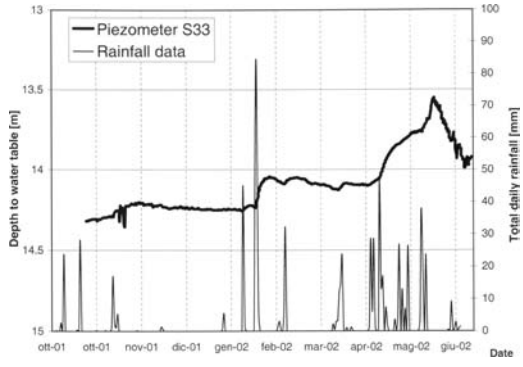

Figure 4. Groundwater table monitoring data (continuous recording) and daily rainfall data recorded in piezometer S33.

low permeability layer of the top of the Villafranchiano deposit.

4.2 *Water head monitoring*

Water head monitoring on the Metro Line 1 wide area has been systematically carried out starting from the beginning of the design phase. Open pipe piezometers were installed in most of the drilled boreholes, where a monthly monitoring activity was initiated. Some piezometers were instrumented with continuous monitoring devices set to 12 hours data recording (Fig. 4), in order to monitor little water table fluctuations in response to recharge input.

Moreover, together with the site investigation campaign and water table monitoring activity, an extensive research of all piezometric level data has been carried out on the whole urban area of Turin. More than 250 data were acquired, referring to water wells or piezometers drilled in different times (from '60s to '90s); most of them are now destroyed and not measurable anymore. Anyway, the significance of the data is important to the understanding of the long-term water table fluctuations.

This activity has also comprised the reconstruction of the "ancient" water table level, determined on the level of the ancient water wells discovered in the old part of the city. These data together with 3D reconstruction of the underground defence adits network (excavated just above water table level) has indicated that the historical groundwater level (referred to XVIII century) could have been some 4–5 m above current level. It must be said that this hypothesis is

based on few observations and on the assumption that water table geometry and mean flow direction hasn't drastically changed over the times.

All the monitoring data have allowed to delineate with a great accuracy the current groundwater table which was used as a reference for the numerical modelling.

5 DATA MANAGEMENT

In order to have a unique platform to store, analyse and manage all the different data, a GIS was implemented. Such a common platform has allowed to analyse in 3D the design data such as the tunnel alignment, deep founded stations and other existing underground infrastructures together with geological and hydrogeological features such as the bottom of the highly permeable unit and the groundwater table. The aim was to highlight the potential critical scenarios where a numerical model should be employed in order to quantify the interference between the underground works and the groundwater table.

GIS data file formats were fully compatible with numerical modelling software so as to allow a fast setting of input parameters. The same GIS platform has already been employed in the construction management of the Section I to collect and manage excavation parameters (TBM) together with externally collected monitoring parameters (settlements, vibrations and water table fluctuations).

6 NUMERICAL MODELLING

6.1 *Problem statement*

When an underground structure is constructed below water table it may cause a partial or total reduction of groundwater flow. Considering that the structure is totally impermeable it acts like a "barrier" to the flow. This causes (Fig. 5) an uprise of the water table along the side of the structure (upflow side) and a symmetrical lowering of the water table on the other side (downflow side). The entity of this interference is proportional to some factors such as the length of the structure, the angle of incidence between groundwater flow direction and the structure, the thickness of the free hydraulic section under the structure, the permeability of the media and the aquifer recharge condition.

The design of Section II of the Metro Line foresees interferences with groundwater table for most of its total length. The tunnel direction is perpendicular to mean flow direction causing, theoretically, the maximum possible interference. Some stations (Marconi and Spezia) have deep foundations that are driven so deep almost reaching the low permeability layer, causing a reduction of the hydraulic section.

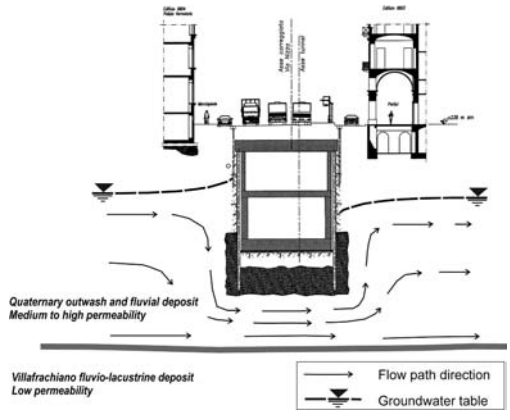

Figure 5. Partial obstruction of groundwater flow caused by a deep founded structure (not in scale).

The potential interference of the deep structures with the aquifer created some concern to the client because potential significant increase of water level in the long term may require heavier design with consequent cost increase. Hence, it was necessary to estimate the real, expected entity of this potential increase of water level. To respond to this need, the 3D numerical modelling was naturally the best approach.

The numerical code employed was MODFLOW (McDonald e Harbaugh, 1988 & 1996) a finite difference model with a user-friendly interface (GMS 3.1 Groundwater Modelling System, Boss International, 2001) able to perform geostatistical data treatment of input parameters.

The model applied was suitable to the hydrogeological setting because the aquifer is a typical porous media characterised by a fair homogeneity. In addition, the two hydrogeological units have little inclined surfaces and moreover, the metro line alignment is easily reproduced by finite difference models that are constrained to a rectangular grid.

6.2 *Large scale numerical modelling*

A groundwater numerical model must reproduce, in practical terms, the groundwater flow conditions as highlighted by the conceptual hydrogeological model, based on field observations.

In this case, the numerical modelling of small and localised scenarios, useful to quantify critical interferences, requires, as a first step, the set up of a larger scale numerical model able to simulate the general setting of groundwater circulation in a big area.

Such model was implemented in order to verify the correctness of the boundary conditions that are:

– lateral recharge prevailing on direct infiltration that is almost annulled in an urban environment.

– drainage towards the river with consequent increase of hydraulic gradient towards and in coincidence of the slope that connects to the river bed.

The area considered for the general model is a rectangle of 6300 m × 4200 m regular grid spacing and with 6300 cells. Total depth is set to 60 m and the model is divided into two layers to simulate the different hydraulic properties of the two hydrogeological units (Quaternary aquifer/Villafranchiano aquiclude). The top surface of the second layer (aquiclude) has been obtained by kriging the core boring results of deeper site investigations. Specifically, the boundary conditions are:

– "constant head" applied on the NW boundary to simulate lateral recharge.
– "no flow" along the sides of the model where flow direction is parallel to model sides.
– "head dependent flux boundary" (drainage) condition along the river boundary. This condition is reproduced by specific draining cells that simulate water drainage from the model. Their efficiency is ruled by a factor (conductance "C" that is dimensionally a L^2/T) that will be calibrated.

Given the reference scenario, a calibration process has been done in steady state, trying to reproduce measured water table contour lines. The calibration process is carried out by varying cell by cell the values of k_h and k_v (horizontal and vertical permeability) in order to obtain a good comparison (Fig. 6) between modelled water table contour (performed by the model) and measured water table (obtained by on-the-field measured data). In addition, the efficiency of the drain cells was calibrated along the riverside of the model.

The permeability range assigned to the model cells is coherent with the range obtained by water permeability tests carried out during the site investigation campaign.

6.3 *Numerical modelling of the interferences*

As a second step in the numerical modelling approach, some localised models were implemented. The aim was to quantify with greater accuracy the entity of possible water table uprising caused by the deep founded structures.

Based on the results of the large-scale model, two local detailed models were implemented to simulate the construction of underground structures (cut&cover stations) and the tunnel below the water table.

Specifically, two critical scenarios were taken into account:

1. the interference due to by cut&cover structures that partially obstruct (almost perpendicularly) groundwater flow.
2. the interference created by the running tunnel itself.

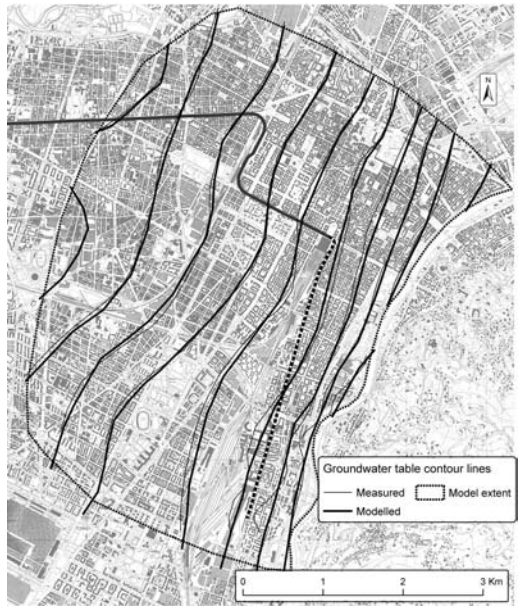

Figure 6. Calibration result of large scale model.

The first scenario refers to the train deposit and nearby Marconi Station and also to Spezia Station. All these structures will be constructed with cut&cover technology. In both cases the model area was about 1200 m × 900 m and wide enough to avoid the influence of boundary conditions on the simulation results.

Grid dimension was variable (cell dimension ranging from 5 m to 25 m) with cells refinement around the structures. Total cell number was about 5200 per layer. Total depth was again set to 60 m and divided into three layers.

Constant-head boundary conditions were employed on opposite sides of the modelled area to simulate inflow (lateral recharge) and outflow (discharge) of groundwater. Lateral sides had no flow conditions.

Calibration process was carried out with reference to a measured water table situation and the final results showed a good agreement between measured and modelled groundwater table. The barrier effect of the cut&cover structures was introduced by assigning very low permeability ($k = 1E^{-08}$ m/s) to the cells referred to the geometry of the structures. Once calibrated, the model was used to simulate the presence of the structure and other scenarios such as a higher groundwater level (up to +2 m from current groundwater level).

The model results were presented in terms of iso-anomalies (differential rising or lowering of the groundwater table with respect to undisturbed situation) due to the interference of underground structures (Fig. 7).

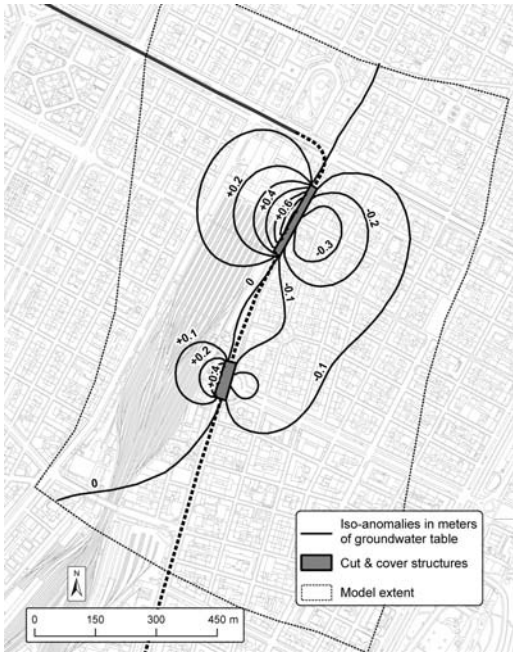

Figure 7. Iso-anomalies (m) generated by the interference of train deposit and Marconi station structures.

6.4 *Results*

The model results have highlighted that the interferences created by cut&cover obstructing structures generate a local variation on the groundwater table. This variation rises up to $+1$ m on the upflow side of the structure and a lowering on the opposite side that is a little less than a metre. In addition, the tunnel itself is responsible for a small rise of the water table that is quantified to be about $+0.2$ m. The choice of some conservative parameters employed in the numerical simulations (i.e. aquiclude deep surface level) indicates that the results obtained can be considered as fair and reasonable.

7 CONCLUSIONS

The design and construction of an underground work like a subway line under the groundwater table have to deal with some geotechnical and hydrogeological problems. These problems mainly refer to the groundwater level to be adopted as reference for the design of the works. Moreover underground structures, when located under groundwater table, cause an interference that create a rising of the groundwater table on the upstream side of the structures that act as a barrier to flow direction.

With reference to these issues, the design of an underground works have to take into account the evaluation of all the interferences caused by the works on all surrounding underground structures.

In the reported case of the Turin metro the problems were faced and solved by collecting and evaluating, in a common GIS platform, all possible data available on the field, in order to highlight all potentially critical scenarios. Then, a numerical model was implemented for chosen situations in the aim of quantifying the interferences. The modelled results have shown that the water table rise on the upstream side of the deep structures is quite small ($+0.2$ m due to the running tunnel and about $+1.0$ m due to the deep stations) in comparison with the long-term potential natural recover of water table of the aquifer.

This can be explained by two reasons:

– high permeability of the unconfined aquifer in which the structures are inserted.
– the deep cut&cover structures, even in the worst scenario, didn't reach the low permeability layer at depth, leaving the hydraulic connection under the structure.

Model simulations were performed in steady state, reproducing, in same way, the long-term scenario. It is reasonable to expect that during the construction phase only a limited amount of these interferences will occur. They will be easily faced with common on-the-site countermeasures. The specific numerical modelling approach proved to be effective and efficient, for the following reasons:

– the numerical model applied was suited to the hydrogeological setting because the aquifer is a typical porous media characterised by a fair homogeneity. In addition, the two hydrogeological units have little inclined surfaces.
– a full range of data (from historical evidences to continuously monitored water table) were available to define, as much as possible, the wider possible scenarios.
– the metro alignment is easily reproduced by finite difference models that are constrained to a rectangular grid. In these scenarios the models are simple but reliable and provide good results in reasonable computing time.

The modelled results together with the data from long-term monitoring and the information on the historical groundwater levels have allowed the project designer to define the appropriate design countermeasures and interventions to be taken for both the construction phase and the exploitation phase.

ABSTRACT: Application of various materials has been increased in construction. The design and construction cases of corrugated structural plates instead of reinforced concrete for a cut & cover tunnel construction are described in this paper. A large slope near the tunnel portal is cut and tension cracks are produced in the slope face during construction. Because a large amount of cut soil and rock have to be dumped in this field, the counterweight fill after cut & cover tunnel construction is adopted as an optimal alternative plan. It is estimated that application of the corrugated structural plates contributes to 70% decrease in construction period and 30% decrease in construction cost.

1 INTRODUCTION

The interest of the protection of environment has been increased because of natural environmental damage by construction of social overhead capital such as road and railroad. Therefore, tunnel construction has been increased in order to minimize the damage of mountains and forests in construction of a new road, in widening a road, and in improvement of an old road alignment. However, even if the tunnel has been constructed, a formation of a portal slope is inevitable. Therefore, the minimization of cut area is very important. In this paper, the first application of corrugated structural plate instead of a reinforced concrete for a cut & cover tunnel of a portal is introduced in Korea. The considering site is located in Ulsan. The portal slope had collapsed and was expected an additional collapse. The purpose of this design is to perform the site investigation and field tests, to estimate the stability of the slope and to work out a countermeasure. Considering site is located in the portal of tunnel planed for widening a existing road. For all that, a portal is planed in a valley and a high slope is come into being inevitably. The geological features of this site are gray green shale and hornfels. Rocks are much crushed and faults are distributed in place. So, stability of slope isn't guaranteed for original slope. Also, the slope slides off after some snow and rains. On the investigation, abandoned soil of the site is very much. Therefore, a counterweight fill after constructing cut & cover tunnel is more profitable than slope reinforcement in slope stability and economical efficiency.

Corrugated structural plate is used instead of a reinforced concrete to reduce of a term of works and construction costs. Reasons of selecting the counterweight fill as an alternative for the slope stability are described in this paper. In addition, the design and construction of the corrugated structural plate applied as a cut & cover tunnel are described.

2 TOPOGRAPHY AND GEOLOGY

The site is located in a small valley that surface water and ground water are concentrated. A great deal of surface water flows down in the whole year. A bed rock of the site is grey green shale and sandstone of the Cretaceous period. The slope concerned is located in a valley with complex geological features and an irregular metamorphism. Faults are composed of an intrusive clay and gravel. The gravel layers have been

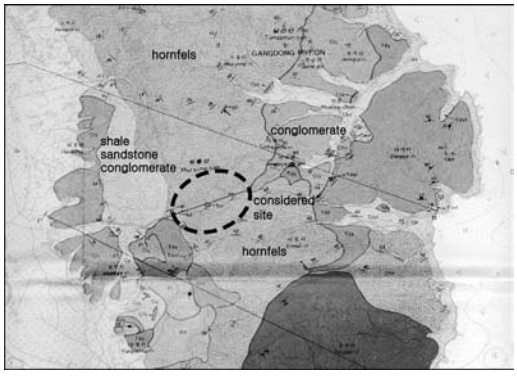

Figure 1. Geological map.

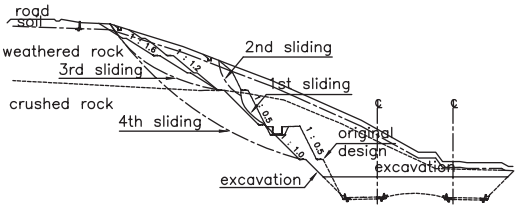

Figure 2. Slope section.

hardened. The gravel sizes are 2∼30 cm. Faults are dense and a groundwater flows out. A small quantity of ground water flows, even valleys are located in the left and right sides of the tunnel exit. Therefore, the water flow will be increased as increasing of surface water in the rainy season.

3 A SLOPE STATUS

The geology of the slope having a height of 54 m and length of 140 m is grey shale and severely cursched hornfels. The upper part of the slope has a thickness of 5 m and is completely weathered or highly weathered. The lower soft rock is a metamorphic fallow hornfels and is highly crushed by crust movements. A joint spacing is very narrow and a joint orientation is irregular. The highly crushed lower soft rock has been collapsed a few times in a small scale. A viscous soil between the rocks of 10 cm diameter exists. The tension cracks are caused at the upper parts of the slope after snowing in winter. Surface water flown in a valley penetrates into the slope in the start points of the slope.

The 31st national road is located in the upper part of the slope. Therefore, if it slides on a large scale, the confusion by transportation interruption is expected. A inclination of the slope is 1:1.2∼1.5 in a soil, 1:0.7 in a weathered rock, and 1:0.5 in soft and hard rock in a design stage. Figure 2 shows the inclination of the slope when tension cracks were caused.

Figure 3. Slope scene.

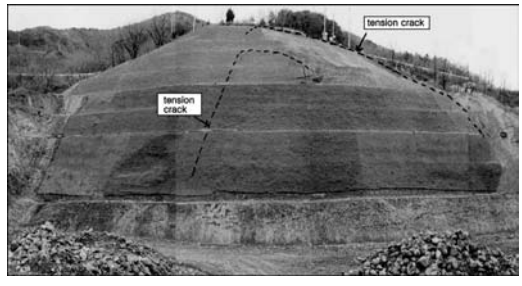

Figure 4. Tension cracks.

4 INVESTIGATION OF AN ALTERNATIVE

The suitable reinforcement methods for slope are examined. The alternatives suitable for the slope are investigated for a long-term stability, a convenience of construction and construction costs in priority. A site investigation and field tests are carried out for the slope, and the stability of it is evaluated and the alternatives are examined. The counterweight fill is chosen. The upper part than 30 m from the formation level is cut with an easy slope 1:1.8 and water drainage pipes are installed. The lower part than 30 m from the formation level is backfilled. In general, the counterweight fill is more expensive than the slope reinforcement owing to cut & cover tunnel. However, the waste rocks cut in this site is very much. So, if the waste rocks are reused, the construction costs are reduced. If a vehicle is dropped from the 31st national road located in the upper parts of the slope, a large scale accident can be aroused. In conclusion, the counterweight fill after constructing the cut & cover tunnel is chosen for stabilizing the slope.

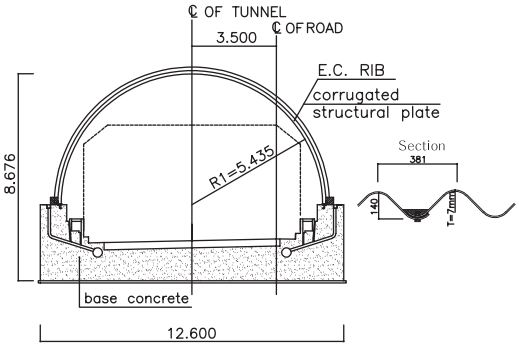

Figure 5. Cut & cover tunnel section.

Figure 6. Ditch excavation.

Figure 7. Rebar assembling.

Figure 8. Base concrete construction.

5 CONSTRUCTION METHOD OF A CUT & COVER TUNNEL

The reinforced concrete and the corrugated structural plate as the construction method of a cut & cover tunnel are examined. A cut & cover tunnel should be backfilled as soon as possible because the slope will be collapsed when it rains heavily. A corrugated structural plate is selected to construct a cut & cover tunnel because a construction period is reduced by 70% and a construction cost is curtailed by 30%.

6 DESIGN OF A CORRUGATED STRUCTURAL PLATE

A design of a corrugated structural plate is based on CHBDC (Canadian highway bridge design code) method. Thereafter, a finite element analysis is executed with the program CANDE89 for verification. The finite element analysis is useful when an overburden of a corrugated structural plate is inclined because the CHBDC method can't consider a tilted backfill. A behavior of a corrugated structural plate is dependent on the compression forces. So, a buckling, a compression yield failure, and the shear failure of longitudinal bolts should be estimated. An failure index is whether a plastic hinge is aroused or not, because the internal forces in the member of a corrugated structural plate are compression forces and moments. A finite element method is another method that can be used in design of an corrugated structural plate. A finite element method can consider the various ground conditions and the inclined backfill, therefore it can be used to verify the results by CHBDC design method. The maximum compression force is 2,037 kN/m. The maximum bending moment is 18.74 kN.m/m at the roof. A plastic hinge is not occurred in the finite element analysis.

7 CONSTRUCTION SCENES

excavation, rebar assembling, base concrete construction, fabrication of a corrugated structural plate and backfill.

8 CONCLUSIONS

This paper presented the construction of a corrugated structural as a cut cover tunnel.

(1) A portal is planed in a valley and a high slope comes into being inevitably. A local sliding failure and large tension cracks are occurred during the construction. On investigation, there is a lot of abandoned soil in the site.

Figure 11. Backfill.

(2) Counterweight fill after constructing cut & cover tunnel is more profitable than reinforcing cut slope in slope stability and economical efficiency.
(3) A cut & cover tunnel should be backfilled as soon as possible because when it rains heavily, a cut slope can be collapsed. Hence, a corrugated structural plate instead of a reinforced concrete is adopted as a substitute.
(4) A corrugated structural plate is selected to construct a cut & cover tunnel because a construction period is reduced by 30% and a construction cost is curtailed by 30%.
(5) The stability of a cut slope is preserved when it rains in 400 mm for 3 days

Evaluation of the stability of anchored diaphragm wall basing on acceptance tests of anchors

A. Siemińska-Lewandowska & M. Mitew-Czajewska
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The paper describes acceptance tests of anchors performed during the execution of 17.5 m deep excavation in Warsaw. The main issue of the investigation was to estimate the real value of an average extension of the tendon Δs as well as to calculate the change of the value of L_{app} within the limits given by the Code EN1537. Considerable variations of the free anchor lengths observed in the 1st and 2nd anchoring levels caused significant changes in the estimated stability factors. Revisions to the detail design had to be introduced.

1 INTRODUCTION

The case was 800 mm thick and 17.5 m deep anchored diaphragm wall joined in upper part to a soldier pile wall. Due to the depth of the excavation and its width (42 m), stability of the wall was provided by 5 levels of ground anchors with the resistance of 500–600 kN. Total length of anchors varied between: 25 m in the first level, 20.50 m and 19.50 m in the second level, 19.50 m, 18.00 m, 17.00 m in the third level and 15.0 m in the fourth and in the fifth level. Fixed anchor length was constant for all levels and equalled 8.5 m. Anchors were spaced 2.7 m centres in the first level and 1.35 m in the other levels. The tendons in the first four anchoring levels consisted of 6 cables, 40.5 mm diameter. Each cable consisted of seven 5 mm diameter wires made of high yield steel. Tendons of the fifth (lowest anchoring level) were made of 7 cables. Grout body of anchors was formed using double cement grout injection. Fixed length of the anchors was separated from its free tendon length. Plastic PVC sheaths, sealed against ingress of water, were used to provide protection against corrosion of the tendon free length and to allow for the movement of the tendon in the borehole. All anchors were executed in a very complex geotechnical conditions, going through soils such as Pliocene clays, silty to medium sands, moraine clays.

According to the geotechnical investigations report, following geotechnical layers were specified:

- layer I – manmade fills, 1–3 m thick, in some places up to 4 m;
- layer II – moraine deposits reaching depth of 8–11 m below ground level (bgl), consisted of medium and stiff sandy clays and clayey sands of Warta glaciation in upper part, deeper - stiff sandy clays of Odra glaciation;
- layer III – continuous layer of sand deposits about 15 m thick represented by fine and medium sands;
- layer IV – cohesive soils (clays and silty clays) 1–5 m thick;
- layer V – sand deposits (medium and coarse sands as well as gravels and sandy gravels, 10–15 m thick).

There were two levels of ground water table observed. The main water table was stabilizing around 14.5 m bgl. Due to the technology of underground works and considering the stability of the bottom of excavation, water table was lowered during construction. Figure 1 presents typical cross-section of the structure including geotechnical conditions and detailed data concerning anchors.

2 DESCRIPTION OF ACCEPTANCE TESTS

Until the year 2002 in Poland there was no code specifying methods of ground anchors testing – today the situation has changed and the translation of European code PN EN 1537 is obligatory. All tests described in the paper, finished before 2002, were performed in accordance with German code DIN4125. Figure 2 presents the chart resulting from loading of anchors during testing.

All working anchors were subjected to an acceptance test. The objectives of acceptance test were: determining the apparent tendon free length L_{app} and demonstration that a proof load of 120% or 150% of load capacity can be sustained by anchor. At each loading level displacements of free tendon length were measured in the 1st, 2nd, 3rd, 4th, 5th, 10th and 15th

minute of loading. In addition one in ten anchors was overloaded to the 150% of the value of it's calculated bearing capacity. Basing on the values of the elastic extension of tendon Δs measured on site the elastic displacements curve was plot as well as limits of the elastic extension of tendon were calculated. Elastic displacements curve of the properly executed anchor should fit the area limited by two lines describing upper (1) and lower (2) limits of the elastic extension of tendon. According to DIN 4125 these limits are defined as follows:

$$S_{up} = \frac{P_p - P_0}{E_t \cdot A_t} \cdot (L_{tf} + 0.5 \cdot L_{tb}) \quad (1)$$

$$S_{low} = 0.8 \cdot L_{tf} \cdot \frac{P_p - P_0}{E_t \cdot A_t} \quad (2)$$

where: P_p is the proof load
P_0 is the datum load
L_{tf} is the tendon free length
L_{tb} is the tendon bond length
A_t is the cross-sectional area of anchor tendon
E_t is the elastic modulus of anchor tendon

These limits are equivalent to upper (4) and lower (5) limits of apparent tendon free length L_{app} (3) defined in EN 1537 as follows:

$$L_{app} = \frac{A_t E_t \Delta s}{\Delta P} \quad (3)$$

$$L_{app} \le L_{tf} + L_e + 0{,}5 L_{tb} \quad (4)$$

$$L_{app} \ge 0{,}8 L_{tf} + L_e \quad (5)$$

Where L_e is external length of tendon measured from the tendon anchorage in the anchor head to the anchorage point in the jack, which was not considered in calculations described in the paper.

It may be assumed that the method of calculation of L_{app} used in the discussed case was compliant with the recommendations of PN EN 1537.

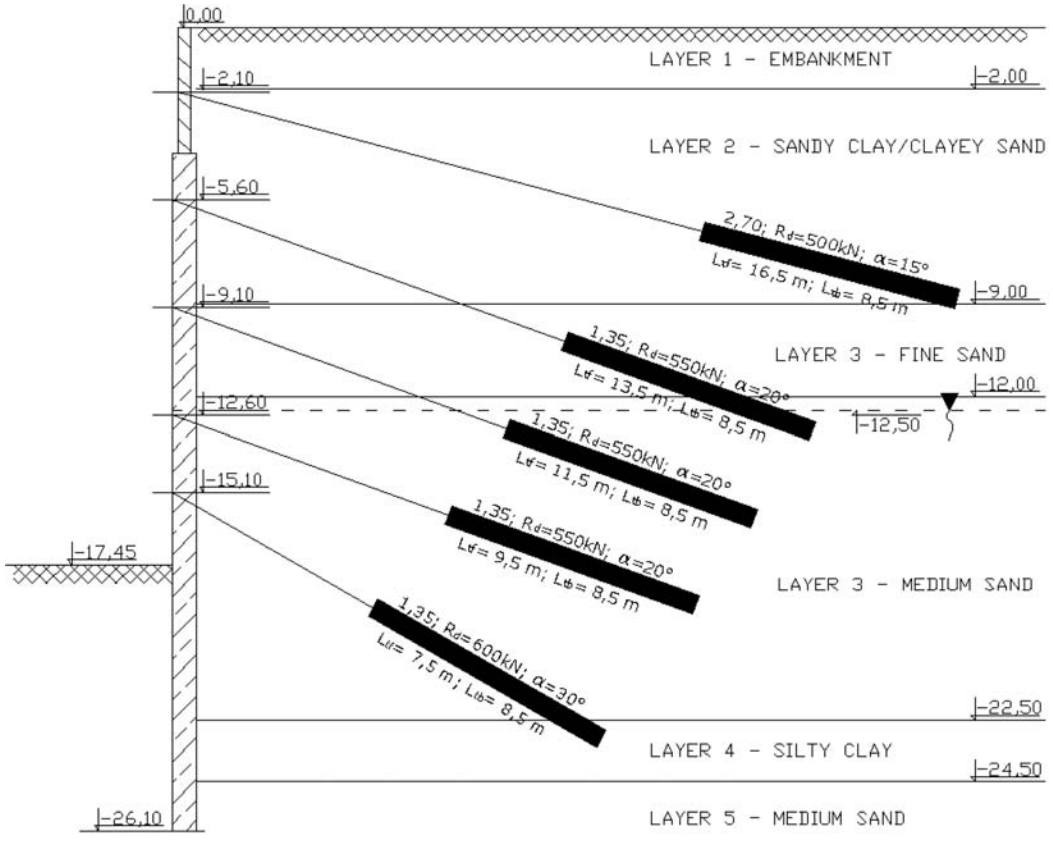

Figure 1. Typical cross-section.

In the paper, in next section, the results of acceptance test of first and second levels of ground anchors are described.

- 1st level – L_a = 25.00 m, L_{tf} = 16.50 m, R_d = 500 kN, $\alpha = 15^{\circ}$, number of tested anchors - 44;
- 2nd level – L_a = 22.00 m, L_{tf} = 13.50 m, R_d = 550 kN, $\alpha = 20^{\circ}$, number of tested anchors - 89;

Values of upper and lower limit of the elastic extension of tendon Δs are presented in table 1.

3 RESULTS

The technology of the execution and also the make-up of the separator were the main reasons that the carried out apparent tendon free length (L_{app}) varied from the one assumed in the design. In order to estimate real values of the free anchor length (L_{free}), the results of 1241 anchor acceptance tests were analysed. Taking into account measured values of the elastic extension of free tendon length (Δs) real values of apparent tendon free length L_{app} were calculated. Two sets of results for the first two anchoring levels (statistic samples) of acceptance tests consisting of 44 and 89 real values of Δs were analysed. Normal distribution curves, average values as well as standard deviations were calculated.

Figures 3 and 4 present normal distribution curves of both statistic samples. Average values, standard deviations and L_{app} are compiled in table 2.

It was assumed that proof load (P_p) amounts to 120% R_d, and datum load (P_0) is 15% of R_d. Were R_d is the value of design resistance of an anchor.

The results of acceptance tests proved that tendon free length L_{tf} had shortened. Taking it into consideration, after execution of the 1st and 2nd anchoring levels additional analysis of the stability of the wall-soil-anchor system was performed using Kranz method.

The objective of the calculation was to verify the stability factor of the wall (Fs) taking into account the value of tendon free length L_{tf} equal to L_{app}. In the calculation the average value of Δs was considered. There was a potential risk that due to the shortening of tendon free lengths (L_{tf}) of 1st and 2nd anchoring

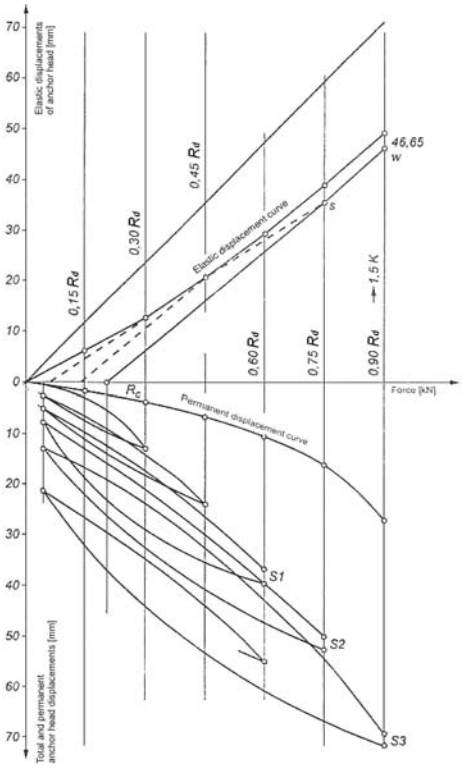

Figure 2. Loading chart.

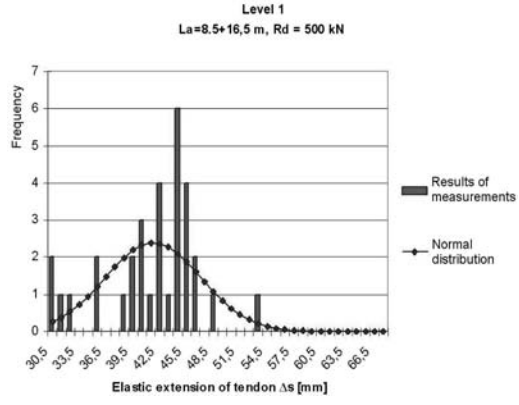

Figure 3. Results of acceptance tests of 44 anchors, 1st anchoring level.

Table 1.

level	R_d [kN]	L_a [m]	L_{tf} [m]	L_{tb} [m]	120%R_d S_{low} [mm]	120%R_d S_{up} [mm]	150%R_d S_{low} [mm]	150%R_d S_{up} [mm]
I	500	25.00	16.50	8.50	42.96	67.53	55.24	86.83
II	550	22.00	13.50	8.50	38.66	63.55	49.71	81.70

levels the wall might loose its stability asset in the design stage.

Parameters of 3rd, 4th and 5th anchoring levels were considered unchanged (equal to values used in the basic design), Figure 1. Minimum permitted value of stability factor was Fs = 1,50. Values of calculated stability factors (Fs), for each of anchoring levels were as follows:

1st level $Fs_1 = 3,1$
2nd level $Fs_2 = 1,88$
3rd level $Fs_3 = 1,20 \leq 1,50$

Too small stability factor was found in the 3rd anchoring level.

4 NUMERCIAL VERIFICATION

Authors decided to verify numerically values of safety factors calculated years ago using Kranz method. Numerical analysis were carried out using Geo5 software, programs: Sheeting check and Slope stability. Construction stages were modelled in accordance with the basic design and with real phasing performed on site. The value of tendon free lengths of first two rows of anchors L_{tf} were considered equal to average value of L_{app}, consequently the L_{tb} lengths were extended. Calculation of internal stability of the system considering the stage after the installation of the 3rd anchoring level showed that Fs values did not satisfy requirements (Fig. 5) and they were as follows:

1st level $Fs_1 = 3,61$
2nd level $Fs_2 = 1,71$
3rd level $Fs_3 = 0,93$

Second calculation run was performed with the input of extended tendon free lengths of the 3rd row of anchors (change from 11,5 m to 13,0 m). Resulting stability factors were as follows:

1st level $Fs_1 = 3,61$
2nd level $Fs_2 = 1,71$
3rd level $Fs_3 = 1,55$

In addition, analysis of overall (global) stability was performed using the method of Bishop. Global

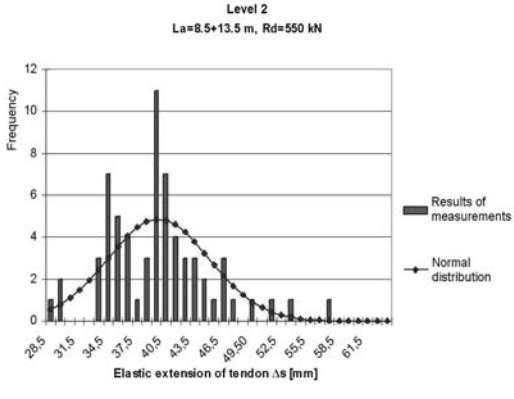

Figure 4. Results of acceptance tests of 89 anchors, 2nd anchoring level.

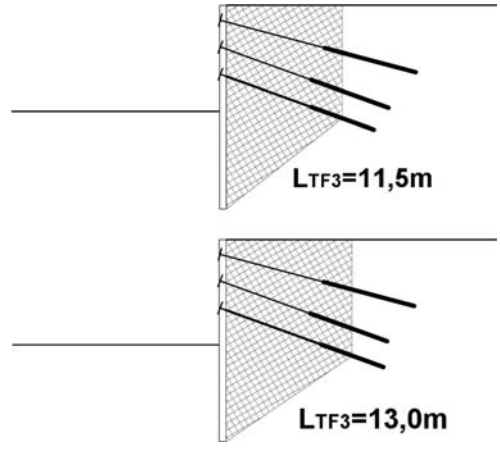

Figure 5. Verification of internal stability – 3rd anchoring level.

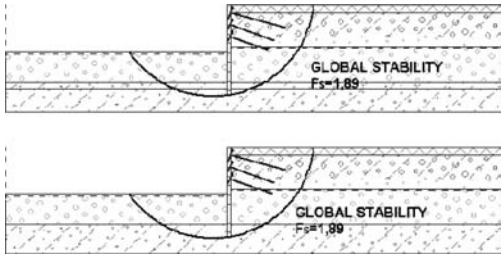

Figure 6. Verification of global stability – Bishop.

Table 2.

	R_d [kN]	L_a [m]	L_{tf} [m]	L_{tb} [m]	ΔS [mm]	σ	E_tA_t [kN]	ΔP [kN]	L_{app} [m]
I	500	25	16.5	8.5	41,74	+/−5,327	161310	525	12,82 +/−1,63
II	550	22	13.5	8.5	39,71	+/−5,325	161310	577,5	11,09 +/−1,48

stability factor in both cases (before and after extending tendon free lengths of the 3rd anchoring level) amounted to Fs = 1,89.

Figure 6 shows both models and estimated slip surfaces.

5 CONCLUSIONS

It was stated that due to a fault technology of the separator of the 1st and 2nd anchoring levels shortening of tendon free lengths of anchors in these rows occurred. This lead to a change in geometry of forces acting on the wall and in consequence caused lowering stability factors estimated using Kranz method. The length of anchors in the 3rd anchoring level determined in the basic design (L_a = 20.00 m, L_{tf} = 11.50 m, L_{tb} = 8.50 m, R_d = 550 kN, $\alpha = 20°$) proved to be to short for satisfying the minimum permitted value of stability factor (Fs). As a result, decision of incorporating changes into the basic design was made. Tendon free lengths of anchors of the 3rd level were extended. Redesigned tendon free lengths were set to 13 m causing anchor's total length to be 21,5 m.

Numerical verification proved that decisions made basing on on-site measurements and simple "by-hand" calculations were right and rational.

The case discussed in the paper proves the importance of acceptance tests and necessity of determination of apparent tendon free lengths (L_{app}) on-site, in accordance with the recommendations of European code. Special attention should be paid in case of multi level anchoring systems. Even small mistakes made in the first construction stages may lead to serious consequences especially in terms of safety in subsequent stages of construction.

London Heathrow Terminal 5 – Construction and monitoring of Piccadilly Extension Junction

A. Stärk & J. Jäger
Beton- und Monierbau Ges.m.b.H, Innsbruck, Austria

ABSTRACT: The new Terminal 5 of London Heathrow's Airport had to be connect to the existing airport terminals by means of seven tunnels in the vicinity of sensitive structures such as runways, fuel mains, and terminal buildings.

The final element of the overall tunnelling projects, the Piccadilly Extension Junction, should complete the connection of the existing Piccadilly Line with the Piccadilly Extension to the new Terminal 5. From a cut and cover box four tunnels have been excavated using Sprayed Concrete Lining (SCL) and LaserShell™ method of construction. The tunnels were built alongside existing running tunnels, with a minimum distance of less than one meter. To prevent existing tunnels from excessive movement they have been plugged with foam concrete over some length. An extensive monitoring regime and a careful selection of trigger limits were also required.

This paper shows how the existing tunnels reacted due to SCL excavation and gives a comparison of measured to predicted deformations. It also explains the SCL construction process, with particular attention paid to the principles of the LaserShell™ method of construction.

1 PROJECT OVERVIEW

The Airport London Heathrow is being upgraded by a new Terminal. This Terminal 5 (T5) is constructed separately from the Central Terminal Area and had to be connected to the existing terminal buildings and to downtown London by means of a total of 7 tunnels. The running tunnels were constructed by Tunnel Boring Machines; all the connecting constructions, such as headshunts, shafts, emergency exits, ventilation openings, cross passages etc. were constructed using Sprayed Concrete Lining (SCL). In total more than 40 SCL structures with an overall length of more than 1100 m had to be built (Hilar et al. 2005, Williams et al. 2004).

The tunnelling work has been successfully completed in 2006 and T5 is about to open in 2008.

This paper focuses on the PiccEx Junction as the last part of T5's SCL tunnelling work and probably the most difficult and interesting one.

London Underground provides public transport to London Heathrow via the Piccadilly Line, which had to be extended to serve the new T5. To connect the T5 Piccadilly Line Extension (PiccEx) with the existing Piccadilly Line, the so called PiccEx Junction had been constructed – in the middle of the heart of one of the busiest airports in the world (Fig. 1).

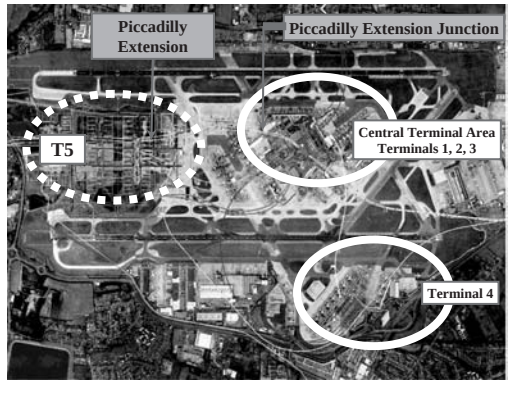

Figure 1. Airport London Heathrow overview.

2 BOX

A box has been excavated, approximately 20 m deep, 50 m long, and 20 m wide, to allow access to the existing tunnel systems.

The box structure consists of 1.2 m thick reinforced retaining 'diaphragm' walls. Half way down it is stiffened by a gallery-like intermediate slab. Two concrete pillars in the middle of the box provide additional

Figure 2. The box.

support. All machines, gear, equipment and material had to be lifted down the box opening by means of a crawler crane. For the first few weeks this included also the shotcrete supply until a permanent shotcrete pipe had been installed to the bottom of the box.

At the openings for the tunnels one meter thick and heavily reinforced headwalls have been cast to support the portal.

3 CONSTRUCTION OF SCL-TUNNEL

To enable trains to reach new T5 a turnout from the existing Piccadilly Line had to be built.

East of the box the existing Piccadilly running tunnels needed an enlargement to provide enough space for the necessary switches for the Piccadilly Line Extension turnout, resulting in Eastbound and Westbound Turnout Tunnel (Fig. 3).

On the West side of the box the connection to the previously built Piccadilly Extension had to be completed, creating a need for Eastbound and Westbound Stub Tunnel.

Table 1 gives a brief overview of all four SCL tunnels at the PiccEx Junction.

3.1 *Ground condition*

The only ground encountered was London Clay, which appeared homogeneous, with almost no water. A layer of scattered clay stones up to Ø 300 mm followed all four headings, approximately at tunnel axis. Occasional greasy backs were of no harm since the excavation followed the principles of the LaserShell™ method.

3.2 *LaserShell™*

Until now, it has been common when using shotcrete support, to enter the unsupported heading to install

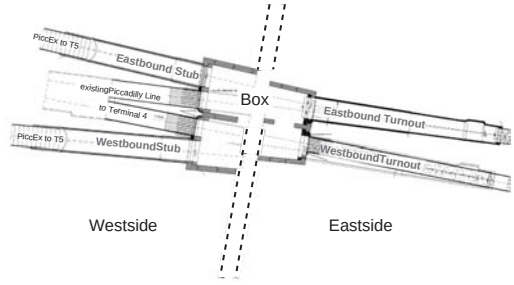

Figure 3. PiccEx Junction overview.

Table 1. Tunnels at PiccEx Junction (in order of construction).

Tunnel	Length (m)	Diameter (m)
Eastbound Turnout	52.9	$Ø_a$ 6.755 – 4.850
Eastbound Stub	26.7	$Ø_a$ 5.500/4.500
Westbound Turnout	52.9	$Ø_a$ 6.755 – 4.850
Westbound Stub	30.1	$Ø_a$ 5.500/4.500

girders and steel mesh. This is a fundamental aspect of the support system in soft ground. Girders provide immediate support and are required to fix the first layer of mesh. In addition, the girders are used to control the profile. Both, mesh and girders can only be installed manually, which includes the necessity to enter the unsupported heading. However, due to British health and safety regulations, no one is allowed to enter under the unsupported or even not completely supported heading. But no access to the heading implies no installation of girders and hence no tunnel construction.

Thus, a tunnelling method had to be developed which could satisfy the British health and safety regulations, does not need any girders and steel mesh, and is applicable in London Clay. LaserShell™ was born (Eddie & Neumann 2003, Eddie & Neumann 2004).

The most obvious feature of LaserShell™ is the inclined and domed face (Fig. 4). The inclined face guaranties that nobody stands under exposed ground at any time, but under the already hardened shotcrete of the previous advance. In addition, the inclination is contribution to a more stable face rather than a vertical one. As permanent support steel fibre reinforced shotcrete is used with a 75 mm initial layer, and a minimum of 200 mm structural layer. A 50 mm finishing layer without steel fibres covers up the steel fibres of the previous sprayed structural layer and provides a smooth finish comparable to shuttered concrete surface. There is no inner lining.

Another less obvious feature: The structural layer is been sprayed circumferential in one go, including

Figure 4. LaserShell™, inclined face.

the invert. This reduces the joints to the absolute minimum, to the radial joints between advances, with the added bonus of increased quality.

3.3 *TunnelBeamer™*

Another issue under rigid British health and safety regulations is profile control. Since profile can only be controlled from a distance, the TunnelBeamer™ is pushed to paramount importance. The TunnelBeamer™ – a laser theodolite – is connected to a laptop. The latter contains all relevant information with respect to geometry. I.e. the chainage of each advance and shape of its face (inclined and domed); furthermore the geometry of the unsupported heading as well as the geometry of every layer of shotcrete. During excavation the profile of the heading and during the spraying process, the thickness of each layer of shotcrete is monitored – continuously, easily and in real time. All as-built profiles are stored on the hard disc for conservation of evidence.

4 MONITORING

4.1 *Existing Piccadilly Tunnel Eastside*

On the Eastside of the PiccEx Junction the existing Piccadilly tunnels had to be enlarged (see Fig. 3 for location). The first half of the existing Piccadilly Eastbound was plugged with foam concrete; the second half remained unplugged during excavation. That gave the unique opportunity to monitor the unplugged area ahead of the SCL-face once the plugged area had been left behind (Fig. 5). Information to be obtained from monitoring the existing tunnel should help to determine the amount of stress re-distribution ahead of the current SCL heading and thus to assess that part of the displacements acting already on the shotcrete lining before the base reading could be done.

It was possible to take readings until the approaching heading was within just one width of a ring, which was 600 mm. Although the database was complete

Figure 5. View into existing Piccadilly Eastbound.

from that point of view, no evidence was given of any deformation ahead of the face. Two conclusions can be drawn from this surprising result:

1. It confirms previous observations that displacements in advance of the heading are small or negligible. This is not a general statement to London Clay, but it applies to this particular condition at the PiccEx Junction.
2. Under common circumstances some time goes by from applying shotcrete, installing the monitoring array, and taking the base reading. During this period of time the freshly applied shotcrete is already loaded and displaced by the stress re-distribution around the heading. Due to this inevitable delay in taking the base reading, this pre-displacement cannot be read and this information is lost. With the knowledge of the results discussed above, it is clear that the unreadable pre-displacement must be very small, so that the ordinary monitoring provides a nearly complete picture of the total displacement and hence of the load acting upon the shotcrete lining. Again, this is not a general statement to London Clay, but it applies in these particular conditions at the PiccEx Junction.

4.2 *Existing Piccadilly Tunnel Westside*

Before this particular part of the monitoring will be discussed some general information on the existing Piccadilly Line tunnels should be given.

The lining of the existing Piccadilly Eastbound Tunnel is made of Spherical Graphite Iron segments (SGI-segments). The joints between the segments were filled with plywood or similar to cope with curves and changes of the gradient. No gaskets have been used to prevent water from intruding through the joints. The London Clay at T5 in general is technically watertight, but somehow water find its way down to the tunnels and through the joints. As a result plenty of stalactites

Figure 6. Stalactites on SGI-segments, exist. Piccadilly Line.

Figure 7. LHS existing Piccadilly, RHS SCL Eastbound Stub.

growing upon the lining and also rusting of the iron segments is visible (Fig. 6).

The distance between the existing Piccadilly tunnels and the SCL Stub Tunnels was very small (Figs. 3, 7). The remaining ground pillar between the tunnels varied from 0.4 m at the box to approximately 3 m at the end.

The integrity of the existing structures during SCL-work had to be ensured; therefore monitoring of the existing Piccadilly Line tunnels was inevitable. Of particular interest was the performance of the existing Piccadilly Line Eastbound during the excavation of the SCL Eastbound Stub Tunnel which was the first SCL Stub tunnel to be constructed.

The existing Piccadilly Line Eastbound is approximately 20 m long (before it unifies with the existing Piccadilly Line Westbound, Fig. 3), of which the first 8 m, measured from the box, have been plugged with foam concrete to enhance stability during excavation of the adjacent SCL Eastbound Stub. In the remaining

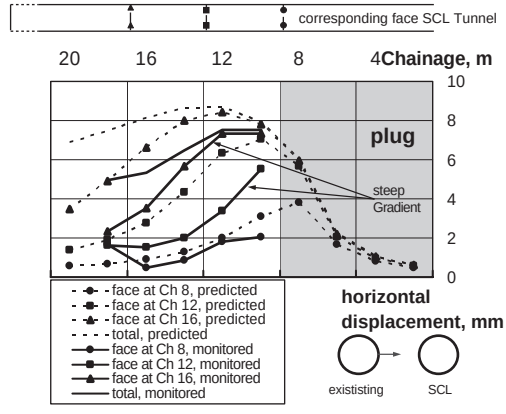

Figure 8. Horizontal displacements exist. Piccadilly.

unplugged part four monitoring arrays have been installed. Access was given through the neighboured Piccadilly Line Westbound Tunnel.

The existing Piccadilly Line Eastbound Tunnel experienced 3 to 5 mm vertical displacement in the crown, and 5 to 7 mm horizontal displacement at axis level directed towards the SCL Eastbound Stub, indicating clearly an ovalisation. All displacements were limited to the crown and that side of the lining where the SCL Eastbound Stub passed by (Fig. 8).

Significant displacements could be observed approximately only 2 m ahead of the current SCL face and continued 4 to 5 m after the SCL face had passed the relevant monitoring array (equivalent to half a tunnel diameter before and one tunnel diameter after passing the monitoring array, or in terms of time equivalent to approximately three days altogether).

Although the overall displacements in the existing Piccadilly Line Eastbound were 2 mm smaller than anticipated in the design (see also companion paper Jäger & Stärk 2007), the gradient appeared steeper, creating a larger longitudinal 'bending' of the SGI lining towards the SCL Stub Tunnel.

This information was important with respect to the stability of the neighboured tunnel, the existing Piccadilly Line Westbound, during the upcoming excavation of the SCL Westbound Stub. It was decided to extent the foam concrete plug in the existing Piccadilly Westbound to full length (instead of only 8 m). Thus any movement of the expanded lining and any further opening of joints were prevented.

5 CONCLUSION

The civil engineering and tunnelling works at PiccEx junction have been completed successfully (Fig. 9). A contributor to that success was the collaboration between contractor and designer. Through this

Figure 9. Completed SCL-work Eastbound turnout Tunnel.

collaboration, new designs and methods were realized and these reduced both cost and construction risk while at the same time ensuring high quality in the finished works.

ABSTRACT: Support problem of complicated loading deep excavation pit at underground engineering are analytically investigated. Through support engineering, advanced technology should be used to assure stability of the slop and safety of the establishment around excavation pit. Subway on YueMa Square grade separation works of Wuhan city receives dense traffic, which suffers from the effect of moving load obviously, for example from buses, cars etc, and surrounds with many buildings. Selection of supporting configuration, with the consideration of change of excavation pit depth, geological environment, traffic demand and situations of the buildings around excavation pit at different area, take different supporting project. In this project, many support styles are used such as retaining wall, pile, bolt and so on. Through monitoring to the support configuration, analyzing the monitor result, evaluating the effect of moving load to the support configuration.

1 INTRODUCTION

Yuema Yard fly-over locates the south of Snake Mountain, Shouyi Square and periphery. The yard, which is around by Yellow Crane Building, Shouyi Square, Hubei Theater and Hubei Library, comes through Shouyi Square from west to Changjiang Bridge, connects Wuluo Road from east to Da Dongmen fly-over. Yuema Yard fly-over tunnel project, which is consisted of west lead path, main tunnel and east lead path, the tunnel adopted open excavation method, tunnel foundation pits move along with change of working face. The situation around foundation pit is complicated, there are five eight-floors concrete structure residential buildings in the right of K0+320∼K0+500, which is 5 m away from top slop of the foundation pit, and key cultural relic Red Building is on the left of K0+565∼K0+605, which is 5 m and 3.2 m respectively apart from top slop of the foundation pit. And there are brick mix structure house on the left of east section of main tunnel and high-level construction on the left. Meanwhile, adopting single side excavation on the east section of K0+720, traffic wouldn't be brought to a standstill under the foundations construction. Cars put an uncertain moving load to the foundation supporting and slope for running close to the pit. Due to great stream of people and traffic at the cross of Yuema Yard and Shouyi Square, and serious disturbance, adopting reasonable supporting form and monitoring supporting structure play an important role in assurance of safety construction. This paper focuses on the monitoring situation of k0+720∼k1+060 section foundation pit to inspect effect of moving load on support.

1.1 *Construction program and supporting form*

With open excavation method adopted in Yuema Yard tunnel Project, the k0+780∼k1+060 section use single side excavation in order to ensure constant traffic. And cars put an uncertain moving load to the foundation supporting and slope for running close to the pit. In the process of excavation, if supporting structure is unstable and validable, the foundation pit and soil would fall into extra-big displacement and settlement even slipping as a result of unstable or ineffective supporting structure, which would bring about destruction of construction and establishment or damage to builders. Therefore, it is necessary to carry out completely systematic monitor and control on supporting form, soil distortion and displacement, change of groundwater, give monitoring information back in time to achieve informational construction.

Because of adopting row piles and prestressing steel supports in this section, row piles use C30 RC perfusion pile, whose diameter is 900 mm, length is 112.0 m, with 0.5 m height C30 RC coronal girder connected each pile. Adopting two horizontal prestressing steel supports, which changes according to depth of foundation pit, the first one is in the position of

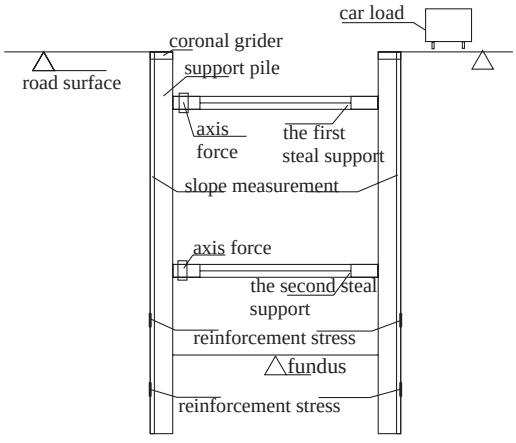

Figure 1. Monitoring measurement disposal of k0+820 Section.

coronal girder while the second one is 6 m away from top of the pit. Middle girders use general hot-rolling I-shape steel.

1.2 *Monitoring program*

1.2.1 *Monitoring item*

Following are the main items: a slope instrument to observe deep-layer level displacement; b. axis force monitoring to inspect force situation of prestressing steel support; c. suffering force monitoring of supporting pile to test suffering force situation of supporting pile by using reinforcement stress buried in it.

1.2.2 *Collocation of measuring point*

According to geological condition, surrounding situation and supporting structure, collocation program of measuring points in k0+780~k1+060 section include: (1) measuring point of slope measurement: dispose a pipe of slope measurement at space between 20 m (space out the pipes 20 m apart); (2) measuring point of reinforcing steel internal force: dispose two reinforcement stress in pile every 40 m; (3) measuring point of axial force: dispose axial force meter on two supports separately every 40 m. Specific disposal position of instrument was shown as figure 1.

2 ANALYSES ON MONITORING RESULT

In k0+780~k1+060 sections, which hold traffic thoroughfare, two section construction method was adopted to avoid blocking traffic. That is carrying out the north side construction first. Meanwhile, the south side keeps transportation and starts construction till the north side is completed and resumes transportation. Considering Yuema Yard project which holds traffic

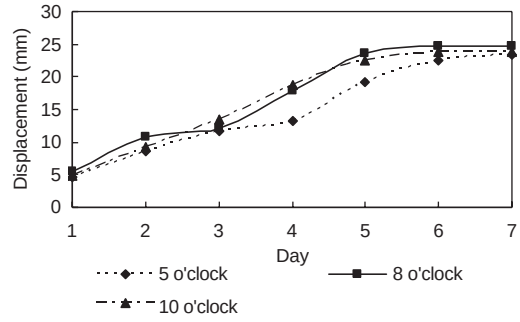

Figure 2. Pile top horizontal displacement-time curve.

thoroughfare and great cars flux, would bring about certain effect on foundation pit supports. Therefore, apart from routine monitor methods, three different break surface were used in the process of foundation excavation for supervising suffering force , level displacement of pile body and pile top of supporting pile under the effect from moving load at different period of time and vary traffic flux.

In foundation pit excavation, three sections would be monitored at 5 o'clock (min vehicle flux), at 8 o'clock(max vehicle flux), at 10 o'clock (average vehicle flux) and three sections (k0+820~ k1+140~k0+360) respectively for a week.

In the position of k0+820, support fashion was cantilever pile and steel support. In this section, pipe of slope measurement and Reinforcement Stress measurement were fixed into support pile, and axis-force measurement was fixed into steel support. Excavation began on Aug.19th and finished on Aug.24th. Monitoring result illustrate in table 1 below:

According to the early monitoring results, we found that horizontal displacements, stress of supporting pile, axis-force of steel supports all rise along with the depth of pit excavation and reach the max in 2 or 3 days after the excavation completed. But then the index value would go down and be stable.

The following three figures express variety rules of displacement, stress in each time for one week. Synthesizing the three sorts of curve, we can see that the variety rules of monitoring result are consistent with early dates in other sections, and stress of supporting piles reach maximal as well as displacement.

The figure 2 expresses variety rules of horizontal displacements of supporting piles top along with time when foundation pit was excavating. From the curve, it is clear that the horizontal displacement is always minimal when the vehicle flux is minimal (5 o'clock); and the horizontal displacement is always maximal when the vehicle flux is maximal (8 o'clock). After 2 days of the excavation is finished, the displacement is consistent in three times. The most discrepancy of horizontal displacement between maximal and minimum

Table 1. Monitoring result of k0+820 section (1).

Day	O'Clock	Excavation schedule(m)	Displacement of pile to(mm)	Max displacement of pile body(mm)
1	5	4	4.7	4.7
	8	4	5.6	4.9
	10	4	4.8	4.8

	10	–	23.9	26.6

Table 2. Monitoring result of k0+820 section (2).

Day	O'Clock	Excavation schedule(m)	Force of reinforcing steel bar in pile(Mpa)	Force of steel support (Mpa)
1	5	4	14.3	–
	8	4	15.7	–
	10	4	15.6	0.5
2	5	6	18.5	1.3
	8	6	19.3	1.8
	10	6	19.7	2.1
3	5	8	20.9	3.5
	8	8	22.7	4.7
	10	8	25.1	5.6
4	5	10	24.3	7.3
	8	10.5	26.7	8.9
	10	finished	24.8	10.6/0.3
5	5	–	25.5	9.9/0.5
	8	–	25.1	10.1/0.9
	10	–	24.9	11.3/1.6
6	5	–	26.3	10.2/2.1
	8	–	27.7	10.5/1.9
	10	–	25.6	10.4/2.3
7	5	–	26.1	11.1/2.2
	8	–	25.8	10.0/2.5
	10	–	26.4	9.4/2.1

vehicle flux was happened on Aug.24 and Aug.25. The maximal discrepancy is 6.5 mm.

Figure 3 expresses variety rules of stress of supporting pile body along with time when foundation pit was excavating. From the curve, it is apparent that stress rises rapidly in the early days of excavation, but the rising trend goes slowly and steadily with the completion of excavation. In the three different times, the discrepancy of stress is not very high.

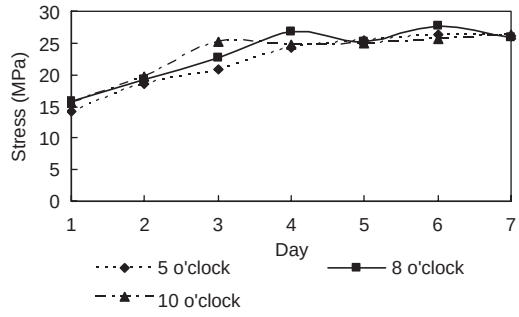

Figure 3. Support pile force-time curve.

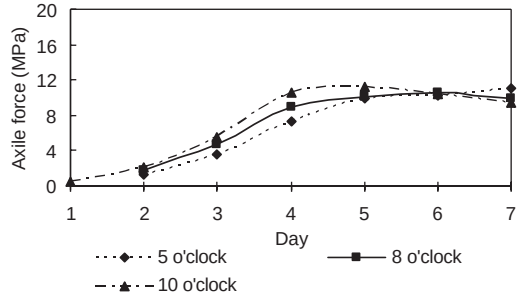

Figure 4. Steel support axile force-time curve.

Figure 4 expresses variety rules of steel support axis-force along with time when foundation pit excavating. From the curve, it is obvious that axis-force rose rapidly in the early days of foundation pit excavation, but the rising trend goes slowly with the completion of excavation. The maximal discrepancy of axis-force between maximal and minimum vehicle flux is 2.5 MPa which was happened on Aug.24. The variety rule is consistent with the horizontal displacement of pile top.

Synthesizing the three results of monitoring, we can see that with the foundation pit excavating, the rising trend of stress of supporting pile and horizontal displacement of pile top go slowly after the first steel support is fixed. It means that the steel support took effect. The position of horizontal max-displacement of pile body is moving down slowly, which is between the two steel support (4∼6 m) after the second steel support is fixed. For different time, vehicle flux is different, as well as the monitoring result. But the discrepancy is not very distinct because of the effective support configuration. On account of

the special geographical position, design unit chose a high safety sector to calculate for the sake of project safety when deciding the support fashion. Furthermore, the support fashion of monitoring section is row pile and steel support, and the support effect of support configuration is very good. So the effect of moving load to support configuration is not very remarkable.

3 CONCLUSIONS

Through monitoring analysis of foundation pit supporting configuration in different time, we can see that the effect of moving load to foundation pit is existed and restricted by many other factors such as supporting configuration, geologic condition, geographic situation, environments, ground water and so on. It is necessary to monitor support configuration in the process of deep foundation pit excavation. Through analyzing the monitoring results to reflect construction effect, it can make for carrying construction organization into execution and choosing economical and rational supporting.

Finite element analyze single shell lining based on contact mechanics

Junru Zhang & Wenge Qiu & Huijian Zhang
School of Civil Engineering, Southwest Jiaotong University, Chengdu,Sichuan, China

ABSTRACT: For the moment, there are mainly three mechanical models (load-reaction model, nonindividual body model, convergence-constraint model) used to calculate tunnel structure. Because of discontinuous section existed in the single shell lining, the above three models can not analyze. Therefore single shell lining mechanical model based on contact theory has been proposed. This model introduced non-thickness contact element to simulate the interaction between surrounding rock and support, support and structure, then used non-linear finite element analysis to study the mechanical property of single shell lining. The study results indicate that under the same conditions single shell lining produced 50%∼80% the internal force of composite lining producing. Another saying is that to produce the same internal force, the thickness of single shell lining could be reduced four times than that of composite lining. In a word, single shell lining used could reduce excavation and concrete amount. Consequently, the cost of the engineering is dropped.

1 INTRODUCTION

Single shell lining is date back to 1970s and the first country who used it is Norway. Compared with composite lining, it is chiefly characterized by canceling repelling board, so shearing force can function in lining[1]. At present, many countries use single shell lining as final lining, such as China, Germany, Switzerland, France, America, Japan and so on. Although single shell lining has been extensively applied in our country, its design method is mainly aiming at concrete reinforced with shot steel fiber. For instance, there are Q system method, limiting state method and energy theory method[2]. Among the three, Q system method is based on experience, the other methods is rarely used due to their small scope of application. Therefore, to find a better mechanical model for single shell lining is greatly significant.

2 MECHANICAL MODELS OF TUNNEL AT PRESENT

2.1 *The existing mechanical models of tunnel*

The tunnel deign model group of ITA sum up in three mechanical models as load-reaction model, nonindividual body model, convergence-constraint model[3]. These three models all have some assumptions and restrictive conditions added, so they have different scope of application.

2.1.1 *Load-reaction model*

Load-reaction model is characterized by its simple calculation method and definite safety coefficient, so it is recommended in tunnel design code of our country[4]. This model mainly considers that surrounding rock loose load and elastic resisting force combined composed on lining at the same time, then calculates the inner force of lining, consequently evaluates whether it is safe or not. It is obvious that how to determine load model and surrounding rock elastic resisting force is the key to accuracy of calculation.

2.1.2 *Convergence-constraint model*

Convergence-constraint model is also a important method. It uses the crossing point of surrounding rock characteristic curve and support characteristic curve to determine the best condition of balance, as shown in Fig. 1 [5]. But in the application of this model, there are several difficult problems. On one hand, the surrounding rock and support characteristic curves are hard to exactly determined, on the other hand, the influencing factors of characteristic curve can not be described with fixed quantity. Therefore this model still stays in the phase of qualitative.

2.1.3 *Nonindividual body model*

Nonindividual body model is based on interaction of support and surrounding rock, which bear the loads together. The surrounding rock is seen as main load-bearing structure, while support is as like as a stiffening

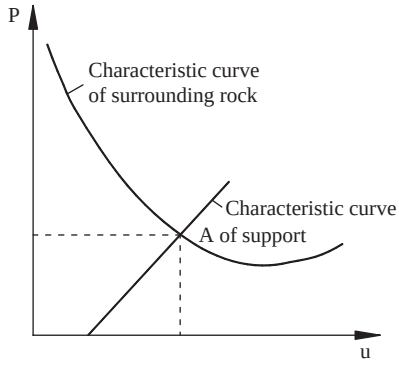

Figure 1. Convergence-constraint model illustration.

ring inlaid in the hole located at semi-infinite body [6]. In the practice of this model, the major work is to analyze the redistribution of ground stress caused by excavation, and then the induced deformation, establishment of surrounding rock and stress in support can be gotten. Afterwards whether the tunnel is safe or not is known. At present, there are two calculation methods for the nonindividual body model. These two methods are analysis method and numerical method. The former can obtain solution only in analyzing few tunnel with regular shape because of difficult in the aspect of math, and the latter can simulate all the features of rock and structure, even it can simulate the construction course. So it is gotten more and more used in underground engineering.

2.2 *The proposing of mechanical model for single shell lining based on contact theory*

For each mechanical model, only when it exactly reflected real state of surrounding rock and how to contact between surrounding rock and support can get the reasonable result [1]. Because it is discontinuous between surrounding rock and structure, structure and structure in the single shell lining, the above three model can not reflect this discontinuous surface. Thus to improve mechanical model to suit the feature of single shell lining is highly required. Substantially to simulate discontinuous surface belongs to contact issue of solid mechanics. When solving the contact issue, more exact deformation and stress feature of contact plane are taken into account, so the calculation result is more like practical situation [7]. This paper introduced non-thickness contact element to simulate the interaction between surrounding rock and structure, structure and structure on the base of regular nonindividual body model, and then using non-linear finite element method to analyze the stress in single shell lining. Consequently the theory for single shell lining design can be provided.

Table 1. Calculation cases.

case	Lining style	Thickness of primary support (C20 shotconcrete)	Thickness of final lining (C25 cast-in-place concrete)
1	Composite lining	15	35
2	Single shell lining	15	35
3	Single shell lining	10	25

3 NON-LINEAR FINITE ELEMENT ANALYSES FOR SINGLE SHELL LINING

3.1 *General situation of engineering*

This analysis took NO.2 inclined shaft of Da-bie-shan Tunnel which located at high-speed railway from He-fei to Wu-han as background. Da-bie-shan Tunnel, which is the longest tunnel in the high-speed railway from He-fei to Wu-han, spans 13.256 kilometers. NO.2 inclined shaft locates at right of line, and its longitudinal gradient is 8.2%, with spanning 1077 meters. The midline of railway is orthogonal to midline of tunnel. Three different support parameters are listed in Tab. 1 The surrounding rock is IV rank. Through analyzing these three cases to compare the stress in structure, then optimum design can be carried out.

3.2 *Finite element analysis*

3.2.1 *Model and parameters for calculation*

ANSYS is used in this analysis and elasto-plastic plan strain model is taken as calculation model. Surrounding rock employed four nodes plane isoparametric element, and its yielding criterion is Drucker-Prager criterion [8]. Beam element is served as primary support and final lining. Face to face contact element of two-dimension (targe169 and conta171) is used to simulate interaction between surrounding rock and primary support, primary support and final lining. Normal displacement of lower boundary is restricted. Horizontal direction restraint is imposed on right and left boundary, while upper boundary is free. The calculation model is shown in Fig. 2. The corresponding physical mechanics parameters are listed in Tab. 2.

3.2.2 *Contact element and its yield criterion*

Face to face contact element of two-dimension is able to simulate bonding, separating and gliding. In ANSYS program, it is realized by targe169 and conta171 sharing one real constant [9]. This element is shown in Fig. 3. Each node has two degree of freedom as moving along X axis and Y axis in the node

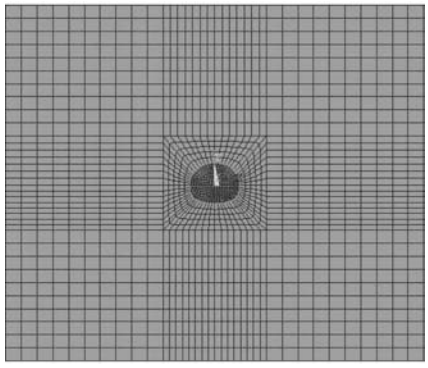

Figure 2. Model and finite element mesh.

Table 2. Physical mechanics parameters.

Stratum and material	Elastic ratio E/GPa	Poisson ratio/μ	Weight γ /kN·m^{-3}	Cohesion force c /MPa	Internal friction angle ϕ/°
IV degree wall rock	1.3	0.35	20.0	0.20	27
C20 shotconcrete	21.0	0.20	22.0	–	–
C25 cast-in-place concrete	28.0	0.18	23.0	–	–

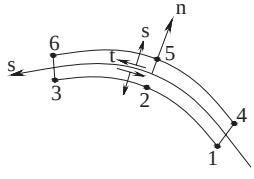

Figure 3. Contact element.

coordinate system. Unknown quantities of this element contain nodal displacement and contact stress, while geometrical condition and static balance condition is considered as additional equation contained in the stiffness equation. Due to this, equivalent stiffness matrix and load vectors of contact element can be established, then to add the contribution of contact element to the total equation by regular method. With that the solution can be done.

Contact element takes maximum shear stress criterion and Mohr-Coulomb criterion as criterion for contact state. Discriminant equation follows:

$$\tau \le [\tau], \quad \tau \le C + \mu\sigma \tag{1}$$

Where τ and $[\tau]$ are the equivalent shear stress and maximum shear stress allowed respectively; C and μ are the cohesive strength and friction coefficient of the material respectively, and σ is normal stress of contact.

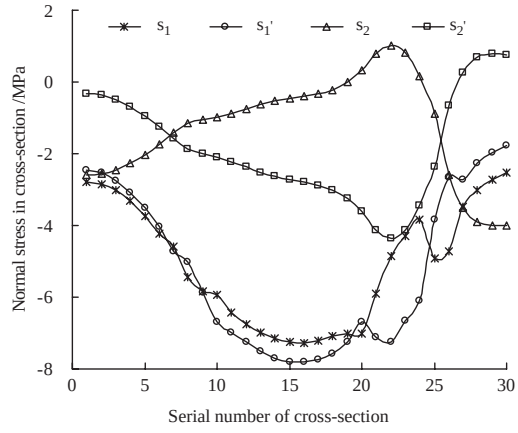

Figure 4. Stress distribution in cross-section in calculation case 1.

3.2.3 *Simulation of tunnel excavation*

Simulation of tunnel excavation is realized by killing corresponding elements, namely to set the stiffness and load of died element to a small value (for example 10–6). To active corresponding elements and modify their attribution can be used to simulate applying lining. Release ratio of stress due to excavation is determined by ratio of surrounding rock displacement at the time of applying lining to total displacement [10].

$$\bar{\delta} = W^{\lambda} \tag{2}$$

Where δ and W are the stress release ratio and displacement release ratio of surrounding rock respectively, and λ is one parameter related to geological condition and construction method (this paper take 0.7 for calculation).

According to the arch crown settlement of NO.2 inclined shaft observed in site, the average stress release ratio is worked out as that: 40% when applying primary support and 60% when applying final lining.

3.3 *Calculation result*

From calculation result, it is seen that relative slip occurred between primary support and final lining under Case 1, while not do Case 2 and Case 3. In order to find out the feature of normal stress distribution under each case, the normal stress distribution map is employed, as shown in Figs 4, 5 and 6. Where horizontal ordinate indicates serial number of cross-section showed in Fig. 7; and vertical ordinate expresses the normal stress in corresponding cross-section. In these figures, the details of σ_1, σ_1', σ_2, and σ_2' are shown in Fig. 8.

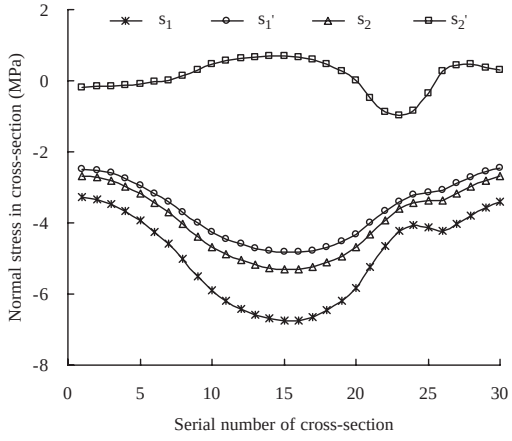

Figure 5. Stress distribution in cross-section in calculation case 2.

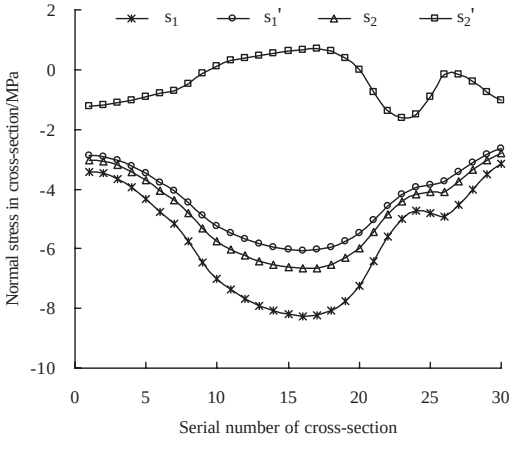

Figure 6. Stress distribution in cross-section in calculation case 3.

The conclusion can be drawn follows:

(1) In Case 1, lining could be seen as composite beam because the friction existed between primary support and final lining is very small. As Fig. 4 illustrating: primary support is totally in compression, and the majority of final lining is in compression except basement and invert. The maximum compression stress locates at side wall (NO.16 section), inside of primary support with -7.81 MPa; and the maximum tension stress locates at basement (NO.22 section), outside of final lining with 1.03 MPa.

(2) In case 2, lining appears deforming entirely, because shear stress can be transferred between primary support and final lining. As shown in Fig. 5, primary support is totally in compression,

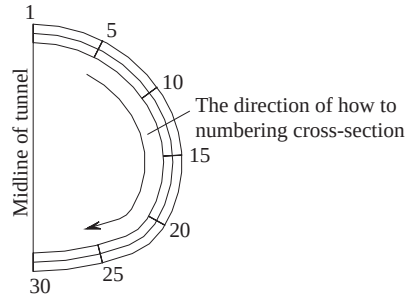

Figure 7. Serial number of cross-section.

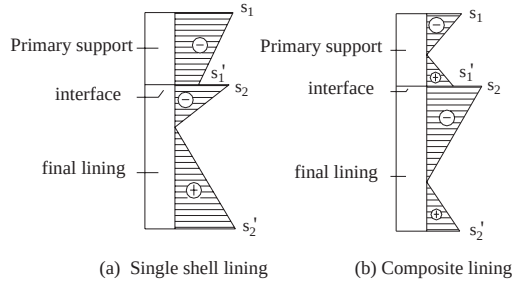

Figure 8. Normal stress distribution in cross-section.

but for final lining, the parts of arch springing, side wall and invert are in tension, the other parts in compression. The maximum compression stress locates at side wall (NO.15 section), outside of primary support with -6.75 MPa; and the maximum tension stress also locates at side wall (NO.15 section), inside of final lining with 0.68 MPa. In addition, normal stress on the interface of primary support and final lining jumped because elastic ratios of the two are different.

(3) Compared to case 2, in case 3 the thickness of primary support is reduced 5 centimeters, and that of final lining decreased 10 centimeters. However, the mechanical feature and vary tendency in case 3 are similar to those in case 2, only the value of normal stress have some difference. Just shown from Fig. 6, the maximum compression stress locates at side wall (NO.16 section), outside of primary support with -8.25 MPa; and the maximum tension stress also locates at side wall (NO.16 section), inside of final lining with 0.68 MPa.

(4) The compression strength and tension strength of C20 shotconcrete are 10.0 MPa and 1.1 MPa respectively, and those of C25 cast-in-place concrete are 12.5 MPa and 1.33 MPa respectively [11]. The above calculation results all feasible. But under the same condition, the maximum compression stress in case 1 is 1.2 times of that in case 2;

Table 3. Economic comparison between composite lining and single shell lining.

Case	Item	Amount of per meter	Unit	Unit price/ *yuan*	Price/ *yuan*	Total price/ *yuan*
1	Excavation	62.76	m^3	98.0	6150.5	13248
	C20 shotconcrete	4.18	m^3	375.9	1571.3	
	f 22 mortar bolt	57	m	23.0	1311.0	
	C25 cast-in-place concrete	9.23	m^3	283.4	2615.8	
	Repelling board	58.58	m^2	27.3	1599.2	
3	Excavation	58.58	m^3	98.0	5740.8	10593
	C20 shotconcrete	2.72	m^3	474.1	1289.6	
	f 22 mortar bolt	51	m	23.0	1173.0	
	C25 waterproof concrete	6.51	m^3	367.0	2389.2	

while the maximum tension stress is 1.5 times. But the maximum tension stress in case 3 is agree with that in case 2, and the maximum compression stress in case 3 is 1.3 times of that in case 2, but all less than allowable value. Therefore, the lining style in case 3 is reasonable and economical.

3.4 *Comparisons of composite lining and single shell lining in economics*

On account of space limitation, only comparison of case 1 and case 3 is illustrated in Tab. 3. The contents in Tab. 3 are quantities of work and construction cost per meter.

From Tab. 3, it is clear that single shell lining can save 2655 yuan per meter without consideration of economic benefits caused by increasing work efficiency.

4 CONCLUSIONS

(1) A mechanical model for single shell lining based on contact theory is proposed in this paper, namely to introduce non-thickness contact element to simulate the interaction between surrounding rock and structure, structure and structure on the base of regular nonindividual body model, and then using non-linear finite element method to analyze the stress in single shell lining. Consequently the theory for single shell lining design can be provided.

(2) For composite lining, the maximum compression stress locates at side wall, but maximum tension stress at basement. For single shell lining, both the maximum compression and tension stress locate at side wall.

(3) under the same conditions, single shell lining produced 50%∼80% the internal force of composite lining producing. Another saying is that to produce the same internal force, the thickness of single shell lining could be reduced four times than that of composite lining. Therefore, single shell lining used could reduce excavation and concrete amount. Consequently, the cost of the engineering is dropped.

The development of early-high-strength shotcrete and the evaluation of improved tunnel support system

Hiroshi Kanazawa & Takahiko Nishi
Japan Railway Construction, Transport and Technology Agency, Yokohama, Japan

Tsutomu Kiuchi, Shoushi Nishizaki & Yukihiro Furuto
Shimizu Corporation, Tokyo, Japan

ABSTRACT: With an aim of further improvement of high-quality shotcrete, JRTT-Japan Railway Construction, Transport and Technology Agency-has developed high-performance shotcrete showing that its rebound and dust during being placed are remarkably reduced on account of the increased viscosity of the shotcrete owing to the mixture of fine powder and the separation resistance developed by separate mixing. The new high-performance shotcrete is successfully evaluated through its application to more than 120 actual tunnel construction sites for the bullet train, so called Shinkansen. This paper addresses the development of high-performance-early-high-strength shotcrete exhibiting increased strength at young ages based on the accumulated technologies on high-quality shotcrete and the trial construction for the evaluation of improved tunnel support system employing it.

1 INTRODUCTION

Lately the growth of social request for reduction of construction cost for infrastructures in Japan, without exception to the area of railway construction, has strongly encouraged the JRCTT-Japan Railway Construction, Transport and Technology Agency-, who takes charge of railway construction in Japan, to have made effort on saving the cost for construction of Japanese bullet train, so called "Shinkansen". As a means for fulfilling the purpose, development of high-performance shotcrete has been processed to make tunnel supports more effective. The high strength at an early age for the newly developed high-performance shotcrete exhibiting $3\,N/mm^2$ of 10-minute compressive strength has been expected to be capable of simplifying tunnel supports on account of the rapid development of early-age strength. This paper addresses the development of rapid high strength shotcrete at length. Again, developed with an aim of promoting fast tunnel excavation, the high-performance shotcrete has been applied to the trial construction for verifying the appropriateness of fast tunneling employing it. In addition, for the purpose of examining the difference between the conventional shotcrete and the newly developed one with respect to load-carrying capacity, a dense package of monitoring has been implemented to investigate the behavior of tunnel supports under the various patterns of tunnel excavation.

2 DEVELOPMENT OF HIGH PERFORMANCE SHOTCRETE EXHIBITING HIGH STRENGTH AT EARLY AGE

2.1 *Background and process for the development*

High-quality shotcrete is created to reduce the rebound during its installation by separate mixing with the use of silica fume and fine lime powder. This study aims the enhancement of tunnel support in a way that development of high strength at an early age on the basis of the preceded technologies puts high-performance shotcrete into practical use.

Regarding the method for gaining early-age high strength, a high-strength admixture is added to base concrete so that the accelerator mainly consisting of extra accelerating cement minerals is utilized to facilitate quick setting. This principle for gaining the high-early-strength can be accomplished in such a way that the structure of cement concrete is densified by the help of ettringite which is fine needle-like crystals created owing to the hydration between the high-strength admixture and the accelerator. In this study, the practical mix designs for high-early-strength shotcrete are suggested based on the optimum mix proportion of

concrete for the target strength of 3/Nmm^2 after 10 minutes. The procedure for the development can be summarized as the following three steps;

(1) Indoor mortar test
(2) Shotcrete test at outdoor model tunnel
(3) In-situ field shotcrete test at actual tunnel site

2.2 *Indoor mortar test*

With an aim of concentrating achievement of a practical mix design for shoctrete as well as the required strength, flow values, setting times and strength characteristics of mortar with varying design mixes have been evaluated.

Table 1 and Table 2 shows the materials used for the indoor mortar tests and range of mix designs, and the results from the indoor mortar tests, respectively.

From Table 2, it is easily understood that the compressive strength at the 10-minute age demonstrates a good correlation with the accelerator added to the mixture, and as the amount of accelerator is increased, the compressive strength also appears to increase. Although it is shown by the test that a few of design mixes can achieve 10-minute compressive strengths greater than 3 N/mm^2, the pursuit of economical design imposes adoption of a dosage of (Cement and Silica fume) 400 kg/m^3, 12% of high strength admixture and accelerator as the mix design for the shotcrete test planned in the next step.

Table 1. Materials used in mortar tests for high early strength shotcrete.

Item	Specification
Cement (C)	Ordinary Portland cement
Silica fume (SF)	$SiO_2 \geqq 9$ % Specific surface area $\geqq 15$ m^2/g
Lime fine powder (LM)	Grain size $\leqq 0.147$ mm
High-strength admixture (H)	Ettringite admixture
Accelerator	Extra accelerating cement minerals

2.3 *Shotcreting test in model tunnel*

The shotcreting test has been implemented as well to examine the pumpability of mixture, pulsating motions of conveying hose, rebound and so forth as to verify the reproducibility of shotcrete designed with reference to the indoor mortar tests. The mix designs in Table 3 obtained from the indoor mortar tests are utilized for the test.

The shotcreting has been executed at the model tunnel with 5.5 m in width, 4.5 m in height and 20 m in length.

Table 4 describes the compressive strengths of concrete. Every specimen from each mix design has shown approximately 5 N/mm^2 in compressive strength at the age of 10 minutes which is greater than that of the mortar in the indoor tests. This result could be attributed to the existence of coarse aggregate and accelerator well mixed in the concrete.

2.4 *Field in-situ testing of shotcreting at Mineyama tunnel*

A series of field in-situ shotcrete tests have been carried out to examine the reproducibility of model shotcrete test using the material and equipments in an actual working tunnel which is a part of Mineyama

tunnel construction site. With a viewpoint of economical aspect, the optimum mix proportion with accelerator and high-strength admixture has been adapted for the in-situ field tests for shotcrete.

Table 5 shows the mix design of shotcrete. Because the Mineyama tunnel employed three types of mixed cements consisting of cement, silica fume and lime fine powder with varying dosages, the same materials have been utilized in the in-situ filed shotcrete test.

To achieve an economical mix design, characteristic of strength development, construction efficiency and spraying nature are evaluated with the dosages of high strength admixture and accelerator changing as 12%, 10%, 8% and 12%, 10%, 8%, 6% for each, as shown in Table 6.

Table 7 indicates the re-testing results. Comparing the two mix proportions, it can be found that the Mixes A_{12-8} with a large content of high-strength admixture come to produce high strength at the age longer than 7 days while the Mixes B_{11-10} with a large content of accelerator come to yield high strength at the age not longer than 1 day.

Considering these characteristics of the high early strength shotcrete, the shotcrete test was carried out again under varying temperature, on the dosage of accelerator 9% against a fixed high-strength admixture content of 11%. This test provided approximately

constant compressive strength reaching more than 3 N/mm^2 for every mix proportion including even the case with a dosage of accelerator reduced by 9% under varying temperature.

Based on the above results, the mix B with 11% of high-strength admixture and 9% of accelerator has been adopted for the main tunnel at the Mineyama tunnel site.

3 APPLICATION OF EARLY-HIGH-STRENGTH SHOTCRETE TO JOB SITE

High-performance early high strength shotcrete is applied to the Mineyama tunnel in the section between Joetsu and Toyama of the Hokuriku Shinkansen, promising a rapid transportation means in the Hokuriku Region. The geological profile are shown in Figure 1. The rock masses of the tunnel section consist mainly of soft rock on the basis of mudstone in the Noudani Formation of Neogene (Miocene to early Pliocene) age. The tunnel is driven by the large partial tunnel face excavation machine. To improve the efficiency and speed of construction, this site has employed the machinery facilities which required appropriate tunnel supports corresponding to the updated driving speed. For that intention, a new tunnel support combined with high-performance early high strength shotcrete has been suggested and its applicability has been verified. The length of the section employing the new tunnel supports extends up to 3,790m out of total length of 7,090 m accounting for approximately 65%. The other section of tunnel has been driven with the conventional supports utilizing steel supports. The driving speed in the new support section has exhibited 304 meters per 1 month, which is recorded as the highest speed of mechanical tunnel driving with NATM.

4 TRIAL CONSTRUCTION

The trial construction has been executed to estimate the different driving methods for a certain part of the Mineyama tunnel. It is intended to evaluate the practical applicability of newly suggested tunnel support employing high-performance-early-high-strength shotcrete through investigating the behavior of rock mass and tunnel supports according to the varying driving speeds and patterns of tunnel supports. Figure 1 shows the geological profile of Mineyama tunnel.

4.1 *Outline of trial construction*

In the trials, the pattern of tunnel excavation described in Table 8 are prepared to compare the effects of varying driving speeds and tunnel supports on the behavior of surrounding rock mass.

In the section of trial construction, monitoring has been carried out as shown in Figure 2. Detail of the monitoring is shown in Table 9.

4.2 *Monitoring during trial construction*

4.2.1 *Behavior of inner section*

Figure 4 and Figure 5 show the settlement at crown and convergence of inner section monitored during 140 days from the beginning of trial construction. The convergence of inner section has been obtained by monitoring the horizontal line at S.L.+1.5 m.

The results of monitoring provide the findings as follows;

- The ordinary advancing with the A tunnel support shows larger settlements at crown than those of the fast advancing with the A tunnel support and the ordinary advancing with the B tunnel support. This behavior, on the contrary to performance of the shotcrete strength, may be due to the local change of the ground condition.
- By the way, regarding the convergence, the ordinary advancing with the A tunnel support comes to produce relatively small convergence compared with the fast advancing with the A tunnel support and ordinary advancing with the B tunnel support.
- From the results of settlement and convergence, in spite of the smaller thickness of shotcrete, it is understood that the new tunnel support can decrease the settlement and convergence of the tunnel comparing to the conventional high performance shotcrete combined with steel support.

4.2.2 *Behavior of tunnel support*

Figure 5 shows the monitoring results about stresses developed in shotcrete, which provide the following findings;

- The measured stresses in the early-high-strength shotcrete adopted in the A tunnel support appears to be relatively higher than that in the conventional shotcrete employing high-quality shotcrete.

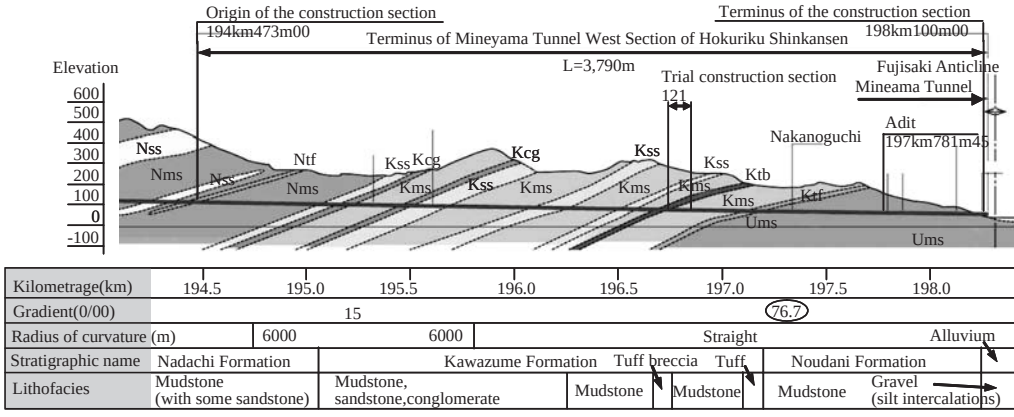

Figure 1. Geologic profile.

Table 8. Patterns of tunnel excavation at trial construction.

Pattern	Speed of advance m/month	1 cycle length m	Pattern of tunnel support			
			Type	Shotcrete	Rockbolt	Steel support
Fast advance Support-A	250	1.5	A tunnel support	High-performance early-high strength t = 10 cm	L = 3 m n = 14	–
Ordinary advance Support-A	100	1.0			ctc = 1.0 m	
Ordinary advance Support-B	100	1.0	B tunnel support	High-quality t = 15 cm	Same as above	H-125 ctc = 1.0 m

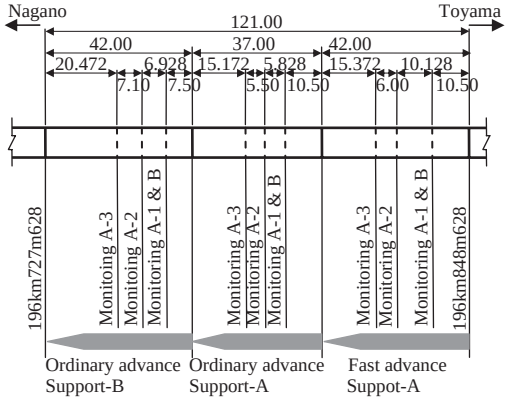

Figure 2. Location of monitoring.

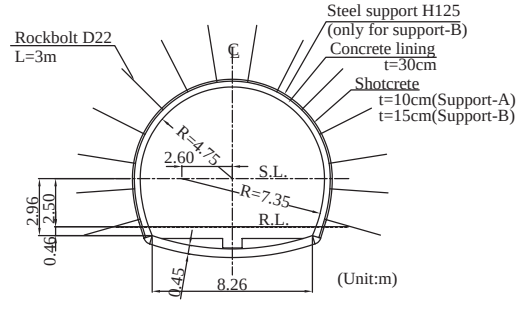

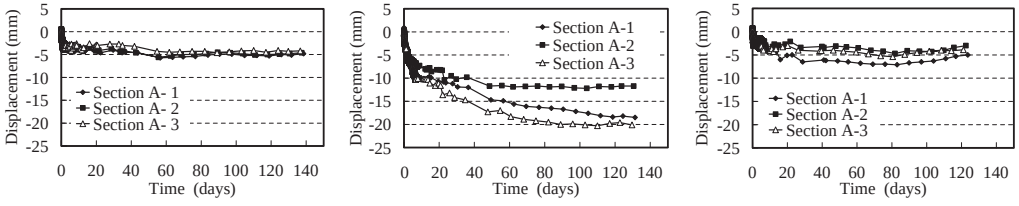

Figure 3. Tunnel support pattern.

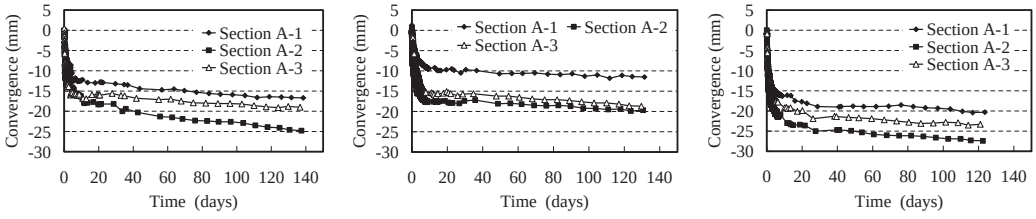
- Although the stresses in the B tunnel support combined withsteel support show a steady increasing tendency for all measuring points, those in the A tunnel support appear to decrease after a certain point in elapsed time, moreover some of them falldown under the zero, which means occurrence of tensile stress. This observation indicates that the shotcrete without steel support is supposed to behave in conjunction with structural changes accompanied by cracks caused by drying shrinkage and ground pressure. while that with steel support appears to steadily behave without abrupt change by virtue of stiffness of the steel support imposing restraint of deformation.

Table 9. Detail of monitoring.



Monitoring	Measurement
A	Convergence Settlement of crown and foot
B	Shotcrete stress Shotcrete strain Axial stress of Rockbolt Stress of steel support Ground displacement Displacement of ground ahead of face

- The large resultant stress of shotcrete observed may be due to the high stiffness of early-high-strength shotcrete at young age. It indicates early load-carrying capacity as a tunnel support, and may be considered as a substitute for steel support having function of support against ground pressure until the conventional shotcrete takes effect in accordance with time passed. Furthermore, it is expected that its high strength at early age, strongly required to increase advancing speed of tunneling, can make a contribution to assure safe excavations, which has been quite difficult because of the weak strength at young ages for the conventional shotcrete.

5 CONCLUSION

- The high-performance-early-high-strength shotcrete showing a compressive strength of 3 N/mm^2 after 10 minutes has been developed in this study, and suggested is the mix design that satisfies the requirements from both applicability to job sites and economical aspect.
- The application of high-performance-early-high-strength shotcrete to the Mineyama tunnel has clearly shown that the newly suggested tunnel support employing the high-performance-early-high-strength shotcrete without steel support can be appropriate for a practical use with sufficient safety, at the same time, for enhancement of advancing speed of NATM tunnel.
- The characteristics of tunnel supports have been successfully investigated through the trial construction providing comparison of the behaviors of the conventional tunnel support combined with steel support and the new tunnel support employing early-high-strength shotcrete without use of steel support.
- The comparative trial construction has informed that the new tunnel support has load carrying capacity no less than that of the conventional tunnel support, furthermore can make a contribution to increasing speed of tunnel excavation by virtue of its early-high strength facilitating safe excavation of tunnel face within a short time after installation of the shotcrete.

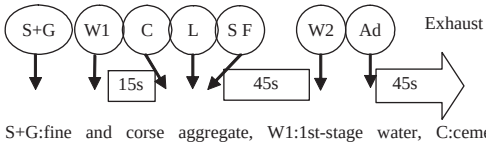
ABSTRACT: Japan Railway Construction, Transport and Technology Agency (JRTT) has applied High-Quality Shotcrete (HQSC) to a supporting member of the tunnel for the New Bullet Train Projects (Hokkaido, Tohoku, Hokuriku, and Kyushu) since fiscal 1997. The number of construction sites using HQSC is beyond 120. The feature of HQSC makes rebound and dust lower, and improves the quality of lining. In this papers, various studies on HQSC such as the site mix, the strength of the ages, the physical properties of fine aggregate are described. Furthermore, the FEM analysis is conducted in order to estimate the stress distributions in and around shotcrete lining. On the basis of the results, it is proposed that the selection method of natural ground and the lining applied the single-shell structure with HQSC.

1 INTRODUCTION

Japan Railway Construction, Transport and Technology Agency (JRTT) has applied High-Quality Shotcrete(1) (HQSC) to a supporting member of the tunnel for the New Bullet Train Projects (Hokkaido, Tohoku, Hokuriku, and Kyushu) since fiscal 1997. The number of construction sites using HQSC is beyond 120. HQSC is a advanced shotcrete, which limestone powder and silicafume are used, and made with two stage mixing method(2). The more powder is mixed in concrete, the higher viscosity and strength becomes. This feature of HQSC makes rebound and dust lower. Furthermore, HQSC helps to keep the quality of lining constantly and to save the cost of tunnel construction.

In this research, various studies on HQSC such as the site mix, the strength of the ages and the physical properties of fine aggregate are studied. These studies clarify the characteristic of the fine aggregate effecting to the performance of HQSC. Furthermore, the results of the strength test of the core samples gathered from construction sites indicate the large value of 27.2 N/mm^2 and the small variation of 8.6% in average. This fact suggests that there is a possibility of raising the conventional design strength of 18 N/mm^2 up greatly.

It is judged that the tunnel lining by using good quality shotcrete allow the design of the single-shell structure with HQSC. Therefore, the FEM analysis is conducted in order to estimate the stress distributions in and around shotcrete lining. On the basis of the results, authors propose the selection method of natural ground and the lining applied the single-shell structure with HQSC. The adoption of a single-structured tunnel lining, which would eliminate the need for secondary lining, would be immensely profitable since it would allow smaller excavation cross-sections, improve the execution cycle, and would not require the use of the centering for a secondary lining. Therefore, it should contribute significantly to the reduction of costs for



constructing new tunnels, as well as for renovating existing tunnels.

2 OUTLINE OF HIGH-QUALITY SHOTCRETE

HQSC is a Shotcrete of a new type characterized by substituting a part of the fine aggregate by a lime stone powder, and mixing silicafume. The feature of HQSC is the mix proportion with much binder. Therefore, plastic viscosity of concrete can be increased. Other features are low rebound and decrease of dust, increase of strength, stabilization of quality, and reduction in construction cost.

About the specified mix proportion, 5% of the weight of cement is substituted by the silicafume, and total weight of binder are set on 360 kg/m^3. The weight of a limestone powder was set for weight in which the fine aggregate of the particle size 0.15 mm or less was added to become 15% of the all up weight of the fine aggregate.

Moreover, about HQSC, two stage mixing method are introduced in concrete mixing process, to promote a viscous effect of a fine powder. The feature of two stage mixing method is to be poured into concrete by dividing into the first water to which water is provided by the examination beforehand and the water of the remainder (the second water). As the results, the mixed powder (cement, silicafume, and limestone powder) is dispersed by the first water and the paste film of a low water cementitious material ratio consisted by is formed around fine aggregate. Example of the mixing flow chart is shown in Figure 1, and example of mix proportion at the site is shown in table 1 respectively.

3 INFLUENCE OF FINE AGGREGATE PROPERTIES ON STRENGTH OF HIGH-QUALITY SHOTCRETE

3.1 *Fine aggregate properties and mix proportion classified into regional*

The distribution situation of the kind of the fine aggregate in Tohoku, Hokuriku, and Kyushu various places are shown in Figure 2. According to this Figure, as for the fine aggregate in the Kyushu region, the crushed sand is a main source, and also as for the fine aggregate in the Tohoku region, the crushed sand including mixed sand is a main source. On the other hand, in the Hokuriku region, natural sand such as the river and the mountain sand is a main source, and the lime stone is used as a raw material for the crushed sand.

Regional comparisons with physical properties of fine aggregate are shown in Table 2. In the fine aggregate properties, it was confirmed that there were differences in the mean value and the coefficient of variation. The cause is difference of distribution situation of kind of fine aggregate. The weight of a limestone powder (L) was set for weight in which the fine aggregate of the particle size 0.15 mm or less ($S_{0.15}$) was added to become 15% of the all up weight of the fine aggregate. Therefore, the amount of the unit of L can be decreased when $S_{0.15}$ is large.

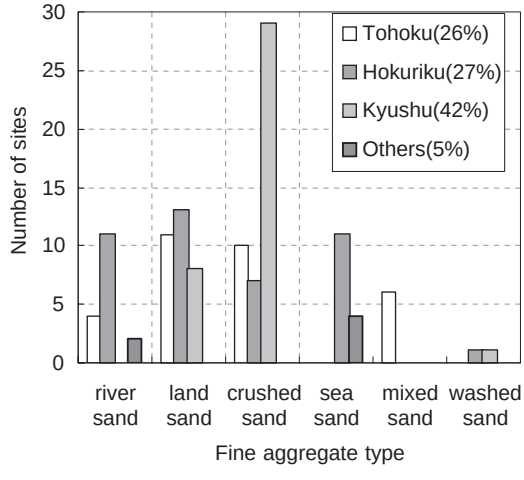

Figure 2. Regional distribution of fine aggregate type.

The regional mixing factor of HQSC is shown in Table 3. $S_{0.15}$ and β_{OH} are different according to the difference of a regional fine aggregate property, and unit weight of binder (B) and the first water cement ratio (W1/B) have varied greatly. The change in these mixing factors exerts a large influence on plastic viscosity, workability, and the mechanical properties of HQSC.

3.2 *Mechanical properties l*

Daily quality control for strength of HQSC was analyzed from the construction results of three Shinkansen tunnel group in Tohoku, Hokuriku, and Kyushu. Results of daily quality control for strength are shown in Table 4. The site data is classified by the site, and also had been calculated to average strength, standard deviation, the coefficient of variation, and design strength, according to the material age. The calculation of design strength of concrete is determined by the method of Japanese Society of Civil Engineers (JSCE), which requests the lower bound value that satisfies the dangerous rate 10% for the mean value (see equation (1)).

$$f'_{ck} = f'_{m} - 1.64 \times \sigma \quad (1)$$

where f'_{ck} = Design strength; f'_{m} = Average strength; and σ = Standard deviation.

According to Table 4, the average concrete core strength at 28day (core f′c(28)) of all sites was 27.2 N/mm^2, and this value was higher than the ordinary shotcrete. Therefore, average value of design strength calculated by JSCE method was 22.3 N/mm^2. Moreover, the coefficient of variation of core f′c(28) is 8.6%, and it corresponds to the value in the general ready mixed concrete plant. Even if the region of site and kind of fine aggregate are different, when same aggregate is used on each site and when the daily quality control in the plant is suitable, it is considered that the change is small.

4 STRESS ANALYSIS OF SINGLE-SHELL STRUCTURES USING HIGH-QUALITY SHOTCRETE

In the NATM, execution management is carried out by field monitoring, which consists of measurements taken as a routine procedure for the estimation of ground properties, and detailed and concentrated measurements taken in areas of relatively unfavorable ground conditions that are generally carried out separately from the former. The routine monitoring for estimation of ground properties combines the crown settlement measurement and horizontal relative convergence measurements taken near the springline with several other convergence measurements. These data are utilized for determining the appropriateness of the supports in the vicinity of the cutting face and auxiliary construction methods, as well as for making the decision on the timing of concrete lining. Therefore, the measurements are taken at extremely short distance intervals, regardless of the ground property conditions, and continued until the convergence subsides. Thus, authors have decided to use the field monitoring data as the basic data for investigating the applicable range of shotcrete as the permanent structure. In the first step of the investigation, the relationship between the tunnel convergence and soundness of the shotcrete was determined based on the field monitoring data. Then, a back analysis was performed to calculate the physical properties, or the applicable range, of the shotcrete and the ground properties. Furthermore, the results were used to determine the applicable range, proposed later in this paper, of the shotcrete that could withstand use as the permanent structure for a given tunnel convergence.

4.1 *Results of field measurements and soundness of the shotcrete*

The measurement data used here are those from the 21.498 km stretch for which excavation has been completed for the Iiyama Tunnel, which is the longest tunnel between Nagano and Toyama prefectures in the Hokuriku Shinkansen (bullet train) railway that should measure 22.225 km when completed. The thickness of the shotcrete is either 15 or 20 cm, with nearly the same number of data points for each. Note that the ground properties for the tunnel displays expansive characteristics, and that the data for sections with steel-fiber-reinforced shotcrete (SFRSC) or which have undergone additional shooting have not been included. Of the measurement data taken for routine field monitoring, the data for horizontal relative displacement measurement taken near the springline and the crown settle measurement are used in the investigation due to their stable data acquisition conditions and availability of data from the earliest stages in the construction.

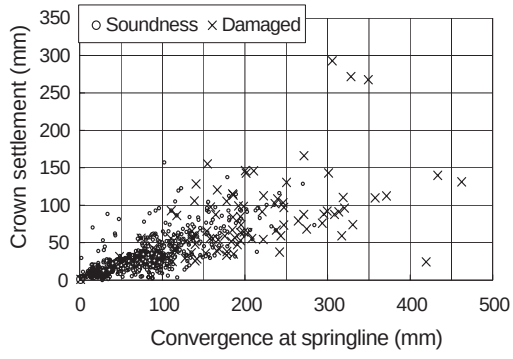

Figure 3. Relationship between horizontal relative displacement and crown settlement.

Figure 3 shows the relationship between the horizontal relative displacement and crown settlement, with symbols representing the soundness of the shotcrete evaluated from the observation records of the tunnel walls. The range of measurement includes a total of 899 data points for horizontal relative displacement up to 500 mm and crown settlement of 300 mm. The open circles in the figure denote sound concrete conditions, and crosses denote points where some form of damage to the concrete had been reported. It can be seen from the figure that damage to the shotcrete appears with increasing frequency. However, there seems to be no clear boundary between soundness and amount of damage, and a gradual loss of soundness and conversion to the damaged state occurs in the shotcrete with progressive convergence. To clarify this point, the convergence data were divided into groups and the proportions of data points with damaged shotcrete out of all data points in each group were calculated. In analyzing the data, the damaged states were categorized by cause of the damage, i.e. whether they were due to the horizontal convergence or crown settlement. Taking into consideration that the horizontal convergence is the sum of displacements of the right and left tunnel wall surface, the threshold value for the horizontal convergence can be regarded as twice that of the crown settlement.

The result of the horizontal convergence is shown in Figure 4. It can be seen from Figure 4 that nearly all data points for the group having horizontal convergence smaller than 100 mm (or crown settlement less than 50 mm) belong to the group of sound concrete condition. If the ratio of displacement between the horizontal convergence and crown settlement is taken into account, then it can be concluded that the point at which the concrete loses its soundness is consistent in both cases.

Figure 5 shows the details for horizontal convergence, which has more data points than crown

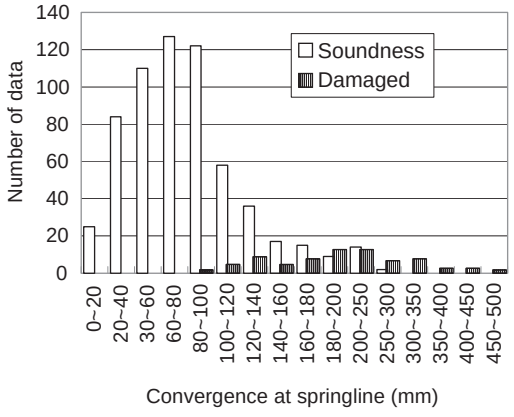

Figure 4. Relationship between displacement and soundness of shotcrete.

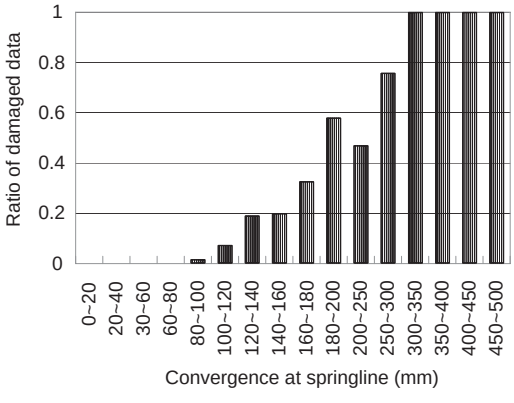

Figure 5. Relationship between convergence and ratio of damaged data.

settlement. For data points where the horizontal convergence is less than 100 mm, damage to concrete occurs in only several percent of the cases. At a convergence larger than 100 mm, there is a sharp increase in the rate of damaged concrete, and at a convergence exceeding approximately 300 mm, all of the data points fall into the damaged state. These results imply that the soundness of shotcrete may be maintained up to a horizontal convergence of 100 mm.

4.2 *Evaluation of the physical properties of shotcrete as support*

It is widely known that the physical strength of shotcrete as tunnel supporting structures must be evaluated lower than those of concrete structures at an age of 28 days. One of the reasons for this is that the occurrence of displacement is restricted to the relative vicinity of the excavation point, except in rare cases where ground properties results in strong temporal dependency in displacement.

Based on the theory of elasticity, it is generally believed that dominant displacement occurs within the 2D range (distance) from the cutting face. In the case of a tunnel for a double-track bullet train having an inner radius of about 10 meters, the 2D range is normally excavated in two to five days. Thus, the shotcrete suffers the effects of displacement during the early age of extreme weakness, resulting in decreased rigidity, including time-dependent rigidity. Also, there is the reduction in effective rigidity caused by drying shrinkage, etc., and so the rigidity of shotcrete must be estimated to be smaller than the rigidity at 28 days. Furthermore, tunnels are often excavated by dividing the cross section of the tunnel, such as in the short bench method, and phenomena such as subsidence of the entire structure caused by the subsidence of the foot and displacement resulting from the small resistance before lining closure are often experienced. There are also structural problems such as the absorption of displacement by the plasticity on the backside of the support, and so the overall rigidity of the shotcrete as a structure must be estimated to be smaller than in normal conditions.

In the present case, the rigidity of the shotcrete will be employed for the single-shell structure, so the structural rigidity was evaluated based on the relationships between concrete strength, convergence, and concrete damage. As stated in Section 3.2, the failure strength of shotcrete is about 27 MPa. On the other hand, the displacement at which shotcrete begins to suffer damage is about 100 mm in the case of horizontal convergence, as stated above. Therefore, using the values of horizontal convergence and crown settlement at which concrete damage is initiated, the modulus of elasticity for when the maximum stress acting on the shotcrete reaches the failure strength was calculated by back analysis and evaluated.

In Figure 6, the two points at which damage to the shotcrete is initiated are extracted, and the effective modulus of elasticity of the shotcrete was calculated by back analysis. The horizontal axis represents the modulus of elasticity of the ground. It can be seen from this figure that there is a tendency for the modulus of elasticity of the shotcrete to decrease with increasing rigidity of the surrounding ground, even for the same amount of convergence. However, the amount of reduction is small, and when combined with the fact that the single-shell method is applied only to regions of relatively good ground properties, it can be concluded that the effects of rigidity of the surrounding ground may be ignored and only the convergence needs to be considered. As a result, the effects of rigidity of the surrounding ground may also be ignored in assessing the soundness of the shotcrete.

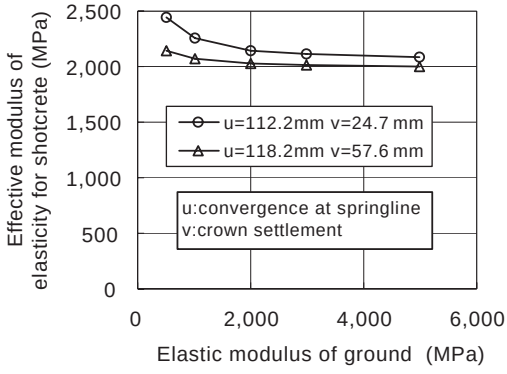

Figure 6. Effective modulus of elasticity for shotcrete.

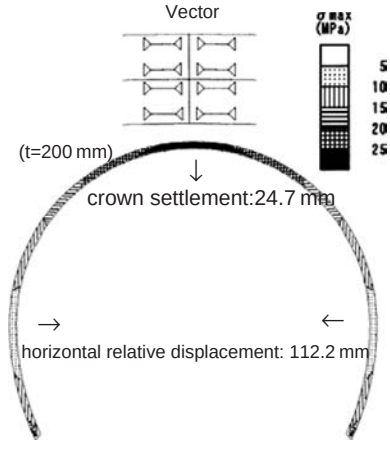

Figure 7. Results of stress analysis.

When determining the applicable range for the single-shell method based on convergence, the deformation capacities of the shotcrete must be taken into account, and so the larger effective modulus of elasticity must be chosen. When a modulus of elasticity of 500 MPa is assumed for grounds with relatively small rigidity, the effective rigidity of shotcrete should be about 2,500 MPa. For a more realistic range of application in which the ground condition is hard rock having a modulus of elasticity of 2,000 MPa, the effective modulus of elasticity of the shotcrete should be about 2,200 MPa. There is no significant difference between the two values, and the latter value is selected for the discussions that follow.

4.3 *Stress of the shotcrete and applicable range of the single-shell structure*

The single-shell structure is required to satisfy the function of the primary support that handles the conventional load placed by excavation, as well as the function of the secondary concrete lining, which is a permanent structure. Thus, it must sufficiently withstand the applied load, and at the same time, a simple management method must be developed for the safety assessment of the single-shell structure. Generally, the safety single-shell structures are assessed mainly by the horizontal relative convergence and crown settlement measurements taken during routing field monitoring practices. Thus, no additional measurements are made for the purpose and judgments are made based on the information available in conventional routine monitoring works. Needless to say, visual inspection compliments the above assessment. On the other hand, damage to shotcrete is initiated at a convergence exceeding 100 mm, as shown in Figure 5. However, damage to the entire structure does not appear until the convergence exceeds 300 mm, and between 100 and 300 mm, there is a gradual increase in the probability of damage to the concrete. Therefore, by assuming that the breaking point of concrete had been reached when the damage is initiated, calculations can be made on the safe side. Furthermore, by setting an appropriate value for allowable stress and carrying out the design based on such, it is believed that the safety factor may be secured.

The inverted part was not included in the range of the singe-shell structure, and the ends at which stress concentration occurs were excluded from the range of stress investigation. However, in the results of the present survey, these ranges are included in the inspection and judgment for damage to shotcrete. In the previous section, it has been shown that the effective modulus of elasticity, failure strength, and allowable stress for the shotcrete used in the investigation of the applicable range and convergence of single-shell structure were about 2,200 MPa, 27 MPa, and 23 MPa, respectively.

Figure 7 shows the results of stress analysis using these data. It can be seen from the figure that the single-shell structure is thin, and that the displacement in the applicable range is small. Furthermore, it can be seen that within the target range of the investigation of the single-shell structure, there exists a stable stress condition in which the axial force predominates due to the lack of excessive unsymmetrical earth pressure. However, note that that the generation of a bending moment is observed at the ends due to stress concentration.

Based on these results, the relationship to the applicable ranges of horizontal relative convergence and crown settlement for failure strength and allowable stress were determined and presented in Figure 8. It can be seen from the figure that the applicable ranges for the allowable stress for single-shell structure may be set up to 90 mm and 55 mm for horizontal relative convergence and crown settlement, respectively.

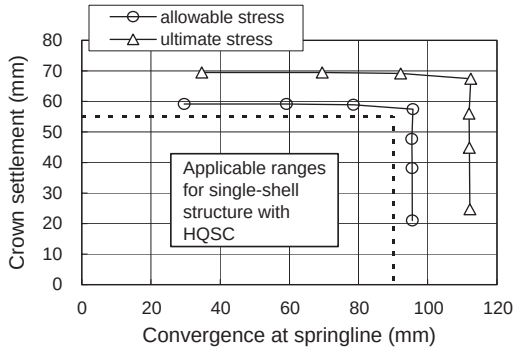

Figure 8. Applicable area to single-shell structure with HQSC.

5 CONCLUSIONS

In this study, execution management data for over 120 locations under the jurisdiction of the Japan Railway Construction, Transport, and Technology Agency were analyzed in order to clarify the effects of fine aggregates which affect the quality of the HQSC, and estimations of ground properties for which the single-shell structures made of HQSC may be applicable were estimated using measurement data for convergence and crown settlement in tunnels. The following conclusions were made in the present study.

(1) The minute particle content of the fine aggregates significantly affects the quality of the HQSC. Especially, the use of crushed sand results in low concrete strength due to the high minute particle content and low limestone powder content.

(2) The average strength of HQSC is large at 27 N/mm^2, and so the design strength may be set at 23 N/mm^2 (conventionally 18 N/mm^2). Furthermore, the variation of core strength is 8.6%, with is comparable to those produced for commercial use by ready-mixed concrete plants.

(3) Based on the analysis results of convergence in the Iiyama Tunnel, it was concluded that the soundness of shotcrete may be maintained up to a horizontal relative convergence of 100 mm.

(4) When evaluating the modulus of elasticity or stress of shotcrete based on convergence, the effect of the rigidity of the surrounding ground on the applicable range of single-shell structures, although present, are small and may be ignored in the evaluation.

(5) The effective modulus of elasticity for shotcrete calculated using the measurement data for convergence in the Iiyama Tunnel is about 2,200–2,500 MPa.

(6) Based on the results of stress analysis of single-shell structures using the above values, it may be concluded that single-shell structures may be applicable for ground conditions having horizontal relative convergence below 90 mm and crown settlement below 55 mm.

Applications of a shotcrete robot for creating an immediate comparability of mix designs

M. Thewes & G. Vollmann
Institute for tunneling, pipeline construction and construction management, Bochum, Germany

ABSTRACT: Shotcrete tests under edge conditions that are repeatable at any time can provide important and unique decision criteria for specific fields of application of shotcrete as a securing mean. Nowadays the emphasis of interest is lying more and more on particular questions of the consistency and adherence of mixture and the possibility of reaching a certain strength level depending on the mix-design. It happens more frequently that for example certain cements or supplements are allowed by a client, whose usabilities for shotcrete have not always been assured completely. Nowadays spray experiments are conducted on site which are restricted to the common spray boxes. Samples gained by this method are only feasible to a limited extent. This paper illustrates how experiments with little deviation among the measurement results can be achieved in comparison to current construction site testing methods. For the purpose of comparison the most important parameters are contrasted and classified with respect to their reproducibility. Therewith the test results are valued in reference to their significance as empiric measurement. Concluding a prospect on the necessary progresses of shotcrete technology is provided and a possible spectrum of application of a set-up under laboratory conditions is developed.

1 INTRODUCTION

Shotcrete is an indispensable building-material for the production of temporary supports for conventional tunnelling methods. The shotcrete-method facilitates according to the concept of flexible rock support the development of a natural structural arch while simultaneously protecting the workers in the tunnel. Therefore, the early achievement of a specific strength of the shotcrete is of particular importance.

The desired strength of concrete can bee guaranteed by standard concrete parameter testing. Test procedures which offer a fast availability of the early strength results while being highly reliable are, however, necessary for tunnel constructions and their specific boundary conditions. Therefore different test procedure were developed in the past, as provided by the Austrian shotcrete guideline (Austrian Society for Concrete- and Construction Technology, 2004) or the preEN 14488-2 (penetration needle method, bolt firing method).

A thorough and reliable comparison of different mix-designs for shotcrete prior a construction project can be problematic, as for example for the finding of mixture with the most favourable strength features or the lowest rebound. Often so-called shotcrete boxes are used for the production of testsamples on the construction site. It can, however, not be made sure that every shotcrete test production is produced under equal conditions. The comparability of shotcrete samples may therefore not be given. Differences in nozzle guidance during the shotcreting for the test samples, differences of the air quantity during spraying or also changing humidities of the concrete aggregates are only a few of the production parameters of the shotcrete which have direct influence on its quality and therefore on strength development and rebound.

In the decision making process for a shotcrete mix it is a considerable advantage if the suitability of particular mix can be tested in examinations which are independent and which are executed under controlled, identical laboratory conditions. For this a special experimental setup is required which guarantees on the one hand the reproducibility of the essential boundary conditions and on the other hand provides for an exact data acquisition of all parameters with significant influence on the shotcrete quality. These requirements are for example fulfilled by the experimental shotcrete test rig at the Institute for Tunnelling, Pipeline Technology and Construction Management at the Ruhr-University Bochum.

In the following the general influences on the quality of the shotcrete are initially discussed and the precision of shotcrete tests performed onsite are discussed. As an alternative the set-up of the laboratory shotcrete testing equipment is described and its possibilities outlined exemplarily. In conclusion, an executed performance test for various competing

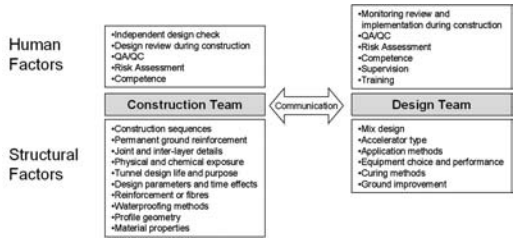

Figure 1. Influences on quality and sustainability of sprayed concrete structures (Melbye & Dimmock).

shotcrete mixes to be used at a large tunnel project is described and further possible options for testing are highlighted.

2 SIGNIFICANCE OF BOUNDARY CONDITIONS FOR THE RESULTS OF SHOTCRETE TESTS

2.1 *Initial situation*

Contemporary requirements on constructions made of shotcrete are focussing on its quality and its durability, as for example provided by the EFNARC-Guidelines (EFNARC, 1999). These attributes are determined in their development by all sorts of influencing factors, which can be divided in human factors and structural factors. These factors further have to be differentiated regarding the two areas of "design" and "construction". *Melbye* and *Dimmock* (Melbye & Dimmock) illustrated this effect in the following image:

Assuming that the choice of a suitable construction method and the accompanying constructive concept has been made according to the state-of-the-art, the influence on quality and durability of the shotcrete caused by application method, the mix-design and primarily also the type of the accelerator becomes recognizable. If furthermore one assumes that the processing of the shotcrete during the construction phase also meets demands of the quality assurance, the choice of an optimized shotcrete mix is finally a question of profitability but primarily of the safety on the construction site.

Therefore a mix-design must be found with an optimized performance regarding the desired strength level and under consideration of minimal possible production costs. Even small differences between different mix-designs, e.g. the development of strength or the rebound, can already show a clear influence on the cost of shotcrete on the construction site depending on the dimensions of the tunnel project and the according quantities of shotcrete being processed. For this reason performance comparisons of mix designs in the preparation phase of a tunnel project can provide an important contribution to the cost reduction related

Figure 2. Creting of a shotcrete box.

to the overall project. A mandatory requirement for a comparative performance test is that the test results are obtained in a test environment under comparable and reproducible boundary conditions.

2.2 *Significance of comparative performance tests under construction site conditions*

Often, performance comparisons of different shotcrete mixes are executed with shotcrete boxes on the construction site. These shotcrete boxes are sprayed manually and serve subsequently as specimen for quality and strength tests (Fig. 2).

It is obvious that such a setup for shotcrete tests results in a fairly high variance of the examined parameters. Different control of the nozzle movements, varying distances of the nozzle to the shotcrete box, changing weather conditions or also fluctuations in the air supply of the shotcreting machine are providing fluctuating conditions which cause scattering of the test results. Furthermore, the geometry of the shotcrete boxes hinders the achievement of a solid shotcrete structure, similar to the quality achieved at the tunnel face. This is due to the fact that rebound partly is included within the shotcrete sample in the area of the side walls of the shotcrete box.

The scattering of the test results and the low reliability and reproducibility of such comparative examinations with shotcrete boxes can also be statistically measured (Fig. 3).

Assumed (3A) that a certain test parameter (e.g. the rebound of a dry spraying method) has a value of 30% at a coefficient of variance of 25%. If, as shown in (3B), a reduction of the rebound to 20% were achieved by using a mixture with a variance of 5%, it is obvious to (3C) that this does not represent any confirmed statement. The apparent obtained improvement still lies within the normal variation range of both parameters. A reduction of the scattering, as for example in (II) on 8%, provides reliable results.

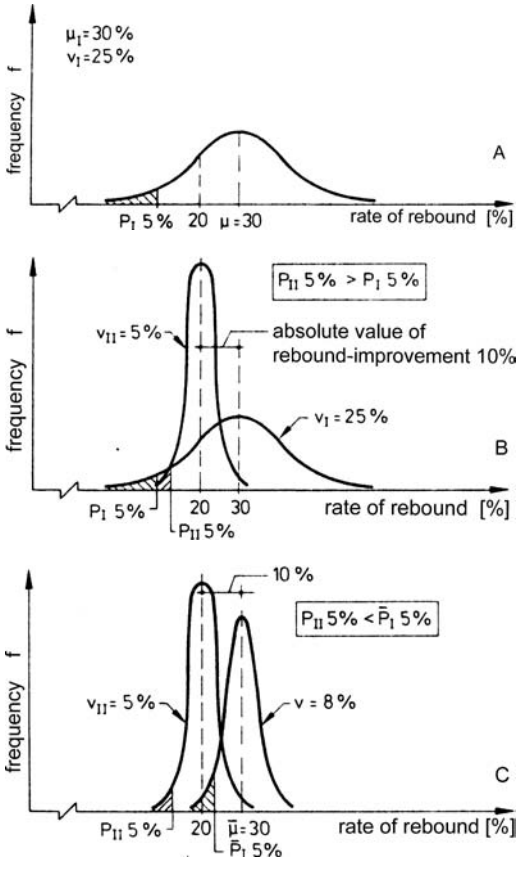

Figure 3. Significance of single results derived from examinations with high variance.

2.3 *Conclusion*

The considerations presented above show that the choice of the mix-design for shotcrete constructions can have an significant influence on profitability and efficiency. However, this circumstance often is not being considered appropriately. When making a choice a suitable design of shotcrete mix test results with highly scattering results are consulted. This can be improved considerably by performing laboratory shotcrete tests under reproducible boundary conditions to provide more reliable test results and to close existing knowledge gaps.

Accordingly, key parameters can be listed which for reliable test results of a performance comparisons are to be kept constant or at least at the lowest possible fluctuation. These important parameters are in particular:

- a quality-assured application method for the shotcrete
- air-flow rate with the necessary quantity

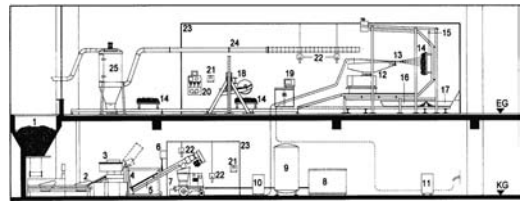

Figure 4. Configuration of the experimental shotcrete equipment.

- the composition of the mixture
- the flow rate of the mixture
- the quantity of the accelerator
- the quantity of water added with the dry spraying method

3 THE SHOTCRETE LABORATORY EQUIPMENT AT THE INSTITUTE FOR TUNNELING, PIPELINE TECHNOLOGY AND CONSTRUCTION MANAGEMENT

3.1 *History and configuration of the experimental equipment*

The experimental shotcrete equipment at the Institute for Tunnelling, Pipeline Technology and Construction Management is part of the experimental facilities of the faculty of civil engineering at the Ruhr-University Bochum. Figure 4 provides an overview of the test rig.

Central unit of the test rig is a modified industrial roboter (12) with which defined and controlled motions of the nozzle (13) can be carried out. The batch mix sprayed with this unit is produced exactly according to a defined recipe in the mixing unit (1–5). The mix is transported with a shotcrete pump (7) to the mixing nozzle. In this section air and the accelerator is added to the mixture and the shotcrete is sprayed on a prepared surface. This way large-sized samples are produced at a minimum of disturbing influences. A test specimen is produced with realistic nozzle motions. As a consequence such test bodies provide better and more reliable results since the boundary conditions of the test are controlled close by. Also, a typical and realistic structure development of the shotcrete sample is realized.

With this test rig numerous important findings for for shotcrete research were reached in the past, for example in the field of dust development (Handke, 1987), in the field of nozzle geometries and nozzle guidance (Gutthoff 1991) or in general process engineering for shotcrete (Halhege 1985).

3.2 *Realisation of an experiment*

During a shotcrete test all significant data for the description of the shotcrete parameters are recorded and the properties of the fresh-mixed concrete are

documented. The weights of the complete mixture before the test of the spraying test specimen and of the rebound are recorded. Thus the quantity of the rebound can exactly be monitored. Furthermore, the consumed amount of accelerator, the air-flow used and the stream of air are measured and evaluated in the mixing nozzle. By exact control of these parameters the creation of constant boundary conditions for shotcrete-tests can be realized. Single selected parameters of the mix-design, such as cement, aggregates or particular admixtures, can be varied while all other parameters remain unchanged.

Moreover, to be able to guarantee least possible deviations of the parameters, which remain unchanged, and to compare the achieved results, it is required that the tests are performed in a defined order with defined time-steps. The individual production steps of a shotcrete test are divided as follows:

(1) Production of the concrete mix
(2) Testing of the properties of the fresh concrete
(3) Starting of the test rig
(4) Beginning of the experiment: Spraying aided by the robotic arm
(5) Completion of spraying and beginning of early strength testing
(6) Cleaning of the test rig and retrieving of the sprayed specimen
(7) Drilling of sample cores and performing of strength and integrity testing

The sprayed samples are treated for curing in the following of the experiment (between step (6) and (7)), to be able to guarantee an optimal hydration-process. For this purpose the samples are kept in a humid environment and stored at a temperature of about 20 degrees Celsius before they are brought to further processing, e.g. the drilling of cores for compressive strength examinations.

3.3 *Conclusion*

The described experimental shotcrete equipment delivers the reproducible boundary conditions demanded in chapter 2, so that protected and reliable statements can be made with regard to single parameters of a mix-design and their influence on the construction process. In the following chapter this is demonstrated with results from a real series of experiments.

4 SELECTION OF AN OPTIMIZED MIX-DESIGN BY COMPARATIVE TESTING

4.1 *General*

For a tunnel project described in the following a temporary lining had to be created by shotcrete, using the wet spraying method. Moreover, the client required the use of a mix-design with certain features, documented in table 1. The use of a cement type required by the client with a comparatively slow hydration rate, which is unfavourable for the production of shotcrete, proved to be problematic.

Table 1. Required features of the mixdesigns.

Task	Target	Test Method
w/c-ratio	$\leq$0,50	Mix design/drying
Workability		
– consistency	Good Slumplife (200 to 220)	Slump-test
– open time	Open time up to 12 h	Penetration
Pumpability	Good pumpability	Mix design -> visual inspection
Cohesion	Good cohesion	Mix design -> visual inspection
Additives	Chemical risk assessment	Approval
Shotcrete rebound	Reduce to minimum	Spraying-tests
Early-Age strength	J2 area (EN 14487-2)	prEN 14488-2
Compressive strength (28d)	C 25/30	EN 12504-1

For the realisation of the lining one of three possible shotcrete mixes had to be applied in a comparative test, in which the focus of attention laid on initial strength and rebound development. Comparative tests were issued for the determination of the respective performance. The fresh concrete properties as well as the development of the compressive strength after 7 days and after 28 days were also to be tested.

The three mixes were developed by the use of different accelerators and different grain fraction distributions. They are called mix A, B and C in the following. Their exact compositions were provided by the manufacturer of the various accelerators under the requirements to use the aggregates which are available on the construction site.

4.2 *Test procedure and evaluation*

4.2.1 *Production of the specimen*

Using the test scheme described in chapter 3, one large-sized specimen was produced with every mix and examined with regard to the mentioned properties of the shotcrete. Figure 5 shows one specimen, out of which several core $d = 100$ mm have already been taken.

The required fresh concrete parameters were obtained by all mixes. All mixes A, B and C were characterized by a good pumpability and by an optical impression of low rebound. This impression was

Figure 5. Example for a shotcrete specimen.

Table 2. Rebound according to different mixdesigns.

Mixdesign	Ø Rebound [%]
A	4,8
B	3,7
C	3,8

verified by analysing the test-data. Table 2 shows the rebound-development:

4.2.2 *Early strength testing*

The following diagram shows the early strengths found out in the comparison.

The test results show, that none of the mixes delivers a young shotcrete which is conform with the strength standard J2 according prEN 14488-2. The shotcrete made with mix B seems to be the most favourable since it delivers the highest early strengths directly after spraying the shotcrete, which will also make over head spraying possible. Mix C achieves the desired strengths after 6 hours, shows however very low strength in the first minutes after spraying. In view of the scheduled application, which also requires overhead spraying, such a low early strength development was judged to be unsuitable.

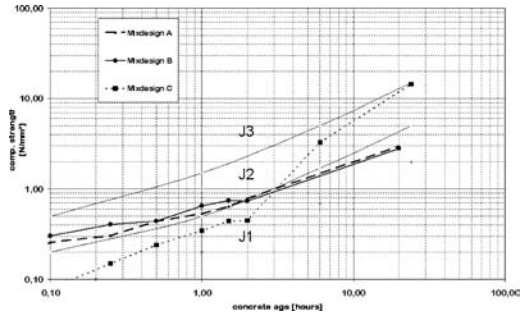

Figure 6. Results of the early strength testing.

4.2.3 *Evaluation*

The available results show that none of the three suggested mixes delivered a shotcrete which entirely meets the requirements. Although the demanded fresh concrete parameters and the long-term strength development were achieved by all mixes (all specimen fulfilled the strength tests after 7 or 14 days with results above the values demanded in Table 4.1), none of the mixes achieved the demanded early strength of the shotcrete. According to the applied standards prEN 14488-2 the shotcrete should develop a strength within the first 24 hours according to J2. This level is obtained by the mixes A and B within the first three hours, both shotcretes, however, fall back to the strength area of J1 after this. Mixture C achieves the demanded strength in the J2 area for the time-span from 4-24 hours, but remains below the necessary strength within the first four hours.

Due to the fact that one of the three mixes was definitely to be used for the construction lots to be driven in shotcrete, mix B was recommended to use. The shotcrete created with this mix delivered the highest strength directly after spraying and thereby made overhead spraying possible. Moreover, mix B reached the highest strength after 7 and 28 days and, compared to the other mixes, it produced the lowest rebound. Furthermore the use of formula B supplied a fresh concrete with very good, long-termed processing features and a high degree of flowability.

4.3 *Possible secondary examinations*

By using shotcrete mix B, a successful implementation of the temporary lining works was executed on the construction site. The optimization potential of the shotcrete was, however, still not exhausted. Secondary examinations could have realized an optimized fine-tuning of the mixture, a reduced addition of accelerator or further optimization of the rebound for example. To achieve this goal it would be possible to vary single parameters, such as the cement content or the amount of plasticizer, to achieve test results with a low variance in a series of low-cost tests.

5 CONCLUSION AND PERSPECTIVE

The details of this article have shown, that modern constructions made of shotcrete are subject to a high degree of requirements regarding durability and quality. In the future, this might become, by further establishing final shotcrete linings, even more common. An optimization of the performance of shotcrete is important to the profitability of the construction site, for the structural concept in general, but also (in case of final shotcrete linings) for the maintenance efforts during operation.

To optimize the performance of a shotcrete mix, examinations are required which provide reliable and reproducible results. To realize such results at a construction site is a complex effort with many sources of errors. Controlled variations of single parameters often are not possible. For this reason facilities like the described shotcrete testing rig can provide an important input for the application of shotcrete with improved performance and quality contributing to the technical and economical success of tunnelling projects.

ABSTRACT: The process of adding accelerators to sprayed concrete of the primary lining applied by Metrostav during the course of the Vítkov tunnels excavation has been monitored in a systematic manner. In addition to the customary check testing carried out to verify whether the set/hardness build-up curves prescribed are maintained, also other relevant quantities were monitored and recorded, e.g. the concrete mixture temperature, ambient temperature, consistency of the mixture and dosage of additives. Also the concrete application by the nozzle operator was monitored, with a view to the correctness of the procedure. The results are currently being assessed and should be used not only as a basis for the development of modified sprayed concrete formulas to be applied in the conditions of production in a certified concrete mixing plant but also for the determination of the minimum theoretical and practical requirements for qualification testing of nozzle operators.

1 INTRODUCTION

Sprayed concrete primary support should be a slender system deforming in a controllable manner, which, owing mainly to experience empirically obtained in the particular rock environment and a properly designed shape and manner of anchoring into the rock massif, properly interacts with the rock massif, forming a higher-level load-bearing system consisting of the primary support itself and the surrounding rock ring. The "skill" of the manager, a tunneller, is therefore based primarily on knowledge of local geotechnical and hydrological conditions, combined with sensitive assessment of whether the deformations of the lining, which depend above all on the dimensions of the tunnel cross section and the excavation technique, will reach the values specified by the design as limits or other possible values. Limiting deformations are determined primarily according to the degree of their transformation to the ground surface with respect to the density and character of surface buildings. The deformations may even significantly affect underground structures, both existing or under construction. Recorded values of deformations measured on the internal surface of the primary lining characterise the presence of earth pressures or hydrostatic pressures. Primary deformations at the lining-rock interface are followed by favourable equalisation of the state of stress along the circumference of the opening. They should, however, approach zero, usually within 72 hours of the first measurement. In the opposite case it is necessary to implement measures leading to reinforcement of the support system. Zero deformations measured on the internal surface of the lining imply high load bearing capacity of the lining-rock system. To follow the economic aspect of excavation, the support should be modified to correspond to a less demanding excavation class, i.e. application of primary support with lower supporting power or even with smaller number of elements providing the interaction with the surrounding rock mass. The "reasonable" degree of the convergences of primary lining should be exhausted as a proof that the performance of the operations is economic. Because of the variability of geological and hydrological conditions, the determined applicable measures and their sequence during the excavation are not intended to apply "forever". However, the scope of proposed measures may be limited due to the inexperience of the parties involved in the construction in tunnelling in the particular geological conditions. The fact remains that, in the Czech Republic, a primary support system is considered to be a temporary element in terms of structural analyses, and its load bearing capacity is not at all taken into consideration once the final lining has

been completed. This opinion is incorrect and the function of primary support will have to be re-evaluated, mainly where hydrological or other conditions do not cause rapid degradation of the primary support. Our dilemma remains: to build a primary support system as cheaply as possible, but never with savings which would lead in a worst-case scenario, to a collapse of the underground excavation, which would result into increased cost of the works and threatened safety of crews, other structures or the public.

The construction of the New Connection tunnels under Vítkov Hill in Prague was selected as a suitable site where some new information about the dominant element of primary lining structures, sprayed concrete, should be obtained. This information had not been sought in the Czech Republic till that time.

2 BASIC DATA ON THE CONSTRUCTION

2.1 *The New connection*

The New Connection project will interconnect railway stations Praha – Hlavní Nádraží and Praha – Masarykovo Nádraží with stations in the Libeň, Vysočany and Holešovice districts, thus the overall reconstruction of the Prague railway junction will be completed. The user, České dráhy, s.o., hired Nové Spojení Praha, a group of companies consisting of Skanska, a.s., Metrostav a.s. and Subterra, a.s., as the contractor. The works started in 2004 and the completion is planned for 2008.

The design of the alignment of the new railway line across the Žižkov and Karlín districts contains two tunnels under Vítkov Hill. This variant of the railway traffic passage through the given terrain configuration proved to be the most suitable with respect to the noise protection of both urban districts.

2.2 *Dimensions of the New Connection tunnel tubes*

Apart from new railway routes, grade-separated intersections and diversions, the extensive railway construction project New Connection comprises construction lots 801.1 "The Southern Tunnel of the New Connection" (the southern tunnel tube – STT) and construction lot No. 800.1 "The Northern Tunnel of the New Connection" (the northern tunnel tube – NTT), which will, when complete, consist not only of mined sections, but also of shorter cut-and-cover sections. The tunnels run along the longitudinal axis of Vítkov Hill. The horizontal alignments are partially straight, with adjacent curves with diameters of 602 m and 648 m for the southern tube and 902 m and 3602 m for the northern tube. The vertical alignments of the tunnels descend from the east towards the west at a minimum gradient of 0.33%. The mined tunnels, together with 4 cross passages and 6 overhead line tensioning chambers represent an excavated space volume of 244 800 m^3; the volume of the wall-in space of the cut-and-cover sections amounts to 26 750 m^3. The most important data regarding the lengths and cross sectional areas of the mined tunnels of the New Connection is shown in Table 1.

2.3 *Geological conditions*

The excavation of the Southern Tunnel of the New Connection project encountered the Šárka Member and Dobrotiva Member rock types. The Šárka Member strata were assessed from the geological viewpoint at the very beginning, during the excavation of construction pits for portals and portal sections of the tunnels. This type of rock developed in the area in so-called "monotonous" sedimentation processes, resulting in facies of black-grey, clayey to sandy bituminous shales to siltstones. These rock types are relatively firm and compact, with platy to heavy-bedded jointing; the rock disintegration requires blasting operations. Further from the portals, the Šárka Member strata were replaced with the Dobrotiva Member, which is characterised by alteration of two lithofacies – the Skalec Quartzite facies and the Dobrotiv Shale facies. The Skalec Quartzite forming the Žižkov massif is characterised by alteration of plates or thick beds of whitish, ochre- or red- tinted siliceous sandstone. The quartzites are medium jointed, locally tectonically disturbed. Discontinuities are tight, coarse, mostly limonitised and hematitised. The shales are quartziferous, grey to grey-black, locally tinted by limonite and hematite. They mostly exhibit platy jointing. The excavation passed through a relatively dry environment. The inflows encountered by the

excavation were only local, weak, in the order not exceeding 0.01 l/s.

2.4 *Excavation technique*

The two tunnel tubes were driven using the New Austrian Tunnelling Method (NATM), with the exception of portal sections, where a horizontal excavation sequence was adopted. The specification of the excavation support for the anticipated geotechnical conditions was determined by application of excavation classes 3, 4a, 4b and 5. The classes defined in more detail the division of the cross section, number of partial advances and their length, the height of the top heading, bench and bottom or invert, thickness of primary lining, spacing of lattice girders, length of rock bolts and method of the supporting the face. Excepting short sections at both portals, the entire length of the tunnels was driven by drill and blast. Standard survey, geological, deformational and other check measurements covered by the general term of "monitoring" were inseparable part of the operations.

Driving the tunnel under the National Monument building and the equestrian statue of Jan Žižka of Trocnov on Vítkov Hill was a unique operation. The overburden height reached nearly 40 m in this location. The seismic measurement design, which was carried out for this section, set out limits for the charges to be used. The aggregate surface settlement value, which was assessed in advance of the work, was determined at 12 mm. This value was exceeded during the excavation of the second tunnel in the location of the monument, therefore eight 108/16 mm grouted micropiles, with the lengths between 12 and 15 metres, had to be installed under peripheral footings of the building.

2.5 *The lining of the New Connection tunnels*

The design of the tunnel lining consists of traditional two shells. The structure of the primary lining of each mined double-rail tunnel is traditional, consisting sprayed concrete reinforced at both surfaces with welded mesh. Lattice girders and friction rock bolts expanded by pressurised water were added to the lining (plus steel needles along the circumference of the top heading in the sections threatened by instability). The thickness of the primary lining varied within a range of 30–20 cm, depending on the determined excavation class.

The final lining design comprises both reinforced and unreinforced cast-in-situ concrete sections. The lining will be cast using a 12.5 m long travelling form set (a half of the spacing of safety recesses). An intermediate waterproofing membrane is installed between the primary and secondary lining. The final lining is designed at a 35 cm thickness.

3 OBSERVATION AND TESTS

3.1 *Observed items*

The construction of the primary lining is one of the most demanding operations of the tunnel driving cycle. The success of the tunnelling method in the particular geotechnical conditions depends on whether the lining is built in due time and good quality, and the dimensions are designed adequately. The design prescribed the sprayed concrete to be of the SC25 (C20/25/II/J_2/8 mm) grade, with the layers 200 mm, 250 mm or 300 mm thick, depending on the excavation class. The design concrete mix formula had to satisfy the required parameters and the early strength development in concrete had to conform to the J_2 curve. Shotcrete was placed using the wet process, with a manipulator coupled with a Meyco-Potenza piston pump. Other observation items and procedures were selected for the southern tunnel of the New Connection project to be added to the set of preconstruction and checking tests; they were intended to help to improve the work process or to achieve the required final quality of the shotcrete primary lining.

To summarise, the following main observation items were introduced:

1. Regular checking on consistency and temperature of the concrete mix supplied to the site
2. Concrete setting and the early strength development to be within J_2 range within 24 hours of application
3. Standard testing of strength at 28 days
4. Measurement of ambient air temperature at the working place during application
5. Temperature measurement during the tests
6. Measurement of consumption and dosage of the accelerator additive relative to the set output of the machine
7. Regular inspection of the manner and procedure of application of shotcrete, including the personnel training.

3.2 *Selected results of the shotcrete testing*

The consistency of the mixture supplied for the construction of the primary lining was prescribed by means of slump values to vary between 180 and 240 mm. These values were the primary criterion for production of the mixture in the certified batching plant. The temperature of the mixture and air and properties of aggregates affected the dosing rates of the SikaViscoCrete 305 superplasticising additive, which was used also for regulation of the application life on site. It was possible to extend the application life even to 4 hours from the moment of mixing. The usual dosage of the superplasticising additive was about 1% of the weight of the binder contained in the concrete mixture. The influence of the consistency of the

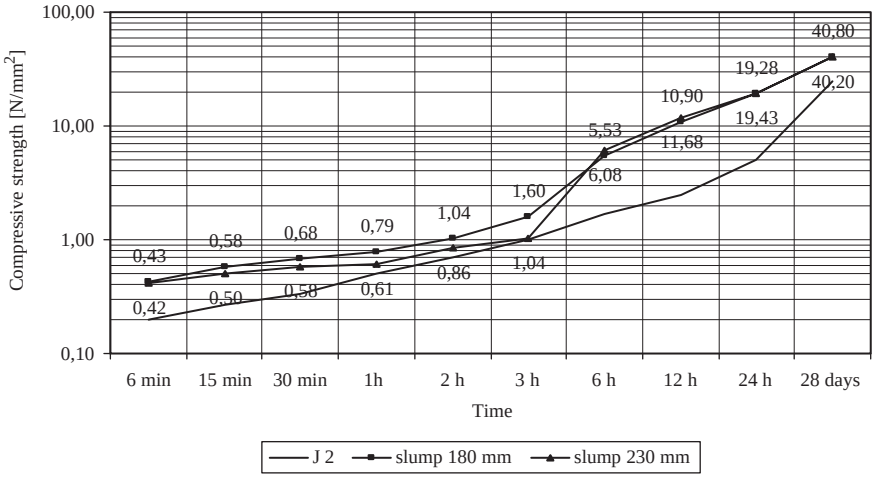

Chart 1. The influence of differing concrete consistency on the development of compressive strengths at the accelerator dosage of 6% (31.8.2005).

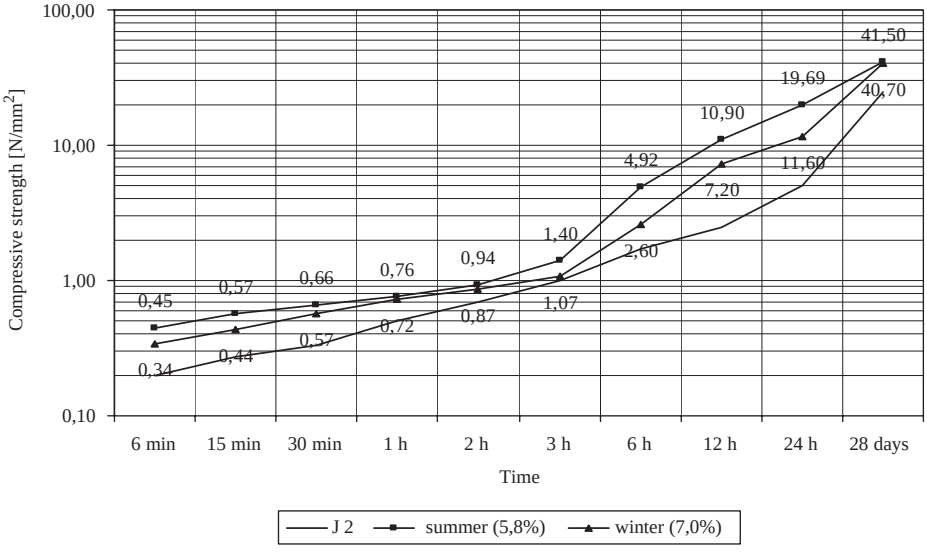

Chart 2. The differences between the time-strength curves in the “summer period” (May – September; accelerator dosage 5,8 %) and “winter period” (November – February; accelerator dosage 7,0 %).

supplied concrete on the development of setting is obvious from the Chart 1 above.

The rate of setting and early strength development in concrete was regularly monitored for the entire time of the STT excavation, once in a month being the minimum frequency. At the ambient temperatures distinguished for the summer period (from May to September) and winter season (from November to February), the most significant difference was observed 3 to 24 hours after the application. The time-setting curves for the summer and winter could get closer to each other when the average dosage of the accelerator additive was increased to 7% in the winter period compared to the summer period value of 5.8%. The average temperatures of concrete mix supplied to the site were 17°C and 26°C in the winter and summer periods, respectively. The strengths of the samples at 28 days were virtually identical. The differences between the time-strength curves are obvious from the Chart 2.

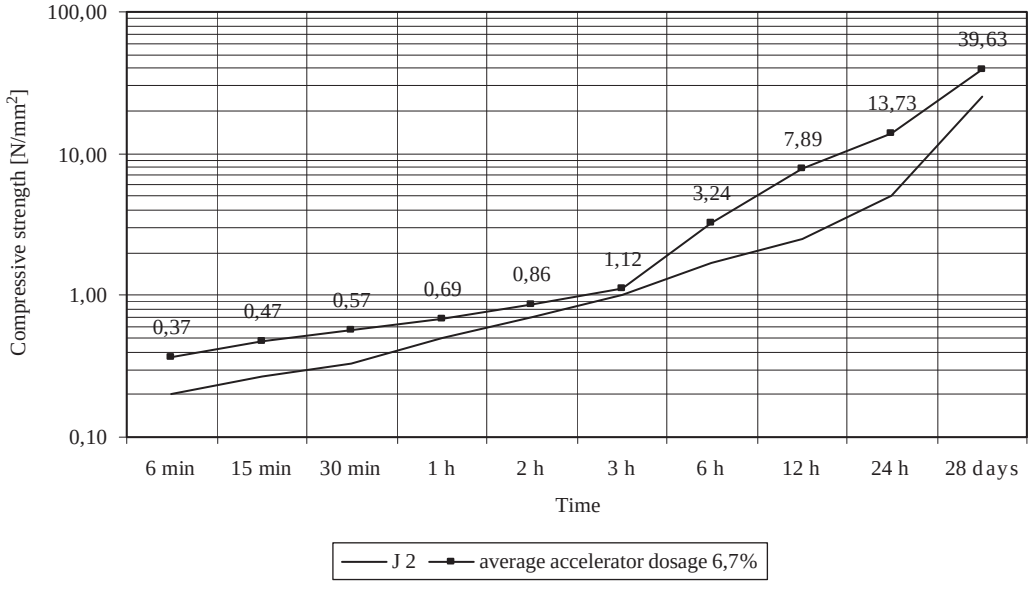

Chart 3. Average values of the time-strength curves for sprayed concrete measured from May 2005 to May 2006.

The Chart 3 shows the average values of the time-strength curve for the primary lining shotcrete during the entire time of the STT construction. The amount of 430 kg of Portland cement per 1 m^3 of the concrete mixture, together with the accelerator additive, guaranteed that the time-setting curves remained within the J_2 range for the entire construction time. The experience was gained that the amount of cement had to be maintained mainly so that the above-mentioned time-setting curve was achieved, despite the fact that the final strength of the sprayed concrete at 28 days substantially exceeds the strength of the required SC 25 concrete grade.

The dosage of the Sigunit L-53AF accelerator additive was observed simultaneously with the measurements of concrete and ambient air temperature at the excavation face. When the several results significantly differing owing to the influence of the human factor during the processing are left out, the relationship between the consumption of the accelerator additive and temperature is obvious from the Charts 4 and 5. The reaction of the accelerator with the concrete applied to the substrate manifested itself after six minutes through temperature of the sprayed concrete increasing in the range of 1°C to 4°C. The temperature after 15 minutes was even higher, approximately by 1°C, then the temperature started to gradually decrease and stopped at the value of the ambient temperature, approximately 24 hours after the application.

Another part of the observation was the assessment and improvement of the manner of spraying concrete by individual nozzle operators. In addition

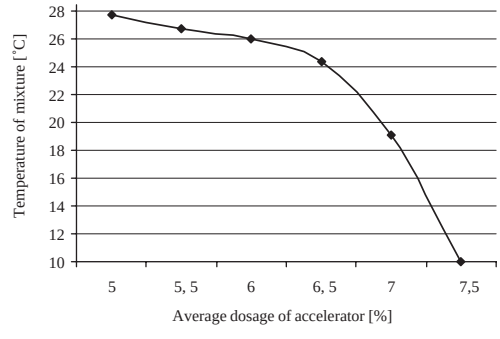

Chart 4. The relationship between the dosage of accelerator and the concrete temperature.

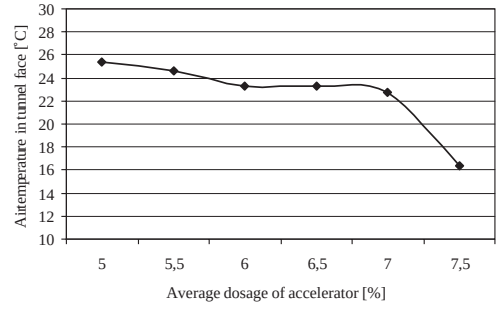

Chart 5. The relationship between the dosage of accelerator and the ambient air temperature at the excavation face.

to the standard rules for an optimum spray application, the theoretical and practical training taught the workers about mistakes made during the last passes of the nozzle. The application rules were delivered in the form of presentations.

4 CONCLUSIONS

There were many measurements carried out during the construction of the Vítkov tunnels of the New Connection project, which exceeded the previous standard scope of checking tests. Apart from consistently observed temperatures of the ambient air and the concrete mixture, even the performance parameters of the Meyco-Potenza pump were recorded, including the rates of dozing and consumption of the accelerator additive. However, to achieve satisfactory results of application of the primary lining shotcrete, it was necessary to continuously work on improving practical working habits of the nozzle operators and broadening their knowledge in terms of both operation of the equipment set and properties of concrete mixtures used. To maintain the quality of sprayed concrete, the process of increasing the level of competence of nozzle operators and the entire crew must be a permanent task.

Concrete and shotcrete with crushed aggregates: experience from the AlpTransit construction site Mitholz

R. Weiss
VSH – Hagerbach Test Gallery Ltd., Sargans, Switzerland

ABSTRACT: For reasons of ecology and economy, efforts are made at large tunnel construction projects to optimally recycle excavated material.

Tunnelling specialists at the construction site Mitholz of the Lötschberg Base Tunnel utilized over 800,000 m^3 of concrete produced with aggregates processed from tunnel excavation material. The use of broken aggregates from excavated material affected the concrete production process in several ways.

The experience gained from the construction site Mitholz proved that high-quality concrete can be produced from aggregates processed from tunnel excavation material. Additional constraints do result, however, that demand that all affected parties are very willing to cooperate.

The experience from construction site Mitholz serves as a valuable basis upon which future structures can be designed in accordance with the latest standards, especially those such as the performance-based design process of SN EN 206–1.

1 INTRODUCTION

Both of the large transalpine railway links in Switzerland, the Gotthard and Lötschberg Base Tunnels, are currently under construction. Both lines will be part of the European high-speed rail network.

The official opening of the 34.6 km long Lötschberg Base Tunnel on June 16, 2007 will complete the first construction phase consisting of two one-way single-track railway tubes.

The northern section of the base tunnel (construction site Mitholz) was constructed between 2000 and 2006 starting from the intermediate point of attack Mitholz, which was reached through an access gallery. The tunnel was driven both to the north and to the south. The construction site Mitholz included the excavation of 23.5 km of single-track tunnel with cross sections of 61 to 64 m^2 and 1.6 km of connecting galleries. Tunnelling was conducted from preliminarily constructed caverns that were accessible through the 1.5 km long 12% sloped access gallery. The entire excavation volume equaled 1.8 million m^3. Tunnelling work was conducted by the construction consortium ARGE Satco, consisting of the contractors Strabag, Rothpletz, Lienhard + CIE AG, Walo Bertschinger AG, VINCI GP and Skanska International Civ. Eng. AG, using drill and blast together with shotcrete support, system rock bolting, waterproofing and an inner lining in the equipped "east tunnel".

The concrete and shotcrete needed for the structure was produced by Mobilbaustoffe AG on site. In total, the ARGE Satco handled 800,000 m^3 of concrete and shotcrete.

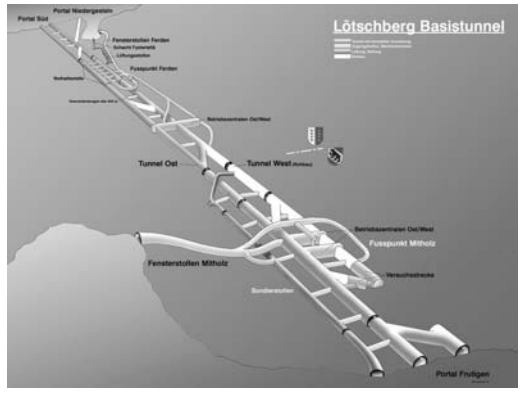

Figure 1. Project layout (Source: BLS AlpTransit AG).

2 CONCRETE SPECIFICATIONS

The concrete type and specifications were defined by the project engineering team. The most common types are presented in Table 1.

Die ARGE Satco defined additional requirements related to fulfilling the client's requirements:

- Production (delivery performance, safety of supply and availability)

Table 1. Specifications included in tender documents.

Utilization	Shotcrete lining	Invert concrete	Concrete lining
Name	Class C/D, SIA 198, wet-mix shotcrete	B 35/25 SIA 162	B 35/25 SIA 162
Compressive strength	B 35/25	B 35/25	B 35/25
Early strength		12 h ≥ 10 N/mm^2	12 h ≥ 10 N/mm^2
Water penetration	<50 mm	<50 mm	<50 mm
Sulfate resistance	if >250 mg/l	if >250 mg/l	
Freeze-thaw resistance	to 2000 m below ground	to 2000 m below ground	to 2000 m below ground

- Workability (oven time to 3 h, pumpability of max. 100 bar pump pressure, low risk of variability)
- Early compression strength, formwork removal resistance (work and tact)
- Total costs

In addition to the requirements of the tender documents, additional constraints which in some cases decisively affected the concrete mix, production, working and quality were establish.

The most important include:

- Procedures regarding AAR-resistance when utilizing AAR-reactive aggregates
- Effects upon supply safety of aggregates (material processing)
- Variations of the aggregate in connection with the processing of the excavated material

3 CONCRETE PRODUCTION AND QUALITY CONTROL

Concrete production for the construction site Mitholz was carried out by the firm Mobilbaustoffe AG. The custom-built concrete production plant was located underground in a cavern of the intermediate point of attack Mitholz. A plant with a twin shaft mixer from SIMEN (batch size 2.25 m^3) with maximum hourly performance of 80 m^3 was installed for the production of concrete and shotcrete. Three cement silos were available per mixer each with a capacity of 100 tons and 14 silos for aggregates each with a volume of 80 m^3.

The quality control tests of the concrete production were conducted by the Hagerbach Test Gallery. The Hagerbach Test Gallery has several construction materials testing laboratories at its disposal throughout Switzerland. For on-site tests in Mitholz, a mobile laboratory was set-up very near the concrete plant. The monitoring of concrete production was realized with systematic testing of fresh concrete. The on-site mobile laboratory was equipped with instruments for determining the early compression strength of shotcrete and concrete. Separately produced test specimens (cubes, cylinders, shotcrete test boxes) and intermittent specimens from the structure itself were tested at the Hagerbach Test Gallery to ensure that hardened concrete requirements were met.

Figure 2. Fresh concrete test at on-site lab.

4 AGGREGATES FOR CONCRETE PRODUCTION

For reasons of ecology and economy, efforts are made at large tunnel construction projects to optimally recycle excavated material.

The excavated material of the Lötschberg Base Tunnel generated from drill and blast operations was therefore assigned a recycling classification and processed accordingly. From the processed muck at the Mitholz site, enough aggregates were obtained to enable self-sufficiency of the site. Surplus material was passed on to third parties. Missing grain sizes were bought according to need.

After each round, the geologist from the overall project management team classified the excavation material in accordance with its recycling class.

In addition to the petrographic evaluation, the suitability of the raw material K1 was verified as deemed necessary with physical tests.

From the K1 material, the material processor prepared the following aggregates for concrete:

- Sand 0–4 mm, unwashed
- Sand 0–4 mm, washed
- 4–8 mm, 8–16 mm, 16–22 mm

Table 2. Recycling class.

Class	Rock type	Utilization
K1	Good rock quality, relatively homogeneous rock formations, e.g. limestone, sandstone, granite with small slate fraction (≤10%)	Material suitable for production of aggregates for concrete, gravely sand for foundations, crushed stone, gravel and drainage gravel
K2	Medium to good quality rock, heterogeneous rock formations, e.g. marl, Triassic dolomite, alternating layers of clay slate, marl and limestone	Material suitable for production of gravely sand. If necessary, it is possible to use K2 material as raw material for Class K1 after preliminary sieving and removal of fines (K2S)
K3	Poor rock quality, e.g. kakirite, anhydrite, flysch	Material suitable for filling of gravel pits and quarries, embankments, backfill, terrain modifications

The quality of the prepared aggregate sizes was monitored and documented by the material processor in accordance with a testing plan within the framework of production control.

Independent of the production tests by the material processor, specimens were systematically taken from the silos of the concrete plant by the contractor ARGE Satco and their grain size was determined.

4.1 *Aggregate variations*

During processing of aggregates of varying composition from tunnel excavation material, the uniformity of the material and its handling is critical, especially of sand.

During the rock crushing process, the raw material behaves in different ways depending on the geology and moisture content of the excavated material. The effects were especially apparent in unwashed sand.

During the start phase in Mitholz, one sand was delivered by the material processor that consisted of both washed and unwashed sand. The large fines fraction <0.125 mm of approx. 16% and large variations affected the amount of water needed for the concrete mix and made concrete production more difficult. The high water content limited the early strength development of shotcrete to an unacceptable level and the w/c ratio was considerably higher than 0.50. After a phase with approx. 13% <0.125 mm, the delivery was modified to the originally planned ratios of unwashed and washed sands so that varying site requirements and the shotcrete mix could be better accounted for.

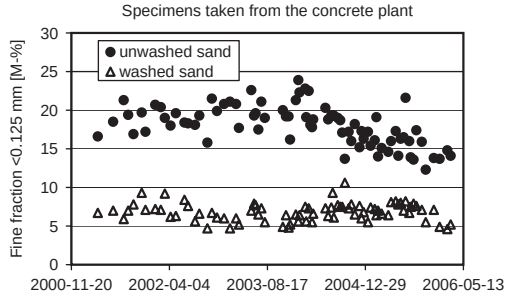

Figure 3. Fine fraction <0.125 mm in sands.

The following graphic shows the subsequent fraction of fines in the sand, as determined from over 80 specimens taken regularly from the concrete plant.

The fine fraction <0.125 mm of unwashed sand was on average 18.0% with a standard deviation of 2.5%. For washed sand, an expectedly lower average value of 6.8% and a smaller standard deviation of 1.2% could be measured.

The handling of unwashed crushed sand was a critical factor. The sand was susceptible to decomposition and often settled at the bottom of the silos of the concrete plant. It therefore had to be re-loosened with much effort. Concrete production workers were permanently attending to water requirements and mix consistency during production.

Visible variations in the consistency of the shotcrete mixes (in area designated for concrete work) increased the risk of changes to the mix through uncontrolled addition water into the mix. The quality of the concrete would thereby be reduced.

4.2 *Ensuring supply*

In addition to the suitability of the excavation material, the supply of enough aggregates to the site had to be ensured. The mix design for concrete and shotcrete therefore had to take the rate of material extraction into account as much as possible. In an initial phase in which much more shotcrete than cast concrete was required, an insufficient amount of grain size 4–8 mm was available. During this phase, approximately one-third of the aggregate of size 4–8 mm was procured externally. The lack of 4–8 mm aggregates was accounted for within the mix design by limiting its use as much as possible. The cast concrete mixes (mainly invert concrete) during this phase were therefore poured without the 4–8 mm grain size. The shotcrete mixes however could not be applied by reducing the 4–8 mm fraction through substitution of 0–4 mm sand, because the quantity of water in the mix was already high and further increases could not be tolerated (see chapter 4.1).

The petrographic composition, the aggregate form and the size distribution of aggregates produced on site differed from the externally procured aggregates. The deliveries of the externally procured aggregates to the concrete plant were carried out without prior notice. The concrete mixes were robustly designed so that resulting variations could be tolerated.

4.3 *Alkali aggregate reaction (AAR) resistance*

The aggregates to be used for concrete production (mainly silicic limestone) were classified to be reactive to highly AAR reactive (microbar values over 0.2%).

With the limitation of the alkali content in the concrete mix and the limitation of the amount of cement, the client made allowances for the AAR reactivity of the aggregates.

For shotcrete, Portland composite cement CEM II/A-M 52.5 with 10% limestone filler and 8% microsilica was utilized. The cement content was limited to 420 kg/m^3. The limitation of the cement content (420 kg/m^3 instead of the usual 460 kg/m^3 in Switzerland) with smaller maximum grain size decisively affected the workability and early-strength development of the shotcrete. The fines content of the shotcrete was approximately 590 kg/m^3, 170 kg/m^3 of which was 100 % crushed aggregates.

In instable areas, a mix with 520 kg/m^3 cement for face support and support in the area L1 was therefore specified to ensure sufficient early strength development.

In cast concrete, Portland cement CEM I and flyash of the ratio 70/30 % to 80/20 % was used.

The testing of the resistance to AAR of the mixes was conducted by the client with LCPC performance tests.

5 CONCRETE

5.1 *Test methods*

The verification of the strength classification was conducted in accordance with SIA 162 on cubes for cast concrete and SIA 198 on drill cores for shotcrete.

The water penetration depth under pressure, tested in accordance with DIN 1048 and SN EN 12390–8, served for verification of impermeability.

The sulfate resistance was tested in accordance with the Swiss standard SIA 262/1, Appendix D.

For the test of the sulfate resistance, six drill cores of diameter Ø 28 ± 2 mm with a length of 150 mm were taken from test cubes, shotcrete testing boxes, or directly from the structure. Cycle of drying and saturation can lead to the transport of significant quantities of sulfate into a test specimen. The sulfate reacts with the constituents of the specimen resulting in an increase in volume and destruction of the concrete matrix. For the evaluation, the changes in length and mass are determined. Initial experience from the test method is available, especially from the site Mitholz and other AlpTransit Gotthard sites.

Table 3. Mixtures.

	Shotcrete	Cast concrete	Cast concrete
Utilization	Sealing/ support	Invert construction	Lining
Max. grain	8 mm	22 mm	22 mm
Cement	CEM II/A-M 52.5 420 and 520 kg/m^3	CEM I 42.5 285–305 kg/m^3	CEM I 42.5 320–340 kg/m^3
Flyash		95–75 kg/m^3	110–80 kg/m^3
Liquefier	1.2–1.4%	1.5–1.8%	1.8–1.9%
Accelerator	0 and 5.5%		

Figure 4. Test for sulfate resistance.

5.2 *Shotcrete*

Image 5 shows that the shotcrete fulfils strength requirements of the classification B35/25. The average value of 290 tests was 49.2 N/mm^2 with a standard deviation of 9.8 N/mm^2. In comparison with cast concrete, the values for shotcrete deviated more widely, which is characteristic for the material.

Table 4. Fresh concrete values for shotcrete.

315 measured values	Slump [cm]	Water content [kg/m^3]
Average value	49	221
Standard deviation	4	10

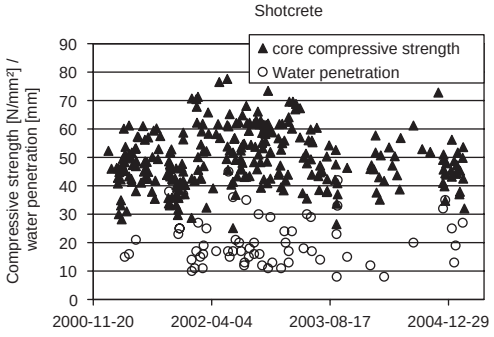

Figure 5. Shotcrete results.

Table 5. Fresh concrete values invert construction.

292 measured values	Slump [cm]	Water content [kg/m^3]
Average value	45	195
Standard deviation	7	13

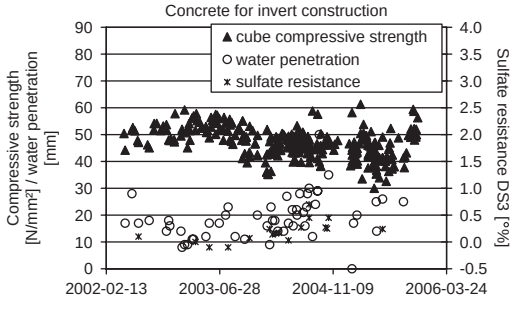

Figure 6. Concrete for invert construction.

The average of 66 tests of water penetration was 21 mm. The amount of reserve to the limiting value was good at three standard deviations (9.1 mm).

5.3 *Concrete for invert construction*

The cube compressive strength reached an average of 47.0 N/mm^2 with a standard deviation of 5.4 N/mm^2. The strength classification requirements for B35/25 were fulfilled. The requirements for impermeability were also fulfilled by with a good amount of reserve with a water penetration on average of 19.4 mm with a standard deviation of 7.7 mm.

For sections with a sulfate concentration of over 250 mg/l, concrete with a high sulfate resistance was required. The Δl(DS3)-values from Mitholz were on average 0.2‰ for 17 tests. As a reference value for concrete with high sulfate resistance, SIA 262/1 requires a series value Δl(DS3) of 0.5‰.

Table 6. Fresh concrete values for inner lining.

313 measured values	Slump [cm]	Water content [kg/m^3]
Average value	53	196
Standard deviation	6	10

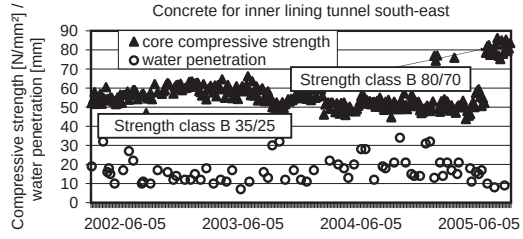

Figure 7. Concrete for inner lining.

5.4 *Concrete for inner lining "south-east"*

The demands on strength (B35/25) and impermeability (water penetration <50 mm) could be met with the average compression strength of 54.5 N/mm^2 (standard deviation 4.5 N/mm^2) and an average water penetration of 17 mm (standard deviation 6 mm) with sufficient reserve. The mixes were tolerant against construction variability and were therefore of little risk for the construction consortium.

For approx. 20 sections in a zone with very unfavorable rock conditions, the strength requirements were significantly increased to B80/70. The concrete mix was adapted. Instead of the cement CEM I 42.5, the cement CEM II/A-M 52.5 with 400 kg/m^3 and a maximum grain size of 16 mm was utilized. The quality control of the production was intensified. This difficult phase could be realized with a impressive compression strength on average of 80.8 N/mm^2 with a very good standard deviation of 3.2 N/mm^2. The average value of water penetration in this concrete was 9 mm.

6 CONCLUSIONS AND OUTLOOK

The experience gained from the construction site Mitholz proved that high-quality concrete can be produced from aggregates processed from tunnel excavation material.

The special constraints demand however that all affected parties are very willing to cooperate. For the

constructive and excellent cooperation at the Mitholz site, gratitude must be passed on the participating personnel of the construction consortium ARGE Satco, the concrete producer Mobilbaustoffe, the representatives of the client and the material processors. Thanks also to the site supervision team, who generously provided the test data used in this report.

The experience gained from construction site Mitholz serves as a valuable basis upon which future structures can be designed.

Engineering design work conducted in accordance with the Swiss standard SIA 260 must incorporate the choice of suitable construction materials as a measure for dealing with hazards of structural members. For concrete, this means that the design engineer must determine the exposition class of the concrete, and accordingly, any further necessary requirements and procedures. Because the expected service life of tunnels usually exceeds 50 years, a performance-based design process in accordance with SN EN 206–1 is to be applied. In Switzerland, many recognized testing methods and assessment values (sulfate resistance, frost and frost salt resistance, water penetration, water conduction) can be utilized by the design engineer.

Certification of shotcrete nozzlemen around the world

C. Larive
CETU, Bron, France

K. Gremillon
DIR IdF, Créteil, France

ABSTRACT: Quality of shotcrete works is deeply linked with the nozzlemen know-how which results from a long experience combined with strictness. That also implies the knowledge of the equipments and the appreciation of the supports, the evaluation of the incidence of the climatic conditions, the knowledge of the rules concerning the mixes and the additives, the respect of health and safety conditions. It is necessary, as well for the owner and for the engineering company, to be able to guaranty the quality of the work. The ITA WG 12, shotcrete Use, has thus decided to study the existing certification procedures and try to establish an all-over-the-world state of the art on that subject. This paper also enlightens the mains points to check to assess the know-how of the nozzlemen.

Shotcrete is being more and more used in the construction industry and it has taken real importance in civil engineering nowadays. It may be seen all around, for instance in:

- tunnels and underground car parks,
- houses and swimming pools,
- repair and reinforcement of concrete structures,
- soil nailing and slope stabilization.

That is why it has become important to propose a way to ensure a good quality of work. It is also suggested in the Eurocode 2 – "Design of concrete structures".

In every country, standards provide guides to obtain high quality projects but one usually recognizes that this is not enough; well-mixed concrete and standardized machines are not sufficient to provide superior quality by themselves, because, hidden behind all these material aspects, people work and a good job needs qualified operators.

In some countries, such as Brazil, Canada, France, Norway and the USA, certification programs for nozzlemen have been established. They tend to recognize the know-how of the workers, and of course, to give a proof that they are capable of providing a good job. Another organisation, the EFNARC, is trying to elaborate a certification which could be used as a reference in the whole Europe, mostly based on practical issues. This certification should be available in 2007. Sweden is also being preparing a certification procedure.

Information available in this paper have been gathered via exchanges with the ITA WG12 members. It may still not be exhaustive. Any comments or additions will be welcomed.

Currently the most well-known and used certification in the world is the North-American one, prepared by the American Concrete Institute (ACI). The first *Guide to certification of shotcrete nozzlemen* was dated from 1991 and has now been withdrawn by ACI. A new nozzleman certification program developed by ACI Committee C 660 is outlined in publication CP-60, "Craftsman Workbook: ACI Certification Program for Shotcrete Nozzlemen". Around 550 nozzlemen are now certified in America (both North and South) and this certification is world-wide delivered. Some countries, for example the United Kingdom, also use it whereas others take it as a starting point for their own certification process, France for example. The documents available in other countries are dated from 1996 for Brazil and 2004 for France.

1 TYPE OF CERTIFICATION

Different types of certification are to be considered: those for « manual » nozzlemen and those for « robot-aided » nozzlemen. In each one, the process (wet- or dry-mix) can be distinguished. Certification can also deal with only one type of position (vertical) or both (vertical and overhead).

Table 1 summarizes the situation.

Table 1. Different types of certification today.

	Type		Process	
	Robot	Manual	Dry	Wet
Brazil		x	x

Note: French examinee has to shoot both vertical and overhead panels during the certification. ACI proposes to be certified in vertical position only or in both vertical and overhead position.

As there are two ways of spraying (aided or not), there must be two types of certifications. Today, the only country that proposes a complete (theoretical and practical) certification for robot-aided nozzlemen is France but the EFNARC will elaborate an other one in 2007 and Brazil also will. In this paper, emphasis is put rather on ≪manual≫ nozzlemen certification but indications are also given on the future EFNARC procedure and on the specificities of the French procedure for robot certification.

Note: ACI is discussing about robotic certification. Many in ACI believe now that a nozzleman must first be certified for manual shotcrete before he/she can be certified for robotic.

Concerning wet- and dry-mix process, some countries chose to separate certifications, judging the process is different enough, because wet-process nozzlemen need to regulate only the amount of air while dry-process nozzlemen need to regulate both air and water to produce good shotcrete.

Norway and Sweden have merely theoretical examinations today. Anyway, it is commonly considered that both theoretical and practical parts of the certification are useful to ensure the operator works well and safely, understands concrete technology, and is able to sort out a problem *in situ* if necessary.

Practical tests are about the same in every country although there are small differences. Theoretical requirements vary depending on the country: it can be an oral or a written exam and the amount of required knowledge is not the same.

Shotcreting on a vertical panel is easier than on an overhead panel. That's why ACI International proposes two different certifications for nozzlemen: one for vertical shotcreting only, and another one for both vertical and overhead shotcreting. However, France for instance proposes only one certification taking into account both positions. The EFNARC will probably propose only one certification, done on a construction site, with both vertical and overhead panels to shoot.

According to an article from *Shotcrete for underground support VIII* dated April 1999, Brazil has only one certification, for dry-mix process and manual nozzlemen. But now another one is in preparation, for wet-mix process and robot-aided nozzlemen.

2 BACKGROUND AND PREPARATION

Is there a "background" needed before having the right to apply for the certification? Here, background means professional experience as well as technical knowledge, diploma, or so.

- Brazil: according to the paper mentioned above, there is no need to have a specific experience to have the certification but the examinee has "to give a proof that he is able to take the test",
- France: there is no need to have any proof of professional background; both practical and theoretical knowledge are tested during an oral examination,
- Norway : the examinee has to attend a one week course specially dedicated to nozzlemen,
- ACI International: a minimum 500 hours of professional experience is needed to apply for the certification and there is a written test in which you have to prove that you not only know how to work safely and how to prepare your work but also that you have a basic theoretical knowledge about concrete.

Concerning the preparation, in Canada and the USA, the American Shotcrete Association (ASA) provides training courses as well as France but they also enable people to learn by themselves with a book: Craftsman Workbook, ACI Publication CP-60 (02).

Some documents published by ASQUAPRO (Association for the Quality of Spraying Concrete and Mortar) are also available in France, for example the technical guide *Mise en oeuvre des bétons projetés* (Shotcrete implementation). The book *Projection des bétons, mortiers & plâtres* is not specific for the preparation of the test but is also helpful. We are not aware of any documents of that type in other countries.

Note: ACI publishes ACI 506R-05, "Guide to Shotcrete", which is used in training sessions and is very helpful to nozzleman candidates.

The EFNARC should propose to send self-study pack to applicants before they take the jobsite test.

3 THEORETICAL CERTIFICATION

There are two different ways of passing the theoretical certification: an oral examination or a written one. This latter implies that the worker can read and write which may not be the case of every nozzlemen, even skilled ones but one can consider that it gives a better impartiality. However, an oral test allows more flexibility, and the inspector can re-direct his questions in order to better evaluate the nozzleman's knowledge, or ask him to precise his answers.

The theoretical part of the certification is closed book in every country (no documents allowed). As other documents are not available yet, here is what the *Craftsman Workbook* from the ACI expects from nozzlemen. This document is divided in 2 sections:

- Basic concrete technology, describing what concrete is made of and how it behaves.
- Shotcrete, section with 10 chapters in it:
  - What is shotcrete?
  - Equipments
  - Materials
  - Environmental conditions and precautions
  - Inspection and preparation of surfaces
  - Shotcrete placement, principles, and techniques
  - Communication (between nozzleman and either the gunman or the pump operator)
  - Finishing and tolerance controls
  - Safety
  - Testing/Quality

The test is made of 60 to 90 multiple choice questions. An oral examination instead of the written one can be permitted in special cases when conducted in accordance with ACI guidelines.

Note: the CP 60 Workbook and ACI Examination are now available in English and Spanish.

What the ACI certification expects from nozzlemen in this theoretical part is probably the highest amount of theoretical knowledge a nozzleman can be asked, along with the Norwegian certification.

The nozzlemen course in Norway has about the same program as ACI, including knowledge on concrete and shotcrete, construction site preparation, health and safety, environmental and strength classes, and so on. A written examination of 45 questions is administrated after the one week training.

In France, inspectors ask questions about machines set-up, substrate preparation, visual control of quality, health and safety, basic knowledge on shotcrete formulation – more specifically on admixtures, but not on other types of concrete. This is because good nozzlemen are expected but they will not be asked to design their own concrete mix.

In Brazil, the examination can be either written or oral. The field of required knowledge seems to be about the same as in France.

Finally, the EFNARC will probably ask questions on practical issues, such as the correct way of spraying, or the conditions of health and safety. This theoretical part should consist of a multiple choice questions test, oral or written.

It can be noted that, even where there is no need to give a proof of a minimum professional experience to take the certification, it is in fact necessary to pass.

Sweden is at the start of a development phase designed not only to raise (via the certification of personell) the competence of shotcrete nozzlemen, but also to increase the understanding of all staff involved in shotcreting. The post-treatment of shotcrete is an important element in this. The main ideas are:

- The results of shotcreting are highly dependent on the skills of nozzlemen. Many elements in the work cannot be subsequently checked. Complete trust has to be placed in such elements being correctly executed in any given situation.
- The results of shotcreting carried out by contractors are also highly dependent on work supervisors, consultants and customers having the necessary knowledge. Because standstill costs in general are considerable in tunnel projects, correct decisions must often taken under great time pressure.
- For shotcrete workers, the Shotcrete Centre and Vattenfall Utveckling shall develop course packages that can be used for licensing. The Shotcrete Centre and Vattenfall Utveckling shall also develop training materials for work supervisors, consultants and organisations buying shotcreting services.

4 PRACTICAL CERTIFICATION

According to ACI, after passing the theoretical test, nozzlemen are allowed to take the practical one. It is usually held in this order, first theoretical, then practical, so that if the first one is failed there is no need to set up the installation.

The practical part usually consists of shooting two panels, both vertical and overhead, except in Brazil where only vertical panels are sprayed. For the ACI program, the examinee chooses whether to shoot only vertical, or both. In France, there is no possibility to take the test only for the vertical panels.

The certification in France is taken either at the end of a training course or on a construction site. In that latter case the examinee's equipment is provided by the company. In the former case, a hard hat, security boots and protective clothings are brought by the examinee. In North America, nozzlemen should have their own equipment to take the test. No information is available for Brazil.

In every country where the certification can be taken, as part of the practical examination, the

examinee has to check that the machine is properly set-up, then he has to shoot a vertical panel.

After this,

- In North America, he is allowed to shoot an overhead one if the first panel has been estimated good by the inspector.
- In France, he shoots the overhead panel without waiting for the inspector to look at the first panel.
- In Brazil, he shoots another vertical panel.

In France, if a nozzleman thinks that he failed his panel, he is allowed to shoot another one.

Those panels are examined by the inspector at least 24 hours later in France. A furrow is sawn in the back face of the panel, perpendicular to the steel bars. A measurement of the voids behind the bars is then performed. In North America, five core samples are drilled through the reinforcing bars and graded from 1 (best quality) to 5 (worst quality).

In France, when the certification is taken after a training course, the concrete used for the test is standardized, otherwise it is the mix used on the construction site. In North America the shotcrete mixture is one in common use in the geographic area of the test site. This information is not available for Brazil.

The test panel has standardized dimensions, in France and in North America. France chose to reduce the dimensions of test panels from $75 \times 75\,cm^2$ to $60 \times 60\,cm^2$, judging it would be enough (the sides of the panels are semi-open) and easier to manipulate. No information from Brazil is available.

The EFNARC will probably only propose to take the test on the construction site. It should consist of shooting sample panels and check the results on cores.

The aim to shoot those panels is obviously to evaluate nozzlemen. A lot of criteria are examined during this test, depending on the country in which the examinee takes the test. In Brazil, the main criterion is the homogeneity of concrete, in order to check that the nozzleman is able to reproduce shotcrete with minimum variations. So the factor water/dry material shall not vary of more than 1% between the two panels, and volume of void shall not vary of more than two 2%. There is also a limit value not to reach: wastes ought to be inferior to 35%.

However, in France and North America, there is no criterion of homogeneity. In France, the main criteria are voids behind steel bars, which represents 60% of the mark; then come the surface quality, which represents 10% of the mark, framed edges quality (10% of the mark) and strength at an age of 7 days (20% of the mark).

In North America, a lot of criteria are also examined, divided in three steps, preplacement, start up, and placement. The examinee has to identify people and machines, to check the installation, and to use proper positions during the spraying, then 5 cores are examined, in which the inspector will detect laminations, sandy areas, shadows and voids.

Note: for the French "robot-aided" nozzlemen certification, the dimensions of the test panels are modified: 1000 mm × 1000 mm × 150 mm. 9 cores are extracted to analyse the compressive strengths at the age of 7 and 28 days and the homogeneity of concrete. Other particularities, not described here, are to be taken in account. For instance, if the examinee uses of fibre reinforced concrete, the amount of fibre should be controlled in situ.

5 NOTATION

Concerning the theoretical part, in Brazil the examinee has to give the correct answer to ten questions out of twenty to pass the test. In the ACI exam, the nozzleman has to give the correct answer to 75% of the proposed questions. In France, each type of question is evaluated between 0 to 4. The examinee must have no marks less than 2 for the five types of questions, which gives a minimum of 10 out of 20 but without any real lack of knowledge in any field.

The percentage of good answers to pass the theoretical exam in Norway is not available.

A lot of points are examined by the inspectors to evaluate the practical part, as seen in the previous chapter.

In France, the way to give a mark is quite complicated:

- Basically, the idea is first to measure the section of voids behind the five steel bars, and to give a mark (on 5, one point per bar). If a mark of 0 is given for one armature, or if the total is 3 or less, the test is failed. So examinee is given a mark on 12 for the two test panels (two marks on 5, multiplied by a factor of 1.2). The way to measure those voids depends on the diameter of steel bars (reference: 16 mm) and can easily be adapted if the steel bars used on the construction site are different.
- The quality of framed edges is marked on 2; the examinator eliminates 5 cm at each extremity and reduces the maximum mark by 0.1 when a default is seen on 1 to 5 cm. The mark 0 to this part means failure of the entire certification.
- The quality of surface is also marked on 2, but a mark of 0 here does not mean failure of the certification.
- Finally, compressive strength at an age of 7 days is marked on 4. The test is done on three cores. The maximum mark is given when the measured compressive strength is greater than 90% of the compressive strength at an age of 28 days. A mark of 0, meaning failure of the certification, is given when the measured strength is below 65% of the compressive strength at an age of 28 days.

Table 2. Notation for ACI certification.

	Grade (%)(a)	Weight (b)	Score (a*b)
Step A		0.25	
Step B		0.20	
Step C		0.55	
Total weighted score (Minimum passing = 75%)			

- The French certification is granted when the total mark is 12 or above.

In the ACI system, the examinee must have more than 15 correct out of 19 points observed in step A, preplacement. Then, more than 7 correct out of 9 points is needed in step B: start up. For step C: placement, each point is given a mark from 0 to 4. The total gives a mark on 36 (overhead panels) or 44 (vertical panels). If two or more 0 are given, the certification is failed. Finally, five cores are examined, and given a mark from 1 (best quality) to 5 (worst quality). If any one individual core is graded higher than 3, the entire test panel is failed, or if more than 2 cores are graded 3 or higher the entire test panel is failed.

To pass the ACI certification, the examinee must have:

- « Pass » for the core grading part
- a minimum of 75% of correct answers for steps A, B and C, with the following calculations

For example, assuming the examinee has taken the exam for vertical shotcreting only, and got 16/19 for step A, 8/9 for step B, and 30/44 for step C, that means 84.2% for step A, 88.9% for step B, and 68.2% for step C.

$$84.2 * 0.25 + 88.9 * 0.2 + 68.2 * 0.55 = 76.3\%$$

The examinee passed his certification.

The way to grant the practical part of the certification in Brazil is not available.

6 VALIDITY AND RE-EXAMINATION

This certification is usually granted for a limited period of time. In the ACI program, it has a validity period of 5 years. After that, nozzlemen have to take another certification examination which includes an oral interview and the practical examination

In France, the system is even harder. The first time you pass the certification, its validity period is 3 years and after you have to renew it every 5 years, as in North America. To lighten this system, heavy for both nozzlemen and companies, ASQUAPRO, that has designed the French certification, thinks about asking for proof that a certified nozzleman has been practising during the period of validity of his certificate, instead of asking him to take the exam again. The main problem is that proof must not be easily falsified. No information is available for Brazil and Norway.

Concerning the re-certification process when one has failed once, the North American certification proposes to retake only the failed part during the same year. For example, if the examinee failed the written exam, but passed the practical test, he will be allowed to retake only the theoretical examination for one year. Otherwise he has to retake the entire certification.

The process is about the same in France. The examinee can even choose to re-shoot a panel during the practical test if he thinks he failed the first one. The theoretical examination can be retaken if failed. The criteria to retake the tests are the same as in the ACI system.

7 CONCLUSION

Certification for shotcrete nozzlemen positively contributes to the good quality of work by insuring that the craftsmen are capable of constructing shotcrete structures in the proper manner.

This paper reflects the existing procedures. It can be updated by sending comments to the author[1] and it should be soon available on the ITA WG12 website.

It would certainly be good to adopt a common certification in every country but it is probably impossible to achieve because of the specificities of the already existing certifications. At least, it should be possible, inside the ITA WG12 “shotcrete Use”, to discuss on minimum adjustments so that foreign certifications could be accepted abroad.

Robotic application of a unique sprayable membrane for the waterproofing of a subsea tunnel

S.L. Lamhauge
Nordöytunnilin PF, Tórshavn, Faroe Islands

K.G. Holter
BASF UGC Europe, Zürich, Switzerland

C. Ziegler
MEYCO Equipment, Winterthur, Switzerland

ABSTRACT: An innovative sprayable membrane was applied by a state-of-the-art computerized spraying robot for the waterproofing of a 6.2 km long road tunnel. The finally applied waterproofing system consisted of a thin composite liner with a 3 mm thick watertight spray applied membrane in a sandwich structure between the sprayed concrete for rock support and a final protective layer of sprayed concrete. This was the first time a completely computerized and mechanized method for the application of a waterproofing system in tunnels has been employed. The robotic application of the membrane included precise scanning of the surface to be sprayed as well as very controlled application of the membrane. This enabled the consistent application of the required thickness at a high speed.

1 BACKGROUND

1.1 *The project*

The Nordöy road tunnel connects the two islands of Eysturöy and Bordöy in the Faroe Islands with a fixed road connection. The second largest town Klaksvik, located on Bordöy, with 5000 inhabitants is thereby linked to the rest of the archipelago. The tunnel is entirely located in rock and passes under the fjord between the two islands.

The design of the tunnel was done according to the standards of the Norwegian Road Authorities. The tunnel was excavated by traditional drill-and-blast methods with rock support based on the single shell lining method with sprayed concrete and rock bolts. For control of the water seepage into the tunnel, a scheme with exploratory percussive drilling ahead of the tunnel face was carried out in the entire tunnel length.

Action criteria based on seepage into the tunnel measured in the exploratory holes defined the use of cementitious pre-injections ahead of the tunnel face in order to reduce the seepage into the tunnel to a cost-effective level.

The length of the tunnel is 6155 m with a cross section of 64 m^2 (two lanes). The maximum depth under the sea is 150 m with a minimum rock cover of approximately 40 m.

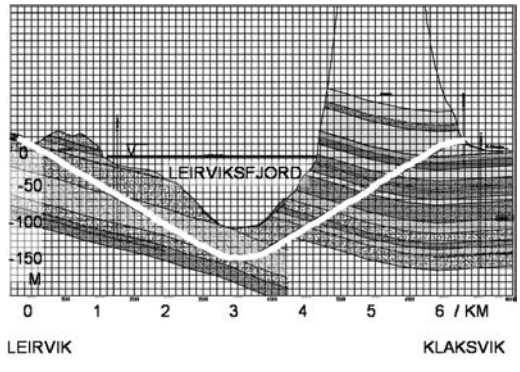

Figure 1. Geological section of the tunnel with main features. The strata indicated with the dark shade on the right (Klaksvik) side represent the weakest basaltic rock which were encountered. The light colored strata represent the competent basalt types.

1.2 *Geological conditions*

The Faroe Islands consist of volcanic deposits which are typical for the North Atlantic basaltic area. The rock types found are mainly extrusive basalts approximately 50 million years old.

The rock mass consists of a stratigraphy of basaltic rocks in which distinct layers can be identified with

thicknesses that vary from a few meters up to approximately 50 m. Each layer represents an event of a lava flow. One basaltic layer which was encountered in about 700 m of the tunnel length had a relatively soft and porous character and required extensive need for pre-injections and continuous rock support with sprayed concrete and rock bolts.

Otherwise the rockmass encountered in the tunnel consisted of very competent and massive basalts with compressive strengths in the range of 80–90 MPa.

2 REQUIREMENTS FOR THE WATERPROOFING OF THE TUNNEL

The original design and the tender documents required a waterproofing system based on Norwegian standards which basically consisted of a drainage shield with polyethylene (PE) foam sheets covered with sprayed concrete. The total cost of the waterproofing of the tunnel made up approximately 10% of the total project cost. The main reason for the waterproofing of the tunnel was to avoid drips on the actual road and to protect the different installations from humidity.

The experiences from the first subsea tunnel built in the Faroe Island, the Vaga Tunnel, completed in 2002, were that water seepages tend to diminish significantly over time. The first four years after opening of this tunnel, the seepage into the tunnel had been reduced by 20%. This was caused by minerals in the groundwater which deposit on the joints, and hence reduced the conductivity of the rock mass.

For this reason the main requirement for the installation of waterproofing was changed to 6 drips per minute from the original requirement of 3 drips per minute in an area of one square meter.

The Faroe Islands has a relatively mild climate. Significant freezing occurs only under adverse weather conditions. The waterproofing was therefore designed with frost insulation in only 200 m of the tunnel from both portals.

In the last few years there has been a trend to avoid flammable materials in underground construction. The flammable PE foam sheets were therefore not in accordance with a modern design philosophy with non-flammable materials. For this reason the owner was interested in alternative technical solutions for the waterproofing which could fit in with the single shell tunnel lining design. The goal was to reduce the amount of the PE foam waterproofing with more than 50%.

Several alternative technical solutions were considered. A technical solution with a sprayable waterproofing membrane in a composite liner based on sprayed concrete was chosen. Favourable experiences with sprayable waterproofing membrane had recently been made in Switzerland (Meier et al. 2005) and in the United States (Blair et al. 2005). This system could be made an integral part of a single shell tunnel lining based on sprayed concrete and rock bolts. Hence, this technical solution offered significant financial benefits over a technical solution with PVC sheet membrane and cast-in-place concrete lining.

The owner and the contractor reached an agreement in which the contractor was to make final decisions as to which waterproofing to apply. The criteria for this decision were based on seepage types and seepage intensities. In addition the cost-effectiveness based on the required amount of additional sprayed concrete was to be taken into account. Both the contractor and the owner had a financial benefit of utilizing the sprayable waterproofing membrane instead of the traditional PE foam waterproofing.

3 THE WATERPROOFING SYSTEM

3.1 *Properties of the chosen waterproofing system*

This waterproofing system is basically a composite liner which consists of a spray applied membrane in a sandwich structure between two sprayed concrete layers. The membrane has a normal thickness of 3 mm and a minimum thickness of 2 mm.

The main property of this membrane is that it bonds to both the substrate and the concrete which is applied onto it. This again leads to the important technical feature that the two interfaces between membrane and concrete on either side are impermeable. Hence, no water can migrate along these interfaces. Figure 2 below shows a core taken through the composite liner with spray applied waterproofing membrane and sprayed concrete.

The membrane-concrete interface has a tensile bonding strength of 1–1.2 MPa when completely cured. The curing of the membrane starts immediately after the spray application. The curing process consists of hydration of the cement part of the product and evaporation of the excessive water. Through this process a continuous waterproof film is formed. The curing process is irreversible. Hence, a subsequent feeding of water onto the membrane after curing, will not lead to a change of the waterproofing properties.

It is essential that the membrane thickness does not exceed approximately 5 mm thickness (other than local spots). Excessive membrane thickness might lead to very slow curing and if exposed to water from the substrate, the bonding and waterproofing properties might be compromised.

Waterproofing with a sprayable membrane embedded in a composite liner creates an undrained surface impermeabilisation. This might lead to local build-up of groundwater pressure immediately behind the membrane. When designing the waterproofing of the tunnel

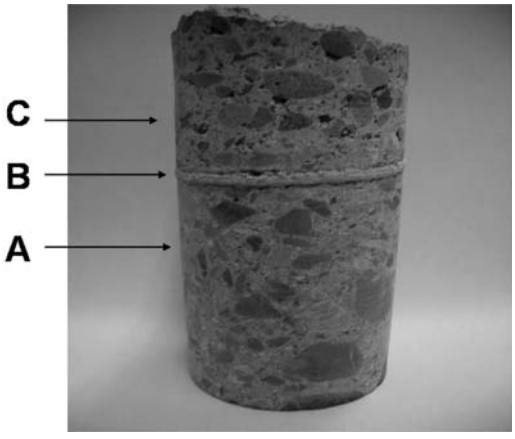

Figure 2. Composite liner, with sprayable waterproofing membrane in a sandwich structure between two sprayed concrete layers. The membrane (B) is applied onto the sprayed concrete substrate (A) with a thickness of 3 mm. Subsequently the membrane is covered with a covering layer of sprayed concrete (C) with minimum thickness 4 cm. (Meier et al. 2005)

one therefore had to bear in mind that a part of the tunnel contour had to remain drained, or a drainage measure had to be considered based on the actual situation.

In most cases, cracks and joints in the rock behind the membrane/concrete sandwich will drain to the invert ("umbrella" solution) without any significant pressure build-up.

4 APPLICATION OF THE WATERPROOFING SYSTEM

4.1 *Sequence of operations*

In order to provide suitable conditions for the spray application it was necessary to establish a proper substrate. The two main issues of the substrate preparation were substrate roughness improvement and removal of wet spots.

After the substrate had met the specified requirements, the application of the waterproofing membrane could commence.

4.1.1 *Improvement of the substrate roughness*

Achieving a continuous membrane with the required thickness between 3 and 5 mm, depends heavily on the quality of the substrate. An acceptable roughness in the cm order is achieved by utilizing a sprayed concrete with maximum grain size of 4 mm. A good substrate can also be achieved with 8 mm if the aggregate is very well graded and the actual application of sprayed concrete is particularly aimed at achieving a sufficiently good surface finish.

The surface characteristics regarding edges, holes and other irregularities were important to improve in a way that a thin continuous membrane was feasible. This involved the filling and smoothening out of holes and "trenches" as well as edges, sharp points and major irregularities in the substrate surface. Additional sprayed concrete had to be applied locally to the substrate for this purpose.

In several areas in the tunnel it was therefore necessary to apply an additional thin coat of sprayed concrete in order to achieve the proper substrate characteristics.

Figure 3. Handling of wet spots prior to the spraying of the waterproofing membrane. Manual application of a rapid curing priming membrane in progress to cover areas with installed drainage half-pipes.

4.1.2 *Handling of wet spots*

The wet areas which occurred where the sprayable membrane was intended had to be treated before the application of the membrane. Basically wet spots had be drained or injected. Only drips in the order of 3–4 drips per minute could be accepted.

The methods which were utilized for removing surface water ingress points were installation of drainage half pipes, polyurethane injections, drainage holes with drainage hoses and priming of the surface immediately before the application with a special rapid curing membrane.

Figure 3 shows the application of a rapid curing membrane as a primer in an area with drips and moisture where drainage half-pipes have been installed.

4.2 *Mechanical application*

The mechanical application of the sprayable waterproofing membrane utilized a state-of-the-art robotic (fully automatic) spraying machine.

This machine was originally designed for the robotic application of sprayed concrete with a very precise layer thickness.

The features of this machine, in particular the scanning of the substrate and the possibility to achieve a constant speed of the nozzle over the surface, made it suited for the robotic application of the waterproofing membrane.

4.2.1 *Scanning of the substrate surface*

Scanning is a digital distance measurement with a laser scanner of the detailed substrate contour. The scanner is located at the very front of the boom just behind the spraying head.

The operator defines the boundaries (corner points) of a square area on the tunnel contour to be scanned. The scanner then records the surface with a predefined grid density. In this case one used a 20 cm square grid density. The file with the scanned area was then in turn used for the robotic spraying of the area.

4.2.2 *Robotic spraying of the membrane*

The actual application of the membrane took place with the dry spraying method. That means the product was delivered using a rotor machine and transported pneumatically in a powdered state through a 32 mm diameter hose to the nozzle. The nozzle for membrane spraying is a standard nozzle for dry mortar spraying. Water is added in the nozzle through the precise adjustment possible with a needle valve. The equipment used for the application is very similar to that of dry sprayed shotcrete, but with minor modifications in order to achieve a low output which could be also be varied.

The robotic spraying of the membrane took place in the area which was scanned immediately in advance. In the given tunnel dimensions with a cross section of about 64 m^2, it was possible to spray sections of 3 m tunnel length covering the entire tunnel contour. The robotic part of the spraying process was the automatic movement of the boom and the nozzle. Feeding of air, water and the output of the product had to be adjusted manually.

The constant speed and smoothness of the spray manipulator movement and the ability to follow the surface topography made it possible for all given points in the scanned area to receive the exact same amount of membrane. These machine parameters had to be defined in advance. This was done in an initial exercise in order to optimize the mechanized part of the application.

When, during the application some irregularities on the surface were encountered, the necessary adjustments of the machine parameters could be carried out online with subsequent immediate response of the machine and consequential best results.

When starting spraying on each shift, one only had to fine-tune the air, amount of water (in order to achieve to correct mixture ratio) and the output of the dry spraying machine. When the crew had gained sufficient experience with the equipment, capacities of approximately 800 m^2 per twelve-hour shift were realized.

4.2.3 *Application of the covering layer of sprayed concrete*

The completion of the composite liner consisted of the final inner layer of sprayed concrete. The minimum thickness of the inner layer sprayed concrete was 4 cm. Steel fibre reinforced sprayed concrete was used for this purpose. This layer was applied after the curing of the membrane, which took 10–14 days under the given temperature, humidity and ventilation conditions.

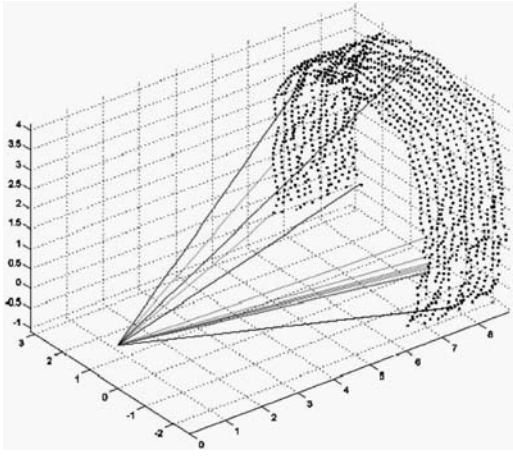

Figure 4. Principal sketch showing a 3D representation of a scan of the tunnel substrate surface prior to the application of the membrane.

Figure 5. Robotic application of the sprayable waterproofing membrane in progress.

The curing state of the membrane was measured indirectly by measuring the hardness of the membrane surface (Shore A hardness). Criteria based on measured Shore A hardness values were specified for the application of sprayed concrete onto the membrane.

4.3 *Quality control issues*

In order to assure that the proper preparations were undertaken and that the actual application of the membrane was done correctly a detailed procedure for the practical works was made. The procedure required the proper preparation works like substrate roughness improvement with sprayed concrete, different surface treatment of seepage points in order to assure feasible conditions for the membrane application.

Furthermore, the details in the application of the membrane were described, in particular how to achieve the correct sprayed thickness on the wall. This included thickness control measurements and the monitoring of the membrane powder consumption. The procedure also specified remedial measures to deal with seepages which occurred through the membrane after application.

5 EXPERIENCES

The composite liner with the sprayable membrane proved to be a successful waterproofing system. The main experience gained was that the importance of preparing the substrate properly cannot be underestimated. It was absolutely essential to have a smooth substrate with a limited roughness in order to achieve a continuous membrane. In this way a continuous regular composite liner was achieved. (Figure 7)

In areas where the waterproofing system was applied only locally in the tunnel contour or in smaller areas, the result was good. No effects of migrating water seepages to adjacent areas causing a possible need for waterproofing in a previously dry area were observed. (Figure 6)

The robotic application of the membrane proved to be cost-effective regarding overall application speed as well as reaching optimum material consumption. With the robotic application a consistent membrane thickness within the intended range was achieved. This again depended much on the substrate quality.

In areas with large substrate irregularities the robotic application could not be successfully completed so an additional application of the membrane with the same robotic equipment in manual-mode together with computerized support had to be done. The areas which were sufficiently treated with drainage measures showed no or only very little need for remedial works.

Some difficulties with the system during the application were experienced. These were mainly seepages penetrating through the lining in areas where a continuous membrane was not achieved during the spray application. This partially resulted in need for remedial local injection works. One important experience is that seepages through the membrane occur within the first day after application. These cases were targeted directly in a simple manner with local injections since the water seeping points in the membrane could be easily found.

Figure 6. Complete tunnel with the composite liner waterproofing system applied locally in one of the walls and half of the crown.

Figure 7. Complete tunnel with waterproofing with the composite liner of sprayable membrane and sprayed concrete in both walls and the entire crown area.

6 CONCLUDING REMARKS

The cost-effectiveness of the waterproofing system with a composite liner with sprayable membrane depends mainly on two main issues; creating a smooth enough substrate and the extent of wet areas which impose a need for wet spot treatment prior to the application of the membrane.

The experienced advantages with robotic spraying definitely favour this application method. Particularly the consistent membrane thickness which can be achieved with the lowest possible material consumption is a significant advantage. High application capacity with low demand on amount of manpower was realized.

ABSTRACT: In Japan, cast-in-place plain concrete has been generally used as the secondary lining of mountain tunnels. In many cases, the small cracks induced by the thermal, autogenous and drying shrinkage were occurred at an early-aged concrete. It can be considered that an overall tunnel stability would not be reduced by this kind of crack, however, in the long term it could cause concrete spalling if cracks run cross one another.

In this study, firstly, the site observations were carried out for investigating the influences of concrete material, construction method and climate on the occurrence of cracks at the tunnels of the Kyushu Shinkansen line (in the southwest area) and the Tohoku Shinkansen line (in the northeast area). Secondly, the specimen tests were performed for observing the temperature and strain of concrete at an early age. Moreover, the model tests of concrete lining were carried out to investigate effects of the factors that detected from site observations. From these results, the methods of controlling crack are proposed and discussed.

1 INTRODUCTON

1.1 *Early-aged cracks on a second lining*

In Shinkansen project, NATM (New Austrian Tunneling method) is mainly used for constructing the tunnel in mountainous area. In this method, cast-in-place plain concrete has been generally used as a secondary lining (Fig 1). In many cases, the small cracks induced by the thermal, autogenous and drying shrinkage were occurred on inner surface (contact with air) at an early age. It can be considered that this kind of cracks would not reduce an overall tunnel stability, but it could cause concrete spalling in the long term if cracks run cross one another and could affect to the safety of a bullet train.

Figure 1. A secondary lining of NATM.

1.2 *Purpose of this study*

In the past, many studies had been carried out to find out the methods of controlling these cracks.

Some of studies focused on the reduction of friction between concrete and ground, because the occurrence of cracks mainly due to difference in strain between inner surface (contact with air.) and outer surface (contact with ground.). As a result, the following methods were developed, and applied widely in Japan.

- Usage of the isolation sheet by placing it between concrete and ground
- Installing of seam controlling cracks

However the above studies were carried out at the beginning of NATM technology that there were few preliminary case studies. Furthermore, the previous reports had a little discussion about the reduction of the thermal, autogenous and drying shrinkages at an early-aged concrete in a quantitative way.

In this study, firstly, the site observations were carried out for investigating the influences of variables on the occurrence of cracks at the tunnels of the Kyushu Shinkansen line and the Tohoku Shinkansen line before operating.

Table 1. Results of site investigation.

Tunnel	Division	Number of span	Ratio of cracks occurred (%)	Month	Temperature	Unit cement content (kgf)	Unit water content (kgf)
A	1	351	12	1∼12	19	271	160
	2	222	19	1∼12	18	273	163
	3	336	38	1∼12	16	273	163
	4	54	13	1∼3, 8∼12	16	276	164
	5	234	24	3∼12	21	272	161
	6	286	22	1∼12	18	279	164
	7	244	59	1∼12	18	298	179
B	1	68	37	2∼11	19	268	162
	2	334	43	1∼12	18	267	160
C	1	57	81	11∼12	–	312	181
D	1	44	39	6∼8	–	312	181
E	1	102	25	1∼12	20	268	155

Next, the specimen tests were performed for observing the temperature and strain of concrete at an early age. Then, the model tests of tunnel concrete lining were carried out to investigate effects of the factors that detected from site observations. From these results, the methods of controlling crack are proposed and discussed.

2 SITE INVESTIGATION

2.1 *Methodology of investigation*

The site investigations focus on the six variables; the ratio of the occurring cracks per span, the month and temperature when placing concrete, unit cement content, and unit water content. They are under concerned because, they have the high possibility to affects the thermal, autogenous and drying shrinkage. The information and data were collected from both northern and southern parts of Japan.

2.2 *Results*

The data of 2,332 construction span (span length = 10.5 m) were collected from 12 divisions of 5 tunnels. Table-1 shows the occurrence of the early-aged cracks in each division and construction variable, and Figure 2 shows the occurrence of cracks per division. The maximum ratio of crack occurrence is 40% and most of all cracks occurred at the tunnel crown.

2.2.1 *Concrete placing month*

The ratio of crack occurrence with month is shown in figure 3 and figure 4. In Tohoku region (table 1, tunnel A and B), the ratio is low in the summer. Whereas, in Kyushu region (table 1, tunnel C, D and E), the ratio is low in October and December.

2.2.2 *Concrete placing temperature*

The ratio of crack occurrence with temperature is shown in figure 5 and figure 6. The ratio was very low when the temperature less than 16°C for Tohoku region (table 1, tunnel A, B). In the case of Kyusyu region (table 1, tunnel C, D, E), the ratio is very low when the temperature is about 22°C.

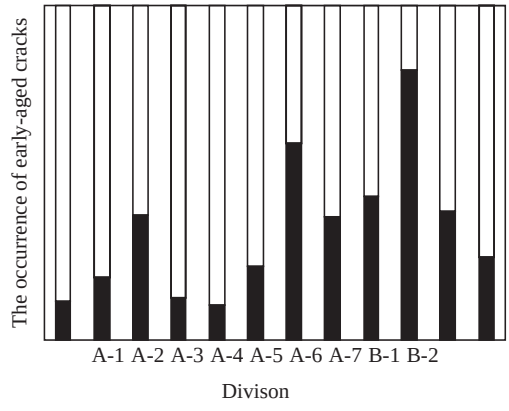

Figure 2. The occurrence of cracks per division.

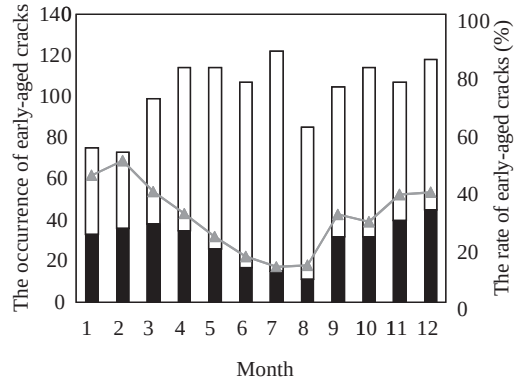

Figure 3. The occurrence of cracks with month in Touhoku region.

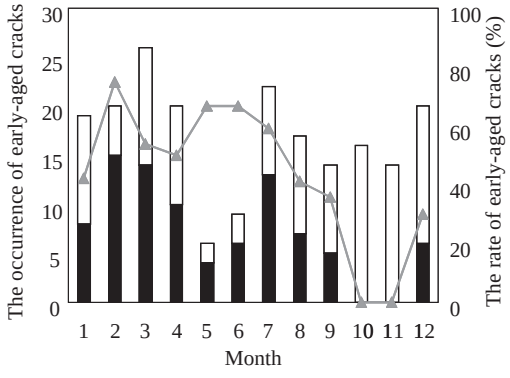

Figure 4. The occurrence of cracks with month in Kyusyu region.

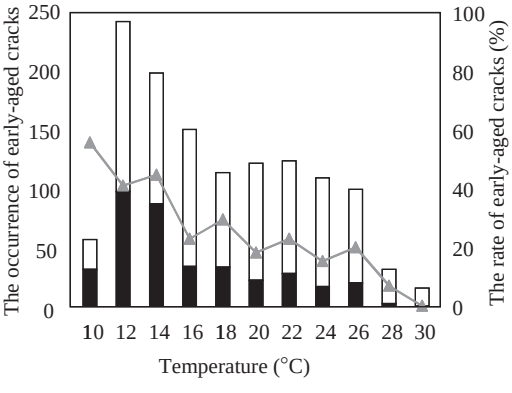

Figure 5. The occurrence of cracks with temperature in Touhoku region.

2.2.3 *Unit water content*

The ratio of crack occurrence with unit water content is shown in figure 7. As the unit water content increases, the ratio also increases.

These investigation results show the effects of the concrete placing month that can be implied to the ambient temperature, placing temperature and the unit water content on the occurrence of crack in tunnel concrete lining. However, there are many unknown factors such as the friction between concrete lining and ground, the amount of shrinkage strain that are very difficult to evaluate by site investigation.

Thus, in order to evaluate and the effects of each factor individually, it is necessary to investigate through the specimen tests and model tests.

3 SPECIMEN TEST

Specimen tests were carried out to investigate the effects of thermal and drying shrinkages on the occurrence of early-aged cracks by neglecting the friction between concrete and ground.

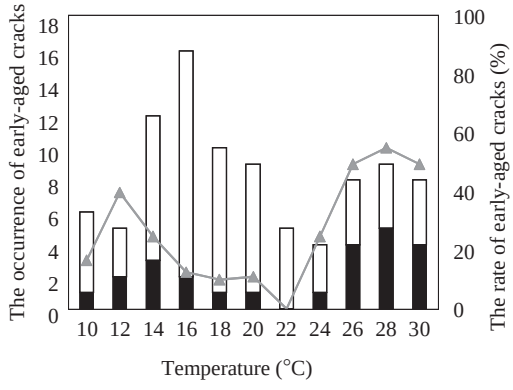

Figure 6. The occurrence of cracks with temperature in Kyusyu region.

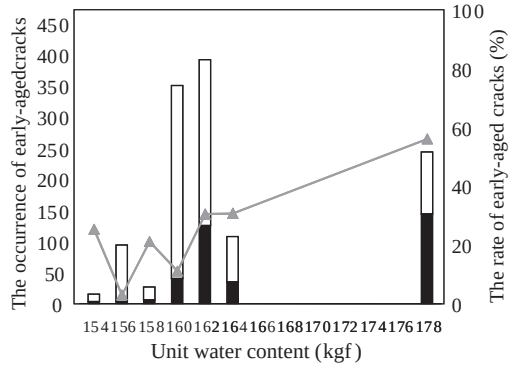

Figure 7. The occurrence of cracks with unit water content.

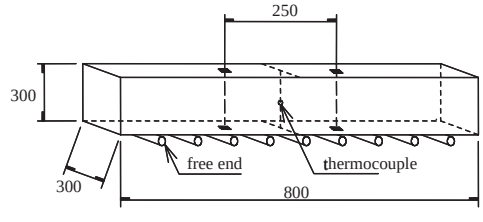

Figure 8. Test specimen.

3.1 *Methodology of test*

Figure 8 shows the specimen which has a pillar shape with 300 * 300 * 800 mm (300 is equal to lining thickness). Strain gauge and thermocouple were installed

Table 2. Mix proportion of concrete specimens.

W/C (%)	s/a (%)	Unit content (kg/m^3) W	C	S	G	Slump flow (cm)
60	48	180	300	847	941	15

Table 3. Test cases.

Case	Drying	Thermal dissipating
①normal	○	○
②No drying	×	○
③Partial drying	○ (only one surface)	○
④Insulation	×	×

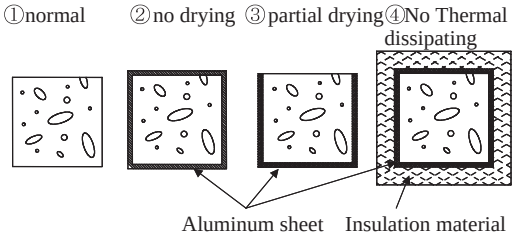

Figure 9. Wrapping conditions of each case.

within the center of specimen. Table 2 shows the mix proportion of concrete.

Table 3 shows the cases adopted in this test and Figure 9 shows image of each cases. Case①is normal type that has drying and thermal dissipating. Case②is no drying type that does not have both drying but has only thermal dissipating. Case③is partial drying type that has only one drying surface, same as the concrete lining. Case④is insulation type that does not have drying and dissipating surface.

All cases were testes under temperature 20°C, humidity 60%, constantly.

3.2 *Results of tests*

3.2.1 *Effects of drying*

Figure 10 shows the strain curves which show effects of drying between Case①and Case②. The strain of Case②is 200μ larger than Case①at about 50-day age. Figure 11 shows the strain curves which show the differences between a drying surface and a non-drying surface drying of Case③. The strain on a drying surface is 200μ larger than the other at about 50-day age.

Comparing with the concrete lining, the drying surface is the inner side of a lining, whereas, the non-drying surface can be implied as the outer side of a lining. Thus, these results show the difference of shrinkage strain between the inner and outer side of a lining that cause the cracks at concrete surface.

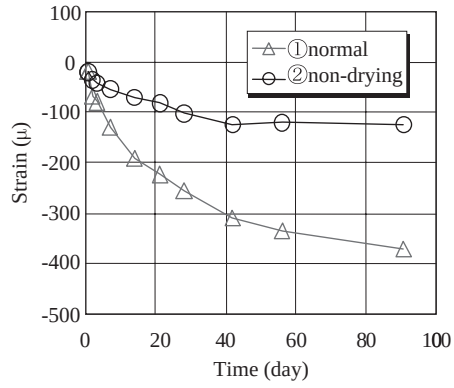

Figure 10. Effects of drying (Case①and Case②).

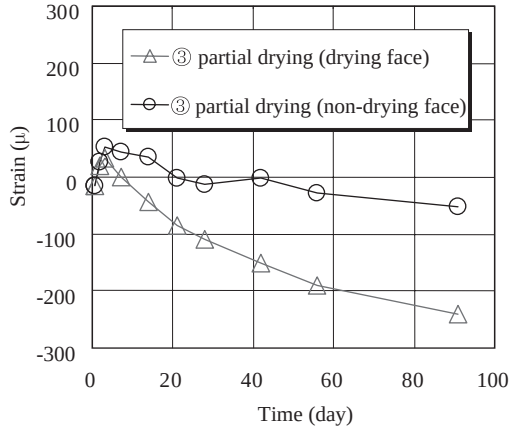

Figure 11. Effects of drying (Case①and Case③).

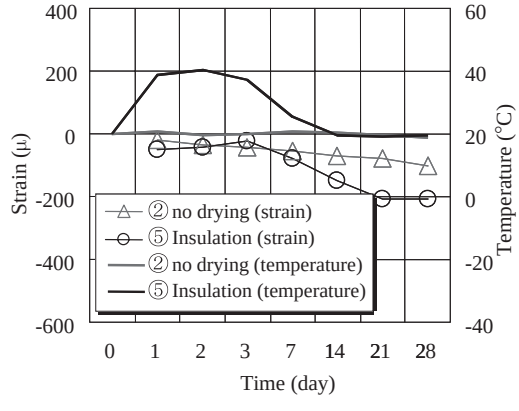

Figure 12. Effects of thermal state (Case②and Case④).

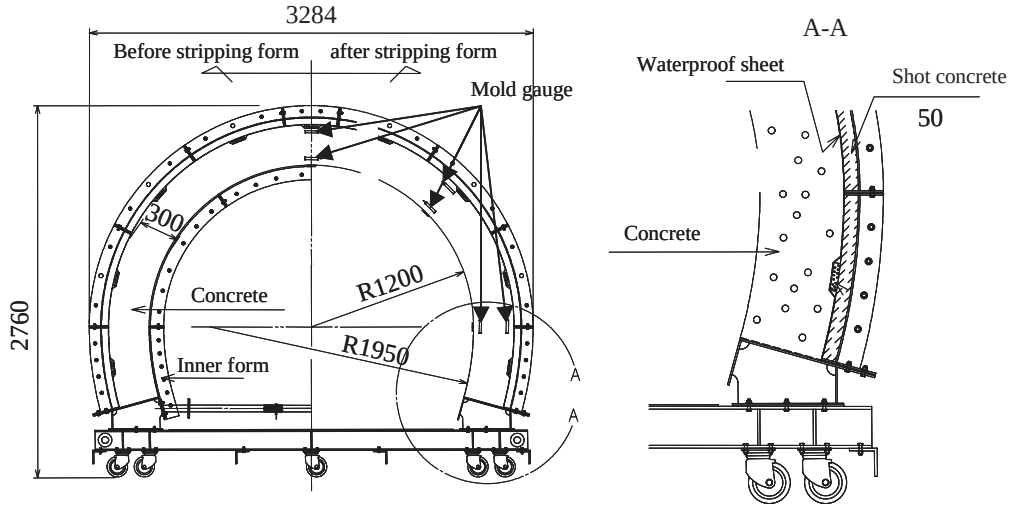

Figure 13. Test piece of tunnel model.

3.2.2 *Effects of thermal state*

Figure 11 shows the strain which show the effects of thermal dissipating between Case② and Case④. The strains of Case④ is 200μ larger than Case② at about 50-day age.

From these results, the outer surface that contacts to a ground were significantly affected by the thermal state while the inner surface that contacts to an air were significantly affected by the drying. The strains at both surfaces differ about 200μ, that is possible to make cracks on concrete lining. Thus it can be concluded that only the thermal and drying can cause the cracks on concrete lining.

Table 4. Test case.

	Material		Condition	
Case	Cement	W/C	Stripping time	Atmosphere
①Normal	Normal	60%	18 h	60%
②Type of cement	Flyash			
③W/C		70%		
④stripping Time	Normal	60%	12 h	
⑤atmosphere			18 h	50%

4 TUNNEL MODEL TEST

To connect the results of site investigation and the results of specimen test and find out the methods of controlling an early-aged crack, the tunnel model test were performed. The test was mainly focused on the following problems.

- The differences of strains between the outer and inner of lining, that show the effects of tunnel shape.
- The differences of construction method and concrete material, that show the relation between drying and thermal dissipating.

4.1 *Methodology of test*

Figure 13 shows the tunnel model that has a horse-shoe shape with 1200 mm and 1950 mm in inner radius and 300 mm in thickness. The mold gauges (combination of strain gauge and thermocouple) were installed at the inner side and the outer side of tunnel crown, springline and 45° from the crown.

Table 4 shows the conditions for each case and Figure 14 shows picture of form. Case①is the normal type that based on the common construction method and normal environments. Case②is the flyash cement type. Case③is the W/C type with high water content and little high concrete placing temperature. Case④is the stripping time type that has shorter time for curing. Case⑤is atmosphere type that was placed in low humidity environment. All of parameters were varied in the range of real tunnel conditions in Japan.

4.2 *Results of test*

4.2.1 *Effects of tunnel part*

Figure 14, 15, and 16 show the strain curves with time of Case①. These results show that outer strain is larger than inner strain at tunnel crown. At the springline, the outer strain decreases and becomes constantly.

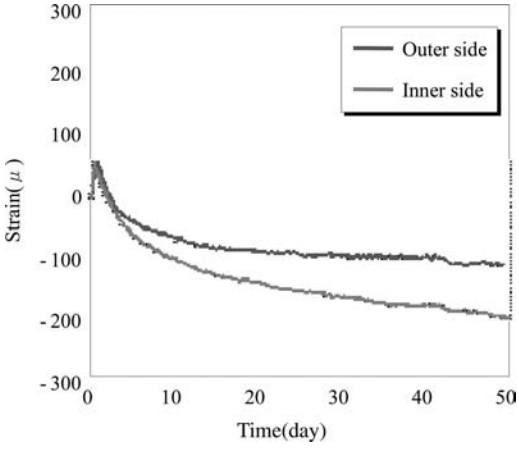

Figure 14. Strain curves at Tunnel Springline.

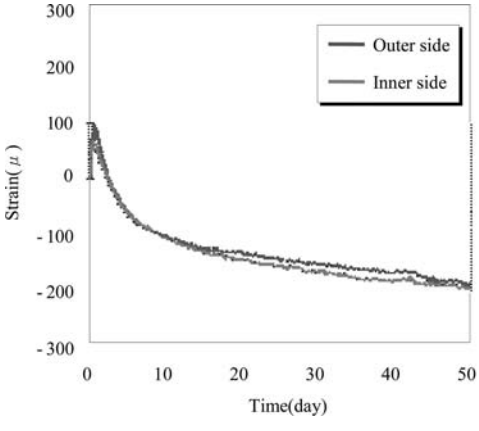

Figure 15. Strain curves at 45° from Tunnel Crown.

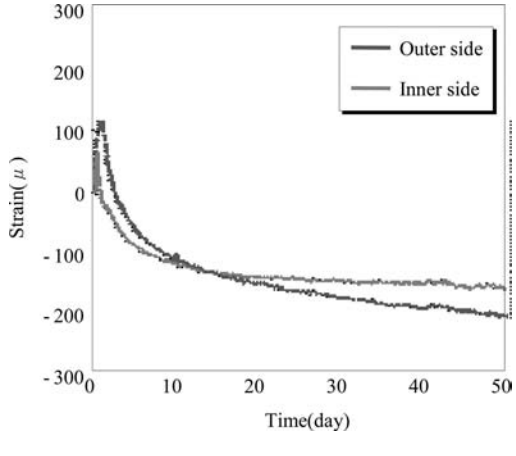

Figure 16. Strain curves at Tunnel Crown.

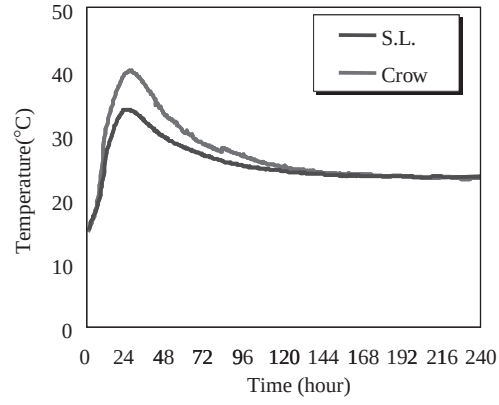

Figure 17. Temperature curves of Case①.

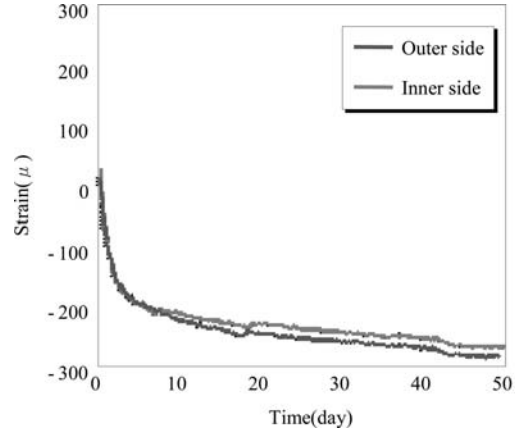

Figure 18. Strain curves of Case③.

Figure 17 shows the temperature curve with time of Case①. This change can be explained at the thermal viewpoint.

The effects of autogenous and drying shrinkage on each part of tunnel lining, do not show the remarkable different. However, about the temperature change, the thermal of hydration increases from tunnel springline to crown.

4.2.2 *Effects of construction method and material*

Figure 18, and 19 shows the strain curves with time of Case③ and Case⑤. The results of Case②, Case④ and Case③ are nearly same and it do not show the remarkable between the inner and outer strain. It can be assumed that there is no remarkable influence on

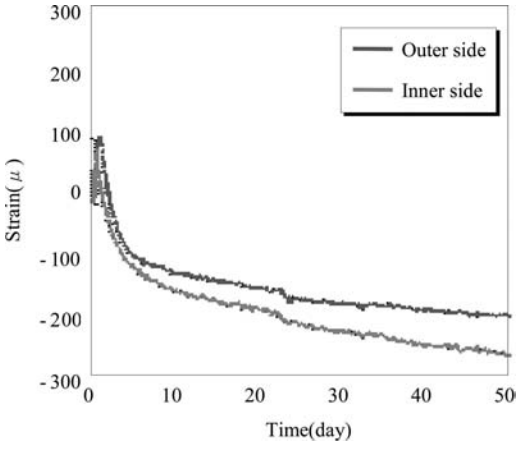

Figure 19. Strain curves of Case⑤.

the occurrence of cracks because both inner and outer sides shrink at the same amount.

For Case⑤, the inner strain is larger than the outer, and that has a possibility to make the occurrence of cracks in this test.

5 CONCLUSION

In this study, site investigation, specimen test and tunnel model test were carried out. The results can be concluded as followings.

- Drying and thermal dissipate have remarkable effects on causing cracks on lining.
- Tunnel crown generally does not have possibility to cause the occurrence of cracks only due to thermal state.
- Only atmosphere, especially the humidity, has the possibility to affect the occurrence of cracks due to drying.

Now, we plan to develop the method of control atmosphere, and the in-situ test to identify its effects.

ABSTRACT: A fire in the current shield tunnel on a highway or railway would cause explosive spalling of concrete lining due to high temperature that mostly result in significant damages to the tunnel structure. The conventional fire protections for the tunnel structure have utilized separate ceramic panels being attached or spraying fireproof materials on the surface of the lining. However, the ceramic panels are rather costly, and the spraying induces poor working conditions. As a substitute, the concrete segments with enhanced fireproof performance have been developed by the use of short fiber resin. A series of fire tests were conducted to verify their fireproof performance. This paper mainly reports on the results of fire tests.

1 INTRODUCTION

A fire in the tunnel on a highway or railway would cause breakages of concrete lining due to high temperature that mostly result in significant damages to the tunnel structure. The conventional fireproofing methods for shield tunnels have so far employed second lining over the primary lining, or utilized fireproof coating being pasted or sprayed to the surface of primary lining, any of which protects the primary lining by the use of additional fireproofing materials. However, these conventionl foreproofing methods have been not so beneficial with respect to econical efficiency, working efficiency and construction periods as to satisfy every requirement for the current construction conditions.

Thereupon, this study, encouraged to impose fireproof performance on concrete segments themselves, has focused on the Polyacetal (hereinafter PA) fiber in addition to the PP that conventionally developed with reference to the AFR concrete employed to practical use of very high strength concerete. And the fireproof performance, manufacture and repair of short fiber reinforced concrete has been experimentally examined on the basis of the concerete used in the RC segments.

The elementary experiments have investigated difference of heat-induced breakages according to the existence of short fiber resin and distribution of temperature. The experiments for practical use have then implemented a series of heating tests with the employment of the specimens reflecting the situation in actual use and manufacture process, which provided an examination of characteristics and performance required to the practical design guide. This paper presents the experimental results that facilitate new development of fireproofing structure for shield tunnels.

2 ELEMENTARY EXPERIMENTS

The favourable effect of AFR concrete has been already verified with the very high strength Concrete (design strength $> 80\,\mathrm{N/mm^2}$) for building construction. However, the elementary experiemts were conducted in the necessity of examining acquisition of similar effect even for the segments showing a low design strength and different mix proportions, and occurrence of heat-induced breakage under the RABT heating curve.

2.1 *Testing methodology*

a) *Materials and mix proportion in base concrete*
Table-1 demonstrates the mix design of base concrete.

Table 1. Mix design of base concrete.

Maximum size of coarse aggregate(mm)	Slump (cm)	Air content (%)	W/C (%)	Sand percentage s/a (%)	Unit weight (kg/m^3)				
					Water	Cement	Fine aggregate	Coarse aggregate	Additive

Table 2. Type and quantity of concrete and heating test.

Mix design	Fiber	Specimen for heating: Mixing Ratio of fabric *1 (%)	Specimen for heating: Small speciment*2	Specimen for heating: Panel
N36.4	–	–	3	2
N36.4-PP0.1	PP	0.1 (1.0 kg/m^3)	3	–
N36.4-PP0.3	PP	0.3 (3.0 kg/m^3)	3	2
N36.4-PP0.5	PP	0.5 (5.0 kg/m^3)	3	1
N36.4-PA0.1	PA	0.1 (1.5 kg/m^3)	3	–
N36.4-PA0.3	PA	0.3 (4.5 kg/m^3)	3	2
N36.4-PA0.5	PA	0.5 (7.5 kg/m^3)	3	2

*1 ( ) indicates the mixing weight per 1 m^3 of concrete (mass)
*2 plain concrete specimen of which the end face is 100×100 mm, 400 mm in length.

b) *Type of concrete and specimen*
7 types of concerete were used in the experiments according to the type of fiber and its mixing ratio as shown in Table-2. Using this concrete, the specimens for heating test, compressive strength test and water content test were prepared.

For the heating test, small specimens with a dimension of $10 \times 10 \times 40$ cm and panel-type specimens as shown in Figure-1 were employed. The small specimens were manufactured without reinforcement, whereas the panel-type specimens were reinforced with single rebar of D10@100 (the depth from the surface to the center of distribution reinforcement: 50 mm).

c) *Procedure for heating test*
The heating tests were conducted with two sets of specimens grouped by curing ages of 36 days and 41 days due to limited space of the heating furnace. The heating temperature was given following the RABT temperature curves for tunnel fire test. According to the capacity of heating furnace, the maximum temperature was maintained for a duration of 25 minutes which had been readily proved to be valid for inspection of heat-induced breakage. Figure-2 illustrates the RABT curves employed to the tests. Also, the figure simultaneously demonstrates the internal temperature of the member (40 cm in thickness, no heat-induced breakage) that was calculated based on the Fininte Difference Scheme.

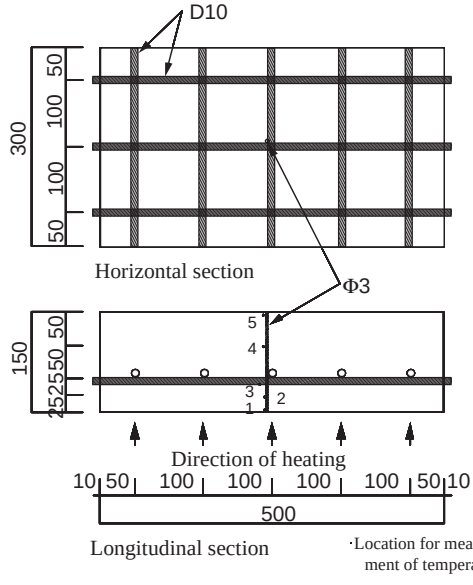

Figure 1. Panel-type specimen for heating.

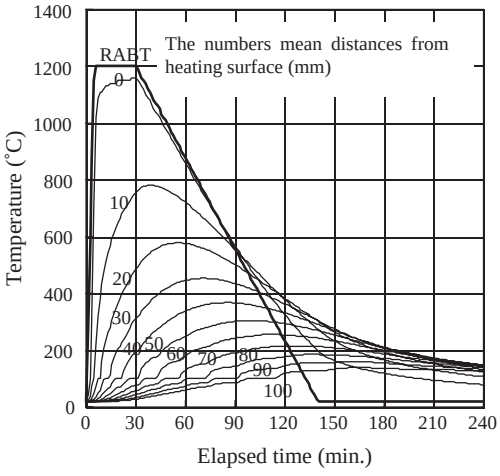
Both of the end parts 5 cm long from each end of a specimen in the direction of long side are located right above the supporting frame for the specimen, those parts are not directly heated. Hence the heated area of the specimen with a dimension of $10 \times 10 \times 40$ cm (hereinafter $10 \times 10 \times 40$ cm specimen) actually becomes 10 cm $\times$ 30 cm, and that of the panel-type specimen becomes 30 cm $\times$ 40 cm.

The heating temperature and internal temperature of specimen were measured during the heating test. (the internal temperature is limited to panel-type specimen). Besides, the depth of heat-induced breakage was also inspected by the use of a vernier caliper before and after the heating test. As for the $10 \times 10 \times 40$ cm specimen, the depth of heat-induced breakage was measured across the heated area (10 cm $\times$ 30 cm) in the form of grid whose vertical and horizontal spacings were identically 2 cm, as for the panel-type specimen, it was measured at a spacing of 5 cm in both the horizontal and vertical directions over the heated area (30 cm $\times$ 40 cm). Photo-1 thru 2 show the situation of specimen after the heating test.



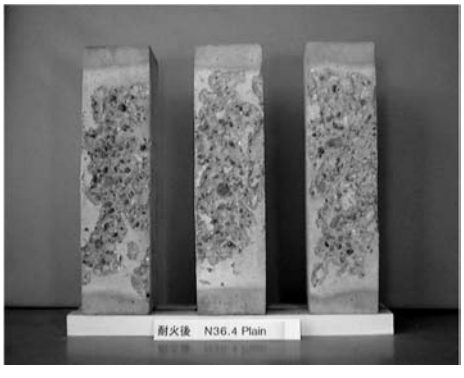


Figure 2. RABT temperature curves and internal temperature of panel specimen (Calculated).

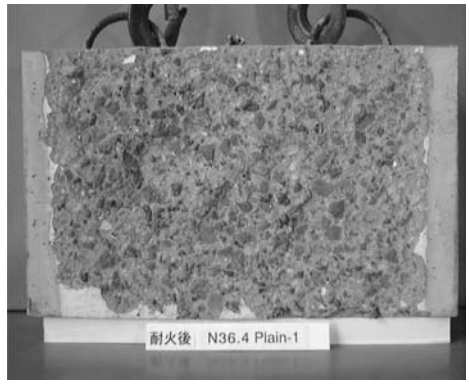

<Without fiber mixed (Mixed design:No.36.4)

Photo 1. Situation after heating test with small specimen.

2.2 *Summary of elementary experiment*

In order to obtain the elementary data regarding fireproof performance (resistance against heat-induced breakage) of AFR concrete for tunnels, a series of heating tests had been implemented with the various specimens prepared by changing mixing ratio of the PP and PA fiber reinforcement to the base concrete with a W/C value of 36.4% that was usually adopted to RC segments in shield tunnels. These testing results provided some findings as follows;

– As for the specimens without fiber reinforcement, heat-induced breakage occurred in all the specimens, regardless of the existance of steel reinforcement in the concrete, showing greater depth of the heat-induced breakage with the reinforced panel-type specimen which resulted in the maximum depth of 13.5 mm.
– No heat-induced breakage could be observed in the specimen prepared with the mixing ratio of 0.1∼0.5 vol% for PP fiber and PA fiber.
– Since the experimental results acquired from this study had shown perfect prevention of heat-induced breakage, it might be valid to cut down the mixing ratio of fiber reinforcement.
– The FDM calculation provided quite suitable estimation of the internal temperatures up to the depth of 50 mm from the heated plane in a concrete specimen, whereas those at deeper depths appeared to become greater than the calculation due to the effect of excessively high heat transmission of the embedded steel rod.

<Without fiber mixed (Mixed design:No.36.4)

Photo 2. Situation after heating test with panel specimen.

3 EXPERIMENT FOR PRACTICAL USE

Product of concrete segments for shield tunnels need to rely on the machinery facilities belonging to the manufacturer. Again, once the segments got assembled in underground space, they would become subjected to large axial forces which are unfavourable to heat-induced breakage.

Therefore, the experiments were set to focus on productability of the segments in conjunction with the facilities at a factory and achievement of the optimum mixing ratio under the axial loadings. In addition, the vital necessity of establishing the repairing methods for application of the AFR concrete to practical use imposed investigation into its repairing performance.

Thereupon, a series of heating tests had been conducted using the specimen manufactured to be subjected to axial forces at a factory. Additionally, the reheating tests were employed to examine the fireproof performance for both of the repaired and

Photo 3. Addition of short fiber at factory facilities.

Photo 4. Compaction of specimen at factory facilities.

non-repaired segments. In addition to the heating tests, situation of heat-induced breakage during being reheated, distribution of internal temperature of a specimen, compressive and adhesive strengths of repair material before and after heating, neutralization depth before and after heating and neutralization depth by accelerated neutralization were measured.

3.1 *Testing methodology and testing specimen (situation of manufacture; Photo-3 to 4)*

Four specimes with an identical dimension of 600 mm wide, 900 mm long and 550 mm thick were prepared as shown in Figure-3. And four mixing ratio of fiber were PA0.1, 0.2, 0.3%, PP0.1% were adopted. Totally 20 thermo couples were installed at every specimen as indicated in Figure-4. As initially heated, the specimen was subjected to 13 N/mm^2 of compressive stress by means of the PC strands. After the initial heating had been terminated, the reheating test was executed with the PC strand eliminated in light of safe core sampling.

Photo-5 thru Photo-6 show the situation of heat-induced breakages in the specimens mixed with PP0.1%, PA0.1, 0.2, 0.3% in conjunction with axial

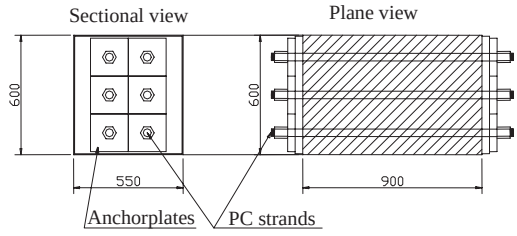

Figure 3. Dimension of specimen.

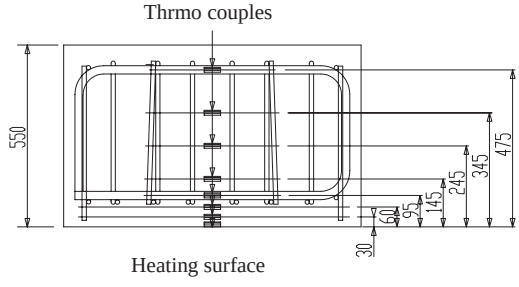

Figure 4. Installation of thrmo couples.

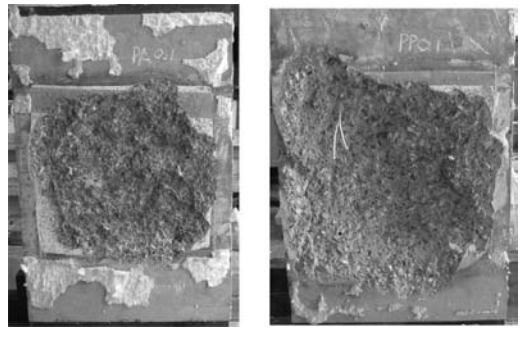

Photo 5. Heat-induced breakages under axial loads (1).

loads. Photo-7 shows the situation of heat-induced breakages after reheating.

3.2 *Summary of experiments for practical use*

At first, summarized are the mixing ratio of short fiber in case of factory manufacture and charge of axial force which was the primary goal of these experiments.

It appears that the mixing ratio up to 0.3% hardly makes any influence on mixing process in factory facilities, even while producing excellent quality. No further machinery is thus required to production of segements. Besides, the mixing ratio of 0.2% enables prevention of heat-induced breakage, which can lead to enhancement of fireproof performance of segments.

Secondly, it appeared from the reheating tests that even the non-repaired specimen hardly created

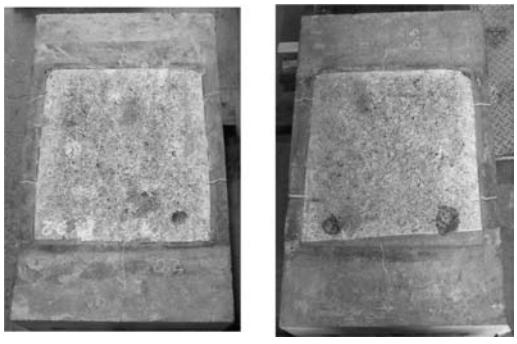

Photo 6. Heat-induced breakages under axial loads (2).

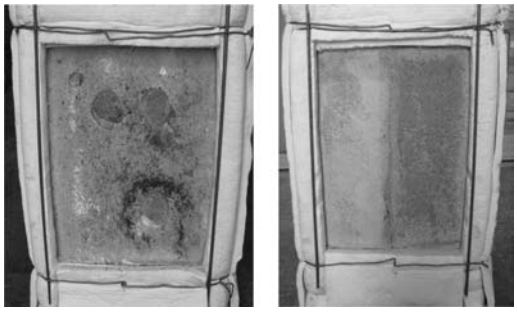

Photo 7. Heat-induced breakages after reheating (None).

heat-induced breakage, and the strength of concrete kept exceeding the design strength at the depth deeper than 25 mm, even under reheating.

In order to prevent decrease of the compressive strength of concrete due to fire in a structural member, an additional thickness of 25 mm that reflects a round of coated cover is considered to be in need. This additional thickness extends to increase of cover thickness above the primary reinforcement by 25 mm which facilitates restraint of increasing internal temperature at the reinforcement, and then enhancement of fireproof performance as a sturctural member. On the contrary, it also appeared that the porous surface caused by heating, made the rate of heat transmission increased so as to make the maximum temperature even higher.

In case that the specimens got repaired, they all hardly showed heat-induced breakage. And their internal temperature appeared to reach no more than 150°C at the depth of reinforcement, the insulating performance of repair materials was also favourably evaluated.

Comparison of the two repair materials informed that the mortar mixed with 0.2% of PA could achieve greater compressive and adhesive strengths, and better performance in service against the inner pressure from surrounding ground and wind pressure due to traffic.

As a result, the following findings have been newly recognized in this study;

- In addition to the polyprophylen fiber well known for its restraining effect against heat-induced breakage from the existing studies, the optimum mixing ratio for poly acetyl fiber has been suggested.
- The manifacture of short fiber-mixed concrete has been successfully verified.
- The serviceability of segments having suffered fire has been clearly evaluated in terms of the existence of repair.

4 CONCLUSIONS

The elementary tests and tests for practical use in this study have successfully demonstrated that the segments employing short fiber-mixed concrete could exhibit excellent fireproof performance and be supplied simply as factory products holding a required fireproof performance with the aid of the existing segment manifactureres. In addition, the applicability of the segment to repair works after a fire has become worthy of consideration in this study.

It can be noted that improvement of fireproofing performance of the segments themselves has considerable influence that the segments enable saving the cost as well as the construction time through eliminating the process of fireproofing panel installation. For the purpose of practical application, despite an additional cover of 25 mm required to avoid reduction of strength due to the increasing temperature of heated surface, given the thickness of currently used fireproofing panel saying 50 mm, the use of fireproofing segments might further lead to saving of the excavated area of tunnels.

Not a small number of shield tunnels is currently being planned for expansion of motor roads passing underground space in Japan. The authors hope that the useful findings and suggestions obtained from this study shall be effectively incorporated to construction of such tunnels from now on.

Basic studies on earthquake-resistance of tunnel linings

H. Miyabayashi, T. Tosaka & A. Isogai
Japan Railway Construction, Transport and Technology Agency, Tokyo, Japan

K. Yashiro & T. Aruga
Railway Technical Research Institute, Tokyo, Japan

ABSTRACT: New Austrian Tunneling Method (NATM) has been increasing in unconsolidated ground and shallow covering by progress of construction technology. In general, tunnel has well seismic resistant as compared to other structures on the ground. However, it is a fact that tunnels are susceptible to a large-scale damage where the seismicity is great and the distance is not far from the focus of seismic activity. On the other hand, there is no evaluation method, which can explain the deformation behavior and the mechanism of suffering quantitatively when earthquake. Therefore, we prepared model tests of 1/4 scale of existing tunnel lining. Moreover, we performed a numerical simulation of model test by non-linear FEM analysis. As a result, we confirmed that lining does not collapse but only cracked, and the analysis evaluates ductility of lining.

1 INTRODUCTION

In October 2004, the Mid Niigata Prefecture Earthquake occurred and many railway tunnels suffered damages (see Fig. 1). Some of the tunnels located adjacent to a focus of seismic activities suffered especially serious damages. Eventually two or more months were required to restore the tunnels that adversely affected reopening of a Shinkansen line or conventional lines. In railway system where many tunnels exist, it is an essential subject to minimize earthquake damages to tunnels. On the other hand, due to recent rapid progress of tunnel construction technology, the New Austrian Tunneling Method (NATM) has increased for unconsolidated grounds and shallow covering in diluvium, which are susceptible to suffer from earthquake damage. For example, NATM tunnels constructed at 60 percent in approximately 80 km of total length on Tohoku-Shinkansen under construction (see Fig. 2). Most of them constructed at shallow covering in the ground that is composed of diluvium. Conventional mountain tunnels are normally constructed in stabilized bedrock, and they are seismic resistant structures compared with other structures on the ground. However, it is a fact that even such mountain tunnels, where the seismicity is great and the distance is not far from a focus of seismic activities, are susceptible to large-scale damages. In order to suppress severe damage of the tunnels to the minimum, it is important to evaluate correctly a mechanism of damages and an earthquake resistance of tunnel, and to make them reflect suitably for design, construction,

Figure 1. A railway tunnel suffered damage by the Mid Niigata Prefecture Earthquake.

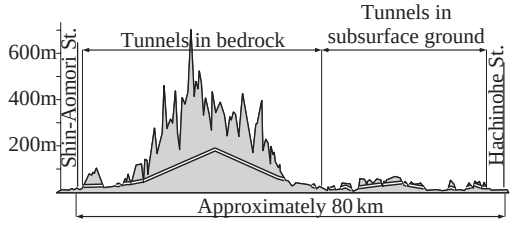

Figure 2. Railway profile of Tohoku-Shinkansen.

and maintenance. However, the method has not suggested that enables to explain deformation behavior or suffering mechanism quantitatively, although suffering conditions by earthquake of the mountain tunnels are experientially arranged. Therefore, we performed

model tests and numerical analyses to elucidate behavior of NATM tunnel lining in the unconsolidated ground and shallow covering.

2 ASSUMPTION OF A DAMAGE MECHANISM

The unconsolidated ground and shallow covering is comparatively soft with ordinary bedrock, thus the ground deformation tends to grow by amplifying earthquake activities. It is conceivable that shearing deformation adversely affects NATM tunnels under such ground condition. The deformations are identical to cut and cover tunnels or shield tunnels. Since a unit-weight of a mountain tunnel is less than one of surrounding ground or equivalent, and hence the structure does not cause a natural vibration. The relative displacement of surrounding ground controls behavior of tunnel during earthquake. It is imaginable that cracks occur on shoulders of tunnel lining due to such shearing deformation (see Fig. 3).

It is preferably to perform an experiment of seismic damages in soil. It considers the interaction between ground and tunnel by modeled tunnel lining and ground because the tunnel is an underground structure. However, the experiment has some problems that are many uncertainties of modeled ground. On the other hand, the NATM tunnel lining is a method of construction applicable after the tunnel become stable by the interaction of ground and tunnel supports, thus an ordinary loading is inactive on the lining in the stable ground. In addition, waterproof membranes or isolation sheets separate the lining and shotcreting. For that reason, the experiment is possible that a seismic loading acts only on a modeled lining without modeled ground. The shearing deformation acts on the modeled lining with one-point loading in horizontal direction in air, based on the above concepts.

3 MODEL TEST OF 1/4 SCALED TUNNEL LININGS

3.1 *Outline*

The object of the test model is to clarify the deformation characteristic and destruction behavior of tunnel lining. A tunnel section for the test model is on the assumption of a double track tunnel driven on Tohoku-Shinkansen Line (see Fig. 4). The test lining model was made as a 1/4 scale of the existing tunnel as shown in Figure 4 by the constraint of the size of the test apparatus. Fig. 5 shows its size and Fig. 6 shows an image of the lining model.

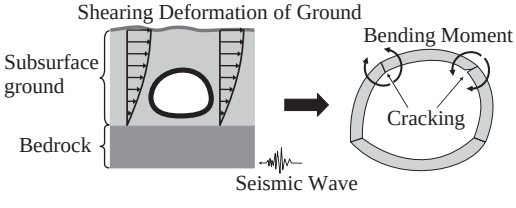

Figure 3. Seismic behavior of tunnel in unconsolidated ground and shallow covering.

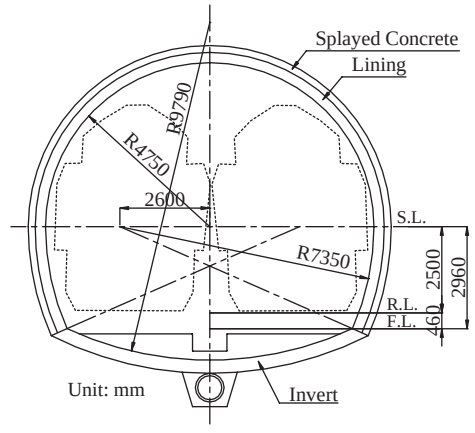

Figure 4. Section of Tohoku-Shinkansen.

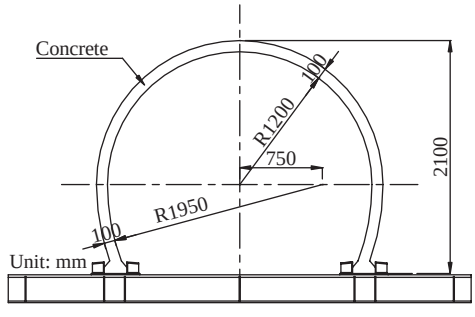

Figure 5. Size of the lining model.

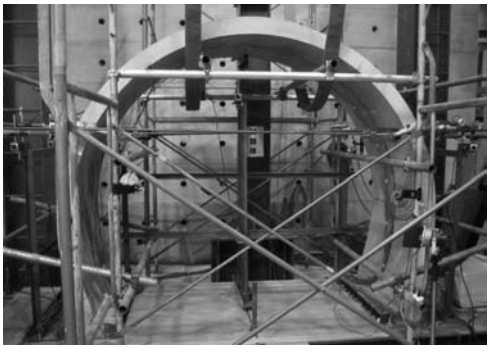

Figure 6. A lining model.

3.2 *Test method*

Table 1 lists the test cases. Case-1 is a test of lining model made of plain concrete as a basic case. Case-2 is a test of lining model made of fiber reinforced concrete that polypropylene fiber mixed. The mixing rate of polypropylene fiber is generally 0.5% per unit volume. However, the mixing rate was 1.0% per unit volume by upper bounds of construction in this test.

The composition of concrete for the lining model was identical to one of the existing lining. Only, coarse aggregates of small grain sizes were used because the thickness of the model lining was 100 mm. Table 2 lists the material properties of the models.

The loading method was alternate loading, thus it assumed the shearing deformation of tunnel lining by ground displacement during earthquake. Tow loading plates were set on outside of lining model and 2/3 of height of the model. The loading plates connected a reaction wall with threaded steel bars. The displacement of lining model was controlled at 0.2 mm/min with rotating the steel bars. Figure 7 shows the location of the loading plates. The specific way was as follows: the displacement was added in one direction still the first crack occurred on the lining model. After it cracked, the displacement was added to right and left alternation to increase gradually amounts of displacement. The displacement of one-step was the displacement ($=\delta$) when the first crack occurred. In the following step, displacement changed to $\pm\delta\times1$, $=\pm\delta\times2$, $\pm\delta\times3\cdots$. Figure 8 shows a conceptual diagram of loading step. We visually identified the progressive of crack, and measured the loading and displacement of the crown to make a load-displacement curve (see Fig. 7).

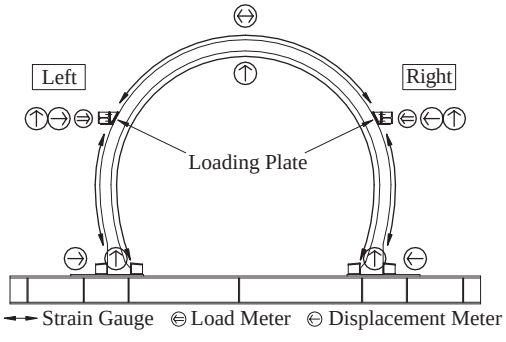

Figure 7. Loading plates and measurement items.

3.3 *Cracking situation*

(1) *Case-1: plain concrete*
At STEP-1 ($\delta=4$ mm), when a load was added rightward, a bending crack occurred on inside of the lining at the left upper loading plate and another crack occurred on the outside of lining at the upper right loading plate (see Table 3). At STEP-2 ($\delta=-4$ mm), when loading was added leftward, the crack closed at the upper right loading plate, and a new crack occurred on the opposite side of that crack. From STEP-3 to STEP-8, the situation of cracks repeated the same as Steps 1 and 2. The situation shows as follows: the number of cracks did not increase; the crack width became large as the displacement of the crown increased. Finally, loading was added until STEP-12 ($\delta=-40$ mm). The lining model has kept the shape of arch and it has not collapsed although it was greatly deformed.

(2) *Case-2: In case of fiber reinforced concrete*
At STEP-1 ($\delta=4$ mm), when a load was added rightward, a bending crack occurred on inside of lining at the right loading plate. It was not passing-through crack. At STEP-2, when loading was added leftward, other bending crack occurred on inside of the lining at the left loading plate. Furthermore, the first crack closed at upper the right loading plate, and new crack occurred on the opposite side of that crack. From STEP-3 to STEP-8, the situation of cracks repeated

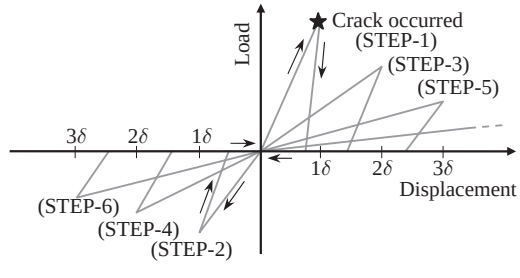

Figure 8. The conceptual diagram of loading step.

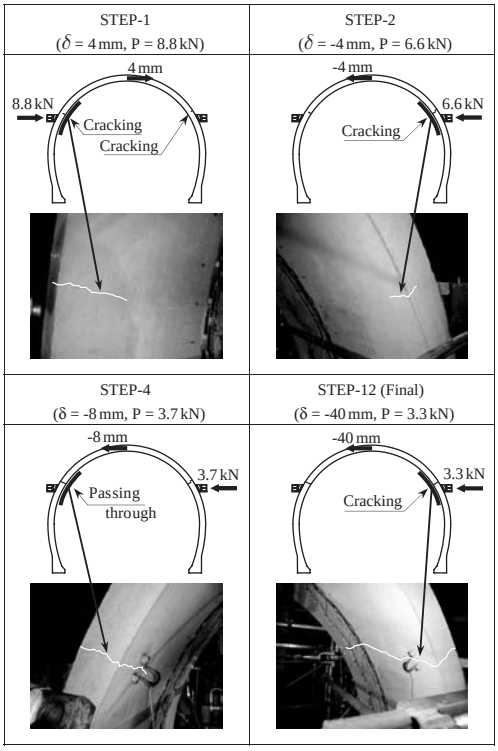
Table 3. Cracking situation on Case-1.



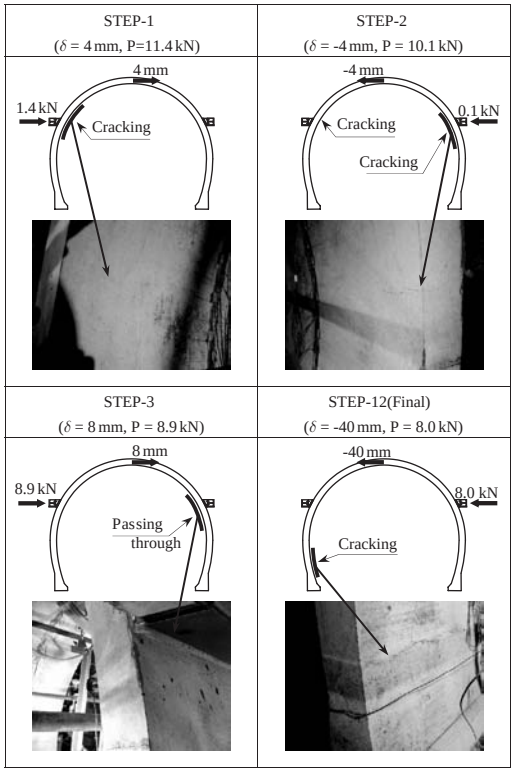


Table 4. Cracking situation on Case- 2.

the same as Steps 1 and 2. Finally, loading was added until STEP-12 ($\delta = -40$ mm). The lining model has kept the shape of arch and it has not collapsed although it was greatly deformed.

3.4 *Load-displacement curve*

Figure 9 and Figure 10 respectively show Load-Displacement Curves of each case. As shown in the Figures, the horizontal displacement of crown of the lining is as shown as a horizontal axis, and the load value at loading point is as shown as a vertical axis. In both cases, it is the maximum load simultaneously with the first crack occurred. The cracking load was approximately 10 kN in both cases. In generally, even when the reinforcement fiber are mixed with concrete, the tensile strength that is the strength for cracking is almost same compared with the plain concrete. In this test, the fracture mode was the flexural and tensile failure by pure bending of a member in both cases. For the reason, it is conceivable that the cracking load as a structural system is almost equal. After cracking, the decline of load and the increase of displacement occurred suddenly in the CASE-1. On the other hand, they occurred gradually in the CASE-2. It is conceivable that the reinforcement fiber (polypropylene fiber) improved the ductility of the lining.

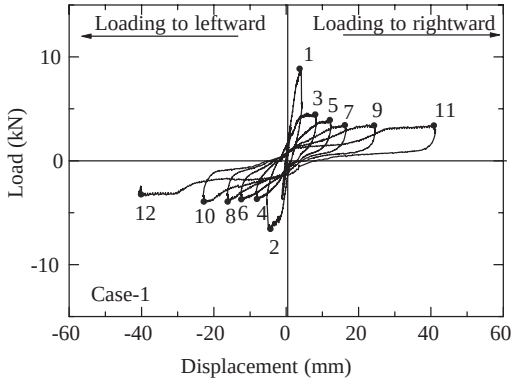

Figure 9. Load-displacement curve (Case 1).

3.5 *Test result*

(1) *Case 1: plane concrete*

The model lining was deformed approximately 40 mm (actual tunnel conversion 160 mm). As a result, the lining model itself did not collapse in brittleness or any concrete flaking did not occur, although the bending crack took place only. Therefore, we observed that

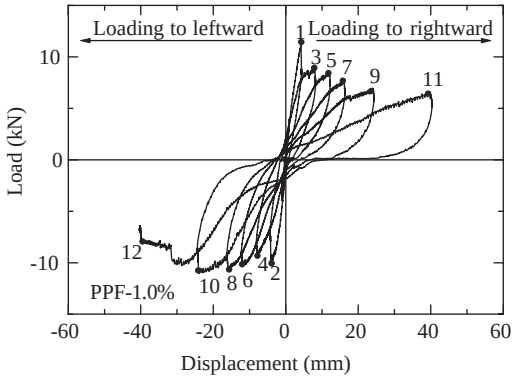

Figure 10. Load-displacement curve (Case 2).

the effect of shape of arch enable the model lining to withstand the large deformation.

(2) *Case 2: fiber reinforced concrete*
The model lining was deformed approximately 40 mm (actual tunnel conversion 160 mm). As a result, the lining mode itself did not collapse in brittleness or any flaking of concrete did not occur, although the bending crack took place only. The crack load was similar to the plain concrete. Therefore, we observed that the effect of mixing of reinforcement fiber improved the ductility of the lining model compared to the plain concrete.

4 SIMULATION ANALYSIS OF MODEL TEST

4.1 *Outline*

The object of numerical simulation is to confirm the behavior of a model test by numerical analysis method in consideration of material nonlinearity. We performed the numerical simulation for the fiber reinforced concrete. Because, it is difficult to analyze appropriately the deformation behavior of the lining made of plain concrete. The loading declines suddenly after cracking, in case of the plain concrete. The numerical simulation has used Non-Linear FEM code WCOMD that took account of the occurrence and progress of crack. Softening behavior of concrete element after cracking is expressed by several parameters: a tensile strength, a cracking strain (εtu) and a softening coefficient (c). Figure 11 shows the conceptual diagram of softening behavior after cracking. This code is applicable mainly for a structure analysis of reinforced concrete. The softening coefficient is 0.4 in case of common RC structure. When the softening coefficient is large, it tends to become large the extent of the decline in stress. However, the softening coefficient has not been defined in case of the fiber reinforced concrete, and thereby we

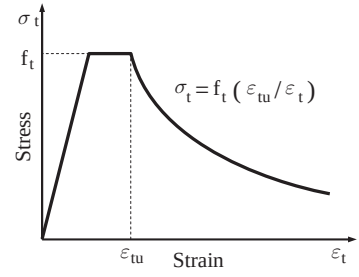

Figure 11. Conceptual diagram of softening behavior after craking.

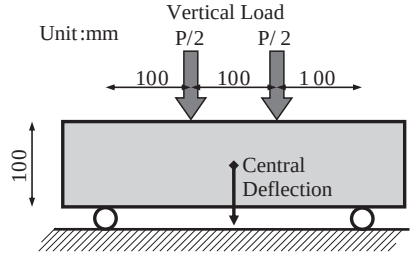

Figure 12. Conceptual diagram of the element test.

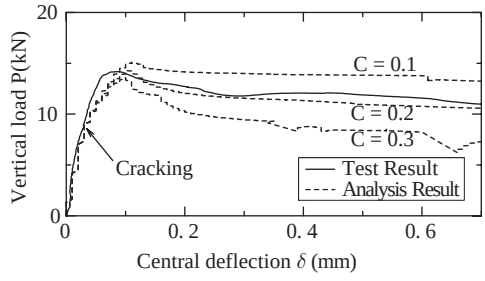

Figure 13. Results of identification analyses.

performed bending test of fiber reinforced concrete and identification analysis to determine the softening coefficient.

4.2 *Element test and identification analysis*

We performed the element test to obtain the load-displacement curve to identify the softening coefficient. Figure 12 depicts the conceptual diagram of the element test. The size of the test specimen was $100 \times 100 \times 400$ mm (loading span: 300 mm) as a shape of beam. The height 100 mm was identical to the thickness of the model lining. The material and strength of concrete was also identical to the model test. Figure 13 shows the load-displacement curve as the result of the element test.

As a result, we performed the fiber reinforced concrete that the bending moment declined slowly

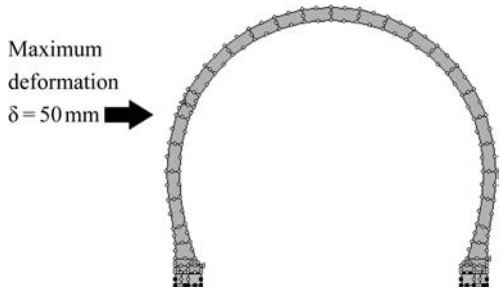

Figure 14. Analysis model.

Table 5. Parameter for analysis.

Compressive strength	$f'_c = 24.9(N/mm^2)$
Tensile strength	$f'_t = 0.23f'c^{2/3} = 1.96(N/mm^2)$
Cracked Strain	$\varepsilon_{tu} = 102.9f'^{1/6}_c = 175\mu$
Softening coefficient	$c = 0.2$

and sustained to some extent after cracked. Next, we performed the identification analysis with that load-displacement curve. Figure 13 shows the results of the element test and the identification analysis. The result of the identification analysis shows that the softening coefficient is between 0.1 and 0.3. When it is 0.2, the analysis result is equivalent to the test result. Accordingly, $C = 0.2$ applies the softening coefficient in this study.

4.3 *The analysis model and material properties*

Figure 14 shows the analysis model. Each element has eight nodes element. This analysis used the joint element on the both feet of lining to allow rotation of the feet. Table 5 lists the material properties for analysis. In addition, the numerical simulation applied a pushover analysis in one direction, although the model test used alternate load.

4.4 *Result of simulation analysis*

Figure 15 indicates the result of numerical simulation of the model test. The Figure shows the test result of a comparison of both results. By comparing the two graphs in Figure 15, the analysis result almost corresponds to the test result. As a result, WCOMD enable to express appropriately the decline of load of lining after cracked. However, the rigidity to the peak in the analysis result, it is in a small tendency as compared with the test result. It is similar to the identification analysis by the element test. The cracking displacement of analysis result was smaller than the one of test result. It is conceivable that the rigidity of the analysis result decreased earlier than the one of the test result.

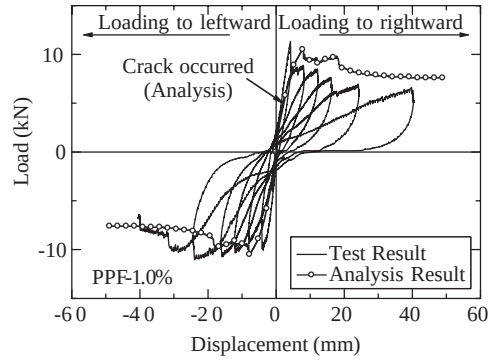

Figure 15. Load-displacement curves.

5 CONCLUSIONS

(1) *Model tests of 1/4 scaled tunnel linings*
Under this test condition, even the lining made of plain concrete did not collapse, although cracks occurred under large shearing deformation. From the previous instances, the deduced shearing deformation is approximately 100 mm when an earthquake occurred. To convert it into the model is approximately 25 mm. The lining of an existing tunnel will only crack, and it will not collapse during seismicity consequently. In addition, to mix reinforcement fibers with concrete improve the ductility of the lining.

(2) *Numerical simulation of model test*
When the softening coefficient used for the analysis of WCOMD is $C = 0.2$, the analysis result is equivalent behavior of fiber reinforced concrete after cracked. WCOMD is possible to analyze behavior of lining made of fiber reinforced concrete under shearing deformation during earthquake.

6 ASSIGNMENTS

We verified that the progress of crack on the lining and the failure mode of the lining during seismicity by the model test. We are preparing to analyze the behavior of lining in ground deformation during an expected earthquake. It is to examine the seismic resistant properties of an existing tunnel and to apply fiber reinforced concrete to an existing tunnel. We will also examine a suitable method to analyze occurrence of cracks on lining constructed of plain concrete.

A study on the seismic design methods for precast concrete lining (PCL)

Du-Hwa Lee, Yeong-Tae Choi & Dong-Hyun Kim
Sambo Engineering Co. Ltd, Seoul, Korea

Byung-Wan Jo
Hanyang University, Seoul, Korea

ABSTRACT: A method of assembling and installing the precast concrete lining (PCL) at the spot in factory was developed and invented in Norway. Earthquake behavior of PCL is different from that of extrude concrete lining (ECL) because it is installed apart from excavation line. Accordingly, we carried on the shaking table tests with one fifth reduced structure model for dynamic behavior analysis of PCL. We found out, through comparing and analyzing the shaking table tests for numerical results, that it is reasonable to apply connecting condition between PCL panels to internal hinge. Stress of PCL is stable at the level of acceleration (0.154 g) provided by the national earthquake criteria but unstable in max acceleration (0.3 g) in case of shallow tunnel depth (less than 1.0D).

1 INTRODUCTION

The construction of road and railway increased for fundamental facilities and improvement of line alignment. Having mountainous landscape, Korean tunnel construction is processed by NATM. The concrete lining in NATM do a primary role of supporting earth pressure by a part of tunnel structure, durability and maintenance of beautiful view. But extrude (cast in place) concrete lining method has some problems, such as construction capability, long-term durability also crack occurrence, increase instability by remained water pressure. As a result, precast concrete lining (PCL) method has been developed in Norway to overcome these problems. PCL method is a part of NMT (Norwegian Method of Tunneling) that uses shotcrete and rockbolt in eternal supports on good rock. PCL method installs PC (Precast) instead of cast in place concrete lining. At the time when PCL method was invented in Norway, there was no study on earthquake resistance design. But as the consideration of earthquake increases recently, Korea needs to research the behavior of PCL during earthquake and develop earthquake resist design from these results to adopt PCL method.

Accordingly, we carried out the shaking table tests with one-fifth reduced structure model for dynamic behavior analysis of PCL. The dynamic behavior of PCL is expected to be different from that of extrude concrete lining (ECL), because PCL is installed apart from excavated surface. We adopted modeling technique comparing the results of shaking table test with numerical analysis. Earthquake resistance capacity of PCL is evaluated from numerical analysis for various conditions. And we evaluated the applicability of simple analysis, comparing simple structural analysis (pseudo dynamic analysis, response spectrum analysis) with accurate analysis (time history analysis).

2 PCL METHOD

NMT is a new tunneling method that uses shotcrete and rock-bolt by eternal supports which adopts precast panel that is made in factory instead of extrude concrete lining of which thickness is about 30∼40 cm. The features of NMT are shown in figure 1 that support

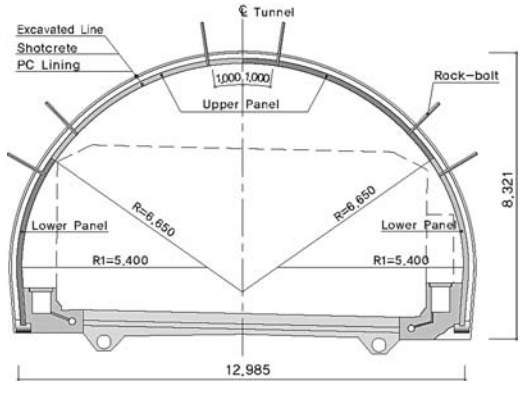

Figure 1. Draft of PCL (Highway tunnel).

good rock with first support (shotcrete, rock-bolt) and then install precast panel. Precast panel performs a role of surfacing in tunnel supporting self-weight and additional facilities.

PCL method is economical and provides good constructional ability because this method uses precast panels that are made in factory. But joins between panels are inevitable. PCL endures self-weight, windy load that occurred by vehicles, collision load, roof fall load, and so on in normal time. But PCL shows complicated behavior during earthquake because PCL is installed apart from tunnel surface. During earthquake, inertia force of PCL is expected to play an important role and we consider stress transfer in joints between panels. Because of these reasons, simple structural analysis is not capable to analyze earthquake behaviors of PCL.

3 EVALUATION METHODS OF EARTHQUAKE RESISTANCE CAPACITY OF PLC

Evaluation methods of earthquake endurable capacity of PCL are divided into two parts.

3.1 *Test schemes*

3.1.1 *Modal test*

Modal test is the method that obtains dynamic properties of structural system from the dynamic results, by applying dynamic forces to structure. Transfer function or Response function can be calculated from the known applied force and measured response results. Then dynamic properties of structure are calculated from obtained modal variable. Modal test is usually used in analysis on resonance of upper-structures, so it is not suitable to analyze dynamic properties of underground structures.

3.1.2 *Pseudo dynamic test*

Pseudo dynamic test obtains similar results with dynamic test by analyzing static test results. This test enables to grasp structural dynamic properties performing static tests. After applying static load corresponded with earthquake wave, the evaluation of dynamic properties, i.e. structural acceleration, velocity etc., by use of measured responsible force. The disadvantage of this method is that it does not simulate soil-structure interaction.

3.1.3 *Shaking table test*

Shaking table test is the method that evaluates dynamic properties of structure applying earthquake force to a real scale or a reduced model on shaking table. This method is used for determine dynamic properties of upper structure (bridge, architecture, etc), underground structure (tunnel), embankment, dam and retaining wall generally. Shaking table test is better for evaluating soil-structure interaction effect during earthquake than pseudo dynamic test and modal test. Therefore, this paper adopts shaking table test for understanding dynamic properties of PCL.

3.2 *Numerical analysis method*

3.2.1 *Simple analysis method*

Simple analysis method is divided into pseudo dynamic analysis and response spectrum analysis. Pseudo dynamic analysis is suitable for earthquake resistance design of upper structure. In the case that inertia force is an important roll for earthquake. Static load which is converted from inertia force of structure is added to structure, and we analyze structure behavior but don't consider the change of SSI (Soil Structure Interaction) and acceleration according to depth. Assumption of response spectrum analysis method is that deformation of underground structure is induced by deformation of outskirts ground. From this assumption, we can calculate displacement by analyzing response spectrum and apply the displacement to structure compulsively to evaluate stress of structure. This method is more exact than pseudo dynamic test but does not represent structure behavior according to time variation and SSI.

3.2.2 *Time history analysis*

Time history analysis method shows the most precise results and can analyze liner, nonlinear behavior of structure during earthquake. But it is not economical method because calculation takes a long time. Time history analysis method is divided into time history method (direct integration method, mode superposition method) and frequency domain analysis method. Time history analysis is the method that input time history earthquake wave to calculate dynamic characteristics of structure, can consider nonlinear behavior and mode damping.

4 EVALUATE DYNAMIC BEHAVIOR OF PCL BY SHAKING TABLE TEST

4.1 *Similitude rule for reduced model*

We executed an experiment by reducing model of highway 2 lanes tunnel section to analyze behavior of PCL during earthquake and applied similitude rule for manufacturing. Roscoe (1698), Kagawa (1978) and Iai (1989) proposed two important concepts. First, it is mechanical behavior of model to represent prototype, as shown in figure 2. We made use of stress-strain relationship that is applied similitude rule with a similitude ratio to evaluate the behavior of prototype from that of model (Iai, 1889). Second, ground and structure are considered not separate but as one. Eq (1)∼(3) is about equilibrium equation and constitution equation of ground, Eq (4)∼(5) is equation that proposed

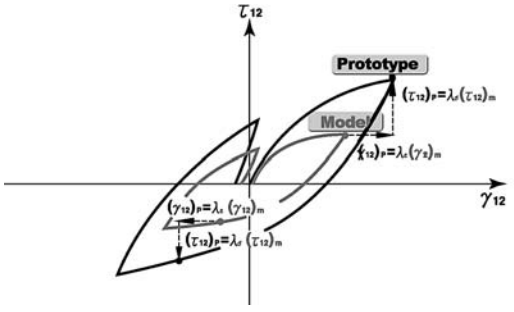

Figure 2. Stress-strain relationship between prototype and model.

similitude ratio for each parameter from relationship of ground and structure that are combining governing equation.

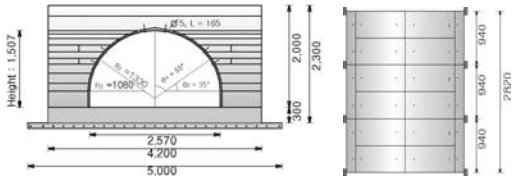
$$L^T f + \rho g = \rho u'' \quad \text{(Equilibrium Eq.)} \tag{1}$$

$$d\varepsilon = L\,du \quad \text{(Strain)} \tag{2}$$

$$d\sigma = Dd\varepsilon \quad \text{(Constitution Eq.)} \tag{3}$$

$$EI\frac{\partial^4 n^T u}{\partial n^4} + \rho_b n^T u'' - \rho_b n^T g + n^T Sf = 0 \tag{4}$$

$$EA\frac{\partial^2 t^T u}{\partial s^2} + \rho_b n^T u'' - \rho_b n^T g + t^T Sf = 0 \tag{5}$$



In this thesis, we adopted similitude ratio 5 consideration of shaking table size and tunnel scale. And Iai's similitude rule is chosen because soil structure interaction is an important factor. Type III among Iai's similitude rule is applied in this thesis because we cannot manufacture the model that has similar density of tunnel outskirt ground.

4.2 *Resource and manufacturing reduced model*

We manufactured reduced model applying type III among Iai's similitude rule.

4.2.1 *PCL panel*

In the case when PCL panel is made of concrete, the thickness of lining is so thin that it is not able to manufacture the lining. Therefore, aluminum is chosen to satisfy flexibility ($EI = 2.03 \times 109 \mathrm{N \cdot mm^2}$) of the model, it is easy to assemble and install, besides, ductility is so high that it can represent soil-structure interaction exactly. Connection of PCL panels completely separates longitudinally and upper panel leaves lower panel simply. As a result the connection of prototype reappears exactly. The 2 strain gauges are adhered on every crown, shoulder part and side wall in lower panels to measure stress and strain of PCL.

a. Front view b. Plan view

Figure 3. Model.

Table 1. Shaking table test results (Unit : Strain $\times 10^{-6}$).

Wave	PGA	Crown	Shoulder	Side	Rock-bolt
El Centro	0.1 g	17	20	13	9
	0.2 g	19	22	14	10
	0.3 g	30	32	22	16
	0.35 g	34	40	28	20
Artificial	0.15 g	22	24	12	11
Northridge	0.1 g	16	20	11	7
	0.2 g	18	20	13	10
	0.32 g	28	34	26	18

4.2.2 *Rock-bolt*

Rock-bolt supports PCL panel by connecting PCL ground. It also transfers earthquake wave to PCL panel during earthquake. Steel rod is used to manufacture model for shaking table test by material of rock-bolt. In this thesis we used steel rod that is reduced by one fifth to execute more exact test.

4.2.3 *Ground*

PCL is installed in good ground condition (more than hard rock), so relative displacement in environs ground of tunnel almost do not occur. Therefore timber is applied to represent environs ground of tunnel as shown in figure 3. Timbers are tightened not to move separately but to behave together.

4.3 *Test conditions*

Input earthquake waves are artificial (0.154 g) and measured waves are El Centro (0.35 g) and Nothridge wave (0.32 g). Artificial wave agrees with Korean design criteria which PGA (Peak Ground Acceleration) is 0.154 g. El Centro wave is the earthquake that occurred in California and its predominant period is from 0.08 seconds to 0.85 seconds. Northridge wave is the earthquake that occurred in Los Angels and its predominant period is form 0.18 seconds to 0.32 seconds.

4.4 *Test results*

In the case input acceleration is over than 0.2 g, strains of PCL panel and rock-bolt increased rapidly

(figure 4). The reason is the effect of inertia due to PCL mass is small below 0.2 g, but the effect of PCL inertia is so important that stress of PCL panels and rock-bolts grow up rapidly over 0.2 g which increases ground acceleration. PCL is weaker that extrude concrete lining for strong earthquake. It needs attention in earthquake endurance design.

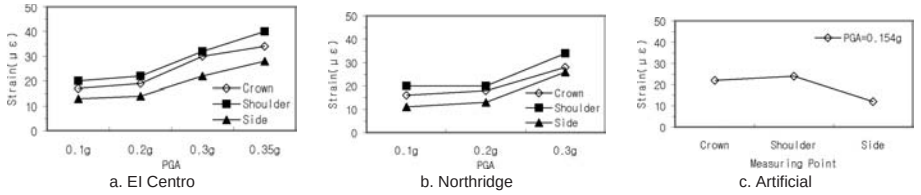
5 EVALUATE OF PCL BY NUMERICAL ANALYSIS

We studied connection condition between PCL panels comparing shaking table test results and numerical analysis. And we evaluated earthquake resistance capacity of PCL by performing numerical analysis for tunnel depth, earthquake waves.

5.1 *Analysis conditions*

We performed numerical analysis with highway 2 lanes tunnel section that is applied in shaking table test. Analysis conditions are same as that of shaking table test. Additional condition is tunnel depth change i.e. 1.0D, 1.5D, 2.0D (D: tunnel diameter). We adopted transmitting boundary condition to avoid reflecting input waves on boundary of model. Numerical analysis programs are AFIMEX 2D, PENTAGON 3D that can analyze non-linear behavior. Other analysis conditions are shown in Table 2.

5.2 *Connection condition of PCL*



Connection condition between PCL panels can affect PCL behavior in earthquake, so we chose most proper condition comparing shaking table results with 2D, 3D numerical analysis results. As shown in figure 5, stress of PCL occur higher in fixed condition than in internal hinge approximately and internal hinge condition show similar results with shaking table test results. This is a reason that PCL panels move separately because PCL is connected panel to panel that is different from extrude concrete lining. Therefore it is reasonable that connection condition of PCL panels is applied to internal hinge in the case of analyzing dynamic behavior. We take 2D, 3D numerical analysis applying internal hinge condition to estimate earthquake resistance of PCL.

5.3 *2D, 3D dynamic behavior of PCL*

Applying internal hinge condition, we performed 2D, 3D numerical analysis. Figure 6 shows relationship of 2D and 3D results. Correlation of 2D and 3D is very high ($R^2 = 0.78$) and 2D results is about 24% higher than 3D. This is the reason why resistance force is estimated lower than 3D because 2D analysis can't consider longitudinal behavior of PCL like 3D analysis.

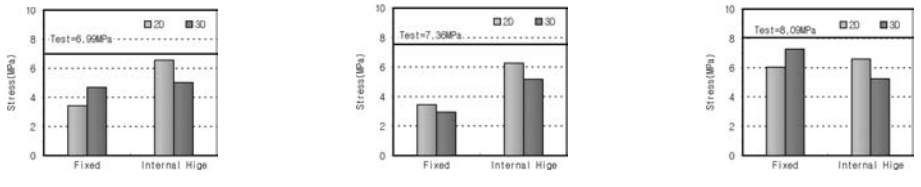


Table 2. Analysis conditions.

	Thickness (m)	Unit weight (kN/m^3)	Elastic modulus (MPa)
PCL	0.15	24.5	27,468
Shotcrete	0.05	23.1	24,525
Rock-Blot	D25	68.7	206,010
Ground	–	24.5	5,600

a. El Centro b. Northridge c. Artificial

Figure 4. Max. response of PCL(Shaking table test).

a. El Centro b. Northridge c. Artificial

Figure 5. Comparison between shaking table test and numerical analysis.

But 3D behavior can be estimated from 2D analysis because of high relationship, Therefore 2D analysis is chosen to evaluate earthquake resistance capacity of PCL in this thesis.

5.4 *Earthquake resistance capacity of PCL*

5.4.1 *Dynamic behavior of PCL*

As shown in figure 7 max. moment, shear force and axial force tend to decrease as tunnel depth increases. This is why behavior of ground amplified that of PCL by connecting rock-bolt. That is to say that inertia force of PCL is main factor for earthquake because PCL panels are installed apart from ground. Therefore stability of PCL increases as tunnel depth increases. The behavior for artificial wave is similar with that of El Centro, the decreasing ratio of stress grows with depth increasing for Northridge wave. It shows that properties of these waves are similar. For Northridge wave, in the case of max. acceleration and tunnel depth of 1.0D, PCL stress is over the allowable stress level. But PCL stress is below the stress for the other conditions. PCL is unstable for shallow tunnel depth (below 1.0D) and strong earthquake. Therefore we consider countermeasures for these conditions.

5.4.2 *Dynamic behavior of shotcrete*

Moment and shear force of shotcrete decreases as tunnel depth increases. This trend is a reason that confining stress of ground that increases in proportion to tunnel depth restrains oscillation of shotcrete and ground. This result coincide with underground structures are affect for earthquake little.

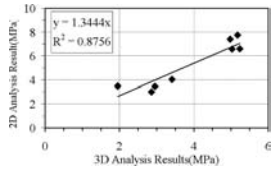

Figure 6. Relationship between 2D and 3D.

5.4.3 *Dynamic behavior of Rock-bolt*

Stress of rock-bolt must be considered at exposed part between shotcrete and PCL panels. So we evaluate stress of rock-bolt at the exposed part. Compressive and tensile stress of rock-bolt decrease with tunnel depth increment as shown in figure 9. Similar with shotcrete, it is estimated that confining stress restrains relative displacement of ground with tunnel depth increment.

Behavior of PCL is similar with rock-bolt but different from shotcrete somewhat. That's why movement of shotcrete is affected directly by ground because shotcrete adheres to excavated surface, PCL and rock-bolt installed apart from ground are affected by inertia force than ground deformation on the other hand. Therefore not only the effect of outskirt ground but also dynamic behavior due to inertial force are considered for earthquake resistance design of PCL. Analysis method that is able to represent these phenomena is applied to evaluate capacity of PCL.

Rock-bolt rust when exposed for a long time. Accordingly rock-bolt needs constant management (epoxy coating etc).

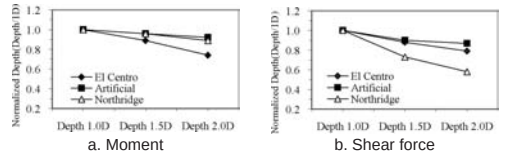

Figure 8. Stress of shotcrete(0.514 g).

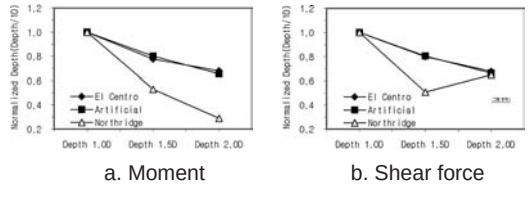

Figure 9. Stress of rockbolt.

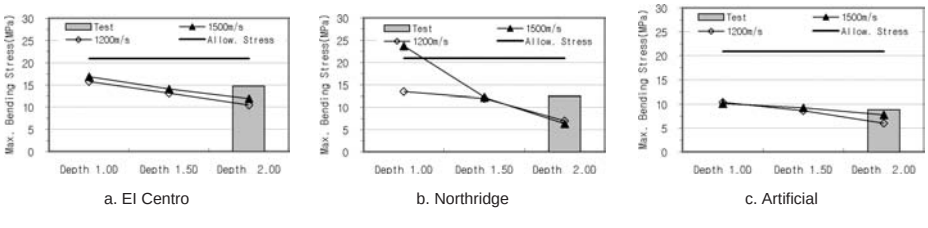

Figure 7. Behavior of PCL according to tunnel depth at max. acceleration.

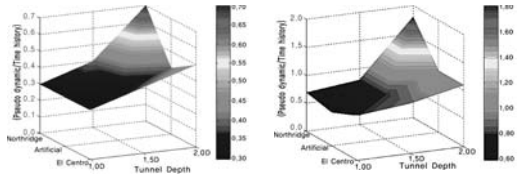
6 APPLICABILITY OF SIMPLE ANALYSIS METHOD FOR EARTHQUAKE DESIGN

Simple analysis method is divided into pseudo dynamic analysis and response spectrum analysis. Pseudo dynamic analysis is applied in the case that inertia force is important, response spectrum analysis considers dynamic response characteristics. Simple analysis method has disadvantage not to represent SSI but is so simple that is used broadly. Therefore we study applicability of simple analysis method for earthquake resistance design comparing accurate analysis methods.

6.1 *Pseudo dynamic method*



Comparing pseudo dynamic with time history analysis, moment in PCL is about 1.3 ∼ 1.0 times higher in time history than pseudo dynamic method. Shear force is 1.0∼2.4 times higher in pseudo dynamic method. This trend is a reason that pseudo dynamic method can't reproduce dynamic behavior of ground to analyze fully. Axial force of rock-bolt is higher than time history analysis approximately. That is, if tunnel depth is deep (over 1.5D), pseudo dynamic analysis is conservative design except moment. But pseudo dynamic method can't estimate stress of PCL partly and in detail, so pseudo dynamic method is not reasonable for earthquake resistance design. Figure 10 shows normalized stress ratio (coefficient = pseudo dynamic method/time history method).

6.2 *Response spectrum analysis method*

Response spectrum analysis is used to evaluate earthquake resistance of PCL. Design response spectrum is shown in figure 11.

Comparing response spectrum and time history method, moment is about 3∼4 times in time history method higher than in spectrum method. Shear force is about 1.4∼2.0 times higher in response spectrum method like pseudo dynamic method. That is, if tunnel depth is deep (over 1.5D), pseudo dynamic analysis is conservative design except moment. But response spectrum method can't estimate stress of PCL partly and in detail, so this method is not reasonable for earthquake resistance design. Figure 12 shows normalized stress ratio (coefficient = pseudo dynamic method/time history method)

As shown above, simple analysis methods show conservative results in deep tunnel depth but PCL is unstable for moment in 2.0D. Therefore simple analysis method is not applicable for earthquake design inspite of deep tunnel depth. Stress of PCL itself and connecting part are so important that time history method is reasonable to analyze behavior of PCL for earthquake.

7 CONCLUSION AND FURTHER STUDIES

In this thesis, we evaluated dynamic behavior of PCL that is different from general concrete lining of tunnel. Performing and comparing shaking table test and numerical analysis, earthquake resistance capacity of PCL is studied and applicability of simple analysis methods is evaluated. Summary of studies is as follows.

(1) Comparing shaking table test with one fifth reduced model with 2D, 3D numerical analysis results, it is reasonable to apply internal hinge to modeling condition between PCL panels.
(2) From results of various numerical analysis with internal hinge, stress of shotcrete and PCL decrease according to tunnel depth increment. It is a reason that earth pressure increase with tunnel

depth so increasing earth pressure confine oscillation of ground. Variation of PCL stress is larger than shotcrete. It is because inertia force plays an important roll in PCL installed apart from ground so ground behavior amplifies PCL behavior.

(3) Performing numerical analysis for various conditions, PCL is stable for Korean criteria (0.154 g) but unstable over 0.3 g in the case that tunnel depth is below 1.0D. Therefore minimum tunnel depth must be over 1.0D to satisfy stability requirement of PCL for strong earthquake (acceleration is over 0.3 g).

(4) In applicability of simple analysis methods, moment for simple analysis methods is lower than time history method. Therefore simple analysis method underestimates PCL stress for earthquake, this method is not proper to apply earthquake resistance design.

Design of inner lining at the Gotthard Base Tunnel, approach for the evaluation of loads, the different types of lining

R. Stadelmann, A. Pfeffer & Z.Q. Wei
Amberg Engineering AG, Regensdorf-Watt, Switzerland

ABSTRACT: The following article deals with the approach for the determination of rock loads based on hazard scenarios, rock pressure and additional design loads that have to be taken into account for the inner lining of the Gotthard Base Tunnel. The decisions for single and double lining as well as cost-reductions were discussed.

1 THE GOTTHARD BASE TUNNEL

1.1 *The purpose*

The 57 km long Gotthard Base Tunnel (GBT) is a key part of the project AlpTransit for the new high speed railway through the Alps in Switzerland. The designed maximal train speed is 200 to 250 km/h so the route must be very flat with gradients no higher than 1%. It is currently under construction and will be put into operation in 2015.

1.2 *The design*

The tunnel consists of two parallel single-track tubes, which are connected by crosscuts at about 300 m intervals. Because it is very long and very deep with a mountain cover up to 2500 m thus the detailed geology is mostly unknown, which gives rise to too many uncertainties in the design and greater risks during the construction: unexpected bad geology, instability, the safety of workers and equipment, logistic plan, construction time and overall costs.

In order to reduce these uncertainties and risks, the tunnel was divided into five sections from the North to the South: Erstfeld, Amsteg, Sedrun, Faido and Bodio. It is being driven simultaneously from both portals Erstfeld and Bodio and from three intermediate points of attack by access tunnels in Amsteg and Faido and by combined access tunnel and two vertical shafts.

Sedrun and Faido sections each has a multifunction station (MFS) with complicated tunnel and adit systems due to the requirements of construction, emergency, ventilation and technical niches.

The two main tunnels have a circular profile and most of them are excavated by Tunnel boring machines. The method of drill and blast is used for the two stations as well as the section of the main tunnel in Sedrun due to expected bad geology in Sedrun.

The major part of the tunnel is designed with double shells. The inner lining is normally not reinforced. The approach for the evaluation of lining loads will be discussed using the examples.

2 OBSERVATION METHOD AND EFFECTIVE LOADS OF ROCK MASS

The loads on the tunnel lining are composed of rock pressure and additional mechanical, physical and technical effects. But the critical part for tunnel stability is the rock pressure and therefore must be correctly determined.

2.1 *Observational method*

The geology in the section Faido is completely different from the prediction. The rock mass contains complicated boundaries of different rocks, folds, a few joint sets and fault zones. Even with many core drillings and boreholes ahead of tunnel faces, the prediction of the rock mass behaviour ahead of the tunnel faces was not very good. In order to obtain realistic geology, it is required to observe tunnel faces and make records. Figure 1 is an example of tunnel face sketch and description at Tm 1152.5 of the Emergency Tunnel West in the MFS Faido. From the sketch, one obtains not only the detailed geology but also the likely loosening rock pressure in the area around this tunnel cross section. With the regional geology and the information from core drillings and boreholes, one tries to get a three dimensional geological structures like rock boundaries, foliations, joint sets, fault zones and groundwater conditions as well as some insight about tectonic activities. These are fundamental information for predicting the short and long term behaviour of the rock mass.

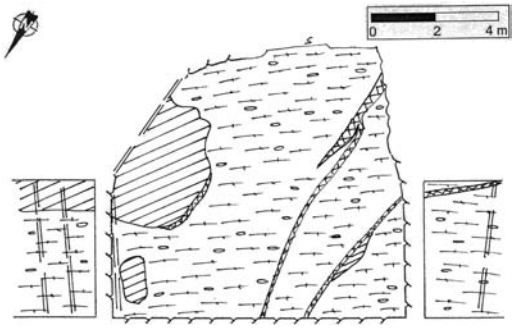

Figure 1. An example of tunnel face sketch and description at Tm 1152.5 of the Emergency Tunnel West in the MFS Faido.

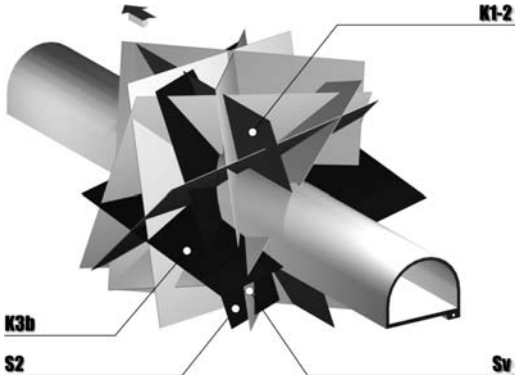

Figure 2. Rock joint systems in Sedrun.

With the information from the tunnel faces, geologists, contractors, construction supervisors, engineers and the owners have to work together to quickly find solutions for the details of construction methods and tunnel support. Rock mass displacements and the reaction of the tunnel support have to be observed, measured and interpreted by existing and possible new computations.

Based on the geological and hydrogeoligical information and the interpretation of rock mass deformation and the reaction of tunnel support, plus long term consideration, one can determine the profile types of inner lining and rock loads.

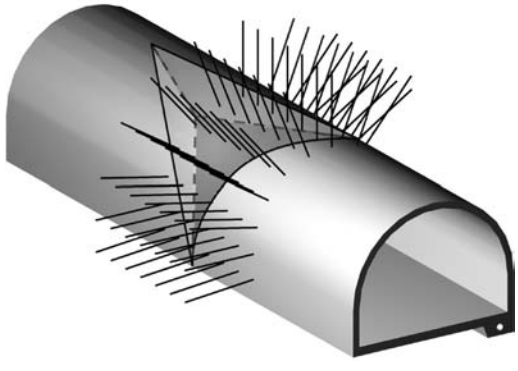

Figure 3. Pattern bolting of wedges.

2.2 *Effective loads carried by rock support*

Due to the importance of the project AlpTransit, it has been assumed that the structural effects of the rock support would not be considered in the tunnel lining design and that the tunnel (inner) lining must alone maintain the stability and functionality of the tunnel. This leads to an assumption that the loads carried by rock support like anchors, shotcrete and steel sets will be transferred onto the tunnel lining. In order not to be too conservative, one has to find out the effective loads carried by rock support.

One possibility to find out the theoretical loads in hard rock is to take the orientation of joints and frictions into account. This method has been used to define loads of loosening zones in hard rock.

Special investigations have been made to find out the joint orientation within the enlarged section of the branch-off structure. Their orientation defines the possible size of wedges that must be fixed. The Figures 2 and 3 are the examples of the MFS Sedrun. After deformations have come to an end the length of actually used anchors limits in a more precise way the real height of these wedges which otherwise would have an unrealistic high and long peak. By that the maximum size of wedges for the caverns has been limited.

As far as excavation has already taken place the measured deformations also give an answer to the question about the real load that the excavation support received. One priority objective of the excavation support is to guarantee security for the workforce under rather unknown rock conditions. After the excavation has been carried out, the geologic documentation and the observation of deformation give much more precise information about the rock behaviour. The check of the inner lining is based on this documentation, which leads to more precise load estimations. Narrow local fault zones can mostly be excluded. Based on the chosen rock support and the measured deformation the effective loads on the vertical closure at the end of the branch-off were identified and compared with the design-loads based on the predicted geology.

During excavation a massive unexpected fault zone was detected within the multifunctional station Faido (MFS). For this part the effective loads could be defined by the characteristic line method. A lot of geological information was collected and evaluated by the Geological Strength Index Method (GSI). This

method gave a vague impression of the parameter. But at least the minimum E-modulus could be defined. To define the necessary rock support a 3D-analysis was carried out to verify the results of the characteristic line method. After the completed excavation and based on the data obtained by the observation numerical calculations followed in order to estimate the rock loads for the permanent lining. This was based on the effectively chosen rock support. The calculated deformation is compared with the measured deformation. By back-Analysis the geotechnical parameter and the lateral pressure coefficient were assigned.

3 DESIGN LOADS FOR THE INNER LINING

3.1 *Design loads of rock mass for the inner lining*

The tunnel is designed for a service time of 100 years. The excavation support needs not to fulfil any long term durability criteria such as being protected against corrosion or against sulphate attack. 100% of the effective loads on the excavation support are taken into account for the inner lining. Remaining supporting effects of the excavation support will not be considered in the calculation for the inner lining.

Pattern bolting and steel arches to ensure safe working conditions loose their importance after the finished excavation. Due to the project importance, the primary supports are neglected by the design of the inner lining.

In the determination of the reaction forces of rock support to rock deformation and transferring them into the design loads of rock mass on the inner lining, the records of observation in Section 2.1 play an important role. Figure 4 is an example of breakout and fractures in the Main Tunnel West South around Tm 228 in the MFS Faido. This photograph shows us that the overall rock pressure is low but the local weak zone and rock joints lead to an asymmetrical distribution of rock pressure.

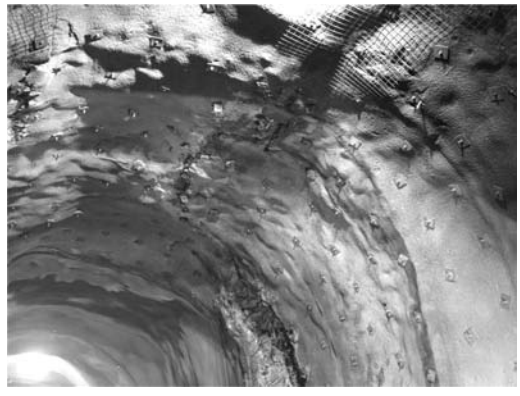

Figure 4. An example of breakout and fractures in the Main Tunnel West South around Tm 228 in the MFS Faido.

Table 1. Design considerations for primary tunnel support and final tunnel inner lining.

Load	Excavation support	Structural safety/ serviceability
Safe working conditions	x	0
Dead load of structure	x	x
Shrinkage	0	x
Effective loads of rock mass	x	x
Fixation of cantilever	0	x
Shock pressure and suction	0	x
Difference of temperature	0	x
Flexible drainage system	0	x

Table 2. Total design loads for the inner lining of the tunnels in the MFS Faido.

Load	Structural safety/ serviceability
Dead load of structure	25 kN/m^3
Shrinkage	0.2 [‰]
Vertical loads of rock mass	90 to 1200 kN/m^2
Horizontal loads of rock mass	0 to 1000 kN/m^2
Fixation of cantilever	4 [kN]
Shock pressure and suction	+/− 10 kN/m^2
Difference of temperature	+/− 20 [°]
Thickness of drainage layers	20 mm

3.2 *Total design loads for the inner lining*

The inner lining of the Gotthard Base Tunnel has been designed for dead load of structure, shrinkage, effective loads of rock mass, fixation of cantilever wire, shock pressure and suction due to train passing, difference of temperature and flexible drainage system (Tab. 1 and 2). Water pressure could be excluded because of the design of an effective and durable drainage system.

4 SINGLE SHELL OR DOUBLE SHELL

4.1 *Operation demands*

Corrosion and malfunction of electric equipment because of humid climate had to be avoided. Therefore the ingress of water had to be limited according to the requirements of the owner, the Swiss railway company. Water sealing was necessary on the whole length of both single-track tunnels. A second important demand represents the limitation of the roughness of the surface. Both demands led to the design of a double

Figure 5. An example of primary drainage of groundwater by half pipe shells in the Main Tunnel East South around Tm 750 in the MFS Faido.

shell tunnel. Nevertheless parts of the ventilation tunnels for the emergency case and small service tunnels within the multifunctional station could be designed with single shells.

4.2 *Advantages of double shells*

Due to the high water pressure a water drainage system is necessary. As mentioned above a double shell system with water sealing leads to an effective minimization of water inflow. The drainage can easily be built between inner and exterior shells. Figure 5 is an example of primary drainage of mountain water by half pipe shells. They will divert most of mountain water into drainage canals but cannot keep lining dry like in Figure 6. After certain time the mountain water may also redistribute. If water pressure builds up, it will crush the tunnel. Figure 7 is an example of high water pressure in the MFS Faido. In the core borehole in the Emergency Tunnel West at Tm 1320 the measured water pressure was 41.5 bars, that is 415 m water column.

The inner shell can be built by in-situ concrete, which is cheaper than shotcrete. The surface can be built smoother and therefore aerodynamically more

Figure 6. A Section with cracks and wet spots of the Main Tunnel West South from Tm 950 to 970 in the MFS Faido.

Figure 7. Measuring of groundwater pressure (41.5 bars, after Volpers) in the core borehole in the Emergency Tunnel West at Tm 1320 in the MFS Faido.

favourable (Fig. 8). Widely ramified cracks, typically for single shells, can be also avoided.

4.3 *Advantages of single shells*

The exterior part of a double shell is very similar to a single shell (Fig. 9). The main difference concerning the design control lies in its missing durability. This can easily be completed by adopting the concrete composition. So why should it be built twice? The cost reduction effect is obvious. In addition, the construction of single shells is much easier compared to double shells, especially when the geometry is changing as in cross-over caverns. In some cases the high requirements can also be fulfilled with low-cost single shells. That will be done in completely dry sections with no or very little reinforcement as well as in short sections with complicate geometry and limited water inflow.

Figure 8. Double shell lining concept.

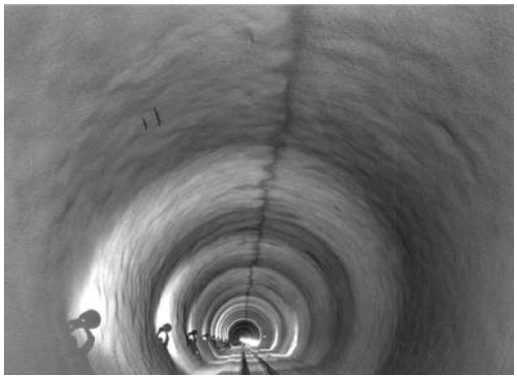

Figure 9. Single shell lining concept.

5 REINFORCEMENT

5.1 *Unreinforced inner lining*

The tunnel geometry will influence the decision concerning the reinforcement. Though this depends on the results of a general design check, the question of the tolerable crack width has to be answered. Concerning the serviceability and the durability cracks have to be checked. It is obvious, that in case of reinforced concrete cracks have to be limited according to the climate because of the possible corrosion. In contrast unreinforced concrete will not rust. Therefore, whenever the inner lining can be dimensioned without reinforcement, corrosion-problems can be avoided. On the other hand wider cracks have to be accepted. Depending on the maximum allowed size of cracks, the inner lining can be dimensioned without reinforcement. Steel reinforcing takes time and costs more, and also requires complicated logistic plan and high quality control to achieve a uniform concrete. When there is no steel and no steel corrosion in the lining, the risk of the railway operation interruption by maintenance work will largely be reduced. Not only the construction costs but also the maintenance costs will be reduced. As mentioned at the beginning this was one main target of the design for the Gotthard Base Tunnel.

6 CONCLUSIONS

The Gotthard Base Tunnel is the most important part of the AlpTransit Project. Advantages and disadvantages of single and double shell tunnel lining were discussed. Due to the importance of the Project, most sections of the tunnel were designed with double shells. Only parts of ventilation and service tunnels have a single shell.

The methods for the determination of lining loads were discussed under consideration of load bearing capacity of anchors and shotcrete, possible wedges and loosening zones, and the effective deformation. The role of the observational method was enlightened.

In accordance with stability, serviceability and durability and under control of allowable cracks, major sections of the tunnel inner lining were designed without reinforcement. This will avoid corrosion problems and therefore have less maintenance work and interruption of tunnel operation, and largely reduce the risk of railway interruption and the construction and operation costs.

Final lining of the Valík Tunnel on D5 express highway – the vault construction

Z. Vozarik
Metrostav a.s., Prague, The Czech Republic

J. Svoboda
Pragoprojekt a.s., Prague, The Czech Republic

ABSTRACT: The Valík tunnel is located on the Plzeň city motorway by-pass which is the part of D5 express highway connecting Prague with German border. It was the last section opened to traffic to complete the entire route. The tunnel is designed as a twin-tube connected by central cast-in-situ pillar within the primary lining. The length of the southern tunnel bore and northern tunnel bore is 380 and 390 m respectively, width of the roadway from curb to curb is 11.5 m and clearance height above the roadway is 8.2 m. Concreting of cut-and-cover tunnels begun before the definitive linings of the driven tunnels. Casting in of the driven tunnel's cross section was realized in two stages – bottom vault and ceiling vault. The basic technology consisted in pumping the concrete behind travelling steel form on rails.

Express highway D5 connecting the capital of Czech Republic Prague with German border is a part of trans European express highway network. Requirements of Czech tunneling directives namely regarding tunnel technological equipment were respected in the tunnel's design. Based on the tunnel's technological equipment and expected traffic intensity in one direction, 18125 cars per 24 hours, the Valík tunnel is ranked into the highest tunnel category TA.

1 GEOLOGICAL CONDITIONS

The slopes of Valík are covered with quaternary era sediments of 0.5–2.0 m thick. Under the layer of about 0.2 thick there are brown to reddish brown clay sands containing humus in some places more clayey with sharp fragments of strongly weathered porphyry. The tunnel itself is routed through moderately metamorphic proterozoic schist. The schist is strongly weathered and the strongest is 3 to 20 m deep along the entire length of the tunnel. A very detailed geological survey was carried out using a survey tunnel in the early stages (Fig. 1).

2 TUNNEL DESIGN

The Valík tunnel is a motorway tunnel with two bores. Each bore has two lanes, each is 3.75 m wide, and one emergency lane 3.25 m wide, the road is 11.5 m wide form curb to curb and the footpaths are 1 m wide (Fig. 2).

The bores are located next to each other with no rock pillar and they share a central pillar made of reinforced concrete. The central pillar was constructed inside the provisory middle tunnel (Fig. 3). This design was chosen because of the requirement to take as little land as possible for the tunnel.

The tunnel bores were made by driving uphill (inclination about 4%) from the temporary Rozvadov entrance. The structural calculation allowed the distance between both fronts from 10 m to max. 30 m. Tunnelling was mainly done without blasting using only mechanical disintegration of the rock and the use of explosives was exceptional.

The subdivision of the excavation area was mainly vertical and only a small scope was horizontal. The primary lining consist of sprayed concrete, braced arches, meshes and bolts.

3 SECONDARY LINING

3.1 *Cut-and-cover tunnel*

The tunnel mouths have shape of canted tubes and are provided with protective attic. The tubes themselves are made of watertight concrete with no outer isolation, only on the contact with the driven tunnel, an isolation membrane GSE – LDPE 3 mm thick was laid on the tubes (Figs 4,9,10)

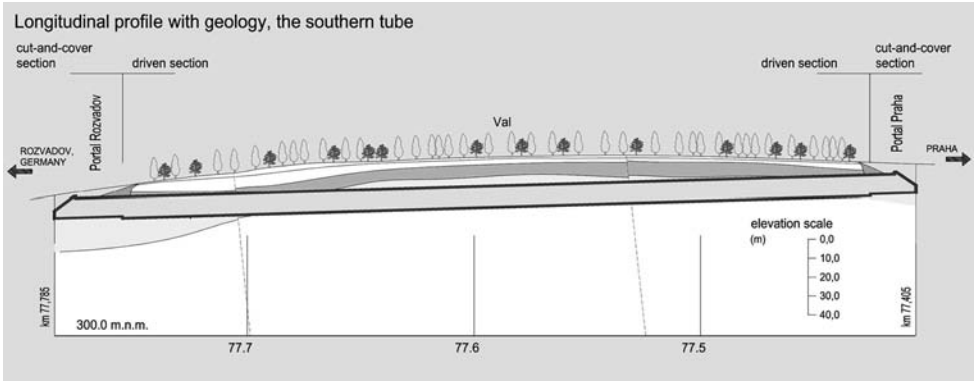

Figure 1. Longitudinal profile with geology, the southern tunnel bore.

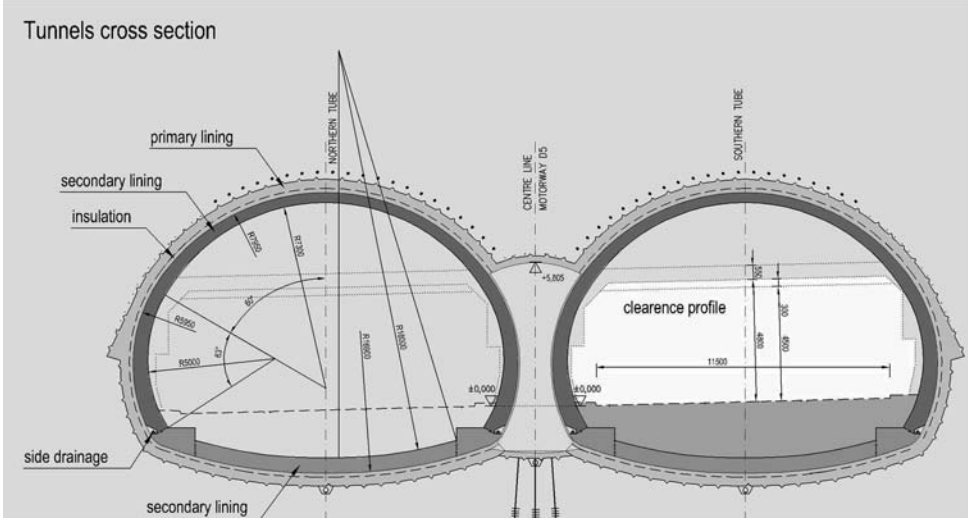

Figure 2. Cross-section of the driven tunnels.

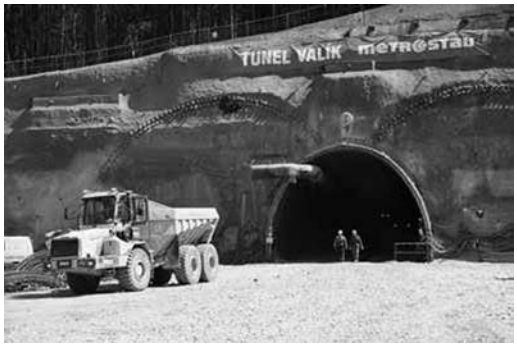

Figure 3. Entrance to the temporary middle tunnel, Rozvadov portal.

Figure 4. Cut-and-cover tunnel formwork at Rozvadov portal.

The cut-and-cover tunnel is a compact vault construction firmly connected with foundations. Minimum thickness of the concrete shell is 550 mm at the top of the vault and broadens down to the foundations. Casting in of the cut-and-cover tunnel was done using travelling steel form (specially made for the cut-and-cover tunnel) by 10 m segments and was begun before secondary lining of the driven tunnel. The steel formwork was made with DOKA system materials using chipboard sheets as facing (Fig. 4).

For the compact vault, reinforced concrete C 30/37 XF4, XD3 was used with maximum water ingress value equal to 20 mm. The foundations were cast of reinforced concrete C 25/30 XA1.

Filling of the tunnel form was done evenly at both sides of the tunnel through several filling windows on outer side of the form, so that the concrete mixture did not fall from height greater than 1.5 m. Compaction of fresh concrete was carried out by pervibration and in lower sections using form vibrators placed to the form.

3.2 *Driven tunnel*

The driven tunnel cross-section was designed having upper and lower compact vault. The tunnel vaults are combined of circular arches, the actual shape of the tunnel cross-section resulted from given clearance profile (Fig. 2). Connection between bottom and ceiling vault was carried out by flat joint. Minimum thickness of the tunnel's definitive lining is 400 mm at the top of the ceiling vault and broadens down to the bottom vault where it is cca. 600 mm thick. Concrete class used for the ceiling vault was C 25/30 XF4, XD3, for the bottom vault was used concrete class C 25/30 XA1, the minimum ingress value for both classes was limited to 20 mm.

Curvature of routing in the tunnel was replaced with polygon of short straight segments where the tunnel lining was longitudinally divided by admitted stop end and key every 10 m. The design of the steel form was subjected to this. Connection between neighboring segments (subblocks) at each polygon break was realized by contact concrete-concrete. Only at the touch between the cut-and-cover tunnel and the driven section, a dilatation joint with inserted polystyrene was carried out.

Static calculations were performed using elastic computational model. Dimensioning was done for the stability limit state and serviceability limit state (structure deformation, width of cracks in concrete). Calculations of crack widths in concrete were performed for the cut-and-cover tunnel and the driven tunnel's definitive lining. Following loads were regarded in the static calculations:

- Load by own weight
- Load by rock pressure (isotropic and anisotropic rock environment)
- Shrinking of concrete and creeping
- Temperature strain by non-uniform warming (summer) and cooling (winter) on the surface of the lining
- Influence of decreased friction between primary and secondary lining (by inserted hydro isolation)
- Influence of deterioration of bearing capacity and other deformational characteristics of the primary lining

By the cut-and-cover tunnel, an impact of car was regarded in the combination of loads. Load by hydrostatic pressure was not included into calculations.

Casting in of the driven tunnel's cross section was realized in two stages. In the first stage, the bottom vault was completed in tunnel's full length. After cleaning the surface of the primary lining, steel formwork was erected at the head of the concreted segment and on vertical sides. Length of each segment in bottom vault was 10 m, width was equal to 14 m. A mobile concrete pump was applied. To prevent extrusion of material by higher laying masses of concrete in the sides, casting in was done in successive layers, starting with lower bottom parts. For doing this, right composition of concrete mixture had to be secured.

After the completion of the bottom vault, works on the ceiling vault could begin. These were done from four working platforms spaced along the height of the tunnel with the use of special car moving on shared rails (Fig. 5). Works included treatment of the basis for hydro isolation, installation of hydro isolation, reinforcement assembly and concreting.

As a hydroisolation, 2.5 mm layer of GSE (LDPE) with signal coat was applied and transverse seams of isolation were covered with strengthened strips. Steel reinforcement consisted of truss frames positioned 1 m apart and steel nets, supplemented with bound steel rods. This design helped to reduce time needed for reinforcement assembly. Concrete cover specified by realization documentation was 50 mm.

Casting in of the upper vault was done into travelling steel formwork (by company OSTU Stettin) which was equipped with hydraulic control, pneumatic vibrators and safety overpressure components (Fig. 6). Construction of the form enabled fixing of additional steel forms for concreting of SOS shelters, tunnel bore connection and for hydrant, cable and drainage inspection niches as well. Concrete mixture was pumped into the divider by stable pump placed in front of the formwork. The mixture was deposited into the form evenly through several filling inlets so the difference between the levels of concrete on both sides of the form did not exceed 120 cm. Compaction of fresh concrete was performed by set of form vibrators. Casting the 10 m segment took cca. 7–8 hours during which approximately 180 m^3 of concrete mixture were laid. After 18 hours since the end of concreting, the

Figure 5. Car travelling on rails, hydro isolation installation, reinforcement assembly.

Figure 6. Steel form used for concreting the driven tunnel secondary lining.

steel form could be removed. Corresponding compression strength of the concrete at this moment reached 14 MPa (as detected by Schmidt impact hammer).

Immediately after the form removal, treatment of concrete against drying out was undertaken. The concrete treatment and other measures were adjusted depending on momentary climatic conditions.

3.3 *Finishing tunnel paintings*

For the surface finishing of the tunnel's secondary lining, protective and reflective paintings were used. Up to the 4 m level above the tunnel sidewalk, protective and reflexive light ochre paint was realized (for this tone a light-technical calculations were performed). Green stripe with the icon of moving walker inside, indicating the direction of evacuation, is running approximately 1 m above the ground (Figs 7–8). Remaining space of the vault above the 4 meter level is covered with uniting gray paint. The cut-and-cover tunnels are finished with uniting light ochre tone from both sides of the lining.

Figure 7. Architectural rendering of the tunnel interior, middle tunnel connection and SOS niche.

Figure 8. Tunnel interior, reflective part of paintings with icons.

The architectural solution of the inner paintings had been subject of discussions with Plzeň region citizens. The designer had prepared three proposals, and the winning design had to be passed by the Fire Department and also by the Police of Czech Republic. Inner architectural concept of the tunnel is purposely adjusted so that it facilitates maximally orientating of tunnel users during any emergency situation (Fig. 7).

Special attention was paid to the selection of the most suitable painting material which had to comply with various mechanical, physical and chemical requirements. The requirements included, for example, resistance to various harmful agents (exhaust emissions, road chemicals, detergents by regular tunnel washing, etc.) resistance to abrasion, flame resistance, resistance to changing temperature, freezing cycles, health harmlessness, color durability and many other factors.

Requirements for reflective part of paintings were best fulfilled with epoxy-based dispersion (Sikagard Wallcoat) applied in two layers – first penetration spray ($0.15\,kg/m^2$) and then finishing spray application ($0.20\,kg/m^2$), total thickness of the paint was 100 μm.

Uniting paint in upper vault was done with two layers of acrylate dispersion (Elastocolor by Mapei).

Before starting painting, quality of the concrete basis was tested on spotlighted referential area with applied paint. Thickness of the paint was regularly checked at 30 evenly spaced out points every 250 $m^2$of finished area, or after ending the day progress.

Inner tunnel painting works could be carried out only after all dusty activities in the tunnel had ended.

4 CONCRETE ROADWAY

An asphalt concrete roadway construction with reinforced joints in both directions was designed in the tunnel. Cement-stabilized aggregate road base is 200 mm thick, the subbase, 250 mm thick, is made of crushed stone (grading 0–32 mm). Filling of the bottom vault was done with two layers of crushed stone (grading 0–32 mm and 16–32 mm) instead of originally intended concrete filler. Under the roadway construction, the calculations regarded subgrade soil with $E_{def,2} = 60$ Mpa, and on crushed stone layer, $E_{def,2} = 110$ Mpa .

Tunnel sidewalks are cast of concrete, class C 30/37-XF4, 120–150 mm thick. Width of the sidewalk is 1 m. Joints in the pavement were cut every 5 m (Figs 7–8).

5 GEOLOGICAL MONITORING (GTM)

The construction was done in line with principles of the observation method when the basic structural design is reviewed on regural basis and can be modified in the course of the construction. There were clearly defined responsibilities for parties involved in the project and they all were provided with technology for fast communication.

As part of the geological monitoring of the structure behavior, selected parameters of all structures affected were monitored in terms of alerts, limit values and trends. In case of deviation from the desirable trends or when the alerts and limit values were exceeded, a signal was received upon which the required action, already incorporated in the design, was initiated.

6 TUNNEL EQUIPMENT

The tunnel is equipped with the traffic control and technical systems that provide more or less automatic control of all operating modes of the tunnel. The equipment of the Valík tunnel meets the requirements of the European parliament an Council on the minimum safety standards in tunnels of the trans European network (C00M 2002/0309-000) and complies with the latest European standards (amatic ventilation, monitoring system, SOS cabinets, CCTV surveillance, weighing of vehicle, spead reading, etc.).

The necessary documentation for operation, management and maintenance of the Valík Tunnel was developed, consisting of a set of documents covering the organization, responsibilities and activities related to tunnel operation. The operation of Valík Tunnel will be controlled by the Police of ČR, from a control room at Svojkovice; the tunnel equipment is maintained and upgraded by the operator who also provides services to the Police of ČR.

7 FIRE SAFETY IN THE TUNNEL

Practical understanding of effects of actions taken during any emergency situation is an essential requirement for choosing a right solution to the situation. This applies especially for the case of tunnel fire. Before opening the tunnel to traffic, in May 2006, a set of test fires with heat release rate equal to 5 MW (corresponding to burning a larger automobile) was performed. During these tests, the influence of tunnel self-venting and forced ventilation on smoke spread in the tunnel was examined.

Findings of the tests offer useful ground for better understanding the principles of spreading of hot smoke in short tunnels. Besides that, the tests are meaningful contribution to the improvement of the tunnel's fire safety. Findings of the tests can be further generalized and implemented into existing codes of practice.

8 CONCLUSION

Great attention was paid by all interested parties, ahead with the chief designer Pragoprojekt a.s. and the contractor Metrostav a.s., to the construction of the tunnel's secondary lining and to choosing the best composition of used concrete mixtures. The result is building work of high quality which is the credit of collective effort of all construction participants.

By construction of definitive linings, adding up of various unfavorable deviations could result in diminishing of the clearance profile. The design of the tunnel regarded these effects, nevertheless it was absolutely indispensable for the contractor to secure working technology as best as possible.

Monthly opened excursions for local public were regularly organized on the building site and local press kept constantly bringing information on progress of the construction. The clearing-house served for the public informedness and informational brochure was issued on starting the construction of the tunnel. The public contributed to the overall architectural concept of the tunnel and its surroundings in terms of public

Figure 9. Cut-and-cover tunnels, Rozvadov portal.

Figure 10. The tunnel entrance, Rozvadov portal.

inquires arranged by local daily paper. The outcomes of the inquires were respected in the design of the tunnel operation building, the tunnel portals, portal cuttings and also inner tunnel paintings (Figs 7–10).

The Valík Tunnel was designed and constructed so it is friendly and safe to its users. At the same time it meets all requirements of local administration as well as of ecological organizations. The hill Valík is, from the environmental point of view, an important landscape element. All actions in this space were therefore closely watched by an expert and general public.

Development in pre-cast concrete segmental circular tunnel linings

Y.K. Vimalanathan
Mott MacDonald, London, UK

ABSTRACT: In the past, the number of segments in a ring was kept high to reduce handling loads and to improve articulation of the ring there by reducing bending moments.

However, to speed up construction the segments in a ring got fewer and larger and this was made possible by strengthening the segments with reinforcing bars and by using stronger erector arms in TBMs so that the weight of segments was no longer a problem.

This now seems to have gone a full circle with the introduction of steel fibres in place of reinforcing bars. The Channel Tunnel Rail Link tunnels in the UK contained nine segments per ring. These segments have low bending strength and therefore required an increase in the number of segments per ring.

Segmental linings from recent projects will be compared to highlight the current trends in segmental lining design.

1 INTRODUCTION

Pre-cast concrete tunnel linings were first used in the 1930's. The designs used un-reinforced pre-cast concrete segments. The number of segments in a ring was kept high to reduce handling loads and to improve articulation of the ring there by reducing bending moments.

Many were used for lining tunnels in clay and the ring of segments was expanded against the ground, rather than bolted and grouted.

Since then design and construction methods have changed significantly.

There are a number of factors which affect segmental tunnel lining design. Some of these are listed below. Each of these will be examined in relation to recent projects to see how they affected that particular design.

- Segmentation
- Segment geometry
- Segment reinforcement
- Radial joints
- Circumferential joints
- Bolts & dowels
- Fire resistance

2 SEGMENTATION

For almost all linings the moment capacity of the joint is much less than that in the body of the segment. Therefore the flexibility of a lining is increased significantly and its 'average' inertia (I) reduced as the number of joints increases. The most common formula used for calculating the equivalent stiffness of the lining is:

$Ie = Ij + I\ (4/n)^2$ (Muir Wood 1975)
$Ij \ll I$ for an expanded and articulating lining
Ij = Second moment of inertia of the joint
Ie = Effective inertia of the ring
n = Number of segments in a ring

Ij is an extremely difficult quantity to calculate, as it is a function of the hoop thrust as well as the geometry of the joint, but usually it would be expected that Ij would be close to zero.

To benefit from a flexible lining that attracts a lower bending moment the number of segments in a ring should be greater than 5. This assumption comes out of studies for the Channel Tunnel (UK) project in the 1970's, which showed that the maximum bending moment (BM) in a 5-segment ring is very close to that of a 4-segment ring. The studies also showed that if the joints in a 4-segment ring coincided with the vertical and horizontal axes, where the maximum BMs occur in a rigid ring, the maximum BMs are not significantly reduced.

The projects listed below have followed this basic principal and the minimum number of segments in a ring is always 5 or greater. It should also be noted that where steel fibre reinforcement is used the linings have 8 or 9 segments in a ring. This is done in order to increase their flexibility as steel fibre reinforced concrete has reduced flexural strength compared to segments reinforced with steel bars.

Segmentation is also dependent on the position of the Tunnel Boring Machine's (TBM's) rams. Segment sizes are chosen to avoid ram positions coinciding with radial joints, but if the rings are rolled to prevent cruciform joints this may be unavoidable. Where this happens the circumferential joints should be detailed to prevent edge damage.

Segments are also sized to allow maneuverability within the confined spaces of a tunnel.

To minimize moments therefore, there are advantages in having a large number of segments. However a balance has to be struck between speed of erection and an economic design. For many projects one of the key costs is overall duration of the tunneling. There in many cases a balance is struck between many segments, which would require low bending stiffness and fewer segments which can be installed more quickly but require heavier reinforcement.

3 SEGMENT GEOMETRY

Most segments built are rectangular in plan with the Top and Key segments having radial joints which are inclined to the long axis.

Trapezoidal tunnel linings as the name implies have trapezoidal shaped segments. The inclined radial joints in these segments make the rings very much more rigid (stiff) than conventional segments which have the joints parallel to the tunnel axis. There is some evidence that trapezoidal segments are easier to erect and assist in ensuring that the lining rings are circular prior to grouting.

There are two disadvantages of the trapezoidal form. The lining has to resist a larger bending moment as the joints do not allow the longitudinal rotation of the more conventional lining. Also the geometry of the lining means that more space is required to erect each individual ring. This in turn means that for any given ring the tunnelling machine erection area and the length of the jacks have to be longer.

4 SEGMENT REINFORCEMENT

As noted above, when pre-cast concrete segments were first used, the individual segments were small to allow manual handling within the tunnel.

As tunneling machines, and in particular the erectors became more sophisticated it became much easier to use larger segments.

Until relatively recently the standard approach was to use steel bars for reinforcing segments to prevent failure or excessive cracking .

In designing this reinforcement the following are the key load cases-

- During de-moulding, handling and stacking
- At radial and circumferential joints due to tensile and shear stresses induced by local stress concentrations
- In the body of the segment due to bending moments generated by non uniform ground pressures and joint eccentricities

However in the past decade steel fibres have been used as an alternative to steel bars. Three projects are listed in Table 1. Since the use of steel fibres on the prestigious Channel Tunnel Rail Link (CTRL) project momentum has grown for its wider use.

Steel fibres give the concrete segments ductility and help withstand high shove loads by its enhanced tensile strength.

Due to the minimal thickness of steel fibres their expansion during corrosion does not cause concrete spalling. Therefore steel fibre reinforced segments would be classed as durable. With steel bars, corrosion of reinforcement can cause early durability problems. Therefore it is essential to have sufficient cover to

Table 1. Segmentation on some of the recent tunnel projects.

Project	Internal diameter (m)	Thickness (mm)	Aspect ratio length/thickness	No. of segments	Year detail
Channel Tunnel, UK, Undersea, Type 1	7.6	270	13.7	8 + key	1988 rebar

Durban Harbour Services Tunnel, South Africa	4.4	250	11	5 + key	2005 rebar

reinforcing bars. However high cover in what are often relatively slender concrete segments can compromise the strength of the segment, and in particular allow damage to corners and other areas which, because of the cover requirements, are effectively un-reinforced. This problem does not arise with steel fibres provided that they are uniformly distributed through the segment thickness.

Although steel fibres are proving to be popular in Europe that is not the case in other areas of the world where steel fibres are not locally produced and the cost of labour intensive activities such as steel fixing is low.

Reinforcement density for reinforced segments is unlikely to be less than 75 kg/m^3 and a normal average figure would be about 90 kg/m^3. A typical dosage of steel fibres is 30 kg/m^3, but the actual figure will depend on the type of fibre used as well as the loads imposed on the lining.

5 RADIAL JOINTS

Radial joints are either designed as curved or flat. Curved joints were developed for expanded linings where convex/convex contact surfaces allow improved articulation at joints when the ring expands against the ground as the key is wedged in.

However the radii required for an efficient joint are large, requiring extremely high tolerance steel moulds for casting the segments. Usually the patterns used for casting the curved joints have to be machined from large steel blocks and then installed very accurately within the main body of the mould. Segment casting tolerances are always, or should be, tighter than the tolerances listed in codes of practice for pre-cast components such as bridge beams.

Therefore the preferred radial joint detail for a bolted gasketted lining which sits within a grout annulus is flat. With flat joints proper consideration needs to be given to the joint geometry to avoid damage due to large eccentricity in the joints due to poor build of the ring. No ring can be built perfectly circular and the design must allow reasonable construction tolerances, particularly at the joints. If contact is a line at or close to a corner of a joint, damage is inevitable, if the forces normal to the joint are anything but trivial.

In the past plywood packers have been specified in flat joints to improve articulation, but more recently flat jointed segments have been constructed satisfactorily without packers. This is due to the increased concrete strength, elastic/plastic deformation of the concrete at the joints and tight construction tolerances now achievable.

The radii given in Table 2 were calculated using design rules derived from the results of tests made on knuckle joints in reinforced concrete test pieces and from other published data.

Although curved joints reduce eccentricity and improve articulation, flat joints sustain a higher load at failure, assuming the flat joints are in full contact (Woods 2003). However with joint rotation the maximum sustainable load for flat joints reduces rapidly but rotation has little impact on the capacity of curved joints.

The present trend appears to be to use curved joints with expanded rings and flat joints with bolted rings.

6 CIRCUMFERENTIAL JOINTS

Circumferential joints are designed and detailed to resist TBM ram loads and to contain gaskets. Of the 11 projects listed in Table 1, 9 have flat circumferential faces, whilst two have a cam and socket coupling system as shown in figure 2. The intended purpose

Table 2. Curved joint radii on recent projects.

Project	Convex/convex joint radius (mm)	Lining types
Channel Tunnel, UK	3200	Expanded

Heathrow Express, UK	1375	Expanded & bolted

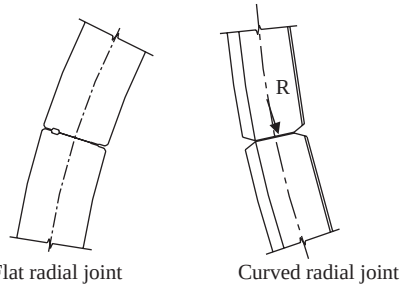

Figure 1. Flat and curved joints.

Figure 2. Cam and socket detail.

of the cam and socket is to assist the TBM driver to locate the segments into position. The other means of positioning segments accurately would be to use laser targets, which is possible with the modern TBMs.

6.1 *Cam and socket coupling*

The beauty of segmental lining is that it creates a flexible tube which can accommodate a small amount of movement. Therefore when a cam and socket is used as shown in figure 2 it is essential that there is sufficient tolerance in the coupling that rings can be installed without damage.

The tolerance in the coupling has to allow for the following:

- Casting and construction tolerances
- Differential deformation of adjacent rings due to ring roll and non coinciding longitudinal joints
- Frictional resistance created between the mating surfaces due to the pre-stressing effect of the ram forces

When all these effects are added together it is possible that the clearance between the cam and socket is exceeded inducing additional load on the joint causing it to crack.

Cam and socket arrangements, therefore, would not be recommended, unless the tunnel is in very soft ground and requires stiffening effect from these couplings. It may then be necessary that additional reinforcement is provided to make the connection work as a shear key. At the same time the rings need to be built to an accuracy which is greater than is usually achieved.

6.2 *Circumferential reinforcement*

Very often segmental lining thickness is determined by the short term TBM ram forces rather than by the long-term ground and water loads. It is therefore imperative that the circumferential joint is designed adequately to resist the large bearing and bursting stresses induced by the TBM rams.

Empirical results obtained from studies for the Channel Tunnel project in the 1980s (Eves & Curtis 1991) shows that the major part of the anti-bursting capacity of a joint comes from the inherent tensile strength of the concrete. However steel reinforcement is also very often required close to the joint face to compensate for the shortfall between the imposed ram load and the concrete strength.

For the Delhi Metro and the Durban Harbour services tunnel projects as shown in figure 3, German contractors introduced closed links adjacent to the circumferential face as anti-bursting steel. These designs were based on the assumption in most concrete design codes that the concrete tensile strength should not be included in determining the ultimate joint load capacity.

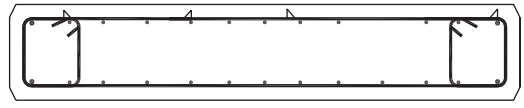

Figure 3. Example of links along circumferential joint.

7 FIRE RESISTANCE

Several major fires in European tunnels have raised awareness about how high strength concrete performs in fire situations. A significant loss of cross-sectional area in the tunnel lining can occur due to the spalling of concrete when exposed to very high temperatures.

Explosive spalling occurs when moisture in the concrete vaporizes under intense heat causing pressure build up within the concrete which is greater than its tensile strength.

The addition of polypropylene fibres at a dosage of 1 kg/m^3 has been shown in tests to significantly reduce this spalling. The basic reasoning behind this reduction is that, as the concrete is heated, the polypropylene fibres melt and create voids for pressure relief. The Airside Road tunnel at Terminal 5 Heathrow UK and the CTRL segmental linings contain polypropylene fibres.

8 BOLTS & DOWELS

8.1 *Bolts*

The purpose of bolts in a segmental lining is only to provide temporary support until the grout annulus hardens. The bolts are required in the short term to keep the radial joint gasket compressed and the circumferential joint gasket compressed when the TBM ram is released. They also assist in supporting the segment weight whilst a TBM ram is removed to install the next segment.

In the 1980s curved bolts were favored as they required smaller pockets in the concrete segments. But with the reliability of plastic cast in sockets now demonstrated spear bolts have become more commonly used in linings of 200 mm thickness and greater. The advantage of spear bolts is that it only requires a single pocket although the pocket size is larger than for a curved bolt.

8.2 *Dowels*

Dowels are very often proposed for circumferential joint connections. Unlike bolts, dowels require no pockets, which is an advantage. However once two segments are joined together with dowels it is nearly impossible to pull them apart.

In gasketted linings the circumferential joint dowels have to not only work in shear but also in tension as they keep the gaskets compressed whilst the TBM rams are

released to insert the next segment. Hence dowels have to fit snugly. Therefore great care has to be taken in choosing the right type of dowel. Dowels made with plastic sockets and push fit steel rods can cause the circumferential joint to crack if there is insufficient room for expansion as the steel rod is hammered into the cast in socket.

9 CONCLUSIONS

This paper summarises very briefly some of the current trends in segmental lining design and discusses some of the issues with the present day designs.

Innovations in TBM design and the need to build deep tunnels in poor ground conditions will lead the way in which segmental tunnel lining design has to develop in the future.

ACKNOWLEDGEMENTS

I wish to thank Mott MacDonald for permission to publish this paper, and John Curtis and Tony Deane for their assistance.

Design of replaceable structural lining segments

Wenge Qiu, Junru Zhang* & Dongmei Li
School of Civil Engineering, Southwest Jiaotong University, Chengdu, Sichuan, China

ABSTRACT: To resolve the problems about waterproofing of single shell lining and surface evenness, the paper put forward a sort of new "flue lining structure" matching the single shell lining – replaceable structural lining segments. Study minutely about characteristics of structure, classified principia of precast lining segments, joint of members and waterproofing and the manufacturing and assembling of the members. The purpose is to gain the types of single shell lining to resolve the problems in practice and to base for the development and popularity.

1 INTRODUCTION

Since 1960, single shell lining, an advanced tunnel supporting structure, have been applied far-ranging at home and abroad. Such as the underground ice hockey rink of Gjolasvik in Norway, the tunnel of Vereina in Switzerland[1], and the project of underground storage of liquefied petroleum gas in Shantou (a city of China)[2], and the most arrestive is the Scandinavian . But single shell lining is mainly used in certain instances without notable deformation of the surrounding rock, gushing water, and water seepage and leakage. The Waterproofing of lining and surface evenness are major factors limiting the further popularize of single shell lining[3–4]. The experts of domestic and international have done a lot of research about the two problems, and the results can conclude thus: the waterproofing method of a structure is self-waterproofing achieving by put some admixture into shotcrete (such as silica power etc)[5]; the actualize of surface evenness achieves by construction technology (such as moulded shotcrete and shotcrete surface reprocessing etc) or decorating the surface of lining. On this foundation according to highway or railway tunnel cross section, the paper put forward a sort of new "flue lining structure" matching the single shell lining – replaceable structural lining segments, to resolve the problems of structure waterproofing and surface evenness. We will introduce the design essential of this new structure.

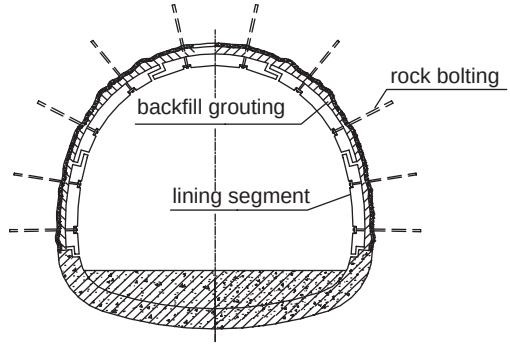

Figure 1. Structure of single shell lining.

2 STRUCTURAL CHARACTERISTICS

A single shell lining supporting system is shown in Fig. 1, carrying on shotcrete and rock bolt support to the arch wall of excavation, and cast-in-situ concrete to inverted arch and bedplate according to loaded of structures after excavation. Besides, a sort of replaceable structural lining segments is installed inboard shotcrete lining to resolve the problems of structure waterproofing and surface evenness. The following are characteristics about this sort of structural:

- The segments are structure lining only, take no account of supporting in principle;
- The segments are prefabrication, guaranteeing and raising the quantity index of the structure, such as strength, durability, corrosion proofing, and waterproofing etc. Besides, construction project time can be contracted;
- The segments are made of reinforced concrete of C30, with 20 cm of thickness, 0.3% of reinforcement ratio, and S8 of waterproof degree.

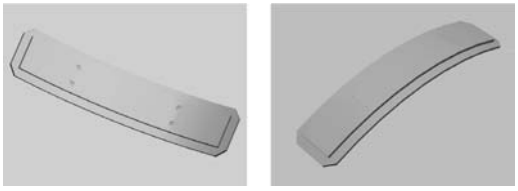

Figure 2. The forms of segments.

- The longitudinal and circumferential joint of segments are connected by ordinary bolt erecting together with radial rock bolting ;
- Do some backfill grouting between segments and shotcrete shell to make them forming a firm and impervious integral structure after completing installation of segments.
- It is convenient for segments to assemble, disassemble and repair.

3 CLASSIFICATION OF PRECAST LINING SEGMENTS

The following factors are considered in classification of precast lining segments[6]:

- Reduce the types of the members possibly to produce on a large scale.
- View to loading, it's better to dowel the joint of segments on the place of zero bending moment or plus bending moment approaching to zero;
- Considering the convenient of producing and assembling , it's better to limit the weight of each member. The weight of a member shouldn't exceed 2.5t∼3.0t if the width is 1.2 m;
- It's should be in favor of processing of joint, the evenness of surface and operation ventilation.

Therefore, it's better to adopt the following classification for lining segments of single-track railway tunnel: the part of arch needs 2∼3 blocks + each of side wall needs 1 + the bedplate or inverted arch. The form and classification of segments are shown in Fig. 2 and Fig. 3.

4 JOINT OF MEMBERS AND WATERPROOFING

The construction of joint and waterproofing are the key technologies of precast effecting usage and durability.

4.1 *The construction of joint*

The joint of members include longitudinal ones and transverse ones, and view to the construction of joint used it include joint by cast-in-situ-concrete, bolted

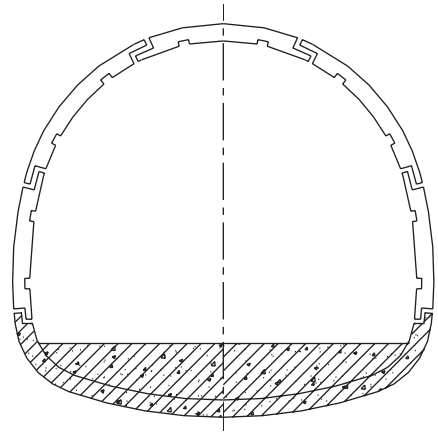

Figure 3. The classification and assembling of precast.

joint by pre-clamping, mortised joint by self-clamping and joint by bolt connection etc. When selecting, whichever, the following terms should be satisfied:

- With shear-bearing capacity of required;
- With waterproofing capacity of required;
- Convenient to combine and locate;
- With certain universality and durability.

Considering convenient to assemble and disassemble, the replaceable structural lining segments mentioned in the paper are jointed by bolt connection.

4.2 *Waterproofing of structures*

4.2.1 *Waterproofing of segments*

The waterproofing of segments carries on self-waterproof by the using of watertight concrete. Quality can be completely guaranteed for it's prefabrication, and the gradation of waterproofing is first-order.

4.2.2 *Joint and joint seal*

Rubber sealing strip, sealing combined around the segment, is adhered to the interface for waterproofing, and it's shown in Fig. 4 and Fig. 5. Considering assembly accuracy and construction, it's made by the material with water-expansion quality the mixture of a kind of polymer material with water-absorbing quality and neoprene rubber. The material can proof the intrusion of water and resist certain water pressure for volume expansion and the counter force produced by the bind of groove when reacts with water.

4.2.3 *Waterproofing of bolt hole*

For the joint of bolt connection, the following is the process of waterproofing of bolt hole: first, set the sealing gasket collar made by water expanded rubber; second, screw the nut tightly; third, put on the helmet;

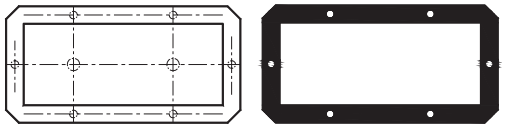

Figure 4. Precast segment and rubber sealing strip.

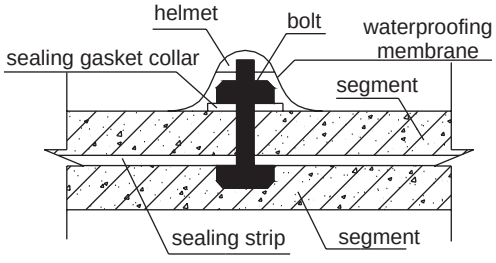

Figure 5. Connection between segments.

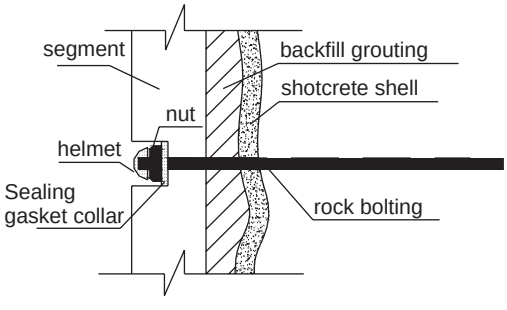

Figure 6. Connection between segment and rock bolting.

the end, coat waterproofing membrane around the nut. That is shown in Fig. 5 and Fig. 6.

5 THE MANUFACTURING AND ASSEMBLING OF THE MEMBERS

The manufacturing of structural segments must guarantee the accuracy required together with the convenient of assembling and the development of the follow-on work. Therefore every segment sets two preformed holes for pressure grouting whose flue lining are steel tube of 85 mm with screw thread on the innerface enclosed when grouting concrete. Screw a special of hook in the holes for hoisting. The following is the particular assembling of structural segments:

- Clearing the bed;
- Grouting inverted arch and bedplate of concrete.
- Installing segments of both sidewall;
- Installing segments of the part of arch;
- Screwing bolt tightly and waterproofing of joint;

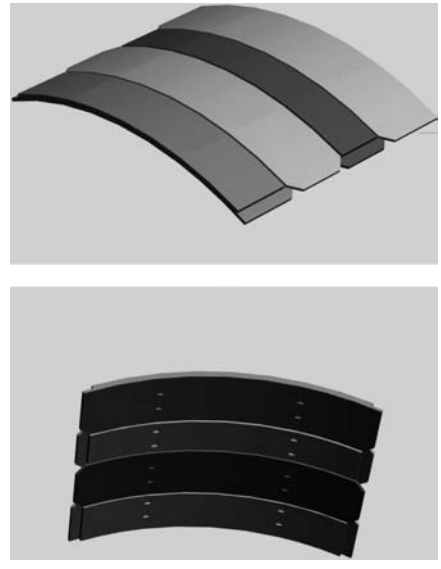

Figure 7. Assembling segments of local.

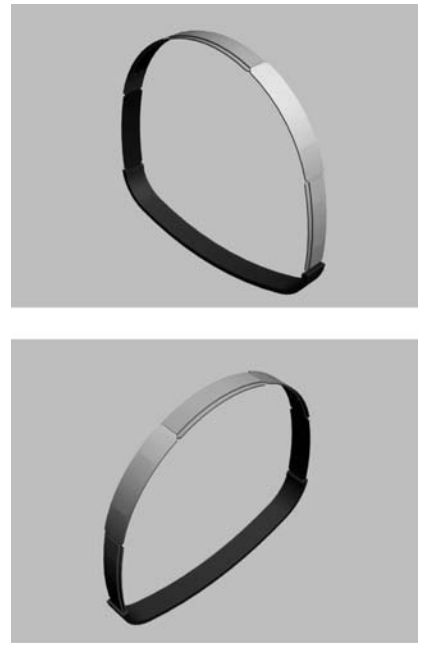

Figure 8. Assembling segments of signal ring.

- filling and grouting from the back;
- Constructing the ditches and cable trenches;

Figure 7 to Fig. 9 displays the process and outcome of assembling the structural segments.

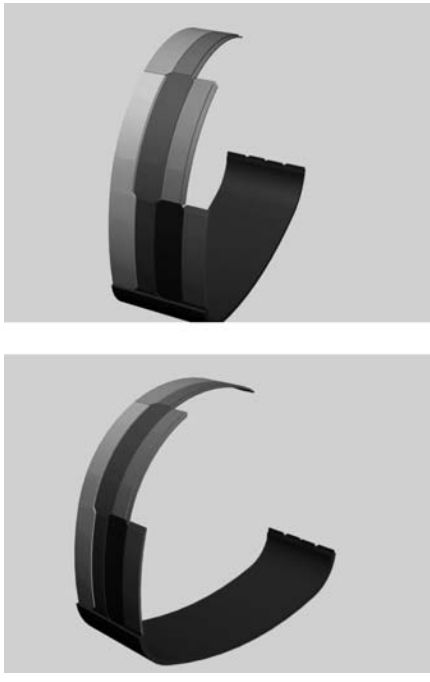

Figure 9. Assembling segments of integral.

6 CONCLUSIONS

The paper put forward a kind of new "flue lining structure" matching the single shell lining – replaceable structural lining segments, it's writers' sum-up about the study of single shell lining, to resolve the problems about waterproofing of single shell lining and surface evenness. Study minutely about characteristics of structure, classified principia of precast lining segments, joint of members and waterproofing and the manufacturing and assembling of the members. Certainly, it needs a process to pullulate for anything, so it's hard to avoid some insufficiencies, pleasing point them out to perfect.

Structural behavior of SFRC tunnel segments during TBM operations

R. Burgers & J. Walraven
Delft University of Technology, Delft, The Netherlands

G.A. Plizzari & G. Tiberti
University of Brescia, Brescia, Italy

ABSTRACT: The paper addresses precast tunnel segments for the new Line 9 of Barcelona Metro. After the experimental determination of the material properties, non-linear analyses allowed to study the structural behavior of the tunnel segments under TBM thrust jack forces during construction process. The paper focuses its attention to the advantages coming from the use of Steel Fiber Reinforced Concrete (SFRC) in terms of crack control and bearing capacity. Finally, Ultra High Performance Concrete (UHPC) has been investigated to study if this material is suitable for the application in tunnel segments.

1 INTRODUCTION

After more than 40 years of research, interest in Fiber Reinforced Concrete (FRC) is continuously growing in many application fields. FRC is already widely used in structures where fiber reinforcement is inessential for integrity and safety, such as in slabs on grade or in first phase linings.

For structural purposes, steel fibers are becoming widely utilized since fibers enhance toughness of the concrete matrix (which involves the ability to resist stresses after cracking), improve impact and fatigue resistance and make the crack pattern more distributed with cracks having a smaller crack width.

Among the structural applications of steel fiber reinforced concrete (SFRC), there is a growing interest in precast tunnel segments to be used with the Tunnel Boring Machines, TBM (Blom, 2002, Plizzari and Tiberti, 2006). These segments are generally made of ordinary reinforced concrete; however, the addition of fibers is gaining considerable attention among designers and producers due to the enhanced toughness that allows a partial or even total substitution of the conventional reinforcement that, in such members, is characterized by a curved geometry. Fibers also guaranties a reinforcement in the corner of the segment or in the large covers that are often required for fire resistance.

In the present paper, the structural behavior of the segments for the Metro Line 9 of Barcelona (Spain) are numerically simulated with non-linear analyses (Plizzari and Cominoli, 2005).

The TBM-excavated tunnel of Barcelona has a diameter of approximately 12 m, a length of more than 40 km and is located from 30 to 70 m below the surface. Every ring is made of 7 segments with a length of about 4.70 m and 1 key segment of half that length (Fig. 1).

Experiments have been performed to determine the materials properties and the constitutive laws of SFRC for use in tunnels.

Numerical analyses have been performed by using a finite element model based on Non Linear Fracture

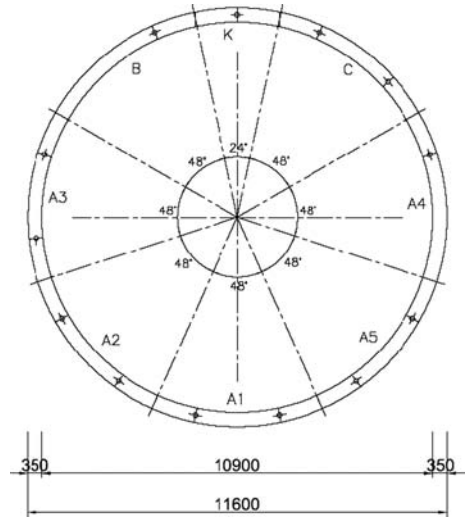

Figure 1. Transverse section of the tunnel for the line 9 of the Barcelona Metro with evidenced the eight precast segments (Gettu et al., 2004).

Mechanics (NLFM; Hillerborg et al., 1976) with a smeared crack approach. The numerical model has been validated by using the experimental results of splitting tests performed on SFRC specimens (Schnütgen and Erdem, 2003). During the validation, different concrete crack models have been tested and compared.

2 MATERIALS

The experimental characterization of the material properties of SFRC was performed on a concrete matrix having the same mix-design of the one used for the Line 9 of the Barcelona Metro.

Segments were reinforced with steel fibers Wirand FF1 having a length L_f of 50 mm, a diameter ϕ_f of 1.0 mm and an aspect ratio L_f/ϕ_f equal to 50. These fibers are cold drawn, have a hooked shape, a rounded shaft and a tensile strength higher than 1100 MPa. Fibers were used with the volume fractions (V_f) equal to 0.58% (45 kg/m^3).

Fracture properties of FRC were determined by using eight notched beams ($150 \times 150 \times 600$ mm) tested under 4-point bending according to the Italian Standard (UNI, 2003; Fig. 2). In addition, 4 beams of plain concrete were used as reference specimens. The slump of the fresh concrete was always greater than 150 mm. Specimens were stored in a fog room (R.H. $> 95\%$; $T = 20 \pm 2°C$) until 24 hours before testing. The mechanical properties of concrete (average values), as determined after about 60 days of curing are the following: tensile strength (determined from cylinders having $\phi = 80$ mm and $L = 240$ mm) $f_{ct} = 4.10$ MPa, compressive strength (from cubes with a side of 150 mm) $f_{c,cube} = 64.1$ MPa and Young's modulus (from compression test on cylinders $\phi = 80$ mm, $L = 240$ mm), $E_c = 37000$ MPa.

Fracture tests were carried out with a closed-loop hydraulic testing machine by using the Crack Mouth Opening Displacement (CMOD) as control parameter, which was measured by means of a clip gauge positioned astride a notch at midspan, having a depth of 45 mm. Additional Linear Variable Differential Transformers (LVDTs) were used to measure the Crack Tip Opening Displacement (CTOD) and the vertical displacement at midspan and under the load points (Fig. 2).

Inverse analyses of the bending tests, based on NLFM (Hillerborg et al., 1976), allowed to determine the best-fitting post-cracking law (σ-w) for the SFRC adopted in the present research (Roelfstra and Wittmann 1986). The Young's modulus (E_c) was the one experimentally measured from the cylinders while the Poisson ratio (ν) was assumed equal to 0.2. The softening law was approximated as bilinear where the first steeper branch can be associated with the

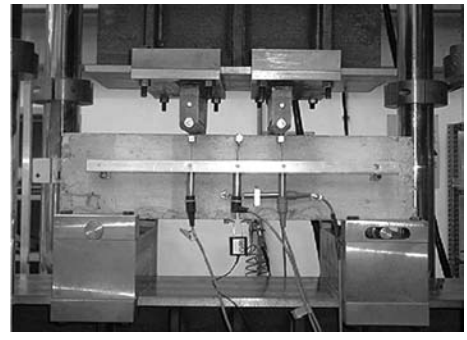

Figure 2. Instrumentation for the notched specimen used for the 4 point bending beam tests.

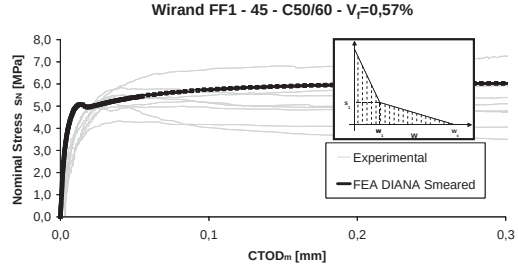

Figure 3. Experimental and numerical results obtained from SFRC beams and the bilinear law adopted.

bridge action of concrete between microcracks while the second branch represents the residual stress due to fiber bridging (Fig. 3). The numerical analyses were performed by assuming both a discrete crack and a smeared crack approach with Diana ver. 9.1 (2005); the latter was also used for the numerical simulations of the tunnel segments.

The material parameters identified from the bending tests are the following (see Fig. 3): $f_{ct} = 4.10$ MPa, $\sigma_1 = 2.134$ MPa, $w_1 = 0.023$ mm, $w_{cr} = 5.35$ mm. The best-fitting numerical curves obtained with Diana are compared with the experimental ones in Figure 3.

Firstly, numerical analyses of tunnel segments were carried out with different amounts of steel fibers; secondly, the response with Ultra High Performance Concrete (UHPC) has been investigated. The post-cracking properties of concrete with different fibers contents were assumed starting from the bi-linear law "experimentally" determined from concrete C50/60 with 45 kg/m^3 of steel fibers.

The stress–strain relations and the values of UHPC were obtained according to den Hollander (2006). The stress-strain diagram for UHPC is given in Figure 4.

UHPC was made with two types of fibers: micro and macro ($l = 50$ mm) fibers; the latter govern the ultimate tensile strain. The characteristic values of the stress–strain diagram are given in Table 1.

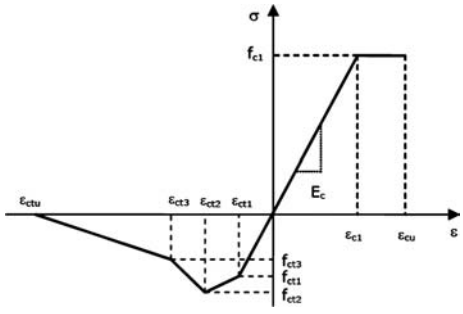

Figure 4. Stress–strain diagram for UHPC with strain hardening (den Hollander, 2006).

Table 1. Material properties for the adopted UHPC mixture.

3 DESIGN ASPECTS

An open question for the construction companies and the designers concerns the reinforcement for these precast elements. Generally, reinforcement is designed according to the design actions on the tunnel segments, resulting from segment transportation, placing process and soil pressure in the final state.

In particular, during construction, the thrust forces and the grout pressure are the most critical factors. Cracks often appears in the tunnel lining in the phase in which these forces occur. Some examples of cracks that have been observed in Line 9 of the Barcelona Metro are shown in Figure 5. Possible causes of these cracks could be: eccentricity, inclination of the thrust jacks. Also a number of phenomena due to the trumpet shape as the torsional deformation or an uneven support of the ring joint cause these cracks.

It is desirable to mitigate or reduce these cracks as much as possible since they determine a loose of quality and leakage and high repair costs. Cracking phenomena can be limited by introducing a change in tunnel design by using, for example, an opportune configurations of the thrust jacks and supports. Alternatively, they can be reduced by using FRC.

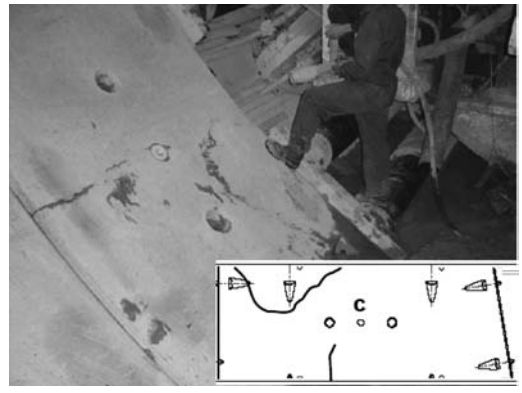

Figure 5. Spalling cracks observed during construction of Line 9 of the Barcelona Metro.

The research work presented herein focuses on the last topic. In order to verify the influence of steel fibers on the crack development in segmental linings during construction, several non-linear analyses were carried out.

Based on the material properties described in § 2, the total strain rotating crack model provided by DIANA was adopted for FE simulations of the SFRC tunnel segments. The numerical analyses were carried out by adopting a 3D solid model with 5184 first order hexahedral elements (eight nodes brick elements HX24L). The constitutive law for concrete under compression was assumed according to Thorenfeldt (1987) that is a suitable model for a concrete grade C50/60. Moreover, the increase of compressive strength due to lateral confinement has been implemented according to Selby and Vecchio (1993).

During excavation process, 30 TBM actuators act on the Barcelona Metro lining. The average service load applied by a single actuator is 3 MN. The load configuration used in Barcelona is a combination of the French and Japanese jack configuration. In practice, two pairs of thrust jacks act on each tunnel segments whereas four bearing pads are positioned in the rear face of the tunnel segments (ring joints).

One single segment with his two pairs of actuators was considered and its boundary conditions (i.e. presence of adjacent segments) were simulated by elastic springs whose stiffness was previously calibrated. Noticing that also ring joints have been simulated by using "no-tension" elastic springs positioned on the bearing pad surfaces (Fig. 6).

Figure 6 shows the loading scheme when thrust jacks are exactly placed in position and the support of the ring joint is uniform.

Figure 7 shows the numerical results in terms of load (from the actuators) versus the average longitudinal displacement under the loading surfaces. The segment collapses at a total load of 30.7 MN; since the service

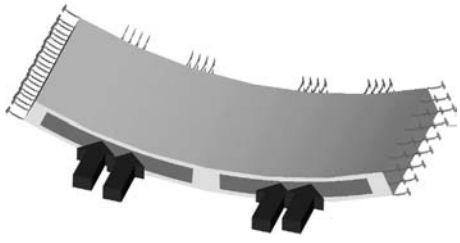

Figure 6. Scheme of a segment with the load from the two pairs of jacks, four rear bearing pad supports and spring representing the stiffness of the neighbor segments.

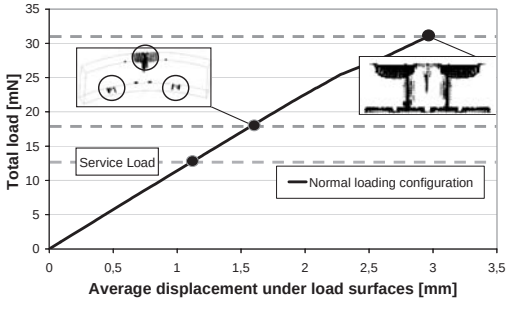

Figure 7. Load displacement curve with the nominal load scheme.

load is 12 MN, the safety factor is 2.58. The compressive strength of concrete is almost reached in longitudinal stresses under loading surfaces ($\sigma_c = 55$ MPa, $f'_c = 58$ MPa). As shown in Figure 7, the first cracks appear between the loading surfaces, due to spalling, at approximately 6.0 MN (0.5 times service load). The spalling cracks develop with an increase of load and penetrate more deeply in the segment.

Splitting cracks appear under the loading surfaces at 17.5 MN, due to splitting stresses in radial direction (σ_r). In the classical elastic solution, the depth of the disturbed zone is approximately the width of the structure that means, in this case, the thickness of the lining.

After cracking, the splitting stresses decrease in the cracked zone and are redistributed over a larger area with respect to the classical elastic solution. Because of the concrete toughness provided by fibers, cracks develop in a stable way.

Figure 9 shows the development of the splitting crack width under the load. The graph represents the relative displacements of two nodes: one located inside of segment and the other on the outside. Three pairs of nodes are taken on 20, 30 an 40 cm along the longitudinal direction from the TBM side of the segment (Fig. 8). The graph evidences that there exists a redistribution of stresses after cracking.

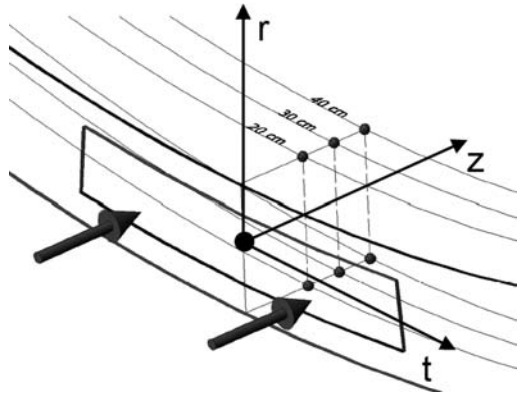

Figure 8. Scheme of the measurements of the splitting cracks.

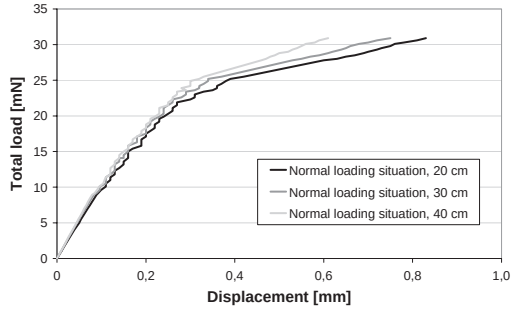

Figure 9. Development of splitting crack width under the load.

However, a number of irregularities can occur in practice. As a consequence, the ring joint may not be plane and the thrust jacks may be not exactly on place. For this reason, a possible eccentric placement of the thrust jack, its orientation and an uneven support in the ring joint have been investigated. In particular, numerical results of and eccentric load are presented herein in comparison with normal load conditions.

Eccentric placement of thrust jack in radial direction has been considered because it will increase the spalling stresses and can damage the segment. The eccentric placement has been modeled in FE analysis as a triangular pressure distribution on the loading surface. This provokes an eccentricity of 37.3 mm (Fig. 10).

When the above mentioned eccentricity is present outward (Fig. 10b) the ultimate load decreases significantly. In fact, the numerical analyses show a maximum load of 23.6 MN, that corresponds to a safety factor of 1.97 (Fig. 11). Spalling cracks initially appear between the thrust jacks; they start with a load of 5.0 MN and significantly influence the segment collapse.

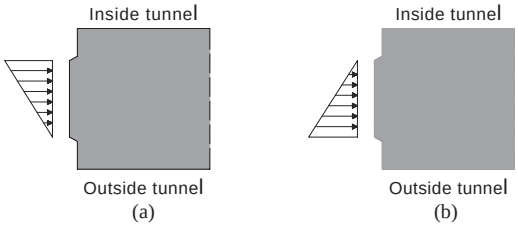

Figure 10. Eccentric pressure of the thrust jack inward (a) and outward (b).

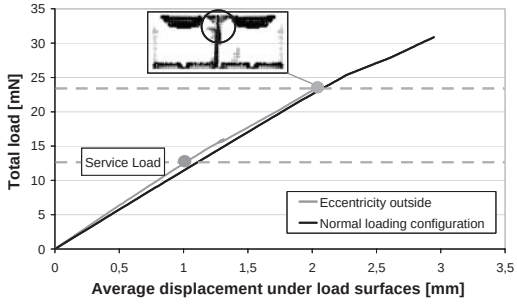

Figure 11. Load–displacement curve with and without eccentricity.

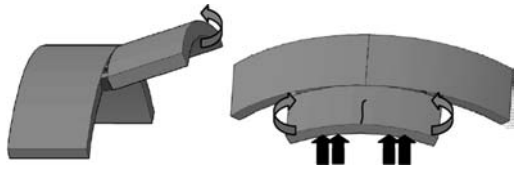

Figure 12. 3D scheme to of the dominant mechanism in the case of the outward eccentricity due to spalling cracks and bending moments.

Because of the eccentricity, the segment tilts outward providing a non-smooth support. Consequently, a bending moment occurs, as shown by the 3D model in Figure 12.

Splitting stresses initiate at an earlier load level (11.4 MN instead of 17.5 MN without eccentricity); this is probably due to higher local stresses in the longitudinal direction. The development of these splitting cracks under the load is schematically shown in Figure 13.

The cracks between the loads develop over the total depth of the segment due to the increased bending moment for the outward tilting. It can be noticed that similar deeply penetrating cracks between the thrust jacks have been observed in the Line 9 of the Barcelona Metro. Figure 14 exhibits the location of the cracks of the segment as well as the crack patterns obtained by

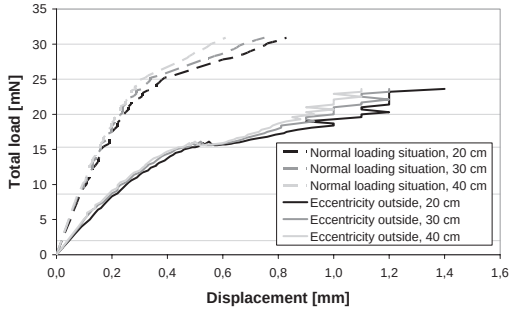

Figure 13. Development of splitting stresses under the load.

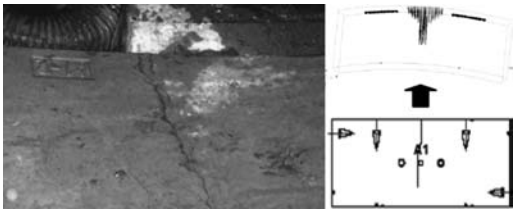

Figure 14. Cracks between the jack loads observed in the Line 9 of the Barcelona Metro and FE crack patterns.

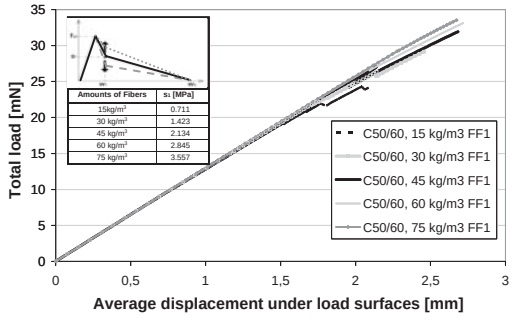

Figure 15. Load-displacement curves for a segment with different amounts of steel fibers.

numerical simulations. In the Barcelona Metro tunnel these cracks appeared when 9.3 MN were applied by the jacks (corresponding to 0.78 times the target load) whereas the numerical crack patterns refers to a load of 11.4 MN. Looking at the similarities between the numerical and the actual cracks in the tunnel, eccentricity could explain the presence of these cracks.

The normal load situation has been simulated by considering also SFRC with a different amount of steel fibers. The adopted fiber contents are 15, 30, 45, 60 and 75 kg/m^3. The numerically obtained ultimate load ranges from 24.3 MN (for 15 kg/m^3) to 33.5 MN (for 75 kg/m^3; Fig. 15). The constitutive post-cracking laws for the different fiber contents are shown in Figure 15.

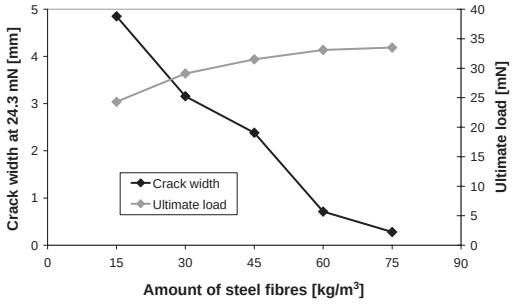

Figure 16. Influence of the amount of steel fibers on the ultimate load and on the maximum crack width.

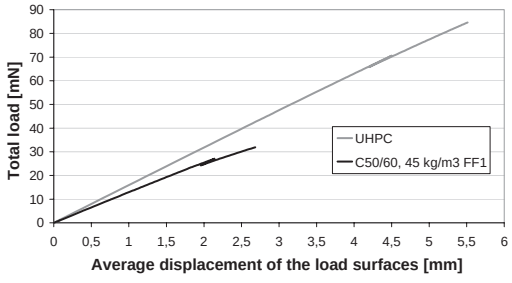

Figure 17. Total load vs. average displacement of loading surfaces for UHPC and C50/60 with 45 kg/m^3 FF1 steel fibers.

Numerical results show a significant increase of bearing capacity of the segment for fiber contents up to 45 kg/m^3; beyond this dosage, fibers has not effect in this tunnel (Fig. 16).

The maximum crack width (at 24.3 MN) for the different amounts of steel fibers is shown in Figure 16. It can be observed that the maximum crack width significantly decreases with larger fiber contents and that fibers play a major role on cracking phenomena; this also emphasizes the role of fibers on structural durability. By comparing a concrete with 60 kg/m^3 and with 75 kg/m^3, it can be noticed that 25% of extra fibers does not increase the bearing capacity but reduces the maximum crack width by a factor of 2.5. This can be explained by the two major cracks in the analyses with 60 and 75 kg/m^3 and by the presence of one mayor crack in the analysis with 15, 30 and 45 kg/m^3.

Finally, the behavior of a tunnel segment made of UHPC has been investigated. Numerical results gave an ultimate load of approximately 85 MN, corresponding to 2.66 times the ultimate load of a C50/60 concrete with 45 kg/m^3 of fibers (Fig. 17).

By using UHPC, the crack width at ultimate load is approximately 7.1 mm. The maximum crack width present with a load of 68.6 MN is 2.375 mm, which is similar to the one with a C50/60 concrete with 45 kg/m^3 of steel fibers with a total load of 24.3 MN.

4 CONCLUDING REMARKS

The present paper shows results of a numerical study of precast tunnel segments for the Line 9 of the Barcelona Metro. The numerical model shows reasonable results in terms of bearing capacity and crack development in a segment during TBM operations.

Eccentric placement of the thrust jack is one of the possible explanations of longitudinal cracks that are often present the in tunnel linings, including the one of the Barcelona Metro. In fact, the presence of eccentricities is one of the possible unfavorable conditions that causes higher stresses in the lining. In this loading situation, it has been demonstrated that the ultimate load reduces significantly and larger cracks are present.

The bearing capacity of the segment under jack load increases with the fiber content up to a maximum value (45 kg/m^3 in the considered case) that depends on the collapse mechanism.

The crack width gets benefits from the presence of fibers and continuously reduces when the fiber content increases. This results underlines the importance of fibers in concrete or r.c. structures for the durability aspects.

Because of the enhanced compressive and tensile strength as well as the higher toughness, a tunnel segment made of UHPC with steel fibers can carry very high thrust forces and only small cracks occur. As a consequence, by using these materials, for a given thrust force the lining thickness could be reduced.

Development of damage detection method on the tunnel lining from the laser scanning data

Jong-Suk Yoon
Inha university, Incheon, S. Korea

Myung. Sagong and J.S. Lee
Korean Rail Research Institute, S. Korea

ABSTRACT: Laser scanning is an emerging non-destructive technology to monitor surface condition of structures from various applications. High density of laser scanning points, point clouds, allows detecting the morphological features and surface conditions of structures. In order to extract useful information from laser point clouds, an adequate and effective approach should be applied. This study proposes a method to detect damaged parts from laser scanned tunnel data using radiometric and geometric properties of laser points. The scanned tunnel data includes all of accessories attached to a tunnel as well as tunnel liners. To apply a mathematical model to tunnel liners, the accessories are first separated and eliminated, and then the damaged parts on the tunnel liners are ultimately detected. The method proposed in this study verifies the capability of a laser scanner to detect physical condition of tunnel lining surface and also expands the usage of laser scanning technology. Furthermore, the developed process of tunnel lining inspection will facilitate the tunnel inspection process and increase efficiency on the tunnel inspection and accuracy of the results.

1 INTRODUCTION

Underground structures, for example tunnels, undergo regular inspection process to ensure the safety and to estimate the remaining life cycle of the structures. Due to aging process, the tunnel supporters, rockbolt and shotcrete, can be deteriorated and lose a portion of their supporting strength. The deterioration could be an initial step to induce deformation of a tunnel. The occurrence of deformation on a tunnel can cause cracking, spalling and leaking of water on the concrete liner. Therefore, the regular inspection process will investigate the detailed conditions of tunnel such as strength of concrete liner, cracks and spalls on the lining, leaking spots and approximate volume, tunnel deformation etc.

Regular inspection scrutinizes the surficial characteristics of tunnel liners. Since the traditional tunnel inspection method relies on the visual and hammering method, the task is time-consuming and labor intensive. Recently, with advance of technology various inspection techniques have been introduced such as the use of line-sensor camera for image capturing (Asakura and Jokima, 2003, Sasama, et al. 1998), and radar technology (Davis et al, 2005). Detailed technical review of the tunnel inspection methods can be found from Haack et al. (1995) and Richards (1998).

Among the others, image and laser scanning technologies show sufficient applicability of surficial tunnel inspection aspect. Existing tunnel scanners using image processing technique acquire images by line camera or video recorder. The images will undergo image processing to detect the cracks and spalls on the concrete liners. This method has high accuracy and resolution depending upon the camera capacity and running speed of the vehicle mounting the image capture devices.

Generally, compared to the image scanning method, laser scanning technology has lower resolution and accuracy even with the laser scanner with high sampling rate. However, the laser scanner collects three dimensional (3-D) data from which restriction boundary of tunnel can be checked. In addition, from the data, the longitudinal and cross-sectional drawings can be extracted for old tunnels, which do not have CAD drawings. In consequence reverse engineering for old tunnel is possible. Furthermore, a comparison between the sets of scanned data for each scanning allows the laser scanner functioning as a member of Intelligent Tunnel Maintenance System (ITMS). From the comparison between the scanned data sets, the overall behaviors of tunnels can be checked: deformation trend at the certain location of tunnel, development of cracks and spalls and conditions of tunnel accessories.

In this study, we developed a filtering method to detect tunnel accessories and damaged part on the concrete liners from the laser scanned data. First, this process can filter tunnel accessories such as electric pipe lines, catenary for railway tunnels and brackets. In conclusion, the laser scanning technology has been expanding its application with the advantage of the high density data and accuracy. This study will provide the potentiality to inspect the underground facilities using radiometric and geometric characteristics of laser technology.

2 METHOD

Laser scanner data has an advantage to provide high density and accurate 3-D information. However, an effective method should be applied to extract useful information from numerous laser point clouds. The method proposed in this study is mainly composed of two steps to discover damaged part of liners (Figure 1). The laser scanned data includes all of accessories attached to tunnel liners such as pipe lines, catenary, etc. The points from the accessories are necessary to be separated and eliminated for the detection of the damaged parts. Subsequently, remaining data showing the state of tunnel liner is mathematically fitted as a plane and the damaged parts are detected based on the residuals of the fitting.

2.1 *Scanned tunnel data*

A laser scanner, Acuity AR-4000 LIR with line scanner, scanned a tunnel for this study. The scanner scans an object far from 0 to 16 m range with 2.5 mm accuracy. The scanner moves forward and scans by 80 cm in a profiling manner. The scanner recorded and stored 245,006 points for 80 cm in width as shown in figure 2. The scanned data contains X, Y, Z coordinates and intensity value. The origin of the coordinates is the location of the scanner. x axis is the horizontal, y axis is the direction to the crown of the tunnel and the z axis is along the tunnel. The intensity is recorded by the backscattered signal power in the 8 bits. Figure 2a illustrates the scanned tunnel data and the axis of the coordinates, and figure 2b is the digital image of the real tunnel at the inset of figure 2a. The black and white color of figure 2a represents the intensity value. The scanned tunnel in figure 2 is one of railway tunnels in Korea.

2.2 *Separation of tunnel accessories*

The data points from the tunnel accessories will be detected and eliminated to fit the points as a plane. Since the scanned data is high density, it will be effective to find the tunnel accessories first rather than processing the whole data. The detection of the tunnel

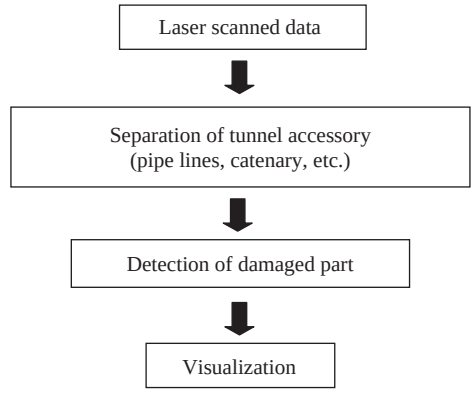

Figure 1. The conceptual flowchart of the processing.

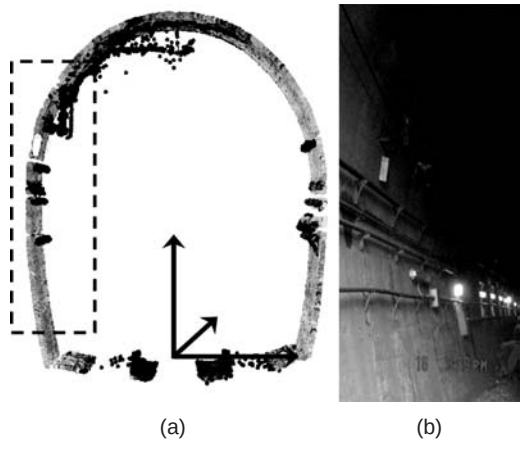

Figure 2. Scanned tunnel data illustrated by intensity value.

accessories uses the calculation of correlation coefficients between x and y coordinates. Since the cross section of tunnel will change where pipes locate, the correlation between x and y directions will be quite low at this location. On the other hand, the data from tunnel liner will have certain type of correlation between x and y directions depending on the tunnel shape. The tunnel profile is separated into several segments to calculate the coefficient of correlation. Once the correlation coefficient of x and y is under 0.92, the part is considered to hold accessories and following steps are conducted to separate the tunnel accessories.

This study proposes to use intensity of laser scanner data for the separation tunnel accessories because intensity is strongly influenced by materials' reflectance (Ahokas et al., 2006). Due to different material types, intensity values of tunnel accessories are quite different compared to the intensity of the

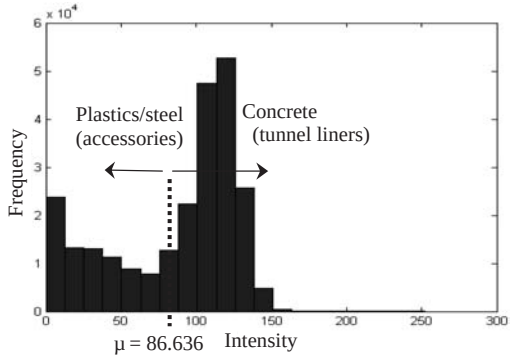

Figure 3. Intensity histogram of the entire scanned points.

tunnel liner as illustrated in figure 2a. The accessories attached to tunnel liners are mainly made of plastics and steel while the tunnel liners are made of concrete. Intensity backscattered from tunnel liners is much higher than that of the accessories as shown in figure 2a and figure 3. Figure 3 shows the intensity histogram of the scanned tunnel data in figure 2a. In figure 3, the pattern of histogram is bimodal with two peaks from accessories (plastics/steel) and tunnel liners (concrete). Based on figure 3, the entire dataset can be initially divided by two groups based on the intensity values. If the intensity of a point is higher than average of intensity value of whole points which is 86.636, then the points are initially considered from tunnel liners. In other case, when the intensity values are less than the average value of intensity, the points are regarded to represent tunnel accessories. The average of each group is used as representative points to calculate Euclidian distance in the following step.

Along with intensity, x coordinates are the complimentary factor to separate accessories since all of accessories are attached inside tunnel. Therefore, the distinctive factors to separate accessories from the tunnel liner are intensity and x coordinates. The separation of accessories is processed a scanned tunnel profile by a section of 50 cm in height (in y axis). If a section holds accessories as explained, the Euclidian distance between a point and each representative point of accessories and tunnel liners is calculated using x and intensity. Since the intensity and x coordinates are the distinctive characteristics, the distance is calculated by the two factors. Depending on the distance, the point is assigned to a closest group, and the group of accessories is separated from the group of tunnel liners.

Figure 4a shows the section with under 0.92 correlation coefficient where the points from accessories are included. Figure 4b is an enlarged plot of inset of Figure 4a. The several points from the accessories which seem to be representing pipe lines are plotted at some distance from the tunnel liners. Figure 4c is the plot of the data within one section illustrated in

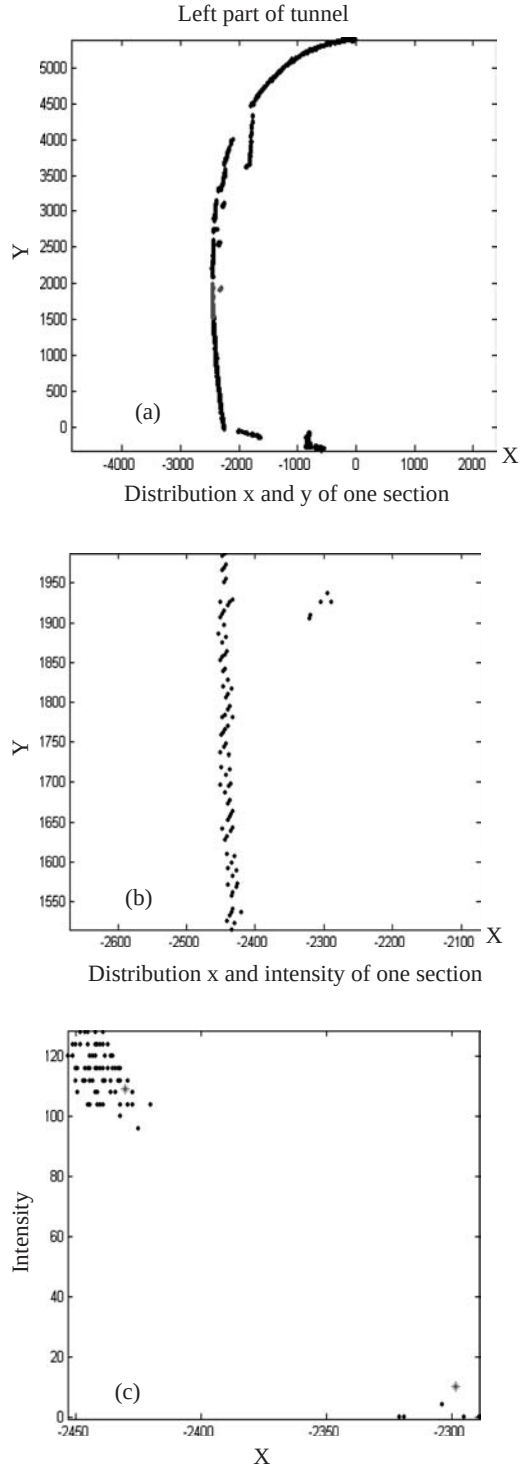

Figure 4. The procedure of tunnel accessories separation.

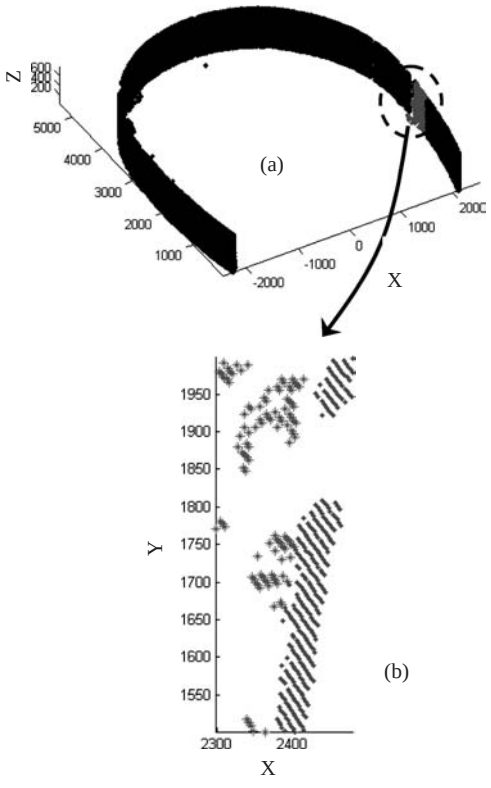

Figure 5. A section to detect damaged part on tunnel liner (a) and the result of plane fitting (b).

figure 4b in x coordinates vs. intensity of the points. The figure shows apparent separation of concrete liner and the accessories. The points from accessories are far distant from the group of tunnel liners' points in the plot of x coordinate vs. intensity (figure 4c). Figure 4c clearly explains the x coordinate and intensity are distinctive factors to discriminate facility from tunnel liners.

2.3 *Detection of damaged part*

Since the tunnel scanning data is in the form of 3-D aspect, 80 cm long tunnel scanned data can be segmented into 2-D data. In this study, the scanned tunnel is segmented in 50 cm in y direction (see figure 5a). The figure shows the section characterized as a plane. Data segmentation process is carried out to identify the data points of tunnel accessories and damaged part on the liner. The tunnel accessories and damaged parts are determined from the distance between the plane and a point. If the distance is greater than a threshold value, the point is determined as a point from the damaged or accessories part. Equation (1) is a formula of a plane, and equation (2) is the calculation of distance between a point and the plane. A plane with equation (1) is established by the points composed of a section of the tunnel liners. Equation (3) shows the decision making process of a point belong to tunnel accessories and damaged part of liner or undamaged part of liner.

Identification of tunnel accessories and damage of liner is conducted by using the normal direction of the points from the plane. The directions of accessories and damaged parts are reverse from the plane because the accessories locate inside of tunnel liner and damaged part can be detected outside of the tunnel cross section. Therefore, the opposite sign of threshold value should be applied for the detection of accessories and damages.

$$ax + by + cz + d = 0 \tag{1}$$

$$d_i = \frac{|ax_i + by_i + cz_i + d|}{\sqrt{a^2 + b^2 + c^2}} \tag{2}$$

$$P_i = \begin{cases} \textit{tunnel liner} & \text{if } d_i < \text{threshold} \\ \textit{damaged or accessories} & \text{otherwise} \end{cases} \tag{3}$$

where, $P_i = i_{th}$ *point*

3 RESULT

Most points backscattered from accessories are eliminated in the first step, using radiometric and geometric characteristics of laser points through the proposed procedure of this study. However, the points are not completely removed, because some part of tunnel liners are mixed with accessories' points because of moisturized dark intensity. As the second step, calculating normal distance from a point to a plane, is performed, the accessories attached to tunnel liners are completely eliminated.

Once a threshold value of equation (3) is set, tunnel accessories, liner and damaged part can be separated as shown in figure 5b. The points (.) in figure 5b are the plane characterized as equation (1), while the asterisks are the points of accessories. The accessories' points are completely eliminated through the second step (figure 6). Figure 6a is the raw data of scanned tunnel and figure 6b plots only tunnel liners after elimination of accessories points.

The detection of damaged part is sensitive to the threshold value used in equation (3). The threshold value is depending on the density of a scanner. If the scanned data is highly dense, the threshold value can be small to detect fine damage such as cracks. In this research, several threshold values are tested. Figure 7 shows the damaged part detected on the tunnel liners with a digital image taken by a digital camera. On the digital image of figure 7, two driven nails on the tunnel liners are within a circle. The two areas are

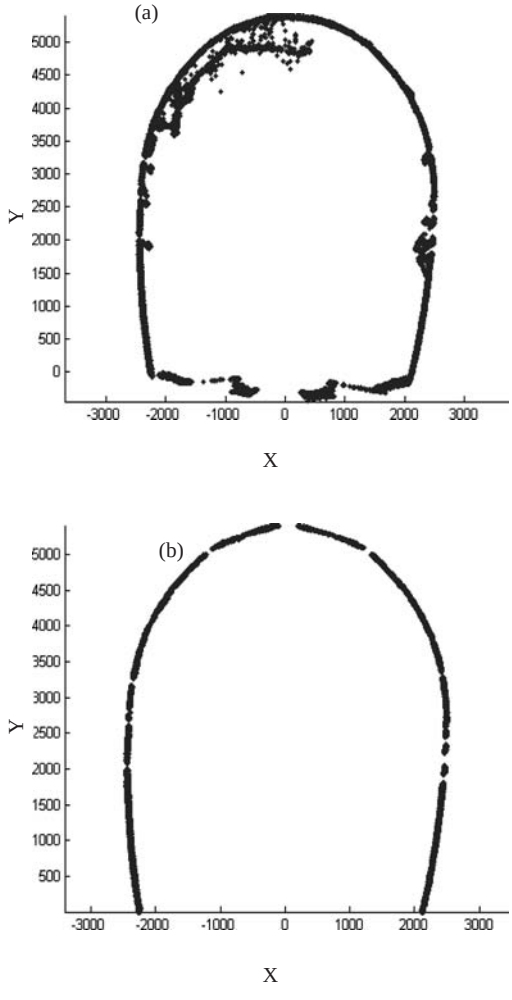

Figure 6. The laser scanned tunnel (a) and the tunnel liners eliminated facility points (b).

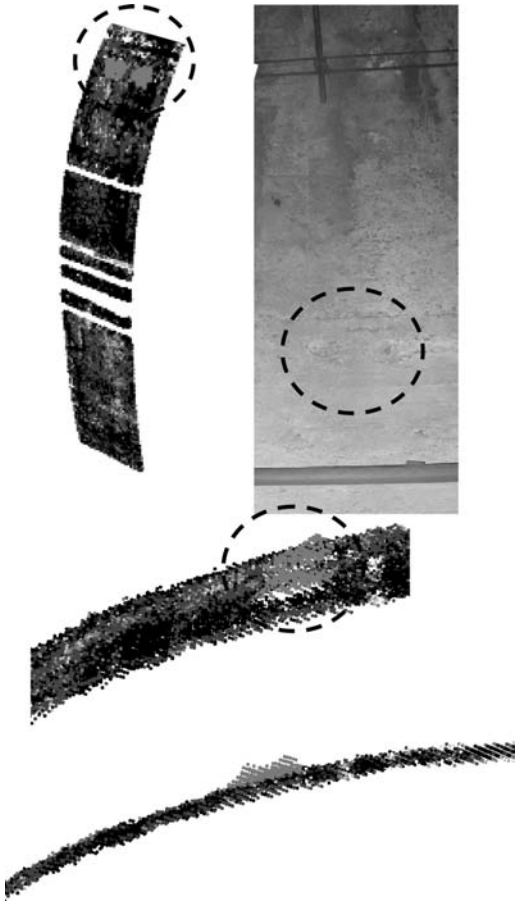

Figure 7. Detected damaged part on the tunnel liners.

physically damaged by the driven nails and detected by the proposed method. In this case, the threshold value is set to 20 mm. If the threshold value was set to smaller, then finer parts would be detected.

4 CONCLUSIONS

This study proposes an approach to detect the tunnel accessories and damaged part of tunnel liners from the laser scanned data. The laser scanned data with high-density and accurate point clouds is composed of three dimensional (x, y and z) coordinates and intensity which is another benefit of laser scanners. For the use of laser scanning technology on the tunnel maintenance, the specific and effective approach is required to extract useful information from laser point clouds.

The approach employed in this study is as follows. First, the proposed method separates points backscattered tunnel accessories from tunnel liner. The intensity and x coordinates are used to separate the points reflected from the tunnel accessories from the entire laser scanning data. As the intensity of laser data is mainly affected by the target materials, concrete of tunnel liners and plastics and steel of accessories are contrast with bright and dark intensity values in the scanned tunnel data. Second, the points from tunnel liners within a section are fitted as a plane. The scanned three dimensional data can be segmented in two dimensions. The segmentation is conducted along the y axis, direction to the crown of the tunnel. By using the threshold value of geometric distances between the plane and points, tunnel liners and accessories are complete separated.

This study provides a preliminary work on the use of laser scanned data to identify the different types of material in the tunnel: concrete liners and tunnel accessories such as pipe lines and catenary. Nevertheless, further work must be required to adopt the laser scanning technology as a key of automated tunnel monitoring system. Detailed works will be on the assessment of accuracy, generation of highly dense point clouds, and data processing techniques.

The MASW method for testing tunnel lining integrity

René-Michel Faure
Centre d'étude des Tunnels, Bron, France

Guy Lefebvre, Mourad Karray
Université de Sherbrooke, Sherbrooke, Canada

Gérard Hémond
Solem SA, Carouge, Suisse

ABSTRACT: The MASW method (Modal Analysis of Seismic Waves) has been developed by the Sherbrooke University for the last ten years. It is now frequently used for soil investigation. In a cooperation with CETU (France) and Solem (Switzerland) the Sherbrooke University has adapted the method for checking the lining integrity of tunnel. The first in situ experiment was in the Mont Blanc tunnel after fire and the obtained results were confirmed by sampling. Since, other experiments were achieved and a 88 square meters slab was built with lot of well defined anomalies in it. The paper, after a reminder of the method will present the last results and will develop the how to use this non destructive, easy to use, in situ method.

1 INTRODUCTION

The big fire that occurred in the Mont Blanc tunnel caused 39 fatalities and destroyed all the equipments of the tunnel. For safety engineers lot of questions raised and for civil engineers the main question was the concrete vault integrity. With other classical investigations, new one were tested, the MASW method, applied for the first time for estimating the damaged concrete.

2 THE MASW METHOD FOR TESTING LINING COMPETENT STRUCTURE

On March 24 1999, a fire was declared in the Mont-Blanc tunnel starting from a truck stationed near the garage 21 (6550 m from the French entry). The fire lasted 53 hours and was equivalent to 200 tons of burnt fuel. Very high temperature was developed, 39 people died and 34 vehicles burnt including 23 lorries.

The damages to the concrete vault (not armed) were limited and rescue teams were delayed only by heat. The length of tunnel the most exposed to the fire lies between garages 19 (5950 m) and 23 (7150 m from the French entry) on approximately 1200 m. Comparatively to other fires (Manche, Storebelt, Tauern) where important chipping (spalling) occurred, concrete in the Mont-Blanc tunnel remained in place. Only some small repaired zones provided falling concrete. Extend of damages to the concrete vault was an important question to be examined after the fire. Faure and Hémond (2001) and Faure et al. (2002) presented the different methods used for the investigation of the vault. Because burnt concrete have a modulus increasing with depth, we decided to use the Modal ASW method that was set first, for soils.

In March 2000, a team from Sherbrooke University (Québec) did the MASW measurements. By performing MASW tests in continuous, profiles of elastic shear modulus can be determined at closely space location in such a way that the results can be presented as a kind of tomography, allowing a good appreciation of spatial variability.

We obtained 15 profiles and several maps (80×80 cm) of speed waves in concrete. As these measures were the first we obtained, we were very doubtful about them. At this time, lot of people believed that all the concrete was destroyed after a 53 hours fire, and the profiles show that only some centimetres of concrete was burnt. Later, other investigations with different methods confirmed the MASW results.

MASW method was used again in 2004 to characterize a modern concrete lining in the newly built Fontain tunnel in Franche-Comté, France.

3 THE MASW METHODS

The shear wave velocity (V_s) is a direct expression of material rigidity since the elastic shear modulus (G_{max}) is related to V_s as:

$$G_{max} = \rho V_s$$

where ρ is the density of the material. For this reason, there has been since a long time interest in evaluating V_s by means of surface waves.

The Spectral-Analyses-of-Surface-Waves (SASW) was developed in the early eighties. The SASW testing procedure was designed to minimize the contribution of higher Rayleigh modes since it assumes that the average dispersion curve is representative of only the fundamental Rayleigh mode. A number of numerical studies first demonstrated that this basic assumption was valid only when the shear wave velocity varies regularly with depth. However, Karray and Lefebvre (2000) have demonstrated, based on numerical simulations and experimental cases that the multi-Rayleigh modes problem can occur in various situations even if the shear wave velocity increases regularly with depth.

The MASW method (Modal Analysis of Surface Waves) was developed in order to identify and separate the energy of higher modes (Karray, 1999).

Other MASW method exists (Multichannel Analysis of Seismic Waves), not so accurate due to not taking in account higher modes. (Park et al, 1999)

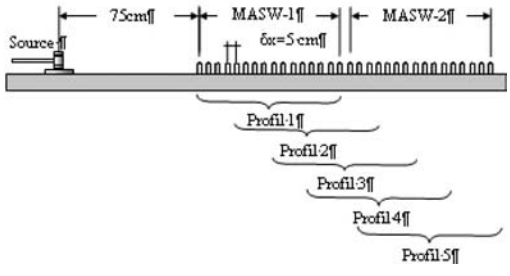

Figure 1. Configuration of the MASW method.

3.1 *Test procedures*

In the MASW method, an array of 16 sensors placed at constant intervals, are excited at the same time using an impact source (figure 1). Several tests can be done successively to establish a mapping of the medium in terms of shear wave velocity. It is indeed possible to combine 16 signals of two or more adjacent tests using the same source Bruel & Kjaer sensors with a natural frequency of 25 kHz were used for the characterization of the concrete tunnel liners.

3.2 *Analysis of the signals*

In the MASW method, the recorded signals are interpreted in series of 16 by carrying out an analysis in time-space domain using a wavelet technique. For each frequency, an energy spectrum is established in the phase travel time and group travel time plane.

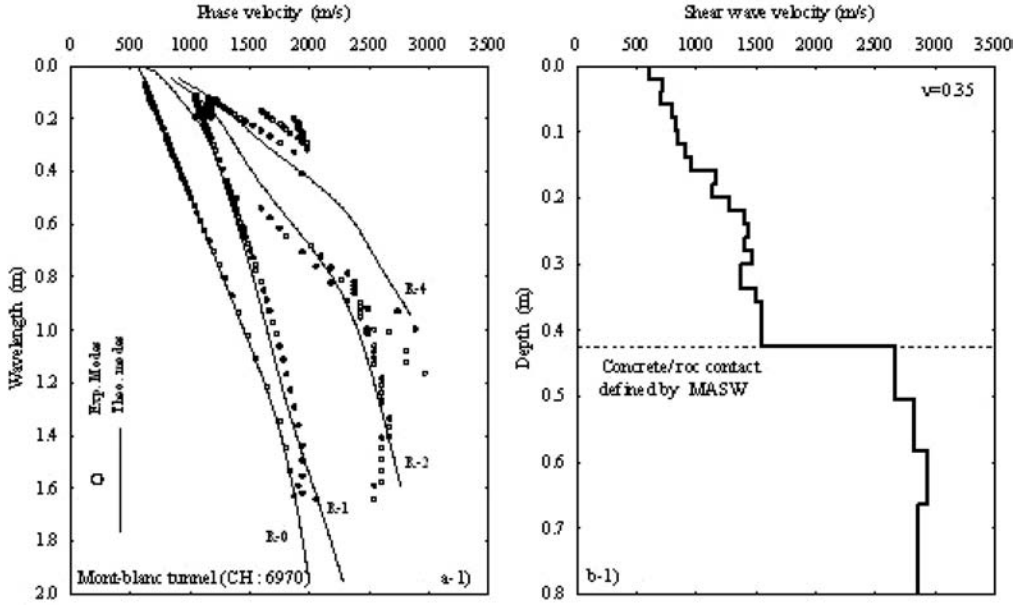

Figure 2. Dispersion curves and V_s profile at the Mont-Blanc tunnel.

The presence of more than one peak of energy indicates the existence of different wave groups. The phase velocity and group velocity of each peak of energy are then computed for each frequency and the dispersion curves of the different Rayleigh modes are established. (Figure 2)

3.3 *Inversion process*

The MASW inversion process is automated and the match between the theoretical and the experimental curves is minimized not only in terms of difference in phase velocity, but also in terms of the shape of the dispersion curve, allowing a more rapid convergence in the automated process and also a better detection of the weaker or stronger layer at depth (Karray, 1999).

4 MONT BLANC TUNNEL TESTS

The Mont-Blanc concrete lining lies on bedrock without any reinforcement or impervious membrane. In terms of surface wave propagation, these conditions are similar to geotechnical formation where the rigidity is generally greater at depth than close to surface. For this reason, the MASW algorithms could be used directly without modification.

Seven series of MASW tests were carried out in April 2000 in the zone affected by the fire.

The average shear wave velocity profiles obtained at each site tested by the MASW method are presented in figures 3 (a and b). The shear wave velocity profile obtained at location 7070 (1120) is repeated in figures 11a and 11b, because located at the limit of the fire zone.

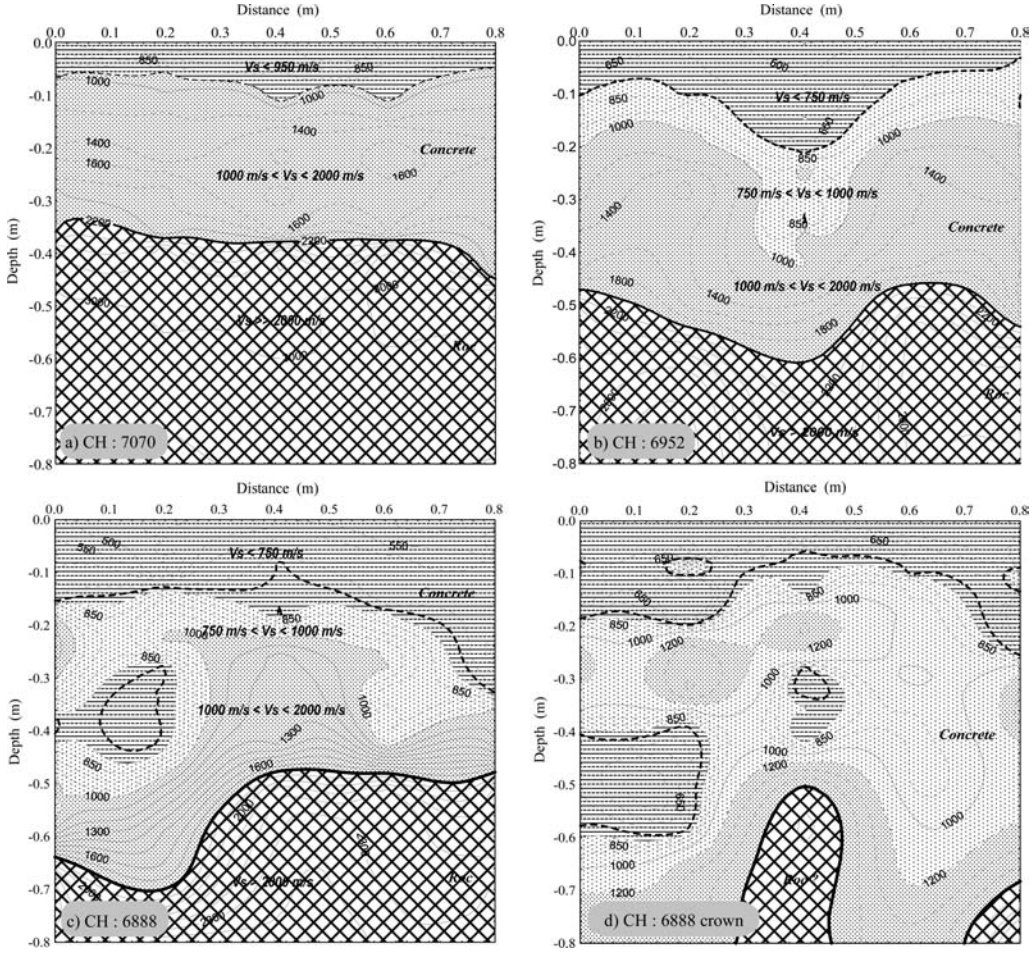

Figure 3. Vs tomography in the Mont-Blanc tunnel a) location 7070, b) location 6952, c) location 6888 and d) location 6888 crown.

Figures 3 a,b,c and d, show contours of shear waves velocity determined at location 7070, 6952, 6888 (wall and crown).

The contact between the lining and the bedrock is easily detected by a jump in V_s of about 1500 m/s in the concrete to values close to 3000 m/s in the bedrock. The thickness of the concrete lining is irregular and varies generally between 350 and 700 mm (Fig. 3a to 3c) except in the crown where over thickness and irregularities are more important (Fig. 3d). V_s values, as low as 500 m/s, were observed near the surface of the lining.

5 MASW TESTING AT THE FONTAIN TUNNEL

MASW tests were performed in March 2004 in the new Fontain tunnel before it was opened to traffic. The modern concrete liner in the Fontain tunnel differs from the Mont-Blanc liner because it was built with high performance (HP) concrete and because it contains an impervious membrane made of a 5 mm geotextile and a 2 mm PVC membrane between a shockcrete layer applied on the bedrock and the high strength concrete. In some areas, the impervious membrane was placed on 2 mm steel plates held by metallic supports. In these areas, a filling concrete was placed between the bedrock and the impervious membrane.

The data acquisition procedures like in the Mont-Blanc tunnel with 100 mm spacing between the accelerometers was used. A total of 154 V_s profiles were determined, spaced at 200 mm on 7 different lines, for a total of 29 m. This impervious membrane incorporated in the concrete lining creates particular conditions for the propagation of surface waves, acting as a discontinuity in the propagation of the shear component of the surface wave. These conditions were totally different of the geological model considered in surface wave testing. New algorithms had to be developed and incorporated in MASW. (Figure 4) For only 7% of the V_s profiles, the surface wave propagated across the impervious membrane. Examples of these profiles, interpreted with the geological model approach are presented in Figure 5. The contact between the HP concrete lining and the shotcrete layer is easily identified on these profiles by a drop of V_s. Behind the shotcrete layer, V_s increases to about 3 000 m/s in the bedrock. It is only in these few profiles (7%) that the material behind the HP concrete liner could be characterized in terms of V_s.

In most cases, the surface wave propagation was limited by the impervious membrane and the V_s profile characterized only the HP concrete liners. The thickness of the HP concrete liner as determined by MASW has varied from 220 to 660 mm except at one location where over thicknesses of 1 100 mm were detected. The thickness determined with MASW were, in general, in good agreement with construction records except occasionally where steel arches were incorporated in the filling concrete to support the impervious membrane. The additional rigidity of the zone of the filling concrete in which were embedded the steel arches made more difficult to differentiate between the filling concrete and the HP concrete, if by chance the surface wave did propagate across the impervious membrane at such location.

The few V_s profiles (11 or 7%) which extended beyond the HP concrete indicate V_s generally between 2 500 and 3 200 m/s in the bedrock. Slightly lower values in a few instances near the rock-concrete contact possibly indicate some dynamiting related fissuring.

6 SLAB FOR CALIBRATION

The Solem society built a large slab (88 m^2) with great number of defaults or inclusions allowing a good calibration of the Modal ASW method. Tests will be performed soon. (Figures 6 and 8).

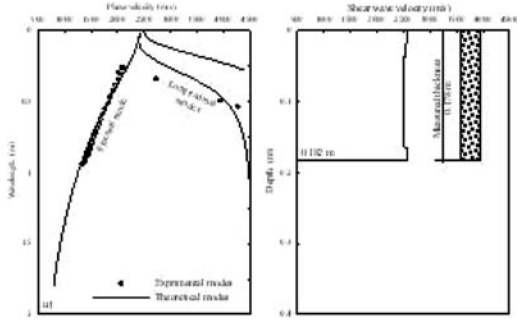

Figure 4. Example of MASW investigations for a concrete slab a) Experimental and theoretical dispersion curves; b) V_s profiles and measured thickness.

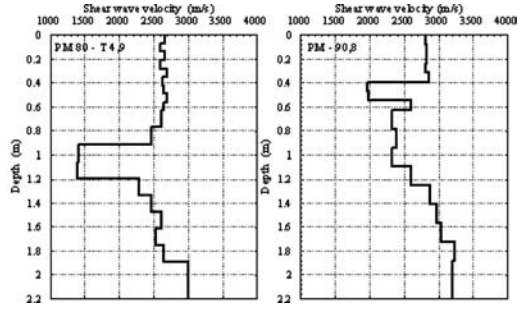

Figure 5. Examples of V_s profiles extending through the impervious membrane.

7 CONCLUSION

Conditions of a tunnel concrete lining can vary rapidly from point to point, particularly its thickness, due to the irregularity of the rock profile after excavation (blasting). A continuous method of investigation allowing a tomographic type of representation is consequently desirable to appreciate thickness variation or inside anomalies. The direct measurement of mechanical parameters (modulus) is also important when the lining investigation has the purpose to detect defect in the lining, the state of degradation of the concrete or simply to determine when the concrete has the necessary strength to support itself after placing.

The MASW results are in good agreement with results obtained in intrusive investigations, namely penetration velocity during drilling and compression wave velocity measured in the laboratory on drilled cores. The contact between the concrete liner and the rock was clearly identified in MASW testing in addition to the characterization of the rock in terms of V_s.

Design of the strengthening of tunnel linings under localized pressures

A.R. Marí & C. Molins
Technical University of Catalonia, Barcelona, Spain

ABSTRACT: Strengthening tunnel linings by means of placing a new interior lining (relining) built with self compacting high strength concrete, connected or not to the existing one, is a feasible solution that can be constructed in a reasonable period of time. This solution is well adapted to resist uniform pressures distributed along the perimeter. However, sometimes severe pressures have limited extension, encompassing merely an arch. Such a loading leads to significant bending moments concomitant with axial forces that have to be resisted. This paper presents and applies a methodology to design such strengthening.

1 INTRODUCTION

The rising number of tunnels under construction in new transport infrastructures increases the probability of crossing hazardous sections with problems related to the expansion of the ground or to cavities filled of water or mud. This is possible in spite of previous ground investigation and geotechnical characterisation. Extraordinary ground movements or water flows can eventually appear and have to be restrained by the lining. In such cases, the overloading of the lining can be far away of its maximum capacity. Because of that, different solutions have to be appraised taking into account the tunnel serviceability, mechanical strength, water tightness, environment and economy. Sometimes the structural strengthening becomes the best possible solution.

Strengthening the tunnel lining by means of placing a new interior lining (relining) built with self compacting high strength concrete, connected or not to the existing one, is a feasible solution that can be constructed in a reasonable period of time. This solution is well adapted to resist severe uniform pressures distributed along the circumferential perimeter. However, ground heterogeneity produces that severe pressures sometimes have limited extension, encompassing merely an arch of circumference instead of the whole one. Such a loading leads to significant bending moments concomitant with axial forces that have to be resisted.

The moment and axial force ratio depends on the radius of the strengthening ring and on the length of the loaded arch, defined by its angle. In addition, there exist multiple axial/moment ratios that can be resisted by a reinforced concrete section with a determinate amount of steel. This leads to an uncertainty on the worst angle of loading that would provide the largest amount of reinforcement.

This paper presents a methodology to design the strengthening of tunnel linings subjected to severe ground pressure of known maximum value but of unknown length and position on the perimeter. The method was used in the design of the strengthening of a Spanish high speed railway tunnel (HSRT) that was subjected to severe ground expansion. In that case, strengthening works were carried out before the tunnel had its first service. The paper describes the design of the strengthening, the analyses performed to find out the worst loading angle using nonlinear finite element models, some features related to its construction and monitoring.

2 DESCRIPTION

In 2002, during the ending work of the linings of three consecutive HSRT: Lilla, Camp Magré and Puig Cabrer (with a total length over 3000 m), abnormal deformations on the base and severe cracking were observed in all of them. Such tunnels belong to the HSR line Madrid-Barcelona-French border, nowadays under construction, and they are close to the city of Montblanc (Tarragona province). Damages in the lining were attributed to unexpected expansions of the surrounding ground consisting of sulphate-bearing clays. The tunnels under construction were bored by NATM, using sprayed concrete and bolts as a preliminary lining, and a final lining of 0.30 m of plain concrete was placed using conventional moulds. Figure 1 shows its typical cross section and its main measures.

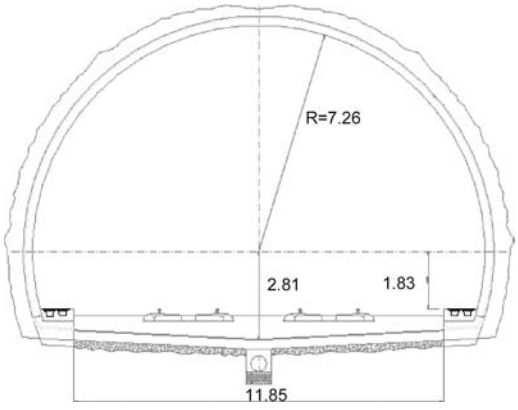

Figure 1. Cross section of the original lining that was under construction in the Lilla HSRT. Distances in m.

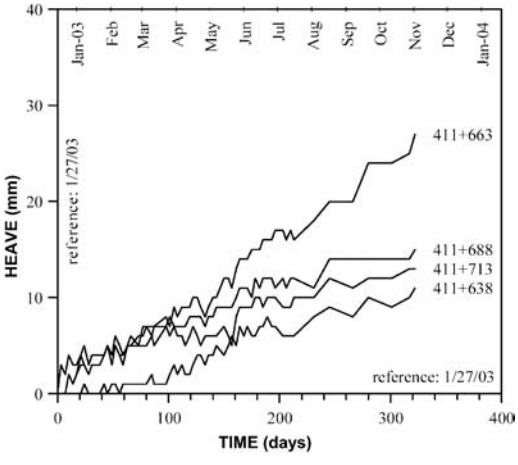

Figure 2. Floor heave in sections with invert (Alonso *et al.*, 2005).

Figure 2 shows the evolution of the floor heave. A team led by the Department of Geotechnical Engineering of the Technical University of Catalonia studied the origin and the nature of the ground expansions. Such studies included laboratory tests to analyse the expansive phenomena, *in situ* measurements of actual pressures in different sections by means of pressure cells placed in the invert-arch and in the vault (Figure 3), and testing of several solutions in experimental sections. Field data and laboratory tests results showed connections between some mechanisms of degradation and the swelling behaviour of the foundation material (Alonso *et al*., 2005). The authors concluded that the safer solution was to build a retrofit system consisting of an inner ring, relining, connected to the existing vault. This relining had to be capable of bearing the pressures of ground expansion,

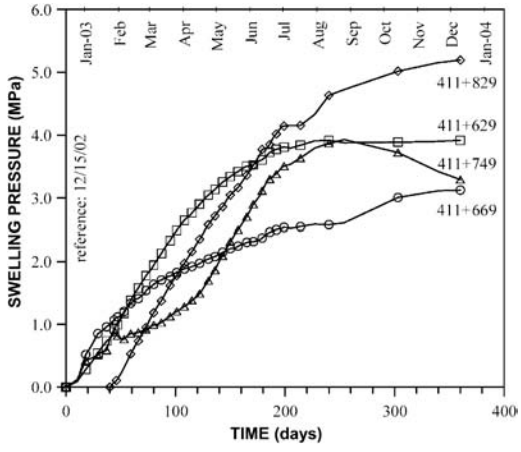

Figure 3. Swelling pressures in sections with invert (Alonso *et al.*, 2005).

which reached maximum values of 4250 kPa on the invert-arch and 1360 kPa on the vault. Such pressures overpass the capacity of conventional relining of tunnels based on steel trusses and concrete. Because of that, the public company responsible of the project management of the Railway Infrastructure, Gestor de Infraestructuras Ferroviarias (GIF), commissioned the developing of a technical solution to the Department of Construction Engineering at the UPC. The solution had to be economically and technically feasible for that challenging problem.

3 PROPOSED SOLUTION

3.1 *Geometry and loads*

Design loads were chosen according to the *in situ* measurements: 4500 kPa on the grade invert-arch and 2500 kPa on the vault. To resist such amount of load a ring shape was selected for the relining. In addition, experimental pressure measurements showed that the distribution was far from been uniform in the transverse direction neither in the longitudinal direction. So, the design pressure could be applied in the worst position and extension. Another condition to be satisfied was that the inner radius had to be at least 6.00 m and better 6.50 m, owing to the required dimensions for HSR traffic.

Lilla tunnel presents two main different sections: section 1 had the tunnel support of sprayed concrete and a lining of 30 cm of concrete, while section 2 had the tunnel support of sprayed concrete with no additional lining. In the Camp Magré and Puig Cabrer tunnels there were always lining. This was taken into account in the overall response of the support of the new lining because these additional stiff layers

Table 1. Thicknesses and deformation properties of the existing support.

Tunnel	Lilla		Camp Magré & Puig Cabrer
	Sect. 1	Sect. 2	
Thickness of tunnel support (cm)	15	15	15
Thickness of lining (cm)	30	–	30
Available thickness (cm)	46	76	126
Ground deformation modulus (GPa)	250	250	120
Ground Winkler modulus (MN/m^3)	334	160	160
Winkler modulus including linings (MN/m^3)	664	444	490

improve the support condition. Table 1 shows the thicknesses of the lining in the different sections and the deformation properties, mainly radial Winkler moduli, used in the analyses. Tangential Winkler moduli were approached by one third of the radial one.

A first approach to the problem showed that the solution had to be built in high strength concrete (HSC) with a significant amount of steel rebars. Because of pressures could present any limited extension, the strengthening had to resist significant bending moments concomitant with large axial forces.

To solve that problem, nonlinear finite element analyses were performed to obtain the worst loading condition on the vault and on the invert-arch.

3.2 *Design analyses*

In-plane nonlinear material and geometric analyses of the lining were carried out using the model of Marí (2000). Assumptions for the nonlinear plane analysis of the ring were: (1) longitudinal contribution of the lining is neglected, (2) the interaction with the ground is simulated by a unilateral Winkler model in both radial and tangential directions, (3) loads acting on the ring are self weight and design pressures, which can act in an arbitrary extension.

The moment and axial force ratio depends on the radius of the strengthening ring and on the length of the loaded arch, defined by its angle. In addition, there exist multiple axial/moment ratios that can be resisted by a reinforced concrete section with a determinate amount of steel. This leads to an uncertainty on the worst angle of loading that would provide the largest amount of reinforcement.

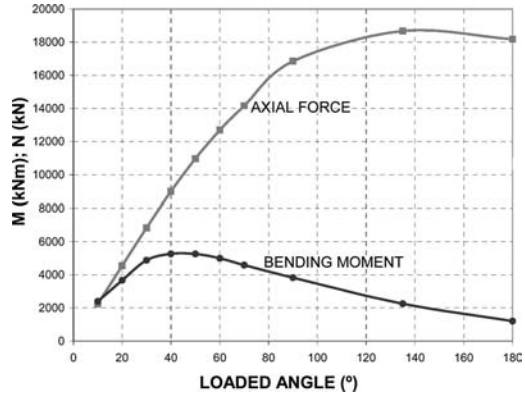

Figure 4. Bending moment and axial force, as a function of the loaded angular extension.

Figure 5. Total amount of steel as a function of the loaded angular extension.

In this case, to obtain the worst loaded angular extension in the invert-arch, an study varying the extension of design pressure (4500 kPa) on a cylindrical lining with a constant depth of 76 cm of reinforced concrete ($f_{ck} = 50\ N/mm^2$ and $f_{yk} = 500\ N/mm^2$) was developed. Figure 4 show the sectional forces obtained. Maximum bending moment was achieved with a loading angle of 40° while maximum axial force was obtained for 135° of loaded extension. However, maximum reinforcement, supposing a mechanical cover (d') of 10 cm, is produced by a loaded extension of 60° as Figure 5 shows. That preliminary result allowed to define the worst loading extension in approximately 60°. More details of the numerical predictions can be found in Marí & Pérez (2003).

Sensitivity analyses were also performed to select the concrete strength. They showed that concrete with a compressive characteristic strength of 60 N/mm^2 was unable to bear the loads. It was possible to use a 70 N/mm^2 concrete but it produced a huge amount of reinforcement. An 80 N/mm^2 concrete was selected

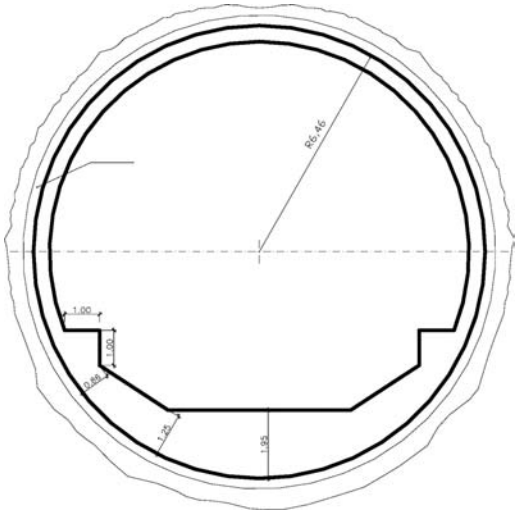

Figure 6. Geometry of the relining designed for section 1 of Lilla Tunnel.

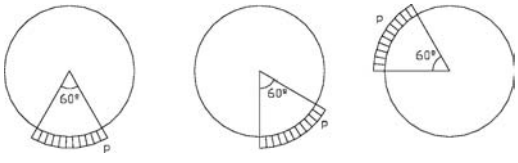

Figure 7. Loading cases considered in final design.

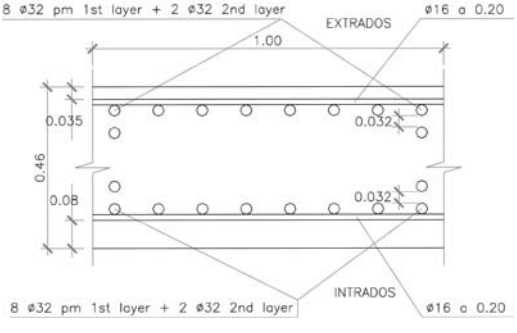

Figure 8. Reinforcement in the vault at the Section 1 of Lilla tunnel.

because the amount of reinforcement, in spite of being very large, was viable.

For final design purposes, three main loading cases with an extension of 60° were considered (Figure 7). The first two cases correspond to a load of 4500 kPa acting symmetrically and asymmetrically on the invert-arch. The last case in Figure 7 corresponds to a lateral unsymmetrical loading of the vault with a pressure of 2500 kPa.

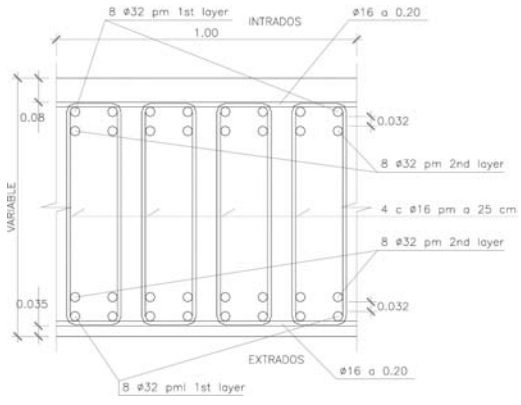

Figure 9. Reinforcement in the base at the Section 1 of Lilla tunnel.

3.3 *Final design*

The final design with the geometry shown in Figure 6 included an amount of steel of 80 cm^2/m in the vault and 128 cm^2/m in the invert-arch. Figures 8 and 9 show the cross section of the vault and of the base, respectively, including the reinforcement. All of them are symmetric.

Reinforcement of the invert-arch presents stirrups, as shows Figure 9.

4 CONSTRUCTION

The amounts of reinforcement, in both base and vault, make difficult placing conventional concrete. To improve the placing of a HSC in such conditions, self compacting concrete was finally chosen.

The composition of the mix deserved a careful design (Barragan *et al.*, 2005) because many factors had to be taken into account: a temperature range from 5°C to 35°C during the construction time, curing by spraying water was not possible owing to the deficient drainage of the tunnel during construction, a transport time of thirteen minutes, a high pump speed and a high initial strength required to reuse moulds. The resulting mix is shown in Table 2.

The construction process of the strengthening presented three main phases. Firstly the demolition of the grade slab and the excavation of the invert-arch were done. Secondly, the reinforcement cage of the whole invert-arch was placed in only one operation because it was prefabricated. Then, it was filled of concrete (Figure 10). Thirdly, the semicircular vault was built. Figure 12 shows the springing of the vault.

The construction of the relining was finished in 2005 (Figure 12). At this stage, vertical boreholes were drilled on the base and horizontal ones on the walls to extract samples for testing in the lab. Tests

Table 2. Composition and test results of the concrete.

Composition		(kg/m^3)

on more than twenty specimens provided information on the actual compressive strength of concrete, that was over 100 MPa. The actual deformation modulus (E_c) was 44 GPa. Water tightness was also tested and segregation was visually checked in all extracted cores.

5 MONITORING

Since the construction was finished, monitoring has provided data about both the behaviour of the structure and the pressures acting on the lining. Figure 13 shows the typical layout of instruments, placed at twenty one cross sections in the Lilla tunnel and seven more sections in the Puig Cabrer and Camp Magré tunnels. One pressure cell and two extensometers welded at the reinforcement of the intrados and of the extrados were placed in selected angular positions.

In addition, three cross sections in the Lilla tunnel have instruments on the vault, where much lower pressures were expected and are actually measured.

Since 2005, the instruments show an overall upward trend that it is not uniform along the time. In September 2006 it is not stabilized yet. Lilla tunnel presents the

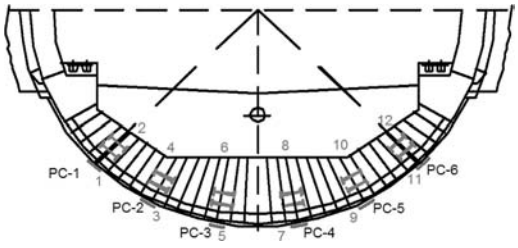

Figure 13. Typical layout of pressure cells and extensometers for the monitoring.

highest values (IIC, 2006). In four sections one of the six pressure cells place in the base has measured more than 3000 kPa and the highest value is 4980 kPa. However, pressure cells on the vaults measured a maximum value of 40 kPa.

6 CONCLUSIONS

A technical solution for strengthening of tunnel linings by placing a new interior lining (relining) to resist severe non uniform pressures along the circumferential perimeter has been described.

In the case presented, relining was built with high strength self compacting concrete, not connected to the existing lining. The use of such a concrete allows good final serviceability conditions, mechanical strength and water tightness. It is a robust solution, environment friendly and at a known final cost. In addition, it was constructed in less than one year.

Monitoring of the pressures acting on the lining and the strains in the steel reinforcement close to the intrados and to the extrados are showing an adequate response of the lining subjected to localized pressures over 4000 kPa. So that, the design and the construction process were appropriate for the considered problem.

The methodology has recently been applied to another HSRT that was subjected to huge water pressures, over 400 m, in a karstified mass rock. In that case, there were also serious doubts about the uniformity of the pressure distribution (corroborated by measurements).

ACKNOWLEDGMENTS

The authors thank *ADIF* (formerly GIF), the public company responsible of the design and construction of the HSR network in Spain, for funding the structural studies developed at the Department of Construction Engineering of UPC (Technical University of Catalonia), as well to the firm INOCSA and the construction companies Ferrovial-Agroman and Corsan-Corviam for their technical support.

DeCo Grout – Innovative Grout to cope with rock deformations in TBM tunnelling

B. Billig, B. Ebsen, C. Gipperich, A. Schaab, M. Wulff
HOCHTIEF Construction AG, Essen, Germany

ABSTRACT: In order to extend the field of application of precast segmental lining in rock tunnelling, efforts were made by HOCHTIEF to develop a flexible segmental lining system which allows moderate rock deformations. The system comprises a defined compressible zone around a segmental lining system. This compressible zone may be made up of compressible grout, a compressible substitute for pea gravel or a compressible layer on the back side of the segment. Different materials were tested in laboratory for the different applications. Very good results with respect to the required stress-strain behaviour were obtained with the so-called DeCo grout – a cement-based mortar with EPS pearls and foam. In a confined compression test the material behaves initially in a linear-elastic manner. When the so-called compression limit is reached the material behaves more or less plastically, i.e. the stresses remain but the specimen is compressed. Compression rates up to 50% of the initial volume are possible. The innovative material opens up new chances for mechanised tunnelling in moderately squeezing rock.

1 STATE OF THE ART: TUNNELLING IN SQUEEZING ROCK

1.1 *NATM vs. TBM*

The New Austrian Tunnelling Method (NATM) as a method for the excavation of tunnels in rock has a long tradition. But in the course of the years TBM tunnelling has gained more and more importance in rock tunnelling. Apart from high advance rates this method provides further advantages. Due to the high degree of mechanism the working conditions for the personnel have been well improved. TBM tunnelling is especially suited and economic for very long tunnels with no possibility of intermediate starting points for tunnelling.

TBM tunnelling in rock generally allows two different kinds of primary tunnel linings:

- shotcrete in combination with reinforcement, anchors, bolts and steel arches according to the principles of NATM or
- precast segmental tunnel lining.

The shotcrete support can be adapted to the existing rock conditions. But in many cases it is not possible to make the most of the TBM power, because the installation of the primary lining is the limiting factor. High advance rates can only be achieved with a precast segmental tunnel lining. But the application of a segmental lining system is limited up to now due to rock deformations.

1.2 *Design of segmental lining*

The design of the segmental lining for tunnels in soft and granular soils with a low overburden height is driven mainly by the loads resulting from the water pressure and the overburden earth pressure. Due to the small overburden only small reductions of the earth pressure are possible. Ground deformations which could allow a redistribution of loads are mostly not acceptable, so the tunnel lining is designed in many cases for the complete overburden pressure.

For deep lying tunnels in rock the circumstances are fundamentally contradictory: The design of a tunnel lining for the entire vertical forces resulting from the overburden rock is in the majority of cases technically not possible. Therefore the tunnelling method must allow for the possibility of deformations. Due to these deformations the acting rock stresses will be reduced so that the tunnel lining can support the remaining acting ground forces.

This principle has been known and successfully realized in the NATM for a long time. On the one hand side the primary tunnel lining with shotcrete and anchors allows the stabilization and the support of the surrounding rock immediately after blasting. On the other hand side the thin layer of shotcrete and the time-delayed development of the compressive strength and stiffness enable a further progression of rock deformation in the tunnel until casting the inner lining with in-situ concrete. Using a precast segmental lining system requires the installation of the first ring under the

protection of the tail shield of the TBM. On the one hand side this gives directly a support and a protection against falling rock fragments but on the other hand side the support is effective with 100% of it's stiffness from the moment of installation. In comparison to a primary lining made of shotcrete a precast segmental lining is more stiff, because the concrete has gained the full strength and stiffness at the moment of installation and the complete ring is erected at once.

In squeezing rock deformations may therefore limit the use of a precast segmental lining.

1.3 *Project examples in the past*

In the past the question of the feasibility of TBM tunnelling in combination with a precast segmental lining came up several times during the tender phase. So the swelling potential of Shale led for example to significant rock deformations which had to be considered in the design of the precast segmental lining. Also when tunnelling in rock with high overburden one is confronted sometimes with large plastic rock deformations. Time dependant rock deformations of very weak or strong weathered rock make the use of a TBM doubtful.

These cases document the interest in and demand for a compressible annular grout. For the future we expect miscellaneous projects especially for tunnels in the Alps with high overburden pressure or tunnels in swelling rock.

2 COMPRESSIBLE TUNNEL LINING

2.1 *Theoretical idea*

The difficulties of tunnelling in squeezing rock have been known since the beginning of underground construction. The theoretical solution to this problem is even known, but only realized so far in the NATM. The following diagram shows the correlation between rock stresses and the stiffness/resistance of the tunnel lining.

The rock loading is found as the intersection point of the characteristic rock line with the respective support line. The earlier installation and the higher stiffness of a conventional precast segmental lining leads to increased rock loads, which are in many cases economical not justifiable. Obviously an initial linear-elastic behaviour followed by a plastic branch allows to decouple rock deformations from rock loads acting on the lining and to reduce rock loading significantly. Such a deformation behaviour may be reached by a "defined compressible precast segmental lining".

On the basis of the theoretical idea of a compressible precast segmental tunnel lining a lot of different ideas were developed and patented in the past, but in the majority the described solutions are very vague

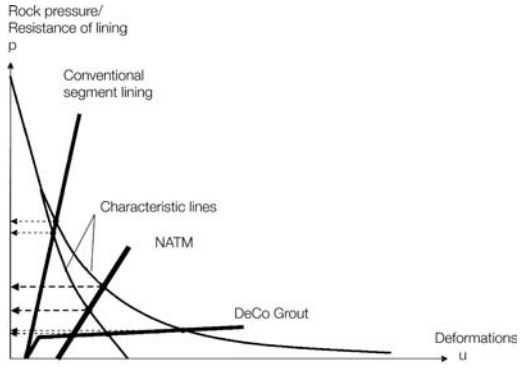

Figure 1. Characteristic line for NATM and precast segmental linings (Principle sketch).

and the actually required compressible materials which could accommodate rock deformations do not exist. Furthermore these patents mostly refer to the preliminary ground and rock support and not to the final tunnel lining, because of the close connection to the developments in mining.

2.2 *Executed projects*

According to our information and a study of literature only a few projects – most of them with pilot character – exist where a compressible lining was executed. One project was the mine in Ibbenbüren, Germany (Maidl et al. 2001). To deal with the expected high deformations tangential compressible elements have been installed between the joints of the segmental lining. In some rare cases tangential compressible elements have been used within the scope of a primary shotcrete lining, for example Gotthard-Basis-Tunnel, Los Faido (Brux 2004) or in the Strengener Tunnel (Budil et al. 2004).

3 RESEARCH AND DEVELOPMENT BY HOCHTIEF

In order to develop a defined compressible lining system R&D works were focussed on two approaches: tangential or radial deformable systems.

3.1 *Tangential compressible elements*

The idea of a tangential deformable system is to decrease the circumference of the lining while deformations take place. Due to the limited deformation capacity of concrete the shortening of the circumference requires special elements which are placed within the longitudinal joints between the segments. With the installation of the tangential compressible elements

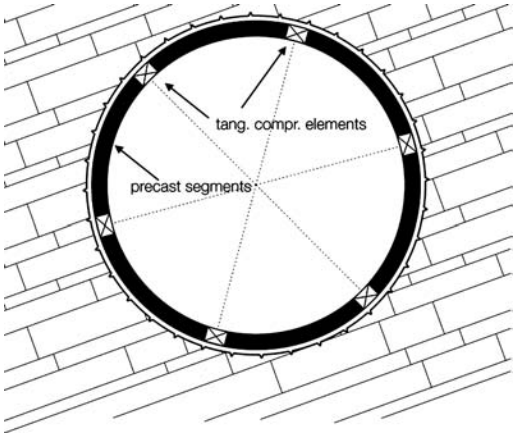

Figure 2. Tangential compressible element.

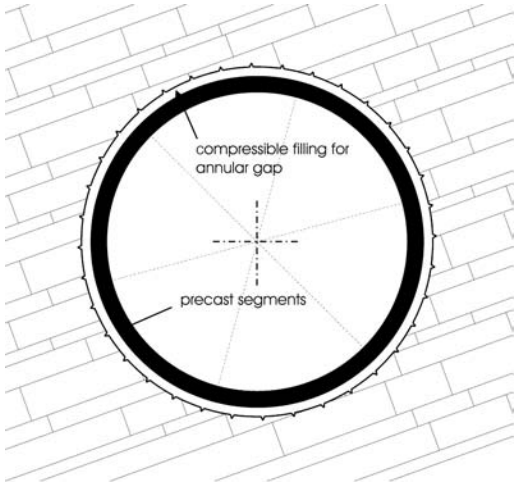

Figure 3. Radial compressible element.

only in the longitudinal joints of the segments the deformations are concentrated in 6 or 7 points according to the number of segments. The following figure serves as an example for the layout of a tangential compressible precast lining system.

Some structural studies about tangential compressible systems indicate that the accommodation of rock deformations is generally possible, but the bending moments in the precast segments are still very high so that thick segments with a high reinforcement ratio are required. Other disadvantages of these elements are especially the high labour costs for their installation and the time delay for the tunnel drive. Furthermore this system of precast segments and tangential elements does not provide a water proof tunnel lining. So this system can only be used in dry rock. All these arguments show that the development of tangential compressible elements are only qualified for temporary tunnel linings in combination with a subsequent final lining.

3.2 *Radial compressible systems*

More promising however seems to be the concentration on radial compressible systems. Generally it is distinguished between three different kinds of installation a compressible layer between the segmental lining and the surrounding rock:

- Filling the annular gap with a pumpable cement-based compressible grout
- Filling the annular gap with a compressible granular material by means of compressed air (compare backfilling procedure of pea gravel)
- Adding of a compressible layer fixed on the back side of the segments before the installation of the ring in combination with a traditional annular grouting or a compressible grout (sandwich)

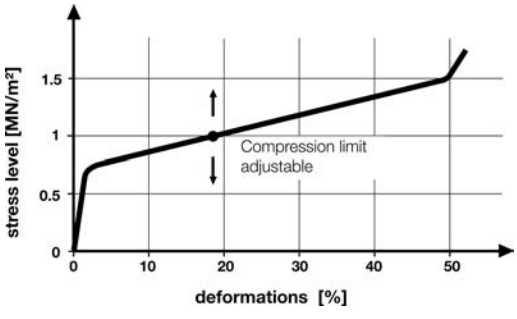

Figure 4. A spired nearly ideal plastic material properties.

In the beginning qualified materials had to be searched for and improved. The definition of a target corridor for the material properties was set up to assess the test results. Figure 4 illustrates the demands concerning the stress-strain properties for a nearly ideal plastic material. In the first part of the stress/strain relationship a stiff reaction with a fast increase of the stresses and low deformations at the same time is aspired. With reaching the so-called compression limit the material shall react more or less plastically, i.e. the stresses remain but the specimen is compressed until approximately 50%.

Although in relation to other well known materials like concrete or mortar the aimed compression limit is quite low but from the point of view of a lining designer rock loads in the range of 700 to 1500 kN/m^2 are quite high.

3.2.1 *Testing apparatus and testing procedure*

In order to compare the mechanical behaviour of different materials an adequate test setup had to be

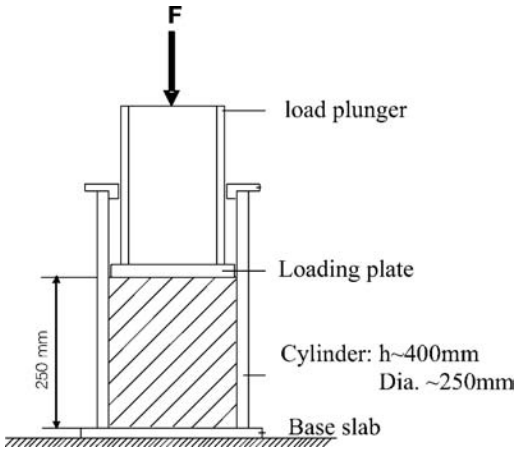

Figure 5. Measuring apparatus.

developed which reflects the restrained deformation conditions of the material in the annular gap.

Finally a test apparatus as shown in Figure 5 was chosen which allows to test the material with full lateral constraint. The loading speed was chosen with 0,2 mm/s.

To analyse the effect of the pot wall's friction on the results a series of tests with varying heights of specimens was executed. The comparison of the stress-strain behaviour showed a slight influence of the pot wall's friction increasing when smaller specimens were used. Even the velocity of testing was varied in several experiments but without any recognizable decisive influence.

3.2.2 *Test results*

The choice of materials tested in the first phase of the research project covers a large range of materials and corresponds to the different kinds of use, as a grout, a granular material or sandwich segment.

For a pumpable annular grout different super lightweight aggregates, several combinations of foam and EPS pearls and varying water-cement-values were tested. To find a granular compressible substitute for pea gravel mainly expanded clays and cellular glasses were analysed. Furthermore material combinations and the addition of other more elastic materials like vulcanised rubber were tested. For the third way – a so-called sandwich segment – plenty of thermal isolating materials and stones of lightweight gas concrete were put to tests.

The results are as well different as the materials. Figure 6 shows a selection of typical stress-strain curves. Some very light weight materials (a) show a more or less linear relationship between stresses and strains but on a quite low level. A typical material for this group is e.g. vermiculite. The initial stiffness is

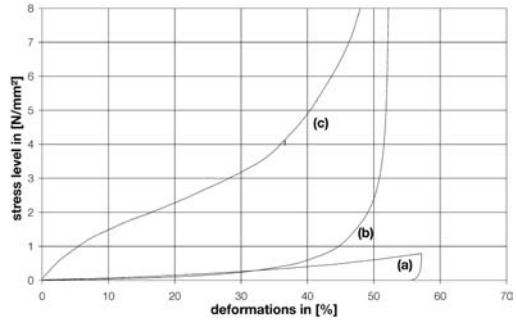

Figure 6. Stress-strain relationship for different materials.

very small as it is for material marked (b) in the beginning. Material (b) is a granular recycling rubber. With increasing compression the stresses increase initially very slowly. As soon as the internal pore volume is used up the stiffness of the material increases drastically. In this state the material behaviour is determined by the material behaviour of the particles. Without any internal pore volume the material is getting incompressible and the stresses grow beyond any limits.

Curve (c) shows a typical stress-strain relationship of light weight concrete aggregates. After an initial elastic branch the stiffness decreases which is typically caused by local crushing of the particles. With increasing compression the internal pore volume is used up and the same mechanism as described above determines the stress-strain behaviour of the specimen.

Although type (c) is most like the aimed behaviour the second branch of the stress-strain curve is to stiff and on a stress level which is too high.

Outstanding results with respect to the aimed stress-strain behaviour (Fig. 4) were achieved with a self created cement-based grout – a further development of the compressible concrete developed by HOCHTIEF some years ago. The development and the characteristic of this grout are described in detail in the following chapter.

4 DECO GROUT – A COMPRESSIBLE ANNULAR GROUT

4.1 *Further development of the compressible concrete*

Some years ago HOCHTIEF developed a damping concrete with an accommodation of approximately 50% of the starting volume for shock absorber slabs in the management of nuclear power plant waste. These test results form the basis for the further development of DeCo Grout. The following diagram documents the good starting position for the optimisation of the material.

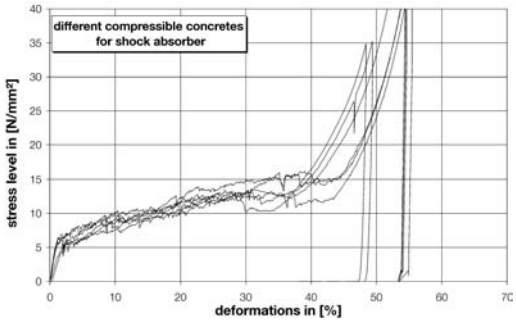

Figure 7. Test results of compressible concrete.

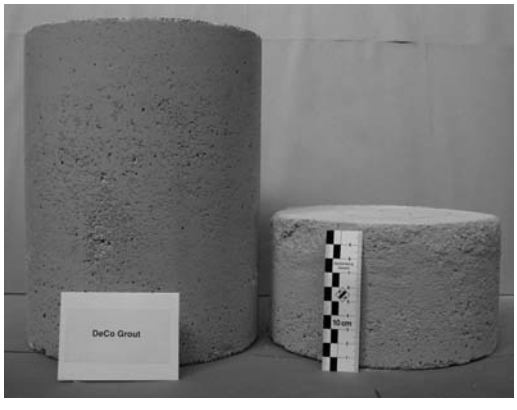

Figure 8. DeCo Grout before and after compression test.

The necessary modifications starting from the above described compressible concrete had to concentrate on four items:

- Reduction of the compression limit
- Improvement of the plastic behaviour
- Increase of the maximal compressibility
- Maintenance of the initial elastic modulus until reaching the compression limit

Tests to replace expanded polystyrene pearls with other lightweight aggregates like expanded clay or glasses were not successful, because these materials own a compression limit which is significant too high. Even with a maximum of expanded polystyrene pearls the stress level was too high and the compressibility not sufficient. To increase the compressibility it was necessary to enlarge the pore volume in the mortar. This was achieved by adding foam.

The result was a pumpable mortar with outstanding compression properties. This can excellently be documented with Figure 8, showing a specimen of DeCo Grout before and after the compression test.

In the meantime this grout has been applied for patent. More material tests have been continued to analyse the qualities of different kinds of cement and relationships of water and cement.

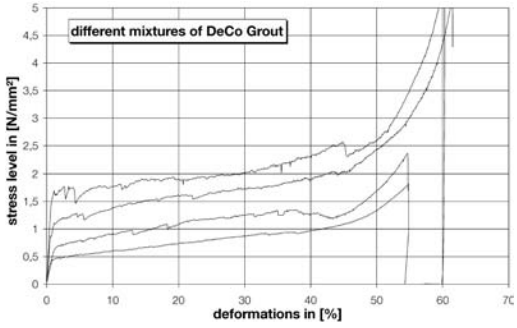

Figure 9. Test results for different mixtures of DeCo Grout.

4.2 *Adjustment possibilities of DeCo Grout*

Under the scope of this R&D project (Dorgarten et al. 2005) a number of tests were done. The numerous test results form the basis to assess the effects of the different materials added to the mix. Figure 9 shows test results from different mixtures of DeCo Grout.

The gained experiences allows now to modify the material properties as required by project specific needs.

4.3 *Defined compressible lining*

The enormous deformation capacity of DeCo Grout of nearly 50% allows with typical dimensions of the annular gap of approximately 15 cm the compensation of 75 mm radial deformations, i.e. 150 mm in diameter. Sensitivity studies showed that beside regular radial deformations also deformations in oval shape or local deformations can be accommodated.

Using this new and innovative material will of course require extensive monitoring during construction. The new system can be used in combination with conventional support methods in order to cope with local zones with increased rock deformations.

5 CONCLUSION

The new materials offer new chances in mechanized tunnelling in hard rock. With the development of a compressible material allowing moderate rock deformations the field of application of precast segmental lining in rock tunnelling can be extended. In the experiments done by HOCHTIEF the compressible DeCo Grout with an adjustable stiffness has shown extraordinary qualities.

The planned tunnels in the Alps with high overburden are an opportunity of using DeCo Grout. From

the comparable projects it is known that due to the high overburden rock deformations will occur and can prohibit common TBM tunnelling with a segmental lining. With the new compressible grout mortar it is possible to deal with moderate rock deformations.

A further example of the use of DeCo Grout is swelling rock for instant in Gypsum Keuper. The rock deformations are time-delayed and sometimes the stopping of deformations is very slowly and the temporary shotcrete lining have to support the ground for a long time until the final reinforced concrete lining can be installed. Here again the DeCo Grout can accelerate the progress of construction work. The time-delayed deformations will be accommodated by the compressible grout even when the final lining is installed.

These two cases are only a part of the complete application list telling where DeCo Grout can make tunnelling possible or easier within the scope of TBM tunnelling.

Immersed tunnels state-of-the-art

L.C.F. Ingerslev
Parsons Brinckerhoff, New York, U.S.A.

ABSTRACT: The ITA Immersed and Floating Tunnels working group issued the second edition of their state of the art report in 1997. This paper looks at recent tunnel design and construction to see changes that have occurred since then. There is still very much a place for immersed tunnels in today's sustainability world and they should be included as an option considered for any water crossing. Design requirements have become much more specific, focusing much more on project specific requirements. Available software has changed significantly analysis methodology and consequently how much can sensibly be presented to reviewing engineers and clients. Interesting new techniques are appearing on the construction side too. Concepts of some of these changes are presented here.

1 INTRODUCTION

It is now 10 years since ITA Working Group 11 Immersed and Floating tunnels issued the second edition of its State-of-the-Art Report (ITA 1997). Where has the state of the art gone in that period? Perhaps the most important changes affecting immersed tunnels are the environmental regulations affecting changes in water quality and concerns about existing fauna and flora, and the handling of contaminated material. In many countries, these are not necessarily new concerns, just that the requirements have been made more stringent and that increases costs.

Technology too has advanced. In the same way that bridges were made to fit the highways instead of highways made to fit bridges, immersed tunnels today are no longer necessarily straight tunnels with a constant cross-section. Much of this may be due to the much greater computing power available at our fingertips on the desktop and the great sophistication of software with user-friendly interfaces. The majority of immersed tunnels today are rectangular, shaped to provide ideal layouts for roads and railways with little wasted space. Immersion and final joint design has also improved. Noteworthy is that TBMs are to bore directly into the Bosphorus immersed tunnel to form the final joints in deep water.

Though there are still no design codes for immersed tunnels, guidance on design can be obtained from the ITA State-of-the-Art Report and in Japanese from the Coastal Development Institute (2002). Many papers have also been published, particularly in the proceedings of the ITA annual congresses.

Reasons for selecting an immersed tunnel (ITA 1999) have still not changed. For crossing a waterway, immersed tunnels are often viable alternatives and should be considered along with other options. Attributes to consider include:

- Immersed tunnels are shallow tunnels, often reducing the overall length of tunnel and enabling flatter approach gradients than would be possible for bored tunnels.
- Immersed tunnel cross sections are highly versatile, making them particularly suitable for wide highways and combined road/railway crossings.
- Most immersed tunnels have been built in water depths between 5 m and 30 m, although schemes have been postulated for 100 m depth. The deepest constructed is in 40 m of water to the underside of tunnel, and 60 m is under construction.
- They are suitable for most types of ground, including soft alluvial materials and conditions often unsuited to tunnel boring machines.
- Many immersed tunnels are in earthquake zones and have been shown to survive undamaged.
- Immersed tunnels can be prefabricated remote from the final immersion site, allowing placement in tight (e.g. urban) locations with little working space.
- The required dredging can generate material for new land reclamation.
- Construction can take place on many fronts simultaneously.

Contract packaging also varies considerably from the traditional design, bid and build, tending much

more towards design-build with the contractor also providing independent design verification. Project management for the owner's side is becoming more of a compliance-with-requirements role coupled with construction monitoring.

2 STRUCTURAL DESIGN

2.1 *Foundations*

Other forms of foundation besides sand and gravel are also used (Ingerslev 2001). Grouting in various forms is a much favored method of filling voids beneath immersed tunnels in seismic prone Japan after setting the tunnel to the design level. Formulations are possible that resist penetration of any underlying gravel layer that might be required to dissipate excess pore water pressures and thus reduce risks of liquefaction.

Ground failure as a result of seismic shaking can include liquefaction, post-liquefaction settlements, slope instability (landslide) and fault displacement. Some of these can result in horizontal and vertical displacements of the tunnel, which, if not taken into account in design, may require mitigation. No matter what kind of soil there is, some movement following a major seismic event is inevitable, but this is acceptable as long as such movements are within design tolerances. The effects of liquefaction and liquefaction-induced ground deformations can include the following:

- Uplift, buoyancy, and flotation;
- post-liquefaction settlements and deformations (total as well as differential settlements);
- lateral sliding stability of the tunnel;
- loss of bearing capacity;
- down-drag and reduction in lateral/vertical resistance of deep foundations.

To ensure that such movements do fall within acceptable limits, some soils susceptible to liquefaction may be improved sufficiently to ensure movements are limited to acceptable values; it may not be necessary to eliminate liquefaction altogether. Methods have included placing free-draining coarse aggregates around the tunnel structure to minimize the uplift potential, and installing sand or grout compaction piles below the tunnel invert to improve the soil properties. For liquefaction potential evaluations, SPT and CPT data requires careful evaluation, taking into account sampling procedures, depths and soil layer thicknesses.

2.2 *Minimizing fabrication facility depth*

For a number of projects, the temporary dry dock has been arranged so that perhaps only a small portion of the dock is deep enough to float out elements when the gate is opened. Elements are moved into that deeper location by pumping water in to a higher level than outside, enabling the remaining elements to float and be moved. This may result in additional flooding operations, though this cost and time may be offset by reduced excavation requirements.

Steel tunnels can have a very low draft when launched empty. For the Bosphorus concrete tunnel, a similar concept was used to minimize dock depth; only the lower half of each element was concreted in the dry dock; a braced steel waterproofing membrane was used as outer formwork for the remaining wall and roof construction. Bracing girders above roof level are later to be removed for reuse or disposal.

2.3 *Closure or final joints*

Where the final element to be placed has to be inserted between two elements or surfaces rather than merely appended to the end of the previous element, space is required to enable insertion. When tunnel ends are vertical, a marginal gap will be necessary at the secondary end. This short length of tunnel will need to be completed using special methods and is known as the closure or final joint. Several methods have been used to complete such joints in the past. It is important that axial and shear capacity of the tunnel is also achieved through the closure joint.

With the terminal block method, a short length of prefabricated tunnel is contained within the structure adjacent to the closure joint, outside a temporary bulkhead. This section can then be jacked or pulled out to meet the adjacent tunnel element and fill the gap. Seals similar to the immersion joints can be used on the end face of this moving section. The gap between the moving section and the oversize tunnel surrounding it must also be capable of being sealed, perhaps using inflatable seals and grout. This method has been used for the Tamagawa and the Kawasaki Fairway Tunnels in Japan. The use of divers is not required.

With the wedge-shaped block method, Figure 1, the width and shape of the closure joint must be fairly accurately known in advance. Sloping ends to the adjacent elements are required. Rubber compression seals permit the joints each side of the wedge to be dewatered and the joint to be completed from within. This method has been used for the Osaka Sakishima and

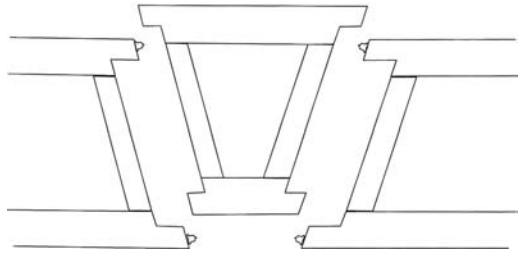

Figure 1. Wedge-shaped block final joint.

Kobe Minatojima Tunnels in Japan. The use of divers is not required.

More traditionally, a temporary external seal can be fitted around the marginal gap, dewatered and the joint completed in the dry. Plates with rubber seals may be attached to the adjacent tunnel elements so that upon placement a seal is obtained. Alternatively, divers have been used to place such plates. Once a seal is achieved, the joint is dewatered and completed in the dry from within. This type of joint has been used extensively, but may need diver support to obtain the initial seal. It may also be difficult to achieve in deeper tunnels.

Tremie joints have been used extensively in the past. Temporary forms are used to minimize the quantity of tremie concrete to be used around the joint. It is also recommended to lower into the gap "biscuits" of weak material to fill the areas that will later be removed to become tunnel voids. The tremie operation has in the past always been an external operation requiring diver assistance. The tremie joint will require waterproofing from within, since it may leak with time.

The need for a closure joint will depend primarily upon schedule, for it is not unusual for the abutting structures to require early completion. These may therefore both be built before the complete immersed tunnel can be laid, and therefore for both terminal elements to be laid early. Laying outwards from both ends results in a closure joint being needed. The immersed tunnel is considerably simpler if the tunnel can be laid from one end to the other without a closure joint. For the first transit tunnel in Hong Kong, connection to the land tunnels was achieved by TBMs boring into prepared ends of the terminal immersed tunnel elements. This method is also proposed for the Bosphorus crossing.

It may also be necessary to provide a flexible joint in the vicinity of a final joint since some forms of this joint are rigid. For Western Harbour Crossing in Hong Kong, completed in 1997, the element to one side of the final joint included a pre-compressed immersion joint containing a Gina-type gasket, and the first few meters of the adjacent element, while the element to the other side was missing the first few meters and the width of the closure joint. The end temporary bulkheads for those two elements were obviously located slightly differently from other elements. A rigid final joint was therefore made from within a temporary external seal and the pre-compressed immersion joint released, creating an element approximately the same length as the others (between Gina-type flexible joints).

2.4 *Applied loadings*

Design of immersed tunnels uses different load factors to those usually considered in design codes. Loads can be characterized as: dead or permanent loads; live or variable loads; exceptional loads that probably occur once during the design life that must be survived without damage; extreme loads that the structure must survive perhaps with limited amounts of damage to be defined; and construction loads. Extreme loads would include sunken or stranding ships, anchor impact, ship collision, flooded tunnel, train derailed with collision, explosion (e.g. vehicular), fire, the design basis earthquake (DBE) predicted for the location, and the resulting movement of soils.

Load cases to be analyzed can be similarly grouped into normal, abnormal (the after-effects of an extreme load, which might include changed soil conditions), extreme and construction. Although Japanese practice is to use partial factoring, when these partial factors are combined, the resulting load factors match those given in Figure 2. Extreme loads should only be combined after taking into account their probability, for example, 100-year storms, tsunamis and earthquakes do not all occur simultaneously. It should be noted that earthquakes have occurred during construction and should therefore be considered; since the construction period is relatively short, it would be appropriate to consider a smaller or more frequent event than the DBE.

2.5 *Watertightness*

The concept of watertightness needs to be associated with a rate of leakage that is acceptable; trivial

Loading / Design Loading Conditions	Normal	Abnormal	Extreme	Construction	Life Safety
Dead load & permanent ballast	1.4/0.9	1.2/0.9	1.05	1.1	1.0
Train/traffic load:					
Normal	1.6/0	1.2/0	_	_	_
Centrifugal	1.6/0	1.3/0	_	_	_
Braking load	1.6/0	1.3/0	_	_	_

Other extreme loads	_	_	1.05	_	_
Construction	_	_	_	1.3	_

Note: Where two values are given, such as 1.4/0.9, the more critical value shall be used.

Figure 2. Ultimate load factors and combinations.

leaks can often be ignored. Tunnels may be considered watertight when:

- Above road or track slab level and in all areas where the structure forms part of a ventilation duct, there are no drips or moving films of water;
- Below road or track slab level, there are no single leaks indicating a high pressure by jetting or spraying;
- The average water intake is below 5 ml/hour/m^2 of internal surface of the external structure.

2.6 *Fire protection*

Within those areas of the tunnel where inundation could occur as a result of fire and material degradation, fireproofing should be applied. The level of protection should be sufficient to evacuate tunnel users and for fire services to attempt to extinguish the fire. It is essential to prevent explosive spalling of concrete that might otherwise prevent fire services from approaching the fire.

3 DESIGN OF TYPICAL TUNNEL SECTIONS

Tunnel Types and concrete construction joints are discussed in some detail in an earlier paper (Ingerslev 2003) and are therefore not repeated here. Nevertheless, since steel sandwich tunnels (Figure 3) seem to be the most popular type in Japan recently and are not widely known elsewhere, a brief note is included here.

Structural steel plates are used on both the inner and outer faces of a steel sandwich tunnel, connected by web (shear) plates that divide the structure into a number of closed cells, each perhaps 10 cubic metres in volume. These are filled with unreinforced non-shrink self-compacting concrete. The concrete takes compression loads and, through embedded stiffeners on the steel plates, acts to stiffen the steel plates and prevent buckling (Japan Society of Engineers 2002). For the Bosphorus tunnel, the collar area of the tunnel elements (the 3 m adjacent to the joints) is designed as a sandwich type, while the remainder of each element is designed as a concrete tunnel.

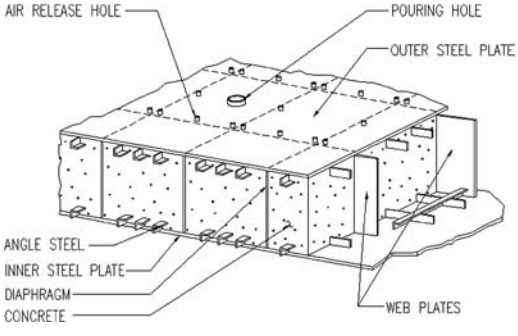

Figure 3. Typical sandwich tunnel.

Since the external plates are structural, they require protection against corrosion; existing tunnels have used sacrificial anodes with a design life exceeding 100 years.

In the seismically active areas of California, Japan and Turkey, shear reinforcement using head bars is becoming more commonly used. They are relatively easy to install and allow a higher density of shear reinforcement to be used. One end is a hook and the other terminates in a friction-welded plate.

4 DESIGN PROCEDURES

For the majority of contracts, design is still a three-stage procedure, namely concept, preliminary and final designs, though they might go under different names. For the Bosphorus tunnel, site response analyses to seismic loading on the tunnel had to be based on site specific response spectra; the spectra were developed by local experts and issued together with the bidding documents to ensure that all bids were based on the same seismic criteria.

The Bosphorus tunnel contract was awarded to a design-build joint venture led by Taisei; an early document produced was a design manual that incorporated the design assumptions, data and the concept design. Material properties and applied loading were defined, including ultimate design factors. Rigid frame models on elastic foundations were used in the structural analyses. The design used finite elements to model the soft ground and bedrock formations. The results provided response acceleration waveforms, velocities, displacements, stresses and strains. For the response analysis of the tunnel in the longitudinal direction, the immersed tunnel was modeled as a single line with each tunnel element subdivided into seven members. In order to determine appropriate ground spring constants at each location, 3-dimensional fiber models of representative tunnel cross-sections were developed. These were divided into elements and provided with ground springs; the backfill and existing ground were modeled and dynamic loads from the response analyses were applied to each section. Sensitivity analysis was included in each case to cover potential variations in soil properties.

Basic or preliminary design should define and analyze every procedure and stage of construction, as well as site-specific material properties for use in the design. Calculations should consider both serviceability and ultimate conditions. All failure modes must be ductile; failure due to shear should not be permitted. Foundation stability and settlement should be checked. Floating stability and buoyancy calculations are essential at each stage of construction. Any

locked-in stresses during construction must be included, both while supported and while afloat. Requirements for achieving the design life should also be defined, such as cathodic protection, waterproofing, joint details with associated gaskets, and fireproofing. Model testing may be needed to verify procedures such as immersion in strong currents. Full scale test construction may be needed for complex areas.

Transverse analyses for the Bosphorus tunnel assumed rigid frames concentrated at member centroids. Reinforcement was determined at serviceability limit state. The non-linear relationship between bending moments and curvature was recalculated and checked at ultimate. Seismic effects were incorporated at ultimate limit state after site response analysis was repeated with new data and new coefficients of subgrade reaction. Increased member forces that occur during a seismic event were determined using a two-dimensional FEM analysis (seismic response coefficient method); non-linear relationships between bending moment and curvature were calculated for each member for the loads applied. Allowance for slip at the surface of the tunnel was a requirement. Locked-in stresses due to stage construction were considered. Longitudinal analyses used three-dimensional beam elements for the tunnel and spring elements for the ground. Seismic effects were input by imposing ground deformations. Additional local analyses were used in the vicinity of the access shaft immersion joint where sandwich construction was used, and in the vicinity of the access shaft where holes are provided in the tunnel roof.

Detailed design essentially firms up on the basic design and should allow for tolerances, wall penetrations, sumps, etc. Design of construction items such as the bulkheads, lifting hooks and bollards, etc., and their effects on element design must be included. For the Bosphorus tunnel, a finite element model was used to verify stresses around the cross-section, especially at the corner haunches. A three-dimensional shell analysis was carried out to determine forces in the vicinity of the immersions and terminal joints due to local variations in stiffness and geometry. Heat transfer analyses verified that effects during a fire met requirements. Ductility was demonstrated by imposing excessive seismic deformations.

Computer analyses have become very much more user friendly, but with this come complications. The volume of input data can become very large and complex, much of it visual and not easy to check. While the computations are essentially the assembly of matrices and their inversion, post processing into useable results can involve methodology and assumptions that may be ill defined and perhaps in some cases inappropriate, being based on assumptions or codes for a different type of structure. This has the result that the sheer volume of input data and output data can be difficult for independent checking. Great care must be taken in verifying that the correct assumptions are used and that results match those obtained independently by other methods.

5 TUNNEL IMMERSION & PLACEMENT

Many immersed tunnels are placed in canals where water velocity is relatively low or in tidal waters where low velocities occur as the tide changes. A few tunnels are placed in rivers where currents do not change, so that methods of controlling tunnel elements during immersion and placing must match conditions perhaps far from ideal. Such conditions exist, for example in the East River of New York, not really a river at all but primarily a stretch of water in which water velocity is controlled primarily by the difference in tidal water levels around Long Island, with a fresh water contribution from the Hudson River through the shallow Harlem River. Here, as in many estuarial waters, variations in salinity with depth exist, resulting in contra-flowing currents with depth so that at no time is the water still; times of tidal changes for surface waters is very different for waters at depth.

The Bosphorus, a narrow river-like channel joining the less-saline Black Sea to the more-saline Sea of Marmara and eventually to the Mediterranean, also has contra-flowing currents driven by the difference in level of the two seas and their variations in salinity. These currents are often 4 knots at the surface southbound and half that value northbound at depth, though both do sometimes reach speeds half as much again. Immersing and placing procedures are based upon infrequent windows of opportunity with lesser currents. Mooring and adjusting cables will need to take into account current reversal during the lowering process, according to depth. Furthermore, the catamaran barges to be used for this operation will initially be aligned parallel to the current while the element is lowered to a region of less current, only then are the barges and element rotated to the placement orientation. Element position will be monitored and controlled remotely without the use of divers. Additional water ballast may be added remotely during immersion as water density increases and again after placing. The elements will be placed on pads equipped with jacks for horizontal and vertical position adjustment. After dewatering the joint between the most recently placed elements, the element position is checked from within and adjusted as required.

For the Fort Point Channel in Boston, a very shallow tunnel in a location with poor access by water, clusters of buoyancy tubes placed on top of the elements allowed controlled placement by ballasting (Figure 4). Elements could be winched into position

Figure 4. Fort Point Channel Tunnel buoyancy cylinders.

from the adjacent fabrication facility located within the alignment.

6 DEEPER WATERWAYS

While immersed tunnels are buried below the waterway, concept, preliminary and detailed designs have been prepared for a few projects where the tunnels would not be buried but would pass instead through the water. This would make the water depth irrelevant. In its simplest form, an immersed tunnel could be supported on piers like an underwater bridge. Other support options considered include hanging the tunnel from floating pontoons and using tension-legs similar to those of tension leg oil platforms together with a buoyant tunnel. All these options passing through the water are known as "floating" tunnels (ITA 1997); none have yet been built.

Where would such tunnels be used? Recent studies have considered deep lakes, fjords and straits such as Høgsfjord and Storfjord in Norway, Lake Lugano and Lake Zurich in Switzerland, the Straits of Messina and Lake Como in Italy, Jintang Strait and Qiandao Lake in China, Funka Bay and others in Japan, Elliot Bay and Lake Washington by Seattle in USA, and out to Vancouver Island in Canada.

If a tunnel has to cross an active fault, a floating tunnel would be capable of providing the necessary flexibility to avoid fracture.

Another serious concept for the future that has been presented employs dynamic positioning and has been proposed for trans-oceanic tunnels.

ABSTRACT: The concept of an immersed tunnel is relatively simple and also time tested. More immersed tunnels are being built today than ever before. Every project has its challenges and this paper describes how many of these issues have been met. Many of these innovations are the product of collaboration involving multiple engineering disciplines, including geotechnical, civil, structural, mechanical, hydraulics, marine and environmental. Seismic events also impact tunnels and methodologies had to be developed to address seismic risk.

1 INTRODUCTION

An immersed tunnel is often the most economical method for an underwater tunnel crossing. These structures are made up of prefabricated steel or concrete sections or "tubes" usually constructed off-site, floated to the site, and placed inside a predredged trench. Steel or concrete construction is used for the elements. Operationally, there is no difference in how the final product functions, and for the same internal space, they weigh the same.

2 GEOTECHNICAL ISSUES OF IMMERSED TUNNEL CONSTRUCTION

Geotechnical risks are always a challenge in any underground project, but for underwater projects, the risks are often higher due to site investigation limitations as well as restrictions in addressing ground and/or groundwater control problems during construction. Geotechnical risks that must be identified and accounted for during the investigation, design, and construction planning include:

- Profiling of the subsurface conditions beneath the open water
- Properties and character of sediments to be dredged and in which the immersed tunnel will be placed
- Slope stability during construction of the immersed tunnel dredged trench
- Environmental restrictions on water turbidity during dredging
- Environmentally sustainable disposal of contaminated dredged materials
- Long term total and differential settlement of tunnel sections
- Liquefaction potential during the service life of the facility

Due to the expense and technical difficulties involved in off-shore drilling, vertical borings must be supplemented by other methods such as marine geophysics.

Geophysics can be useful not only in establishing a reliable bottom profile, but also sediment depth above bedrock, the character of the sediments, and the presence of buried obstructions within the shallow sediments to be dredged.

Conventional offshore site investigation techniques include Standard Penetration Testing (SPT) and cone penetration testing (CPT) for in-situ determination of strength and deformation characteristics, as well as variations in material properties. Laboratory testing

of soil and rock samples are necessary to establish engineering design parameters.

3 IN THE BEGINNING . . . THE DETROIT-WINDSOR TUNNEL (1927–1930)

In 1927, Parsons Brinckerhoff (PB) was retained for a monumental job—the design and construction of a 2.4-kilometer-long, single tube, two-lane immersed tunnel under the Detroit River from Detroit, Michigan, USA, to Windsor, Ontario, Canada. It was a challenging task for the primary reason that underwater vehicular tunnels were still a new concept—this would be only the third subaqueous vehicular tunnel constructed in the US, and the country's second immersed vehicular tunnel. Additionally, the project—the first vehicular tunnel to connect two countries—was to be delivered similar to a current design-build-operate project, a revolutionary concept at the time (and still noteworthy today).

The project, which employed a pioneering combination of construction techniques, including immersed, shield-driven and cut-and-cover tunneling, included a number of other innovative aspects, such as an improvement in installing tunnel elements by concreting them as they floated—rather than using sand or water to ballast the elements and then concreting them in place in the river-bottom trench. Additionally, the Detroit-Windsor Tunnel set the pace for a new procedure in tunneling that used welding for the first time in a double-shell immersed tunnel. The octagonal outside form plates and circular inner lining (Figure 1), together with welded steel construction, captured the imagination of tunnel designers and has been copied for many subsequent tunnels.

Not only were the tunnel's construction techniques innovative, but completion in just 26 months was unprecedented for a project of this scale and complexity; in fact, it is a construction record for immersed tunnels that has yet to be surpassed!

4 BART TRANS-BAY TUBE—PROVIDING STABILITY IN SHAKY GROUND (1953–1970)

Studies for the Trans-Bay Tube Project began in 1953 and the tunnel opened in 1970. This crucial link in the Bay Area Rapid Transit (BART) system provides a subaqueous rapid transit connection between San Francisco and Oakland, California. The 5.8-kilometer tunnel is 15 meters wide and 7 meters high. Binocular in cross-section, the tunnel provides two track compartments, an inspection gallery and space for utility lines. It is made up of 57 elements averaging 100 meters in length plus one short connector element. Each prefabricated element consists of a structural steel shell, generally 9.5 millimeters thick, with a 0.6-meter-thick concrete internal lining. The elements were immersed and joined in a trench dredged to depths of 41 meters below the water surface. This deepest immersed tunnel in the world will be surpassed by the Bosphorus Tunnel, currently under construction.

Since the Trans-Bay Tube was to be located in a seismically active zone, the development of design criteria for earthquake resistance merited special consideration. Much of the research on earthquake effects was unprecedented, resulting in pioneering engineering design. To meet seismic criteria, the immersed tunnel was designed to move as a flexible tube during an earthquake. To rest on soft alluvial soils, conform with the profile of the San Francisco Bay bottom, and accommodate navigational channels, the tunnel alignment changes direction twice horizontally and six times vertically along its length. Beneath the Oakland shipping channel, concrete slabs protect the top of the tunnel.

Teflon-lined, sliding seismic joints were designed for the landfall connections to allow longitudinal, transverse, and rotational movements during an earthquake (Figure 2). These special joints faced their first major test in October 1989 when an earthquake

Figure 1. Detroit-Windsor Tunnel tube under construction.

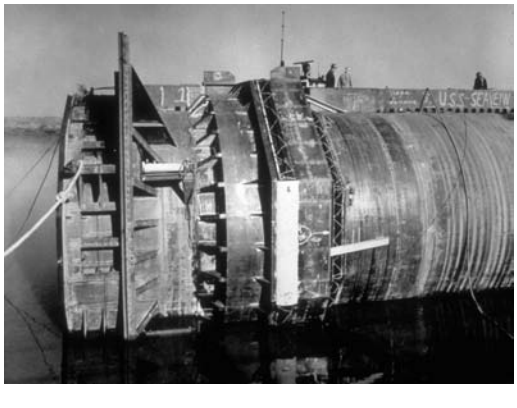

Figure 2. BART Trans-Bay Tube seismic joint.

measuring 7.1 on the Richter scale shook the San Francisco area. Interestingly, BART was one of the few major transportation (life line) links that was fully operational after the disaster struck.

The Trans-Bay Tube is the longest and deepest immersed tunnel in service, and was the first time a single shell tunnel was protected by impressed current cathodic protection. The patented triaxial seismic joints at the landfalls performed successfully during the earthquake when area bridges did not. The tunnel features the first US use of a double gasket system (American version of GINA), as well as ventilation buildings constructed in huge hydraulic caissons with built-in seismic joints.

5 CREATING ISLANDS IN THE SEA—THE HAMPTON ROADS CROSSINGS (1954–1976)

In 1954, the state of Virginia initiated the design for a crossing of the strategically significant Hampton Roads ship channel. Just three years later, the First Hampton Roads Bridge-Tunnel opened, across the James River, a major military and shipping channel. Twelve years later, in 1969, our firm was once again tapped to provide design and construction inspection services for a parallel second crossing to meet increasing traffic demands. Both of these crossings are noteworthy for several reasons.

The original 6.4-kilometer crossing, joining the cities of Hampton and Norfolk, is a combination bridge and tunnel. Engineers solved the problem of minimizing the length of the tunnel under the busy ship channel by terminating it on artificial islands on each side of the channel. Concrete trestle bridges connect the mainland with each island, and for the first time in the history of vehicular tunnel design, an immersed tunnel was constructed with portals emerging on man-made islands. The islands were constructed from suitable hydraulic fill placed within stone dikes built in stages as the islands rose out of the water (Figure 3). The south island had to be constructed on soft ground, heavily testing the soil mechanics technology of the time. The tunneling operation also took great care not to negatively impact nearby shellfish beds. When completed, the First Hampton Roads Crossing was the second deepest immersed tunnel in the world, reaching a trench depth of more than 36 meters; was one of the longest at 2.4 kilometers and 23 elements in length; and featured state-of-the art "tremie joints," whereby the joints between elements featured overlapping steel collars and hoods buried and sealed in tremie concrete.

The Second Hampton Roads Crossing is composed of a 1,930-meter southern approach trestle; a 965-meter northern approach trestle; 600 meters of open approaches on the two enlarged portal islands; and a 1,920-meter immersed tunnel under the channel.

Figure 3. Second Hampton Roads Crossing south island under construction.

It opened to traffic in 1976. Constructing the second parallel crossing involved some unique challenges never faced before. The alignment had to be a compromise between being close enough to the first tunnel to limit the footprint of the crossing, while not being so close as to cause settlements or displacements of the existing tunnel or ventilation buildings.

The existing islands had to be substantially widened to accommodate the new open approaches, while avoiding settlement issues. The North Island widening was mostly over sandy strata. Because some of the strata were fairly loose, vibrocompaction was used for densification. During the South Island sand-drain/surcharge construction program, settlements, displacements, and pore pressures were continuously monitored using deep settlement points, inclinometers, and piezometers.

The centerline of the second tunnel trench was kept a minimum of 75 meters away from the first tunnel to assure that there would be no influence on its stability. The dredging of the trench was carried out by a cutterhead suction dredge until reaching its maximum operational depth. Then a large bucket dredge using split barges for disposal was used to complete the trench. The joining of the tunnel elements benefited from earlier experiences gained on the BART Trans-Bay Tube in the form of a double gasket hydraulic immersion joint.

6 GROUNDBREAKING ENVIRONMENTAL SENSITIVITY—THE FORT McHENRY TUNNEL (1979–1985)

This massive eight-lane facility in Baltimore was the single largest interstate project in the US when it opened to traffic in 1985.

Figure 4. The Fort McHenry Tunnel west approach and wetlands mitigation site over the tubes.

Figure 5. The Fort McHenry Tunnel near shore CDF was later developed into the Seagirt Marine Terminal.

This tunnel was conceived and constructed as two four-lane, twin-bore immersed tunnels installed side-by-side in a 54-meter-wide common trench. Each tunnel consists of 16 double steel shell elements about 105 meters long for a total length of about 1,646 meters. There are 32 elements in total. The geometry was complicated by the fact that both tunnels had to be constructed on concentric curves while also featuring vertical curves.

It was constructed with the side-by-side elements only 5 meters apart at the ends where the elements were the widest (Figure 4). For the first time, a special folding wedge system was used that allowed for quick, simple alignment corrections at the gaskets.

The dredging was one of the most environmentally sensitive undertakings ever attempted in the US, as the first 2 meters of the Patapsco River bottom contained the residue of centuries of industrial wastes, including oils and heavy metal deposits. An environmental task force with representatives from the joint venture, federal environmental agencies, and city and state governments, worked together to identify acceptable alternatives. After a year of study, it was decided that a 59-hectare decommissioned open water disposal site in neighboring Canton/Seagirt would be used as a nearshore confined disposal facility (CDF). The contaminated sediment would be contained within a sealed cofferdam separately from a larger cofferdam area for cleaner sand and stiff clay material. Most of the dredging of the wide trench was carried out by a very large cutterhead suction dredge that pumped the material about 4 kilometers through a booster pump to one of the two containment areas. The overflow was treated with flocculants and allowed to settle in a 210-meter-long basin before being released to the harbor.

After project completion, the CDF was turned over to the Maryland Port Administration and developed into the modern Seagirt Marine Terminal, a major container port in Baltimore Harbor (Figure 5). The aquatic habitat lost to the CDF site was mitigated by the development of a tidal wetland between the historic park site and the west ventilation building.

7 THE BIG DIG—THE TED WILLIAMS TUNNEL (1987–1995)

The Ted Williams Tunnel, Boston's newest harbor crossing to Logan International Airport, opened to traffic in 1995, as part of the Central Artery/Tunnel Project, a massive program to upgrade the area's transportation infrastructure. Named for the legendary American baseball player, the tunnel doubles Boston's cross-harbor tunnel capacity from four to eight lanes.

The 1.2-kilometer underwater portion of the 2.6-kilometer tunnel is made up of 12 binocular-shaped steel tunnel elements, which were assembled in a shipyard in Baltimore and barged to Boston. Each element consists of two circular tubes set over a flat base. One tube holds the eastbound traffic, the other westbound traffic. They are each approximately 12 meters in diameter and over 91 meters long.

The project was environmentally sensitive due to the dredging of contaminated sediments from the tunnel trench. Commercial fisheries were concerned about potential impacts, especially during certain seasonal migrations. Mitigations included real-time monitoring of silt during dredging; sealed dredge buckets; a lined, sealed and fully enclosed upland CDF for contaminated sediments near Logan Airport; some disposal at designated underwater locations outside the harbor; and a specially designed common disposal site at Spectacle Island, south of Boston Harbor.

This project broke ground in many areas of state-of-the-art engineering applications, including the solidification/stabilization of contaminated dredged sediments. For the first time anywhere, this project involved processing 53,000 cubic meters of contaminated dredged material in an upland CDF, chemically solidifying the material, and compacting the CDF for future use (Figure 6).

Figure 6. The Ted Williams Tunnel upland CDF where contaminated sediments were chemically amended for solidification/stabilization.

Figure 7. The Fort Point Channel Tunnel Construction site.

8 TUNNELING IN EXTREMELY TIGHT QUARTERS—THE FORT POINT CHANNEL TUNNEL (1988–2002)

Although not very long, the Fort Point Channel Tunnel in Boston is noteworthy for several reasons, including its placement only 2 meters above two operating century-old transit tunnels. This is also the first immersed vehicular tunnel in the US to use a rectangular reinforced concrete configuration.

The tunnel carries 11 lanes of highway traffic from South Boston to Logan International Airport. Crossing the Fort Point Channel in this vicinity was extremely challenging given the site constraints—poor access from the harbor, and busy rail lines crossing the alignment of Interstate 90 just west of the project area. In addition, a large industrial plant and US Post Office facility were located close to the site (Figure 7). Because of these constraints and the shallow water depth, a rectangular immersed tunnel was selected as the preferred approach.

The crossing comprises six tunnel elements, each approximately 99 to 127 meters long, 7.9 meters high, with widths varying between 21 and 47 meters. The tunnel features side ventilation inlet and exhaust ducts, providing full transverse ventilation. The elements were placed three in each direction in two close parallel lines across the channel, with cut-and-cover approaches on the east and west. The foundation of the ventilation building and 12 piers for the new Dorchester Avenue Bridge were built integral with the elements that were placed at the west end of the tunnel—the first time this has been done on an immersed tunnel. This approach eliminated the need for expensive cofferdams to build the bridge and building foundations in the channel.

Drilled shaft caissons 2 meters in diameter extend as much as 56 meters into the bedrock below the channel to support tunnel elements that were placed only 2 meters above the crown of the existing Red Line subway tunnel, which remained in service during construction. These subway tunnels, constructed by "sand hog" methods with un-reinforced concrete, needed to be treated very carefully. If uncovered, they might have become unstable and collapsed, flooding most of Boston's subway system.

9 CONNECTING TWO CONTINENTS—THE BOSPHORUS TUNNEL (2004–2010)

Split in two by the Bosphorus Strait, the city of Istanbul has always sought ways to move people and goods across this narrow and busy waterway separating Europe and Asia. In 1985, a consortium led by PB conducted feasibility studies, planned and performed the preliminary design of a rail tunnel beneath the strait. In 2002, the Ministry of Transport & Communication, General Directorate of Railways, Harbours and Airports Construction, commissioned Avrasya, a joint venture led by Pacific Consultants International of Japan, to assist the Ministry in implementing the project as its general engineering consultant. Subsequently, in 2004, a design/build contract was awarded to a joint venture of Taisei, Kumagai, Gama and Nurol.

The project, involving the world's deepest immersed tunnel as well as related improvements to 63 kilometers of at-grade rail lines, is one of the most ambitious and complex undertakings of its kind. It features a 1.5-kilometer-long tunnel in more than 50 meters of water below one of the busiest waterways in the world. The complex hydrology of the Bosphorus will be a challenge to placing tunnel elements: bi-directional currents are not tidal but vary according to the hydraulic gradient between the Black Sea and the Sea of Marmara. The currents vary rapidly and can reach 6 knots southbound at the surface and 2 knots northbound. Tunnel elements will be placed when surface currents are below 1.5 meters/second (3 knots). The shallowest element will be 40 meters deep—twice the depth of most immersed tunnels in

Europe and Japan—while the deepest will reach a depth of 58 meters.

The immersed tunnel starts and ends in deep water. At these locations, after each terminal element is placed, a soil mix fill will be used to form a weak concrete-like connection to the rock. Starting from Sirkeci Station excavation on the European side and Üsküdar Station on the Asian side, tunnel boring machines (TBMs) will bore two circular running tunnels—one each for eastbound and westbound tracks—out to two receiving sleeves fabricated at the ends of the terminal elements. Until then, access for constructing the immersed tunnel will be limited to one shaft to be installed on the first element to be placed, located offshore, upstream of KizKulesi (Leander's Light)—the famous ancient lighthouse. This access shaft will be reached by a trestle and bridge constructed to it from the Asian shore.

The tunnel is designed to resist seismic events. Ground conditions in the tunnel subgrade vary considerably. A zone from Element 11 (Asian end) to Element 8 was found to have a risk of liquefaction during an earthquake. To counter this risk, the area has been treated by compaction grouting (CPG). Nearly 2,800 grout columns spaced on a 1.7-meter grid have been injected into the seabed below tunnel level to compact the deep foundation soils.

Dredging is being carried out by a large grab dredge with a capacity of 28 cubic meters. In a zone near the European side, about 136,000 cubic meters of contaminated soil has been dredged and transported in barges to the port of Kartal, approximately 30 kilometers to the southeast, where it was trucked to a specially constructed upland CDF. The use of a CDF for contaminated dredged sediments is unprecedented in Turkey (Figure 8). The clean materials were loaded into split barges and transported to a designated deep open water disposal site in the Sea of Marmara 25 kilometers from the tunnel trench.

The design of the tunnel is based on a rectangular concrete box with a central wall dividing the trackways. The base and sides are made watertight by a 7-millimeter-thick steel membrane. The roof slab is covered with a special PVC membrane that is protected with a reinforced concrete slab. The ends of the elements are steel/concrete sandwiches structurally tied to the longitudinal reinforcing steel in the concrete section. These "end shells" support the temporary GINA gasket of the immersion joint and the watertight bulkheads. The casting yard at Tuzla consists of two specially built drydocks each large enough for two elements and deep enough to allow about half of the concrete cross section to be placed before the drydock must be flooded and the element towed to an outfitting pontoon within the adjacent harbor. The elements remain moored at the pontoon while the concrete and waterproofing work are completed.

Figure 8. The Bosphorus Tunnel upland CDF.

After final outfitting, a placing barge with the element will be taken upstream of the trench where the first anchor will be run out on a windlass. As the barge nears the trench, this operation will be repeated with a second anchor placed the same way. The barge and element will be end on to the current to limit drag forces. More anchor lines will then be attached using a tender and the element will be lowered to a regime of acceptable current where it will be rotated to its alignment in the trench. As the final lowering proceeds, the inboard end of the element being placed will engage centering guides installed on the tunnel already in place. The outboard end will sit on an alignment correction frame that will rest on prepared bedding. A jack will be extended from the existing tunnel to pull the element being placed and obtain an initial seal by compressing the soft nose of a GINA-type gasket. The immersion joint will then be fully activated by lowering the water pressure in the joint space by pumping it out. The bulkhead doors can then be opened to permit position survey of the new element and any adjustment thereto using jacks on the alignment correction frame.

As the tunnel progresses, backfilling over the elements will take place, which will return the bottom of the Bosphorus to its original contours. The Bosphorus Tunnel is scheduled to open to rail traffic in about 2010.

10 CONCLUSION

Seven case histories spanning over 75 years have shown that innovative engineering is necessary in immersed tunnel projects. Environmental issues are more challenging today than ever before. Close coordination of multiple disciplines with an open-minded, teamwork approach is a common denominator for success.

Case study for the deterioration of lining in vehicular tunnel based on ventilation system

J.H. Choo, H.S. Ryu, Y.S. Shin & S.R. Ahn
Tunnel Division, Korea Infrastructure Safety and Technology Corporation, Goyang, Korea

ABSTRACT: The ways of tunnels ventilation system are classified as natural, semi-transverse, full-transverse according to the place of duct. Most of aggressive causes in deterioration on the tunnel lining are as follow: water, smoke, atmospheric conditions, impact damage, overburden, etc. In this paper, the distribution of deterioration on concrete lining is investigated as a part of precise safety diagnosis in 8 service-in vehicular tunnels in South Korea. Three methods have been implemented to measure the range and trend of deterioration; Schumidt hammer test (NR-type), ultrasonic test, and carbonation. Depending on the ventilation system, the trend of deterioration is compared with the way of ventilation system within each vehicular tunnel and examined the mutual influence between the distribution of deterioration rate and ventilation system. The output of this paper is demonstrated that the tendency of deterioration rate is bigger along the exit. Also, the depth of deterioration rate is high on the duct slab primarily, then lining inside duct, beneath the duct slab in sequence at the same section.

1 INTRODUCTION

Depending on the construction situation, the shapes of the tunnel can be presented functionally as follow: circle, horse shoe, ellipse, oval, etc. Most of the shapes in vehicular tunnels are flat horseshoe or circular section. One of schematic characteristics in general shape of vehicular tunnel is the duct, which is adapted to evaluate the capacity of ventilation. With or without duct, ventilation system can be classified with natural, semi-transverse, and full-transverse, etc.

Most structures related to the precise safety diagnosis (government regulated it since 1995 in South Korea) have shown problems in structure or non-structure by the change of tunnel circumstances and deterioration of lining as the years of use for tunnel goes by.

In this study, the deterioration of lining in vehicular tunnel based on ventilation system have been inspected by three conventional NDT(Non-Destructive Test) methods such as Schumidt hammer test (NR-type), ultrasonic test, and carbonation. These mostly preferred NDT methods in precise safety diagnosis are well researched and conducted by over 500 companies since those NDT methods have been introduced in precise safety diagnosis field.

The general procedure of precise safety diagnosis in vehicular tunnel is shown in Figure 1. This study aims for discerning the amount of deterioration of the surface on lining concrete depending on what kinds of ventilation system has been adapted in vehicular tunnel. Also, the purpose of this study is to suggest how to arrange and analyses the previous data in re-diagnosis (precise safety diagnosis which is repeatedly conducted in every 5 years in South Korea).

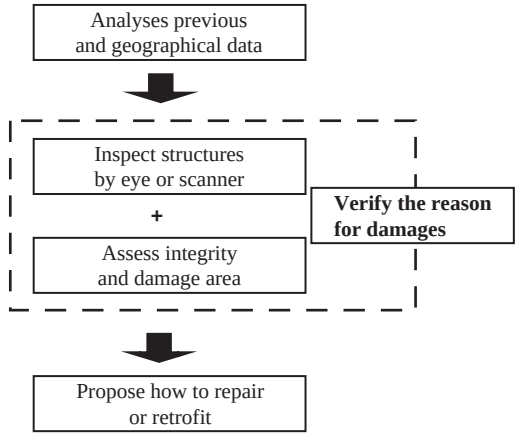

Figure 1. General procedure of precise safety diagnosis in vehicular tunnel.

2 TUNNEL EXPLANATION

Three methods for assessing the deterioration on lining concrete have been implemented in 8 service-in vehicular tunnels. Two major fields of precise safety

diagnosis are the strength and integrity. Schumidt hammer Test (NR-type) and ultrasonic test are well known for estimating the strength of lining. To assess the area of deterioration on lining, carbonation is a mandatory test item especially in reinforced concrete structure such as duct, ventilation ways in vehicular tunnel. Conventional cross-section of vehicular tunnel for this study is shown in figure 2. Natural system is applied for mountain area or low traffic zone, which is not required of ventilation supplies. Either semi-transverse or full-transverse system can be applied in urban area or heavy traffic zone depending on the geological level, fan capacity, and maintenance fee, etc. The specific information of 8 tunnels is detailed in table 1.

3 CHARACTERISTICS OF CARBONATION ON LINING SURFACE

One of primary considerations of design step in vehicular tunnel is to sustain the airflow steadily for the safety for tunnel user and evaluation for efficiency. The carbonation of lining concrete is mostly affected by CO_2 (carbon-dioxide) which is major combustion products of vehicular while the car is passing through. According to this study of carbonation classified by ventilation system, the depth of carbonation in natural system is not progressed as much as its extent and speed compared to the semi-transverse or full-transverse system. The depth of carbonation on slab in the duct is faster and deeper than its wall in the road at same section in semi-transverse system.

Also, the same extent of carbonation on slab is investigated in the road area in full-transverse system. In particular, the extent of carbonation on exhaust duct is severely progressed than supply duct. These outputs for carbonation can be shown in figure 3 as in order: natural, semi-transverse, and full-transverse.

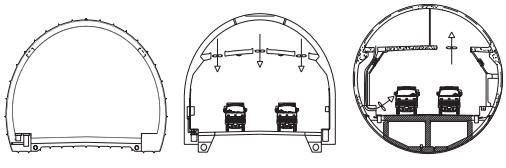

Figure 2. General cross-section of vehicular tunnel.

4 CHARACTERISTICS OF SCHUMIDIT HAMMER ON LINING SURFACE

The general trend of the rebound number by Schumidt Hammner in this study is getting lower compared to

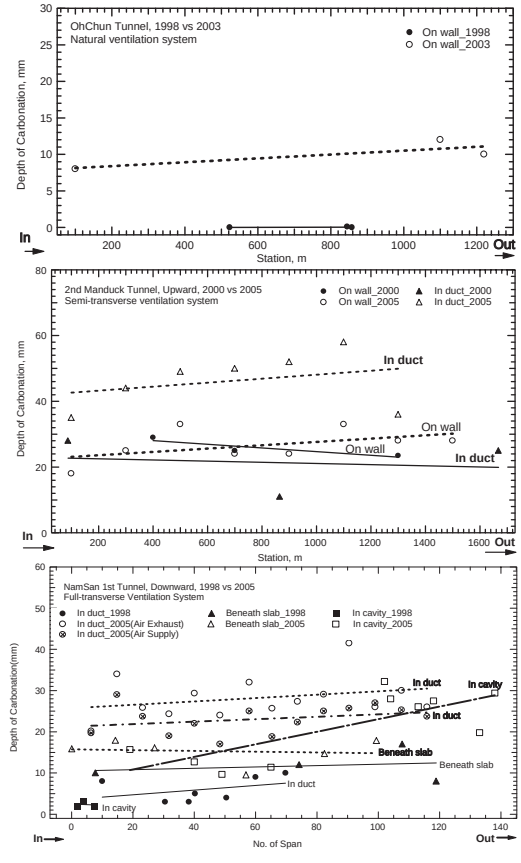

Figure 3. The outputs of carbonation as ventilation system.

Table 1. The detailed tunnel information in this study.

Name of tunnel	Location	Length (m)	Ventilation system	Construction method	Completed year
OhChun	KwangWonDo	1,296	Natural	NATM	1990
HaeSan	KwangWonDo	1,986	Natural	NATM	1980
NamSan 1st	Seoul city	1,532	Semi/Full transverse	ASSM/NATM	1980/1994
NamSad 3rd	Seoul city	1,280	Semi transverse	ASSM	1988
KwangAhn	BuSan city	1,136	Semi transverse	ASSM	1980
Gudeok	BuSan city	1,880	Semi transverse	ASSM	1984
ChangWon	ChangWon city	2,340	Semi transverse	NATM	1993
Manduk 2nd	BuSan city	1,840	Semi transverse	ASSM	1988

the result in 5 years ago due to its deterioration of the lining surface. Shortly, the difference of range in rebound numbers for estimating the strength is bigger in semi/full-transverse than natural system. As we can see in figure 4, the discrepancy of extents in rebound numbers for strength is greater on slab in the duct than on wall in the road at the identical section in semi-transverse system. Also, the fluctuation of rebound numbers is larger on the exhaust duct than the supply duct in full-transverse system.

5 CHARACTERISTICS OF ULTRASONIC WAVE VELOCITY ON LINING SURFACE

There is another well-performed testing method for estimating the deterioration of lining surface in precise safety diagnosis field. Ultrasonic test is one of useful techniques in NDT scopes for detecting the depth of crack and for evaluating of the penetrating sonic velocity through concrete lining. In this study, indirect technique has been implemented on lining surface along with Schumidt hammer test and core sampling for acquiring the coefficient of correlation and evaluating the range of lining deterioration.

The velocity through lining is influenced by the extent of deterioration and the quality of construction. The more poor quality and bad deterioration, the later sonic wave velocity due to the long propagation time is elapsed.

Considering the fresh air condition and less traffic, the difference between 5 years with sonic wave velocity in natural system is determined with a general aspect. As we can see in figure 2, the basement in full-transverse system is conventionally used for drainage of water, passage of power or communication cable, etc. Due to the convection and moisture in full-transverse basement, the lining surface is constantly moisturized so that the discrepancy of the determined velocity by ultrasonic test is larger than dry condition. In semi-transverse, the determined velocity by

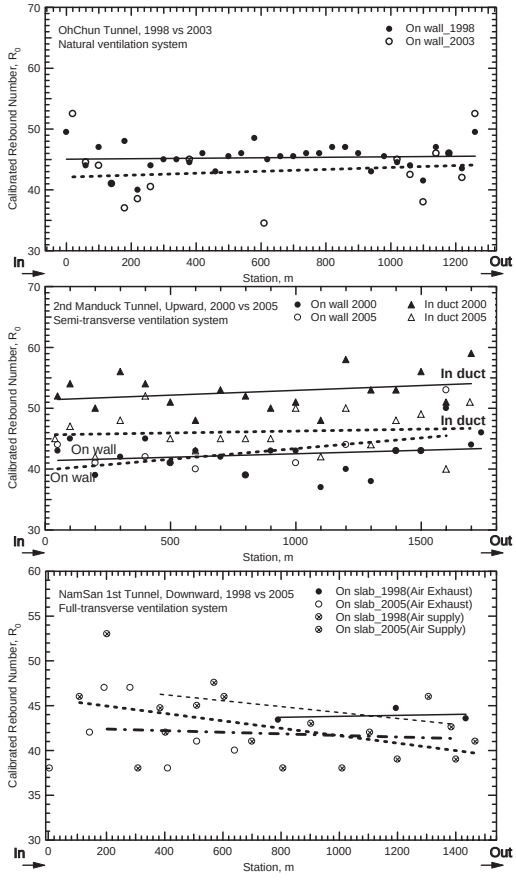

Figure 4. The outputs of rebound numbers in Schumidt Hammer test as ventilation system.

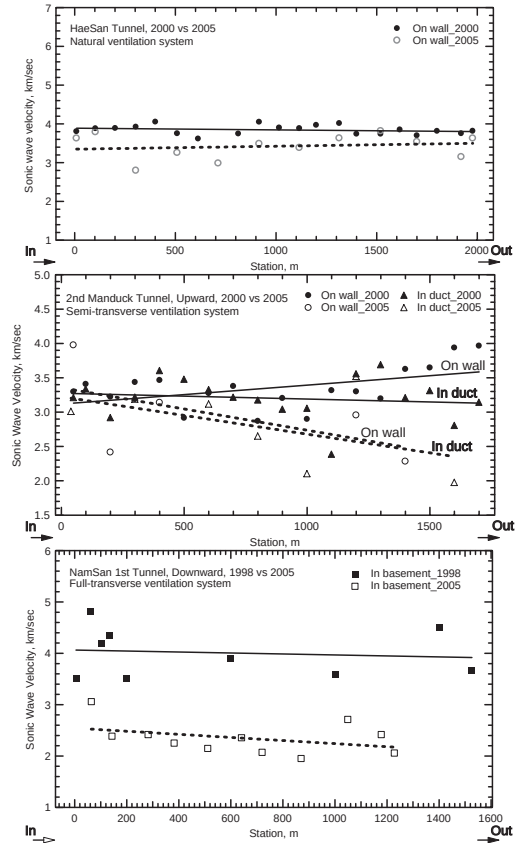

Figure 5. The outputs of ultrasonic wave velocity test as ventilation system.

indirect technique is gradually decreased on slab in duct area far from the fan because the slab surface is badly deteriorated by the accumulated combustion product depending on the distance from the fan.

6 CONCLUSION

In this study, the deteriorations of lining in vehicular tunnel based on ventilation system have been investigated by three conventional NDT methods such as Schumidt hammer test, ultrasonic test, and carbonation. The aims for this study are estimating the extents of the deterioration of lining concrete and verifying the validity of three NDT methods depending on the types of ventilation system. Also, the goal of this study is to suggest how to arrange and analyses the previous data in re-diagnosis.

First, three conventional indexes for assessing the deterioration of lining surface such as depth of carbonation, number of rebound, velocity of sonic wave is well-matched with the same pattern and one another.

Second, three NDT methods validate to estimate the deterioration of lining surface depending on the three ventilation system; natural, semi-transverse, and full-transverse.

In conclusion, the deterioration of lining is severe in semi/full-transverse system rather than natural system. The depth of carbonation, decrease of rebound number and sonic velocity is deeper and larger in semi/full-transverse system than natural system. Especially, the badly deteriorated part in vehicular tunnel is on slab in the duct because of the accumulation of combustion products. The output of this paper is demonstrated that the tendency of deterioration rate is bigger along the exit. Also, the depth of deterioration rate is high on the duct slab primarily, then lining inside duct, beneath the duct slab in sequence at the same section.

To maintenance properly, like in the basement in full transverse system, dry condition should be sustained not to progress the deterioration of lining and damage the convenient supplies.

ABSTRACT: The Březno Railway Tunnel is located in the North of the Czech Republic, near to the town Chomutov. The construction of 1.8 km long single track railway tunnel started in May 2000 and was interrupted in May 2003 due to the large collapse while tunnelling with pre-cut method using Perforex machine. After resuming the works in 2004, an emergency escape shaft was sunk in the collapsed area, just above the buried machine. The shaft lining was formed by secant piles, supported by reinforced concrete ring beams and shotcrete rings, respectively. The paper describes the main features of the unique shaft design and its construction.

1 INTRODUCTION

1.1 *Brief history*

The tunnel construction started in 2000, the tunnelling using pre-cut method with Perforex machine started in March 2002. In May 2003, after completion of approximately 800 m, the primary lining created by non-reinforced shotcrete sprayed into the pre-cut slot, collapsed. The collapse started at the face, followed by collapse of approximately 100 m of the primary lining behind the tunnel face. The collapse created a depression on the surface and completely buried the Perforex machine.

1.2 *Construction after collapse*

Due to the legal and financial problems caused by the tunnel collapse, the tunnel construction was stopped for more than year, and restarted in October 2004. The works started from the other portal, using sequential excavation method with initial lining consisting of shotcrete, lattice girders and bolts. During the entire stretch of the tunnel from the portal towards the collapsed area, the overlapping steel pipe umbrellas were applied. The tunnel face was reinforced by overlapping fibre glass bolts.

1.3 *Emergency escape shaft*

The planning process of the Březno Tunnel started well before the year 2000. At that time, according to the valid safety regulations, the emergency escape shaft was not required for the Březno Tunnel.

Due to the relatively long planning process and delay due to the collapse, the updated safety regulations valid in the time of works restarting in 2004, already required an intermediate emergency escape shaft for the tunnel length of 1.8 km. The Client decided to build the emergency escape shaft to comply with all the latest safety regulations.

2 SHAFT DESIGN

2.1 *Shaft location*

After careful consideration, it was decided to locate the shaft directly above the buried machine and in this way to make the removal of the machine much simpler than would be from the mined tunnel.

The shaft was not located directly above the tunnel axis; shaft axis was shifted approximately 1.5 m of the tunnel axis.

2.2 *Geological conditions*

The entire area in which the shaft construction took place was a part of former tunnel collapse. Immediately after the collapse few boreholes were drilled in the collapse area and basic tests performed. The results gave relatively low geotechnical parameters, as could be expected.

Because the time period between the collapse and the shaft construction was more than two years, it

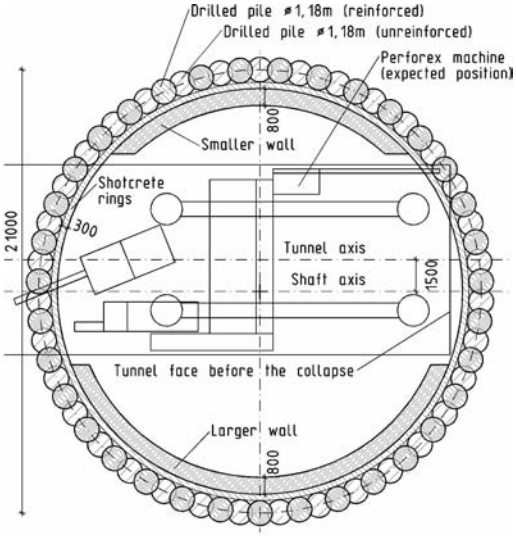

Figure 1. Shaft cross section.

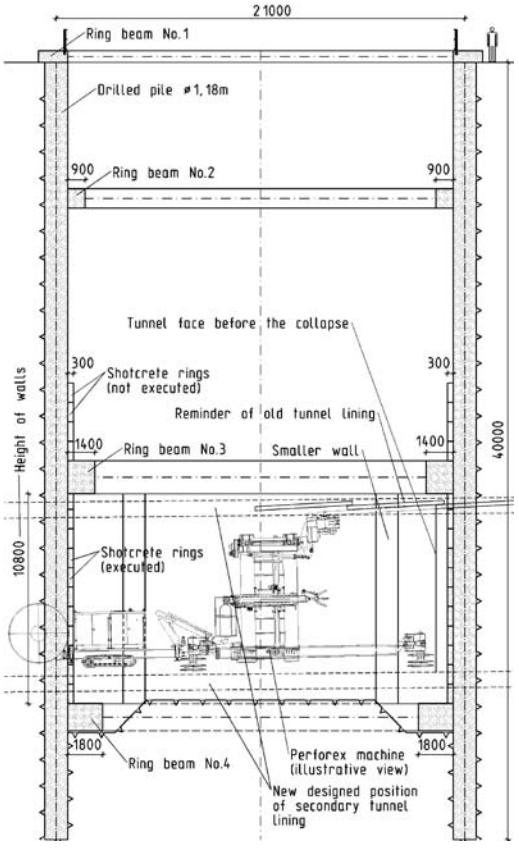

Figure 2. Shaft longitudinal section.

was decided to verify the geotechnical conditions by one borehole (core drilling), located inside the shaft. Besides gaining samples for basic laboratory tests, the aim was to find eventual voids or larger empty spaces. The ground water conditions were also a concern.

Naturally, the conditions for shaft construction were considerably affected by presence of buried Perforex machine, together with utility lines and collapsed primary lining.

The results of core drilling were surprisingly good, the material in the area was "consolidated" and dry. This was also confirmed by piles drilling.

2.3 *Secant piles*

The shaft lining consists of 70 secant piles, with diameter of 1.18 m, distance of their axes 0.942 m and piles' length 40 m. The diameter of the shaft is 21 m (measured to the piles' axes) and depth of the shaft is 35 m. Every second pile is reinforced by 32 mm rebars. The shaft cross section is shown on Figure 1.

For the successful construction process the verticality of piles was of paramount importance; a tolerance of 1% of the drilled length was given to the contractor as a maximum allowed deviation.

In some areas it was obvious that the pile will during the drilling hit steel parts of buried machine; in such case the drilling was supposed to be stopped and the space between two adjacent piles filled by steel braces and shotcrete.

2.4 *Grouting*

Before pile drilling a total number of 29 grout holes (diameter 50 mm) provided by PVC pipes was drilled in the shaft area and grouted with approximately 750 cubic meters of cement grout. Obviously, some open spaces around the machine and collapsed lining contributed to the relatively large grout consumption.

2.5 *Other structural members*

The need to consider construction tolerances (especially piles deviations from the vertical) and construction of two large tunnel openings after shaft completion, led to the design of other structural members; namely four large cast concrete reinforced ring beams (No. 1 to 4), reinforced shotcrete rings and two walls between the ring beams No. 3 and 4 (see Figure 2).

The large reinforced ring beams (height 1.7 m, thickness 1.4 m), were designed to support the pile lining. Their installation was proposed as part of shaft excavation process, after reaching ring beam bottom level.

Shotcrete rings installation was depending on vertical tolerances of piles. Their height was 1.0 m and thickness 0.30 m. Their installation during the

Photo 1. Shaft lining – piles and ring beams.

construction was proposed to start 4 m above the ring beam No. 3.

Two heavily reinforced walls, between the beam rings No. 3 and No. 4 were designed to be cast after the shaft excavation completion. Their purpose was to provide support to the shaft lining (secant piles), after its integrity is disrupted by two large tunnel openings.

2.6 *Structural analysis*

The structural analysis presented extremely difficult part of the shaft design process. The reasons were complicated geological conditions in the space of former collapse, unique construction scheme (e.g. no possibility to use anchors) and not predictable positions of piles with increasing shaft depth. To ensure the safe function of the whole system, a probability model of piles' position was prepared and based on the results the specified deviation for the pilot drilling was established max. 1%. The standards for pile drilling use the value 2%.

The analysis took relatively long time, before it was possible to prove sufficient safety margins of the shaft lining design. Considerable help with the analysis came from A. Zapletal (Metrostav a.s.) and J. Masopust (Zakládání staveb a.s.).

3 SHAFT CONSTRUCTION

3.1 *Pile drilling*

The construction of the shaft was subcontracted by Metrostav a.s. Prague to the Zakládání staveb a.s. Prague, Czech Republic.

The pile drilling was performed by AU BG25 machine; the subcontractor made a very good job resulting in minimum deviations of piles from vertical direction (see Photo 1).

The drilling started in February 2006 and was completed in March 2006. Totally 3 piles hit the steel structures of Perforex machine and were not drilled to the full prescribed depth.

Photo 2. Ring beam No. 3 – heavy reinforcement.

Photo 3. Buried Perforex machine and remainder of collapsed tunnel lining.

3.2 *Shaft excavation*

After piles completion, the ring beam No. 1, located on top of the piles was built.

The shaft excavation started in April 2006. After reaching the bottom level of ring beam No. 2, relatively heavy reinforcement was installed, followed by formwork installation. The same procedure was re-peated during the shaft excavation for beam rings No. 3 and 4 (see Photo 2).

Below the level of ring beam No. 3 was the buried Perforex machine, which considerably complicated the excavation works (see Photo 3).

Because of minimum deviations of piles from the vertical direction, shotcrete rings were installed as late as 3 m below the ring beam No. 3 and their installation continued until the shaft bottom was reached.

The last construction members built were two walls, fixed to the beam rings No. 3 and 4, located on the sides of future tunnel opening. Due to the shaft eccentricity towards the tunnel, one wall was larger than the other one.

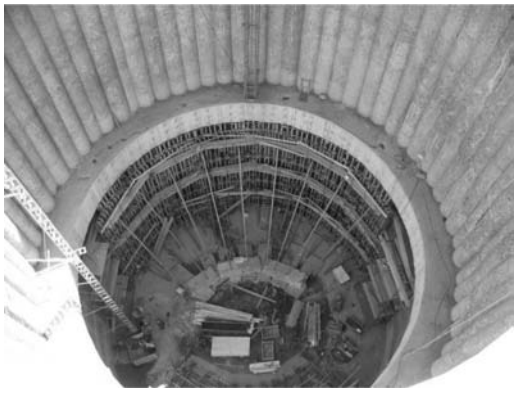

Photo 4. The formwork of the larger wall.

Photo 5. Tunnel breakthrough to the shaft.

Difficult technical task was to provide formwork and find the optimum procedure for casting the concrete of the walls between the ring beams No. 3 and 4. The walls are relatively high (10.8 m), the designer insisted on casting the entire wall without horizontal cold joint; later was agreed to cast one of the walls in two parts. Walls construction presented problems with support of formwork and concrete casting.

Two different methods were applied. Larger wall was cast using self-compacting concrete, with precise timing of casting, depending on the sufficient strength of previously cast layer, but still not creating cold joint. This wall was cast without cold joint (see Photo 4).

For the smaller wall one cold joint was allowed and one-sided formwork was used.

The first opening for the tunnel mined through the previously collapsed tunnel was broken through in July 2006, the breakthrough of the second one for the tunnel mined from the opposite portal was in October 2006 (see Photo 5).

3.3 *Geotechnical monitoring*

To monitor the behaviour of the shaft lining during the construction, six inclinometers were installed in the piles; eight of measuring points in five levels for geodetical measurements were installed on ring beams and piles. Based on construction progress, inclinometers and measuring points were regularly monitored during the whole construction period.

The measured values were very small, no significant movements were monitored during shaft excavation; after tunnel breakthrough expected small deformations on sides of openings were monitored.

3.4 *Main problems encountered during construction*

The shaft construction went relatively smoothly, without any significant problems.

Few problems were encountered during the start of the shotcrete application to build shotcrete rings, which were fixed immediately.

As already mentioned, the buried Perforex machine made the excavation in its vicinity relatively complicated.

4 CONCLUSION

The design of 21 m diameter and 35 m deep shaft in the area of collapsed tunnel proved to be a difficult task, with many unknown features.

The designer had to deal with complicated structural analysis, in some cases using non conventional approach. But even in such circumstances the designer used flexible approach and provided the possibility to change the construction process and the designed structural members, depending on actual conditions, namely geological conditions and accuracy of piles drilling.

Thanks to high quality pile installation there was possibility to take advantage of mentioned flexibility and reduce some of the proposed measures, which would complicate the construction process. The shaft construction was therefore shorter by 2.5 months than was expected according to the original construction schedule.

Repair and reinforcement of damaged tunnel by Acid Mine Drainage (A.M.D.)

Lee Yu-Seok, Yoon Tae-kook, Shin Yong-Suk & Han Ja-Jung
Manager, Korea Infrastructure Safety & Technology Corporation(KISTEC), KOREA

ABSTRACT: This study was carried out in order to figure out the effects of Acid Mine Drainage (A.M.D.) generated from abandoned mines on the adjacent Bam-Je tunnel which is located in Kang-Won province, Korea. To complete this study, visual inspection and G.P.R as well as geological, geographical, water analyses are implemented, and these methods enabled us to identify how influx of A.M.D. cause damages on the tunnel. In addition, based on various experimental supports, we have set up and displayed how to repair and reinforce the damaged areas of the tunnel caused by A.M.D.

1 INTRODUCTION

There are more than 900 metal and mines in Korea, which are currently being mined or exist as abandoned mines. It's reported that hard coals are mainly produced from the coal mines, and gold, zinc and copper are mined from the metal mines. These mining activities, however, cause some serious problems that undermine surrounding environment and we call the result of the problems as "The mine damage" This mine damage is usually caused by some factors which are contaminated water generated from mines, acid mine drainage, and collapse in abandoned mines.

This study was carried out in order to figure out the effects of Acid Mine Drainage (A.M.D.) generated from abandoned mines on the adjacent Bam-Je tunnel structure which is located in Kangwon province, Korea. To complete this study, visual inspection and G.P.R as well as geological, geographical, water analyses are implemented, and these methods enabled us to identify how the influx of A.M.D. cause damages on the tunnel. In addition, based on various experimental supports, we have set up and displayed how to repair and reinforce the damaged areas of the tunnel caused by A.M.D.

Abandoned Mine and A.M.D.

2 BAM-JE TUNNEL

The Bam-Je Tunnel is located between Ok-Ge and Jung-Dong-Jin in Kang-Won province and was completed in 1960. It is a horseshoe-shaped single track railroad, and its lining is made up of concrete. It was built by means of a conventional method (ASSM). Since the completion, its concrete lining has repaired and reinforced the damaged areas of the tunnel caused by cracks and leakage 10 times for 40 years. Thus, the repaired areas with liquid water proofing and powder water proofing in its interior structure are found. Furthermore, cracks, leakage and exfoliation exist over its whole interval since the concrete lining was built with hand work a long time ago.

3 ΔΔ MINING STATION

3.1 *Y-Y region*

Y-Y region of the ΔΔ mining station is an area including the start point of the Bam-Je tunnel.

Its surrounding geological layers are tilted about 20–40 degrees toward northeast. The "7th Y-Y pit",

the central area of Y-Y region, has repeating an anticline and synclinal structures, and the axis of fold is toward northeast. This area had been developed until the year of 1989, and now abandoned mine as a coal industry promotion policy. Total 6 pits including "Y-Y developing pit (103 ml)" have been built, and coal are mined. While the time of mine development, totally 4,400 tons were produced and it has been reported that the coal quality was 4,000 kcal/kg, which is good.

3.2 *H-H region*

The surrounding geological layers of H-H region are inclined at approximately 50 degrees toward northeast. It had been mined until the year of 1989, producing 1,800 tons, and then abandoned mine as a coal industry promotion policy.

3.3 *Bam-Je tunnel and ΔΔ mining station*

A number of abandoned mines in ΔΔ mining station was detected and for the effect of that, abandoned mines in ΔΔ mining station and cross section of a geological stratum, <fig. 1, 2> are shown. Also, <fig. 1> is shown the pH about ground water, which is the neighborhood tunnel. The Bam-Je tunnel is located within "Hong-jum series". Carboniferous period in Paleozoic Erathem and there is an expressway above the tunnel of which ground level from the tunnel is 40 m. The tunnel is at intervals of 130 m far from a planned Dong-He expressway route and 260 m far from the nearest abandoned mine.

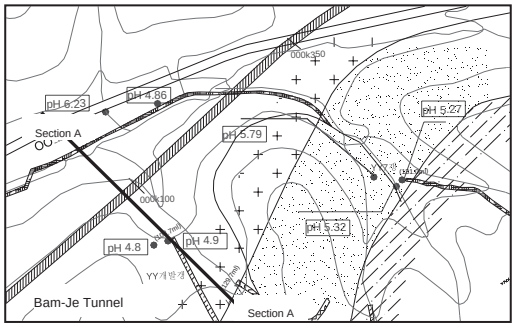

Figure 1. Bam-Je tunnel and surface water pH around ΔΔ mining station.

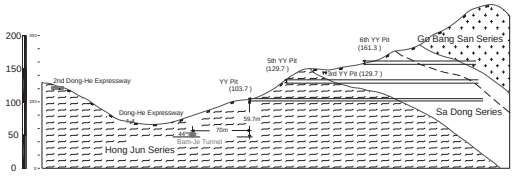

Figure 2. Bam-Je tunnel and ΔΔ mining station (Section A-A).

4 MINE DAMAGE

"The mine damage" is an environmental pollution caused by mining or development of underground natural resources. The mine damage happens due to lack of consideration for natural environments while developing mines or after closing mines. The significant is that the mine damage lasts for a very long time and has seriously unpleasant effects on natural environments and human living circumstances. In addition, the mine damage occurs more often in inactive mines and closed mines rather than the ones under mining.

The mine damage is mainly classified as follows

- The influx or leakage of acidic water containing heavy metals
- Wash away of gobs and efflux of poisonous sludge
- The ground settlement around the mine
- Scattering of fine aerosols or dusts in dry seasons

If we don't take an action for restoring or repair on the areas where the mine damages happen, it's certain that the impact of mine damage will expand and result in serous environmental and social problems.

4.1 *The mine damage caused by mine drainage and wastes*

A sulfide of iron is one of main factors that compose of many metalic mineral, and it is contained with significant amount in a layer that has a lot of organic compounds such as coal. The sulfide of iron mainly consists of sulfur and metal elements that are combined to the sulfur. These would be preserved consistently as long as there is no material interchange with the exterior surroundings and little change in temperature and pressure. However, the metalic mineral and sulfide in coal layer can be dissolved or oxidized when contacted with the air or water that contain dissolved oxygen. This matter usually happens while building a pit mouth or removing an upper-level layer in order to mine metalic mineral or to develop coal layer.

Among sulfide, pyrite has the most effect on the acidification of wastewater produced from mines. pyrite is often observed in metalic ore and is contained a lot in coal layer. If there is a significant activity of microorganisms in the interaction between water and pyrite and in the oxidation between those two, the consistent oxygen supply needed in the interaction between pyrite and underground water and the residence time for the interaction play a very crucial role in the acidification of the wastewater. In fact, the wastewater around abandoned mines shows very low pH. It's because while the underground water that has dissolved oxygen runs along with abandoned mine, the

water is allowed to have enough time to interact with pyrite. However, the acidification of the wastewater is little in active mines since the reaction time between pyrite and the underground water is relatively short due to an artificial drainage.

The theoretical chemical procedures of acidic wastewater containing heavy metals are like followings:

$$2FeS_2 + 2H_2O + 2FeSO_4 + 2H_2SO_4 \quad (1)$$

$$4FeSO_4 + 2H_2SO_4 + O_2 \rightarrow 2Fe(SO_4)^3 + 2H_2O \quad (2)$$

$$Fe_2(SO_4)^3 + 6H_2O \rightarrow 2Fe(OH)_3\downarrow + 3H_2SO_4 \quad (3)$$

$$7Fe_2(SO_4)^3 + FeS_2 + 8H_2O \rightarrow 15FeSO_4 \quad (4)$$

The hydroxide generated from the procedures produces yellow, brown or red sediment along with the wastewater way. We call the sediment "yellowboy." If wastewater is once produced, even though there is no oxygen, the oxidation of pyrite can be proceeded. From the oxidation procedures of pyrite above, Fe^{2+} or SO_4^{2-} saturated wastewater occurs and the quality of the wastewater is various depending on the kinds of pyrite and the magnitude of chemical reaction with surrounding materials.

4.2 *The mine damage caused by ground settlement*

The mining activity produces underground cavity . If cavity doesn't fill back and a balance between pressures and stress forced from upper-level layers is lost, cavity is subject to collapse. If the stress working in the upper-level is less than a ground strength at cavity roof or pillar, there would be no damage. However, the damage or destruction of cavity can happen due to a reduction of the ground strength, a creep transformation of ground and a water migration caused by seepage pressure with the passage of time after the start of mining. Specifically, over a short or long time interval, high humidity of cavity changes the strength of rocks and causes deformability. Also, the underground water in fragmental zone of fault which is a weak part in geological structures weakens the strength of ground.

5 INSPECTION (DIAGNOSIS)

Topographical, Geological inspection, Boring test and non-destruction test etc. were carried out to figure out the condition of tunnel and area around the tunnel.

5.1 *Visual inspection*

Some damages such as cracks, leakage and exfoliation are observed over the whole tunnel including the original concrete lining and the repaired and reinforced concrete lining. In the Figure 3, we can see a water leakage at the boundary between original concrete lining and repaired area on the ceiling where it was built with liquid water proofing. Specifically, the leakage in the right-side wall is very serious. Furthermore, a large amount of efflorescence is produced along with the right-side wall. Considering the tunnel's location close to abandoned pits such as y-y developing pit, y-y 3rd pit and 5th pit, water examination was also carried out.

5.2 *Water experiment*

In order to analyze and figure out the effects on the concrete lining durability of the tunnel, we took surface water and incoming water that leaks into the side of concrete lining at three places and implemented tests on the content of harmful ions. The focus of the test was pH, dissolution evaporation residue, SO_4^{2-}, Cl^-, Na^+, Mg^{2+}, K^+ and Ca^{2+} etc. Figures from the test were compared with the ones from lakes and swamps. The results are shown in the Table 2.

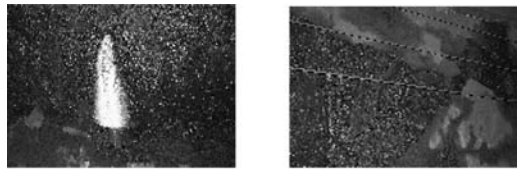

Figure 3. Leakage (Left: the influx of acid mine drainage(pH 4.7), Right: normal leakage).

Table 2. Water experiment (mg/ℓ).

Station	pH (20°C)	Dissolution evaporation residue	SO_4^{2-}	Na^+	Ca^{2+}	K^+	Cl^-	Mg^{2+}
000k030-RW	6.3	420	373	3.14	91.9	2.42	6.60	28.3
000k189-LW	7.8	4.27	54.4	1.93	32.3	2.12	6.57	4.27
000k350-LW	4.7	3.01	56.3	1.16	11.3	3.26	6.83	3.01

The pH of 6.3 and 7.8 at the locations of 000k030 and 000k189 respectively don't seem to harm or damage the tunnel's concrete lining. It is also regarded that the small content of Mg^{2+} and SO_4^{2-} would not harm the concrete lining. However, the 4.7 pH at 000k350 may have a harmful effect on the concrete lining. Thinking about nearby abandoned mines and geological state, we assume that pH is affect by abandoned mine drainage.

5.3 *pH test for abandoned mine water and surface water*

Since A.M.D. was observed, to figure out how the A.M.D. flew in and the acidity of the interior of the closed abandoned mines, we had taken the pH test with ph-meter on the leakage area in the tunnel, closed mines around the tunnel, and surface water. The test results in tunnel and out are listed in the Table 4 and Figure 1.

The pH range of abandoned mine entrance and of surface water around the entrance was recorded at between 4.8 and 5.79(Figure 1). The pH of incoming water leaking to the tunnel and the one of surface water above the tunnel were compared. In case of Y-Y developing pit, mine drainage has reached the entrance of the pit mouth and leakage and efflorescence have been observed over the tunnel areas to which it's assumed that mine drainage leaks. From this observation, A.M.D seems to have harmful effects on the tunnel structure. There is a feasibility that concrete lining might be damaged or ground slackness would happen due to continuing influx of A.M.D. So, we need to take an immediate action for solving the A.M.D. problem.

Table 3. pH and influence on concrete.

pH	Influence on concrete	Decision
∼ 4.0	Melting Cement	Danger
4.1∼5.0	Unevenness on surface	Danger
5.1∼6.0	Infirm onsurface	Caution
6.1∼7.9	Caution early age	Safety
8.0∼	Safety	Safety

Table 4. pH in tunnel.

Station	pH	Station	pH
000k080	4.99	000k441	7.45
000k341	7.52	000k502	7.64
000k350	5.56	000k571	6.18
000k353	7.26	000k735	7.53

6 HOW TO REPAIR AND REINFORCE THE DAMAGED AREAS

In order for A.M.D. not to flow into the tunnel, the tunnel concrete lining has to prevent a water leakage incoming into some areas of the tunnel where waterproof is not applied. In addition, a proper method of the injection for cavity usually happening on the ceiling of the tunnel between bedrock and tunnel concrete linings should be considered carefully. We need to take some considerations for first, the works of grouting on the leakage areas and cavity areas, and second, for selecting inorganic cement needed in injection. Among many considerations, the most important one is to check out the change of concrete strength and the decreasing rate of weight caused by loss of cement element. Ordinary Portland cement (C1), Sulphate Resistance Portland cement (C5), Blast Furnace Slag cement (SC), and Blast Furnace Slag cement and fine powder mixture 55% (SM) were taken for the experiment and the results are as follows.

6.1 *Considerations about acidity*

The experiment was implemented by putting the 4 cement samples into sulfuric acid. The focus of this experiment was to find out the most effect of the strength of concrete and mass ratio on the stability of the tunnel. In the experiment, it was found that the decreasing compressive strength of C1 and C5 had been very steep as the time had gone by, while the compressive strength of SC and SM had showed an increase for 28 days, and then had decreased after that.

We also examined the change of weight ratio in order to figure out weight change of cements caused by acidic erosion. In the exam, we observed that mass of C1 and C5 had decreased rapidly along with soaking acid while the one of SC and SM had showed a very slight change or even had increased. From the X-ray experiment, it's found that $Ca(OH)_2$ is produced less, has more resistance against sulfuric acid. In the following list, $Ca(OH)_2$ is produced less in a order respectively: C1, C5, SC, and SM. Thus, category such as SC and SM which produce the least amount of $Ca(OH)_2$ has the most resistance against acidity.

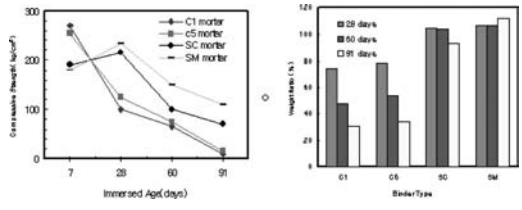

Figure 4. About acidity (Moon, ph.D., 1996).

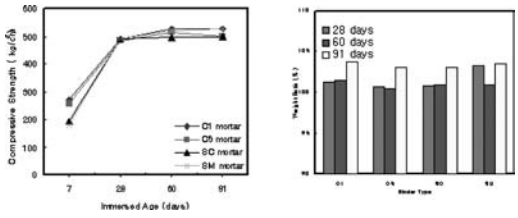

Figure 5. About SO_4^{2-} (Moon, ph.D., 1996).

6.2 *Considerations about SO_4^{2-}*

We took another experiment, putting the 4 cement samples above in sulfate solution. This experiment showed that there had been little change in compressive strength. And regardless of time, in the experiment of weight ratio change against sulfate, the weight of mortar has a little heavier than the one of water curing.

6.3 *Method of repair and reinforcement*

Leakage usually happens in places of crack, construction joint, and insufficient waterproof, and its magnitude depends on the conditions of layers and a structure. So how to repair the leakage relies upon the condition of leakage. Considering concrete's erosion and harmful effects on surrounding layers due to A.M.D. incoming from abandoned mines in ΔΔ mining station adjacent to the tunnel, it seems that the damaged areas are need to be repaired and reinforced with Sulphate Resistance Portland cement grouting that fights well against acidity and Blast Furnace Slag cement and fine powder mixture 50–55%. Also, adding an liquid water proofing to cement during construction helps to prevent water leakage behind concrete lining. As a sub-method, it's recommended that the drainage channel method on the face of concrete lining should be applied.

About cavities of lining, Lightweight form grouting is recommended to prevent stress by self weight, which is caused by mass above the tunnel's ceiling while filling back.

And about affected A.M.D. cavities, Sulphate Resistance Portland cement grouting and Blast Furnace Slag cement and fine powder mixture 50–55% is recommended.

6.4 *How to select areas influenced by A.M.D.*

To find out the areas influenced by A.M.D. in the tunnel, we have used the results of geological, topographical and water examinations. Using these results, we have selected two places close to an abandoned mine in the east of □□ mountain and another area (extended length 340 m) where acidic water incomes into the tunnel. From the observation showing that the leakage was concentrated more seriously on the right side of the tunnel and acidic water was also found there, it's been assumed that the path of A.M.D. is surface water way along with valleys rather than a path along with fault of bedrock.

7 CONCLUSIONS

In order to find out effects of A.M.D. from abandoned mines around the objective tunnel, visual inspection, water experiment, G.P.R, geological and topographical inspection were taken, and from the examinations results, we have found conclusion.

(1) The result of visual inspection, leakage was concentrated seriously on the right side of the tunnel. The result of water examination pH is 4.7 and specifically, as supposing, influx of A.M.D. section is produced a large amount of efflorescence and some erosion with leakage. For such reason, we have conclusion A.M.D. seems to have effects on leakage and the tunnel structure.

(2) The distribution of bedrock in the tunnel goes through the interior of "Hong-Jum series" consisting of limestone. And with an analysis of geology around the tunnel and a place of leakage it's been assumed that the path of A.M.D. is surface water way along with valleys rather than a path along with fault of bedrock and determined its influencing area.

(3) There are some main solutions for A.M.D. are like followings, as prevent generation of A.M.D., neutralize A.M.D. which is already generated and prevent A.M.D. from influx to a tunnel.

For the third solution above, on the basis of experimental results, it's suggested about leakage and cavity that grouting with mixed cements of Sulphate Resistance Portland cement grouting and Blast Furnace Slag cement and fine powder mixture 50–55% need to be applied.

Data management for highly mechanized shield tunnelling in the construction of the Line 9 Metro Barcelona

Ing. Carme Deulofeu & Dipl.-Ing. Henning Schwarz
Gestió d'Infraestructures S.A. (GISA), Barcelona, Spain

Dr.-Ing. Ulrich Maidl & Ing. Marc Comulada
Maidl Consulting Engineers, Bochum, Germany

ABSTRACT: In shield tunnelling in urban areas a rapid reaction to unexpected situations requires an efficient data management. Practical experiences have shown how an optimum management, processing and evaluation of the available data provide a tool to react against initially unforeseen situations. Furthermore, data management allows optimizing shield tunnelling from the point of view of all the parties involved in the construction. The factors concerning safety, settlement minimization, tunnel lining quality, production maximization and cost minimization are taken into account. Since the planning phase of Line 9 Metro Barcelona, special attention has been focused on the management of the large amount of monitoring and shield machine operational data, as well as of the ground information from the soil investigation programs. The tunnel is built with three different shield machines under very dense urban areas and in heterogeneous ground conditions.

1 INTRODUCTION

To comply with the present safety standards and with demands on risk minimization, tunnelling methods are developing by the improvement of more realistic calculation models and also by the introduction of more efficient and safer construction methods. However, these factors have to be complemented by efficient controlling systems during construction.

The Metro Line 9 in Barcelona is a reference tunnelling project due to the large variety of geological and hydrological conditions which it encounters. Furthermore, the vast figures which characterise this Metro Line with a total length of shield driven tunnels of more than 40 km, large tunnel excavation diameters of 9,4 m and 12,0 m and the use of two earth pressure balanced (EPB) shields and one convertible shield TBM, give an idea of the magnitude of this project.

In a project of these dimensions it has become clear that Process Controlling needs to be part of an efficient Data Management system.

2 PROCESS CONTROLLING IN SHIELD TUNNELLING

In shield tunnelling a particular machine technology is applied to deal with ground conditions, which may be variable and partly uncertain.

Not only are the underground conditions determinant in shield tunnelling. Specially in urban areas, the surface conditions, with the presence of different types of structures and pre-existing underground infrastructures, also condition the performance of the tunnelling process.

Taking these facts into consideration, it becomes clear that any controlling system in shield tunnelling should be continuously oriented to the construction processes. Such a controlling system must also help to improve and accelerate the decision taking processes.

As well as in other construction methods, the complex shield tunnelling process is formed by a series of partial processes. Specially in shield tunnelling, these partial processes interact with each other, in order to successfully perform the ground excavation and to provide a safe ground support.

The control of the partial processes and their interactions is defined as Process Controlling.

2.1 *Process Controlling circuit*

The Process Controlling system has to be fed with data to provide the basis for a founded analysis.

Presently most shields are equipped with a large number of sensors which record the main operational parameters of the machine. This makes shield tunnelling specially adequate for highly automatised Process Controlling systems with an important number of

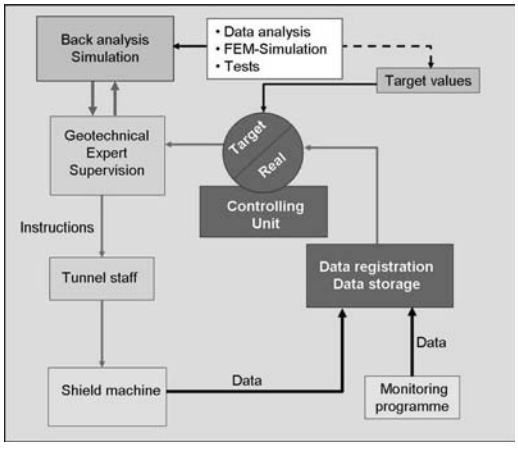

Figure 1. Scheme of the Process Controlling circuit in shield tunnelling.

treated data. The more significant data is provided, the more efficient will the Process Controlling system be.

The typical control circuit for state-of-the-art shield tunnelling is schematically represented in Figure 1.

The operational data from the shield machine are electronically registered and recorded. Additionally, the external monitoring programme provides data about the influence of the tunnelling process on the ground and on other infrastructures and buildings.

On the other hand, previously to the tunnel construction, the theoretical values for the machine operational parameters and for the interaction between the machine and the ground are determined. These theoretical values are set as initial target values for the shield drive.

On the basis of the estimations, previously to the TBM drive start, the first decisions can be taken concerning both, the shield machine operation parameters and the execution of additional measures. Such measures comprise ground improvement treatments and protective measures for buildings and infrastructures located in the influence area of the tunnel construction.

Once the tunnelling process has started, the controlling circuit is principally based on the comparison of the measured real values with the target values. This comparison is generally performed by the board of experts on-site, taking into account the geological and geotechnical characterisation of the ground, as well as other external conditions. The aim of this comparison is, to be able to take the appropriate decisions in order to adapt the construction process to the really encountered conditions.

A permanent check of whether the tunnelling process is behaving as expected has to performed through the comparison analysis. Then, if necessary, specific countermeasures have to be decided and carried out. Such countermeasures comprise changes in the machine operational parameters, as well as additional ground treatments or protection measures.

2.2 *Determination of the target values*

The expected theoretical values of the shield operation parameters and of the ground movements are obtained by calculations based on the existing ground models, theories and experiences in previous projects, Burland (2001). The simulation of the shield drive in complex conditions by means of numerical models is particularly convenient for the determination of the theoretical values.

As discussed in Maidl (2005), numerical models provide a realistic simulation of the tunnelling process, as well as a good estimation of the interaction between the shield machine, the ground and the buildings or other infrastructures. Thus, it is possible to obtain realistic values for the expected settlements under different assumptions concerning the shield machine operation and the ground conditions.

3 DATA MANAGEMENT

One of the main sources for the Process Controlling are the data from the construction process and from the monitoring program. Additionally, a great amount of information from the soil investigation programs is generated in tunnelling projects, before and during the construction phase.

Shield tunnelling is characterised by high production rates. Thus for the Process Controlling to be able to provide rapid responses to the needs of the shield drive, it is firstly necessary to have an organised and interconnected data management system.

3.1 *Monitoring data*

The monitoring data becomes an essential tool when tunnelling in urban areas. Only by monitoring the external effects of the tunnelling works, can any decisions concerning the TBM operation be taken. Therefore a georeferenced monitoring data system has to be installed and connected to other databases. Extensive information about monitoring is included in Dunnicliff (1993).

3.2 *TBM data*

The machine operational parameters measured by the different sensors installed in the shield machine are continuously registered and recorded. These data are generally available by real-time transmission, as well as in digital format in data files. By this way, both a real-time as well as a post-process access to the TBM data is possible at any time.

The number of registered parameters and the coding and structure of the data is different depending on the TBM manufacturer. From the experience of working

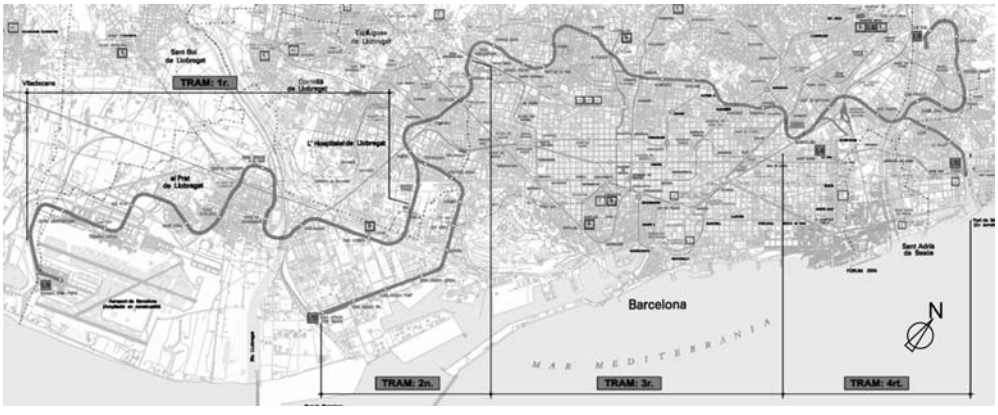

Figure 2. Ground plan of the Metro Barcelona Line 9.

with different TBM manufacturers, it has also become clear that a unified coding system for the machine parameters should be attained in future.

Taking into account that about 400 parameters or more are registered and stored in frequencies comprised between 10 to 60 seconds, it becomes clear that the management and processing of these data must be prepared to efficiently provide the required information for the Process Controlling.

3.3 *Geotechnical ground parameters*

The analysis of the interaction between the shield machine and the ground has to be based on the geotechnical characterisation of the excavated ground.

The geotechnical ground parameters are obtained from the soil investigations programs generally performed before the start of the works. However, new boreholes and tests are sometimes performed also during the construction phase, in order to provide additional ground information.

In large and complex projects, all this information ought to be easily available as well as updatable at any time, to allow an efficient and rapid analysis, as it has been done in the Barcelona Metro Line 9 project.

4 BARCELONA METRO LINE 9

4.1 *Project description*

The Barcelona Metro Line 9 project comprises a total tunnel length of approximately 45 km and the construction of 47 underground stations. As it is shown in Figure 2, through this completely new Metro line, Barcelona will be provided with new connections to the metropolitan area, north-west and south-east of the city of Barcelona. By this way the public transport system will take a new structure within the Barcelona Metro network. Additionally, new public transport connections will be created to strategic areas such as the airport, Barcelona's industrial area or the new high-speed railway station.

Most of the tunnel length is being built by means of shield machines. The construction methods for the rest of the stretch are the shotcrete method and cut and cover. Part of the Line 9 runs on a viaduct.

In total three shield machines take part in the construction of the tunnel sections. A 12 m EPB shield is in charge of the construction of about 11 km of the line, in different areas formed respectively by stiff Miocene conglomerate, Miocene marl, soft Quaternary alluvium soils and Pliocene claystones and siltstones. A second 12 m diameter convertible TBM shield has already excavated along 4,5 km through fresh to highly weathered granodiorite. About 10,5 km still have to be driven through different kinds of rock with several fracturing and weathering grades and also through faulted areas. Finally, a 9,4 m EPB shield is driving southwards for about 15 km, through the fine sands and silts of the Llobregat river alluvium. For more extended descriptions about the Line 9 project, please refer to Boté (2004a,b) and Tersol (2005).

The Client of the project is the public enterprise Gestió d'Infraestructures, S.A. (GISA).

Due to the length of the line and to the vast amount of information related to the project, GISA has implemented a Data Management system, including the Process Controlling software.

4.2 *Data Management in the Line 9*

This section describes the way that the Data Management is being performed for all the tunnelling construction lots of the Line 9.

To start with, there are two main groups which ought to be distinguished. On one hand there are data which are updated only in frequencies of several months, such as the geology, the topography or the information about the buildings and infrastructures.

On the other hand, there is a group of data which are regularly updated. These are, for instance, the monitoring data or the machine operational data.

The most representative data, the ground information, the monitoring data and the TBM operation parameters, and its management are described in this section.

4.2.1 *Geotechnical ground parameters*

All the existing borehole information and test results from the soil investigation program of Line 9 have been introduced in a database, named DINS-L9. Additionally, since the ground investigation program is being extended also during the construction phase, this database is continuously updated with new information.

The Contract to develop the access to this information through a Geographical Information System (GIS), has been awarded by GISA to the engineering consultant Eurogeotècnica.

Specially in such a large project as the Line 9, the possibility of accessing all the project data in one organised database allows to save time and to increase the analysis capacity of the engineering teams involved in the project.

4.2.2 *Monitoring data*

With the purpose of having a unified monitoring system for the whole length of the Line 9 project, GISA has grouped in one single contract the monitoring of all the construction lots which comprise the Line 9. The monitoring Contractor is a joint venture formed by Sol-Data Iberia, Applus and IIC.

Most of the monitoring performed in the Line 9 construction is oriented to the shield drive. However, extensive monitoring programs have also been developed for the construction of the station shafts. Additionally, the tunnel lining's deformations and stresses are monitored by means of instruments installed in the concrete lining segments and 3D-LADAR survey. Details of the monitoring program are provided in Bono (2004) and Soteras (2005).

The monitoring database allows all the data to be georeferenced, clearly identified and easily traceable. From the moment when the data are introduced into the database, this information is available at any moment via the Internet to each of the Contractors and Site Supervisors. In the case of the Line 9, the access to this data is performed through a project specific software developed by the monitoring Contractor.

GISA has also developed its own database, named MIDA-L9, to extend individual monitoring data into groups and to provide pre-analysis tool as well as connections to other databases.

4.2.3 *Process Controlling of the TBM drive*

The TBM operational data are automatically stored in the form of files on a computer at the jobsites. For the TBM data management, GISA is applying for the Line 9 a Process Controlling software (ProCon) developed by Maidl Consulting Engineers. This software reads the TBM data in the format given by the respective TBM manufacturer.

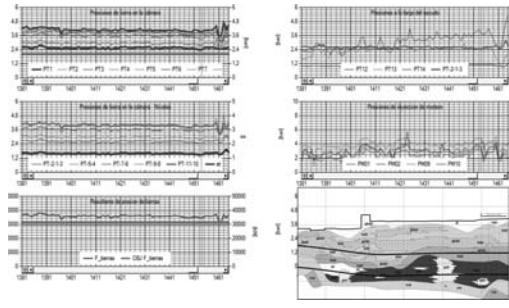

Figure 3. Process Controlling surface for the TBM data and correlation with the geological profile.

The way in which the data are processed and provided to the user for its assessment, is based on the premise stated earlier about the decomposition of the global shield tunnelling process in a series of comprehensible partial processes. The behaviour of each of the partial processes and their interactions shall be recognised as soon as possible by the site engineers.

This software is organised in a series of surfaces. Each single surface graphically represents the data for a given partial process of the shield drive. The surfaces for each of the partial processes are organised in a series of graphics, which allow to visually follow the correlations between different machine operational parameters. Figure 3 shows the general graphical distribution of the Process Controlling surfaces when working with the ProCon software.

Aiming to provide a global assessment which does not only include the TBM operation itself, but also the assessment of the interaction with the excavated ground, additional calculation parameters are also processed by the software. These additional parameters help to provide more complete information about important aspects of the shield tunnelling, such as the quality of the material flow in the excavation chamber, the pressure communication between the tunnel face and the ring gap behind the shield or the ground conditioning.

Additionally, the target values which have been set for specific TBM operational parameters along the tunnel alignment, are also represented on the corresponding surfaces in order to control that the tunnelling process is following the theoretically expected behaviour.

Since the interaction with the ground is one of the main aspects which has to be assessed, the software allows to superpose the geological profile on the graphical representation of the TBM data, as it is also shown in Figure 3.

For a complete analysis of the TBM drive and of its influence on the surface and on the surrounding structures and infrastructures, the Process Controlling software also allows to show selected data of the monitoring program to directly contrast it with the TBM operation.

Through the Process Controlling software, the time costly processing and organizing of the TBM data are avoided. This helps to react more rapidly when deviations of the expected behaviour in the tunnelling process occur. Process Controlling aims to be an effective decision-taking tool, by making a rapid processing and use of all the information available concerning the shield tunnelling process.

4.3 *Process Controlling case studies in Line 9*

Through the case studies presented here it can be seen how Process Controlling helps to understand the behaviour and interaction between the shield drive and the ground.

The case studies correspond to the 12 m EPB shield drive in the soft alluvium soils of the Besòs River delta. In this area difficult heterogeneous ground conditions were expected and have been encountered. The ground is characterised by the interbedding of sediment layers with a high variety of grain particle distributions. The tunnel face is variably composed by layers of medium grained sands (Qb2), gravels and blocks in a sandy matrix (Qb2g), clay and silts (Qb3) and coarse sands and gravel (Qb4). The tunnel is driven below a high groundwater table.

4.3.1 *Face pressure control and ground conditioning*

The settlement curve in Figure 4 shows how, around ring 1000, a gradual increase of the surface settlements has been measured. The control of the TBM operational parameters shows a coincident gradual decrease of the earth pressure in the crown area in the excavation chamber. This correlation between the supporting pressure decrease and the increase of the surface settlements seems clear, however the causes for the loss of control of the supporting pressure are complex.

Additionally, around ring 1000 an increase of the cutterhead torque between 25% to 30% occurs. Generally the magnitude of the cutterhead torque is related to the properties of the excavated ground. Once the tunnel geological profile is superposed, it can be seen that at the point when the torque increase occurs, the clay and silt layer (Qb3) disappears from the tunnel face. This means that the plasticity of the ground in the excavation chamber has reduced and, thus, its internal friction increases. This is directly related to an increase of the cutterhead torque.

After some rings, a drastic reduction of the injected foam flow occurs. This is reflected by the FIR (Foam Injection Rate) parameter shown in Figure 4.

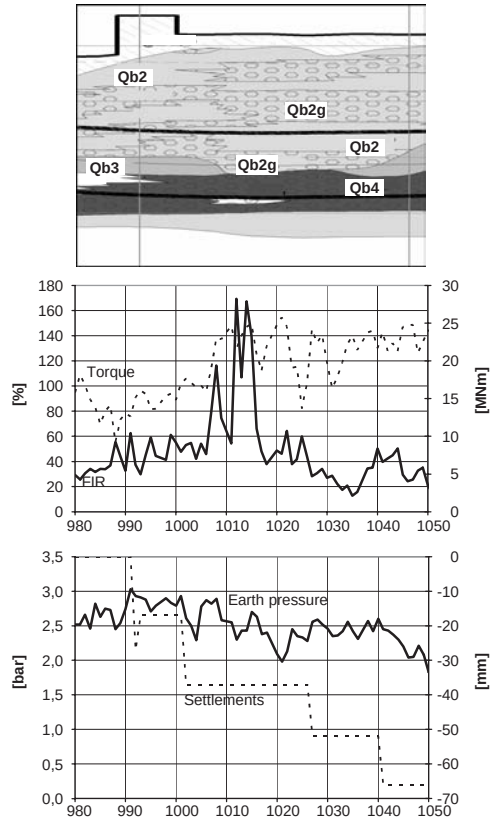

Figure 4. Application of the Process Controlling for the analysis of the TBM-ground interaction (Case study 1).

Generally, in EPB tunnelling the combination of reduced ground plasticity, together with a decrease of the conditioning of the excavated material automatically yields the hindrance of the material flow from the tunnel face to the screw conveyor. At the same time this complicates the control of the supporting pressures in the excavation chamber. Eventually, the supporting pressure becomes too low and the surface settlements increase, as the tendency between rings 1000 and 1050 shows.

After the corrective measures were adopted, i.e. improvement of the foam ground conditioning, the supporting pressure and thus, the settlements could be controlled.

4.3.2 *Improvement of the ground support pressure between the tunnel face and the ring gap*

In comparison to conventional EPB shield technology, the shield machines of the Line 9 are equipped with an additional injection system around the shield shell. This system allows injecting a grout or bentonite suspension between the shield and the ground. The aim of

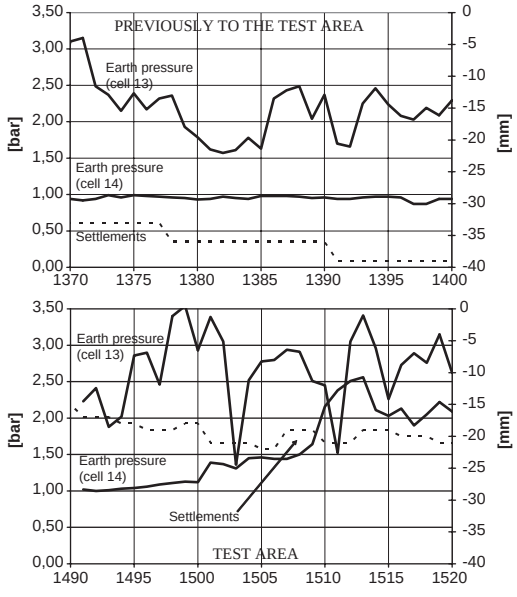

Figure 5. Application of the Process Controlling for the analysis of the TBM-ground interaction (Case study 2).

this system is to provide a more active control of the ground support along the shield.

The active control of the pressure from the tunnel face until the grout injected ring gap should allow to control the ground decompression and the ground deformation. Eventually, this should result in a reduction of the surface settlements.

For this reason a test stretch was performed where a controlled injection of a bentonite suspension around the shield shell was carried out.

Figure 5 shows the pressures measured by the pressure cells 13 and 14 which are installed on the outside of the shield shell at the crown area.

Before the test stretch, settlements generally lied between 30 mm and 40 mm, as it can be seen in Figure 5 between rings 1370 and 1400. In the test area however, a reduction of the ground settlements of up to 50% was measured between rings 1490 and 1520 (Figure 5), in comparison with the previous section.

The analysis of the TBM operation data shows a correlation between the reduction of the settlements and an increase of the pressures measured by cells 13 and 14. Cell 13 is located closer to the tunnel face and therefore it is more influenced by the face support pressure. This shows that the shield shell injection has improved the pressure communication along the shield. This has resulted in a better support of the tunnel profile ground, i.e. lower decompression of the ground stresses, and an improved grouting process in the ring gap behind the lining segments. Consequently, the final surface settlements have been reduced.

5 SUMMARY

The data related to tunnelling projects, which includes the monitoring data, the TBM operational data and the results of the soil investigation programs are a valuable source of information. All these data should be used and updated during all the different phases of a project.

Data Management is the tool to provide all the available and necessary information for Process Controlling in shield tunnelling.

Shield tunnelling is characterised by high tunnel production rates. In order to satisfy the needs of the construction process, one of the main aims of Process Controlling is to allow processing the large amount of available data rapidly, so as to reduce the reaction time against any deviations from the expected conditions and behaviour. This way, the decision taking process for the performance of countermeasures can be accelerated.

The application of Process Controlling in the Metro Barcelona Line 9 project, in combination with an organised Data Management system, is providing positive results as it has been shown in two case studies in this paper.

ABSTRACT: The 3,990-m-long north work section of Takaoka Tunnel, is being excavated using the short bench cut method based on NATM. The ground is unconsolidated throughout the tunnel length and the groundwater level is above the tunnel. Excavating the tunnel in the water-bearing unconsolidated ground was required. Disturbances were therefore of concern such as the failure of tunnel face or tunnel crown and large-scale liquefaction. In order to avoid such risks, auxiliary methods were adopted such as long forepoling for tunnel crown with a multiple packer sleeved pipe system using water glass grout and long forepoling for supporting tunnel face. A decision was made to flexibly adopt according to the soil condition with a view to achieving high cost effectiveness, because the geology consists of alternate layers of sand, gravel and silt and transverse folding and anticlines were found.

1 INTRODUCTION

Auxiliary methods including those with long forepoles have recently been used for tunneling in water-bearing unconsolidated ground on an increasing number of occasions. Unconsolidated ground with shallow depth frequently consists of alternate layers of sand, gravel and other materials and exhibits a lens-shaped body owing to the mode of sedimentation. The characteristics of the ground never remain unchanged over a long distance. In such a soil condition, adopting the pattern of an auxiliary system and materials that have been determined in the design phase without any modification would be detrimental not only to the effectiveness of soil stabilization but also to cost performance. Flexibly applying materials and determining the length of drilling a steel pipe per shift according to the soil condition would be important. In the north work section of the Takaoka Tunnel, construction is being carried out varying the material to be injected for soil stabilization, injection specifications and the range of injection according to ever changing soil conditions regardless of the predetermined design. Tunnel excavation has been progressing smoothly without any serious accidents. It has been found although the construction is still in progress that the twin tube double packer system is highly effective for making the best use of long forepoling in water-bearing unconsolidated ground and that downward cutoff from the upper half of the working face using injection piping used by the system is effective for controlling water seepage. This paper describes the process of implementation of auxiliary methods.

2 PROJECT OUTLINE

The Nagano-Kanazawa section of the Hokuriku-shinkansen railway line is being constructed by the Japan Railway Construction, Transport and Technology Agency based on the National Shinkansen Railway Development Law. The length of construction between Nagano City and Kanazawa City via Joetsu, Uozu, Toyama and other cities is approximately 230 km (Figure 1).

The Takaoka Tunnel on the Hokuriku-shinkansen railway line has a length of 6,938 m and penetrates a hill between Takaoka and Nagaoka in the city

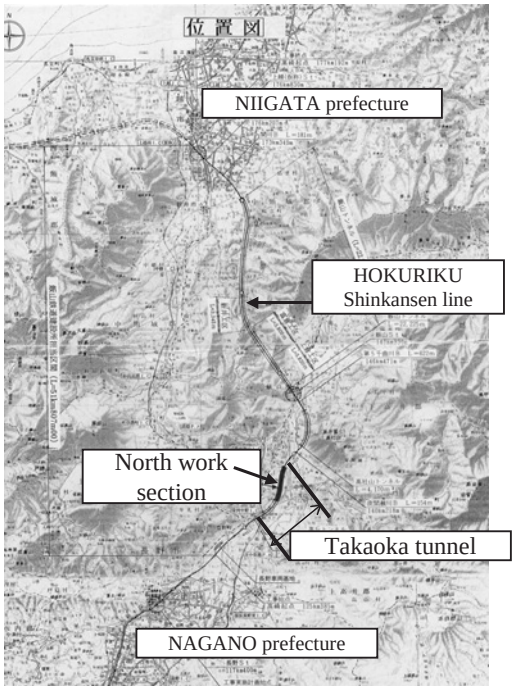

Figure 1. Location map.

of Nakano, Nagano Prefecture. Construction over a length of 3,990 m will be carried out in the north work section on the side of Joetsu. The tunnel cross section will be 80.1 to 83.3 m^2. The top heading is being constructed first by mechanical excavation. A road haulage system has been adopted for muck removal.

Construction of an inclined adit for working space (sectional area: 26.8 to 54.2 m^2, length: 656 m and slope: 2.8%) was started in March 2001. The excavation of the tunnel was commenced in November 2001. The tunnel is being excavated to both portals. Excavation has been completed over a length of 2,720 m at the end of May 2006.

3 GEOLOGICAL AND TOPOGRAPHIC OUTLINES

The geology at the site consists of lacustrine and estuarine sediments of the Pliocene epoch of Neogene period through the Holocene epoch of Quaternary period such as gravel, sand, silt and volcanic ash. The ground is unconsolidated throughout the tunnel length and the groundwater level is above the tunnel. The excavation site in the north work section is in the Sarumaru formation at a relatively great depth and composed of gravel, tuff breccia, sand and silt. The Sarumaru formation is composed mainly of well graded large conglomerates, but is not so much consolidated in the matrix and likely to become vulnerable when subjected to wetting and drying. Tuff breccia is composed of pumiceous tuff breccia mainly consisting of pumiceous gravel, and andesite tuff breccia containing hard andesite gravel, and is assumed to be in the water-bearing formation. Sand and silt exist in narrow areas in thin layers of a few meters. In some sections, coarse sand particles with few fine particles and a low uniformity coefficient are widely distributed. Occurrence of quicksand is therefore of concern. Figure 2. shows a geological profile in an area with a thin earth cover drawn based on the results of pre-construction borehole exploration.

At the working face, layers composed predominantly of 20- to 30-cm-diameter gravels, those composed only of sand and of sandy silt alternately appear although all are classified as sand and gravel layers. Folding of rocks and formations of anticlines are also found perpendicular to the tunnel alignment (Photograph 1).

4 SELECTION OF AUXILIARY METHODS ACCORDING TO THE GEOLOGICAL PROPERTIES

The water-bearing unconsolidated ground detected in the tunnel as described above was likely to cause disturbances such as the collapse of working face or tunnel crown, or large-scale quicksand or deteriorate the bonding of shotcrete.

Before excavating the tunnel, a study was made to select the method for controlling water seepage. Installing deep wells from the ground level was considered because there was a relatively shallow depth. The method was, however, found to have limited effects because of drastically varying soil conditions. It was decided instead to drill dewatering boreholes from within the tunnel regularly.

Long forepoling methods were selected as listed in Table 1. from among those that had an excellent track record in water-bearing unconsolidated ground. Then, screening was made in view of the effectiveness for chemical grout injection in sand or sandy gravel layers. As a result, long forepoling with a twin pipe double packer system using water glass grout (AGF-R method) was adopted.

For supporting the working face, methods listed in Table 2. were examined. To use the same material and maintain the uniformity of construction cycle with the forepoling method, the long face grout method (FG method) using water glass grout and AGF-R steel pipes was adopted.

Face grout method (L = 12 m) drilled every 9 m (silca resin injection) or (Denka S pack injection)		Δ	Δ	O

5 OUTLINES OF SELECTED AUXILIARY METHODS

The AGF-R method is a long forepoling method. Steel pipes with injection nozzles equipped with a check valve are drilled into the ground. A grouting sleeve is formed around the steel pipe, and then highly flowable grout is injected by the twin pipe double packer grouting method. Composite ground composed of the steel pipe and cylindrical soil-grout column is intended for soil stabilization or improvement.

Forming solid soil-grout columns is extremely difficult in collapsible sedimentary ground. Conventional AGF methods have frequently caused soil collapse between steel pipes. The AGF-R method adopted in this project injects highly flowable grout into steel

pipes in steps using the twin pipe double packer grouting method to consolidate the ground between steel pipes.

6 IMPLEMENTATION OF AUXILIARY METHODS

6.1 *Basic pattern*

The diameter (thickness) of the soil-grout column for soil stabilization either at the tunnel crown or on the working face was set at 1.5 m where there was water seepage or at 1.0 m otherwise.

The injection rate was set at 35% : 10% in the primary injection (rough injection of Denka S Pack) and 25% in the secondary injection (penetration injection of Silicarizer). Where alternate layers of silt and gravel were found in the soil stabilization area, primary injection was carried out throughout the area but secondary injection only in the gravel layer. The range of implementation of the AGF-R method was basically 160 degrees, but reduced to 120 degrees depending on the soil or seepage conditions. The length of drilling a steel pipe per shift was set at 9 m. Figure 3 shows a basic flow of steps of the AGF-R method. Figure 4 provides a typical cross section in the case without any seepage.

At the tunnel site, the ground consists of alternate layers of sand, gravel and silt and folding of rocks and formations of anticlines are also found perpendicular to the tunnel alignment. In order to obtain the greatest effect possible of soil stabilization and cost performance under ever changing soil conditions, therefore, the construction specifications such as the length of drilling a steel pipe per shift, grout material, injection rate and grout pressure were modified wherever required during construction.

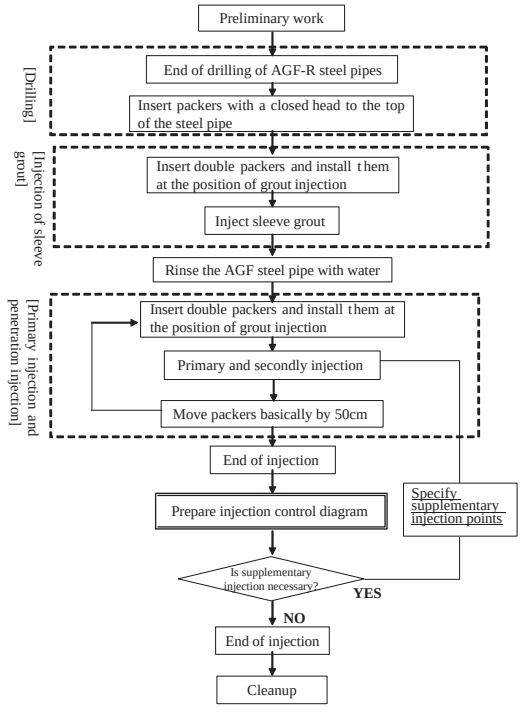

Figure 3. Basic flow of AGF-R method.

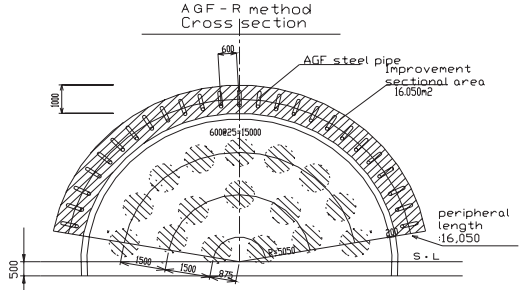

Figure 4. Typical cross section in the case without any seepage.

6.2 *Construction in sandy soils*

Ground collapsed between steel pipes in a sandy soil section. It was determined that the collapse occurred probably because drastically changing grading of sandy soil particles caused the chemical to easily run out resulting in insufficient stability (Figure 5). Then, the following changes were made to construction conditions.

(i) In order to ensure soil stability between steel pipes, steel pipes were drilled at a pitch of 45 cm instead of 60 cm perpendicular to the tunnel alignment and the longitudinal length of injection was increased from 10 m to 11 m.

(ii) Material for primary injection was changed to cohesive cement-bentonite grout to enhance the effectiveness of primary injection.

(iii) Both volume and pressure of grout were controlled. Final pressure in each step was verified at the end of grout injection. For the step in which grout pressure was below the requirement, supplementary grouting was carried out.

Modifications to specifications are listed in Table-3. Construction to the revised specifications contributed to the prevention of collapse of unconsolidated sandy layers and smooth progress of tunneling.

6.3 *Construction in sections with alternate layers*

In sections with alternate layers of gravel and silt, soil-grout columns of varying shapes were formed in respective types of soil, so they were not uniform

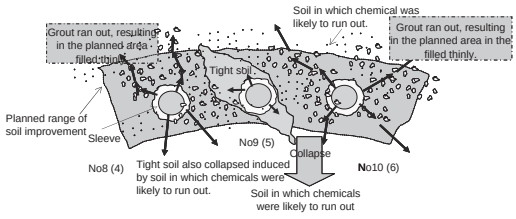

Figure 5. Conceivable reason for soil collapse in the sandy soil section.

Table 3. Modifications to specifications in a sandy soil section.

Item	unit	137 km502 m ～	～137 km511 m	remarks
Pitch of steel pipe	m m	600	450	
Sift length	m	9.0	9.0	
Length of injection	m	10.0	11.0	
Material of sleeve		Denka-s-pack (5 L/m)	Denka-s-pack (5 L/m)	
Material for primary		Denka-S-pack 5～10%	Cement bentonite	
injection (Required grout pressure)			5% (less than 1.0 Mpa)	
Materia for secondary injection (Required grout pressure)		Silicarizer 25～30%	Silicarizer 30% (less than 1.7 Mpa)	
Layer boundary measure		non	2 m lap	Secondary injection to silt layer

throughout the section. As a result, soil-grout columns suffered spalling at the bottom edge of AGF-R steel pipes. To solve the problem, soil-grout columns were restrained in the sandy layer by forepoling with silica resin grout injection during excavation following the implementation of the AGF-R method. In silt layers where penetration injection (secondary injection) is inapplicable, only primary injection was carried out. Forepoling was adopted during excavation. Where the ground was composed of silt layers throughout the section, the AGF method was employed that involved the injection of silica resin grout. Figure 6. shows examples of forepoling in different types of soils.

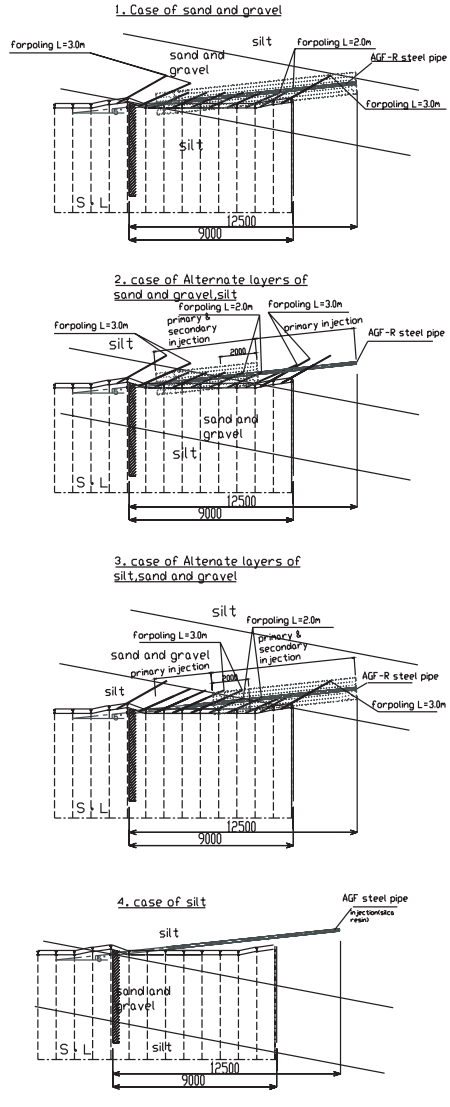

Figure 6. Examples of forepoling in different types of soils.

6.4 *Construction in seepage sections*

In sections with seepage, drilling a dozen of FGs with a design diameter of one meter at the working face inevitably resulted in gaps being left, so no sediment runoff was likely to be prevented. Grout injection was therefore applied at the working face using the twin pipe double packer system to stabilize the soil throughout the face (provide a water cutoff).

At the bottom of the top heading, no FG steel pipes could be drilled by a drill jumbo. Manchette tubes instead of FG steel pipes were drilled by a drilling machine. Ground over a length of 18 m was stabilized (water cutoff was provided) in a shift for higher

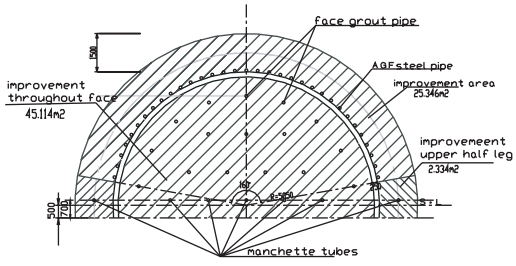

Figure 7. Pattern on face stabilization in the case with water seepage.

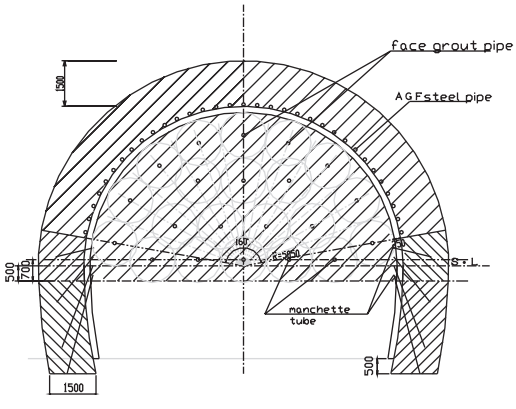

Figure 8. Face improvement pattern in the case with seepage throughout the section.

efficiency. Figure 7. shows a pattern of working face stabilization in the case with water seepage at the working face of top heading.

Sandy layers with seepage also appeared in the bench and runoff of the sandy layers occurred during excavation. Soil improvement was therefore necessary as in the top heading. In sections where top heading face advanced, only side walls of the bench were improved over a length of 18 m in a shift using manchette tubes at the bench face.

Both top heading and bench were improved from the top heading face ahead of the top heading face to shorten the cycle. The length of drilling a steel pipe per shift at the bottom of the top heading was reduced to 9 m from 18 m as in bench excavation. Soil-grout columns for the side walls of bench were constructed diagonally downward ahead of the top heading face. Figure 8. shows a face improvement pattern in the case with seepage throughout the section.

7 CONCLUSIONS

Basic soil stabilization patterns were defined before excavation in water-bearing unconsolidated ground.

Construction has taken place according to the basic patterns only over a length of approximately 40 m so far. Patterns have been modified continuously in response to changing soil conditions. Table-4 lists major modifications to the specifications for auxiliary methods.

The following findings have been obtained.

(a) In order to achieve a sufficient level of soil stabilization by long forepoling in water-bearing unconsolidated ground, the AGF-R method employing twin pipe double packer grouting system is very effective.
(b) Downward cutoff from the top heading working face using the twin pipe double packer system with manchette tubes is effective for controlling water seepage.
(c) In sand and gravel layers, chemicals are likely to run out. Cohesive materials are therefore effective in primary injection.
(d) Controlling both quantity and pressure of grout is effective during the injection in sand and gravel layers.
(e) In alternate layers of sand and silt, soil-grout columns are formed in varying shapes and are not uniform, so restraining soil-grout columns by forepoling during excavation is effective.
(f) In the case where considerable seepage is found and sediment runoff is likely to occur, injecting grout throughout the working face (providing a water cutoff) is necessary.

Large-scale soil collapse has been prevented during the excavation so far by predicting varying ground conditions by exploratory drilling and making modifications to specifications in the next shift accordingly.

8 FINAL REMARK

In sections with drastically changing soil conditions, predicting changes is difficult and whether an auxiliary method selected suits the ground or not cannot be determined without identifying the soil deformation or stress acting on supports after excavation. Constantly monitoring the process of construction and making improvements based on the determination of effects of excavation are therefore important. Then, the auxiliary method will have the minimum effects on construction progress and be more cost effective.

In the north work section of the Takaoka Tunnel, the above principle was applied and specifications for auxiliary methods have been modified frequently. Nearly optimal specifications have been identified for auxiliary methods under respective soil conditions. It is hoped that similar applications will increase and that specifications for auxiliary methods will be established.

Table 4. Modifications to specifications and tunnel sections.

Tunnel sector distance(m)		137 k466 m–137 k511 m 45	137 k511 m–137 k520 m 9	137 k520 m–137 k556 m 36	137 k556 m–137 k562 m 6	137 k562 m–137 k568 m 6	137 k568 m–137 k592 m 24	137 k592 m. 24
Geology		Alternate layers of sand and gravel, sandy silt and sand	Sandy soil mixed with gravel and coarse sand in a complicated manner	Mainly composed of sand, and congested with sand and gravel, and silt	Same as stated to the left	Composed predominantly of sand and gravel with seepage	Same as stated to the left	Sandy layer mixed with gravel
Modifications to specifications for auxiliary method	Tunnel crown	Basic specifications – Length of drilling a steel pipe per shift: 9 m – Pitch of steel pipes drilled: 60 m – Depth of grout injection: 10 m – Grout for primary injection: Denka S Pack – Grout for secondary injection: Silicarizer – Controlling the volume of grout – Required thickness of soil-grout columns: 1.5 m(with seepage) or 1.0 m (without seepage) – No secondary injection overlapped the silt	– Pitch of steel pipes drilled: 45 cm – Depth of grout injection:11 m – Change of grout in primary injection (to cement bentonite) – Secondary injection overlapped the silt layer 2 m from the layer boundary. – Grout pressure (during supplementary injection) is also controlled.	Soil stabilization according to the soil type – Sand and gravel area: Addition of 2 m-long friction bolts with silica resin injection – Silt area: Only silica resin injection was adopted but secondary injection overlapped the silt area over a length of 2 m.	– Length of drilling a steel pipe per shift changed to 6 m (Steel pipe length changed from 12.5 m to 9.5 m)	– Increase of injection rate in primary injection from 5% to 10% – Increase of injection pressure	– Reduction of injection pressure and reduction of volume of supplementary grout (50%)	– Reduction of injection rate in primary injection from 10% to 5% – Reduction of injection pressure
	Tunnel face	Basic specifications – Length of drilling a steel pipe per shift: 9 m – Pitch of steel pipes drilled:1.5 m – Grout for primary injection: Denka S Pack – Grout for secondary injection: silicarizer – Controlling the volume of grout – Required diameter of soil-grout column: 1.5 m(with seepage) or 1.0 m (without seepage) – No secondary injection overlapped the silt.	– Change of grout in primary injection (to cement bentonite) – Secondary injection overlapped the silt layer 2 m from the layer boundary. – Injection pressure (during supplementary injection) is also controlled.	No modifications.	– Length of drilling a steel pipe per shift changed to 6 m (Steel pipe length changed from 12.5 m to 9.5 m)	– Soil improvement throughout the working face – Injection using manchette tubes at the bottom of the top heading – Increase of injection rate in primary injection from 5% to 10% – Increase of injection pressure	– Reduction of injection pressure and reduction of volume of supplementary grout (50%) – To resist injection pressure, ordinary shotcrete was changed to steel fiber reinforced concrete.	– Reduction of injection rate in primary injection from 10% to 5% – Reduction of injection pressure
Reason for modification		– Tunnel crown collapsed at 137.510 km. – No chemicals found in the soil mass that collapsed – Chemicals ran out due to drastic changes of soil conditions.	– Spalling of the soil-grout column at the bottom end of an AGF-R steel pipe	– Frequent spalling of the soil-grout column in later stages in a shift of drilling a steel pipe – The length of drilling a steel pipe per shift was long, and soil-grout columns were broken due to the displacement at the end of the steel pipe	– Quicksand occurred at lower part of face at 137.559 km. – An unconsolidated sandy layer with seepage was expected to appear at the working face.	– Tunnel deformation during injection – High injection pressure in secondary injection led to excessive injection	– Soil was stabilized by improvement throughout the section. – For higher cost performance

Use of risk management plan for urban mechanized tunnelling projects: From the establishment of the method to the successful practice

P. Grasso, E. Chiriotti & S. Xu
Geodata S.p.A., Turin, Italy

N. Kazilis
Geodata S.p.A., Thessalonica, Greece

ABSTRACT: Tunnelling in urban environment demands for particular methods and flexibility to guarantee minimum impact on whatever already existing above the tunnel, on the daily activities of the city, as well as on the routine life of its inhabitants. The method of mechanized tunnelling can permit to realize the work and minimize at the same time the undesirable interferences. However, mechanized tunnelling is not a risk-free technology. Encountering geological conditions different from those foreseen, or a non ideal performance of the shield machine itself will all open the way to a series of risks, which are often disastrous to the project if not properly managed. Most risks can be effectively managed through the use of a Risk Management Plan (RMP). The RMP was integrated and successfully applied in recent years to a series of important urban transformation projects like the Turin Metro (Italy), Porto Metro (Portugal) and the Bologna Railway Link (Italy).

1 INTRODUCTION

The design and construction of tunnels in urban areas are often associated with risks that can arise from different factors such as: inadequacy of the geotechnical information; geological and hydrogeological conditions locally different from those foreseen for the design; inappropriate choice of the construction method; in case of mechanized tunnelling, non ideal performance or behaviour of the shield machine itself or deviation of the actual ground-machine system behaviour from the theoretical one; etc. The various potentially critical scenarios will all open the way to a series of problems and risks, which are often disastrous to the project if not properly managed.

We strongly believe that the first response to risk is the selection of the appropriate construction method. Considering the huge technological improvements achieved in the last decades, the method of mechanized shield tunnelling can permit to realize the work and minimize at the same time the undesirable interferences. However, mechanized shield tunnelling is not a risk-free technology, even though it is a modern and advanced technique.

Risks cannot be ignored, they have to be managed, reduced, shared, transferred, or simply accepted once they are known. Nowadays within the international tunnelling community (ITA) there is an agreement that Risk Management is the key of success for all kind of tunnelling works, including urban mechanized tunnelling.

In the last decade we developed and applied in various urban mechanized tunnelling projects (Turin Metro Line 1, Italy; Porto Metro, Portugal; Bologna High Speed Railway Junction, Italy; reconstruction of the Lesnaya-Muzhestva section of the St. Petersburg Metro, Russia; Santiago Metro Line 4, Chile; SMART Project, Malaysia) the concept of RMP - Risk Management Plan, a robust and transparent risk management methodology made of clearly identified steps that aims not only to manage risks but also guaranteeing safety, quality, cost and duration limits by:

- systematically quantifying residual risks which has to be known, communicated and further reduced or controlled;
- extending the concept of risk management from the design to the construction phase;
- offering specific tools for facilitating the decision-making process in the management of both initial and residual risks during design and construction.

The following sections are devoted to specifically address the concept of RMP for urban mechanized tunnelling, giving the background of the suggested methodology and practical examples from the Designer perspective.

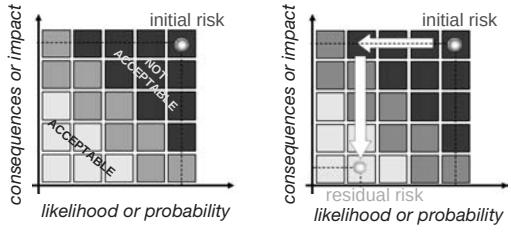

Figure 1. Risk as a combination of probability and impact: from initial risk to residual risk through mitigation.

2 APPROACH FOR RISK MANAGEMENT

2.1 *Definitions*

'Hazard' is an event which may give rise to elements of uncertainty or the property of a situation that has a potential to cause damage. Each hazard is associated to a probability of occurrence, P, and an impact (consequences), I, in terms of safety, time, and cost. The risk, R, associated to an identified hazard is defined as the product R = PxI, and is called 'initial risk' (figure 1).

Hazards are something we can do little about except identifying them. The risks they pose can be (and should be!) reduced. A project-based 'acceptability criterion' has then to be set, allowing to define if a certain initial risk in a certain context can be assumed or has to be reduced through specific mitigation measures at the design and/or construction phase. The 'mitigation measures' usually consist of a set of predefined measures to be systematically implemented at the various stages of a project in order to reduce each single, unacceptable initial risk within the acceptability criteria by acting on its probability and/or its impact.

Risk remaining after the implementation of the mitigation measures is called 'residual risk' (figure 1). It consists of the acceptable risk and the risks that have not been properly assessed or the risks that have not been identified. Initial risks have to be constantly updated during the project life, while residual risks have to be constantly controlled through key-parameters and re-assessed.

2.2 *Sources of risk in urban mechanised tunnelling*

The main sources of risk in a urban mechanized tunnelling project are related to geology and hydrogeology, design, construction (finance and exploitation risks are not specifically addressed in this paper).

– Geology and hydrogeology related risks can include, *inter alia*: limited investigations at design and/or construction phase; inappropriate on site and/or lab tests; insufficient understanding of the peculiar mechanisms of failure and of rock mass/soil behaviour; availability of resources and equipments; lack of site accessibility; lack of systematic face mapping during construction; lack of validation/update of the geological and hydrogeological model during construction; etc.
– Design related risks can include, *inter alia*: insufficient experience of the Designer; uncompleted analysis of the potential risk scenarios; evaluation of loading conditions acting on the lining is not complete; low or difficult constructability of proposed solutions; lack of design flexibility vs. actual ground conditions; inadequate method for predicting settlements and assessing potential damages on existing buildings/utilities; inadequate monitoring system and/or readings; no threshold limits or operational ranges for the monitored parameters or TBM key-parameters, respectively; poor or missing definition of countermeasures and related triggering criteria; etc.
– Construction related risks can include, *inter alias*: poor management of the 'learning curve' period; lack of Contractor experience; lack of personnel training; inadequate procedures; incompatibility of the machine with the ground; major mechanical failures; inadequate logistics; inadequate face pressure; inadequate injection of the tail void; lack of TBM's parameter controls and/or review and interpretation; insufficient probing ahead; etc.

2.3 *The first step of a Risk Management Plan: the Risk Register*

The objective of a RMP is to reduce as low as reasonably possible all the risks identified in each phase of the Project life. The activation of the RMP assures the timely identification of the potential problems and initial risks, the implementation of the appropriate measures for risk mitigation, and the control of the residual risk. Hence, the RMP should be implemented as soon as possible and integrated in all phases of the project from conceptual design to exploitation.

The main principle of a RMP (Grasso et al., 2002) is that risks have to be identified, quantified and reduced for every single investigation, design and construction discipline involved in the project. Once the Designer has identified the basic requirement of the Owner and his tolerance to the risk, the process of risk identification should go through the following: (a) formation of a group of specialists according to the size and complexity of the project; (b) collection of published data on the regional and local geological conditions, to be complemented later on by adequate investigation; (c) production of a geological model and estimate of the likely ground conditions and their variability; (d) identification of the possible construction techniques; (e) use of workshops and engineering judgment based on previous experience for identifying the risks, using 'checklist'; (f) preparation of a formal Risk Register which should be used as a base for selecting the optimum project alternative.

The Risk Register should be structured to include: the families of hazards and, within each family, the list of hazards and their causes; the quantification of their likelihood and impact and hence of risks; the indication of unacceptable initial risks; the identification of a specific strategy to reduce each initial risk (mitigation measures); the quantification of residual risks through a re-assessment assuming that mitigation measures have been implemented. The Risk Register has to be updated constantly during the project life and used to communicate and share risk policy and residual risk acceptance.

2.4 *Use of the Risk Register and further steps in the RMP*

If properly used, the Risk Register becomes the real guideline for the development of the project, since it allows to track in a 'tabloid' the proposed action plan in terms of organisation, investigations, design and/or construction needs to reduce the identified risks. If seen from the Designer perspective, the Risk Register highlights various requirements not only related to the level of detail of the design or to the correctness and state-of-the-art implementation of the construction procedures, but also to the effective management of the interface issues among the involved disciplines. As a matter of facts, urban mechanized tunnelling is generally related to huge infrastructure projects such as metros, urban railways, storm-water conveyance tunnels, service tunnels for utilities, sewerage or roads. Consequently, urban mechanized tunnelling is part of a complex process where different disciplines have to converge to deliver the final result in time and within budget. The method for successfully ensuring this convergence is explained in the next section.

2.4.1 *Management of interfaces*

According to our experience, being aware of the importance of managing interfaces is a real added value that the Consultants can bring to a project, either acting as Designers or as Supervisors, provided that the Consultant can suggest effective solutions to problems before they rise thus preventing blockages of works.

We suggest the use of a 'Centralised Design Management' involving all project disciplines (geology, geotechnics, structures, monitoring, construction techniques, as well as architecture, electrical and mechanical, etc.) to ensure that design fulfils primary objectives of completeness, availability, compatibility, buildability and maintenance, additional to the 'basic internal correctness' of each design element. The check of the 'basic internal correctness' (consistency with Technical Design Specifications and to local and international norms and codes of practice, correctness of assumptions and calculations, completeness of drawings, etc.) is the easiest part to deal with, since it is based on a sort of routine checks. Setting a strategy to ensure the achievement of the primary objectives in a complex project is the real challenge.

Since 1998, when the idea of the Turin Automatic Metro Line 1 (9.6 km of double-track, single-tube mechanised tunnel) started to become reality, we experimented with success a way to make the Centralised Design Management happen; the establishment of an 'Exchange Table' (ET) within a 'Group of Permanent Coordination' (GPC). The GPC is set by the Owner, through his Consultants and Supervisors or can be promoted by the Designers. The group is in charge of guaranteeing the coherent and integrated development of the project, of leading the onset of the interfaces among the disciplines and of organizing and running a common system for sharing documents and information. This involves the specialists of tunnelling (geologists and engineers), architects, urban planners, system engineers, etc., according to the type of infrastructure being developed. The group acts through the overall implementation period of the Project in a continuous effort of mediating among the various needs, that could be in conflict. The ET is not only a physical place of interface coordination, but also the expression of a shared working methodology that permeate all the Actors, no matter of their level of involvement and responsibility in the Project.

2.4.2 *Management of tunnel design risks*

The Designer of the underground works should be able of managing all kind of design risks related to geology, hydrogeology, load conditions and impact at the surface from the conceptual design to the follow-up of the construction. Risks related to tunnel design that are identified at the Risk Register stage generally emphasize the need for the following RMP components:

- Planning investigations that are adequate for the level of geotechnical risks of the project.
- Recognizing that the deterministic approach may be less accurate and give preference to sensitivity and risk scenarios analysis and to probabilistic approaches;
- Design through risk scenarios: for example, not only the most likely load condition or the average geotechnical parameters should be considered. Especially in a urban area the consequence of encountering even locally the most unfavourable situation must be analysed and designed for.
- Adopting a flexible design for taking into account unfavourable situations. It entails, for each critical key mechanism: defining countermeasures to manage adverse trends during construction; identifying parameters and key events to be controlled and monitored during construction; defining the relevant operational ranges or threshold limits;

predefining triggering criteria for activating countermeasures, if ranges/limits are exceeded.
- Adopting a transparent risk mitigation policy through the design process: from the design of segmental lining to the design of the consolidation works to avoid damages due to tunnelling-induced settlements, each identified initial risk has to be dealt with through adequate design choices (tracked in a transparent way!).
- Quantifying and communicating any residual risk affecting the design choices, e.g., using the probabilistic methods to assess the design reliability: average factors of safety (of the support, prescribed face pressure to be applied by the TBM, etc.) are replaced by the probability of a negative event (e.g., face instability) to occur, and the probability has to be reasonably low.

When tunnelling in urban areas, special care has to be used for establishing a Building Protection Strategy. This is based on: survey all identified buildings in the construction-influence zone before construction starts (BCS – Building Condition Survey); use the BCS results for assessing the vulnerability of buildings to damage; establish a specific damage classification system for the project; perform settlement-sensitivity analysis for each identified building and define its tolerance to tunnelling-induced movements; classify all identified buildings into different risk categories; single out those buildings at risk and requiring protection; identify those buildings requiring survey and special monitoring during construction; perform BCS post-construction, independent of whether damage occurred or not; archive and maintain all relevant data in a dynamic and relational database for use by all Actors.

2.4.3 *Management of tunnel construction risks*

We already addressed the role of the right choice of the excavation method as the primary response to risk. However, the complete effectiveness of the RMP is achieved if the appropriate excavation method is accompanied by culture and training of personnel and by the establishment and implementation of procedures to guide all the relevant construction processes, to govern the key events and to address all the potential anomalies with a proper and predefined action plan. Within the RMP framework the Designer plays two important roles during the construction phase:

- The Designer must have the capacity to interact with the TBM manufacturers in order to contribute in suggesting new ideas for technological innovations, with the aim to assure safety and improve the production in terms of advancement in all kind of geological context.
- The Designer must validate the design hypothesis during construction and make use of the construction feedback to match the design prescriptions to the real encountered conditions and to optimise the design, also in terms of costs. We were the first to introduce in 2000 for the Porto Metro, Portugal, the concept of the iterative design through the use of a TAP – Tunnel Advancement Protocol (or PAT, in Portuguese). The TAP is a low-cost, easy-to-implement practical procedure for the designer-contractor-engineer team to continuously update the risk scenarios and the corresponding mitigation plans as construction proceeds. TAP facilitates the management of residual risks. It is a detailed and dynamic design document produced for each 200 to 500 m of the tunnel to be excavated, prepared prior to the actual excavation of that section and based on the construction feedback from the previous section(s).

In addition, all the Actors of the Project have to be conscious of the importance of using the 'learning curve' section (e.g., first 300–500 m of TBM excavation) to validate the TBM procedures and to collect all the monitoring data to start validating the majority of the design assumptions (a special monitoring section has to be designed and implemented and a strict follow-up made).

2.5 *Tools to support the RMP*

Properly managing risks in urban tunnelling projects demands for special thinking, particular approaches and innovative tools. We mentioned the probabilistic design approach and the TAP as being the answer to quantification and follow-up of residual risks (mainly related to geology, design and construction). However, additional risks are related to the likelihood of exceeding scheduled planning and budget and to the availability and integrity of information in real time. This is why we commonly and systematically use, within the RMP, two additional tools:

- DAT (Decision Aids for Tunnelling), and
- GDMS (Geodata Master System) used for managing information in real time via web.

DAT is used to simulate the process of underground construction in a probabilistic manner and was developed by the MIT (Massachusetts Institute of Technology, USA) and the EPFL (Ecole Polytechnique Fédérale de Lausanne, Switzerland) and was used by Geodata on various tunnelling projects around the world resulting in further development of the software (Einstein et al., 1998). DAT simulates the construction cycles of a linear infrastructure by following a predefined construction sequence along a probabilistic geological model that stochastically changes for each complete simulation process, for a probabilistically relevant number of times. The output of DAT is a probabilistic cost and time distribution. DAT allows

Table 1. Recent examples of successful application of the RMP in urban mechanized tunnelling projects.

Project description	RMP elements used in the project	Benefits to the project
PORTO METRO, Portugal  Double-track, single-tube tunnel (L = 7.0 km; D = 8.7–8.9 m), 3 access ramps, 2 EPB-TMBs. Excavation end: 2003. Geodata role *: FD, CD, CS	– Identified Risks: heterogeneous rock mass; residual soil with local metastable structures sensitive to hydraulic gradient; brittle rock mass behaviour; – Organisation: Designer on site, Resident Engineer and Follow-up Team after severe problems occurred during the TBM 'learning curve'. – Design: Risk Register; risk-scenarios-driven design; statistical geotechnical characterisation; BCS and BRA; provision of a procedure to calculate required face pressure and operational ranges of TBM key-parameters; activation of TAP. – Construction: adoption of TAP; development of GDMS for managing monitoring and TBM data; new TBM procedures; new TBM devices ('secondary face support system'; alarm system in the TBM-driver cabin); systematic interpretation of TBM data (Gaj et al., 2003: Chiriotti et al., 2003).	No accidents; average settlements of 5 mm even in low cover areas (3–4 m); production: 40–50 m/ week; reduction of foreseen consolidation works; optimisation of monitoring instruments (numbers and readings). BCS/BRA method adopted as standard by station designers, by LNEC, used for technical specs of Athens Metro extensions and now in use by the Tel Aviv Metro Owner.
TURIN METRO Line 1, Italy.  Double-track, single-tube tunnel (L = 9.5 km; D = 6.8 m), 15 stations, 15 ventilation shafts, 3 EPB-TBMs. Excavation end: 2005. Geodata role *: PD, FD, CS	– Identified Risks: Politically sensitive project (risk of not meeting 2006 Winter Olympics deadline in presence of damages and adverse public opinion); difficult ground (abrasive rock, blocks up to 1 m3, high permeability, locally less than 5% of fines). – Organisation: Activation of PCG and ET. – Design: Risk-scenarios-driven design; standardisation of stations to smooth cw/e&m interface issues and improve industrialisation; BCS; BRA; GDMS for sharing data/documents; – Construction: TBM procedures (Porto); use of GDMS for real time management of monitoring and TBM data; systematic interpretation of TBM data; special consolidation works ('Cittadella' historic tunnels); additives in the TBM chamber to correct natural soil grain size (Grasso et al., 2006).	Impressive result of conceiving, design, tender, built and operate a completely new metro line in less then 6 years, thanks to a huge coordination effort, a special attention to risk management. Construction value of the tunnels – 15% than design budget. Construction value of the tunnels plus stations, finishes and e&m works exceeding only 4% the available budge, equal to 50% of the total.
BOLOGNA RAIL LINK, Italy.  Twin-bore, single-track tunnels (L = 6.1 km; D = 8.3 m), 2 EPB-TBMs. Excavation end: 2006. Geodata role *: CD, TC on TBMs restart after stoppage.	– Identified Risks: alignment right beneath existing surface railway (strict limitations on settlements); soft marine sands and clays to be excavated also under water table; close proximity of the 2 tunnels (TBM2 runs through disturbed soil). – Organisation: consultant responsible for TBM added to allow restarting the TBMs excavation. – Design: preparation of TAP as in Porto Metro. – Construction: adoption of TAP; new TBM procedures and controls; new TBM devices ('secondary face support system'; two balances and a volumetric scanner to control the extracted muck weight; systematic interpretation of TBM data (Minguez et al., 2005).	Since the excavation restart dramatic reduction of settlements (from 10–45 mm before stoppage to 1–5 mm up to the end of tunnel excavation). Best daily performance for both TBMs: 25 rings (37.5 m). Best monthly performance: 612 m in March 2006 for TBM1 and 635 m in April 2006 for TBM2.

*PD – Preliminary Design; FD – Final Design; CD – Construction Design; TD Tender Docs preparation; CS – Construction Supervision (the Engineer); TC TBM Consultant for technical assistance during construction.

comparing the effectiveness of different risk mitigation strategies or plans, and identifying the optimum solution with minimal residual risks in terms of time and cost.

According to the authors' experience, a typical RMP for a urban tunnelling project should also include a real-time data-sharing and management system accessible to all parties involved (Owner, Contractor, Designer, Engineer, Consultants, etc.) to facilitate the communication and support the decision-making process. GDMS is based on the modern GIS (Geographical Information System) and web technologies (accessible via Internet) to give an answer to the need of real-time management of design documentation, construction records, monitoring data, TBM parameters and back-analysis.

GDMS started to be developed in 1999, to be used in parallel in Porto and Turin Metros. Then it underwent continuous software improvements and was supplied in various urban projects such as the Santiago Metro (Chile) and the SMART Project (KL, Malaysia). The aim of GDMS include: (a) to collect in a database and geo-referring all the *ante operam* information and to the design data (e.g., geology, alignment, etc.), including additional investigations during construction, within a unique reference system; (b) to collect and geo-referring all the information related to BCS and BRA; (c) to manage the manual and/or real-time acquisition of the geotechnical and structural monitoring data, doing standard graphical representation, comparing readings with thresholds, identifying adverse trends and automatically sending warning messages to pre-selected responsible people in the organisation by SMS, e-mail, etc.; (d) to make the TBM parameters available by direct connection with the TBM acquisition system; (e) to guarantee data integrity; (f) to permit extractions and analyses of data to allow correlations and cross-checks (e.g., TBM parameters vs. geology; building monitoring vs. TBM parameters; etc.); (g) to produce factual data reporting.

3 FROM THE ESTABLISHMENT OF THE METHOD TO THE SUCCESSFUL PRACTICE

In Table 1 examples of successful RMP application in urban mechanized tunnelling are given. Details can be found in the reference documents.

4 CONCLUSIONS

The geotechnical risk, in the form of unforeseen or unforeseeable geologic conditions, together with design and construction risks are a decisive factor in controlling the time, cost, and safety of all major civil engineering projects, especially in urban areas. Experience have shown that even with mechanized tunnelling such risks cannot be avoided. Hence, all phases of the Project need to be developed with due attention to the sources of risk and their identification, quantification, and reduction. This requires a risk management culture from all the Actors in all phases of the Project. The enforcement of this culture could be greatly facilitated by adopting a RMP. The implementation of RMP needs operative tools, and probabilistic design, DAT (Decision Aids for Tunnelling), TAP (Plan for Advancing the TBM) and GDMS (GIS-based system for the management of monitoring and TBM parameters) are just some example tools developed by Geodata in recent years. The recent case histories of RMP application in urban mechanised tunnelling show how management of risk can only provide benefit to the overall community.

Texas A&M University, Texas, USA

ABSTRACT: The risk analysis of geotechnical stability factors were performed by classifying the factor of safety calculated SSR method, the damage of neighboring structure due to settlement, the groundwater inflow rate into the tunnel and the potential damage by the certain earthquake. Also, the social environmental factors can be grouped into two aspects such as the construction stage and the operation stage; vibration, noise and the drawdown of the groundwater level caused by tunnel construction. Each risk factor was evaluated as a classified term to be the fixed quantity based on various probabilistic and statistic technique, then it was analyzed the distribution characteristic of risk along tunnel line. Finally, the impact was evaluated that how much each risk factor influences on the construction cost with a tunnel construction period by analyzing social charge, so it is possible to perform reasonable tunnel design which was capable of minimizing the risk in the construction stage as well as the design stage.

1 INTRODUCTION

The concept of safety factor was used mainly in the design of underground structure. Such safety factor could be expressed with the ratio of the resistance and the load. It is the most important disadvantage that the conventional design must assign the representative value about the design parameters although the ground itself has the variation and the uncertainty. Therefore, in the conventional design method, estimating the relative reliability of the underground structure is unreasonable. The risk analysis which is referring in this research is the method to use the various probabilistic technique and statistical data.

To complement the traditional design performed by the analysis of the mean ground behavior, the risk analysis considers the uncertainty of ground investigation result and environment element of circumference rationally. Risk factors, which will be able to occur in the design and construction stage of the underground structure must be selected, and quantitative analysis about the risk factors must be performed. The risk about each risk factor can be represented as follows:

$$RISK = \Sigma P_f \times C_f \quad (1)$$

where P_f = the probability of failure; C_f = the cost of failure.

In risk analysis, the assessment about the probability of failure which has the reliability is most important. We estimated the uncertainty of soil parameter and failure model using probabilistic techniques. But, risk factors such as environmental problems are very difficult to be evaluated by probabilistic techniques, so we evaluated the environmental risk using verified statistical data within the related laws and ordinances.

2 SELECTION OF RISK FACTORS IN TUNNEL DESIGN

With a case of the railroad tunnel design in the urban area, we try to explain the method for the analysis and assessment of risk factor in tunnel. As shown in figure 1, the railroad tunnel is comprised of a 3,516 m long main tunnel with two inclined shaft. The residence areas of large scale are located at the tunnel portals and the vicinity of tunnel section with shallow soil-depth. And, the road tunnel intersects at the middle part of tunnel. Risk factors in that tunnel can be categorized by

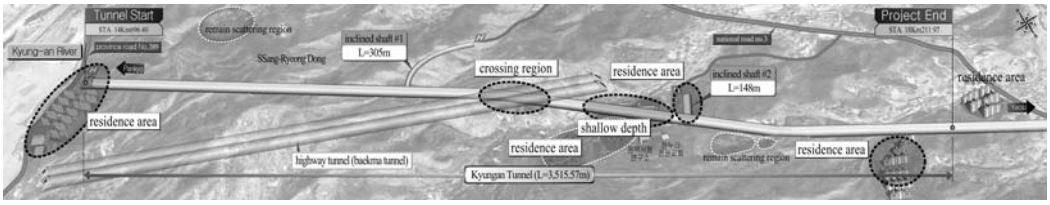

Figure 1. The overview of tunnel region.

geotechnical stability factors and social environmental factors.

2.1 *Risk factors for geotechnical stability*

(1) Support capacity of ground: Tunnel stability is analyzed by using shear strength reduction method (SSR), which is repeatedly calculated the safety factor of tunnel for quantitative evaluation in according to reduction of shear strength (c, ø) of soil and rock.
(2) Ground settlement: Influence on adjacent buildings in tunnel excavation is evaluated by numerical analysis. In this study, maximum strain and settlement of buildings are analyzed for the stability of adjacent buildings.
(3) Inflow of groundwater: Ground water flows into tunnel due to ground excavation and affected the stability of tunnel. In this study, seepage and flow analysis are conducted for the evaluation of groundwater inflow into tunnel.
(4) Earthquake: It is important of influence of earthquake in urban subway. Thus, tunnel stability for earthquake is evaluated by dynamic analysis using amplification of earthquake vibration.

2.2 *Risk factors for social environment*

(1) Vibration and noise by blasting under tunnel construction: Estimation the compensation amount for mental and property damage by tunnel blasting and noise
(2) Vibration and noise by operating train: Estimation the compensation amount for mental damage and property damage by train operation
(3) Drawdown of groundwater: Estimation the compensation amount for damaged wells by tunnel excavation

3 RISK ANALYSIS FOR GEOTECHNICAL STABILITY

3.1 *Support capacity of ground*

The risk for support capacity is analyzed by evaluating the probability of failure due to uncertainty of

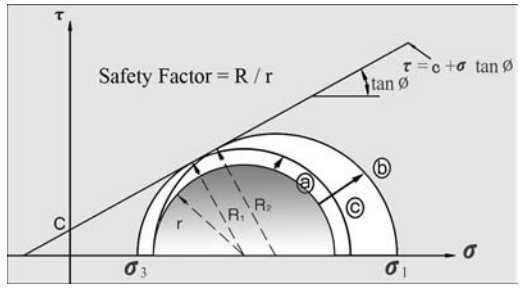

Figure 2. Evaluation safety factor by SSR method.

ground characteristics. Although the sufficient site investigation was performed, the characteristics of the ground behavior couldn't be grasped perfectly. Therefore, strength parameters of the ground include certain level of uncertainty.

The coefficient of variation is the quotient of the empirical standard deviation and the expected value:

$$C_v = \sigma / m \tag{2}$$

The safety represent support capacity of ground itself is evaluated by using shear strength reduction method. Figure 2 shows the concept for evaluation safety factor by SSR method.

The probability of the failure may be expressed by the central safety factor v_c. In the case of normal distribution

$$P_f = 1 - \Phi[(v_c - 1)/\sqrt{v_c^2 C_{vR}^2 + C_{vQ}^2}] \tag{3}$$

where C_{vR} and C_{vQ} are the coefficient of variation of the resistance and the load respectively.

The corresponding relationship for the lognormal distribution is as follows:

$$P_f = 1 - \Phi\left[\frac{\ln v_c \sqrt{(1+C_{vR}^2)/(1+C_{vQ}^2)}}{\sqrt{\ln(1+C_{vR}^2)(1+C_{vQ}^2)}}\right] \tag{4}$$

The risk is evaluated by multiplying the unit cost of tunnel construction with the probability of failure obtained by equation (4).

Table 1. Assessment criteria for the inclination and settlement.

Grade	Management	Inclination	Deg. of damage
A	Normal maintenance	<1/750	0%
B	When the continuous careful observation is needed, normal maintenance after simple repairing.	>1/750 <1/500	5∼10%
C	Partial repairing, reinforcement; the continuous observation	>1/500 <1/300	20∼40%
D	Judgement of the utility limit; overall large scale reinforcement	>1/300 <1/200	40∼60%
E	The utility prohibition, emergency reinforcement; the dismantle and reconstruction	>1/200	60∼100%

Table 2. Groundwater parameter in RMR rock classification criteria.

Parameter		Range of values				
Inflow per 10 m tunnel length (ℓ/min)		0	<10	10∼ 25	25∼ 125	>125
Ratio	Joint water pressure	0	<0.1	0.1∼ 0.2	0.2∼ 0.5	>0.5
	Major principal stress					
Rating		15	10	7	4	0

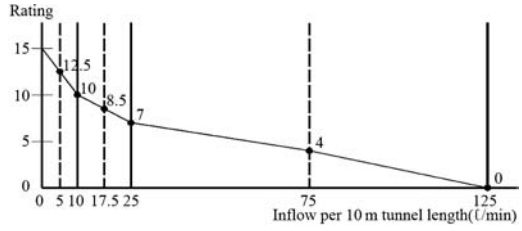

Figure 3. The Continuous graph of RMR rating.

3.2 *Settlement of ground*

The damage of the structure in proximity, which is happens to the ground settlement due to tunnel excavation is important factor in risk analysis. The equal settlement and the inclination of the structure are computed by the numerical analysis and empirical equation, and the damage degree of each structure is estimated. The risk of ground settlement can be evaluated from the damage degree and the unit cost of construction.

3.3 *Inflow of groundwater*

As the failure probability according to the reduction rating from a groundwater inflow at the tunnel face is computed, uncertainty of rock classification is considered in risk analysis. RMR rock classification is computed to the sum total of the assignment rating to be composed of five parameters. Because the rating to be assigned is represented by an unity rating about the case of the schedule range of the parameter, the assignment of continuous rating is impossible and the assessment rating is overestimated or underestimated about a specific parameter.

Charging the rating against the center-value vicinity for the groundwater parameter is performed using interpolation method in consideration of the corresponding RMR value of the phase which is good. As the rating is continuously charged by the stage, the continuous RMR value against the parameter value is expressed as shown figure 3.

The continuous RMR graph of groundwater parameter represent the rating to zero, but in the case which the inflow quantity is large, the rating has a negative value. The continuous RMR rating for tunnel inflow can be expressed by numerical equation as like equation (5).

$$\text{Reduction rating} = -8 \times (\text{inflow quantity} - 0.125) \quad (5)$$

The probability density of an each interval in figure 2 can be evaluated as shown table 3 and the probability density of RMR reduction rating can be expressed in normal distribution as shown figure 4.

The probability of failure for each RMR reduction rating is represented in table 4. The risk for groundwater is evaluated by multiplying the unit cost of tunnel construction with the probability of failure obtained.

3.4 *Earthquake*

At the sections where the computed earthquake acceleration exceed the acceleration criteria based on the coefficient of the earthquake area, it is assumed structures in that dangerous area are collapsed when the earthquake occurs. There, the risk for earthquake is evaluated by considering the damage repair cost for the structure which the collapse is predicted.

4 RISK ANALYSIS FOR SOCIAL ENVIRONMENT

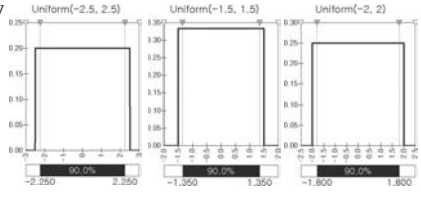
4.1 *Vibration by tunnel blasting*

The estimation criteria of compensation follow the related laws and ordinances and the risk (social cost) by the vibration is divided by mental and property damage. The compensation amount for mental damage can be represented as follows:

$$D = E_{vt} \times P \tag{6}$$

$$E_{vt} = \Sigma(V_e - V_t) \times T \tag{7}$$

where $D =$ damage, \$; $P =$ unit compensation cost, \$/dB·day; $E_{vt} =$ total over exposure of vibration, dB·day; $V_e =$ evaluated vibration level, dB(V); $V_t =$ threshold vibration level, dB(V); $T =$ exposure time, day.



The compensation amount for damage of property can be represented as follows:

$$D = C_{st} \times V_c \tag{8}$$

$$V_c = \frac{V_o}{(15 - S_{st}) + V_o}, \qquad C_v = \frac{V_{pr}}{V_{cr}}^{1.5} \times 4 \tag{9}$$

where D = damage, \$; $C_{st} =$ estimated cost of structure, \$; $V_c =$ vibration contribution; $V_o =$ operation vibration level; $S_{st} =$ status estimation of structure; $V_{pr} =$ presumption value of vibration; $V_{cr} =$ vibration velocity criterion.

Table 3. The probability density of RMR rating.

Inflow	0 ~ 10	10 ~ 25	25 ~ 125
Rating	10 ~ 15	7 ~ 10	0 ~ 4
Probability density graph			

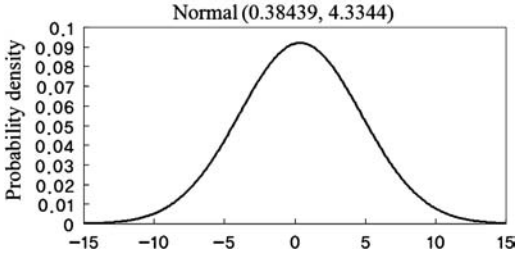


Figure 4. Probability density graph of RMR reduction rating.

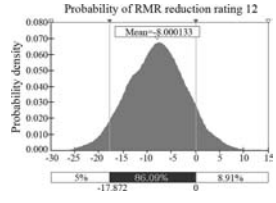
4.2 *Noise by tunnel blasting*

The risk of mental damage by blasting noise is evaluated with deductive equation (eq.10) through regression analysis based on the cases of actual damage compensation.

$$M = 12.5D - 102.5 \tag{10}$$

where $M =$ damage amount per a person, \$; $D =$ value in damage conversion table.



The noise by excavation blasting can be estimated as follows:

$$dB\,(A) = -16.02 \log\,(d/W^{1/3}) + 95.195 \tag{11}$$

where $d =$ distance of the object point, m; $W =$ charging amount of the explosive, kg/delay.

Table 4. The probability of failure for RMR reduction rating.

Rating	Probability of failure	Rating	Probability of failure (%)
12	8.91%	6	0.93
11	7.04%	5	0.65
10	5.12%	4	0.42
9	3.47%	3	0.22
8	2.62%	2	0.22
7	1.76%	1	0.07

The noise by blasting can be predicted by equation (11) based on the charging amount of general blasting in tunnel. And, the compensation amount by general blasting method can be estimated by multiplying the unit compensation cost from equation (10) with the number of residents.

4.3 *Vibration and noise by operating train*

The noise by operating train can be calculated by Lange equation (11) assuming the design life of the tunnel in 30 years.

$$La = 59 - 20 \log d \quad [dB(A)] \tag{12}$$

where d = distance of the building in tunnel

The vibration by operating train can be calculated by Tokita equation (13) through the correction of the vibration level, the transfer characteristic of the vibration wave and the correction about the interaction with structures, etc.

$$L_v = L_o - [A_1 \log (r / r_o) + A_2 r] \tag{13}$$

It is assumed that the noise increases as shown in equation (14) than the initial value as the period to be happened the noise increases.

$$\Delta L = 5 / \log 3 \times \log T \, [dB] \tag{14}$$

Because the damage by the operating train has many continuance periods relatively, the risk by the operating train has very big value than the risk by the blasting.

4.4 *Drawdown of groundwater*

The risk against wells of the neighborhood area which is caused by the tunnel excavation is evaluated. Groundwater levels at each bore hole are measured by groundwater flow analysis before and after the excavation, the influence range which the drawdown of the groundwater is happened is computed. And, the damage compensation cost is estimated by grasping the number of wells in the range of the damage influence.

5 RESULT FOR RISK ANALYSIS

As it is explained from the preceding paragraph, from the risk assessment for risk factors, the relative distribution of the risk in tunnel can be obtained as shown in figure 6 and figure 7. Tunnel engineers can select danger zones and consideration items in the design stage. And, the risk to be inverted to the cost of the failure or the compensation can be expressed as shown in figure 8 and figure 9. The risk amount is very high at the tunnel portals and at the vicinity of tunnel section with shallow soil-depth. Therefore, various design solutions to lower the risk amount were examined in such danger zones.

6 APPLICATION OF THE RISK ANALYSIS IN TUNNEL DESIGN

With application for the evaluation grade of 5 phases for each risk factor, the holistic design index (HDI) system based on the risk analysis is developed in tunnel design.

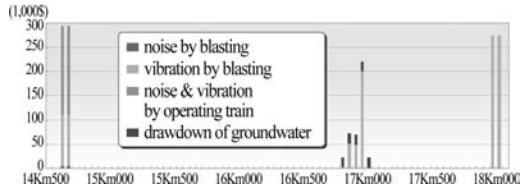

Figure 9. Result of the risk analysis for social environment.

HDI-T represents the relative risk for the geotechnical stability, and HDI-E represents the relative risk for the social environment. The holistic design index of two kinds to be obtained is expressed in figure 10 with the class of rock mass. In the selection of excavation method, the application of reinforcement method and the decision of region for water-proof grouting, the holistic design index offer rational data which can come down the judgement to tunnel engineers.

For example, from comparing the compensation cost due to general blasting method with the increment of the construction cost due to controlled-blasting or non-blasting method in the selection of excavation method, economic design having the rationality is possible.

In the event, we suggested the design method which supplement to the conventional tunnel design based on the class of rock mass through the application of the risk analysis in tunnel design.

7 CONCLUSION

As the tunnel construction increases, there have been risen many environmental issues as well as the stability of the tunnel itself caused by the tunnel excavation. Because tunneling works have many risk factors in both design and construction stage due to the uncertainty characteristics of the ground, the risk assessment and its control is very important for the tunnel construction. In this research, risk factors in tunneling distinguished into two groups such as geotechnical stability factors and the social environmental factors. Each risk factor was evaluated as a classified term to be the fixed quantity based on various probabilistic and statistic technique, then the distribution characteristic of the risk along tunnel line was analyzed. The impact was evaluated that how much each risk factor influences on the construction cost with a tunnel construction period by analyzing social charge, so it is possible to perform reasonable tunnel design which is capable of minimizing the risk in the construction stage as well as the design stage.

With applying the assessment technique for the risk to the conventional tunnel design which be dependent on the class of rock mass preponderantly, we

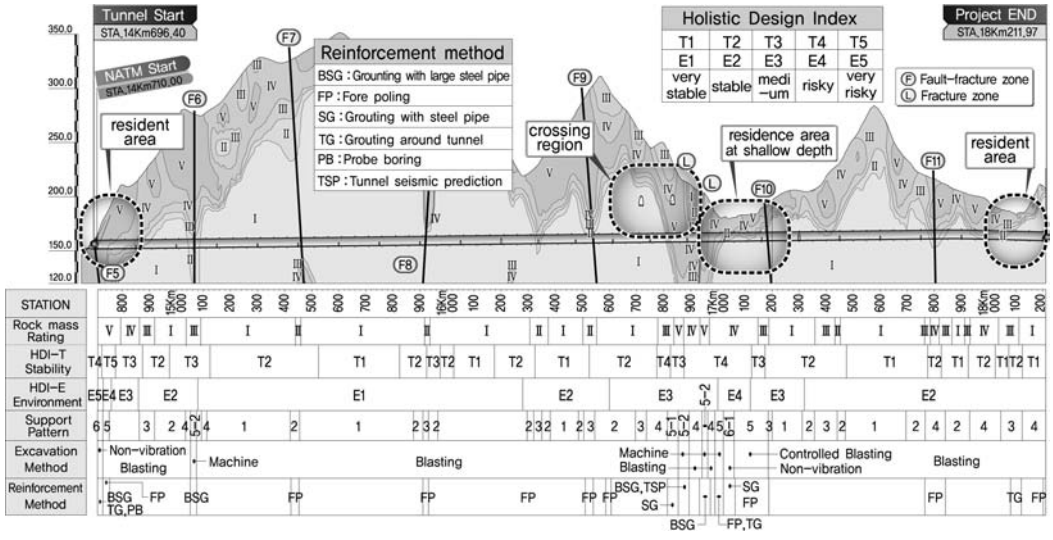

Figure 10. Application of HDI-system for tunnel design.

attempted the rational design for tunnel which considers both the geotechnical stability and the social environment.

In the future, it is needed that the supplementation between the predicted risk in design stage and the actual risk which will occur in the construction stage through the risk management in the construction stage.

Third party safety issues in international urban tunnelling

Guy Lance & John Anderson
Consultants, UK

Donald Lamont
Health and Safety Executive, UK

ABSTRACT: The worldwide expansion in the development of civil engineering infrastructure has led to a major increase in the numbers and types of tunnels constructed for road, railways and water supply/sewerage schemes. This development has seen significant innovation in design, construction and procurement methods which often involve balancing the commercial risk of new forms of construction against proven methods while maintaining effective control over workplace and third party risks. However a number of identified tunnel failures have led to incidents involving loss of life and damage to property resulting also in substantial underwriting losses. As a number of major tunnelling projects are planned for London, the UK Health and Safety Executive (HSE) commissioned a world-wide research study to obtain a better understanding of the risks posed by urban tunnelling which would also contain conclusions and recommendations.

1 INTRODUCTION

In the development of urban infrastructure over the last thirty years there has been significant innovation in the development of tunnel linings, tunnelling machines, specialist equipment, ground investigation techniques, methods of procurement and in contractual relationships between parties. The evolutionary process of developing innovative design and construction often involves balancing the commercial risk of newer forms of design and construction against proven methods while maintaining control over workplace and third party risks during construction. However a number of tunnel failures have led to ground and sub-surface impacts involving loss of life and damage to property. These events have also resulted in substantial underwriting losses. Consequently, in the UK these events have resulted in an increased awareness of societal risk issues; prosecutions for health and safety offences; and a requirement for risk-based management systems for all independently insured tunnelling projects.

The HSE therefore commissioned a study (Lance and Anderson, 2006) to research a list of the incidences of internationally occurring "emergency events" in urban soft ground tunnelling construction. The term "emergency event" included tunnel collapse, tunnel lining failure, fires, floods, excessive surface settlements (such as surface craters) and significant damage to third party surface and subsurface infrastructure. The study also drew upon the information obtained to produce findings on causes of such emergency events and sought to identify preventative measures that might be adopted.

The methodology of this study was to establish databases on the size of the world market and on numbers of emergency events that have occurred during recent world wide tunnel soft ground construction projects and to draw out conclusions from this information. Published data was collected for all soft ground tunnel types and construction methodologies, and, where sufficient information was available, the primary and underlying causes of emergency events were pinpointed. This information was then used to consider what recommendations might usefully be made to improve the delivery processes of urban soft ground tunnelling projects in order to minimise the risk to third parties arising from construction work. The report has been posted on the HSE website and readers are invited to consult the full text for a more comprehensive report of the research findings and recommendations.

2 INTERNATIONAL MARKET

There is no centralised international database on the number of tunnels that are constructed around the world each year. A few countries regularly publish data regarding their own tunnelling statistics, but these are not presented in a common format that would aid the collation of all international data. The UK, for example, does not publish data on its tunnelling output. In order to establish reliable information on the

Total	2	11	21	10	44

size and rate of growth of the world market, a number of web sites listing current and planned tunnel projects were interrogated. The accuracy and completeness of the available information cannot be fully verified and needed to be taken at face value.

From these sources a substantial data set was abstracted, which lists the lengths of tunnel projects that have been announced in each of over 100 countries for the last six years in each of these countries. The database has also been interrogated and re-classified to include the GNP (Gross National Product, per capita, using the World Bank definition) of the countries listed.

3 SOFT GROUND TUNNEL INCIDENTS

The specific focus of the research report was urban tunnelling and, given this objective, further research of the published literature was undertaken to identify and list the numbers of tunnel projects around the world that had experienced emergency events during such construction. These data sets on historic projects have been divided into two main categories, i.e. The New Austrian Tunnelling Method and other tunnelling methods (non-NATM). Both sets of data were then interrogated to identify projects where emergency events had taken place in urban areas sited in soft ground, and the results are shown in Tables 2 and 3.

It can be seen that Table 3 demonstrates a consistent rise per decade in the proportion of emergency events in soft ground urban tunnels to the number of emergency events in all types of tunnel world-wide.

Table 3. Breakdown of tunnel emergency events by ground environment.

Tunnel emergency events	1970s	1980s	1990s	2000–2005
In soft ground	22%	32%	46%	53%
Other ground types	78%	68%	54%	47%

3.1 *NATM incidents*

The HSE report on the Safety of NATM tunnels (HSE, 1996), published in 1996 following investigations after the Heathrow Express tunnel collapse, identified over 100 incidents recorded during NATM tunnelling. Table 1 of this 1996 document describes 39 significant NATM incidents and collapses throughout the world in both urban and rural environments. That information was obtained from an extensive literature search and was supplemented by other sources including private correspondence. Table 2 of this document classified the primary cause of each identified collapse. It was emphasised that, for a range of reasons, most incidents that occur are not reported in any 'official' way and therefore the data must be considered as incomplete. In addition to these listed incidents, the HSE report (see Para. 48 page 16) also identified that 71 incidents had been reported in 65 tunnels constructed in Japan between 1978 and 1991 at unspecified locations. These ground collapses ranged from the 'quite small' through volumes of between 50–500 m^3 of ground (15 Incidents.) to volumes of over 1000 m^3 of ground (3 Incidents.). Additional research undertaken by the authors since 1996, and for the 2006 study, has extended the HSE 1996 list of NATM incidents from 39 to 66 including two incidents that occurred in early 2005.

A feature of the data obtained for the 66 NATM tunnel incidents was the high number of "*failures that were recorded in the area between the tunnel face and the first completed ring of the sprayed concrete lining*". These types of failure were classified as Type A in the 1996 HSE Report. Of the total number of 66 incidents, 44 have a reported failure type, and from those 44, 39 are of the Type A. Of the total number of 25 incidents in soft ground urban tunnelling, 22 have a reported cause of which 20 are of the Type A. Of the total number of 22 with a reported cause, 12 of those incidents also reported the incidence of a surface crater. Other features of the 66 incidents include, (1) the overall ratio of urban incidents to rural incidents as reported by HSE (1996, Para. 47) remains at 2:1, and (2) high levels of consequences, in terms

Table 4. Numbers and causes of non-NATM incidents.

Cause	All	Urban soft ground
Unpredicted ground	20 (63%)	10 (52%)
Fire	3 (10%)	2 (11%)
Compressed air explosion	2 (6%)	1 (5%)
Methane gas explosion	1 (3%)	1 (5%)
Defective workmanship	2 (6%)	2 (11%)
Temporary works failure	2 (6%)	2 (11%)

Unknown (despite investigation)	1 (3%)	1 (5%)
Total	32	19

of disruption to construction work and to third parties, were associated with the incidences of craters in urban areas.

3.2 *Non-NATM tunnels*

A list of identified incidents that have taken place since 1970 on Non-NATM tunnels in all types of ground and environments has been researched, and totals 42 emergency events. As before, this list has been examined to extract details of those urban projects that were constructed in soft ground. The 42 incidents demonstrate a wider range of primary causation and consequence than for the NATM data. This is demonstrated in the following breakdown and analysis of the information from 32 of the most reliable data sets. The list of causes for "all incidents" and for "urban soft ground" incidents is as follows:

At least half of the above incidents have been recorded as being caused by "unpredicted ground conditions". In general terms, unpredicted ground conditions may arise from poor or inadequate site or ground investigations and for other reasons. In these non-NATM emergency events there are few recorded instances of collapses at the tunnel face. Within the 19 incidents listed above there were 8 instances of surface craters. A further feature of the data set of 32 incidents is that they are randomly distributed in terms of country of location.

Following surface crater incidents in UK involving closed face Tunnel Boring Machines which reflected other incidents that had taken place in other countries (Shirlaw et al, 2003) the British Tunnelling Society (BTS) set up a Working Group to research the backgrounds to these events and draw conclusions. Their Report (BTS, 2005) brought together information on over 100 incidents including 14 incidents associated with Slurry Machines, and 47 incidents relating to Earth Pressure Balance Machines. None of the incidents whose data are included in the BTS Report are specifically identified, but the Authors of this paper are aware that at least three of the UK incidents are also included in the summarized data on non-NATM incidents included in this paper.

4 CONCLUSIONS AND RECOMMENDATIONS

The main conclusions of this research were that quantification of third party risk could not easily be undertaken because of a lack of sufficient and reliable data on a world- wide basis.

Information on the number of tunnel emergency events recorded in the last four decades indicated that both the total number of emergency events and the proportion of these events taking place in urban areas with soft ground tunnels, increased in the three decades since 1970. The latter trend has continued into this part decade.

There were differences between non-NATM and NATM tunnel failures. In non-NATM tunnels there was a tendency for surface craters to form some distance behind the tunnel face and there was greater diversity in the primary causes for such incidents which could involve engineering, management, procurement, organisational, competence, resource or communications issues.

NATM tunnels exhibited different failure characteristics, with surface craters forming above the tunnel face whilst the primary cause of failure was attributed to unpredicted ground conditions.

Urban projects introduced additional risks to tunnelling work due to the density of the existing infrastructure and the close proximity of aging and unfavourably sited infrastructure that was not met on rural sites.

Incidents and emergency events that occurred during underground construction did so as a result of failures of the engineering and health and safety systems devised and put in place to prevent such happenings. It follows that effort should be put into devising, implementing and continuously improving the overall management systems tailored to fit the specific circumstances of the particular underground project. No safety management system, by itself, can eliminate all risk of danger and harm, and some hazards and risks have to be effectively managed on a day-to-day basis by competent persons and organisations. This needs commitment and input from the workforce right through to the higher management levels of key organisations within the specific project structure.

Because of the diversity of underground design and construction work there is no single management methodology for all projects. The authors believe that the factors listed and described below, together with existing published information and guidance, provide a strategic framework of approach that can lead

to a satisfactory safety management system for any underground construction project in any location.

- *Effective Project management*
- *Organisational, procurement and contractual arrangements*
- *Specific Engineering systems*
- *Specific Health and safety systems*
- *The consideration of human factors, and*
- *Availability and use of "enforcement" action*

Effective Project management

Each of the parties needs to project manage effectively his particular input to the development of an integrated safety management system – starting with the client and his initial outline considerations for his project. Consideration of the whole-project risk spectrum from the beginning is appropriate and there are significant advantages to be gained from, for example, integrated management teams, early contractor involvement; early supplier involvement and early operator involvement.

Organisational, procurement and contractual arrangements

Organisational, procurement and contractual arrangements, such as between the client and his chosen design teams, can be crucial to the quality and effectiveness of the overall safety management systems (ITA Working Group No.2. 2004). Project organisational systems also need to relate to those third parties who may be affected by the works. The internal contractual arrangements provide an opportunity to emphasise the importance of cooperation, coordination and communication in the effective identification and control of hazards and risks throughout the project by all parties and the responsibility of all parties to expend the necessary competence and resources to ensure 'best practice' approaches. There is no other field of civil engineering where the integration of design and construction is more important or necessary. Poorly drafted procurement and contractual arrangements can conflict with statutory obligations; impose unfair and unreasonable conditions; create ambiguity, misunderstanding and doubt; and cloud areas of responsibility.

Specific Engineering systems

Much of both design and construction on underground projects relies on the choice and implementation of the engineering systems that are commonly applied to this type of construction work. This could range from the overall design, specification, layout and detailed design of the tunnel lining to the specification and manufacture of complex tunnel boring machines to work effectively in the tunnelling medium of the particular project. The inappropriate choice of, for example, computer analysis software; persons to fill key safety-critical engineering management positions; open or closed face tunnel boring machines; the wrong type of ground stabilising technique; the tunnel lining/surrounding ground monitoring system or the depth of the construction work within the ground in urban situations etc., can compromise the effectiveness of the overall safety management system.

Specific Health and safety systems

The provision and effective implementation of specific systems for the purposes of health and safety are essential (Anderson and Terezopoulos 2000). These range from the provision of specialist advice on health and safety and risk management to those working in both design offices and construction sites and to the provision of persons with special expertise on project expert advisory panels. The prompt, thorough and timely investigation of any accidents, incidents and 'near misses', together with the downloading of the information and conclusions obtained to all who need to know, is of the first importance. Also important is the auditing and review of the elements of the safety management systems with the objective of seeking ways of improvement. Health and safety standards never stand still, and there needs to be the flexibility, coupled with appropriate leadership, to seek to apply higher health and safety standards where this is both practicable and appropriate whether or not required by law.

The consideration of human factors

In large projects it is almost inevitable that safety management systems will be complex and diverse, but they will have to be implemented and managed by persons with a range of skills, experience and knowledge. Some persons will also be given the task of exercising judgments in both engineering and in other contexts – in other words aspects of the overall safety management system will be dependent on 'human factors'. The question then arises, when and where might 'human errors' of one kind or another be made, and, if so, what the possible consequences of these 'errors' might be. It is undoubtedly the case that some 'emergency events' have also been caused by persons intentionally violating work systems and procedures that have been correctly set out, and it is also the case that high level 'errors' can play a major part in creating the circumstances where others might make errors at the workface. The potential for human failure, error or misjudgment is almost everywhere within the system, and as such merits careful consideration by all parties.

Availability and use of "enforcement" action

Where shortcomings in the safety or engineering management systems have been pinpointed, there needs

to be a mechanism by which, if appropriate, effective corrective action can be taken. In some cases it may be necessary to stop the construction work so that the necessary remedial measures can be given priority. This power exists within the statutory enforcement body for health and safety, but should also exist within the contractual arrangements. The sanction of ultimately stopping construction work on health and safety grounds or for deviation from the design could be retained by the client – if necessary on being properly advised about the proposed course of action. Alternatively, the client could retain an organisation with the appropriate competence, skills and knowledge to exercise the role of construction supervision on his behalf.

Risk management in connection with execution of underground structures and surface development securing

A.J. Lossmann
SG-Geotechnika, a.s., Brno, The Czech Republic

B.V. Motyčka
University of Technology, Brno, The Czech Republic

ABSTRACT: The characteristic features of modern management are comprised of the ability to work successfully in risky conditions. Technically and organizationally complicated engineering structures are usually also demanding from the financial perspective. This applies also to execution of underground structures – tunnel advance and the related securing of the surface development. Application of risk management with utilization of the observation method enables quality, safe, and cost-efficient execution of such structures. At the same time, environmental burden of the construction site surroundings is minimized.

1 INTRODUCTION

Risk management is connected with various areas and it is also understood that way (natural disasters and accidents, environmental risks, financial risks, design risks, commercial risks, organizational risks, technical risks).

However, there are also general regularities of risk management which jointly apply to all areas. The main goal always is to limit the effects of both existing and future risks and to propose solutions which will help to eliminate the consequences of such effects. The process of risk management always comprises the decision making process based on the risk analysis.

Assessment and management of technical (engineering) risks usually consists of the following parts [1]:

- Identification, quantification (determination of quantity) of existing risks
- Risk evaluation (acceptable risk level definition)
- Design and implementation of a program aimed at existing risks reduction
- Monitoring of the implemented program's efficiency
- Possible corrections of the risk reduction program

The above-mentioned parts of the technical risks management process must be carried continuously during the entire course of construction for all significant projects.

2 GEOTECHNICAL RISK MANAGEMENT

Modern projects incorporate certain risk level into underground structures and surface development securing designs. The risk is expressed by the probability that an undesirable effect with certain economic consequences will occur in case of a given project solution in the assessed conditions. The value of acceptable risk is defined, which must be acceptable for all parties involved in the construction and the agreement must clearly stipulate who will bear what part of such risk. The purpose of all this is to achieve a fair saving of work equipment, means, labor force, and of course also time, i.e., in a final context, the saving of construction costs. **At the same time, the quality of the completed work must not be affected.**

This procedure is based on the fact that the rock massif behavior during the tunnel advance can be foreseen less or more successfully, however, it can not be determined precisely. That is why the geotechnical risk of tunnel advance is defined. The geotechnical risk is understood to be a coincidence of the probability of an undesirable development of rock massif interaction with the tunnel lining and resulting impact on the construction. Such negative development would have a negative impact on the economy of the entire project.

Prerequisites for the geotechnical risks management therefore comprise monitoring and evaluation of the interaction between the rock massif and the tunnel lining so that the undesirable development of such an

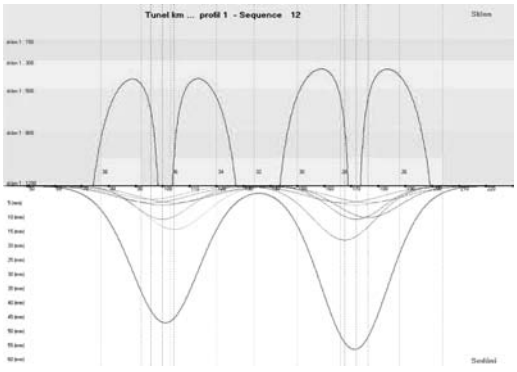

Figure 1. Example of subsidence though prediction for tunnel.

Figure 2. Tunnels often pass below densely developed areas which must be properly secured against the effects of tunneling.

interaction is envisaged and clearly defined in a timely manner.

A group of activities aimed at rock massif condition determination, monitoring of its development, and directing its further behavior is collectively referred to as control monitoring. The control monitoring is based on a measurement design, which comprises a hypothesis of the rock massif deformation, technical and economic analysis of the geotechnical risks and determination of the control monitoring goals, i.e., forecast of the rock massif behavior and related measures. A major part of the control monitoring is comprised of extensive measurement and monitoring of pre-defined quantities (monitoring) within the entire area of the construction (both below and above the terrain level) both during the tunnel advance and after its completion.

3 OVERGROUND DEVELOPMENT SECURING USING THE OBSERVATION METHOD

The so called observation method represents a special control monitoring method. This monitoring method was first described in geotechnics in 1969. The principle of the method is that the initial construction project including the selected execution technology is adjusted and further corrected during the construction process depending on additional information identified regarding in particular the rock massif behavior, its interactions with the tunnel lining, and depending on the real impact of the tunnel construction on the surface development. The construction phase thus provides large amounts of information which was not obtained by previous (although detailed) geological survey.

The structures executed on the basis of traditional design methods (based on geological survey and high safety level) are considerably more expensive when compared to those using the observation method. This method is therefore used in particular to reduce labor demands, material and time saving during the construction execution (including securing of the surface development and therefore the total costs of such construction).

Monitoring thus represents a significant component of the observation method. This in principle comprises measurement and monitoring of selected quantities – their values changing during the construction and their partial evaluation. First of all, these measured values represent the groundwork for verification of correctness of the designed structures and technological procedures or new technical and organizational measures are adopted in order to ensure an uninterrupted and safe course of the construction. Such measures can comprise, for example, tunnel lining modification or changes in surface development securing, etc.

Monitoring relating to tunnel advance and to surface development securing is usually comprised of the following activities:

- Geotechnical assessment of the tunnel
- Convergence measurement of tunnels deformations
- Measurement of stress in the tunnel lining and in the adjacent rock massif
- Extensometric and inclinometric measurements for identification of rock deformations
- Geotechnical surveying of points on the surface and on buildings
- Observation of cracks and deformations of the development
- Dynamic and acoustic measurement of the effects of tunneling on the surface development

The main goal of monitoring and of the observation method is to enable safe execution of construction on the basis of continuously identified values of monitored quantities while minimizing related financial

Figure 4. Detail of reinforced ribbon vault ceiling securing in subbasement of a residential building.

costs of construction and obtaining the data necessary for passportization and re-passportization of surface development after tunnel advance; this data also serves as the groundwork for possible litigation regarding faults and damages caused by the construction on the surface structures.

Observation method utilization thus relates to the underground structure and, at the same time, to the surface development securing. It is important to emphasize that the securing of surface structures against dynamic effects and subsoil displacements caused by tunnel advance represents the key part of the tunneling process. It is important in particular to secure those structures located in the subsidence trough, for which subsidence, deformations, and inclination are supposed.

4 PRACTICAL APPLICATION OF THE OBSERVATION METHOD DURING CONSTRUCTION OF TUNNELS IN BRNO

The countries of Central and Eastern Europe have been recently subject to a steep increase in individual road transport. In particular in the post-communist countries, where changes in the economic environment have influenced the behavior of most people, the number of cars has doubled during the past fifteen years and this number is still increasing. High loading of transport systems is common in particular in large and medium sized cities, which become jammed during rush hours several times a day.

This unfavorable transport situation has also had to be solved in the Czech Republic, in particular in Prague but also in other major towns including the second largest city – Brno. Due to high technical and technological demands, there has been a long search for a solution, which would be acceptable for the city from an economical perspective.

In the end, it was decided to build the Large Municipal Ring which will be comprised of several long tunnels. It is expected that the entire structure will be executed with geotechnical risks management system utilization. This method of construction should enable significant economic savings for the city and also for the state budget.

This project is based on Brno's new transport organization concept, which consistently enforces protection of private property and environment in the city. This was the reason why tunnel sections have been incorporated into the basic municipal communication system. Two of these tunnels are already in construction – Pražská radiála tunnel below Strážný Hill, which forms part of the western link road and Husovický tunnel, which forms part of the Large Municipal Ring. The third tunnel structure will consist of two tunnel tubes – Dobrovského I and Dobrovského II tunnels (their axial distance reaches up to 100 meters in some places), which are located in Královo Pole and Žabovřesky municipal districts. These municipal districts will be interconnected by the tunnels. They represent the biggest project of its kind in Brno area.

The municipal circuit section passing through these tunnels is approximately 1.2 kilometers long and the tunnels pass below densely built-up area with numerous residential and communal facilities. This places high demands on securing of the surface structures which are subject to vibrations and subsequent subsidence as a consequence of tunnel construction.

Vertical arrangement of both tunnels has been determined with respect to the limitations given by portal sections of the tunnel, municipal main sewer lines, and by the geological conditions in the given area. Surface layers of loess loans and backfills with thickness between 3 and 10 meters with gravel and sandy terraces underneath occur at the construction site. The subsoil of these terraces consists of Neogene clays, so called

Figure 5. Basic Dobrovského drift lining structure consisting of shotcrete C 20/25 (thickness of 100 mm) with mesh size from 60×60 to 150×150 mm and with stiff steel frames from K24 profiles with spacing of 1.0 or 0.5 meter.

"tégly". Vertical positioning of the tunnels has been proposed to ensure minimal thickness of these non-permeable clays between two and three meters above the stope. In order to keep the underground water above these clays in the gravel sand layers. The total overburden thickness varies between 4 and 21 meters in these tunnels.

5 DOBROVSKÉHO TUNNELS – DRIFTS

In order to obtain detailed information about geotechnical parameters of the rock environment along the Dobrovského I and II tunnels route, a project named Silnice I/42 Brno, VMO Dobrovského A, Tunely DOBROVSKÉHO – PRŮZKUMNÉ ŠTOLY (Road I/42 Brno, Dobrovského A City Ring, DOBROVSKÉHO TUNNELS – DRIFTS) has been carried out. It is comprised of three drifts which comprise approximately 20% of the total volume of both tunnels.

These drifts have also been constructed for other reasons:

- verification of the tunneling technology in the environment of Neogene clays,
- identification of previously unspecified problems which could occur during tunnels construction,
- verification of tunnel advance effects on municipal development in order to provide for subsequent extrapolation of these effects on advance of full tunnel profiles.

The construction of the Dobrovského tunnels is currently at the phase where work on drifts has been completed. Work relating to surface structures securing still continues and construction of the tunnels is being prepared.

The Roads and Motorways Directorate of the Czech Republic (Brno Branch) is the investor in this project. Design has been prepared by Amberg Engineering Brno, a.s.

Tunnel advance is expected to start in 2007.

6 CONCLUSIONS

The securing of surface structures against the dynamic effects and subsoil displacements caused by tunnel advance represent an important part of drift and tunnel construction. It is in particular important to secure those buildings which are located in the subsidence trough, and for which subsidence, deformations, and inclinations are therefore expected.

Complicated geological conditions caused by the rock environment of Brno's Neogene clays (tégly) and dense surface development consisting of residential and communal facilities, utility networks, and roads, make the construction of the Dobrovského tunnels a unique engineering project within the whole Czech Republic. This is reflected in modern construction methods comprising the risk management system, which enables significant economic savings to be achieved for the entire project.

The aim of geotechnical risks management is therefore to ensure timely technical and organizational response to an undesirable interaction development including any consequent deformations of structures on the surface and to ensure a continuous, economic, and safe course of construction.

Contracting issues for conventional tunnelling

Nasri Munfah
Parsons Brinckerhoff, New York

ABSTRACT: Conventional tunnelling, also referred to as the New Austrian Tunnelling Method (NATM) is different from other tunnelling methods because of its dependency on the means and methods and the qualifications of the contractor and his work force. In addition, conventional tunnelling is often used in unknown or difficult ground, and has high construction risks. The main issue that overrides all aspects of underground construction and particularly conventional tunnelling is risk. The level of risk sharing between the owner and the contractor is a major factor in deciding the type of procurement practices and the contractual terms and conditions to be implemented.

1 GENERAL

1.1 *Conventional tunnelling*

The International Tunnelling Association (ITA) Working Group 19 defined Conventional Tunnelling as: the construction of underground openings of any shape with cyclic construction process of:

- Excavation, by using the drill and blast methods, or mechanized excavators except for full face TBM
- Mucking
- Placement of primary support elements such as steel ribs or lattice girders; soil or rock anchors; or sprayed or cast in situ concrete.

In this context the conventional tunnelling, also referred to as the New Austrian Tunnelling Method (NATM) is different from other tunnelling methods because of its dependency on the means and methods and the qualifications of the contractor and his work force.

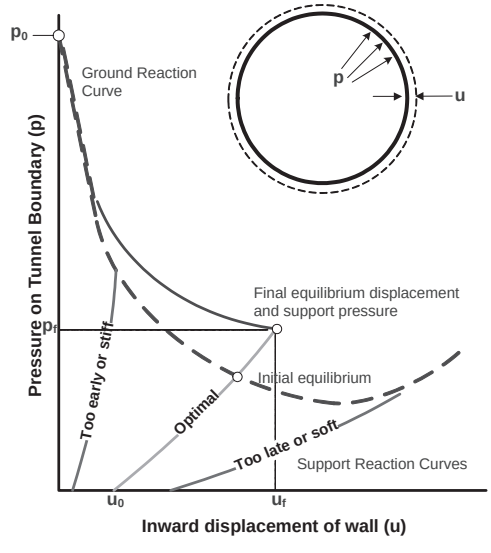

Figure 1. Ground reaction curve concept.

1.2 *Principles of conventional tunnelling*

Conventional tunnelling is used for long and short tunnels, of constant cross section or irregular shape; it is used for large opening such as storage caverns, rail stations, or complex intersections; it is used in rock, soft ground, or mixed face and difficult ground; in dry and wet conditions; it can be used for deep excavation as well as in the case of low overburden.

The design philosophy is based on mobilizing the inherent ground strength to the maximum extent possible through controlled deformation of the ground (see figure 1). Therefore, it is critical for the success of conventional tunnelling that the stiffness, the strength and the timing of the initial support are compatible with the ground deformation. Hence conventional tunnelling is dependent on a rigorous instrumentation and monitoring system to verify the ground stability and the adequacy of the support.

The principles of conventional tunnelling consist of:

- Sequential excavation
- Curvilinear profile (cross section)
- The ring must promptly be closed
- Initial support using shotcrete in combination with steel fibres or welded wire mesh and lattice girders or steel ribs
- Stability confirmed by rigorous monitoring of stresses and deformations.

In addition, conventional tunnelling has a variety of tools to improve the performance of the ground by increasing its stand-up time, limit deformations, control ground loss at the face, create ground arch and increase the ground inherent strength. Some of these tools include:

- Ground reinforcement such as rock bolts
- Pre-support including spiles, pipe umbrellas, horizontal jet grout, etc…
- Vacuum dewatering
- Face support by earth berm, fibreglass bolts, and shotcrete
- Abutment piles to increase the lateral stability
- Adjustment to the geometrical configuration and sequence of excavation.

Conventional tunnelling is a flexible tunnelling system and depends on the observational method and the qualifications of the workers; therefore its contractual terms should also be flexible to be able to compensate for variations in ground condition encountered and its performance, and be able to address potential construction risks.

The main issue that overrides all aspects of underground construction and particularly conventional tunnelling is construction risk. The level of risk sharing between the owner and the contractor is a major factor in deciding the type of procurement practices to be implemented.

1.3 *Construction risks in conventional tunnelling*

Conventional tunnelling imposes risks on the owner, the contractor, the designer, and potentially the public. There could be the risk of unknown and unanticipated ground and groundwater. There could be risk of delay and cost overrun and potentially environmental risks. In urban areas, there is the risk of subsidence and potential damage to third party properties or persons. In addition, public opposition of the tunnelling project due to its disturbance to the neighbourhood, noise and vibration, and other issues could result in significant delay.

In a study conducted by the US National Committee on Tunnel Technology (USNCTT) in 1988, it was documented that over 55% of construction claims in tunnelling projects are related to unforeseen ground conditions, with over 95% of these claims relatively substantial in value and a significant percentage of these claims are settled for their full (or almost full) values. It is no surprise that most cost increases in tunnel projects are related to unforeseen geotechnical conditions. These generally include type and behaviour of the soil and rock; ground water conditions; presence, size, and nesting of boulders; contamination of the soil or the ground water; presence of methane gas or other hazardous materials; etc. Therefore it is essential to have a complete and comprehensive geotechnical exploration program. However, it is more important to properly interpret the geotechnical parameters and the anticipated behaviour of the ground and document such interpretation in the contract documents.

Undocumented abandoned foundations, uncharted utility lines, uncontrolled rubble fills, and man-made obstructions buried underground are some of typical construction risks. These elements add to already difficult ground conditions and may increase construction risks and cost, and negatively impact the project schedule.

Generally tunnelling projects need the approvals of various public and private entities, each with its requirements and interests. Approvals from environ mental agencies, funding agencies, and project stakeholders are critical. Public opinion and the approval of citizen groups especially in well-established communities and cities where such organizations have significant political influence are critical. Typical concerns related to construction are impact on property values, disruption to businesses and daily routine activities, emission of dust, noise and vibration, working hours, and the potential increase in pests and rodents. Buy-in of construction methodologies and approaches by the public in the early stages of the project is critical for its successful completion. Agreements reached with the public should be reflected in the construction contract documents. Continual interfacing with the public during construction is important to assure the people that agreements reached are being implemented, and also to address new concerns that might develop after the start of construction.

2 RISK MANAGEMENT

Traditionally construction risks have been managed indirectly through the design process often resulting in conservative design that would lead to higher contractor contingencies in his bid price. ITA Working Group 2 developed guidelines to manage construction risks using systematic risk management techniques from the project conceptual development through implementation in the construction phase.

As stated above, most claims in underground construction are related to unforeseen conditions. Therefore, the underground construction industry in the United States tried to provide a viable trigger by means of the Differing Site Condition (DSC) clause, culminating in the use of the Geotechnical Baseline Report (GBR) and Geotechnical Data Report (GDR). It is important from a risk-sharing perspective that the contractual language in the DSC and the GBR is harmonized.

2.1 *Risk allocation/sharing*

The allocation of risk between the owner and the contractor will have a direct relationship to the contractor contingency as part of the contractor's bid. Therefore, it is important to identify a risk sharing mechanism that is fair and equitable and that will result in a reasonable contingency by the contractor and sufficient reserve fund to be provided by the owner to address unforeseen conditions. For example unforeseen conditions due to ground conditions are paid for by the owner if certain tests are met, while means and methods are generally the contractor's responsibility and his inability to perform under prescribed conditions are risks to be absorbed by the contractor.

2.2 *Contractor's contingency/owner's reserve*

With proper contracting form and equitable allocation of risks between the owner and the contractor, the contractor contingency, which is part of its bid price, will be reduced. Similarly, the owner's reserve will be used only if certain conditions are encountered, resulting in an overall lesser cost to the owner.

3 CONTRACTING PRACTICES

Generally, two categories of delivery methods have been used in the past for underground construction, with various levels of success. They are:

- Design-Bid-Build
- Design-Build

The contractual terms of these two delivery methods vary widely. The most common is the fixed price approach, although for conventional tunnelling unit prices approach is the most suitable and prevailing. However, other contract terms used include:

– Fixed Price lump sum
– Low bid based on unit prices
– Quality based selection
– Best and Final Offer
– Cost plus fixed fee
– Negotiated Compressed Process (NCP)
– Quality based selection

The following discussion addresses the advantages and disadvantages of these methods with respect to conventional tunnelling.

3.1 *Design-Bid-Build with fixed price contract*

The form of contract known as Design-Bid-Build is traditionally for a firm fixed price. In this contract form the work must be performed as shown and specified in the contract documents, and may not be qualified or conditioned. Generally, the owner engages a design engineer to provide a complete design and document it in contract documents consisting of drawings and specifications, obtain all approvals, secure right-of-ways and easements, obtain third party and stakeholders approvals, and obtain required permits. In this form of contract, it is presumed that the owner is getting the fixed price and the contractor will have the benefit of profit and accept the full responsibility of losses. As such, the contractor is assuming the full risk, and therefore he adds high contingency to his bid. This form of contract is easy and straightforward. It delineates clearly the roles and responsibilities between the owner and the contractor, the owner provides a complete design and obtains all approvals, while the contractor executes the work with the best means and methods it sees fit; it provides strong owner control, as a result potentially higher quality is achieved, although it will often cost more; in this form of the contract, the owner should have a complete identification of the geotechnical issues and resolutions to the environmental issues prior to bid otherwise, they are added cost. However, this method of procurement has its disadvantages, including: higher contractor contingency. Since the contractor is assuming all the risks, he would place a high contingency in his bid, regardless of whether such risks materialize or not. The owner will have no input on the contractor's means and methods in order not to assume the contractor's risk, however if the means and methods selected by the contractor are not suitable, the owner will suffer by having a delayed schedule or a lesser quality product. Because the contractor is bidding on a completely pre-established design with no provisions for qualifying the bid, the contractor will have little incentive to be creative or to deviate from the prescribed design. In this form of the contract, the contractor's qualifications are established post bid opening which might result in a selection of inexperienced or unqualified contractor to perform conventional tunnelling which is highly dependent on the workmanship and the qualifications of the workers.

3.2 *Design-build project delivery method*

In this process, the project is awarded to the low responsive and responsible bidder to prepare the design and construct the project. The owner's engineer usually prepares bidding documents based on preliminary design level identifying the owner's requirements. For conventional tunnelling projects, the geotechnical and environmental investigations are generally advanced to a higher level of completion to provide better information. The selected contractor then prepares the final design and constructs the project. This process is gaining interest among owners for underground projects in order to reduce the overall time required to complete the project, avoid dealing with disputes over changed conditions, and avoid lengthy and costly litigations.

The procurement options of the design-build approach vary based on the project goals and the owners objectives. Examples of the procurement options include: Competitive Bid (low price), Competitive Bid with High Responsibility Standards (cost and qualifications), Competitive Bids with Alternative Proposals, Price and Other Factors, Price after Discussion including "Best and Final Offer", Quality Based Selection, or Sole Source Negotiation.

The intent of the design-build process is to accelerate the schedule by shortening the time of the design, to develop the design to meet the construction means and methods, and to advance the procurement of long lead items.

It is imperative in a design-build process for tunnelling projects that the owner obtains all right-of-ways and easements, and necessary approvals and permits. It is also important to carry the geotechnical investigation to a high level of completion and to identify and resolve all interfacing with adjacent properties, private and public organizations, and other stakeholders prior to awarding the contract in order to avoid potential delays and unanticipated cost.

The advantages of this procurement process are: potential accelerated schedule; contractor's input in the design, which may result in better details for construction and implementation of less costly methodologies; early interaction with the designer to identify and address constructability issues; it encourages innovation and allows creative construction approaches; it provides a simplified accountability and responsibilities process; and it may shelter the owner from potential construction claims and changes.

The major disadvantage is the overall loss by the owner of the control of the project during the final design and construction. While owners are concerned about the long term performance of the project and about peripheral yet critical issues such as maintenance of existing operations, adjacent utilities, environmental issues, and the long term maintenance and operation of the facility, the design-build contractor is often less concerned about these issues. Although owners try via this process to shift the risk of unforeseen site conditions to the design-build contractor, unless a full geotechnical investigation is performed and a baseline is established, such shifting of risk is usually unsuccessful. Other disadvantages include: a potentially lower quality product, it requires complete definition of the project requirements early, and it may result in higher overall cost.

It is recommended that for conventional tunnelling projects where design-build delivery method is to be used the geotechnical and environmental investigations are completed, all right of ways and easements are acquired, all approval processes be completed, and all permits obtained prior to awarding the contract. It is also recommended that a GBR be included as part of the bid documents.

3.3 *Qualification based selection*

Qualification based selection is suitable for conventional tunnelling but seldom used. The contact is modelled similar to Construction Manager/General Contractor (CM/GC) approach using a qualification based process. In this contract the cost is established either as a guarantee maximum price, or as an estimated reimbursable (the Portland Model) which is the sum of the anticipated cost reimbursable plus a fixed fee. Labour, equipment and materials are paid on cost reimbursable while contractor overhead, superintendent, management, general conditions costs and profit are parts of the fixed fee.

The selection process is modelled after the two-step selection process similar to procuring professional services. A key element of this process is an interview in which contractors would have the opportunity to demonstrate their understanding of the project and highlight their experience.

In this form the selected contractor would review and comment on the design and would perform constructibility reviews, value engineering, and risk assessment and jointly with the designer and the owner establish baseline values and the contract's general provisions. The estimated reimbursable cost (ERC) would be developed and negotiated. The goal of the ERC is to establish a baseline budget and a cash flow plan. The intent is to establish a reasonable construction cost without contingencies. The contingency would be separately established based on the risk analysis and would be held by the owner. The estimated reimbursable cost plus the fixed fee becomes the contract value. To accurately track and control the cost an accurate cost control program would be needed.

The advantages of this approach are: the selection is based on the best value rather than the lowest cost; it provides evaluation of the contractor's qualifications, techniques, and processes; it provides the ability for the contractor to be involved in the design, including constructibility review, value engineering, provisions for means and methods, etc. . . . These are important factors for a successful project. It also provides opportunities for creativity and innovation. In addition, the determination of contractor responsiveness is made prior to award, and the contingency is held by the owner and would be used only if conditions are different than stipulated in the contract.

However, this approach has disadvantages: it may not be able to protect confidentiality of means and methods, resulting in contractors' reluctance to fully disclose their means and methods prior to award; it may invite protests from bidders identified as unqualified,

or from bidders challenging the technical ranking of the various proposals; it requires significant oversight by the owner and an elaborate project control program, without it may result in uncontrolled project cost; and it is difficult to implement.

Variations of this approach is the Two-Envelope approach in which the selection is made purely based on qualifications; and the Negotiated Compressed Process (NCP) which elements include pre-qualification of contractors, establishment of a technical working group, and execution of a technology acceptance agreement.

4 CONTRACTUAL MEASURES FOR CONVENTIONAL TUNNELLING

Using conventional contracting, design build, or qualification based selection, it is important to establish measures to manage construction risks in conventional tunnelling. These measures may include prequalification of contractors, full geotechnical disclosure, Dispute Review Board (DRB), the use of differing site condition clause, escrow bid documents, unit prices and contingent bid items, value engineering, owner controlled insurance program, and partnering. Some of these provisions are discussed here.

4.1 *Prequalification of contractors*

This involves technical and financial qualifications of the potential bidders to ensure their ability to perform the work effectively, economically, and to a high quality. The pre-qualification would include the company's or the joint venture's technical ability to perform the work. Items to be evaluated include: approach, experience with similar projects, with similar ground, and similar proposed methodology. Pre-qualification of the key staff, such as the contractor project manager, the field manager or superintendent, the senior staff, and he workforce is critical for a successful project. In addition the bidder's financial ability to obtain bonding and its solvency, its history of completing projects on time and within budget are factors in the bidder financial qualifications. Pre-qualification should extend to major subcontractors and major suppliers.

4.2 *Unit prices and contingent bid items*

It is recommended that for conventional tunnelling unit prices be the basis of the bid. The unit prices should reflect the various anticipated ground conditions and their support systems. They should also reflect the various "tools" in the conventional tunnelling tool box such as spiling, forpoling, pipe umbrella, horizontal jet grouting, vacuum dewatering, rock bolts, face stability measures, abutment piles, and changing in the excavation sequencing. In addition providing contingent bid items to supply some of the conventional tunnelling tools in the field is recommended. Some of these tools may not be anticipated but their provisions in the field would be beneficial to address unanticipated conditions. The unit costs of these items would be established as part of the bid and would be used only if needed and if approved by the engineer.

4.3 *Full geotechnical disclosure*

Experience has shown that full disclosure of geotechnical information would reduce the risk to both the owner and the contractor and thus the project cost. Therefore it is important for owners to invest in a comprehensive geotechnical program. The information should be included in the contract documents in the Geotechnical Data Report, Geotechnical Interpretive Report, or Geotechnical Baseline Report. The intent of the disclosure of geotechnical information is to share and allocate construction risk between the owner and the contractor.

The Geotechnical Baseline Report establishes quantitative values for selected conditions anticipated to have great impact on construction. These values are established through technical interpretation of the data and commercial considerations of risk allocation and sharing. The advantages of this report are ease of administration of contractual clauses, unambiguous determination of entitlement, clear basis of contractor's bid, and clear allocation of risk between owner and contractor.

4.4 *Dispute Review Board (DRB)*

The dispute review board process started in the United States in the mid-1970s as a result of accelerated claims and disputes in underground construction and expanded dramatically in the 1980s and 1990s. In this process a board of independent, experienced, and impartial members is selected to hear and address disputes. Generally the board consists of three members, one representing the owner, one representing the contractor, and the third, who will act as the chair of the board, selected by the other two members. The board provides recommendations to resolve disputes that participants are unable to make. It was found that this process has resulted in lower bid prices, better communication and less animosity at the job site, fewer claims, and more timely and cost effective resolutions.

4.5 *Partnering*

Recently, partnering clauses have been included in tunnelling contracts. The goal of partnering is to minimize disputes and to prevent them from escalating in time and value by resolving them at the lowest possible level

in the project organization. It attempts to establish a win-win attitude between the project participants. This process encourages dialogue among the various participants and relies on reasonable people to resolve disagreements reasonably. It seeks to eliminate adversarial posturing and positioning that often develop when disputes and claims arise.

4.6 *Differing Site Conditions clause (DSC)*

The Differing Site Condition clause was established as a measure of allocation of risk between the owner and the contractor relative to the ground condition.

There are two categories of DSCs: Category 1 governs when subsurface conditions differ from those indicated in the contract documents. Category 2 applies when conditions which were not known to the contractor at the time of contracting, differ from those normally encountered in the area. It is generally related to unusual conditions and not based on contract documents. It is important to note that to recover on the DSC clause the contractor must show impact on cost and time and must show causality.

4.7 *Escrow bid documents*

In this process the lower bidder bid documents are placed in an escrow, that is, held in trust by a third party and turned over to the grantee only upon fulfilment of a condition. These documents would then be utilized if needed to assess a fair entitlement and adjustment for additional work, differing site condition issues and claims. However, in this process owners fear that the contractor could condition its bids and contractors fear that they could lose confidentiality of means and methods. This process has not been used extensively.

5 CONCLUSION

The need for a creative, progressive, and fair contracting form is critical to control the rising costs of underground construction. The contract form should address the uncertainty of conventional tunnelling work and its associated risks. It is important that conventional tunnelling be preformed only by qualified contractors with fair contracts that would allocate risks equitably between the owner and the contractor, in order to have safe, on time, and high quality underground projects.

ABSTRACT: The TBM Excavation Control System developed by authors has already been put to practical use. It can monitor the drill energy coefficient calculated from the drill logging data as an index of rock properties and the TBM driving data during the excavation. In this paper, the new TBM risk management system is developed to realize the automatic, real-time prediction of the rock properties ahead of the tunnel face with good precision. The core feature of this system is to analyze data by means of the geostatistical methods such as the Kriging and the Sequential Indicator Simulation. It allows us to use outputs as a form of risk management. This system is put into practical use and validated in the ongoing construction site.

1 INTRODUCTION

The TBM method is used because of its potential for high-speed excavation. However, if there is some ground trouble such as collapse, it hinders the progress, making it impossible to fully achieve the high-speed excavation capability of the TBM. It is important, especially in countries like Japan that have complex geological conditions, to have a detailed information of ground conditions and to be able to take appropriate action as soon as necessary to avoid trouble.

For this purpose, the authors have developed the TBM excavation control and monitoring system (Shirasagi et al. 2000), which can combine the results of the drill logging (Aoki et al. 1990), TBM driving data, an amount of muck measured by conveyer belt scales (Inou et al. 2001), a ground evaluation method based on the state of muck (Inou et al. 2000) and display in one system so as to predict geological conditions ahead of and surrounding the tunnel face and to help an operator control TBM excavation.

However, all these data are independently used for ground evaluation and it is difficult to link them to make real-time geological prediction. Thus, the authors have developed comprehensive geological evaluation methods that could coordinate these data and process more data with highly accuracy. One of the methods statistically describes ground information such as the drill energy coefficient obtained from the drill logging, TBM driving data and the observational rock mass grade as a regression equation derived from multivariate analysis, calculating the rock mass grade at cutting face by means of the regression equation (Yamamoto et al. 2003). The other analyzes the drill energy coefficient and TBM driving data by means of geostatistical method such as the Kriging and the Sequential Indicator Simulation (Mito et al. 2003), creating distribution maps of rock mass properties and maps showing the distribution of the probability of weak rock emerging.

This paper reports on the results of the new TBM risk management system which can conduct real-time geological assessments using multivariate analysis and geostatistical methods. The method, which is applied to the TBM construction of an evacuation tunnel in the Miyazu No. 12 Tunnel, is found to be able to make more accurate predictions of geological conditions than previous methods. This paper also reports that construction could be undertaken while conducting accurate risk management because of this system.

2 OVERVIEW OF THE MIYAZU NO. 12 TUNNEL

2.1 *Description of the construction*

This project is to construct the main tunnel which is 3,660 m in length and the accompanied evacuation tunnel which is 3,692 m in length. The length of 3,457 m of the evacuation tunnel has already been excavated by the 5.0 m-diameter open-type TBM as you see in Figure 1. The TBM was equipped with a percussion-drilling machine used in drill logging and in reinforcement in loose ground.

2.2 *Topography and geology*

The geology is composed of granites of the Mesozoic-Cretaceous. However, because this base rock is intruded by other types of granites, the geology is more complex than that of ordinary granitic ground. The maximum overburden depth is approximately 280 m.

2.3 *Support pattern*

Table 1 shows the structure of each support pattern, while Figure 2 shows a comparison between the designed support proportions and adopted ones. The actual ground conditions were about one or two ranks worse than the designed. Furthermore, the support patterns were often changed because of the ground conditions changing every few meters to every few dozen meters.

The steel liner (SL) as you see in Figure 3 was developed by Kajima so as to support tunnel walls by means of wire net coupled to two ribs of C-100 steel beams. It is adopted as a special support for well-fractured and continuously collapsing ground condition in order to quickly prevent the rock around the tunnel from loosening. It is built up in the TBM roof in advance, and then pressed against tunnel walls as soon as they appear.

Although it is initially designed for a shielded hard-rock TBM, it is expected that the main ribs are bent because the wire net, which is rigidly welded to ribs, is pushed out against walls by TBM main grippers of the open-type TBM. Consequently, the buffer spring

Table 1. Structure of support patterns.

Support pattern	Geological evaluation score	1 stroke (m)	Fiber shotcrete		Steel support size, intervals
			Angle (°)	Thickness (mm)	
B-T	65∼100	1.5	–	–	–
CI-T	55∼70	1.5	120	20	–
CII-T	35∼60	1.5	180	20	H-100, 1.5 m
DI-T	0∼40	1.0	180	30	H-100, 1.0 m
SL	0∼40	1.0	–	–	C-100, 1.0 m

coupling the wire net with the ribs loosely is developed as you see in Figure 4.

3 NEW TBM RISK MANAGEMENT SYSTEM

The New TBM risk management system sorts out and processes various data automatically, such as TBM driving data, drill logging data, and wall rock mass grade. And it applies them to a multivariate analysis and the geostatistical methods. Thus, this system can visualize the geological conditions ahead of the tunnel face in real time, and provide feedback on the geological conditions for the next excavation.

3.1 *Characteristics of the new TBM risk management system*

Figure 5 and Figure 6 show flow charts of the conventional geological evaluation method and the New TBM risk management system respectively. As shown in Figure 5, in the conventional method, drill logging and TBM driving data and observational rock mass grade have been collected as the excavation progresses, and the ground conditions have been evaluated separately.

Figure 4. Buffer spring connecting rib and wire net.

On the other hand, in the new TBM risk management system (shown in Figure 6), when data are collected to some extent (e.g. when the face reached 700 m from the portal at this site), a multivariate analysis is conducted using drill logging and TBM driving data as explanatory variables and rock mass grade as criterion variables to derive a regression equation. The regression equation can thereafter calculate the rock mass grade at the cutting face for the next excavation automatically in real time, using drill logging and TBM driving data.

Using the geostatistical methods, the drill energy coefficient obtained from drill logging and the predicted rock mass grade are processed, creating a drill energy coefficient map ahead of the tunnel face as well as a probability map of collapse occurring ahead of the tunnel face. The latter map, in particular, largely contributes to risk management during the construction, as it helps to grasp a risk of the occurrence of collapse as probability. Moreover, these maps are updated along the progress of TBM excavation, therefore, it is expected that the precision of geological prediction will be improved.

3.2 *Components of the new TBM risk management system*

The new TBM risk management system consists of five components.

First is the TBM driving data. Its components such as the penetration rate, torque, revolutions, excavating

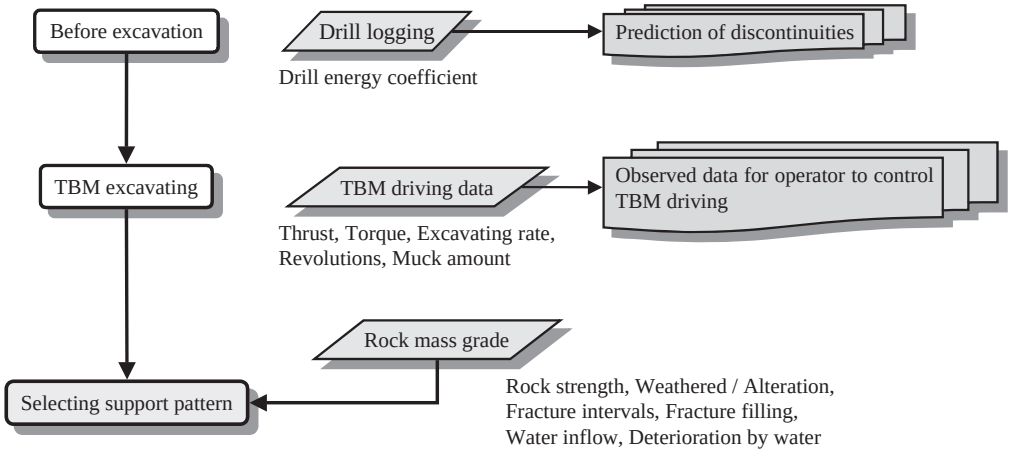

Figure 5. Flow chart of ordinary evaluation system.

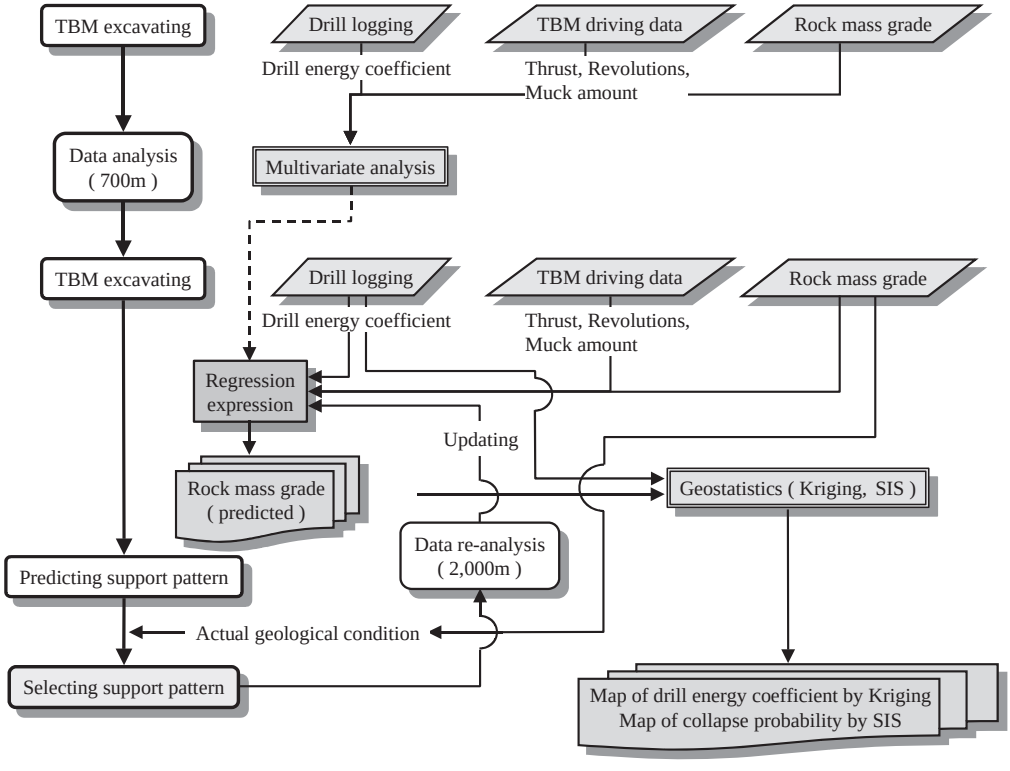

Figure 6. Flow chart of geostatistical evaluation system.

rate, thrust, and muck amount are recorded in the TBM excavation control and monitoring system. The real-time monitoring of these data is of great help to TBM operators.

Second is the drill logging system. It aims to calculate a drill energy coefficient based on drilling data. To collect the drilling data, a percussion-drilling machine installed on the TBM bores about 40 m ahead. A drill energy coefficient is defined as the energy required for crashing a unit volume of rock and shows good correspondence with rock mass quality.

Third is the rock mass grade (RMG). The geology behind the TBM tail is observed and six items, such as rock strength, alteration due to weathering, joint spacing, joint condition, water inflow and deterioration by water, are graded 4, 5 or 6 ranks. Every tunnel support pattern is decided predominantly based on a such weighted averaged rock mass grade and stability of tunnel wall.

Fourth is the multivariate analysis to set of a regression equation for predicting rock mass grade. This project has two regression equations. One is obtained from another site which was under similar condition. The other is calculated after the excavation progressed to 700 m and 2,000 m from the portal. The second regression equation applied to the depth of 2,000 m or below is shown as Equation 1

$$S = 3.3\ R + 0.0034\ T_h - 0.36\ M + 35 \quad (1)$$

where S = predicted RMG; R = revolutions; T_h = Thrust; M = Muck amount.

Finally, the geostatistical methods for prediction of geological conditions ahead of the tunnel face are the core features. One of the major objectives of geostatistics is to estimate with high precision the spatial distribution in a broader area using limited sample data from limited sections. In such cases, it is notable that spatial random structure is estimated based on probability. In the prediction of geological conditions ahead of the tunnel face using the geostatistical methods, two distribution maps are created: one is a rock property distribution map by Kriging, and the other is a probability map, which describes a probability of rock property exceeding a certain threshold by the Sequential Indicator Simulation (SIS). The procedure is shown below:

(i) To estimate spatial property (spatial structure) of the target physical values from a mean value, variance and covariance showing spatial random

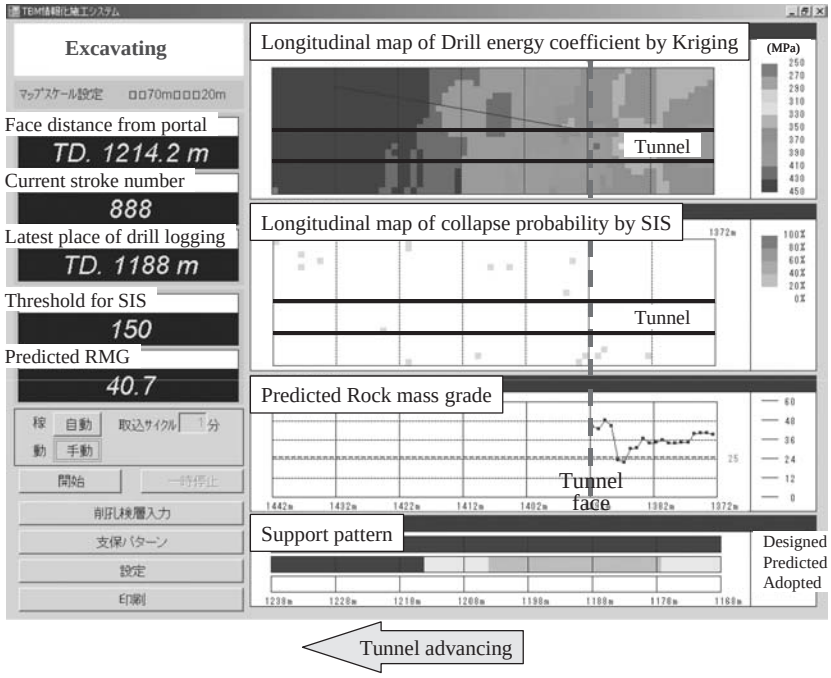

Figure 7. Monitor display of the TBM risk management system.

structure of observation values, and create a random field model (Calculating Variograms).

(ii) To estimate values at somes point with no observation values as linear sums of the observation values, using a modeled spatial structure (Kriging).

(iii) To use an estimated value for a point with no observation value as an observation value (as a known value) in sequentially estimating the next value, and develop an estimation map.

(iv) To develop a number of estimation maps by changing the order of estimation points based on random numbers, and evaluate and output the probability of an estimated value at each point (SIS).

3.3 *Observational construction using this system*

Figure 7 shows a screenshot. On the left side of the screen, the basic status of TBM is displayed, such as the present position of the face and a stroke number, whereas on the right, the results of comprehensive geological evaluation are shown. These indications can be analyzed and updated at every stroke of excavation (every 1.0 to 1.5 meters) with one click. In such a way, the geological evaluation using various data and geostatistical methods can be conducted easily at a site, enabling observational construction to be promptly implemented.

The window at the top shows the drill energy coefficient map by Kriging. Based on drill logging and TBM excavation data, drill energy coefficient is mapped using Kriging to show ground conditions ahead of and surrounding the tunnel face.

The window under that shows the probability map of collapse occurring by SIS. This is useful to estimate the probability of collapse occurring and to show particularly risky place. At this project site, the probability of a drill energy coefficient of 150 J/cm^3 or below is mapped using SIS.

The window under that shows the predicted rock mass grade as a graph. It is obtained by substituting a drill energy coefficient and TBM driving data into the Equation 1.

The window at the bottom shows the support patterns. It is possible to display a designed tunnel support pattern, a predicted one based on a predicted rock mass grade and the adopted one.

4 RESULTS OF APPLICATION TO THE ACTUAL CONSTRUCTION

Figure 8 shows the application results of the new TBM risk management system to 3,320 m to 3,370 m from the portal. A longitudinal geological profile based on the observation is shown at the top, followed by a comparative graph of the designed and adopted tunnel support patterns. Below this graph, a drill energy coefficient map, a probability map of collapse occurring,

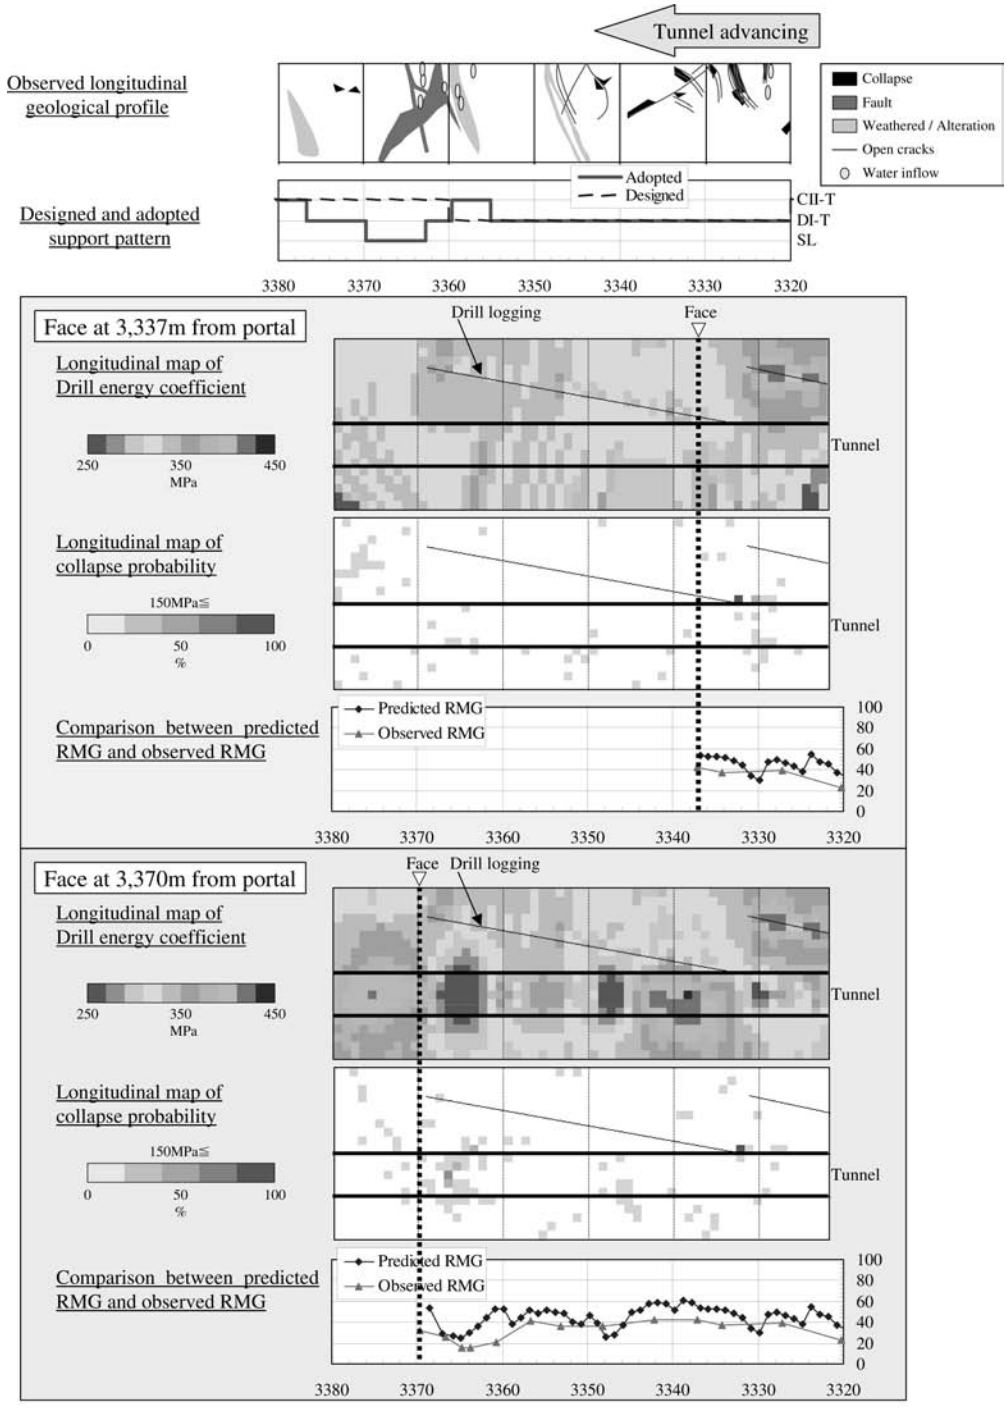

Figure 8. Application results of the new TBM risk management system.

and a comparative graph of the predicted and observed rock mass grade output from this system when the tunnel face was at 3,337 m are shown as the initial value; then, similar graphs for 3,370 m are shown as the final results.

It is clearly shown by these maps and graphs with the progress of the excavation that the distribution of low drill energy coefficient, high probability of collapse occurring and low predicted rock mass grade are around 3,348 m, where a weathered or altered layer exists, and around 3,365 m, where much amount of weathered granite falling off was observed. Because the probability map of collapse showed that the blocks with high probability of collapse accumulated around 3,363 m, it became possible to change the tunnel support pattern to the steel liner. Thus, a probability map, in particular, could largely contribute to the risk management against collapse, by changing the tunnel support patterns or examining the auxiliary methods.

Although the predicted rock mass grade fluctuates more frequently than the observational one, the former almost correspond to the latter on the whole. The rock mass grade at the tunnel face that cannot be observed can be estimated in advance, making it possible to decide the tunnel support pattern before the TBM roof passes.

Moreover, these analytical results will provide important data for confirming whether or not the construction on the ground with severe geological changes has been implemented appropriately, too much, or not enough.

5 CONCLUSION

In this paper, the outline of the new TBM risk management system is given in the beginning; that is, this system introduces a multivariate analysis and the geostatistical methods to visualize the geological conditions ahead of the tunnel face in real time using TBM driving data, drill logging data, and rock mass grade, then feedbacks the geological conditions to the next excavation. Then, this system was installed on the TBM used for the excavation of the Miyazu No. 12 Tunnel, and the results of application to the actual construction were examined. As a result, the following points are validated: (1) The rock mass grade at the tunnel face that cannot be observed visually can be estimated with high precision, (2) The geological conditions ahead of the tunnel face can be estimated as a rock property map with high precision, and (3) The blocks where collapse is likely to occur can be predicted from a probability map. Thus, this system has been proved to be a geological evaluation system that largely contributes to the implementation of the reasonable TBM construction method. Moreover, it can also provide important data to verify after the construction whether the adopted tunnel support pattern is appropriate, too much, or not enough for the actual ground.

In the future, we aim to make this system more sophisticated by analyzing data again more precisely. Furthermore, by applying the geostatistical methods to the main tunnel construction of this project, we hope to establish this system as a risk management system for the main tunnel accompanied by an evacuation tunnel.

ABSTRACT: Excavation of tunnel in Japan recently faces a lot of difficult conditions such that very complex geology, interaction with adjacent structures and groundwater problems in relation to environmental impact. In addition, the large amount of groundwater that happens in the tunnel construction is an important problem of the tunnel construction. That is, Groundwater is one of the important risks in the tunnel construction. Moreover, the risk evaluation technology that is related to groundwater is an indispensable technology to construct the tunnel of the economy and the high quality. This paper describes a new evaluation method executed in the mountains tunnel intended to carry out construction with higher reliability, including methodology of risk evaluation method that is related to groundwater.

1 INTRODUCTION

Groundwater poses problems for the construction of mountain tunnels in that measures to prevent or control face collapse and tunnel drainage are needed due to the large quantities of water inflow that result from the discontinuous nature of the ground. Groundwater problems in the surrounding environment include the chain reaction of damage to the surrounding water environment that occurs due to the drainage of groundwater and the impacts of groundwater on existing water resources. There have been many cases in which such problems have inevitably led to enormous cost overruns and missed deadlines. Numerical analysis has been a primary method to evaluate such groundwater problems, but it requires the time and effort of preparing ground models of a certain scale and processing the data. For this reason, in almost all cases, the evaluation of groundwater problems has relied on preliminary evaluation throughout, and reverse or verification analysis rarely been performed during the construction. Moreover, even with current analysis tools it is difficult to conduct impact evaluations that reflect the preceding excavation data. This study proposes a new observational system for mountain tunnel construction, the Simplified Seepage Analysis System ("SWING"), which enables streamlined construction with risk evaluation for cost fluctuations while at the same time considering measures to deal with groundwater problems.

2 DEVELOPMENT OF THE SWING SYSTEM

Groundwater poses problems for tunnel construction in that measures to prevent or control face collapse and tunnel drainage are needed to deal with large quantities of water inflow, as well as measures to ensure safety during the construction process. The damage to the surrounding water environment due to groundwater drainage and the impacts on existing water resources of a drop in the groundwater level also pose problems in the surrounding environment, and conservation of the natural environment is an important issue for tunnel construction.

Groundwater analysis has been used to evaluate such groundwater-related problems. However, existing groundwater analysis methods require the preparation of ground models of a certain scale, and even with the improved calculation performance, analysis and data processing are still both time-consuming and labor-intensive. As a result, unlike deformation analysis, groundwater analysis has rarely taken the form of reverse or verification analysis based on preceding data collected during actual tunnel excavation work, and thus has conventionally been performed as

preliminary analysis in almost all cases. As such, it is difficult even using current analysis tools to conduct, in accordance with the progress of tunnel excavation, an impact evaluation that reflects preceding data gathered during the construction process. Given this, a new evaluation system called the Simplified Seepage Analysis System (SWING) is proposed here, which is easy to use and is capable of making accurate predictions for the conservation of water environments in the area around tunnels and groundwater problems in tunnel work.

This paper presents an overview of the SWING system, which has been developed to enable economical, streamlined tunnel construction while considering hydrologic systems, as well as the development of related analysis methods and evaluation techniques. The tunnel used as a case study for analysis here was running under a water system inhabited by rare hydrophilic species and waterfalls that are tourist attractions, which required environmental conservation considerations. Behind the development of the SWING system, there was the need for development of a groundwater analysis method that satisfied the following basic principles of dealing with water inflow during construction and the impacts on the surrounding water environment.

3 HYDROLOGICAL BALANCE ANALYSIS MODEL IN THE CROSS-SECTIONAL DIRECTION USING THE SWING SYSTEM

The SWING system is not a numerical analysis method using a ground model, as represented by seepage flow analysis or the modified tank model. Based on the water inflow incurred by actual tunnel excavation, modeling is conducted with a unit slice volume of 50 meters in the excavation advance direction, and a hydraulic equation is applied within this slice volume to determine the coefficient of permeability and the effective porosity. Furthermore, based on the hydraulic constant determined from preceding data, the range and volume of the drop in groundwater level and the drop in the quantity of marsh water are determined for the slice volume. Then, during tunnel construction, it is used to validate the results of predictions made against site measurements (marsh water flow and groundwater level) and the current impact of droughts.

In the case of this study, the pre-construction input values consisted of the seismic velocity in the tunnel longitudinal direction, the specific resistance, and other results of physical exploration which were used to determine the hydrological categories in the tunnel longitudinal direction. The SWING system was used to make predictions based on these initial settings. As the construction progressed, the excavated sections were reviewed based on the preceding construction data, and continued estimates of the as-yet-excavated sections were made. In the case study here, identification of the excavated sections and predictive evaluation for the as-yet-excavated section (with respect to the tunnel water inflow, the range of the drop in the groundwater level, and the marsh water reduction) was done in about 2–3 hours, including correction of the input data. In some cases, the results of drain boring at the face were retrieved rapidly and determination of the quantity of water inflow during the main shaft excavation and predictions of the effect of the accompanying drought were done instantaneously. The equations used to assess the hydrological balance elements in the SWING system are shown below.

3.1 *Assessment of tunnel water inflow and drop in groundwater level*

The one-dimensional unsteady flow shown in Figure 1 was considered in order to determine the basic nature of tunnel water inflow accompanying excavation and the mechanism of groundwater flow in the event that water inflow is produced. In short, it was assumed that a tunnel with a sufficiently small diameter with respect to the ground size had been constructed within an aquifer above horizontal impermeable ground. With the passage of time following excavation, the groundwater level for which the initial water level H is constant drops gradually starting from directly above the tunnel. At this time, the groundwater flow is a two-dimensional unsteady flow. In the SWING system, this is replaced with Dupuit's quasi-uniform flow analysis. Other methods that take the similar approach as the SWING system in which groundwater during tunnel excavation is analyzed using a slice coordinate system include the methods proposed by Nishigaki et al[1)] and by Sato et al[2)]. As shown in Figure 1, assuming that the groundwater level in the aquifer accompanying rainfall seepage ε is level for an initial value of $t = 0$, the groundwater level at $t = 0$ can be derived from Dupuit's quasi-uniform flow equation. Thus, the tunnel water inflow quantity q(t) considering time-history is given by Equation (1).

$$q(t) = \frac{k(H_0^{\,2} - h_0^{\,2})}{2\left[\frac{k(H_0^{\,2} - h_0^{\,2})}{2\varepsilon}\left\{1 - e^{-6\varepsilon t / \lambda e(H_0 - h_0)}\right\}\right]^{\frac{1}{2}}} \quad (1)$$

where, ε: Rainfall seepage, K: Permeability, H_0,h_0: Groundwater head, q(t): Water inflow per unit of length, R(t): Length of section in which groundwater level has dropped, h(x,t): Water level at arbitrary point, λe: Effective porosity. This enables the characteristics of the reduction in tunnel water inflow quantity within each slice volume to be calculated. However, here it is necessary to take into consideration the rainfall seepage ε as a hydrological cycle element.

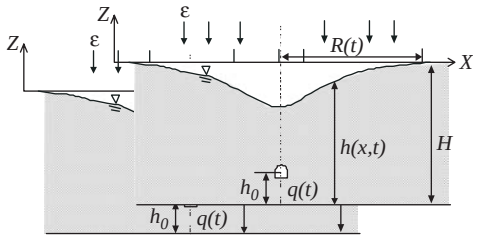

Figure 1. Flow of groundwater accompanying tunnel water inflow.

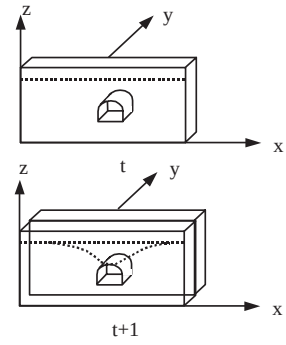
Here, a rainfall seepage value that matches the amount of rainfall is adopted, using the critical storage height at the surface and a one-dimensional tank model that recreates the Horton's uniform flow. This value is determined for each tunnel excavation slice, and the tunnel excavation distance is calculated successively as a time-history parameter. Naturally, the tunnel water inflow within existing work sections continues to decline over time. The accumulated quantity of water in each slice volume is the amount of water inflow at the tunnel entrance.

In addition, the degree and range of the drop in groundwater level will increase along with the amount of tunnel water inflow, but these values can be determined for each slice volume using the hydraulic equation shown in Eq. (1). Tunnel water inflow is closely related to the geological conditions and the groundwater in the surrounding ground, and fluctuations in tunnel water inflow over time and rainfall response constitute extremely important information regarding ground conditions.

In addition, because face water inflow gushes out from the face at the front of the excavated section and the surrounding uncovered sections, it will usually fluctuate in sequence with the progress of the construction.

3.2 *Evaluation of impacts on surface water*

This section will show the procedure used in the SWING system to assess the impact on surface water. The base flow in the valley topography shown in Figure 3 will be considered. Because "base flow" is normally synonymous with groundwater runoff in the river basin, based on the shape of the valley topography, the base flow component of surface water can be approximated using a hydraulic equation for impenetrable wells and open channels. Accordingly, the drop in groundwater level caused by tunnel excavation can be substituted with the drop in groundwater level in the river basin, and that reduction can be used to assess the decrease in base flow. In other words, in this procedure the average drop in groundwater level is calculated based on the drop in groundwater level within the river basin, followed by the calculation of decrease in base



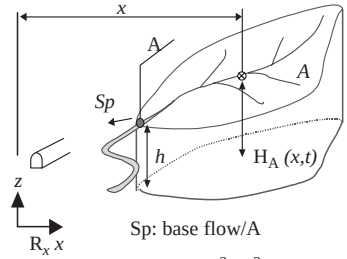


Figure 2. Cumulative unit slice volume accompanying progress in tunnel excavation.

$$Sp(t) = \frac{\pi K (H_A^2 - h^2)}{Ln(R/r)} \cdot \frac{\theta}{360} \cdot \frac{1}{A}$$

R: Width of river basin
r: Width of river channel
θ: River basin angle of aperture
A: Area of river basin

Figure 3. Assessment of effect on surface water.

flow for an arbitrary river basin. Surface water fluctuates considerably along with rainfall, and the impact on base flow will be different from the flow of surface water observed directly in site surveys. Given this, tank models for each flow monitoring site are linked and the fluctuations in flow are determined from the original surface water hydrograph accompanying the reduction in base flow. Figure 3 shows the hydraulic equations for each hydrological cycle element used in the SWING system. The figure shows the equations used to assess the water inflow mode and the drop in groundwater level in the slice volumes for the increased tunnel progress length, as well as the drop in groundwater level at an arbitrary point and the marsh water impact.

4 EVALUATION OF CONSTRUCTION COSTS NEEDED FOR GROUND RISK AS DETERMINED USING THE SWING SYSTEM

This section deals with the additional study of ground risk, which is defined as the anticipated loss (the

probability of occurrence multiplied by losses due to preventive measures) for events that are assumed to cause groundwater-related damage, based on the statistical models considering the uncertainty of ground during tunnel excavation and the remedial work cost by incorporating ease of use, one of the SWING system's characteristics, and its impact evaluation technique. Ground risk incurred by tunnel excavation includes construction-related risks (such as face collapse and unexpected water inflow gushing out during construction) as well as the impact on the surrounding water environment. However, this evaluation will focus on the risks to the surrounding water environment as a result of tunnel excavation.

4.1 *Assessment of tunnel water inflow quantity and drought impact using the SWING system*

The tunnel boundary conditions were applied to the aforementioned analysis conditions and an assessment was conducted of the quantity of water inflow expected to be produced inside the tunnel, as well as the drop in groundwater level and the reduction of marsh water. As was mentioned earlier, all of the water inflow produced in the tunnel is the result of physical properties in the tunnel longitudinal direction, and the values are calculated for each slice volume using the SWING system. With regard to the prediction of specific water inflow quantity and impact estimates, assume that the number of Monte Carlo simulations is noted as N and a permeability distribution in the tunnel longitudinal direction is created for each realization. In this case, a tunnel water inflow quantity and degree of impact will be calculated for each realization using the SWING system. Estimates of water inflow quantity, groundwater level and marsh water reduction that are in accordance with N will also be assessed.

4.2 *Risk of cost fluctuations for measures to deal with water inflow and droughts*

Based on existing references and interviews with specialists with regard to the control of and countermeasure against water inflow to deal with the quantity of water inflow, the cost Ci of water inflow and drought measures with respect to the results of analysis of realization i are assessed from countermeasure scenarios for the drop in groundwater level and the reduction in marsh water and the relationship between the degree of impact and the quantity of water inflow for realization number i. Therefore, the cost of water inflow and drought measures that indicate the estimation method will be discrete probabilities derived from the Monte Carlo simulations. Accordingly, a risk curve is used with an evaluation of costs in which the vertical axis is the exceedance probability and the horizontal axis is the cost of water inflow and drought measures. The risk curve is used primarily in the fields of finance and engineering to evaluate the uncertainty of income (loss) from the relationship between income and exceedance probability. The main characteristic of the risk curve is the advantage of being able to visually judge income (loss) in accordance with exceedance probability.

4.3 *Case study*

This section will present a case study using the SWING system. Here, as shown in Figure 4 , there is an important marsh water river basin directly above the tunnel route, and the need to preserve the amount of water in this river basin is a prerequisite for the tunnel excavation. Figure 5 shows the permeability model in the tunnel longitudinal direction. Table 1 shows the scenarios for countermeasures to deal with the reduction in marsh water, based on existing references and interviews with specialists[3)]. The specific scenarios for countermeasures are to provide additional wells if the impact is slight; if the impact is considerable, it will not be possible to preserve the quantity of water through the placement of new wells alone, and in such cases tunnel water inflow will have to be used, and addition of catchment pits inside the tunnel shaft and application of high pump head pump-up will be needed.

Monte Carlo simulations were conducted 50 times and the values were assessed using the marsh water reduction histogram shown in Figure 6. In addition, by applying the countermeasures scenarios shown in Table 1 in accordance with the reduction in marsh water, the cost of drought measures needed to preserve the water quantity can be assessed for each realization. Figure 7 shows the risk-curve indicating the relationship between exceedance probability and the cost of countermeasures.

5 CONCLUSIONS

The objective of this study was to develop a method for quantitatively evaluating the risk of cost fluctuations with regard to the control of water inflow and drought incurred by tunnel excavation. The findings of the study can be summarized as follows.

(a) A method of quantitatively evaluate the cost of water inflow and drought measures in ground of highly uncertain nature using a risk curve has been developed. Through introduction of the financial engineering theory, risks can be proposed as one of decision-making factors even when the owner is outside the civil engineering discipline.

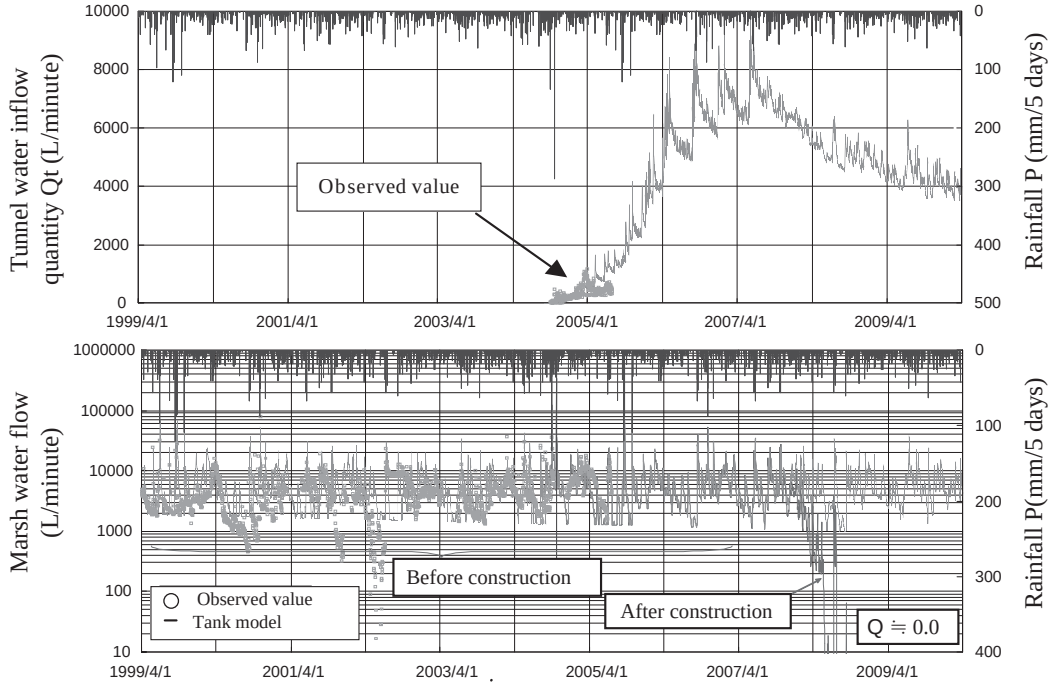

Figure 4. Prediction of tunnel water inflow and fluctuations in surface water as determined using the SWING system.

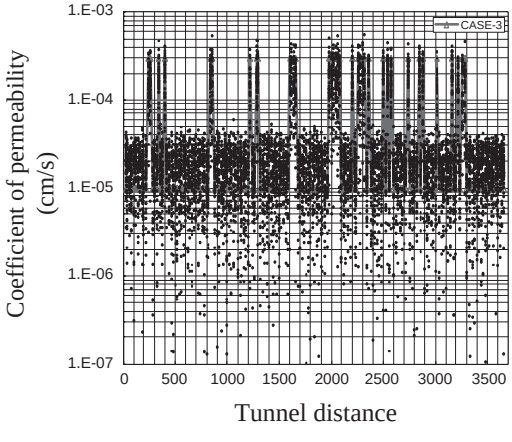

Figure 5. Prediction of tunnel water inflow and fluctuations in surface water as determined using the SWING system.

(b) It was shown that the uncertainty of preliminary surveys could be expressed in the cost dimension by means of the risk of cost fluctuations for water inflow and drought measures. Moreover, it is anticipated that the ease of use of the SWING system will make it possible to express in the cost dimension the tunnel excavation results and, in the event that additional surveys are implemented, the incentives

Table 1. Drought measures scenario.

Impact (m^3/min)	Conservation measure	Cost (JPY)
0.0–0.5	No measures	0
0.5–1.0	Add new well (one location)	98 million
1.0–3.0	Add new wells (three locations)	150 million

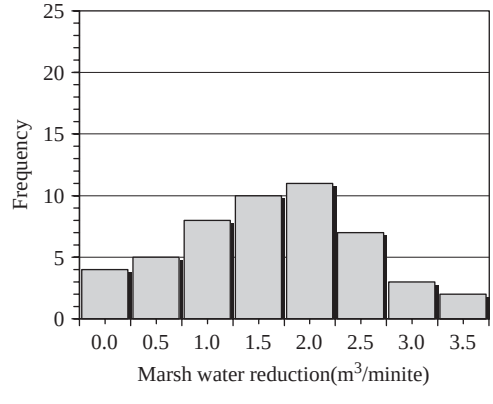

Figure 6. The marsh water reduction histogram.

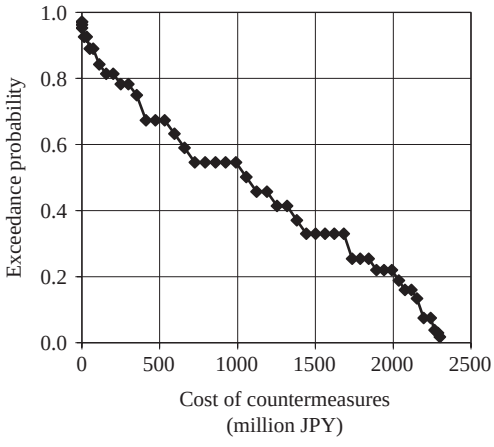

Figure 7. The risk curve indicating the relationship between exceedance probability and the cost of countermeasures.

for conducting the survey in terms of the reduction of cost fluctuation risk.

(c) Introduction of financial engineering theory makes it possible to propose risk evaluation as one of the tools in the decision-making process even the project personnel are outside the civil engineering discipline. For example, one example of specific decision-making using these risk evaluation techniques is expected to be the expression, in the dimension of the cost of water inflow and drought measures, of the value of reducing the uncertainty of the ground from the standpoint of computerized construction that takes into consideration preliminary surveys and the results during the construction process.

Driving of shallow tunnel in uncertain geological boundary conditions – A case history

R. Pöttler, F. Thum & W. Jöbstl
Feldkreuzstraße, Innsbruck, Austria

ABSTRACT: In the course of the new Nuremberg – Ingolstadt high-speed railway line, the 7-km long Irlahüll Tunnel was driven mainly through karstified chalk marl. In the southern section of the tunnel the chalk marl is covered by Tertiary. For a length of about 500 m the tunnel traverses a transition zone of chalk marl, weathered chalk marl and Tertiary. The tunnel was constructed according to the principles of NATM with heading, bench and invert. Between tunnel metre 300 and 400 of the southern section the deformation in the heading did not cease and exceeded the predicted values considerably. To prevent a total collapse of the tunnel, additional measures had to be carried out. After the shotcrete invert had been placed, the work on site was stopped for about 1.5 years. One year after the construction works had been stopped, cracks occurred in the invert and additional settlements occurred. The settlements could only be stopped when the tunnel was partly refilled with material and the shotcrete lining of the heading was supported by wooden columns. Extensive numerical calculations were performed, aiming at detecting the reason for this failure. 12 different possible scenarios with different numerical methods and models were investigated to define the reason for the failure and thus to be able to design the inner lining in an optimum manner. The outcome of the investigation was that none of the investigated scenarios was the reason for the failure. Therefore the dimensioning of the inner lining was done in a very conservative way.

1 PROJECT AND GEOLOGIE

The Irlahüll Tunnel, connecting with its length of 7260 m the Altmühl valley and the plateau of the southern "Fränkische Alb", is part of the new Nuremberg-Ingolstadt high-speed railway line. The tunnel was planned according to NATM principles, with heading, bench and invert. Between shotcrete lining and cast-in place inner lining a waterproofing membrane was installed. A drainage system prevents any water pressure from acting on the lining. The inner lining has to take over the loads resulting from the traffic in the tunnel, the loads of the electrical–mechanical installations of tunnel and of the deterioration of shotcrete, as well as the loads of the primary shotcrete lining and of the anchors which will corrode with time.

The tunnel was driven mainly through karstified chalk marl. In the southern section of the tunnel the chalk marl is covered by Tertiary. The prognoses of the geological situation were done based on the well known geological mapping and additional drillings spaced over the course of the tunnel.

In this southern section discussed, the tunnel traverses a transition zone of chalk marl, weathered chalk marl and Tertiary for a length of about 500 m. In that area the overburden is about 25 m thick. According to the prognosis, the interface was predicted to be monotonous, both in longitudinal and transverse direction. The foundation of the shotcrete lining of the heading was prognosed to be situated on rock mass.

Numerical analyses for verifying the stability of the tunnel were done prior to the construction based on the geotechnical report. The geotechnical parameters were verified and improved by back analyses. The main input parameters, for the finite element calculations, modulus of elasticity E, and the undrained parameters cohesion c_u and angle of friction ϕ_u could be determined quite well. Supervision of the tunnel drive was done by comparing and interpreting the geotechnical measurements on site with the calculated displacements.

2 EXCAVATION OF HEADING, BENCH AND INVERT

The FE model used for calculation is shown in Figure 1. The material law of Tertiary and of the rock mass is Drucker Prager. Differentiation in the chalk marl (TER1 to TER3) takes into account that the weathering of rock mass nearer to the surface was expected to be higher.

The thickness of the shotcrete lining was 280 mm. In addition to the lattice girders, anchors with a length

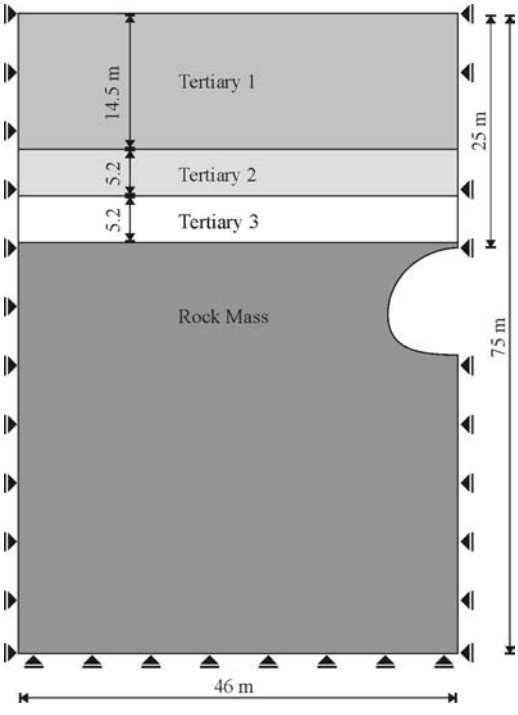

Figure 1. Numerical model for FE calculation.

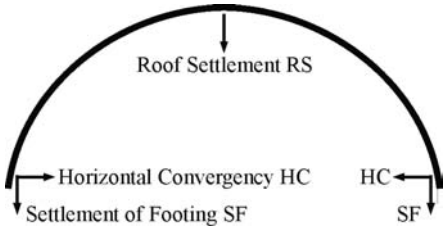

Figure 2. Observation of displacements.

of 6 m spaced every 2 m × 2 m were installed. For the excavation of the heading the following ranges of displacements were calculated (Figure 2):

- Roof settlement (RS) 45 mm–50 mm
- Horizontal convergence (HC) 10 mm
- Settlement of footing (SF) 25 mm–30 mm

As there was no prognosis on long-term behaviour of the ground it was expected that displacements due to tunnel drive would cease 1–2 tunnel-diameters behind the face. The normal force in the shotcrete lining was 2,1 MN/m, resulting in stresses of 3,5 MN/m^{2}in the footing of the lining. Although these stresses are well below the sustainable stresses of the rock mass, additional numerical analyses were performed to investigate the influence of an enlargement of the shotcrete lining at the footing ("elephant

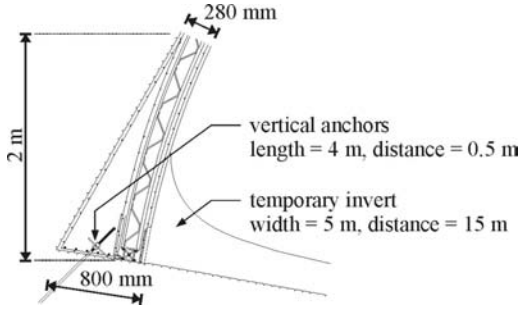

Figure 3. Additional support measures (elephant footing, vertical anchors).

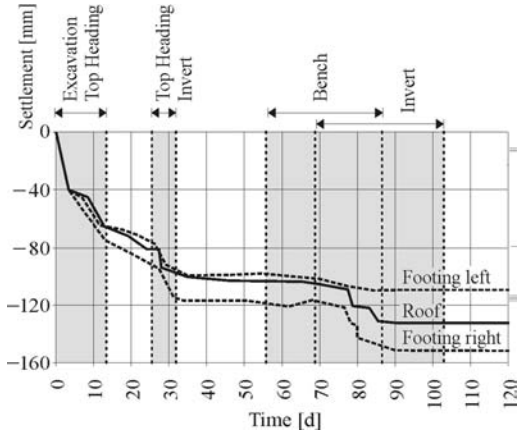

Figure 4. Measured displacements.

footings" – Figure 3) up to 800 mm to reduce the stresses in the footing of the heading.

Enlargement of the shotcrete lining at the footing had only minor influence on the stress-strain behaviour of the tunnel. The same investigation was done for the placement of additional vertical anchors at the footing. This additional support measure also had no major influence on the overall stability of the heading. Therefore there was no reason to carry out both support measures from an engineering point of view.

In the course of the tunnel driving, the measured displacements became bigger than the calculated displacements (Figure 4). This was mainly because the transition zone of Tertiary and rock mass was located lower than in the prognosis. Numerical analyses with reduced values for the geotechnical parameters resulted in higher allowable displacements.

For the excavation of the heading the following adapted ranges of displacements were calculated:

- Roof settlement (RS) 75 mm–85 mm
- Horizontal convergence (HC) −10 mm–60 mm (- .. divergence)
- Settlement of footing (SF) 65 mm–80 mm

As said before, it was assumed that the displacements would cease 1–2 tunnel-diameters behind the face. But the results of the measurements showed no abatement of displacements at that distance (Figure 4). As the geotechnical parameters of the weathered rock mass had been assumed to be almost the same as of the Tertiary, from a geotechnical point of view the ground behaviour could not be explained. Additional support measures had to be installed based on engineering judgement to prevent a collapse of the tunnel. In a 1st step these consisted of enlarging the shotcrete lining at the footing, in a 2nd step of installing vertical anchors at the basement and in a 3rd step a temporary invert of the heading, 5 m wide and at a distance of 15 m. The 1st and 2nd step did not have any influence on the deformation behaviour of the heading. Thus the numerical investigations done at the beginning, showing no major influence of these support measures, have been proved. Deformations only ceased after installing, a temporary invert arch in a 3rd step in the relevant section. Also, in the invert a shotcrete lining with a thickness of 250 mm was installed.

3 STOP OF CONSTRUCTION WORK – ADDITIONAL GROUND INVESTIGATIONS

After the shotcrete invert had been placed, the work on site was stopped for about 1.5 years. During this time additional ground investigations were performed in the karstified zones of the tunnel. Geological anomalies due to karst phenomena located in the vicinity of the tunnel, that may have an influence on the permanent stability and serviceability of tunnel for a service life of 100 years had to be detected. These investigations were done by geophysical measurements and drilling in an area of about 15 m around the tunnel (Pöttler 2004). So all in all, the geological and hydrogeological boundary conditions of the relevant surroundings were investigated in more detail than for any other tunnel.

Using these investigations, it was possible to generate a realistic geological 3D model. The 3D model of the area under discussion is shown in Figure 5. A major discrepancy between the geological model in the prognosis stage and reality is evident. A main discrepancy is that the weathered rock mass is not situated in the area of the heading but under the invert. The surface of the weathered rock mass is quite irregular both in longitudinal and transversal direction.

4 UNPREDICTED EVENT

During this period of no construction, regular inspections of the shotcrete lining were undertaken by the site management. One year after the construction works had been stopped, cracks appeared in the invert lining

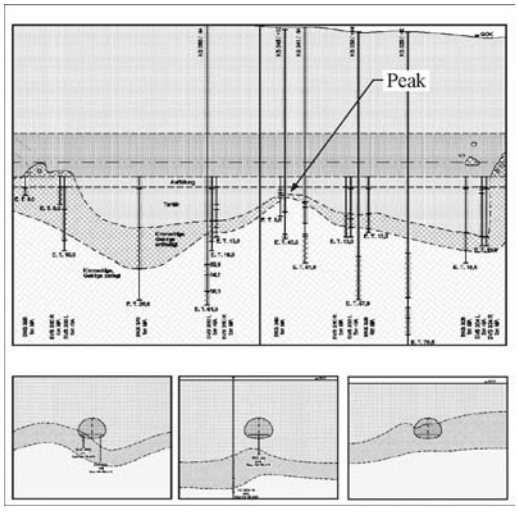

Figure 5. Geological situation in reality.

Figure 6. The wooden support.

and additional settlements occurred. The settlements could only be stopped when the tunnel was partly refilled with material and wooden columns placed to support the shotcrete lining of the heading (Figure 6). Due to the large settlements of up to 150 mm, the tunnel lining had to be reconstructed again to provide enough space for installing the inner lining. Additional drilling had been performed to get even more information on the ground in this area. The main questions to be answered were:

- What was the reason for the unpredicted restart of movements?
- What is the realistic load on the inner lining caused by shotcrete deterioration?

Different scenarios to explain the behaviour of the tunnel have been discussed:

Scenario 1: Change of location of geological strata: The tunnel is situated in Tertiary and the weathered rock mass is about 10 m below the invert. The reduced

Table 1. Comparison of numerical analyses and geotechnical measurements.

	RS [mm]	HC [mm]	SF [mm]
Numerical analysis	114	75	100
Measurements	125	80	125

values of the geotechnical parameters have been used for the numerical analyses. Taking account of the excavation sequence, the numerical analyses yielded the same results in terms of displacements which were measured (Table 1), therefore it could be assumed that the ground behaviour and the excavation process were modelled realistically.

But the numerical analyses showed no failure of the shotcrete lining in the invert section. The stresses in the shotcrete lining were considerably lower than the sustainable stresses. The actual location of the geological strata differed from the prognosis, but this could not be the reason for the unpredicted event.

Scenario 2: Influence of rock "peak": As can be seen from Figure 5, the weathered rock mass forms a peak in the vicinity of the area where the crack in the shotcrete lining appeared. This geological situation was also analysed, assuming a great difference in the stiffness behaviour between Tertiary and rock mass. The modulus of elasticity of the rock mass was assumed to be 300 MN/m^2. The influence of this rock "peak" on the stresses in the shotcrete lining was minor. No failure of shotcrete lining occurs.

Scenario 3: Influence of the rock "peak" and additional weathering of ground in the invert. It was assumed that the Tertiary under the shotcrete lining of the invert weathers due to water ingress from inside the tunnel, cohesion decreases to zero and the modulus of elasticity is considerably lower. This scenario is rather unrealistic as no water was in the tunnel and only a small wet zone of Tertiary of about 100 mm was detected when the shotcrete lining in the invert was replaced. The numerical analyses based on this model (Figure 7) showed that a failure of shotcrete lining would occur only if the weathered zone was very large.

Scenario 4: Influence of excavation procedure of the heading: The heading was driven without applying an enlarged footing of the shotcrete lining. Scenario 4 shows that because no enlarged footing was constructed, the amount of vertical displacement of the heading was so great that a loosening of the Tertiary at the crown occurred, resulting in the total load of overburden resting on the lining. The geotechnical parameters of the Tertiary have been proved and the numerical analyses based on these parameters made it possible to model the overall behaviour very realistically. These numerical analyses also showed that the influence of an enlargement of the footing of the lining has only minor influence on the behaviour and

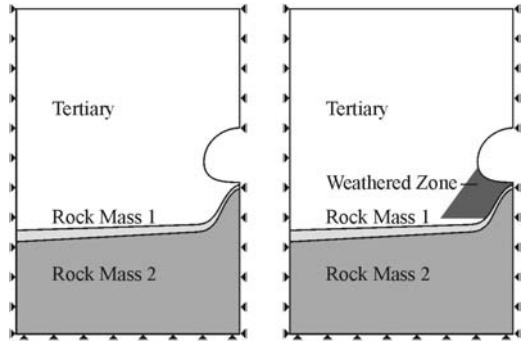

Figure 7. Numerical Model for FE calculations.

on the factor of safety. This was in addition proved by geotechnical measurements.

Scenario 5: Long-term behaviour of rock mass: The geological formation of the Tertiary and Chalk Marl does not show any aspects of creeping or swelling. The tunnel is situated well above the permanent groundwater level. No change in groundwater conditions occurred in the relevant period.

Scenario 6: Pore water pressure: The change of stresses and strains due to the excavation process also changes the pore water pressure and thus the effective stresses of the ground. In case of low permeability this process takes a long time. The permeability of the Tertiary is high so that this process, even if it had had occurred, would have taken only a few days. From this point of view, the change of pore water pressure as the reason for the unpredicted event can be excluded.

Twelve different possible scenarios with different numerical methods and models were investigated to ascertain the reason for the failure and thus to be able to answer the two questions above in a satisfactory manner. Some of these scenarios are more unrealistic than the one described, such as heave of the tunnel due to groundwater and change of temperature. But every scenario that was brought up by an involved expert was discussed. None of the investigated twelve geotechnical models could answer the question in a satisfactory manner. So the client and the engineer had to face the question of additional geotechnical and geological investigations. Both came to the conclusion that it was not possible to do more – neither in terms of extent nor accuracy – as had already been done.

5 SOLUTION

In the heading additional injection rock bolts were installed to support the shotcrete-lining during the time of removing the temporary support and constructing the inner lining. The transition zone of weathered chalk marl and Tertiary below the invert was grouted to homogeneous the basement of the tunnel.

Figure 8. Construction of the inner lining.

The dimension of the inner lining was done very conservative so that it could sustain the entire loads of overburden. The thickness of the lining is 550 mm, concrete grade B45 (DIN 1045) and reinforced by 23.2 cm^2/m on both sides. The arched invert-lining was replaced by massive monolithic blocks of about 400 m^3 of concrete, which had to be cooled while casting – sometimes even with nitrogen, depending on the weather situation – because of the high setting temperature. The wooden support of the heading and the filling of bench and invert were replaced step by step shortly before constructing each single block of the inner lining (Figure 8).

In summary, the discussion and investigation showed that a reason for the unpredicted event could not be identified, not even after a lot of additional numerical analyses and additional ground investigations.

6 CONCLUSION

The prognosis of the geological situation was done based on the well-known geological mapping and additional drillings spaced every 500 m over the course of the tunnel. After problems as described appear, "experts" may state that a greater number of ground investigations have to be carried out before tunnel driving. It goes without saying that the better the ground investigations are before the construction starts, the lower the risk of an unpredicted event is. The amount and quality of ground investigation representing the state of the art is found in the relevant standards. But even if the standard is met, like in the described case study, unpredicted events may occur. In this case study, the reason for the unpredicted event could not be defined in a proper way, although a far greater number of ground investigations were performed than ever done in a tunnelling project and although the geological situation was well known.

As numerical analyses were used to a great extent, and as there was time for a lot of discussion and meetings after the completion of the tunnel, at the end of the process one had to become aware that, for the present, the limit of understanding and numerical modelling has been reached. It becomes evident that tunnelling in such ground conditions can be done only by an experienced team. The numerical analyses are helpful but not the only tool for success.

There was no complete collapse of the tunnel and no loss of life. This section of the tunnel was expensive, but all in all economic with regard to other possible and realistic scenarios. This was thanks to the proper work done on site by the client, construction company, site supervision and designer.

Geotechnical risk management for tunneling beneath open water

D.P. Richards
Parsons Brinckerhoff, Portland OR, USA.

B. Nilsen
Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: Tunnel construction beneath open bodies of water presents certain types of risks not encountered when tunneling beneath "dry land". If major problems develop with tunnel equipment, ground control, or ground water control, construction personnel are exposed to risk of catastrophic flooding in the tunnel and recovery operations from the surface are generally not possible. Under these construction conditions, management of geotechnical risk during construction is of paramount importance. This paper addresses some of the more critical risks that must be considered and evaluated for such tunnel construction, starting with the planning process, and continuing through design and construction. Due to the increased difficulty and expense of geotechnical site exploration under water, the extent of the site investigation is sometimes decreased rather than increased, increasing the geotechnical uncertainty, requiring more detailed planning of construction methods and sequences, and appropriate redundancies and contingencies. The paper discusses the investingation, planning and construction processes for both soft ground and hard rock tunnels, and both conventional and machine excavation.

1 INTRODUCTION

The planning, design and construction of underground facilities beneath open water is always a challenge. In contrast to on-shore tunnel operations, when ground and/or ground water control problems are encountered, the physical constraint of no access from above for recovery operations when problems are encountered, introduces a higher degree of risk during construction, requiring an increase in the level of effort in the site investigation, design detailing and construction planning.

2 GEOTECHNICAL RISKS

Geotechnical risks are always a challenge in any tunnel project, and must be accounted for to minimize risk during construction, but for under water projects, the risks are often higher due to site investigation limitations and restrictions in addressing ground and ground water control problems during construction. Geotechnical risks that must be identified and accounted for in the investigation, design, and construction planning include:

- General profiling of the bottom surface
- Identification of low spots in the bottom profile
- Depth and character of sediments
- Variations in type and character of bedrock
- Location and extent of geological weaknesses
- Identification of rock structure patterns
- Characterization of the in-situ permeability

Potential risks associated with construction of hard rock subsea tunnels may be illustrated by the following examples from Norwegian projects (Blindheim et.al., 2005):

- The Bjorøy tunnel (1996), where a more than 10 m wide fault zone filled with clay, sand and coal fragments quite unexpectedly encountered. This was a zone of extremely high permeability and very poor stability, and a very time-consuming procedure involving stepwise grouting, drainage, spiling and shotcrete arches was necessary to tunnel through it.
- The North Cape tunnel (1999), where flat lying, broken sedimentary rocks caused very poor stability, resulting in slow progress and requiring shotcrete and concrete lining at the face. The difficult conditions were not realized from the pre-investigations due to the relatively high seismic velocity of the flat lying layers (4,500–5,500 m/sec).
- The Oslofjord tunnel (2000), where a deep cleft filled with Quaternary soil was encountered, necessitating ground freezing to tunnel through. A distinct weakness zone was detected prior to tunnelling. Despite very comprehensive pre-investigations

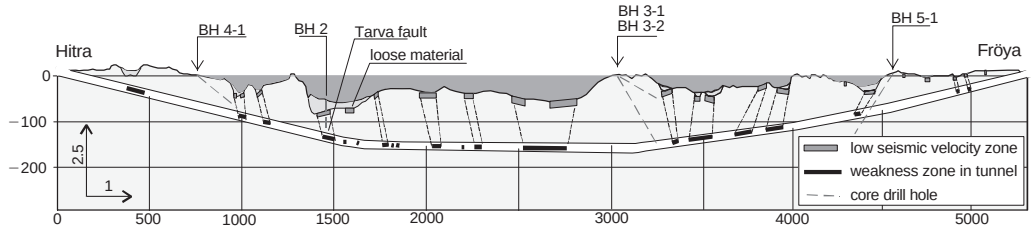

Figure 1. Longitudinal section illustrating low velocity/weakness zones in the Frøya tunnel (from Nilsen & Palmstrøm, 2001).

including traditional refraction seismics as well as directional core drilling and seismic tomography it was not found that the zone was eroded to a deep cleft. A by-pass tunnel was prepared to allow continued tunneling under the fjord. The soil filled section was frozen (at 120 m water pressure) and excavated through.

- At one of the most recent Norwegian projects, the Frøya sub sea tunnel, a pattern of very distinct, regional faults was identified by pre-construction investigations. Some of these faults could be followed over a distance of more than 200 km. Challenging ground conditions were documented, including high permeability zones as well as weakness zones containing very loose, sandy material and extremely active swelling clay. The locations of the main weakness zones are shown in Figure 1. In the planning of the Frøya tunnel, great benefit was gained from the previous construction of the nearby Hitra tunnel, where the major fault in the fjord was found to consist mainly of a mixture of heavily crushed rock and clay minerals (including swelling clay). The water seepage through the zone was minimal, and a combination of short blast rounds, spiling, steel fiber reinforced shotcrete, straps and conventional rock bolts, was used for getting through it.

The risks noted above for conventionally excavated drill and blast tunnels are similar for hard rock TBM tunnels, but they are sometimes more difficult to cope with using a TBM, due to limited access to the face for grouting or other ground improvement procedures, as well as problems in getting around a TBM if it becomes stuck. Aside from ground water inflows being a potential risk, other geological risks such as unanticipated faults or intrusions, either associated with an increase in fracture frequency, increases (or decreases) in rock strength, and increased abrasion also become more significant for a TBM excavation.

Significant risks for soft ground tunnels are mostly related to pressurized face TBM driven tunnels, since compressed air as a ground and/or ground water control technology is being replaced by improvements in soft ground TBM technology. Considering this though, there are still significant risks, mainly related to the presence of unanticipated ground conditions such as higher permeability, higher/lower cohesion, presence of boulders, buried obstruction, abandoned exploratory boreholes, extremely weak (or strong) materials, increased abrasiveness etc.

3 SITE INVESTIGATION AND PLANNING

3.1 *General*

A comprehensive site investigation is critical to the successful planning and execution of a tunnel beneath open water. Due to the additional expense and technical difficulties involved in off-shore drilling, vertical borings penetrating to tunnel level are often limited, and are often supplemented by directional drilling beneath the water, and by the use of marine geophysics. Geophysical techniques often considered for such off-shore investigations include:

- Hydrographic surveys: River, lake, or ocean floor bathymetric mapping
- Multibeam sonar: Multichannel hydrographic surveying that records a wide swath of data
- Sub-bottom sonar profiling: Detection of layering beneath the floors of rivers, lakes, or oceans
- Marine Seismic Reflection: Multichannel profiling of sediment and rock layering beneath the floors of rivers, lakes, or oceans
- Marine Seismic Refraction: For mapping of thickness and character of sediments, rock mass characterization and faults/weakness zones based on seismic velocity (see also Figure 1)
- Seismic tomography: Investigation of rock mass character between drill holes or between drill hole and sea floor
- Marine Magnetometry: For mapping of rock type boundaries and weathering
- Electrical Imaging: Two-dimensional (cross-sectional) imaging of sub-bottom electrical properties to detect and delineate sand, clay or gravel lenses, bedrock fractures – sensitive to water salinity.

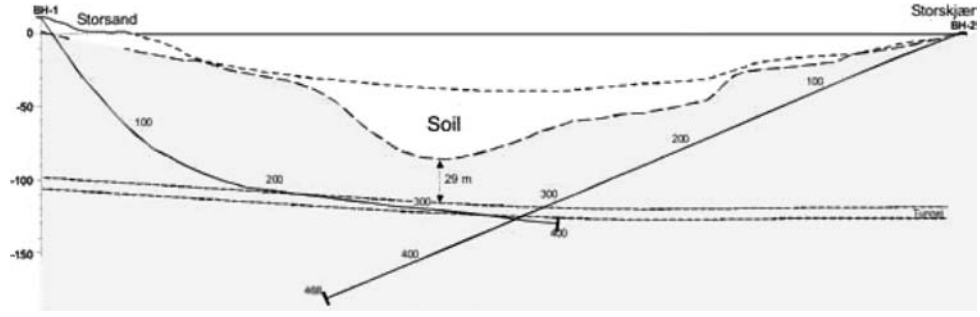

Figure 2. Conventional and directional core drilling at critical part of the Oslofjord tunnel (after Palmstrøm et.al., 2003).

In addition, conventional site investigation requirements are applicable, including sampling for determination of strength, weathering, mineralogy, deformation characteristics, porosity, abrasion potential, as required to make decisions with respect to applicable construction methods. For hard rock this would be a decision between tunnel boring machine and conventional excavation by drill and blast techniques. For soft ground, this would be a decision between types of pressurized closed face tunnel boring machines – slurry shield or EPB technology.

3.2 *Norwegian hard rock practice*

As a supplement to normal geological surveys, seismic investigations are crucial in the first stages. Acoustic profiling is first carried out for a large area to determine the most suitable corridor. Extensive refraction seismics is then carried out to select the best alignment and to provide information about soil deposits above the bedrock and about weakness (low velocity) zones in the bedrock. If possible, directional core drilling as illustrated in Figure 2 is used from shore to the critical deepest points of the alignment, which typically also could be the location of major fault zones. Core drilling from drilling ships has been applied in a few cases in Norway, when other drilling has not been feasible.

The costs for the site investigations for Norwegian sub sea tunnels typically amount to 3–7% of the construction costs. The established practice of site investigations has proven to be reliable, but exceptions have occurred as noted above.

Optimizing the minimum rock cover is crucial for safety as well as economy. Increased rock cover makes the tunnel unnecessarily long, representing extra construction costs and increased operating and traffic costs over the project's lifetime. Too little rock cover may cause severe stability problems, unacceptable work safety, heavy water ingress, and need for excessive grouting and high pumping costs.

A minimum rock cover of 50 m is basically required. A rock cover of less than 50 m can be accepted when detailed site investigations have demonstrated fair rock mass conditions (taking into account the typical occurrence of fault zones at the deepest point). This is left open to interpretation and rock cover less than 20 m has been used, but is then typically restricted to shallow waters and for good rock conditions.

3.3 *Hard rock TBM tunnels*

Investigation requirements for TBM tunnels in hard rock are similar to those for conventional excavation, since the risks are similar. However, as noted above, ground and/or ground water control problems are often more difficult to cope with for a TBM excavation, often making the understanding and reliability of geological conditions a bit more critical.

3.4 *Soft ground tunnels*

Soft ground tunnels passing beneath open water are usually relatively shallow. For example, transportation tunnels passing beneath rivers or shallow bays or channels usually have the depth restricted by the gradient of the approaches to the tunnel.

While site investigation practices for such soft ground tunnels are very similar to those identified above for hard rock tunnels, they must also include adequate material property characterization to allow informed decisions to be made with respect to soft ground TBM technology. The usual material property tests contributing to the ability to make these decisions include density, permeability, gradation, and plasticity.

For these applications, conventional sampling by both Standard Penetration Testing (SPT), and recovery of "undisturbed" samples are both commonly used, in addition to CPT (Cone Penetration Test). For such shallow soft ground applications in historic urban areas, it is often required to identify buried obstructions such as sunken ships and abandoned foundation piles, both of which can often be detected by geophysical techniques.

4 CONSTRUCTIONAL ASPECTS

4.1 *General*

It is during the construction planning phase, that final decisions must be made for the appropriate selection of means and methods of construction best suited to the subsurface geological conditions identified during the site investigation phase. These selected means and methods of construction must be an integral component of the risk management process, and must be chosen to best satisfy the intent of the mitigation measures for reducing risk exposure.

Key considerations in selecting construction means and methods for hard rock tunnels include:

- Rock types, distribution, and conditions
- Rock properties; strength, hardness, abrasiveness
- Discontinuity characteristics; frequency, orientations, continuity, roughness
- Major structural features; fault number, orientation, thickness, character

Key considerations in selection of construction means and methods for soft ground tunnels include:

- Thickness of overburden cover
- Soil type, layering, stiffness/relative density
- Soil properties; plasticity, gradation, permeability
- Hard inclusions; boulders, cemented zones
- Hydrostatic water pressure
- Ground water chemistry

4.2 *Hard rock conventional excavation tunnels*

The Norwegian hard rock sub sea tunnels have all been excavated by drilling and blasting. This method provides great flexibility and adaptability to varying rock mass conditions and is cost effective.

Systematic percussive probe drilling with the drilling jumbo is most critical for safety. By applying criteria related to inflow per probe hole on when to pre-grout, the remaining inflow can be controlled and adapted to preset quantities for economical pumping, which is normally 300 liters/min per km. Grouting against water pressures of 2∼3 MPa can be efficiently achieved with modern packers, pumps and grouting materials. Grouting pressures up to 10MPa are today quite common. Follow-up at the tunnel face by well qualified engineering geologists (and rock engineers) is of great importance.

In the Norwegian projects, all rock support structures are drained, whether they are made of cast-in-place concrete (mostly horseshoe) lining, sprayed concrete ribs or sprayed concrete. Sprayed concrete is dominantly applied as wet mix steel fiber reinforced. Extensive testing demonstrates that, if the thickness of the sprayed concrete is above a minimum of 60–70 mm, and the concrete quality is good (C45), corrosion of steel fibers is not a problem. Rock bolts have extensive corrosion protection. Rock support is always adjusted to the actual rock mass conditions, with heavy support applied only in very poor stability conditions. The use of spiling and shotcrete ribs has mostly replaced a concrete lining.

4.3 *Hard rock TBM tunnels*

Although numerous rock TBMs are operating around the world, many below the static ground water table, not all of these pass beneath open water. As with any rock TBM, good ground conditions usually allow good TBM excavation rates. However, as noted by McLearie et.al. (2001) for bored rock tunnels recently completed in Hong Kong, tunnel excavation success was largely dependent upon ground and ground water conditions, with intensely fractured zones (faults and dikes) often introducing large amounts of ground water infiltration, requiring extensive cut-off grouting before the TBM could progress, delaying the schedule and increasing the costs.

At the opposite end of the spectrum, was the Channel Tunnel, where ground conditions were ideal for TBM excavation in the relatively consistent chalks and chalk marls (Varley et.al., 1992 and Barthes et.al., 1994a). As noted by Barthes et.al., (1994b), although the chalks were relatively consistent on both sides of the channel, the French side was more faulted, with higher in-situ permeabilities, and these factors influenced the selection of TBMs as well as other means and methods of construction.

4.4 *Soft ground tunnels*

A fairly recent example of a large diameter soft ground tunnel excavated by a pressurized face TBM beneath open water, was the crossing beneath the Nile River by the Cairo Metro Line 2 bored tunnels in Egypt (Richards et.al., 1998). This was excavated by a 9.43 meter diameter slurry shield TBM in dense saturated sands and crossed two separate branches of the river. A subsurface profile is shown in Figure 3.

Prior to starting the tunnel bore beneath the river, a risk assessment was performed, addressing both design, construction, and long term performance issues. Based upon this risk assessment, a number of design issues were double checked to ensure adequate construction term and long term performance of the tunnel. This risk assessment was also used for construction planning, in which emergency response plans, contingency plans and appropriate redundant construction systems were identified and implemented.

Key issues identified to minimize risk while tunneling beneath the river included: maintenance of face stability, lining ring shape, ring position, reduce blowout risk, avoid bridge foundation, avoid TBM

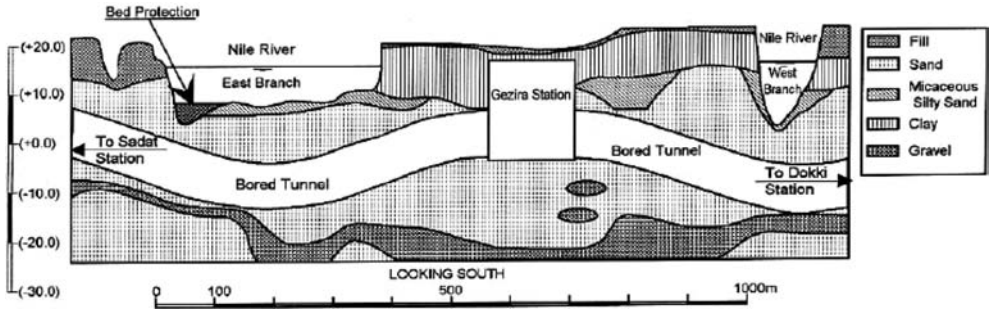

Figure 3. Nile crossing subsurface profile (Richards et.al., 1998).

break downs. Construction related contingency measures put into place to achieve these goals included: back-up electrical power, back-up compressed air supply, back-up locomotives, redundant slurry pumping equipment, extra reserve supply of bentonite, TBM improvement and/or modifications before passing beneath the river channel, and redundant communications between underground and topside personnel.

The tunnel beneath the river was completed in two separate tunnel drives, with continuous operation until the TBM had safely passed beneath the open water portion of the alignment. Both were completed without mishap, with no problems encountered which could not be handled by the contingency measures put into place prior to starting the excavation beneath the river.

5 RISK EVALUATION AND MANAGEMENT

To better control the complexity of underground projects, new codes and guidelines for design, modern quality systems and special methodologies for risk analyses have been introduced. Such tools provide a better basis for planning of investigation as well as construction and time/cost estimation.

The basic principle for determining the extent of investigation should always be related to the type and complexity of the project, and to the prevailing geological conditions.

A risk analysis may be divided into the following steps (Nilsen et.al., 1999; Pennington, et.al., 2006):

1. Identification of hazards and damage events
2. Assessment of probabilities for hazards and damage events identified
3. Description and valuation of consequences including analysis of initiating events
4. Calculation of pre-mitigation risk rating
5. Identification of appropriate mitigation measures for each risk
6. Calculation of post-mitigation risk rating

Within a project, risk analysis and quality control/assurance should be focused upon:

- Identifying and elimination or reducing hazards
- Reducing the probability of initiating events
- Finding barriers to stop damage events
- Reducing the consequence of possible damage
- Implementation of mitigation measures

The types of geotechnical risks to be considered include:

- Hard rock tunnels
  - Geology more complicated than anticipated
  - Weathering deeper than anticipated
  - Rock stronger or weaker than anticipated
  - More/wider fault zones than anticipated
  - Rock more fractured than anticipated
  - Rock more abrasive than anticipated
  - Rock mass (including fractured/faulted zones) permeability higher than anticipated
  - More voids (e.g. karst) than anticipated
- Soft ground tunnels
  - Bottom profile more irregular than anticipated
  - Sediments softer/harder or stiffer/denser than anticipated
  - Soils more granular /cohesive than anticipated
  - In-situ permeability greater than anticipated
  - Soil profile more irregular than anticipated
  - More boulders or inclusions than anticipated

Hazards and uncertainties are not only related to the soil or rock, but also with people involved in a project. A major task within risk analysis is to understand, describe and handle uncertainties. The Frøya sub sea tunnel case may be used to illustrate this. Here, the refraction seismic measurements showed more low velocity (weakness) zones than for any of the subsea tunnel previously constructed in Norway. In addition, the core drillings penetrated long sections of rocks with weakness zones having a higher degree of alteration than is normal in Norwegian hard rocks. The results

of the investigations indicated that the Frøya tunnel required thorough evaluations to assess its feasibility, and that special routines be implemented during planning and construction.

As a part of this, two groups were established to evaluate the feasibility of the tunnel. In their two independent reports excavation methods and rock support were analyzed, supported by a cost estimate and risk assessment. Construction time and cost estimates were based on a detailed prognosis of the expected ground conditions, and the estimate proved to correspond quite well with reality (Palmstrøm et.al, 2000).

6 DISCUSSION AND CONCLUSIONS

Tunneling beneath open water is usually more challenging them landside operation, often with a higher degree of uncertainty and risk. The following lessons of general relevancy for the planning of future projects are applicable.

- The extent of ground investigation and planning should always reflect the complexity of the geology, the type of project, and the degree of risk.
- Risk assessment should start in the planning phase and carry on in design and construction.
- The results from the investigations should be properly documented and their use in calculations and assessments shown.
- The geological setting and understanding of the tectonic are vital for all large tunnel projects.
- Ground investigations where the extent is based on bidding, may cause vital information to be lost, and should never be accepted.
- Sufficient time must be allocated for necessary investigations and testing.
- The ground investigations should continue through the entire construction period. Tunnel mapping and following up should be done by experienced engineering geologists representing owner as well as contractor.
- Risk analysis, assessment of uncertainties and development of mitigation measures are critical.
- The tender documents, including geological/ hydrological/hydrographic reports, should be thoroughly prepared, with full quality control.
- An independent reference committee should be established. For the construction period, strict requirements should be put on the engineer's and contractor's competency and qualifications.
- Planning and investigation should always carry risk assessment forward to the detailed design and construction phases, since residual risk remains, even after significant and relevant site investigations.

Impact of a geological incident on the construction of a land sewer outfall in Ferrol, northwest Spain

J. L. Sánchez Fernández

Road, Canal and Harbour Engineer, North of Spain Water Agency, Spain

ABSTRACT: The land sewer outfall tunnel in Ferrol is 7,344 metre long and has an excavated diameter of 3.70 metres. It forms part of a large scheme including four interventions to depurate and clean up the waters in the town of Ferrol. The total investment of the project is about 125 million euros. The excavation of the tunnel began at the end of August 2004, with an open face Robbins TBM 1215–265. The project required to go through the Cariño Fault, located between chainage 3 + 210 and chainage 3 + 400, spanning a length of approximately 200 metres. However, at the beginning of July 2005, a geological incident occurred at chainage 2 + 746.077, which led to halt the excavation of the tunnel until November 2005. This article describes the geological and geotechnical conditions in the area, as well as the technical solution used to carry on with the excavation of the tunnel. The effects of this geological incident are also analyzed, both from the contractual point of view and the time frame of the project.

1 BACKGROUND

Construction of La Malata-Cape Prioriño land outfall commenced at the end of August 2004. To bore the tunnel, an open face ROBBINS tunnel boring machine is used, model 1215–265.

The selection of excavation by TBM was based on the fact that the rock was predominantly granodiorite. The grain size is medium to fine, with feldspar mega crystals. In general, it can be considered very hard rock with a high quality index.

Nevertheless, the bedrock that the tunnel crosses includes a major fault, the Cariño Valley Fault, where substantial weathering process can be observed, with kaolinization and oxide zones associated with water. This fault will be crossed by the tunnel between chainages 3 + 210 and 3 + 400, as can be seen in the geological profile in Figure 1.

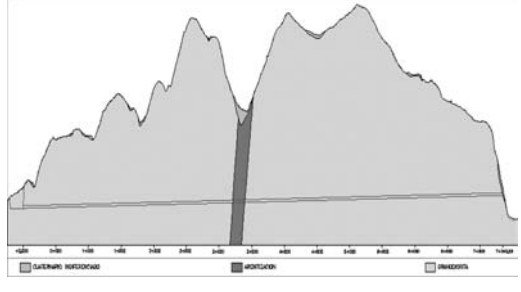

Figure 1. Geological profile.

2 WORK SCHEDULE

Tunnelling commenced at a slower pace than initially planned. This was partly due to the need to train the personnel to the tunnelling method and to delays in organizing continuous work shifts.

The achieved work advance can be seen in the next diagram.

As can be observed in Figure 2, the best monthly progress was achieved in April 2005, with advance of about 600 metres/month.

3 ENCOUNTERING A GEOLOGICAL INCIDENT

In early July 2005, tunnelling was seriously affected from chainage 2 + 746 by the presence, at the tunnel face, of some very fine porphyry dikes.

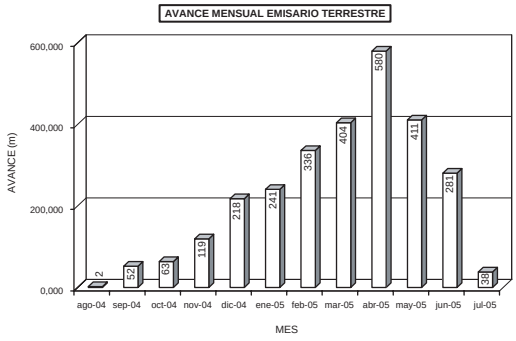

Figure 2. Achieved work advance.

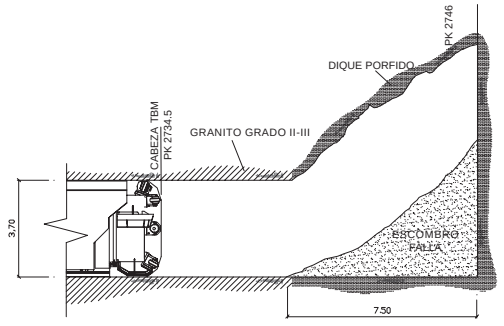

Figure 3. Overbreak height.

Figure 4. Overbreak.

The highy fractured material encountered and its poor geotechnical quality, together with substantial meteorization of the contact zone between the granodiorite and the porphyry and the presence of water, caused the tunnel face to become totally instable.

As a first option, it was decided to try to cross the area, performing short advances and installing TH-16.5 steel arches and Bernold sheets, immediately behind the TBM shield, given the own limitations of the TBM, which does not have special equipment to treat the face.

This progress option did not have good results, since the rotation of the cutterhead was often blocked and the TBM had to stop due to saturation of material on the conveyor belt.

Similarly, as a consequence of the poor stability of the face, the initial overbreak quickly became a big chimney.

Before that situation and with the objective of avoiding that overbreak worsened, it was decided to halt tunnelling with the TBM and to find out alternatives to be able to cross the area the earliest possible, by minimizing risks for the personnel and the TBM.

With the TBM method, access to the tunnel face is practically restricted, since it is limited to a manhole for the maintenance and change of disc cutters.

The manhole is a hole of approximately 60 centimetres, that is situated on the TBM cutterhead and can be accessed from the lower part of the conveyor belt. Such a restriction limits very much the possibilities of intervention to consolidate the face because nearly all the face is occupied by the cutterhead.

Faced with the impossibility to be able to access to the tunnel face to do any work, it was decided to try to fill the overbreak with concrete, by sealing the face and pumping concrete into the overbreak area. To do it, it was necessary to move the machine backwards, approximately six (6) metres.

Such an intervention could be achieved because in the area before where the geological incident occured, no support had been installed, thanks to the fact that the ground before the fault was of good quality. Had crews installed some type of support, then it would have been necessary to stabilize the area beforehand to be able afterwards to take the machine backwards, because placing supports behind the TBM shield reduces the inner diameter of the tunnel and it is therefore not possible to try to have the machine to move backwards.

Once the TBM could be moved to the back, a timber plug was installed at the tunnel face, that played the role of a formwork. That step was followed by the subsequent drilling of the face to install steel pipes to pour concrete into the overbreak. The mentioned overbreak can be seen in Figure 4.

It is important to stress that, since the tunnel has a small diameter (3.70 metres, outer diameter), the equipment and device limitations extremely restrict the implementation of efficient and rapid solutions. The concrete pump had to be placed in the California switch rail of the TBM (at approximately 235 metres from the face) and the steel pipes for concreting had to be carried through all the TBM back-up, then through the manhole to finally reach the face where was the overbreak.

The steel pipes were installed at approximately three (3) metres above the crown level, with the objective of

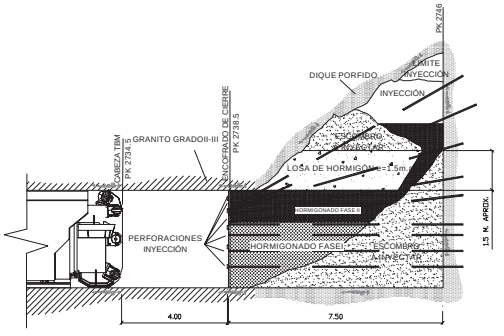

Figure 5. Alzado de la solución planteada.

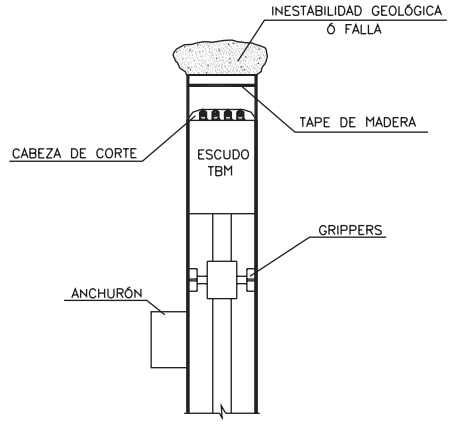

Figure 6. Construction of the lateral siding.

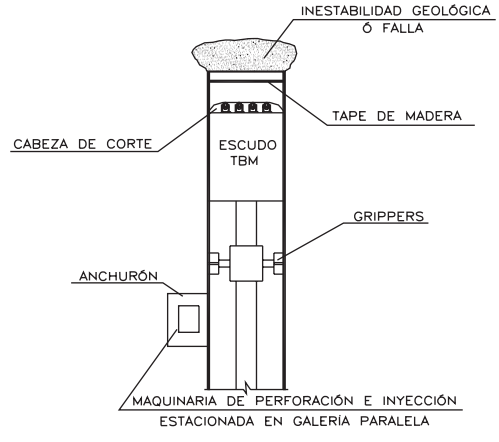

Figure 7. Placement of the TBM parts in the siding.

making sure that a concrete cushion would be poured on the tunnel vault in the overbreak area.

Altogether, 66 cubic metres of concrete has been pumped.

Once the concrete pouring operation ended, crews waited for the setting of the concrete. After that, they removed the timber formwork and reinstated the TBM at the face into its initial position to resume tunnelling.

It is also important to underline that the adopted solution, though it did not fully guarantee stability of the area, aimed at consolidating the ground to overcome the problem with the resources available at the site and reduce to the minimum the stoppage of tunnelling.

When tunnelling resumed, it was found that the alternative used did not overcome the problem since material continued to collapse from the crown and walls.

As an alternative solution to the geological instability, it was then decided to perform injections into the face and drill a canopy of steel pipes around the tunnel vault.

Such intervention, which was not chosen at the beginning to avoid a long stoppage of tunnelling works, required the use of equipment that was not available at the site and obliged to analyze how to bring them to the face to be able to do the reinforcement works.

To be able to bring the drill rig to the face ahead of the TBM cutterhead, two (2) alternatives were analyzed. The first consisted in boring a by-pass tunnel while the second consisted in building a siding in one of the tunnel walls.

For cost and time reasons, engineers decided to build the siding. Its construction, performed by means of hydraulic jack hammers, included a small lateral tunnel in one of the tunnel walls, approximately 2.50 metres in length and 2 metres deep. It was not possible to use the drill and blast method for lack of permit to use dynamite and also to avoid any damage to the TBM.

The siding was bored immediately after the grippers of the TBM since it is in that area that the largest room is available to manoeuvre the excavation equipment.

Once the siding was completed, the drilling equipment was placed in it further to its partial disassembly so that workers could carry the parts through the TBM back-up.

Once the drilling rig pieces were stored in the siding, the TBM was moved backwards to approximately 20 metres behind the face, far enough to place the cutterhead downstream the siding just built. It then was possible to reassemble the drill rig to proceed to the reinforcement works.

It is important to emphasize that during the backward movement of the TBM, it was necessary to take away the precast concrete segments placed on the floor by the machine as it progresses.

Once the teams finalised all the necessary handling prior to the reinforcement stage, they commenced to

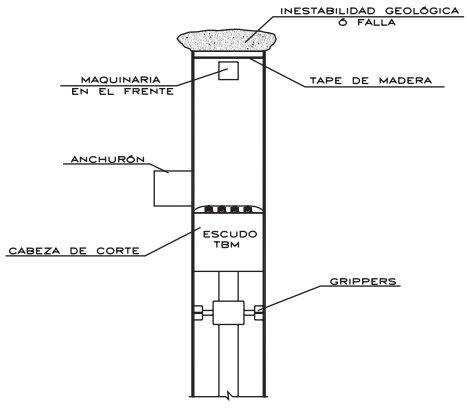

Figure 8. Access of the drilling rig to the face.

consolidate the subsoil collapsed from the vault at chainage 2 + 746.

The consolidation programme basically comprised the following phases:

3.1 *Concreting of the face*

Concreting was performed for the purpose of sealing the caved-in face and guaranteeing the confinement of the cement grout to be injected in the zone to be stabilised.

3.2 *Consolidation*

Given the heterogeneous materials that had to be grouted, shallow drilling was first carried out, then deeper drilling later on. In addition, the drilling time for all the drill holes was monitored, with the aim of trying to collect some information on the quality of the rock mass, according to the resistance to penetration of drilling rods.

The drilling and grouting process was started at the tunnel invert and continued up to the top heading, to try to guarantee the confinement of the rock to be treated.

Cement grout was first injected with a dosing of 1.25:1 and dosing even varied up to 1.5:1 according to the consumption observed on the spot.

The maximum grouting pressure applied by crews was 5 kg/cm^2.

Altogether, approximately 65 tonnes of cement was used for these reinforcements.

3.3 *Consolidation of the tunnel periphery*

As a final consolidation, project managers decided to install a canopy of approximately four (4) metres, concentric with the outer contour of the tunnel.

Figure 9. Drilling to reinforce the face.

This canopy was installed by tubes a manchettes (TaMs) and the grouting pressure utilized ranged from 10 to 20 kg/cm^2.

During that phase, approximately 26 tonnes of cement was injected.

3.4 *Forepoling*

When the injection process ended, the forepoling technique was implemented, consisting in the construction of a canopy (umbrella) of sub-horizontal steel beams. The implementation of the technique was decided to consolidate even more the tunnel crown.

The drilling diameter applied to form a supporting arc in the rockmass was 133 millimetres, with a space between each forepole piles of 15 centimetres.

The incline angle varied from 6 to 9 degrees.

The forepoles are formed by 114.3 × 6.3 mm steel pipes.

It is important to remember that, since the intervention with forepoles was applied inside the cross section excavated by the TBM, it was necessary that all the forepoles – in the first metres of the drive – be applied using plastic pipes, until the forepoles could be applied outside of the cross section excavated by the TBM, to avoid any damage to the disc cutters when the TBM was going to resume tunnelling.

Altogether, approximately 13 tonnes of cement has been injected in the steel pipes.

The length of the steel pipes drilled sub-horizontally ranges from 15 to 18.70 metres. These forepoling lengths were mainly conditioned by the capacity of the drill rig. Miners attempted to drill the longest holes possible to avoid having to drill another umbella vault after resumption of tunnelling, which would have obliged to move again the TBM backwards and bring back the drilling rig to the siding.

When the consolidation process ended, the drill rig was taken back to the siding and stored there. The TBM could therefore be moved forward to the tunnel face.

Once the TBM grippers had moved forward ahead of the siding, the drilling rig was taken out of the tunnel

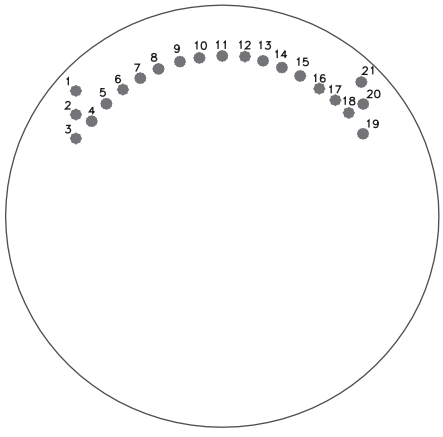

Figure 10. Location of the forepole piles.

Table 1. Summary of the reinforcement works.

Number of drills	Drilled metres	Kg injected
90	680.60	91,525

and tunnellers started preparatory works to cross the reinforced segment with the TBM.

Tunnelling resumed in early November 2005 very slowly, in order to evaluate the behaviour of the reinforced ground.

The zone disrupted by the geological incident had a length of approximately 15 metres. Beyond that zone, it was not necessary to do any additional work further to the reinforcements already achieved and tunnelling continued at normal pace.

In all, tunnelling was halted for four (4) months while reinforcement works were under way.

4 CONSEQUENCES

The occurrence of a geological incident of such a magnitude during construction of the tunnel has important consequences for the project, not only from the financial point of view and the time frame but also socially and politically.

The consequence of the fact that tunnelling has been halted for such a long time is that the project will be behind schedule.

From the social point of view, the project forms part of a complete programme that includes wastewater treatment and discharge facilities in Ferrol. The future wastewater treatment plant will be built in the area currently occupied by the tunnel worksite. Therefore, the fact that the targeted completion of the tunnel is behind schedule may greatly impact on the commencement of construction of the wastewater treatment plant.

Regarding the project time frame, the delay compels to carry out an in-depth analysis of what happened so far and find out mechanisms that restore the project within its initial schedule.

From the financial point of view, the consequences affect both the main contractor and the project owner (the North of Spain water agency). They are linked by contractual relationship that allows to determine the responsibilities for such events.

5 RECOMMENDATIONS

It is well known that tunnel construction entails great risks. The latest advances gained in recent years in tunnelling technology have considerably mitigated those risks. Nevertheless, there still are projects around the world affected by problems similar to the one described in this paper.

For that purpose, we consider it is convenient to do efforts to try to resolve such problems and keep the construction of tunnel projects with the budget and time frame determined during the design phase.

To reach that goal, we consider it is important to suggest the following recommendations:

- Contracts must include clauses that enable to share the risks incurred by the geology of a tunnel, above all for projects where unpredicted adverse geological conditions appear.
- Designers and public administrations must be aware that more investment is required during the initial geological investigation phases, which will contribute to reduce surprises during tunnelling.
- The process to choose a tunnelling method must be reinforced.
- It is necessary to include in the decision-making process all the persons and organizations linked to the project, by establishing real mechanisms of participation.

Sub-sea Microtunnel by Pipe Jacking Method – Construction challenges

Syed Shakil Ahmed
Assistant Construction Manager, Parsons Brinckerhoff (Middle East) Ltd.

Sam Alfaour
Construction Manager, Parsons Brinckerhoff (Middle East) Ltd.

Mohammad Al Ghanem
Project Manager, Parsons Brinckerhoff (Middle East) Ltd.

ABSTRACT: The paper describes the challenges faced during the construction of sub-sea microtunnel. The method of construction was pipe jacking and excavation was done by Tunnel Boring Machine (TBM). During jacking operation an abnormal point load condition to the section of the pipe string were observed creating obstacles to the jacking operation that required high jacking force and resulted in tension as well as compression cracks to the pipe. This paper explains the possible causes for the increase in jacking forces encountered during jacking operation and remedial works carried out to remove the obstacles. It also describes the steps taken to overcome this construction difficulties starting with the investigation conducted, risk assessment for restart of jacking operation after cracks occurred, and culminating in successful completion of the jacking drive.

1 INTRODUCTION

Two sub-sea microtunnels were recently constructed by a private developer in the Middle East region. The concept of microtunnel by pipe jacking method of 3.0 metre diameter precast concrete pipes at an elevation of −26 metre below sea level was a challenging task for designer, contractor and the project management team.

2 PROJECT DESCRIPTION

The construction of sub-sea microtunnels had numerous design and construction challenges. Al Naboodah Engineering Services (ANES) was awarded to design and build two microtunnels, one to the west and one to the east of the main arterial. The design of these tunnels was performed under the supervision of Dr. Mikhail Ryjevski of ANES. The design build contract in a fast track delivery within 16 months, consisted of installation of a 3.0 metre outside diameter tunnels, 750 and 675 metre in length, at an elevation of approximately −26.0 metre below sea level, in mainly sandstone ground conditions.

The west tunnel which was 750 metre long is the focus of this paper. The challenges faced by the developer, contractor, and project management team and risks associated with it during the jacking operation are discussed.

3 GROUND CONDITION

Based upon 14 exploratory bore holes drilled to 35 metre depth, the existing subsurface condition comprised of loose to very loose, to medium dense to dense, gray, silty fine to coarse sand from the existing ground (±4.0 metre) level up to 12 metre (fill material); underlain by weak to moderately weak, fine to medium grained calcareous sandstone, sandy siltstone, and conglomerate up to −35 metre depth.

4 MAJOR TUNNEL COMPONENTS

The major components of the microtunnel works were; launching and receiving shafts, precast concrete pipe, and TBM. The shafts were necessary to be constructed before commencing with the jacking operation to attain the required elevation of approximately −26 metre below sea level, to reach sandstone and maintain the required design profile of the tunnel. This section summarizes these three key components used for the construction of the microtunnel.

4.1 *Launching and receiving shafts*

The launching shaft was constructed on frond up to a depth of approximately −27 metre and having an

internal diameter of 12 metre. This shaft was used to lower the TBM to the bottom of the shaft.

Receiving shaft was constructed on the crescent side up to a depth of approximately −20 metre and having an internal diameter of 9 metre. This shaft was used to recover the TBM from the bottom of the shaft, after the completion of the drilling and pipe jacking operations. Each shaft was made of three main components: secant pile wall, base slab and capping beam.

Both shafts were constructed using secant pile method of shoring of 1.2 metre diameter piles. These piles were drilled to about 2 metre below the base slab level of the shafts. Initial design of the secant pile wall required excavation depth of toe level to −33 metre for the launching shaft, however to control seepage and avoid soil collapse due to high external water pressure the length was increased to −34 metre. A capping beam was constructed at each shaft at top of the secant piles to provide lateral support.

Both shafts also had permanent reinforced concrete liner of 0.35 metre thickness over two layers of water proof PVC membrane and inner protection layer of geotextile.

4.2 *Precast concrete pipe*

The reinforced concrete pipes that have been used for the tunnel drive were off site factory precasted of 3.0 metre length and having 3.0 metre outside diameter, transported to the site, lowered in the launching shaft and jacked by means of a hydraulic jacking frame system. Inside diameter of each pipe was 2.4 metre with wall thickness of 300 millimeter and concrete design compressive strength was 45 N/mm^2. There were three types of pipes manufactured and used for the tunnel; standard pipe of 3 metre length, pipe with Injection Port (IP Pipe) of 3 metre length and inter jack station pipes of 0.5 metre and 1.5 metre. The weight of each standard pipe was 20 ton. Figure 1 shows a typical standard precast concrete pipe used in the tunnel drive.

Every fifth pipe jacked was an IP pipe, which was used for lubrication during the drive and for grouting after the completion of jacking operation. Four inter jack pipes were installed to serve as an intermediate jacking station due to extraordinary length of the tunnel, as during excavation the jacking force generated by the main frame could not fulfill the required force to push the pipe and TBM.

4.3 *Tunnel Boring Machine (TBM)*

TBM used was Herrenknecht AVND2500 mix shield slurry machine. Prior to installation of TBM and commencement of the jacking, all components of TBM which include thrust block, TBM launch rails, and seal pipe brake along with the main jacking cylinder were installed. TBM consisted of 6 parts, a total of

Figure 1. Standard precast concrete pipe.

approximately 12 metre in length, which were installed in 3 phases due to space limitation at the launching shaft.

The TBM was controlled by remote control from the control cabin. Guidance System was installed in the control room having graphical and numerical display of TBM axis position against the design tunnel axis.

4.3.1 *TBM operation*

The TBM was equipped to operate in slurry mode in which water was pumped from the separation plant to the face and mixed with the cuttings produced by the cutting wheel. This mixture was then pumped back to the separation plant and treated, by separating the solids and allowing cleaned water to be recycled.

The excavation procedure consisted of 2 phases; excavation cycle in which the pipe line and TBM was advanced through the ground at a distance of 3 metre and pipe change during which a new pipe was lowered and positioned for jacking. During this phase the slurry circuit was closed off at the shaft via gate valves in the shaft bottom. The pipe brake was tensioned and the thrust ring pulled back. All slurry lines and services were then disconnected from the previous pipe. A new pipe was dropped onto the guide rails and then pushed into the seal of the preceding pipe. All services and slurry lines were then reconnected and the pipe brake relaxed and the excavation cycle begin again.

4.3.2 *Intermediate Jacking Stations (IJS)*

The intermediate jacking stations are pipes adapted to hold hydraulic cylinders and are placed periodically during the advance. Due to the length of the pipe line 4 intermediate jacking stations were installed as the force generated by the main jacking station was not sufficient to move the pipe line. The IJS allow the pipe line to be moved in sections. The IJS pipes were installed using the same procedure as for a standard pipe.

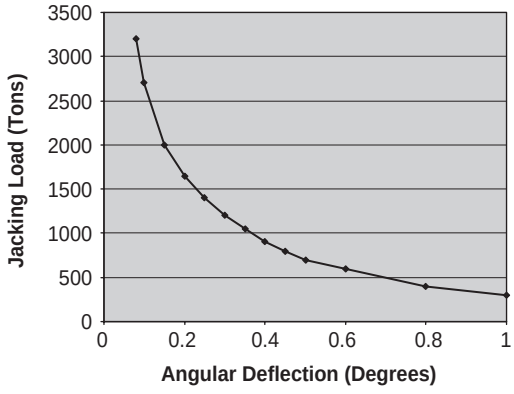

Figure 2. Permissible load at various angular misalignments.

4.3.3 *Pipe line lubrication*

The annulus between the outside of the product pipe and the excavation profile was filled with bentonite to prevent the collapse of the excavated ground onto the pipe thus reducing friction forces.

The bentonite mix was Baroid Tunnel Gel mixed with water to a ratio of 3–5%; in addition Baroid PAC-R polymer was added to the bentonite mixture at approximately 0.5%. The polymer was used to reduce water loss from the bentonite mixture. The bentonite mixture was constantly monitored and adjusted during the jacking operation depending on jacking forces experienced.

Injection of the bentonite was done through injection ports which was cast into the concrete pipe and was controlled by the Herrenknecht Automatic Lubrication System 80.

5 JACKING FORCE AND INTERJACK STATION

Jacking operation involves pushing pipes through ground surface and therefore exposes them to high loading during the construction. The critical area is at the pipe joints where the risk of stress concentration from pipe misalignment and or angular deflection is very high. Therefore, it was extremely important to control and monitor the alignment during jacking operation to ensure allowable angular deflection is not exceeded. Jacking load was assessed and the designer had recommended allowable jacking force of 900 ton, while maximum permissible force at joints with 0.5 degree deflection was 730 ton. Figure 2 shows allowable jacking force with respect to angle of deflection.

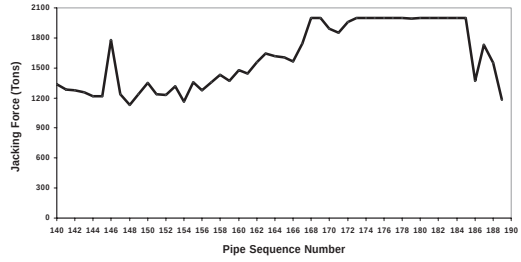

Figure 3. Maximum jacking force for the West Tunnel.

It was also recommended to use inter jack stations when the jacking force reaches 66% of the permissible load.

5.1 *High jacking pressure*

During initial jacking operation, a maximum jacking force applied to a pipe was around 900 ton or less which was below the allowable pressure and drive was running smoothly with a rate of production of around 9–10 metre per day. A sudden increase of jacking pressure was noticed during driving operation at the main jacking station and jacking force went as high as 1550 ton causing minor cracks to few of the jacked precast concrete pipes (pipe number 142, 143 and 146) located approximately 504 metre from the launching shaft.

Figure 3 shows the maximum jacking force applied to each of the jacked pipe between 420 metre (pipe sequence number 140) and 567 metre (pipe sequence number 189) of the tunnel drive. A meeting was immediately called with the designer and contractor to discuss this issue. The contractor and the designer explained that in their opinion there was an obstruction outside the pipe and they plan to push through and grind away obstruction and they expect damage up to 10 more pipes. It was also believed that jacking is a time related operation; therefore usually it is not a good practice to keep TBM idle for 3 days or more and lubrication must be maintained all along.

The question remained what would be the line of action if pipes continue to get damaged after jacking 10 more pipes? It was agreed by all that washing out material under the pipe would be the next option. It was also noticed that the contractor has to apply maximum jacking force to allow the material underneath to grind away, which could be as high as 2100 ton, which was also the ultimate capacity of the main jacking station.

After discussion with the contractor, designer, tunnel experts and the project management team, it was agreed to continue with the jacking operation at a much slower pace and monitor jacking force and survey pipe for damages every 20 cm of push. Damaged pipes were repaired by epoxy injection and concrete patching and

Figure 4. Damaged pipe number 146.

jacking operation was restarted after suspension of 3 days.

5.2 *Failed attempt to restart jacking operation*

During subsequent drive the jacking pressure continued to increase and reading went up to approximately 2050 ton and production rate decreased to 4.5 metre per day. After jacking approximately 66 metre tension and compression cracks appeared in 5 pipes (pipe number 143, 144, 145, 147 and 148) and deformation was noticed in one of the pipe (pipe number 146). Thus, it was obvious that condition has worsened and appeared that above solution of grinding away the hard material underneath the pipe with high jacking force had failed. It was decided that jacking must immediately be stopped, remedial measures be assessed, viable solution agreed by all and risk assessment should be carried out to determine the safety of the crew and tunnel itself as there was a very strong opinion that worst case scenario of complete failure of the pipe was a real possibility. Figure 4 shows damaged pipe number 146.

5.3 *Possible Causes of High Jacking Pressure*

Based upon detail investigation and field survey it was concluded that the prime reason of the cracks and deformation of the pipes was misalignment of the pipes resulting in non symmetrical loading condition. There could have been several factors for these pipes to be misaligned.

A field survey of the damaged pipes revealed that the pipes moved in the upward direction during the jacking operation resulting in grinding with the rock above it and small size (4–5 cm) rock fragments kept falling under the pipe and get accumulated which tend to push the pipes in upward direction. These deposited materials beneath the pipe became compacted and hard when jacking operation was stopped (ranging from 1 to 5 days) on number of occasion during the drive, due to maintenance works, and to control leakage at the inter jack stations.

Few cores were drilled through invert of the pipes to investigate the conditions underneath the pipe and it was observed that soil, very elastic in nature almost glue like material was found which was contributing to the excessive jacking force and misalignment. It appears that the use of polyurethane, bentonite mixed in with seawater could have resulted in chemical reaction ending up in a sticky elastic material which could have caused the pipes to slide horizontally and with continuous high jacking pressure applied these pipe instead of moving forward was forced to move upward resulting in misalignment.

It was also investigated whether steel collar of the concrete pipe has detached which might have caused the pipes to crack. This theory was rejected as no water was found leaking at the joints, no cracks at joint were visible and no crushing of pipe was noticed.

6 REMEDIAL MEASURES AND RESTART OF JACKING OPERATION

By now, it was clear that there was some obstruction which was creating these pipes to deflect and misalign. Pipes 143 to 148 have deformed and seemed unstable and there was a strong possibility of a total failure, therefore a procedure was worked out which included installation of steel in-liner to stop deformation, grouting between damaged pipes and the steel liner, and flushing out materials underneath the pipes which was believed to be causing high jacking forces for pipes 143 to 148.

6.1 *Installation of steel liners*

The steel in-liner was installed in all six damaged pipes which were designed to take the form of a segmental structure consisting of 6 segments with bolted flange joints. There was a provision in the steel in-liners to accommodate gate valves to be used for drilling of core holes and flushing the materials from behind the pipe. After the installation of the in-liners the area between the damaged pipe and steel liner was grouted using high strength non shrink grout. The grouting operation was done in three stages, starting from the bottom third. This sequence was necessary to reduce any uplift forces during the grouting operation.

6.2 *Flushing out of hard material*

100 mm drilled openings were made through the invert of each damaged pipes, 25 degree offset to the 6 o'clock vertical position in each of the lined pipes followed by the installation of gate valves in each of the

openings. Once gate valves were installed, jetting of materials under pipe was done by controlling the flow of material through these valves, material removed by natural water pressure and by suction methods. It was noted that approximately 27 cubic metre of material was flushed out.

6.3 *Safety and risk*

Prior to restart of the jacking operation it was agreed by all that the use of high pressure water for removal of material is highly risky operation and all protective equipment must be in place and used by all crew member working inside the tunnel and shaft. A comprehensive briefing and drill was conducted for the risk associated with this work. Minimum number of crew was allowed to work inside the tunnel and it was decided that no personnel should be inside the tunnel when jacking is in progress. In this respect, CCTV, pressure and length monitoring devices were installed in the damaged area inside the tunnel to monitor the movement of the pipes from the control station.

Trigger values and hold points for monitoring the pipe movement were discussed and implemented which included maximum length reduction of 10 mm for the steel in-liner, maximum jacking load of 1500 tons, and increase of pressure on any single cylinder gauge of a maximum of 150 bar.

7 CONCLUSION

The remedial measures performed on the damaged pipes described above helped in reducing the jacking pressure. Continuous monitoring of the jacking pressure was done and when there was an increase in jacking pressure from the hold point values, flushing was performed and jacking recommenced. This flush and push operation was a success and the jacking of the pipes continued till the completion of the tunnel and approximately 180 metre of jacking was done with an average of 6 metre per day.

It is a known fact that the success of TBM operation depends on many factors, which includes type of TBM selected, experience of the steering crew of the contractor, control and supervision and proper use of mix design for lubrication. TBM will not move in a straight line due to change in ground condition, grade, gravity and extreme water pressure might tend to move the TBM from straight path, they can create misalignment of the tunnel which would result in high jacking force resulting in severe damage to the tunnel itself. Proper and constant supervision of the work is also essential and any abnormalities noticed during initial stage must be addressed immediately to avoid major damage. It is also important to note that lesson learned from this tunnel drive was successfully applied to the east side tunnel and east microtunnel was completed with an average of 12 metre per day and jacking force was well within the allowable limit through out the drive of 675 metre in similar soil condition.

ACKNOWLEDGEMENT

The authors wish to express their appreciation to Dr. Mikhail Ryjevski of Al Naboodah Engineering Services for his assistance in the preparation of this paper. Useful comments made by colleagues in reviewing this paper are also acknowledged.

Geotechnical safety management on site

W. Schubert
Graz University of Technology, Austria

ABSTRACT: The uncertainties in the ground model and consequently the design of tunnels call for an observational construction approach. To allow for safe and economical tunneling a safety management plan has to be implemented. Basis for the safety management plan is the design, which continuously is updated, as information increases. The contribution deals with following topics:

- Targets of the Safety Management
- Basic elements and structure of the Safety Management Plan
- Parties involved and their responsibilities
- Determination/Definition of the expected behavior; definition of warning and alarm levels/criteria
- Monitoring program; layout and frequency of monitoring in accordance with expected behavior and boundary conditions
- Information and communication flow
- Action plan; organization, and mitigation measures in case observed behavior deviates from the expected
- Management of a crisis

A key element for establishing realistic warning and alarm criteria is a profound understanding of geotechnical processes and the ground-structure interaction. Thus a meaningful plan can be only established in close cooperation between designers, geotechnical experts, and the site management. Advanced tools for monitoring data evaluation and interpretation assist in establishing expected behaviors and check the monitored values against the warning and alarm criteria. The implementation and execution of safety management plans on site will be shown with case histories from the Wienerwald railway tunnel in Austria.

1 INTRODUCTION

Even with an excellent investigation, testing, and ground characterization program, as well as the application of up to date design methods, uncertainties with respect to geological conditions and ground reaction remain during construction. To obtain safe and economical tunnel construction, an observational approach is required.

Rules, methods, definition of responsibilities, etc. are laid down in a safety management plan, which is basis for all safety relevant actions on site. The procedures outlined here reflect the practice, as executed by the Austrian Federal Railways (OeBB, 2004).

2 TARGETS OF A SAFETY MANAGEMENT PLAN

The targets of the Safety Management Plan are:

– Allow for safe and economical tunneling in not completely known conditions
– Definition of preparatory steps, methods, and procedures for the implementation of the observational method
– Definition of responsibilities and procedures to prevent unfavorable effects or stability problems
– Definition of required procedures and measures in the case of a crisis to avoid damage, in particular to third parties

3 BASIC ELEMENTS

The geotechnical safety management plan consists of following basic elements:

– Definition of the parameters to be observed
– Definition of the expected behavior of the underground structure during construction
– Definition of monitoring methods, locations, amount, and reading frequency
– Definition of warning and alarm levels
– Organisation required to conduct monitoring, data handling, evaluation and interpretation and

communication structure between the paties involved
- Procedures and measures in case the behaviour deviates from the expected one
- Procedure for the case of a crisis, including alarm criteria, organisation, and protection priorities
- Framework construction plan
- Updating of the prediction made during the design, as new information is available

The geotechnical safety management plan consists of two parts, the first being valid fort he whole project, the second part containing the detailed regulations for different sections with different ground or boundary conditions.

4 PARTIES INVOLVED AND THEIR REPONSIBILITY

In the general part of the Safety Management Plan the function, addresses, phone and e-mail numbers of all parties involved in the project are listed. Also listed are the contact details of institutions and organizations, which have to be informed in the event of a crisis, where third parties are at risk.

In addition the general part contains a detailed description of the responsibilities of the individual positions in the project.

5 DEFINITION OF EXPECTED SYSTEM BEHAVIOUR AND WARNING AND ALARM CRITERIA

The designer defines the expected system behaviour of the tunnel during the excavation and the influence of the tunnelling works on surface and subsurface structures being influenced for the single sections of the tunnel. This serves as a basis for the geotechnical engineer on site, who has to evaluate the monitoring results.

Following details have to be given:

- Deformations of the tunnel
- Surface settlements and settlement trough
- Deformations of the ground in the vicinity of critical objects
- Deformations in the influence area of retaining structures
- Influence of tunnel works on utility lines and indication of advance mitigation measures

6 MONITORING PROGRAM

The monitoring methods have to be selected to capture the parameters relevant for the safety. The monitoring intervals shall be frequent enough to detect unfavourable developments in time, and the evaluation of the monitoring results has to be sufficiently rapid in relation to the possible evolution of the system.

Monitoring includes observation of the geological and water conditions, measurements of displacement on the surface, the ground, and the tunnel, as well as measurement of vibrations if required.

Type and amount of monitoring, as well as minimum reading frequency for the single sections of the tunnel are put down in the Framework Construction Plan.

6.1 *Specification of monitoring criteria and control measures*

For the single parameters observed, following is specified for each section:

- Expected behaviour
- Method of observation evaluation of data
- Criteria for attention level
- Criteria for the warning levels 1 to 3
- Mitigation measures
- Alarm criteria for the warning levels 2 and 3
- Method of intervention in case of an alarm

6.2 *Warning levels*

In case the actual behaviour deviates from the predicted one, one of the four warning levels is applied, depending on the severity of the deviation.

The attention level applies, when the actual behaviour, respectively the predicted actual behaviour exceeds the expected one or is close to the limits specified by the authorities.

The criteria for warning level 1 are set at significant deviations from the expected behaviour, but with a reasonable safety margin against failure.

The criteria for warning level 2 are reached in case of progressive deformation development, low margin of safety, or local failure. When level 2 is reached, alarm is announced. Warning level 3 applies, when warning level 2 is reached and third parties are affected.

Conditions for resetting a warning level are the stability of the tunnel, or when observation results show that objects or utilities are not influenced, as well as, when the mitigation measures have proven to be effective.

6.3 *Monitoring methods and extent*

Monitoring methods in general include documentation of geological and hydrological conditions and interpretation, visual observations in the tunnel and on the surface, displacement measurement, and vibration measurement, measurement of water and gas quantity/concentration.

Displacement monitoring includes measurement of surface points and objects, inclinometers, extensometers and 3D displacement monitoring of the tunnel itself.

The basic monitoring layout and minimum reading frequency is determined by the designer and the geotechnical on-site engineer, and is shown in the Framework plan. Detailed adjustments of the program are made by the on-site geotechnical engineer according to the requirements.

6.4 *Execution of measurements*

The owner usually takes the responsibility for making the geotechnical measurements, while the contractor is responsible for the correct position of the tunnel.

The survey team receives the instructions for the type of measurements and minimum reading frequency from the geotechnical engineer. The evaluation of the data has be done in a way, that the results are available for the geotechnical engineer within the same day of the reading.

7 INFORMATION FLOW

In general everybody involved has to report unusual observations immediately to the Engineer and the geotechnical on-site engineer, as well as the contractor.

To allow for an efficient flow of information and up to date access to evaluated data, a ftp-server is installed. The parties involved in the evaluation of data have to store the evaluation results on the server immediately after evaluation. All parties involved in the project have access to the data stored on the server.

Preferably a daily joint site visit of the representative of the contractor, the Engineer, the geotechnical on-site engineer and the geologist is made. After evaluation of the monitored data, a meeting among the parties mentioned above is held, where information is exchanged, and necessary measures are decided.

In case of deviations from the routine, for example due to an increased or changed reading frequency or unusual events requiring a change of the routine, the geotechnical engineer informs the Engineer and the external expert about the storage of out of routine data by email or phone.

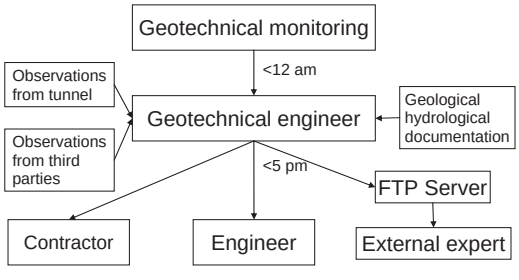

Figure 1. Routine safety relevant information flow.

8 PRACTICAL APPLICATION

Besides the stability of the tunnel itself, the effects of the tunnel works on other objects and utilities is of particular importance. In the design those issues have been addressed, and consequently the design form the initial basis for the geotechnical safety management plan.

All critical objects and utilities are listed in a table as well as the acceptable impact on those structures by the tunnelling works. The expected "normal" behaviour of the tunnel, its influence on the surface and objects is quantified. For a timely detection of deviations from the normal behaviour it is not enough to define final deformation values, but also the timely and spatial development. It has shown beneficial to specify expected deformations in relation to the face distance, for example in distances of 1/2 diameter and 2 diameters in addition to the final displacements. Thus it is possible to detect deviations in time to initiate strengthening or mitigation measures.

The table also includes the methods of observation and evaluation of the safety relevant parameters. For example for the assessment of the stability of the face usually only visual inspection is available, while for the deformations of the tunnel and the surface geodetic and geotechnical instrumentation can be used. The method of evaluation in this case can reach from simple plots of displacement histories (time-displacements plots) to more sophisticated ones, like the trend of the displacement vector orientations.

Following the definition of the expected behaviour the warning and alarm criteria are listed. For the tunnel displacements or surface settlements, the trigger for the attention level might be taken at the expected values, while the criterion for the warning level 1 might be an increase of deformations in the order of 20% above the expected values. The mitigation measures in this case would be an increase in the support if only the tunnel displacements exceed the warning level. If the warning criterion is reached also on the surface, additional face support, a decrease in the round length and the excavation rate might be the recommended mitigation measures. In the case of houses and other objects in general the criteria are admissible distortions. The observation of trends, as the tunnel progresses allows a timely detection of unfavourable developments, provided that appropriate tools are used for the data evaluation.

While the attention level and warning level 1 are considered to be managed with relatively low level mitigation measures, levels 2 and represent serious hazards for the structure or third parties. Top priority

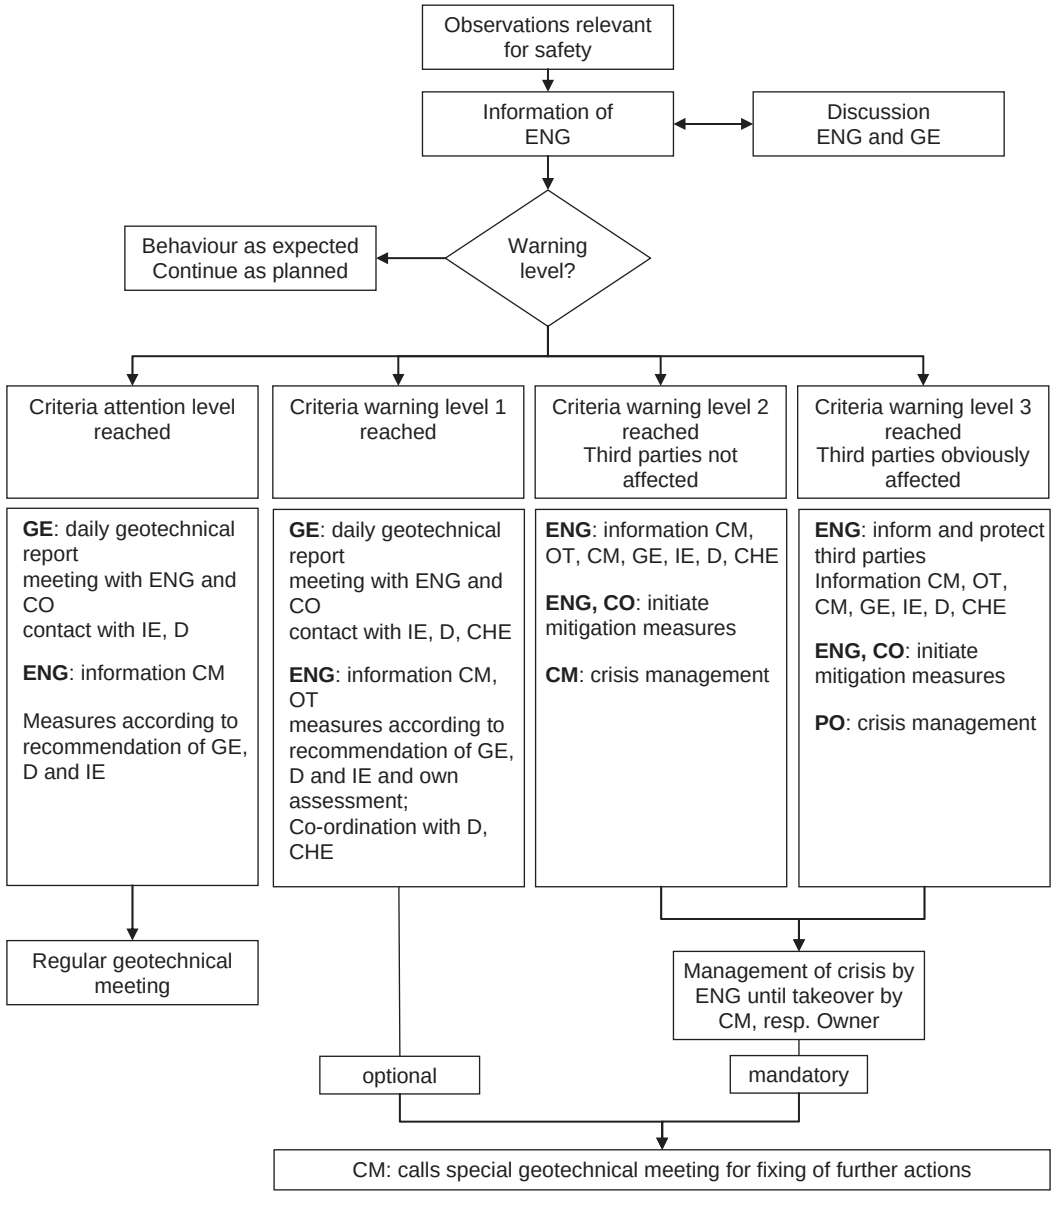

Figure 2. Procedure in Geotechnical Safety Management Plan; Abbreviations: GE – Geotechnical Engineer on site, ENG – Engineer, CO – Contractor, IE – Independent Expert, D – Designer, CHE – Checking Engineer, CM – Construction Management, OT – Owners technical representative, PO – Owners Project Representative.

in those cases has the public safety, followed by the safety of those involved in the project, and finally the stability of the structure.

Naturally in the case of a crisis also parties are involved, which are not familiar with the details of the construction and the evolution of the system. Thus a good routine documentation of all facts is essential to quickly convey the critical developments, and to arrive at mitigation measures appropriate to the situation. All parties involved must be aware, that in the case of a crisis, appropriate decisions can only be made if the data basis is excellent. As a crisis usually is unexpected, the monitoring and data quality have to be at a top level at all times.

Good preparation therefore is essential. A list of all those to be protected, as well as the contact details of all parties and organisations to be alerted has to be prepared well in advance. Also means, methods, and equipment required to conduct appropriate mitigation measures must be available on site at al times.

9 APPROPRIATE TOOLS FOR DATA ACQUISITION AND EVALUATION

It can be observed, that on many sites the methods of monitoring and data evaluation have not developed beyond the status of the 1970ies. Still convergence tape measurements seem to be the state of the art, while the only evaluation method is a plotting of the displacements versus time.

Since more than twenty years geodetic 3D displacement measurement techniques allow to gain much more information. Parallel to the advance in measurement technique, methods of data evaluation have been improved. Plotting of displacements versus time nowadays is only one method of visualizing the results of monitoring. Deflection line diagrams, trends of displacements, or ratios of different displacement components, allow a much better assessment of the mechanical processes during tunnelling, than was possible with the traditional methods.

Efficient software for the data processing and evaluation is available (Tunnel:Monitor, 2006; GeoFit, 2005). In particular the possibility to predict the development of the displacements in relation to face advance and time after a few readings allows a timely detection of unfavourable developments (Grossauer et al., 2005).

10 CASE HISTORIES

Two case histories from the Wienerwaldtunnel, a double track railway tunnel located at the western outskirts of Vienna shall illustrate the practical application of the safety management plan.

On November 21st, 2005 the geotechnical engineer on site detected, that the development of the surface settlements at the measuring sections 390 and 400 reached the criteria of warning level 1 (criterion 37,5 mm). Via e-mail he informed the Engineer, the construction management, the technical representative of the owner, the contractor, and the external tunnel expert. As a building is located close to the face and the displacement trends showed an increasing tendency, the geotechnical engineer proposed to change the excavation and support sequence, with a shortening of the ring closure distance of the temporary top heading invert. In a site meeting in addition the thickness of the shotcrete in crown and invert was increased, as

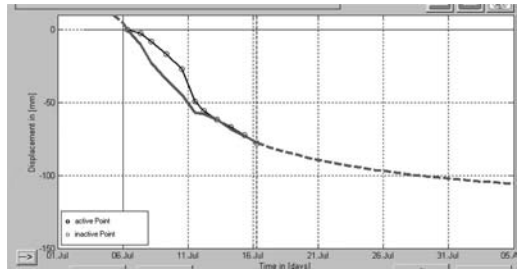

Figure 3. Predicted development of settlements (dashed line).

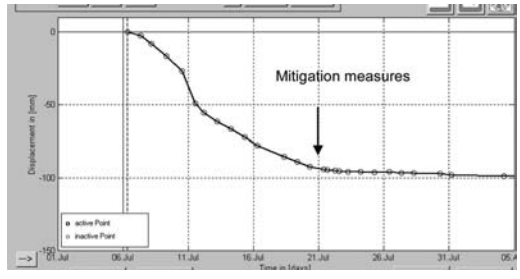

Figure 4. Development of displacements after mitigation measures were put into effect.

well as the number of bolts starting from station 422. The increase in support and the reduced ring closure distance reduced the amount of the displacements in the tunnel.

Another unfavourable development was observed at the same tunnel around station 1.000. Obviously due to the influence of a fault zone outside the right sidewall, displacements increased in a progressive manner in measuring section 997 (see figure 3). The situation was assessed by the geotechnical engineer, the designer and the external expert. As the tunnel is located outside built up areas, no immediate action was required, but increased attention paid to the further development. Additional bolting was ordered and executed on a length of around 20 m. In addition, the tolerance for deformation was increased to 20 cm. As a local phenomenon could have caused the increase, it was decided to continue with the excavation, while simultaneously mitigation measures were evaluated, should the additional bolting not show the desired effect. With the data available from July 16th, it was clear that the tunnel is in the process of stabilization, but total displacements would most probably exceed the deformation allowance (figure 4). Thus in an extraordinary geotechnical meeting, the previously discussed mitigation options were fixed. Those consisted of additional bolts, and the installation of three stripes of temporary invert with a length of 4 m each. The excavation was stopped and the strengthening measures put into effect.

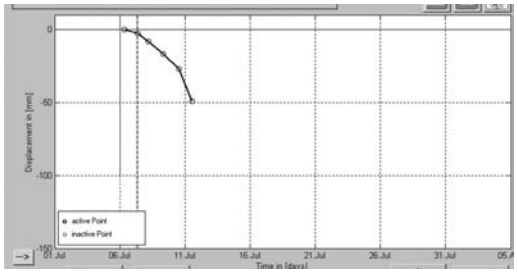

Figure 5. Development of vertical displacement of the right footing of the top heading.

Figure 5 shows, that the displacements came to a complete stop, as the strengthening measures became effective. No further problems were encountered in this section, even when the bench and invert were excavated, and the total deformations were within the tolerance.

11 CONCLUSION

Especially when tunnelling in sensitive areas with adjacent buildings and utilities, increased attention is required to minimize adverse influences caused by the tunnel works. A thorough planning and preparation is required to allow for quick and appropriate action in case of unfavourable developments.

For a successful establishment and execution of a safety management, all possible hazards have to be assessed prior to construction. Limitations of surface settlements, as well as criteria of serviceability have to be observed. A well structured plan of communication and action has to be fixed to allow for efficient response to unexpected or unfavourable developments. In addition the site has to be equipped with experienced staff, and appropriate software for efficient data evaluation. Up to date displacement monitoring evaluation software should have features to predict displacements with a few readings only in relation to time and tunnel advance, as well as the possibility to assess the degree of utilization in tunnel linings.

IT nowadays allows that also off site experts are fully informed about the performance of the project at all times, and can give advice whenever required, based on a sound information level. A precondition for complete information of all parties involved besides of the installation of a server is the continuous feeding of quality data and evaluations.

It has to be stated, that a safety management plan is not rigid, but requires updating, as more information about the ground and the system response is acquired during construction.

NATM tunnelling at Dulles airport

Ermin Stehlik
Tunnelling Consultant for D2 Consult Prague, The Czech Republic

Martin Srb
D2 Consult Prague, The Czech Republic

ABSTRACT: Tunnel collapse in 2000 during excavation of connection tunnel at Dulles airport causing fatal injury raised the Client's (airport authorities) concerns about construction safety. Ambitious expansion of the airport foreseen for the next decade with airport capacity increase up to 50 mil passengers/year when expansion completed, requires numerous underground facilities to be partly located in mined (both conventionally and TBM driven) tunnels under the airport. All consequent tunnelling works have been set under new systematic supervision scheme including position of a "NATM Engineer" as a part of contractor's team to be present during all excavation & support works. This position has specified strict requirements on experience and qualification of individual experts. Since 2004 to 2006 several conventionally mined (NATM) tunnels have been successfully completed. Paper briefly describes specifics and procedures of some of these drives as well as an experience with the "NATM Engineer" role as part of the Contractor's team.

1 INTRODUCTION

1.1 *Brief summary*

Washington Dulles International Airport (WDIA) is at present undergoing ambitious expansion, which is enabled by availability of land around the existing airport facilities thanks to the Client – Metropolitan Washington Airports Authority (MWAA) policies in the past. Long term planned modernization includes the construction of a new runway, air traffic control tower, new terminals and service buildings, and also service and transport tunnels.

Construction aspects of these tunnels with emphasis on New Austrian Tunnelling Method (NATM) application and especially on the NATM Engineer role are the main features of the paper.

1.2 *Tunnelling contracts*

The tunnel construction involves all kinds of tunnelling methods; there are many open cut construction sites serving as starting or receiving pits for either TBM or NATM tunnelling contracts. NATM was used in parts with complicated geological conditions or in tunnel stretches with difficult horizontal alignments and small radiuses.

Construction of mined tunnels started in 2000 with so called "Walkway Tunnel" between the Main Terminal and Terminal B, using NATM tunnelling method. In November 2000 a tunnel collapse, causing death of one worker, happened. The accident and following investigations delayed the construction process; construction of another contract – "West Utility Building Tunnel (WUBT)" was awarded to the Kiewit construction company and construction started in 2004. The part of the contract was 348 m long horse-shoe shaped tunnel with 6 m wide cross section, excavated according to the NATM principles.

Following contracts included the construction of Automatic People Mover (APM) tunnels, with total length of more than 3 km with four stations built in open cuts, divided into several contracts and awarded to the Clark/Shea JV (east) and Atkinson/Clark/Shea JV (west). These included open cut, TBM and NATM tunnelling. NATM tunnels were circular, 6.5 m outer diameter tunnels, divided in east and west part (see Fig. 1, 2).

1.3 *Contract stipulations – NATM Engineers*

Due to the problems experienced with the first contract, the Client's requirements defined specific position as a part of the Contractor's team designated as "NATM Engineer". Contract stipulations called for permanent presence of NATM Engineers, with sufficient experience of the method application.

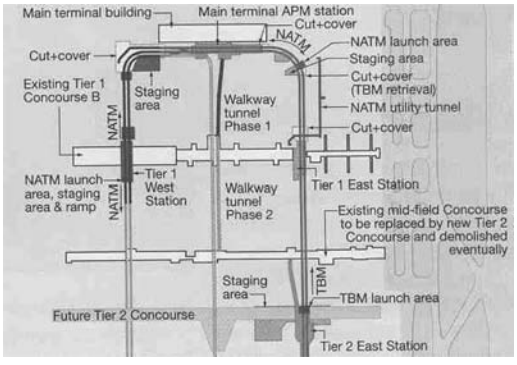

Figure 1. General Dulles airport layout.

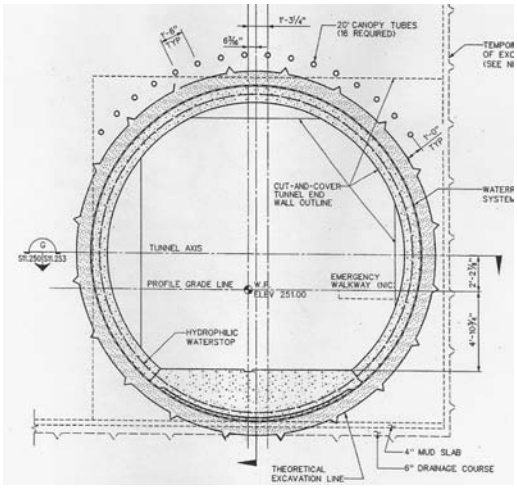

Figure 2. Typical cross section of NATM APM tunnel.

The situation in the US tunnelling market driven by the low cost rule, with few NATM tunnels, resulted in shortage of suitably qualified engineers and tunnel workers. Even the largest companies are commonly hiring external specialists for tunnelling contracts.

Position of NATM Engineers for both mentioned contracts were subcontracted to the Austrian tunnel consultants D2 Consult, and through its daughter company D2 Consult Prague, several Czech tunnel engineers worked on the project as a part of the contractor's teams.

2 TUNNEL CONSTRUCTION

2.1 *Geological and Hydrological conditions*

Geological conditions for the tunnel construction are relatively favourable. The bedrock, in which the tunnels have been predominantly mined, consists mainly of competent hard mudstone and claystone, with few sets of joints and UCS range between 20–40 MPa. Only at limited locations rock weathering process created softer soil with clay characteristic.

Figure 3. Typical face conditions.

The earlier conventional tunnelling at the airport was performed using drill&blast excavation technique, with large amount of explosives used, significantly disturbing the surrounding rock. As a result, when crossing in the vicinity of previous construction works with newly built tunnels, excavation and support installation have to consider earlier affected broken rock conditions.

Massive mudstone and claystone were during excavation relatively dry, the water penetrated into the excavation only through joints and was related to surface precipitation.

2.2 *TBM tunnelling*

There were several contracts, in which TBM tunnelling with bolted precast segmental lining assembled in the TBM shield has been used. The latest technology for the segment production has been introduced; for the tunnel lining water tightness the modern sealing systems with rubber sealing gaskets have been applied.

2.3 *NATM tunnelling*

2.3.1 *Generally*

Designed support classes (I–III) for the tunnel excavation and support were applied according to the NATM Engineer's decision.

Both, horseshoe and circular tunnels were excavated in two steps. Firstly, the top heading was excavated and support measures as specified for the initial lining applied. In the second step the invert was excavated and initial lining completed.

2.3.2 *Excavation*
The excavation in all contracts was done by roadheaders, blasting was strictly prohibited. There were several types of roadheaders, mostly Voest Alpine models AM 75 for large profiles and AM 50 for e.g. invert and final profiling.

2.3.3 *Support Classes*
The following description is related to the APM contract.

The round length was corresponding to the applied Support Class. In the Support Class I, which was used for massive sound rock, this length was 1.5 m; and at the same distance lattice girders were erected. Initial lining was formed by 15 cm thick shotcrete with steel fibres.

In the Support Class II, applied for jointed rock, 4 m long spiles were installed in each round to prevent loosening of the rock blocks and their falling from the excavation roof. Round length was 1.2 m, shotcrete thickness 20 cm, lattice girders at 1.2 m distance. Probing ahead of the face was performed every fourth round, the length of probe drill hole was 12 m.

Support Class III was applied when the tunnel profile entered into the area of heavily weathered rock having character of clay. The round length was 0.9 m and the pre-support measure consisted of grouted steel pipe umbrella length of 9.0 m. In some cases the Support Class III was applied during tunnelling under other structures or utilities as a safety precaution measure.

Bolting was considered as an additional measure, bolts installation was based on NATM Engineer's decision. SN bolts installed into boreholes fastened with resin cartridges have been applied.

2.3.4 *Shotcrete*
There were batching plant directly on the site; mixing of the wet shotcrete mix was done in truck-mixers. From the trucks the shotcrete was delivered to the stable pump located on the surface. From the pump the shotcrete was pumped by delivery line (slick line) to the shotcrete spraying robot with remote control, close to the tunnel face. Accelerator was delivered to the nozzle by small pump at accelerator storage tank.

2.3.5 *Final lining*
Final lining was made of reinforced cast in situ concrete of 30 cm thickness. Specific feature was universal use of corrosion protection coat of all reinforcement bars. Between shotcrete and final lining a waterproofing membrane was installed.

2.3.6 *Problems during tunnelling*
The biggest problem encountered during tunnelling was shotcrete delivery to the tunnel face. Due to the pump location on the surface, the delivery lines were long, with many bends. They were also exposed to the heat or cold conditions and as a result there were many blockages on the lines, leading to delays in shotcrete delivery. Very often the problems with accelerator dosage caused delays during shotcrete application.

Figure 4. Finished final lining of east APM tunnel.

The biggest problem, from the NATM Engineer's point of view was long time period required for shotcrete support application in the cases of unstable rock conditions.

Another problem was presence of water in the tunnel, affecting the conditions of the temporary top heading invert. The water was mainly technological water from the roadheader spraying the face during cutting; the water used for cleaning and in some cases the water coming from the portal areas. As a result there was permanently thick layer of mud on the tunnel invert, making the working conditions difficult.

Application of roadheaders for the tunnel excavation did not allow for partial suitable excavation of the face. In some cases, it would be advantageous to excavate only top part of the face and apply shotcrete layer to support unstable rock. With the roadheader, the excavation had to start at the lower part to create the space for roadheader apron, to allow cutting boom reaching the top of the face.

Typical tunnel worker has not NATM tunnelling experience and is trained for required specific skills before project starts. Also Trade Union labour rules make it rather difficult to use available labour force in tunnel with required flexibility and efficiency.

3 NATM ENGINEER POSITION

The NATM Engineer is a specific position, present in the moment only on the USA tunnelling market, therefore brief explanation of his position and role follows, together with few comments based on experience gained on the Dulles Airport contracts.

Generally, the NATM Engineer could be characterized as bearer of NATM know-how, who is responsible for effective and safe application of the method. There are strict criterions stipulated in the contract documents as far as the NATM Engineer qualification and experience is concerned (years of experience, type of works done, both design and site experience requirement, etc.).

Actual role of the NATM Engineer on Dulles Airport tunnelling contract encompassed few more tasks. NATM Engineer provided also geological mapping of tunnel faces and monitored probe drilling in relevant support classes. He was taking decision on what support class will be applied for given conditions and also about any additional measures required (additional shotcrete, bolting). Part of his responsibility was evaluating the results of geotechnical monitoring (deformation measurements) and proposing relevant measures to react on the results.

NATM Engineer was an important partner during technical discussions and negotiations with the Client's Representative, who was at Dulles Airport project called Project Management Consultant (PMC). In the PMC team there was highly qualified international staff with long term experience regarding NATM tunnelling.

Two years project experience demonstrated importance of the newly established position. Responsibility of the NATM Engineer was quite high and his activity significant, especially in the case of worsening geological conditions and a need to take and imply quickly the decisions in respect of changing to another support class or to apply additional support or excavation measures. Although a part of contractor's team, quite understandably sometimes the priorities of both subjects (NATM Engineer vs. Contractor's management) were slightly different. This fact was also confirmed at the meetings with PMC an/or Client, where NATM Engineer's position and reasoning were considered by the parties as rather neutral and objective, not much affected by project economical interests.

From the personal experience, a serious problem for the NATM Engineer was to get support measures done as fast as possible and in required quality. This is valid mainly for the timely shotcrete delivery in the case of unstable rock conditions. To improve and accelerate this process was beyond the NATM Engineer capability and competence, although he was generally responsible for proper and timely application and safe and stable conditions.

4 CONCLUSION

The presence of "NATM Engineers" on the Dulles airport tunnelling contracts definitely contributed to safe realization of WUBT and APM conventionally driven tunnels. European tunnelling experts experienced working in different contractual environment and different working conditions with respect to local workforce experience with NATM, tunnelling qualification, and local practises. It is probable that on follow up tunnelling contracts on Dulles extension, the same or similar model of NATM expert working directly for contractor shall be applied.

Risk Management of the construction of tunnels using Tunnel Boring Machines (TBMs)

A.H. Thomas & J.P. Banyai
Mott MacDonald, London, UK

ABSTRACT: As one stands inside one of the new hi-tech closed face TBMs one could almost believe that everything is computerised and all risks are completely under control. Sadly the truth is that, not only do surface collapses sometimes occur above TBM tunnels, but also the costs associated with the collapses are increasing rapidly. This has caused a crisis in the insurance industry and prompted the publication of a Code of Practice for Risk Management of Tunnel Works in the UK. Insurers are demanding that contractors adopt the code of practice if they are to be given project insurance. An international version of this code is being prepared. This paper will discuss the risks associated with TBM tunnels and how risk management can be applied to TBM tunnelling. This paper will illustrate how these general procedures can be applied by describing a recent project where TBM tunnels have been driven successfully in a high risk urban area.

1 INTRODUCTION

Tunnelling is a risky business. Unlike other types of civil engineering, tunnelling is exposed to greater risks, primarily because of the limited knowledge about the ground ahead of the tunnel and how it will behave. In tunnels under mountains or water the knowledge is limited because of the natural obstacles to site investigations. In tunnels in an urban environment there is uncertainty over how the tunnel will interact with surrounding buildings. Throughout the history of tunnelling engineers have developed informal ways of handling these risks.

However, these have not always been successful. High-profile tunnel accidents highlight the dangers (e.g. T&TI 2003, Forrest 2006). Coupled with some notable financial failures in the 1990's, this refocused attention on how risks are managed in tunnelling. Coming from different viewpoints, several groups have concluded that one answer to these problems is an improved management of the inherent risks.

In line with European Union health and safety directives, risk management has been introduced into safety legislation (e.g. the CDM regulations in the UK (HMSO 1994)). This affects all aspects of life from theatre performances to civil engineering. In the context of tunnels in the UK the CDM regulations have had a pronounced effect on the design process. While it may be difficult sometimes to identify how the final designs are different because of CDM, the formal process of risk management is clearly visible on all projects. The same applies during construction.

Often the financial consequences of a major problem end up being carried by an insurance company. Insurers in several countries have become so concerned about the impact of large losses on the handful of projects which go wrong that they are threatening to refuse to insure the projects. This would expose clients and contractors to huge financial risks and planned projects could be cancelled. To address this, the British Tunnelling Society (BTS) teamed up with the Association of British Insurers and published a Joint Code of Practice on Risk Management of Tunnel Works in the UK (BTS/ABI 2003). The International Tunnelling Insurance Group, in conjunction with the BTS and supported by the International Tunnelling Association (ITA), is currently developing an international version of this code of practice.

In parallel, tunnellers themselves have promoted the use of risk management too. Various organizations have published guidance on the subject (e.g. the BTS/ABI (2003) the German Committee for Underground Construction (DAUB) – outlined in (Naumann & Brem 2004) and the ITA (2004).

2 RISK MANAGEMENT IN TUNNELLING

2.1 *A general overview*

"A plan is nothing" General Eisenhower is reputed to have said "but planning is everything" he continued. This quotation – to a degree – could be applied to risk management. The act of a project team sitting down to

consider everything that could affect the tunnel and the actions that result from this can be more important than the mere fact that documents called risk assessments are produced.

Risk management can be used at all stages of a project – during concept design and planning, detailed design, tender evaluation and construction, as well as during operation and maintenance. The concept can be applied to safety, environmental, financial and contractual risks. In each context the details of the approach differ but the underlying theory is the same. To avoid creating a negative atmosphere, this process is sometimes called "hazard and opportunity" management. There may be beneficial conditions – opportunities – which could occur and steps can be taken to maximise the chance of the benefit being realised. Risk management in tunnelling has been discussed in detail in many other papers so the general principles will not be repeated here.

The overall philosophy is to reduce the risks to As Low As Reasonably Practicable (ALARP). At least in the UK there is a preferred hierarchy of mitigation measures.

- remove
- mitigate
- protect

First, one should try to remove the hazard completely. If this is not possible, one should use mitigation measures that protect everyone exposed to the hazard. Finally, one can provide protective measures that individuals can use. There is also a preference for "passive" protection – i.e. something which protects a person without them having to do anything – rather than "active" protection. A handrail beside a deep excavation is an example of passive protection whereas a safety harness is an active protection measure.

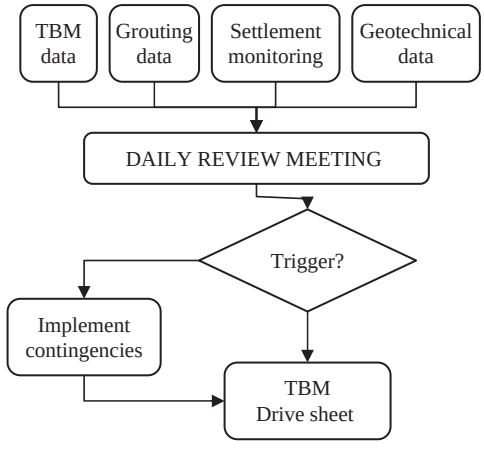

Figure 1. Typical flow of information through Daily Review Meeting.

During construction, the best way to manage these risks is, firstly, by monitoring the performance of the tunnel – to verify that it is behaving as intended by the designer – and, secondly, to have a representative of the designer (or a person with sufficient understanding of the design) on site to assist in the review of proposed changes in construction method and the interpretation of the monitoring data. This process has been successfully implemented on many SCL tunnelling projects (e.g. Hilar & Thomas 2005b).

In addition to helping to manage risks, a benefit of the presence of the designer on site is that he can help to realise opportunities and with them come cost and programme benefits for the client. The ideal situation is one in which a "single team" culture is created and the client, designer and contractor work together for their mutual benefit.

The process outlined above is not just applicable to SCL tunnels. It can also be applied successfully to tunnels constructed using Tunnel Boring Machines (TBM). In urban environments it is important to monitor how the TBM is being operated, how surrounding buildings are responding and how the tunnelling is interacting with other works, such as compensation grouting. As before it is important that all parties are at the Daily Review Meetings (DRM) to interpret and react to the monitoring data as each one brings with him an understanding of his own activity and its influence on the others. Figure 1 illustrates the typical flow of information. The output of the DRM can be formally recorded in a TBM Drive sheet which is then sent to the TBM pilot. This is analogous to the Excavation Support sheet in SCL tunnelling (Hilar & Thomas 2005b).

2.2 *Opportunities*

A pint of beer that looks half empty to one person appears half full to another. There is a danger with this subject of focusing solely on all the things that could go wrong. One should not forget that the regular systematic review of a project can just as easily throw up opportunities to improve a project as it can highlight deficiencies that must be resolved. The same processes and tools that are commonly labelled "risk management" can be applied potently to the search for improvements to a project.

3 APPLICATION TO TBM TUNNELLING

3.1 *Scope of application*

TBMs are often perceived as a lower risk option, particularly when a closed face TBM is compared against the open face sprayed concrete lined (SCL) tunnelling method. Although well established in practice, it is arguable that the development of closed face TBMs

has outstripped the understanding of how they operate. As a result, despite their capabilities, failures do occur. For example, accidents in London (T&TI 2003) and Porto metro (Forrest 2006) – both involving closed face TBMs served to demonstrate the huge impact that failures can have. Apart from such visible problems, there is a litany of projects that have suffered delays and cost overruns due to difficulties with TBMs (e.g. see Barton 2000). This has even prompted some to argue that TBMs are a higher risk option in the case of long tunnels in hard rock (Barton 2000).

Research is ongoing in many places to close the gaps in understanding – e.g. on soil conditioning and EPBMs at Cambridge and Oxford Universities (Nattrass 2003) or face and grouting pressures at Ruhr University Bochum (Kasper & Meschke 2006).

Publications such as the British Tunnelling Society's guidance on closed face TBMs (BTS 2005) have echoed the call for the application of active risk management to TBM tunnelling.

3.2 *Hard and soft risk management*

One could differentiate between the "hard" and "soft" application of risk management. Where there are legal imperatives or strong demands from a client or third parties, one can observe a formal and systematic application – a "hard" usage of risk management. This could be characterized by mandatory procedures such as daily reviews, a fixed programme of activities such as workshops and an explicit desire to document the process. The latter is in part for the benefit of the project team but often largely so that an audit trail is generated to serve as proof to others that the project is being well managed. This approach is often used for SCL tunnels but less frequently applied to TBMs.

A "soft" application could be characterized by the adoption of risk management as an ethos for the project that suffuses its activities. Common tools such as risk workshops and live risk registers appear just as in the more formal approach but these are used on a more ad hoc basis. The project team applies them as and when it feels a need, as opposed to a predetermined timetable. For example, as a tunnel approaches a high risk area, such as the under-passing of another tunnel or a river valley, the team might decide to gather – the client, design and construction teams – to review the possible risks and the planned mitigation measures.

The case study below illustrates an example of a "hard" application. If one takes the example of a TBM in Iceland that became mired in a series of fractured zones (T&TI 2006), one could speculate that this was the type of situation that would have benefited from a "soft" application of risk management. The TBM was stuck for more than 3 months, causing huge disruption to the programme. While the contractor and supervision team discussed at length the options and hazards, the rigorous, dispassionate forum of a risk workshop might have helped to highlight the perils of certain strategies and to identify one which would have been more successful. When faced with an obstacle there is always a temptation to hope for the best and try to battle through it. However, sometimes it is more prudent to take a more cautious approach. In the case above, one could hypothesize that applying systematic pre-treatment ahead of the face from the point when the first fractured zone was encountered could have saved time, despite the time that such grouting would have required. Such is the benefit of hindsight but how is tunnelling to progress if not by learning from past failures?

4 CASE STUDY – THE AIRSIDE ROAD TUNNEL, HEATHROW, UK

4.1 *Project description*

The Airside Road Tunnel (ART) is a 1.3 km long twin bore tunnel constructed under London's Heathrow Airport (Williams & Audureau 2005, Hilar & Thomas 2005a). The 8.1 metre diameter pre-cast concrete segmentally lined tunnel, passes under taxiways, with as little as a 7 metres cover to the ground, and passes over the Heathrow Express (Hex) tunnel with a clearance of 3 m. The tunnel carries a road for airport vehicles moving between the Central Terminal Area and the new Terminal 5. To link these areas, the tunnel must traverse a large area of taxiway as well as sensitive and important structures such as fuel pipelines and fire mains.

In general settlement had to be kept below 25 mm and trigger levels were set for the important structures – see also Table 1.

The tunnel is located in the stiff overconsolidated London clay which is overlain by 6 to 8 m of waterbearing granular material.

Sprayed Concrete Lined (SCL) tunnelling was used to build cross-passages for emergency egress and to house equipment (Hilar & Thomas 2005b).

This work will not be discussed here as it was managed in the normal fashion for SCL tunnelling.

4.2 *Risk-based design*

The key risks were excessive ground movements resulting in unacceptable settlement and encountering

Table 1. Examples of trigger limits on settlement for ART.

Structure	Slope	Deformation
Taxiways	1 in 100	
Aircraft stands	1 in 60	
Hex tunnel	(change in diameter)	34 mm

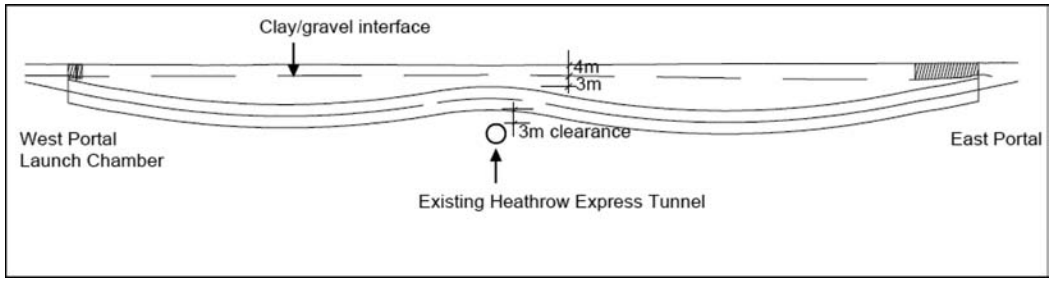

Figure 2. Vertical alignment.

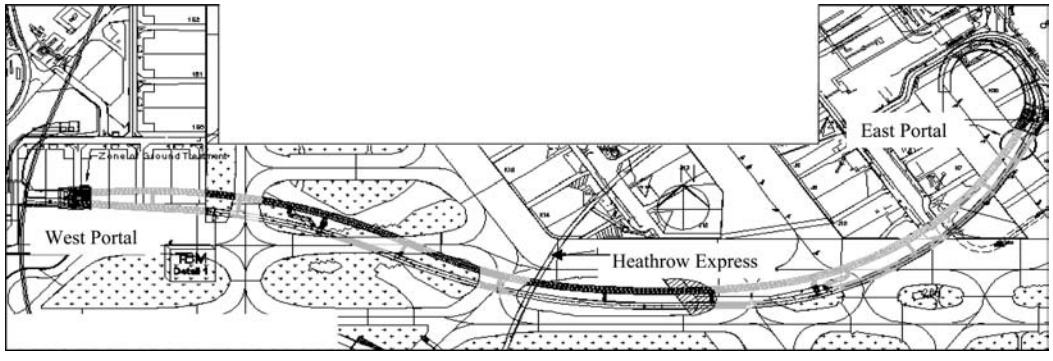

Figure 3. Horizontal alignment.

Figure 4. Cutterhead being lowered into place.

the water-bearing gravels, resulting local face collapse and again unacceptable settlement. These risks were explicitly addressed in the design.

Within the constraints of the design (e.g. existing structures, maximum gradients for the road vehicles, etc.) the vertical alignment was set to reduce the risk of encountering the clay-gravel interface (see Figure 2). Additional site investigation using cone penetration tests was done to map the interface.

As far as possible the horizontal alignment avoided sensitive areas such as taxiways (see Figure 3).

A closed face Tunnel Boring Machine (TBM) was chosen as the lowest risk option (see Figure 4). A hybrid TBM that had both an earth pressure balance (EPB) system and a compressed air system was developed with the manufacturer, Herrenknecht. This allowed the TBM to excavate rapidly through the large amount of London Clay using the compressed air, but also deal effectively with any gravel or mixed ground encountered during the excavation. Closed-face TBMs are renowned for their ability to control settlement.

Despite all these risk mitigation measures, significant residual risks remained for the construction team to manage.

4.3 *Risk management during construction*

A feedback loop of monitoring and modifying TBM operations was used to control the risks during construction.

The TBM was fitted with a data logger which allowed the engineers to monitor the performance on a real time basis. This recorded several critical parameters for controlling settlement, namely the air pressure/face pressure, the pressure of the bentonite in the annulus around the TBM and the grout pressure. These could then be compared directly within the logger to the tunnel excavation and ring building sequence.

Based on the detailed examination of performance over the first 300 m of the drive, the design parameters for the TBM operation were refined. The optimum combination was found to be: 0.5 bar air pressure in the TBM cutterhead; bentonite pressure of 1.0 bar in the annulus around the TBM and a grout pressure of 90% of the overburden pressure at the crown plus 0.5 bar (up to a limit of 2.85 bar).

Each tunnel bore was excavated continuously – 24 hrs a day, 7 days a week – over a period of almost 6 months. The only exceptions were the routine maintenance shifts. This programme was chosen to reduce the time the TBM was at a standstill, which also helped minimise settlement.

The monitoring of the TBM as well as settlement continued throughout construction. When the information from the data logger is examined in conjunction with the relevant settlement data and TBM shift report, the monitoring team have a far better understanding of why settlement may be occurring, and with this information, can make a judgement on the best way forward to halt the settlement, and prevent further settlement in the future.

The monitoring team was assembled from representatives from the Client (BAA), the Designer (Mott MacDonald) and the Contractor (Morgan Vinci Joint Venture) and met routinely every day to discuss the current data available.

The benefit of the daily review meetings (DRM) lay not necessarily just in spotting any gross errors or the identification of individual problem areas in the tunnel excavation, but the DRM could highlight any trends that have occurred, and to flag up any warning signs. This proactive approach not only reduced the severity of settlement that might occur, but also helped to reduce the frequency of more significant settlements.

4.4 *Performance*

The majority of the tunnel bores were constructed in compressed air (semi-open mode), with EPB mode only being utilised at the portals.

The success of this method of construction management is clear when we consider that, while face loss was predicted to be 1.0%, an average of 0.2% (7.5 mm settlement) was achieved, with a maximum of 0.35%. All surface settlements were less than than the maximum limit of 25 mm.

Due to aircraft operations, the surface settlement over the entire route could only be measured once a day (not real time), which meant the TBM face pressure and other parameters could only be adjusted on a daily basis. Real time monitoring would have had the benefit of observing any settlement trends faster, enabling the construction team to react faster to the movement on the surface.

5 CONCLUSIONS

Despite the advances in TBM technology, tunnelling remains a risky business and the consequences of failures can be very serious.

Formalized risk management offers one way to handle these risks. This can be applied in a "hard" or "soft" manner. As illustrated by the case study, this rigorous approach to examination of the TBM excavation parameters and assessment of the monitoring results, it is possible to achieve better control the effects of tunnelling. In particular, this method can assist in reducing the likelihood (risk) of those undesirable effects, such as settlement.

This method of continual assessment of the excavation movement and using the results to tune the excavation technique is more commonly used when constructing using sprayed concrete, but the application used on the ART shows how it can be effectively used on TBM excavated tunnels too.

ACKNOWLEDGEMENTS

The authors would like to contributions of numerous colleagues to discussions of this subject, in particular those of Mike Talliss.

Assessment of ecological safety in the process of underground development on the example of a big Russian city

V. Umnov & N. Vorozheykina
Moscow State Mining University, Moscow, Russia

ABSTRACT: The intensive development of underground construction in a big city is inseparably linked with its ecological safety. This paper deals with the effect of underground construction on the environment, as well as the impact of surface infrastructure on the underground space. The analysis of the situation has been performed for the biggest city of Russia – Moscow. The characteristics of basic reasons causing emergencies linked with the use of underground space are presented. The paper includes the methods for the assessment of potential damages.

1 INTRODUCTION

The majority of urban population in Russia (73%) is subject to ecological, economic and social problems caused by the growing density of construction and population. One of the most effective ways to address this problem with regard to Russian cities is to develop underground space. However, the growth of underground construction increases risks of underground and surface catastrophes, pollution of underground waters and other consequences that threaten health and lives of people and their property. Due to the lack of appropriate economic tools, administrative structures, methodical basis and legal norms the regulation of underground space usage in Russian cities is not adequate.

2 DESCRIPTION OF THE UNIT

Moscow has been chosen as an object for investigations since it is a city with well-developed and growing underground infrastructure. Underground space of Moscow from surface to 20 m is stable (= competent rock) in character, below there are unstable Jurassic clays and floating earth under which it is limestone. So the underground units are being build either close to the surface in depth of less than 20 m or at a considerable depth >80 m.

The conditions of the city with respect to geology are considered unfavourable. Incompetent rock and watering create engineering difficulties. Sedimentary rocks are not very fit for the construction of heavy tall buildings. General geological risks on the territory of Moscow are connected with the development of such geological processes as karst-suffosion, subsidence, landslides, flooding of the territory and soil compressibility.

Ecological safety is an urgent problem for Moscow. There are a number of emergencies occurring in Moscow every year and some of them are connected with the use of undergrounds space. Large accidents of product pipelines with human victims were recently made public and naturally caused considerable economic and ecological damage. The problem of terrorism has intensified.

The state of underground space in Moscow, its usage and ecological safety has been analysed and the characteristics of possible emergency situations provided. The method for the assessment of ecological risks and consequences of emergency situations occurring in the use of underground space has been developed along with economic estimation of measures intended to prevent possible emergencies.

There is one of the biggest in Europe underground commercial-recreation complexes "Okhotni ryad" (a museum, offices, commercial centre, restaurants, parking etc.) in Moscow. Moscow international business centre "Moscow city" that is under construction is designed to be three levels deep under the surface. One of the largest constructions is an underground part of Atrium on the square of "Kurskaya" railway station. The construction of section of the 3-rd transport ring road is being completed underground with a cross-section of 17.5 m × 5.2 m.

3 ANALYSIS OF ECOLOGICAL SAFETY IN THE USE OF UNDERGROUND SPACE

There is a considerable impact of the city over subsoil that leads to instability. Main reason is the inadequate

calculation for loads not taking into account the condition of subsoil in the process of design and construction. Under the pressure of surface units, changes in hydrogeological conditions, pollution caused by water, soil erosion, and damage of subsurface and surface. Surface pressure, vibration and underground water contamination effect the underground units and the impact is actively noted at the depth of up to 60–100 m.

Surface units (buildings, constructions, and embankments) put significant pressure upon the surface of the ground (from 0.01 to 2 N/mm^2 and more). Compacting of strata under the weight of tall house of the Moscow University caused 4.7 cm of soil settlement in the centre and created depression of settlement to the distance of 50–120 m along the perimeter of the construction (situation is the same round other tall buildings of the city). Change of topsoil upsets evaporation. This leads to settlement and shift of surface and subsurface. Dynamic loads by mainly transport tighten (compact) porous grounds and destroy insubstantial thixotropic grounds. Buildings along the streets with intensive traffic have settled on average to 3–8 mm (up to 5–20 cm) compared to those situated in side streets or blind alleys.

The conditions for surface waters change as well and result in excessive moistening and flooding of territories. This in its turn destroys foundations, lowers toughness, complicates location of technical collectors and pathways, intensifies corrosion of pipelines and steel structures, which are assembled in the ground without appropriate electrochemical protection. In the result of flooding there are cases of collapse and subsidence that destroy surface and underground units. Because of floating earth it was necessary to suspend the construction of new lines of Moscow underground (Metro). As a whole the flooded territories make about 40% of the surface area of Moscow which houses over 30 large enterprises. Approximately 500,000 m^3 of water is annually infiltrated to the subsurface of Moscow. Half of this quality is leakage from underground pipeline for water supply and sewerage, ponds and water reservoirs.

Dehydration of karst carbonate solid monolith, ingress of acid surface water and other factors lead to subsidence of rock and surface. Within last 25 years in the Northwest of Moscow there were 42 cases of crater formation with diameter of up to 40 m and depth up to 8 m, which resulted particularly in the destruction of residential constructions.

As subsurface waters get depleted they become chemically and bacteriological polluted due to the pulling of overlying and surface water. For example, in some points of water inlet in Moscow (Centre, Paveletski railway station, Lyublino-Nagatino, Dorkhimzavod, Ostashkovki highway) the concentration of mercury, lead, zinc, cadmium and chromium in subsurface water exceeds maximum allowable concentration several times.

Washout and suffusion processes restore their activity along the route of underground communication and in the bulk of filled-up soil, slope development renews landslide processes especially along Jurassic clays in the lower parts of Moscow River valley. Landslides occupy about 3% of the territory of the city. In Moscow there are 15 large areas with deep (up to 100 m) landslides and 200 small (1–5 m) surface landslides in quaternary sediment (overburden). The number of landslides doubled within last ten years. In some regions of Moscow the deep landslides mainly caused by man's activities move with the speed of 5 to 30 cm a year.

4 INFLUENCING FACTORS AND METHOD OF THEIR ASSESSMENT

Analysis of factors that influence origination of extraordinary situations and their consequences allowed forming a cause-and-effect model of extraordinary situations in the course of underground space usage (fig. 1). According to the model the environment in which the extraordinary situations are being developed is divided into three parts: *A* –an underground object itself, *B* – surrounding solid monolith of rock, *C* – earth surface. Factors that cause extraordinary situation or determine its development (upper part of the chart), and influence the consequences of this event (lower part of the chart, indices with quotation mark) are presented for each of them.

where: *C*1 – mechanical effect of the objects on the surface, *C*2 – availability of resources, *C*3 – surface water bodies (reservoirs), *C*4 – atmosphere, *C*5 – type and work load of the territory; *B*1 – depth, *B*2 – rock mechanical properties, *B*3 – watering, *B*4 – gas composition of the solid monolith, *B*5 – adjacent underground objects, *B*6 – confining pressure, *B*7 – courses that connect with surface; *A*1 – access to surface, *A*2 – power supply, *A*3 – dewatering,

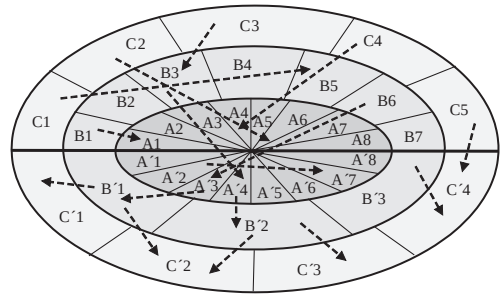

Figure 1. Cause-and-effect model of extraordinary situations in the course of underground space usage.

$A4$ – ventilation, $A5$ – maintenance of solid monolith, $A6$ – fire fighting, $A7$ – space workload, $A8$ – location of objects (processes); $A'1$ – fire, $A'2$ – explosion, $A'3$ – monolith fall, $A'4$ – flooding, $A'5$ – ventilation damage, $A'6$ – failure of electric power supply, $A'7$ – equipment fault, $A'8$ – hazard caused by located objects and processes; $B'1$ – damage of solid monolith, $B'2$ – failure of geological conditions, $B'3$ – pollution of underground waters; $C'1$, $C'2$, $C'3$, $C'4$ – impact on atmosphere, aquatic environment, territory, soil.

This model allows creation of possible scenarios for extraordinary situations that occur in the use of undergrounds space and their consequences.

Basic elements of emergency situation and their characteristics have been identified in order to assess the size of damage caused by extraordinary situation in the use of underground space and efficiency of measures directed to reduce the consequences (Table 1).

Measures on the reduction of damages are intended to change one or several characteristics of the extraordinary situation elements. The above mentioned elements have been taken into consideration in the development of the method for the assessment of the consequences of extraordinary situations and efficiency of measures intended to reduce them, which is based on the following criteria:

Table 1. Elements of extraordinary situation in the use of underground space and their characteristics.

Elements of extraordinary situation	Characteristics
Source	– type (ignition, flooding, mechanical impact, etc.)
	– location
	– probability of occurrence
	– duration of event

	– economic
	– social

$$D=P\cdot W\cdot\sum_{i}^{I}(F_i\cdot T_i\cdot\sum_{j}^{J}(S_j\cdot k_{ij}^{s}\cdot\sum_{l}^{L}(Q_{jl}\cdot D'_{il})))\rightarrow\min \qquad (1)$$

where D – damage caused by extraordinary situation, \$; P – probability of initiation of the source of extraordinary situation, fraction; W – strength of the source of extraordinary situation, un.1, i – index of the type of negative factor that arises in the result of the effect of the source, $i\in I$; F_i – power of the factor of consequences caused by the source of extraordinary situation, un.2 /un.1; T_i – duration of hazardous factor, sec.; j – index of the zone of territory affected by the factor of consequences, $j\in J$; S_i – area of the territory affected by the factor of consequences, m^2; k_{ij}^{s} – coefficient of the factor of consequences propagation i in zone j, fraction; l – index of the type of consumers of the factor of consequences, $l\in L$; Q_{jl} – number of objects of the type l, situated in the zone j, pieces/m^2; D'_{il} – average damage caused to the object type l by factor i, \$/(un.2·pieces·sec); un.1 – unit for the power of the source of extraordinary situation (for example, earthquake magnitude); un.2 – units of negative factor arising in the result of extraordinary situation (for example, content of harmful substances in atmosphere).

Recommendations on the improvement of legislation relating to the use of urban underground space that allow to regulate the underground activities more effectively and thus to reduce possible damages caused by emergencies have also been developed.

5 CONCLUSION

This paper considers interrelation of underground usage and ecological safety in a big city. Moscow has been used as an example for performing analysis of major factors of underground units that effect the environment and vice versa. As a result the paper suggests systematization of reasons causing damage in emergency situations in the course of underground space usage. Assessment of major damages and measures for their mitigation are given.

Managing risk – successful project delivery, underground infrastructure for Terminal 5 Heathrow Airport, UK

O.I. Williams
BAA plc, London, UK

ABSTRACT: Terminal 5 (T5) will open in March 2008 and ultimately provide Heathrow Airport with an additional 30 million passenger annual capacity, giving a total annual capacity of about 90 million passengers. T5 is one of the largest construction developments in Europe with an estimated outturn cost of £4.3 billion. The Terminal's infrastructure includes approximately 14 km of tunnelling to provide road and rail links.

Managing risk is vital to the success of any project and in particular with those involving tunneling. In the last 15 years there has been a number of projects where their overall success was affected when the consequence of risk became a reality.

Fundamental to the success of T5 was the contract strategy developed by BAA and the implementation of risk management. The strategy was a non-adversarial contractual approach based on relationships and behaviours with risk management as a core activity. This paper describes BAA's contract strategy and the processes developed and implemented by the Team.

1 INTRODUCTION

1.1 *The Project (T5)*

The T5 project consists of a main terminal building and two satellites, additional 56 aircraft stands, car parking for 5000 vehicles and road and underground rail infrastructure. The key element of T5's infrastructure is approximately 14 km of tunnelling to provide the terminal with road and underground rail links, Figure 1 shows an aerial view of the T5 project and Figure 2 the plan location of the tunnel projects. The tunnels range in length from 1.3 km to 4.1 km and from 3 metres to 8.1 metres in diameter. The majority of the tunnels were constructed using Tunnel Boring machines (TBMs) and innovative developments of the single shell shotcrete lined method, Lasershell™, (Eddie et al 2003) for the construction of the numerous short, complex underground structures such as shaft and cross passage complexes. The specific details of the projects are described in detail by Hilar et al (2005).

1.2 *Why manage risk?*

In the last 15 years there has been a large number of UK and international projects were overall success was affected when the consequence of risk became a reality. These consequences ranging from cost and time overrun, technical failures (tunnel excavation and

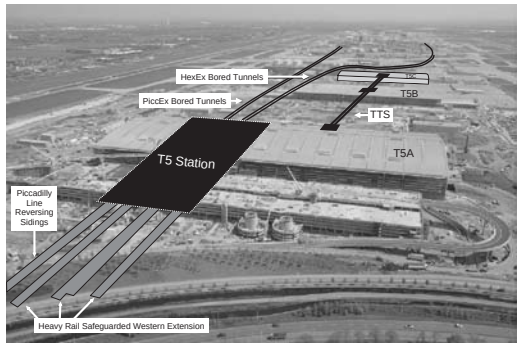

Figure 1. Aerial view of the T5 project.

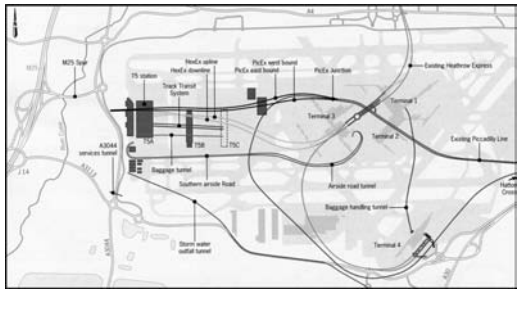

Figure 2. T5 project and the location of the tunnel projects.

collapses for example), injury to people, damage to property, and, corporate and industry credibility.

Notable tunnelling project examples include the Jubilee Line Extension (UK), whilst being a technical success, significant time and cost overruns occurred, Heathrow Express (UK) tunnel collapse in 1994 (HSE 1996), Munich (Germany) tunnel collapse in 1994, and most recently in 2004 the Nicoll Highway excavation collapse in Singapore (Magnus et al 2005). There are other worldwide instances too numerous to mention (Lance et al 2006).

It is generally accepted that all risks cannot be removed but it is also accepted that identification of risks and their proactive management can decrease the probability of occurrence, and in the event that they do occur, the severity of the risk event can be minimized with robust control processes and mitigation in place.

Given historical events, the delivery of T5 presented BAA with a challenge in respect of the tunnelling risk. The key factors contributing to this were: £4 billion plus project privately financed by a private company, the scale of project not undertaken previously by BAA, ambitious technical challenges to be delivered in the environment of the world's busiest airport. BAA's objectives from T5 were to deliver on time, within budget, compliant with specifications, safe and meeting customer needs and expectations.

From the experience of other projects and BAA's own experience of the Heathrow Express tunnel collapse in 1994, BAA recognised to meet its objectives they needed to develop a procurement and project delivery strategy that was able to meet the challenges of delivering a complex project. BAA accepted that to achieve different future results it was necessary to do something different to what was historically done by the construction industry. BAA recognized that to successfully meet these objectives BAA needed exceptional performance from it's suppliers. BAA considered the key success criteria for the strategy would be a non-adversarial contractual approach, based on relationships and behaviours with cost reimbursement as a cornerstone rather than conventional contractual approaches. Furthermore, BAA acknowledged that the risk of not achieving a successful T5 was so large that to achieve exceptional performance BAA would need to be for the time and cost risks all the time. These factors led to the T5 Agreement.

2 MANAGING PROJECT RISK

2.1 *The T5 Agreement*

The T5 Agreement is a unique contract which outlines processes and strategies to manage successful project outcomes in an uncertain environment and not contractual positions when things go wrong. It focuses on principles such as behaviours and relationships, risk management, performance and success, and, people as individuals contributing to integrated teams to achieve a common goal. The consequences of conventional contractual risk of cost and time are not shared, they are held by BAA. Suppliers' actual costs are reimbursed with a guaranteed element of profit and an incentive target payment to reward exceptional performance, and if achieved, shared between the suppliers and BAA.

2.2 *T5 tunnel projects delivery team*

BAA put together a single, multi-company integrated team to deliver the tunnel projects, this included: BAA (client and project leadership), Morgan Vinci (tunnel constructors), Mott MacDonald (overall civil and tunnel designer), and Beton-und Moniebau (Sprayed Concrete Lining [SCL] design and on site specialist support).

2.3 *Risk management*

The strategy of managing risk was through integrating risk and delivery management. Initially the process involved exposing the risks through project risk reviews and thereafter regularly updating and reviewing 'live' risk registers and live risk response plans within the framework of a project execution plan. Each of the specific tunnel projects presented a number of challenges. The two most significant physical challenges were controlling ground movement (and eliminating tunnel collapse), and workforce safety. It was considered that if these two areas were managed successfully, the other key risks of time and cost would directly be influenced positively. The Team adopted the fundamental principle of providing control measures not consequence control measures as a basic risk management approach to achieve the optimum solution. Specifically, the Team concentrated on eliminating the risk, for example ground movement, face collapse etc. by implementing control measures thereby preventing or minimising the hazard happening in the first instance rather than rely on a consequence control measure.

Notwithstanding that risk management was a core objective to the Team. UK legislation also imposes duty on parties to address risk. The legislation and its relation to risk are well documented by Lance et al (2006). The Project Team implemented these obligations and whilst not mandatory, the Team, through commitment to adopting best practice, followed the guidelines of the Joint Code of Practice for the procurement, design and construction of tunnels and associated underground structures in the UK. (ABI & BTS 2003).

3 MANAGING SAFETY RISK

3.1 *Incident & Injury Free program (IIF)*

A central project risk objective was ensuring workforce safety. A number of innovations and initiatives were developed and followed on T5 to meet this objective. Adoption of cause control measures and targeting attitude to personal safety were the two key elements of the strategy. It has long been considered that significant improvement in safety can only be achieved if a positive safety culture exists in everyone. To address this, a behavioural safety imitative was introduced, the Incident and Injury Free program (IIF). The key element of the program was to make safety a personal commitment, moving safety to a core value and creating a vision and expectation that all incidents and injuries are avoidable.

3.2 *Technical innovations*

The Team investigated and developed methods and techniques to reduce workforce exposure. One of the main innovations involved further developments with the sprayed concrete lining (SCL) technique. The Lasershell™ method was developed to improve safety by eliminating the need for miners to enter an unsupported face area and to mechanise the process to reduce injuries. Other key factors in the development were fast ring closure with minimum joints in the shotcrete lining and its suitability for complex structures. The application of the method at T5 is described in detail by Williams et al (2004).

A typical advance for SCL works in soft ground consists of a top heading, bench and invert. Girders and mesh are used for support along with the shotcrete and require miners to work in the face area. The basic concept of the innovative Lasershell method is a circular cross section with an inclined domed face and rapid shotcrete ring closure and eliminating the need for lattice girders. Figure 2 illustrates a typical cross section of Lasershell™. Traditionally lattice girders are used to aid shape control. To eliminate the need for lattice girder, the TunnelBeamer™ survey tool was developed which could accurately guide the excavation and spraying process. All excavation is carried out by machine and the shotcrete has a permanent load function, with no girders or mesh, no horizontal joints and only one circumferential joint.

4 MANAGING GROUND MOVEMENT RISK

4.1 *Ground movement risk management process*

The tunnels crossed beneath Heathrow airport infrastructure consisting of one of the runways, aircraft taxiways and stands, buildings, strategic fuel and fire mains and two existing underground railway tunnels. Despite having appropriate tunnelling methods, ground movement was inevitable. A holistic approach to the control of ground movement was developed which covered the full spectrum from selection of tunnel excavation method through to a robust geotechnical and TBM data output monitoring and review cycle, Figure 3.

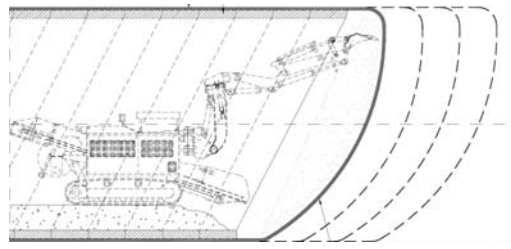

Figure 3. Cross section of typical Lasershell™ method.

This process did not prevent ground movement but provided the Team with a robust framework in which to manage the consequence with third parties. Whilst the emphasis was on cause control measures, detailed emergency and recovery plans were prepared in partnership with third parties to address the prevention of the occurrence of consequence escalation.

4.2 *Technical solutions – appropriate tunnelling methodology*

The Airside Road Tunnel (ART) presented the most significant ground movement risk to the project. The diameter of the twin tunnels (8.1 m inside diameter) and its need to remain shallow from an operational requirement had potential ground movements which could severely damage the existing airport infrastructure and existing railway. Whilst the tunnel horizon was anticipated to be stiff clay (London Clay), the possibility of encountering the overlying water bearing gravels existed. To meet the challenge the Team worked closely with Herrenknecht and Putzmeister to develop a TBM which had specific features to address the tight ground movement criteria (less than 25 mm), low cover and ground conditions (Williams et al 2005).

The solution developed consisted of a closed face TBM (9.18 m external diameter) capable of applying low air pressure to the face and to address the risk of encountering the water bearing gravels the TBM also had the capacity to convert to Earth Pressure Balance (EPB) mode. Tests confirmed London Clay would not form a plug in the screw conveyor, capable of reliably maintaining 2 bar pressure, therefore a mechanical method of maintaining pressure had to be developed. Following a significant development and testing program, a Putzmeister twin piston pump screw conveyor airlock system, consisting of two 750 mm diameter

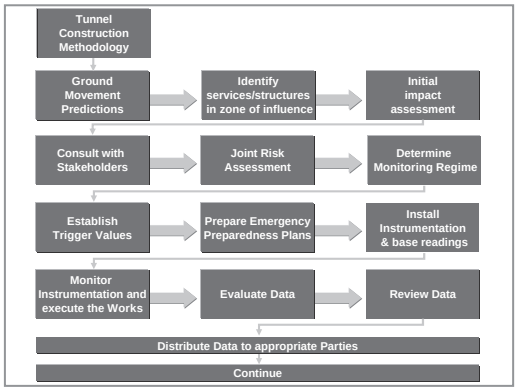

Figure 4. Ground movement management process.

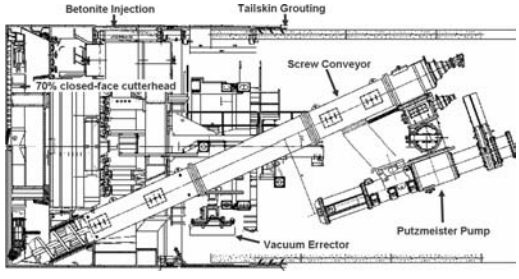

Figure 5. Cross section through the ART TBM showing the main components (Williams 2005).

pistons with an output of 400 tonnes/hour was fitted to the end of the screw conveyor. This allowed material to travel along the screw conveyor and then drop into the pump, where its two piston pumps acted as airlocks to control the air pressure in the chamber of the TBM, Figure 4.

Other features incorporated into the TBM, to aid the control of ground movement, included: keeping the cutterhead within the extrados of the TBM so that the front edge of the shield acted as a cutting edge; limiting the conical shape of the TBM; bentonite injection around the tailskin to provide ground support and maintain the face air pressure and simultaneous automated pressure controlled tailskin grouting.

4.3 *Tunnelling performance*

The surface monitoring data for the ART tunnels show that ground movements were kept within the maximum range and in most areas the actual ground movement was in close correlation to predictions. Figure 6 (Williams et al 2005) summarises the ground movement along the centreline of ART. In summary, the ground movement for over 36% of the drive length was between −5 and +5 mm, for 90% of the drive the

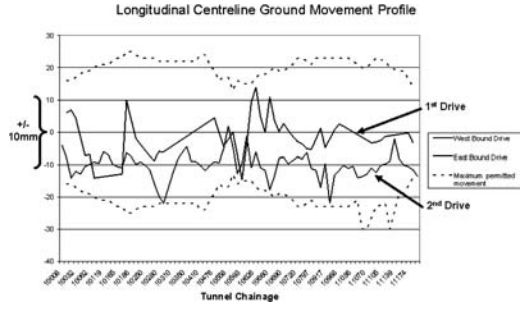

Figure 6. Ground movement along the ART tunnel drives (Williams et al 2005).

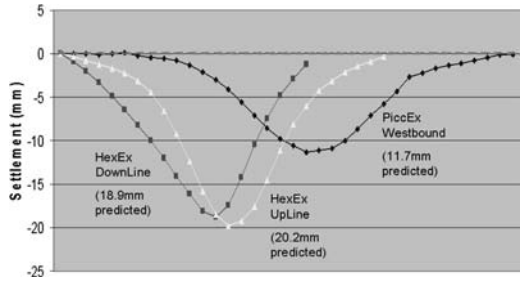

Figure 7. Existing rail tunnel movement caused by tunnelling.

movement was in the range of −10 and +10 mm and there was no significant movement greater than 20 mm was recorded.

The significant challenge for the Piccadilly Line and Heathrow Express tunnels was crossing beneath the existing Piccadilly line railway tunnel. Figure 6 shows the vertical movement recorded in the existing railway tunnel as a result of three tunnel crossings. The movement recorded was about 20 mm for the Heathrow Express tunnels (5.75 metres diameter passing 5 metres beneath the existing and the tunnel) and 12 mm for the Piccadilly Line tunnel the tunnel (4.5 metres diameter passing 4 metres). In both cases the actual movement was within 5% of the prediction value.

In all cases, tunnel construction proceeded without affecting the operation of the existing railway infrastructure and that of the airport.

5 CONCLUSIONS

14 km of incident free tunnel construction was completed on T5. The fundamental factors which underlined this achievement were the contract BAA developed and implemented, the T5 Agreement, and acceptance that the risk and its consequence rested with BAA. The principles of the Agreement focused on

success with all parties having aligned objectives and using risk management as a tool to support decision making, enhancing workforce safety, and eliminating unforeseen events. The implementation of the principles enabled the project to be delivered within the cost and time targets. Successful risk management was also supplemented by the introduction of IIF, a comprehensive behavioural safety program and the development of technical innovations.

ACKNOWLEDGMENTS

The author thanks the many individuals and companies who were fully committed to the principles of the T5 Agreement, these being of Trust, Commitment and Teamwork, without it none of the successes would have been achieved. Notwithstanding the commitment of individuals the author acknowledges the courage of BAA to implement the T5 Agreement.

Development and application of process-oriented shield tunneling risk management system

Tang Xuan, Wu Huiming & Bob Chow
Shanghai Tunnel Engineering Co., ltd. (STEC), China

ABSTRACT: Based on the risk management flow suitable to construction enterprises, the paper creates a set of risk analysis structure for shield tunnel construction risk management. Moreover, combined with the platform of knowledge management in construction enterprises, a risk knowledge management system for shield tunnel construction is developed. The system helps to optimize the allocation of resources within enterprises and promote the efficiency of overall control in risk and construction cost.

1 INTRODUCTION

Risks can be divided into two types, pure risk and speculative risk. Pure risks cause only losses, while speculative risks may bring profits if the risk control measures are properly taken. The paper mainly concerns about pure risks caused by the uncertainty of staff capability, equipment performance, materials, accuracy of construction schemes and environment factors during shield tunnel construction. At present, researches in most domestic construction enterprises in this field still pause on the level of contingency plans. A systematic leap is anticipated in domestic construction risk management to effectively reduce the possibility of construction risk and the resulting losses during construction.

In that background, fully considering the needs of STEC in shield tunnels construction, we've set up a research group and worked out a practical process-oriented risk management system structured on the platform of knowledge management. Practices show that the combination efforts of construction risk management and knowledge management in construction enterprises helps to continuously promote its ability of risk control during construction, and also has great significance in enhancing its core competence.

2 FLOW DESIGN OF CONSTRUCTION RISK MANAGEMENT

2.1 *Construction risk analysis*

2.1.1 *Risk identification*

Risks in construction stage of a project come from either inaccurate evaluation of its resources by the construction enterprises, or the uncertainty of environmental conditions surrounding. Those risks will eventually cause several kinds of losses. Thus, at the beginning of risk identification, Risk classification in construction should first be done. Generally speaking, construction risks can be classified into four categories according to what kind of losses they induce (see Table 1).

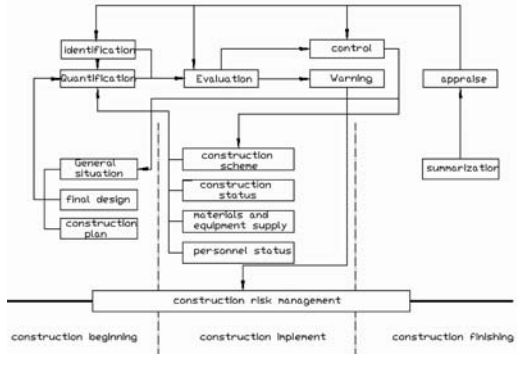

Figure 1. Flow design of risk management.

Following the sequence of construction procedures, we can analyze these four kinds of risks by identify their influencing factors during construction from different angles of view, such as staff, technology, equipment, materials, and environmental conditions, etc. Then, a primary risk factors hierarchical structure comes out for further analysis.

2.1.2 *Risk quantification*

In this process, we need determine unified evaluation criteria. Then proper appraisal indicators should be chosen or created to fully reflect the current status of

every risk influencing factor. In doing so, make sure that the value of chosen parameters should be easy to get and have enough representation. On that base, expert investigation or statistical methods from history cases can be used to determine the membership function of each risk factor corresponding to the evaluation criteria.

2.1.3 *Risk evaluation*

Use Analytical Hierarchy Process (AHP) to get the weighs of levels of risk influencing factors required in the evaluation of the objective hierarchy. Then second-order Fuzzy Comprehensive Evaluation (FCE) model can be presented to evaluate construction risk.

2.2 *Risk control*

According to whether the risk events have already occurred, risk control can be classified into pre-control and post-control. Pre-control measures including risk early warning are needed when the evaluation result of a certain risk in the objective hierarchy exceed the expected warning line. In such situation, the relating measures should be taken in advance to prevent losses. Post-control measures are taken when some risk events and their resulting losses have been inevitably detected. Such measures are taken to control existing losses from deteriorating or restrict other losses. The knowledge of both kinds of measures can be accumulated and improved by experts or case investigations.

2.3 *Evaluation after risk management*

In the progress of construction, the validity and effectiveness of the risk analysis model and risk control measures can be optimized continuously during construction by analyzing the difference between actual risk status and the forecast one, the difference between actual risk control schemes and the proposal ones, or the effects of the proposed scheme if it is taken.

Table 1. Classification of construction risks.

No.	Risk category	Resulting losses
1	Project quality risk	Project quality reduces.
2	Environmental safety risk	Personnel casualty, equipment destroy and environmental disasters such as destroy of buildings, underground utilities, etc.
3	Economic risks	Construction cost increases.
4	Time risk	Time of project completion delays, duration of the project is prolonged.

3 RISK EVALUATION SYSTEM OF SHIELD TUNNEL CONSTRUCTION

3.1 *Evaluation criteria*

Risk evaluation in shield tunnel construction can follow the criteria in Table 2. Standard get from index function provides a conservative choice for projects with more critical restricts to construction.

3.2 *Risk analysis model*

Through the process of risk identification according to Table 1, we can set up the shield tunnel construction risk factors hierarchical structure based on seven objective risks. These seven risks consist of two risks of Project Quality (Axis Deviation, Liner Deformation), three risks of Environment and Safety (Surrounding Structure Destroy, Personnel Casualty and Equipment Destroy), one economic risk (Cost Overrun) and one Time Risk (Construction Delay). Take the Axis Deviation Risk for example, its influencing factors hierarchical structure is shown in Table 3.

Indicators, which can reflect the status of risk influencing factors, can be divided into qualitative indicators and quantitative ones. The quantitative indicators consist of design parameters and construction variables. Design parameters can be determined before construction, while construction variables should be frequently updated during construction. In the process of risk evaluation, if the current value of some construction variable is unavailable, then a historical value or statistical predictive value will be used to get a predictive result.

4 RISK KNOWLEDGE MANAGEMENT OF SHIELD TUNNEL CONSTRUCTION

4.1 *Methodology*

The process of risk knowledge management in shield tunnel construction enterprises can be described by 3-level circle (see Figure 2).

Table 2. Criteria of shield tunnel construction risk evaluation.

Risk ranking	1st	2nd	3rd	4th	5th
Linear function	0∼0.20	0.20∼0.40	0.40∼0.60	0.60∼0.80	0.80∼1.00
Index function	0.1∼0.13	0.13∼0.29	0.29∼0.48	0.48∼0.71	0.71∼1.00
Risk descriptions	Can be neglected	Give early warning in some key projects	Attention give early warning	Take pre-control measures	Unacceptable take post-control measures

In Figure 2, the outer circle of risk knowledge gained from many separate construction projects shows the diversity and specialty of risk knowledge. After absorbing by technicians, the risk knowledge of shield tunnel construction becomes tacit knowledge in experts' brain (in the middle circle).

The knowledge in the middle circle still needs further regularization and integration to become the core competence of construction enterprises. So a risk knowledge management system with the function of self-improvement is needed to accumulate risk knowledge like human brain during construction processes. The function of self-improvement can be realized by adding new cases to case base, gaining new rules from risk control measures and optimizing the model of risk evaluation, etc.

4.2 *Management platform and system frame*

The risk knowledge management system of shield tunnel construction is developed based on Browser/Server mode and can store the instructional content in databases and release it on the network.

The system includes five domains: Project Data Management, Risk Management, Risk Knowledge Learning, System Management and Case Management.

4.2.1 *Project data management*

The value of key parameters determined in final design and construction scheme can be imported

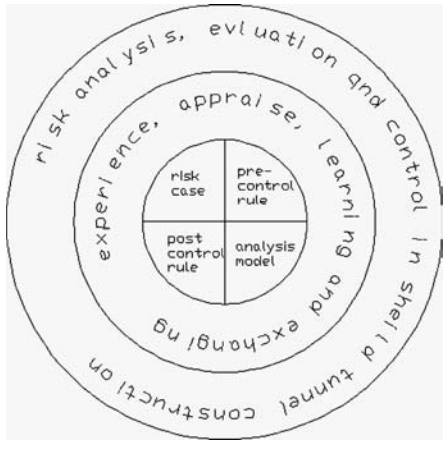

Figure 2. Three-level circle of risk knowledge.

Table 3. Risk influencing factors hierarchical structure (Axis Deviation Risk).

Objectives	Influencing factors I	Influencing factors II	Indicators	Type
Axis Deviation	Starting attitude of the shield	Position-setting of basement	Direction, slope, horizontal and vertical position	Construction variable
		Supporting system	Structure's safety factor ε	Design parameter
			Deformation of rear supporting structure	Construction variable
		Soil strength after foundation stabilization	Strength of sample	Construction variable
	Accuracy and efficiency of surveying	Equipments error	Error of equipments	Design parameter
		Surveyors' ability	Experience, qualification	Design parameter
		Efficiency of control measures	Accuracy of control points	Qualitative indicator
			Accuracy of orientation	Qualitative indicator
			Fitting of the curve	Construction variable
	Shield attitude control	Instability of excavation face	Pressure of cutting face	Construction variable
			Volume of discharged soil	Construction variable
			Driving speed	Construction variable
			Ground Settlement at cutting edge	Construction variable
		Rectification control	Degree of rectification per ring	Construction variable
		Soil condition	Value of Penetration N, water content	Design parameter
	Stress and attitude of lining	Efficiency of synchronous Injection	Injection Volume	Qualitative indicator
			Materials proportion	Construction variable
		Axis of segmental ring during erection	Settlement of segments	Construction variable
			Accuracy of lining axis direction	Construction variable
	fault of equipment	Jacking system	Accuracy of journey position	Qualitative indicator
		Regional pressure Control	Pressure deviation	Qualitative indicator

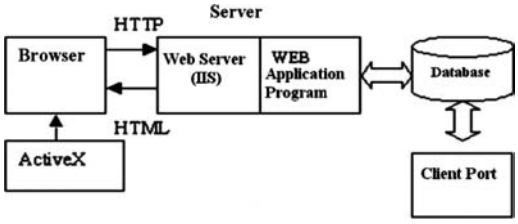

Figure 3. Structure of knowledge management systém.

before constructions, including information of tunnel length, tunnel lining, construction period and cost, geology parameters, embedded depth of tunnel, and surrounding conditions, etc, which are the basis of risk management.

4.2.2 *Risk management*
Main part of shield tunnel construction risk management, including five processes (risk identification, risk quantization, risk evaluation, risk control and evaluation after risk management) as previous discussed.

4.2.3 *Risk knowledge learning*
Provide a platform for learning and exchanging knowledge by forum, experts map and connection to the Case Base.

4.2.4 *System management*
It is the core of whole system, stored with all users and knowledge information including case base, rule base and risk analysis models. The system authorizes different users with different levels of rights to ensure safe operation and no leakage of core information.

4.2.5 *Case management*
History Cases can be accessed by matching algorithm based on risk categories, shield type, environment or geology characteristics and construction process when risk events occur, etc.

4.3 *Application in construction*

The system has applied in a certain shield tunnel project in the process of tunneling beneath a building. Before construction, parameters determined by design proposal and construction scheme should be input into Project Database. During construction, engineers can make risk identification with the help of system. The accuracy of this process is close related to the accuracy of input data or system prediction (if lack of input data). On this basis, the system goes further to evaluate every risks of seven.

If the result of any risk evaluation exceeds the expected line, the precaution warning and pre-control measures or post-control measures according to current risk status will be proposed based on the data base of rules and risk analysis model. But if the value

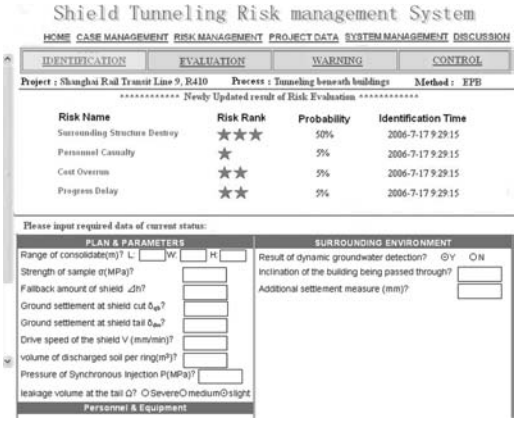

Figure 4. System interface of risk identification process.

is lower than warning line, the system only records current information for future references.

5 CONCLUDING REMARK

The system runs well during trail application in the process of tunneling beneath a building. The function of system evaluation after each cycle of risk management makes the risk knowledge management system an open one to continuously optimize itself in applications. It helps to promote efficiency of risk management. It can be anticipated that with the continuously improvement of the system, it will play an important role in optimizing the allocation of resources within enterprises by comprehensively consider the factors of personnel, materials, equipment and environment.

On the other hand, risk-cases occurred in application will be constantly imported into Case Base for further study. These cherish data is helpful for further understanding of the distribution and induction of construction risk during shield tunneling.

Evaluation of tunnel behavior and decision making of counter measures in weak zones

Hiroshi Yagi & Masaaki Hashimoto
Central Nippon Expressway Co., Ltd., Japan

Yasutoshi Yoshida, Kouji Tamamura & Atsushi Uneda
Kajima Corporation, Japan

ABSTRACT: The Kanaya tunnel on the New Tomei Expressway is a large-section tunnel 4.6 km long with an excavation section of about 190 m^2. This tunnel is constructed by driving a drift 5 m in diameter using TBM, then enlarging the section. For the area in weak geological conditions, suitable support structures for main tunneling were determined by in-depth preliminary investigations to correctly grasp the ground properties, including studies on data obtained during excavation by TBM, various surveys and tests, and numerical analyses. During enlarging the section in the poor ground primarily composed of mudstone that lies near the center of the tunnel sector, convergence reached around 200 mm, rock bolts broke and cracks were induced in the shotcrete. Ultra-strong rock bolting (with prestressing steel bars) was selected to solve these difficulties through analyzing data of various measurements and conducting numerical analyses. This support worked effectively to reduce displacements. In this tunnel, an efficient and economical construction is aimed at by feeding back the construction results to the construction of the following section.

1 INTRODUCTION

Central Nippon Expressway Co., Ltd. is currently constructing the sector in Shizuoka prefecture of the New Tomei Expressway. A mudstone stratum lies in the line of the Kanaya tunnel where the competence factor (ratio of unconfined compressive strength to earth covering) is 2 or less with a large earth covering. In this sector, rock bolts broke and cracks occurred in the shotcrete, inducing excessive convergences and settlements at the tunnel foot. As countermeasures against such difficulties, rock bolts of prestressing steel of 748 kN in tensile strength were driven, aimed at limiting displacements and providing stronger supports. This solution was proved to be effective. Prestressing steel bars have generally been used for prestressed concrete. Table 1 shows the properties of the prestressing steel bar and rock bolts widely used. This paper discusses the results of studies on the deformation behavior of ground in large-section tunnels and applicability of prestressing steel bars to tunneling supports, referring to construction records of the west sector of the Kanaya tunnel in a mudstone stratum.

Table 1. Features of prestressing steel bar and rock bolt.

	Prestressing steel bar	High strength bolt	Normal bolt
Diameter	32 mm	24 mm	24 mm
Strength	748 kN (930 kN/mm^2)	297 kN (685 kN/mm^2)	180 kN (510 kN/mm^2)
Cross section	804.2 mm^2	433.1 mm^2	353 mm^2
Elastic modulus	210 kN/mm^2	210 kN/mm^2	210 kN/mm^2

2 OVERVIEW OF THE TUNNEL

2.1 *Construction summary*

The Kanaya tunnel is the longest tunnel on the New Tomei Expressway. It is located in Kakegawa City of Shizuoka Prefecture, including eastbound lanes spanning 4,527 m and westbound lanes spanning 4,667 m. The tunnel shape is a slightly flattened oval, with excavation sectional area of about 190 m^2 and width

of about 18 m (Figure. 1). The tunneling technique selected is TBM drift accompanied by enlargement, i.e., a drift is cut by a tunnel boring machine, then the tunnel cavity is enlarged by the top heading method for the westbound lanes first.

The main tunnel of the Kanaya tunnel is divided into east and west sectors. The westbound lane length in the west sector are 2,540 m. The top heading of this length took 36 months, comprising weak ground zone about 920 m long. Since measures were provided against various adverse changes in this weak ground zone, top heading took about 16 months. As of July 2006, the construction of the westbound lane tunnel (preceding tunnel) had been completed, and the eastbound lane tunnel (succeeding tunnel) is under construction.

2.2 *Geology*

The geology of the Kanaya tunnel site is composed, as shown in Figure 2, of Kurami group of Miocene Epoch of the Neogene Period and Setogawa group of Oligocene Epoch of the Paleogene Period. The boundary of these groups is located at the tunnel center. The west Kurami group is roughly divided into Matsuba formation, Towata mudstone stratum and Amagata sandstone stratum. Although the Matsuba formation is relatively hard Neogene mudstone, it is composed of significantly cracked sandstone. The Towata mudstone and Amagata sandstone strata are more brittle than Matsuba formation. The Towata mudstone stratum is especially weak, prone to slaking. In the zone from the Towata mudstone to Amakata sandstone strata, there were problems with TBM excavation of the westbound lane tunnel, such as significant convergence and crown settlement of the drift, constraint of the TBM movement and collapse of the crown. The ground in the Towata mudstone zone is liable to deformation after excavation due to their geological properties, with a large earth covering of approximately 250 m.

The east Setogawa group is alternately composed of sandstone and shale that has slickenside due to strong folding, with many cracks exhibiting noticeable spalling.

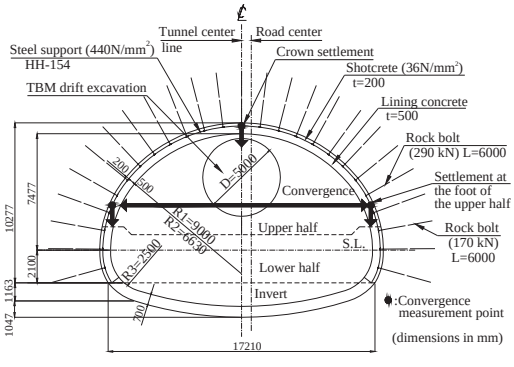

Figure 1. Standard cross section.

3 DEFORMATION CHARACTERISTICS OF THE LARGE-SECTION TUNNEL

On the basis of the measurement data obtained in this tunnel construction, a study was conducted to identify the deformation behavior of the large-section tunnel in mudstone ground, by determining relationships between convergences, crown and foot settlements with different support patterns.

3.1 *Relationship between crown settlement and convergence*

Figure 3 shows the relationship between final crown settlement and final convergence after invert closure. The ratio of convergence to crown settlement is 1 to 0.5 almost regardless of support pattern. As demonstrated by this result, the convergence is large in comparison with crown settlement.

3.2 *Relationship between foot settlement and crown settlement*

Figures 4 depicts the relationship between final foot settlement and final crown settlement. Strong correlation exists between foot settlement and crown settlement independent of the support pattern, the ratio being 1 to 1. As can be seen from this result, the crown subsides with the foot.

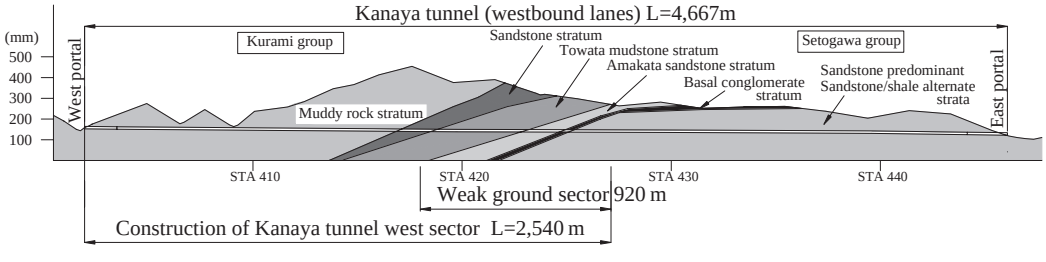

Figure 2. Geological overview of Kanaya tunnel.

3.3 *Relationship between value of crown settlement minus foot settlement and convergence*

Figure 5 illustrates the impact of crown-foot settlement relationship upon convergence after invert closure, by showing the relationship between the value of crown settlement minus foot settlement and convergence. In the region where this value is negative, that is, crown settlement exceeds foot settlement, convergence is not so large, 70 mm or less. In contrast, in the range where the value is positive, that is, the foot settlement is greater than the crown settlement, the convergence is larger as the absolute value of crown settlement minus foot settlement increases. These facts demonstrate that measures against foot settlement are essential to reduce convergence.

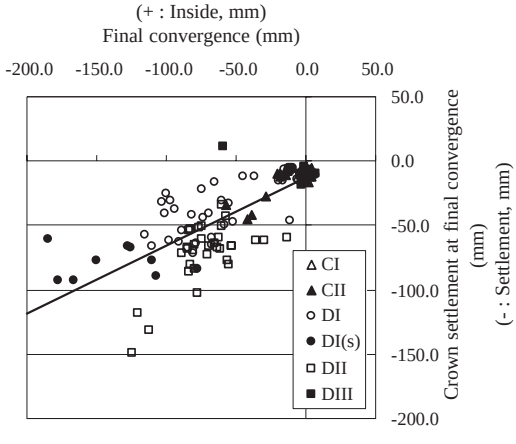

Figure 3. Relationship between crown settlement and final convergence.

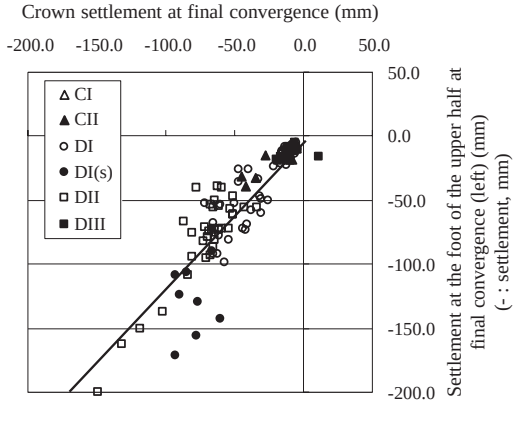

Figure 4. Relationship between foot settlement and final crown settlement.

4 MEASURES IN THE WEAK GROUND ZONE

In the study on the relationship between convergence and measures against foot settlement, focus was placed upon the zone from STA418+50 to 420+58.1 in the Towata mudstone sector greatly affected by ground displacements. For this zone, Figure 6 summarizes the ground data, support states and magnitudes of displacements with different support patterns. TBM excavation had revealed relatively poor geological conditions in this sector.

Therefore, geological surveys and FEM analyses were used to study support structures in advance. However, the geology turned out to be poorer than anticipated, and there were problems with supports along with increased displacement, such as cracks in shotcrete and deformation of rock bolt washers. Consequently, additional measures had to be taken and the support pattern had to be changed. In the following, support structures, measures against troubles and displacements are described for each ground zone.

4.1 *DI zone (STA418+50.5~STA419+32.1)*

Referring to the construction record of the tunneling project in question, the standard support pattern (DI) for road tunnels was adopted. However, the convergence reached around 80 mm at maximum during top heading near STA418+90. Since deformation occurred in plates of rock bolts at the foot and cracks in crown shotcrete, additional high strength bolts (strength: 297 kN) were driven to reinforce the rock bolts at the foot. When excavating the lower half section, a support pattern was used, with 6 m long prestressing steel bars (strength: 748 kN) placed into the lower half section. Consequently, the crown settlement increased very little during excavation of the lower half

Settlement and convergence measurements (final values)

Figure 6. Construction data of Towata mudstone section (STA 418+50.5 – 420+58.1).

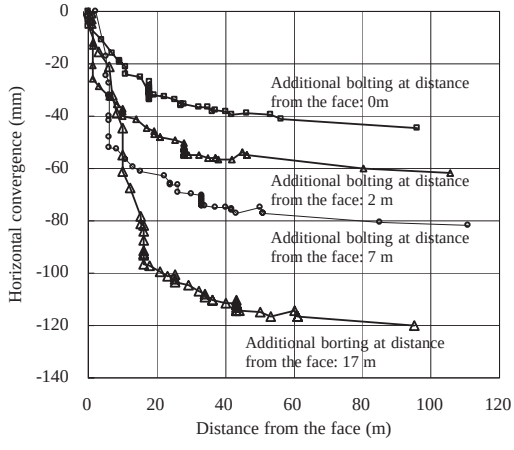
and invert, and increase in convergence was limited to about 20 mm.

4.2 *DI (s) zone (STA419+32.1∼STA420+01.1)*

From the result of the preliminary investigation from the TBM drift, the ground in the DI(s) zone was predicted to be poorer than the DI zone. The supports selected for upper half excavation in the DI(s) zone were steel arch supports with wing ribs and 25 cm thick shotcrete. However, near STA419+30 as shown in Figure 6, settlement at the left foot increased and the induced force exceeded the strength of the rock bolts at the foot. At first, additional high strength bolts were placed, but they did not exhibit a satisfactory effect.

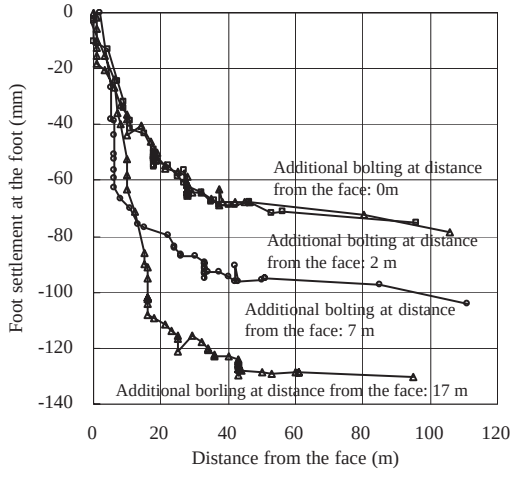
Then, since measurements with extensometers at STA419+71 revealed displacements up to about 9 m from the tunnel wall, measures were taken, including reinforcement of the foot portion with 12 m long prestressing steel bars and piling at the left foot.

As a result, displacements were confined, but the convergence reached approximately 120 mm at maximum in the upper half excavation. During the lower half excavation, a support pattern was used with 6 m long prestressing steel bars driven into the lower half section. This pattern enabled increase of convergence due to lower half and invert excavation to be limited to around 60 mm. However, in this DI(s) zone, the final convergence was 180 mm at maximum since the convergence had already exceeded 100 mm in upper half excavation. These results prove how it is important to provide an appropriate amount of supports during upper half excavation to confine final displacements.



4.3 *DII zone (STA420+01.1∼STA420+58.1)*

Since ground in the DII zone was weaker than the preceding zones and satisfactory reinforcing effect of prestressing steel bars at the tunnel foot had been confirmed in the preceding zones, the support pattern in this zone used 6 m long prestressing steel bars at the foot of the upper half during upper half excavation. Consequently, the convergence was not more than 40 mm and the settlement at the foot was 60 mm or less. Measures against foot settlement such as foot piling were therefore unnecessary. However, because the upper half foot was constrained by prestressing steel bars in the area beyond STA420+02, ground extrusion concentrated at the shoulder of the tunnel, which induced cracks in the shoulder shotcrete. To accommodate further stress increase due to lower half excavation, 12 m long prestressing bars were driven into the shoulder as preliminary reinforcement, then 6 m long prestressing steel bars were placed as pattern bolts into the lower half section. As a result, beyond STA420+00, convergence increase was limited to about 20 mm in the lower half and invert excavation, and the final convergence was within about 100 mm.



5 VERIFICATION OF ROCK BOLT EFFECT USING PRESTRESSING STEEL BARS

5.1 *Displacement confining effect of prestressing steel bars*

Figure 7 illustrates the relationship between placement timing of prestressing steel bars and convergence/foot settlement of this tunnel. The graphs in this figure reveal the fact that the smaller the distance between the face and the rock bolting position, the higher the convergence confining effect. Judging from the change in gradient of displacement graph before and after rock bolting, restriction of ground with prestressing steel bars contributed to prevention of settlement at the foot.

(a) Horizontal convergence

(b) Settlement at the foot

P=Total inertial pressure of tunnel
P_1: Inertial pressure of shotcrete
P_1=Axial force in shotcrete/ radius
P_2: Inertial pressure of steal support
P_2=Axial force in steel support/ radius
P_3: Inertial pressure of rock bolts
P_3=Tensile force in rock bolt/ shear area

Figure 10. Relationship of the acting force to the tunnel support and inner pressure.

5.2 *Relationship between tunnel deformation and supports*

The relationship between convergence and support inner pressures (Figure 10) is graphed in Figures 8 and 9, which will help investigate relationships between tunnel deformation behavior and support

Photo 1. Rock bolts with prestressing steel bars.

structure. These graphs demonstrate that the support pattern provided in the very vicinity of the face exhibits higher convergence confinement effect, and that pressures in the rock bolts effectively work to confine convergence.

The record of the Kanaya tunneling, in the sector with larger earth covering and lower ground strength, confirmed that rock bolts of prestressing steel bars were very effective to confine settlement at the foot and convergence. With this type of rock bolt pattern driven immediately near the face (shorter bolts were satisfactory in this case), tunneling could be performed highly efficiently and less costly compared

with the case where additional measures were taken from time to time referring to the measured data of displacement.

6 CONCLUSIONS

In large-section tunneling projects such as the tunnel discussed in this paper, the displacement speed is high in the initial stage of excavation, with plastic regions expanding rapidly. It is therefore essential to rapidly compile and evaluate the results of observation of the face and measurements, in order to select the best solutions suited to the ground mechanical properties. The experience of the Kanaya tunnel project proved that it is important to place a suitable support structure at an early stage after excavation, for fully utilizing the sustaining capability of the ground. Especially in large-section tunneling projects, ground reinforcement at the foot of the upper half section is vital to stabilize the whole of the tunnel. It can be concluded that prestressing steel bars are very effective supports that effectively confine ground maintaining triaxial compressive state.

ABSTRACT: The exposed sulfide minerals contained in rocks are easily oxidized, when they contact with oxygen in air and water during tunnel excavation. The oxidation generates acid rock drainage (ARD) contaminating soil and water and corrodes tunnel lining and support such as rockbolt and shotcrete. This phenomenon has a bad influence on environment and tunnel. When a construction work plans in the area with high ARD potential, a proper evaluation for ARD should be conducted in advance. The potential of acid rock drainage could be judged from rock crop survey and geological maps and guideline for the estimation of acid rock drainage risk was presented through the results of acid rock drainage assessment and numerical analysis of contaminant transport modeling.

1 INTRODUCTION

There were a lot of cases that surface and ground water were contaminated during constructing tunnel. Three tunnels (Tunnel A, Tunnel B1and Tunnel B2) were designed at Kim-Hae City, Kyeung-Nam province, Korea in 2005. The key issue was that Hwa-Po wetland located within 250 m near tunnel portal should be preserved during tunnel excavation. We found that rocks containing sulfide minerals were scattered in the site and might cause severe environment contamination on Hwa-Po wetland.

We accomplished the site investigations, the Acid-Base Account (ABA) test, the Net Acid Generation (NAG) test and numerical analysis of contaminant transport modeling to analyze the environmental impact on Hwa-Po wetland and to set up long-term management strategies. We reports novel strategy for the protection of environment, tunnel support and portal slope from ARD.

2 SULFIDE MINERALS AND MECHANISM OF ARD GENERATION

2.1 *The minerals which can generate ARD and reaction process*

There are thousands of known minerals. But the most common minerals to generate ARD are pyrite (FeS_2), marcasite (FeS_2), and pyrrhotite ($Fe_{1-X}S$, where $x = 0$ to 0.17). Among those minerals, Pyrite is present around Kim-Hae City, Korea. The oxidation of pyrite starts with exposure of pyrite to oxygen (in air) and water (rain, snow, humid air). Pyrite is less reactive if submerged in water. It is reactive because of repeated wet/dry cycles and the action of bacteria present at the earth surface that generates acid drainage. Some of the generalized chemical reactions used to describe the cycle of pyrite oxidation are described below.

$$FeS_2 + 3.5\ O_2 + H_2O \rightarrow Fe^{2+} + 2\ SO_4^{2-} + 2H^+ \quad (1)$$

Ferrous iron released from initial pyrite oxidation is oxidized to ferric iron by bacteria that are ubiquitous in the environment. There are several aerobic autotrophic bacteria that can obtain energy from oxidation of sulfide minerals, such as *Acidithiobacillus ferroxidans*. The oxidation of ferrous iron by bacteria is much faster than abiotic oxidation. The oxidation of ferrous iron is described by the reaction:

$$Fe^{2+} + 0.25\,O_2 + H^+ \rightarrow 0.5\,H_2O + Fe^{3+} \quad (2)$$

Once formed, ferric iron is a powerful oxidant that can attack pyrite and release significant amounts of ferrous iron and acidity that can further propagate the cycle of pyrite oxidation:

$$14\,Fe^{3+} + FeS_2 + 8\,H_2O \rightarrow 15\,Fe^{2+} + 2\,SO_4^{2-} + 16H^+ \quad (3)$$

Note that the initial reaction (1) produced 2 moles of H^+, but the propagation reaction with ferric iron as the oxidizing agent produces 16 moles of H^+. Sulfide minerals that have metal/sulfur ratios = 1 such as sphalerite (ZnS) and galena (PbS) are not strongly oxidized by oxygen, but are affected when ferric iron presents as the oxidant:

$$ZnS + 8\,Fe^{3+} + 4\,H_2O \rightarrow Zn^{2+} + 8Fe^{2+} + SO_4^{2-} + 8H^+ \quad (4)$$

Unless the acid (H^+) generated by these reactions is counteracted by a neutralizing agent, a serious acid-drainage problem can develop. Most metal ions that behave as cations are more mobile at low pH.

2.2 *Sulfide mineral distribution*

In Korea, There are lots of sulfide minerals that might cause acid rock drainage as shown fig 2. Generally, they are rich in the Mesozoic volcanic rocks and the tertiary volcanic rocks. They are rich around Kim-Hae city.

The area for tunnel A mainly consists of tuff with quartz porphyry dyke at entrance. Sulfide minerals are not found in tuff. But they are found only in quartz porphyry.

The bedrock of tunnel B1 consists of sandstone. Several dykes with high content of sulfide minerals such as pyrite and sphalerite also occur at the entrance of tunnel B1 and between tunnel B1 and tunnel 2. The bedrock of tunnel B2 mainly consists of sandstone and granite. The granite contains a significant amount of pyrite.

2.3 *The mechanism of ARD in Tunnel Portal*

Sulfide minerals which exist in subsurface can hardly react oxygen in atmosphere and water. But, in excavating tunnel portal, exposed sulfide minerals can easily react with oxygen and generate sulfuric acid. The

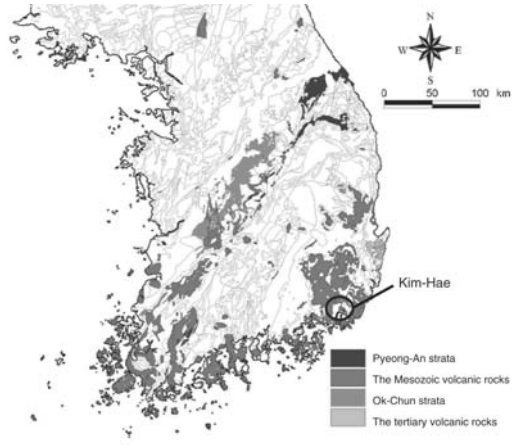

Figure 1. The sulfide mineral distribution map in Korea.

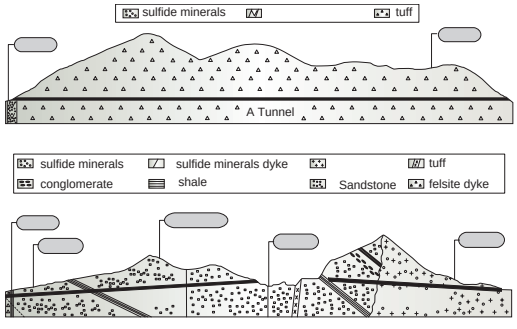

Figure 2. Sulfide mineral distribution in tunnel.

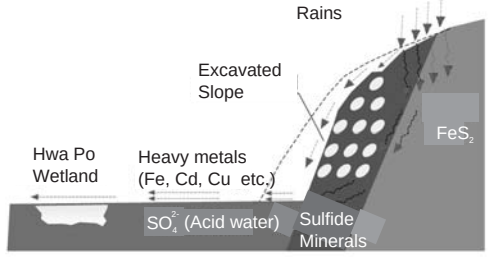

Figure 3. The mechanism of acid rock drainage.

oxidation of sulfides loads heavy metals contained in them.

3 ACID ROCK DRAINAGE ASSESSMENT

3.1 *The acid base account test*

The Acid-Base Account test (ABA test) is the most commonly applied method to acid rock drainage assessment. The results of ABA test in this site were

Table 1. The results of ABA (acid base account) test.

Sample no.	Sample location	Total S (%)	MPA ($KgCaCO_3/t$)	NP ($KgCaCO_3/t$)	NAPP ($KgCaCO_3/t$)	NAG (KgH_2SO_4/t)	(NP/MPA)	NAG* (pH)

TB-22	B2 tunnel exit	0.027	0.844	14.850	4.006	0.000	17.598	6.49

shown as table 1. The Maximum Potential Acidity (MPA) may be indirectly estimated by determining content of Sulfur (S) in a sample, assuming the S occurs as pyrite form

$$\text{MPA} = \text{total Sulfur (\%)} \times 31.213 \quad (5)$$

The MPA that can be generated by a material is expressed as a positive value. This value is usually expressed in Mg of lime equivalence per 1000 Mg of material tested. The convention of using Mg/1000 Mg is equivalent to kg/ton.

The Neutralization Potential (NP) of a sample represents as carbonates or other acid neutralizers in a sample. Negative NP values may occur when a sample contains weathering products, such as certain sulfate minerals, that produce acidity upon dissolution. If the resulting value is negative the material should produce acidic water upon complete and kinetically balanced reaction. Positive results indicate water drainage will be alkaline.

The Net Acid Producing Potential (NAPP) is calculated with following equation

$$\text{NAPP} = \text{MPA} - \text{NP} \quad (6)$$

3.2 *The net acid generation test*

This approach to determining acid potential is used in hydrogen peroxide (H_2O_2) method. The basis of the method is that H_2O_2 oxidizes sulfides and generates sulfuric acid, which presumably will react with alkaline components if present. The net acid generation (NAG) is determined by final titration with NaOH.

3.3 *The acid rock drainage assessment*

The possibility of acid rock drainage according to NAPP-NAG Chart was shown as fig 4.

The samples of TB-1, TB-9, TB-20 were classified as potential acid forming (PAF) It highlights one possibility that excavated slope surfaces are likely to react with water and generate ARD.

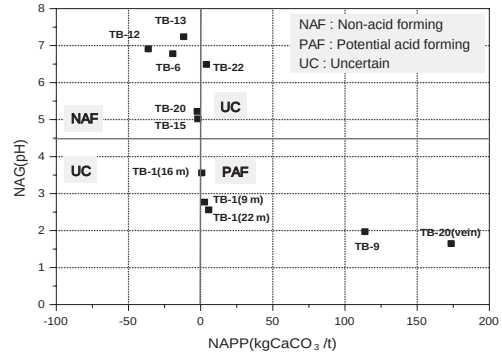

Figure 4. Acid base account assessment according to NAG and NAPP.

Table 2. Risk grade of acid rock drainage according to NP/MPA.

Risk grade	NP/ MPA	Sample no.	Remedy on acid rock drainage
dangerous	<1	TB-1, TB-9, TB-20(vein)	needed
warning	1-2 or 3	TB-13-2	needed if necessary
safe	>2	TB-6, TB-12, TB-20, TB-22	Not needed

The risk grade of acid rock drainage according to NP/MPA was shown as table 2. The possibility of ARD was very high in TB-1, TB-9 and TB-20 (vein) like the results of NAPP-NAG chart.

3.4 *The heavy metals leached by ARD*

The concentration of major cations and heavy metals was shown as table 3, after rock powder sample

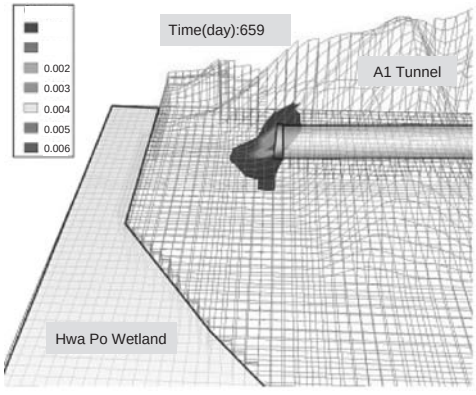

Figure 5. The Cd concentration of A Tunnel at the end of excavation.

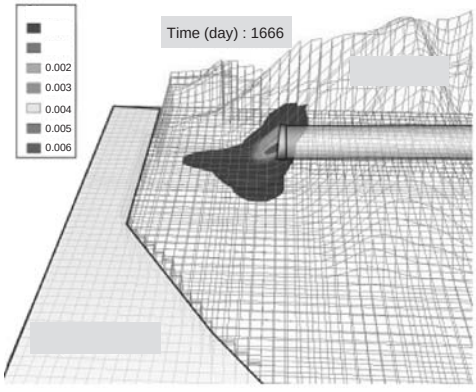

Figure 6. The Cd concentration of Tunnel A after 3 years of excavation.

reaction to 15% H_2O_2 solution (1 solid : 100 solution). Heavy metals (Cd, Fe, Mn, Al) concentrations of TB-1, TB-9 and TB-20 (vein) samples were high. So, remediation on not only neutralization of acid rock drainage but also removal of heavy metals should be made.

4 THE CONTAMINANT TRANSPORT MODELING

4.1 *The tracer of pollutants*

Considering heavy metal concentrations in the study area and ecological impact of heavy, cadmium (Cd) was selected as tracer of pollutant because the rock samples contains high concentration of Cd and Cd could cause very significant harm on men and ecological environments. We predicted Cd transportation behavior through groundwater flow induced by tunnel excavation.

4.2 *The contaminant transport analysis*

In analyzing Cadmium (Cd) transportation through groundwater flow induced by tunnel excavation, the regional groundwater flow was calculated as non-steady state flow using MODFLOW. The results of MODFLOW analysis showed that the groundwater head went down because of tunnel excavation and went up after installing tunnel lining.

In case of A Tunnel, excavation was planed to start from tunnel portal near Hwa-Po wetland and acid rock drainage would be caused and heavy metals could be transported into wetland.

In case of B1 Tunnel and B2 Tunnel, excavation was planed to start between B1 and B2 tunnel, could be transported into the valley between B1 and B2 tunnel.

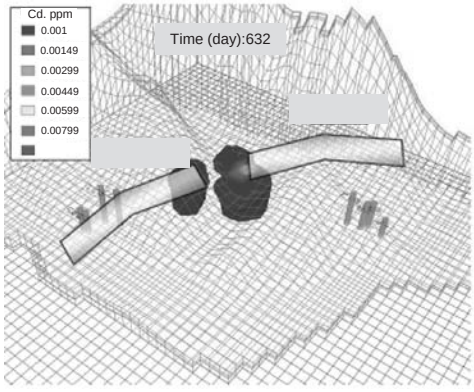

Figure 7. The Cd concentration of B1 & B2 Tunnel at the end of excavation.

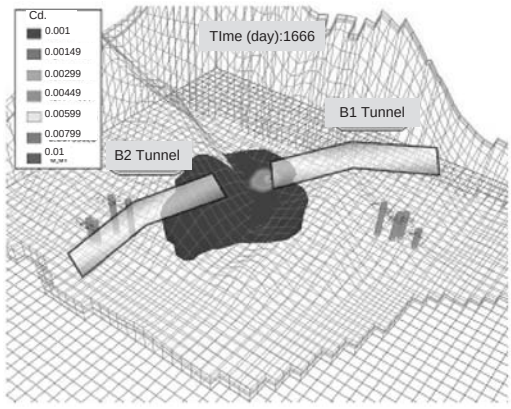

Figure 8. The Cd concentration of Tunnel B1 and Tunnel B2 at 3 years of excavation.

In the end of excavating A Tunnel, contamination area of Cd which excess 1.0 ppb spreads from tunnel portal to 10 m. After 1000 days, the area of Cd concentration below 0.1 ppb spreads to Haw-Po wetland. Vertical spreading of Cd reaches to depth 6 m. According to the standard Cd concentration of water which can be used in life and agriculture, 10 ppb, the Cd concentration which occurs in A Tunnel have no harmful effect on environment.

In the end of excavating B1 Tunnel and B2 Tunnel, contamination area of Cd which excess 1.0 ppb spreads from tunnel portal to 1000 m. The characteristics of Cd concentration in B1 Tunnel and B2 Tunnel are that Cd spreads far through valley. Vertical spreading of Cd reaches to depth 1.5 m.

5 THE TREATMENT ON ACID ROCK DRAINAGE

5.1 *The environmental protection strategies for Hwa-Po wetland*

The results of contamination transportation analysis show that there is low potential of heavy metal inflow into Hwa-Po wetland from the proposed site except the entrance portal of tunnel A.

The counter-measurement of acid rock drainage are chemical treatment, artificial wetland, and limestone channel. The artificial wetland is applied for acid rock drainage with high concentration of and strong acidity. This is relatively expensive and needs large space.

The limestone channel neutralizes acid rock drainage and removes heavy metals by passing through. However, it is effective for a short period and should be replaced worn limestone by new limestone.

The chemical treatment using NaOH is adopted because it has low maintenance cost and small site. This treatment is that NaOH is added to polluted water treatment settling tank and it neutralize acid rock drainage and precipitate heavy metals.

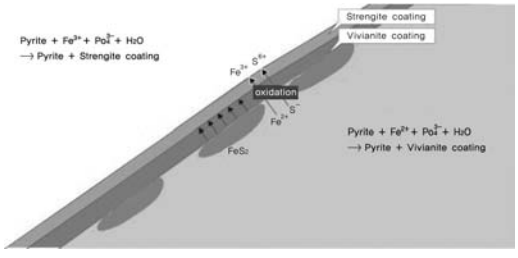

Figure 9. The surface coating that block acid rock drainage.

5.2 *The preventing strategy for tunnel lining and support deterioration*

Acid rock drainage that flows into tunnel portal even accelerates deterioration of constructed tunnel. It is important that acid rock drainage be interrupted before sulfide minerals of tunnel portal slope that are exposed to air and water are oxidized. The strategy is that excavated slope is covered by surface coating and anti-acid cement mortar (Fig. 9) and is installed by the double-casing rockbolt for long-term safety.

Tunnel portal structure is made of anti-acid cement to prevent lining from being impaired.

5.3 *The treatment of excavated rock fragment*

Generally, excavated rock was crushed and used as road base and fill. If rock fragments include sulfide minerals, metal-laden acidic (pH < 3) drainage cause surface water and ground water contamination.

The quartz-porphyry that exists in entrance portal of tunnel A include lots of sulfide minerals. So, It

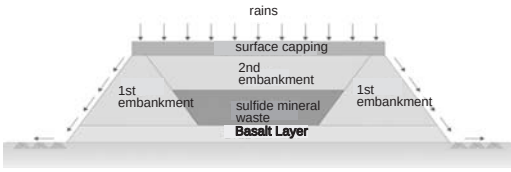

Figure 10. The proposed embankment slope encapsulation for preventing ARD.

is not good to use excavated rock fragments into roadbed-filling and aggregates. Though they are used into roadbed-filling, they should be encapsulated for preventing ARD.

6 CONCLUSION

During tunnel excavation, the exposed rocks containing sulfide minerals are easily oxidated, when they contact with oxygen in air and water. They generate ARD to contaminate ground and water environment and to corrode tunnel lining and support such as rockbolt and shotcrete, sometimes.

But, this phenomenon has a bad influence on environment and tunnel itself. As the chances of acid rock drainage through acid base account test(ABA test) is high, the measures are prepared in advance.
The results of ABA test shows that acid rock drainage contains lots of heavy minerals (Cd, Fe, Mn, Al etc.).

The results of contamination transport numerical analysis shows that cadmium (Cd) is not distributed into the ecosystem of Hwa-Po wetland. But, NaOH that can neutralize ARD was added to settling tank.

Anti-acid shotcrete, double casing rockbolt and surface coating were applied to portal slope to prevent sulfide mineral from contacting oxygen in air and water. Anti-acid cement is applied to portal structure of tunnel not to prevent deterioration of tunnel.

State of the art tunnelling technologies

Ž. Žderić, G. Pervan & Đ. Radić, CE
Konstruktor inženjering, Split, Croatia

ABSTRACT: Intensive motorway construction, as a crucial infrastructure project, has inevitably led to intensive road tunnel construction as well. Various organizational and technical specific details that had to be dealt with in an extraordinarily short time have given rise to a specific tunnel construction method that was used in Croatia. The paper discusses construction methods and construction problems caused by greatly varying ground properties along the excavation path, as well as applicability and effects of new technologies and application of new materials in tunnel construction. The demand for speedy construction called for most efficient adjustment of existing and construction of new facilities and equipment needed for construction. Co-ordinating project planning and actual excavation and construction has proven to be an extremely important pre-requisite for achieving the best possible result. Only the most competent construction companies have been able to fully address the demands set forth regarding organization and quality of work carried out.

1 INTRODUCTION

Fast paced construction of motorway network connecting northern and southern parts of Croatia has been set as one of the priorities for the 1995–2007 development of the Republic of Croatia.

Such investments have led to development of modern construction facilities and equipment that is capable of executing highly demanding construction.

It is also important to note that it was the introduction of new construction methods and modern equipment that made possible construction of all required tunnels in extremely short time. This is greater achievement still considering that each of those tunnels had different and very specific plan as well as different geological properties of various excavation sites.

This paper provides an overview of the specific details of various tunnels along with an emphasis on the importance of simultaneous investment in equipment and human resources development.

2 WORK METHODS AND TECHNICAL SOLUTIONS

Construction of the tunnels has been carried out using the most recent equipment with optimum work effect, depending on the type of tunnel and the type of rock. Some of the solutions regarding excavation, support in freshly excavated areas and lining of the tunnels built so far are as follows:

1. Excavating the tunnels with common methods (boring and mining) in its full cross-section where rock properties permit that, resulting in faster progress of tunnel excavation.
2. Using smooth blasting with non-electric charge detonation system.
3. Applying rock improvement system, using anchors, shotcrete, steel mesh and arches (NATM), allowing greater efficiency of modern equipment, faster and safer work progress.
4. Using rotary equipment, i.e. milling excavation in softer types of ground being excavated.
5. Applying complete waterproofing of rock and primary substructure using two-millimetre thick PVC foil lined with geotextile.
6. Using dumpers in either full or half of cross-section of the excavation in order to facilitate faster removal

Figure 1. Computer guided rock boring.

of excavated material from the working face of the tunnel.
7. Protecting the primary substructure excavation using steel fibre micro-reinforced shotcrete and execution of non-reinforced secondary concrete lining using polypropylene fibres.
8. Using design solutions such as wheeled and telescopic hydraulically adjustable formwork that has been used for concreting more complex portions of tunnels (turnarounds, transformer stations, power niches).
9. Construction of vibration platforms used for continuous vault concreting.

3 A REVIEW OF EXCAVATION PROTECTION REGARDING CAVERNS

In motorway tunnel construction, various in situ plans and solutions have significant role where the excavation is carried out in rock that has limited load-bearing capacity and in rock containing cavern systems. Although these zones present a danger for workforce and equipment used in tunnel construction, using proper equipment and built-in support systems can help avoid serious problems.

In excavations carried out so far, one can distinguish several basic methods of excavation protection in zones containing cracks and caverns, depending on the way a cavern intersects excavation path:

1. excavation protection in crack systems through enlarged crack opening
2. excavation protection using substructure through filled caverns
3. excavation protection using substructure through unfilled caverns
4. excavation protection using substructure through caverns intersecting lateral portion of the excavation path
5. excavation protection using substructure in places where excavation path enters top of a cavern
6. excavation protection using substructure in places where excavation path passes through a cavern or on the bottom of a cavern

Technical solutions and experience used for safely excavating through faults and caverns have a very important role in tunnel construction and require expert knowledge and responsibility of technical staff. Because of those reasons, quick and quality solutions bring about cost cuts and safer working conditions.

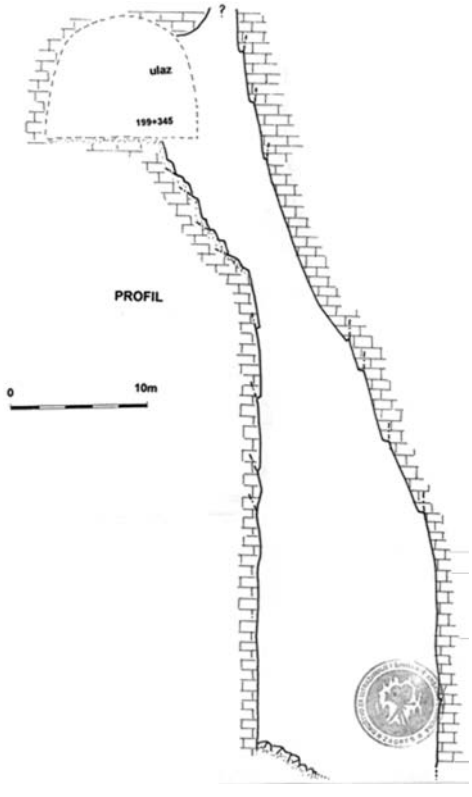

Figure 2. Cross-section of cavern system intersecting lateral portion of the excavation path.

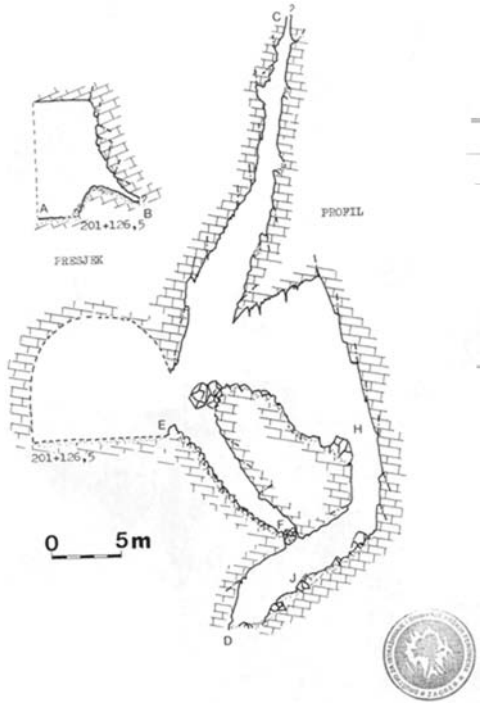

Figure 3. Cross-section of cavern system that is tangential to the excavation path.

4 TYPES AND A BRIEF DESCRIPTION OF EXECUTED TUNNELS

During the period between 1991 and 2007, "Konstruktor-Inženjering" d.d. alone has executed 24 tunnels. Three of those are hydro-technical tunnels, while the rest are road tunnels. As the most of the tunnels are a part of motorway network, they have been built as dual carriageway tunnels. Apart from the distinction by type, here is the breakup of the tunnels by various other criteria:

1. By length:
   a) medium length tunnels between 500 and 2000 metres long.
   b) very long tunnels with length exceeding 4000 metres.
2. By type:
   a) road tunnels.
   b) hydro-technical tunnels.
3. By cross-section size:
   a) small cross-section size, up to 20 m^2.
   b) medium cross-section size, up to 60 m^2.
   c) large cross-section size, up to 120 m^2.
   d) sections of "Sv. Rok" tunnel – turnarounds and vehicle emergency areas (approximately 1000 m^2).
4. By excavation type:
   a) single carriageway excavation: "Sv. Rok", "Javorova kosa", "Stupe", "Grude".
   b) simultaneous excavation of dual carriageway: "Sv. Rok" (central portion), "Ledenik", "Dubrave", "Vrtlinovec", "Konjsko".
5. By type and technology of excavation protection:
   a) tunnels with standard NATM substructures: "Sv. Rok", "Ledenik", "Dubrave".
   b) "Stupe", "Grude", "Konjsko".
   c) tunnels with additional protection "pipe roof" in geologically soft materials: "Vrtlinovac", "Konjsko", "Javorova kosa", "Rožman brdo".

Review of several tunnels executed so far contained in this paper therefore discusses tunnels that are generally defined in terms of these five divisions.

5 EXECUTED TUNNELS

As it has already been mentioned, the most important tunnels that "Konstruktor-Inženjering" d.d. has executed over the last ten years can be divided into two categories.

Those are road tunnels (with two or four lanes for traffic) and hydro-technical tunnels.

Road tunnels are further divided into two groups by length:

a) very long tunnels – exceeding 4000 m in length
b) medium length tunnels – 500 to 2000 meters long

According to the construction difficulty, the tunnels are normally divided into:

c) intermediately difficult construction
d) difficult construction
e) very difficult construction

6 SV. ROK TUNNEL

Among the very long tunnels, "Sv. Rok" tunnel is most notable. "Sv. Rok" tunnel is a part of the Zagreb – Split motorway and it is the longest road tunnel in the Republic of Croatia. Also, it is entirely Croatian product. It runs through Velebit massif under Tulove grede peak. It has been planned as a dual carriageway tunnel, with carriageway axes 35 m apart. The carriageways are 5.685,00 m and 5.766,00 m long respectively including portal structures.

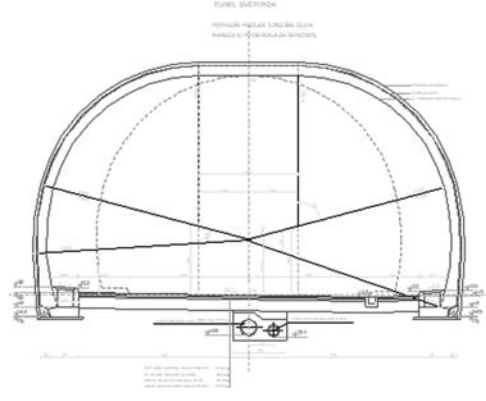

Figure 4. Cross-section of widening section.

Figure 5. Excavation using hydraulic drilling equipment.

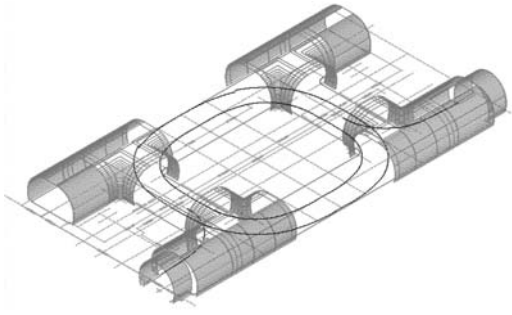

Figure 6. Sv. Rok tunnel turnaround schematic.

Figure 7. Formwork joint, concreting a part of a turnaround.

One of the carriageways is open for traffic and is a part of the motorway, while the other one is completely excavated and rough-in completed.

One particular speciality of this tunnel is the fact that it has been excavated sequentially, i.e. with partial progress on one work face and in the inner section, with excavation on several work faces simultaneously.

During the excavation of this tunnel, non-electric charge detonation system was used (it provided enhanced safety and greater efficiency of the excavation). This type of charge detonation system has been used in all tunnel excavations in Croatia since.

It should be also noted that this tunnel has twelve (12) vehicle emergency niches and four (4) turnarounds with two transversal passages connecting the left and the right carriageway. For concreting secondary lining in those locations, special formwork had to be obtained in addition to the standard cross-section (58,09 m^2) formwork.

Those portions of the tunnel are very complex regarding their construction.

Sv. Rok tunnel is a very long tunnel, while its construction is defined as intermediately difficult in fissured Karst with light substructure. Sv. Rok tunnel, like other tunnels has been executed in NATM tunnelling method.

Figure 8. A view of Sv. Rok tunnel right hand side carriageway portal.

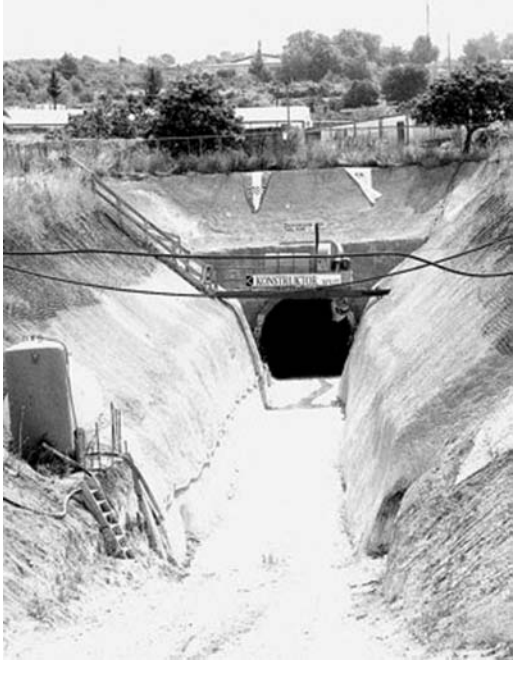

Figure 9. A view of a portal of hydro-technical tunnel "Stupe", a part of Kaštela environmental protection system.

7 TUNNELS UP TO 1000 M LONG

In this paper, tunnels of medium length (500 to 2000 metres long) will also be discussed. Among those tunnels, "Ledenik", "Dubrave", "Konjsko", "Rožman brdo", "Pod Vugleš", "Javorova kosa", "Bisko" and "Stražina" tunnels are distinguished by their construction difficulty. All of the listed tunnels are road tunnels.

"Ledenik", "Dubrave", "Bisko" and "Stražina" tunnels construction is defined as intermediately difficult in fissured rock with light and heavy substructure.

Figure 10. A view of northern portal of "Ledenik" tunnel.

Figure 11. A panoramic view of Ledenik, Čelinka and Bristovac tunnels.

"Stupe" tunnel, a part of Kaštela environmental protection system, is another tunnel of medium length that should be well noted. "Stupe" tunnel has been built for waste water transport from northern parts of Split and Solin with coastal environmental protection in mind. Also there is tunnel "Grude", which is a part of hydro-electric power plant and tunnel "Peć Mlini" in neighboring Bosnia and Herzegovina, both built using special technology.

"Ledenik" tunnel that is a part of motorway section between Sv. Rok and Maslenica, has 748,00 m long left carriageway and 764,00 m long right carriageway, both including portal structure, falls into category of tunnels with thin rock layer above (40 m on average) and has been excavated in geologically unfavorable rock. Its specific detail was simultaneous work on both sides, i.e. on four work faces at the same time. Excavation and concreting work carried out in this tunnel was organized as two separate construction sites with all required equipment for each site.

It is important to stress that the tunnel has been completed, starting with initial excavation through to completion of construction in nine and a half months

Figure 12. A view of completed portal of Dubrave tunnel.

(9,5), which represents a record performance as far as tunnel construction in Croatia is concerned.

"Čelinka" and "Bristovac" tunnels have been executed on the same motorway section, in very demanding and poorly accessible Karst as well.

Another one tunnel in this series is "Dubrave" tunnel, which is a part of motorway section between Vrpolje and Prgomet. This tunnel falls into same category as "Ledenik" tunnel, with average thickness of rock layer above tunnel of merely 25 m, and carriageway axes spaced 47 m apart. Its carriageways are 810,50 m and 779,50 m long respectively. It is also well noted that it has been completed quickly. Construction was completed in nine (9) months.

8 TUNNELS EXCEEDING 1000 M IN LENGTH

It is also necessary to mention "Konjsko" tunnel which, in terms of geological structure, falls into all intermediately difficult, difficult and very difficult construction category. It is a part of Zagreb – Split motorway section between Prgomet and Dugopolje. It has been planned and executed with two carriageways 1.265,80 m and 1.137,90 m long respectively, including portal structure. Pipe-roof construction technology has been used for this tunnel, i.e. excavation was carried out in extremely fragmented and porous rock with underground flows of water.

9 TUNNELS IN GEO-MECHANICALLY EXTREMELY WEAK MATERIAL WITH PIPE- ROOF CALOTTE PROTECTION

Tunnel excavation in geo-mechanically weak material is very complex. Instability of such material after excavation requires fast construction of primary substructure, with stabilization of tunnel calotte. Pipe-roof

Figure 13. Using laser to determine direction of excavation.

method development as additional reinforcement of calotte has very effectively addressed stabilization of calotte and it has made excavation work significantly safer and efficient.

Pipe-roof represents a grouting system in tunnel calotte. The pipes are generally 15,0 m long, spaced 30–35 m apart, while grouting is carried out with pressure of 20 bar. Usual overlap is 3,0 m long, which means that 12 m of excavation is carried out under one pipe-roof. Bore holes for the pipes are drilled at an angle (up to 5°) and radially in order to gain enough space for another pipe-roof to be drilled after next 12 m. The direction of bore holes is usually determined by surveyors and in combination with laser set in focus.

After the pipes are in place and pipe-roof is executed, excavation and primary substructure is carried out step by step. Excavation is usually carried out in 1,0 m increments and in several phases (usually 3: calotte, bench and base of the vault). Primary substructure consists of cross-bar steel arches, reinforcing steel mesh and 30 cm thick layer of shotcrete. This reinforced concrete substructure is radially drilled and anchoring and grouting is carried out. Special care is taken of continuous tunnel convergence monitoring by surveyors in order to detect any shifting (direction, amount, growth) and compare it to the planned values. This method has been applied in excavations of "Javorova kosa", "Konjsko" and "Vrtlinovec" tunnels.

"Vrtlinovec" tunnel is an example of tunnel in material of extremely poor properties with large excavation cross-section (approximately 123 m^2), what places it into the most difficult category to execute. According to Eurocode 7 (Geo-technical category 3, which includes the most complex structures and technological procedures in execution). Pipe-roof consisting of 35 pipes was applied. The overlap was 3 m long, and the pipes were made of 3 m long sections connected to each other and installed using existing equipment.

In static sense, pipe-roof functions as permeable substructure and acts as an unbroken reinforced concrete load carrying element supported by elastic bearings at each cross-bar steel arch (spaced 1,0 m). However, at the place where new set of bore holes are drilled and 3 m long pipes overlap, that part of structure acts as a cantilever allowing for greater deformation and shifting.

Equipment and personnel numbers were scaled for optimum work in both carriageways excavations, with a phased shift in each, in order to make best use of all resources. Extraordinarily demanding time scale set for excavation has been met by means of good site management, excellent execution and good effort, and the tunnel was opened for traffic before the deadline.

It is very important to stress that all of the tunnels, and especially the ones that are part of Zagreb – Split motorway, have been excavated using most recent technology and the very short terms for their completion did not affect quality of work carried out.

10 CONCLUSION

During the last ten years, tunnel excavation as a part of civil engineering has taken an important place in the economy of the Republic of Croatia.

Most of the tunnels concerned are road tunnels within motorway network, starting with the northernmost "Vrtlinovec" tunnel near Varaždin to the last – "Stražina" tunnel near Omiš, passing through "Sv. Rok" tunnel, for which it is fair to say that it has determined the course of Zagreb – Split motorway. The tunnels were of various cross-sections (from small to large cross-sections), of various lengths (medium length and very long), with one or two carriageways and running through material of varying geomechanical properties. NATM method has been used for excavating all of the tunnels, which is consistent with the tunnel excavation practice throughout the world.

Two long hydro-technical tunnels have been excavated during this period as well, with specific organizational and technological requirements due to their relatively small cross-section.

Extremely short terms have been met with preservation of high quality of work carried out.

Equally important is new generation of civil engineers that has developed in this period and forms the basis for development of Croatian tunnel excavation.

And finally it should be well noted that a special care must be given to tunnel excavation, especially on motorways, since the tunnels are time critical parts of all motorway sections making them objects of extraordinary importance. The point is that excavation of tunnels cannot be hurried (unlike the motorway route itself) because of specific technology and practice of work around the clock, while achieving completion term and preserving safety and quality of work carried out.

Safety analysis of the Branisko tunnel ventilation

M. Bettelini
INELMEC Ltd., Minusio, Switzerland

M. Bakoš
Amberg Engineering Slovakia, s.r.o., Bratislava, Slovak Republic

N. Seifert
ASIT Ltd., Berne, Switzerland

ABSTRACT: The Branisko tunnel in the Slovak Republic is in operation since 2003. The tunnel system consists of a single tunnel tube of nearly 5 km length with bidirectional traffic and a parallel emergency escape gallery transversally connected to the main tube.

This paper is mainly devoted to the detailed analysis of the performance of the semi-transverse ventilation system. This investigation was carried out in the framework of the safety analysis conducted by the authors for the administrator of the Branisko tunnel (National Motorway Company, Slovakia).

As expected the ventilation system proved to be critical for the overall safety of the infrastructure. The existing system is generally well suited for the Branisko tunnel. The main improvements proposed are related to an increase of the smoke-extraction rate and the implementation of an automatic system for mastering the longitudinal velocity of the tunnel air in case of fire. Both requirements are necessary for a proper smoke confinement.

1 INTRODUCTION

The Branisko tunnel, the first motorway tunnel in the Slovak Republic, was set in operation on June 29, 2003. The tunnel system consists of a single tunnel tube, 4,975 m long, with bidirectional traffic. The ventilation is of the semi-transverse type. Escape is allowed by means of a parallel safety tunnel with 13 cross connections to the main tunnel.

A safety analysis was conducted by the authors for the administrator of the Branisko tunnel (National Motorway Company, Slovakia). This effort included the following elements:

- Identification of relevant hazards and scenarios.
- Qualitative risk analysis.
- Quantitative risk analysis based on the OECD/PIARC model QRAM (Quantitative Risk Analysis Model).
- In-deep analysis of the ventilation system.

The present paper illustrates the analysis of the performance of the ventilation system, with focus on the following aspects:

- Performance in normal operating conditions.
- Safety in case of fire.
- Protection of the users in the safety tunnel and in the cross connections.

Figure 1. The west portal of the Branisko tunnel.

Further aspects of the safety investigation are described in a companion paper by the same authors (Bakos et al. 2007).

2 METHODOLOGY

The main steps of the investigation were:

- Gathering of tunnel documentation and operational experience.
- Normative comparison.
- Verification of normal operation, based mainly on analysis of the available data from tunnel operation.
- Analysis of fire scenarios by means of one-dimensional (1D) and three-dimensional (3D) simulation.

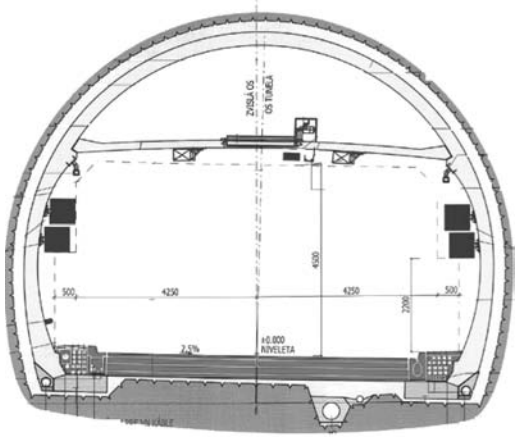

Figure 2. Tunnel cross section.

– Experimental verification of the performance of the fire-ventilation system.
– Assessment of operational safety.
– Formulation of recommendations.

A similar structure will be followed in the present paper.

3 THE BRANISKO TUNNEL AND ITS VENTILATION SYSTEM

The key data of the Branisko tunnel are as follows:

– Tunnel length:	4,975 m
– Slope (West → East):	+1.2% (4,550 m)
	– 1.65% (425 m)
– Length of ventilation	2,161 m (West)
sectors:	2,814 m (East)
– Current traffic	6,000 vehicles/day
– Expected traffic	10,000 veh./day
– HGV ratio	25%.

In spite of the expected increase after completion of the E50 highway, the expected traffic volume is comparatively moderate.

The Branisko tunnel is equipped with a semi-transverse ventilation system. From the operational point of view its key characteristics are as follows:

– Natural ventilation in case of normal operation with low traffic intensity.
– Central extraction during normal operation, with the additional possibility of fresh-air injection from one or from both portal stations, depending on needs.
– Concentrated smoke extraction through 6 dampers in case of fire, with the additional possibility of fresh-air injection in the opposite tunnel half.

The key components of the ventilation system are (Figure 3):

– Two exhaust fans (V_{A1}, V_{A2}) in the intermediate ventilation station, on top of the vertical exhaust shaft. Total capacity up to 215 m^3/s.
– One fresh-air fan in each portal station (V_{ZO}, V_{ZW}). Capacity: V_{ZO} 238 m^3/s, V_{ZW} 182 m^3/s.
– Ventilation duct used for both fresh-air supply and exhaust.
– 90 remotely-controlled dampers (K_{L1} . . . K_{L90}, surface 2 m^2) installed every 50 m in the false ceiling.
– 8 dampers (K_{A1} . . . K_{A8}, surface 6.5 m^2) for the intermediate extraction.
– 2 dampers separating the ventilation ducts from the ventilation station (K_{KO}, K_{KW}).

The available smoke-extraction rates for different locations are:

– Central part 215 m^3/s
– Portal zone 110 m^3/s.

As shown in chapter 8 the large reduction of the available smoke-extraction rate close to the portals is partly due to leakages.

4 NORMS AND RECOMMENDATIONS

4.1 *Applicable norms*

The national guideline for tunnel ventilation and safety in the Slovak Republic is still in preparation and not yet officially available. The Directive 2004/54/EC of the European Parliament and of the Council of 29 April 2004 on minimum safety requirements for tunnels in the Trans-European Road Network is fully applicable to the Branisko tunnel, which is part of the E50.

While the European Directive provides the basic elements, several modern national guidelines provide much more detailed specifications on minimum requirements. The following national guidelines were accounted for, as a part of the documentation of the international state-of-the-art:

– The German RABT (2006).
– The French Circulaire n° 2006–20 of March 29, 2006.
– The Swiss Guideline on tunnel ventilation (FEDRO/ASTRA 2006).

4.2 *Choice of ventilation system*

The requirements for the Branisko Tunnel are clearly stated in the European Directive (Annex I, Section 2.9.5):

"For tunnels with bi-directional traffic, with a traffic volume higher than 2,000 vehicles per lane, longer than 3,000 m and with a control centre and transverse and/or semi-transverse ventilation, the

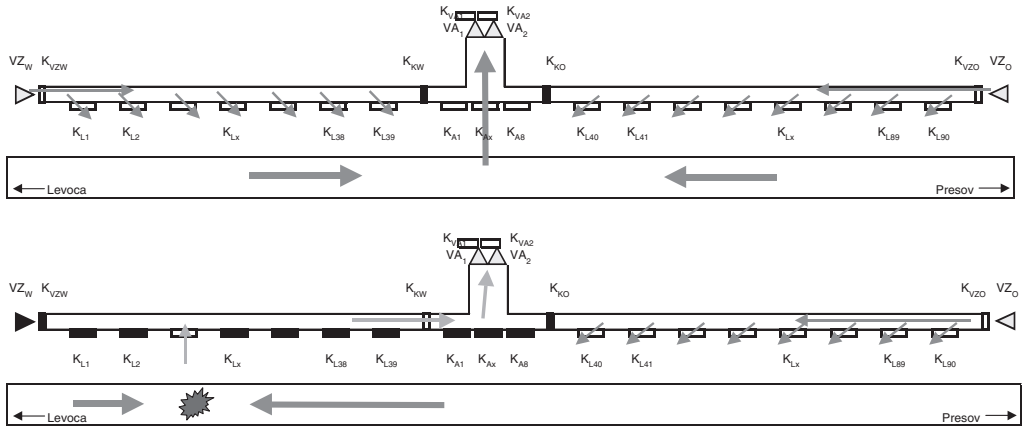

Figure 3. Ventilation in normal operating conditions (upper picture) and in case of fire (lower picture).

following minimum measures shall be taken as regards ventilation:

– air and smoke extraction dampers shall be installed which can be operated separately or in groups,
– the longitudinal air velocity shall be monitored constantly and the steering process of the ventilation system (dampers, fans, etc.) adjusted accordingly."

These requirements are confirmed by all the national guidelines considered. The choice of ventilation system in the Branisko tunnel is basically correct.

The goal of the two requirements contained in the EU directive, concentrated smoke extraction close to the fire and mastering of the longitudinal velocity, is to generate on both sides of the fire a sufficiently high longitudinal velocity directed towards the fire, which can effectively prevent smoke propagation outside the smoke-extraction zone. It is therefore essential to verify, for real-life fire scenarios, how far these conditions are satisfied.

4.3 *Smoke-extraction rate*

The national guidelines mentioned above contain detailed specifications on minimum smoke-extraction rates, Table 1. The available smoke-extraction rate in the central part of the Branisko tunnel is in line with these national requirements. Conversely, the available smoke-extraction rate in case of fires in the vicinity of the portals is significantly lower.

4.4 *Smoke management in case of fire*

The main goal of fire ventilation is the correct management of smoke propagation. An appropriate combination of concentrated smoke extraction near the fire origin and control of longitudinal velocity shall ensure that, after the initial transient phase, smoke propagation is confined to the exhaust zone with open dampers, see e.g. AIPCR/PIARC (1999) or Bettelini (2006).

Table 1. Smoke-extraction rates based on national guidelines (leakages not included).

Country	Minimum Smoke-Extraction Rate
Germany	180 m^3/s (300 m^3/s for a 100 MW fire)
France	155 m^3/s (110 m^3/s with control of longit. velocity)
Switzerland	191 m^3/s (143 m^3/s until July 2006)

The managements of longitudinal velocity is most commonly realized by means of jet fans. In the case of the Branisko tunnel this fundamental task can be accomplished only by means of the fresh-air injection through the portal stations. The available airflow is substantially sufficient, but this functionality needs yet to be implemented in an automated manner and thoroughly tested.

5 NORMAL OPERATION

The analysis of normal operation was based on 1D simulation (Figure 5) as well as on the analysis of the operational data collected since tunnel opening, between January and December 2005. The available data included detailed record of the following parameters: operation level of the exhaust and fresh-air fans, 14 opacity measurement stations and one CO measurement station. The series were quite detailed and encompassed 2,881 CO-values/day and 8,640 values/day for all further parameters.

The analysis of the data showed a number of short episodes with excessive pollutant concentration,

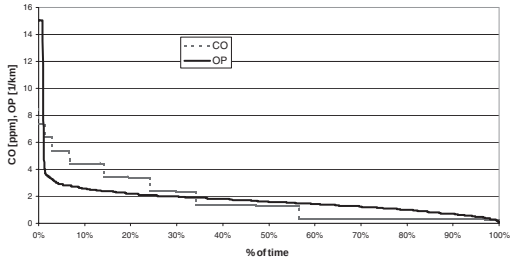

Figure 4. Pollutant levels distribution (06.04.2005).

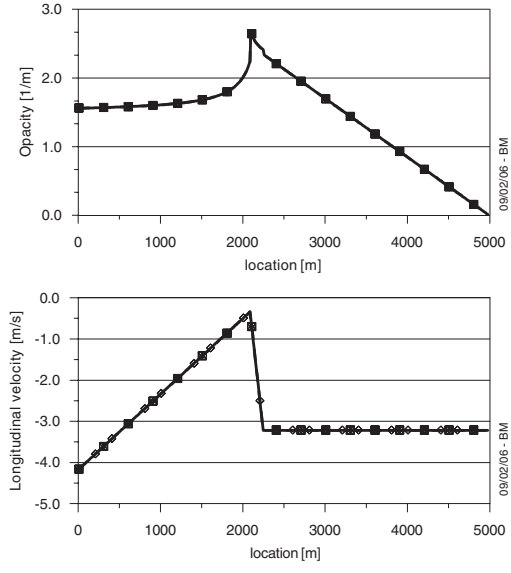

Figure 5. Ventilation in normal operating conditions (asymmetric traffic, exhaust in the middle of the tunnel, fresh-air injection from the western portal (left in the pictures).

resulting locally in very low visibility levels, which are mainly related to a relatively small number of highly polluting vehicles. The analysis showed that the automated system response is mostly appropriate, but that the ventilation system reaches its performance limit. These issues can be solved by iterative adjustments.

6 ONE-DIMENSIONAL SIMULATION OF FIRE SCENARIOS

The events in case of fire are intrinsically transient. The very first minutes are decisive for saving lives and for getting control of the fire. It is therefore important, not only to know the asymptotic state of the ventilation, but to simulate with sufficient detail its development. The analysis has therefore to be carried out based on a large number of particular fire scenarios, chosen as to be representative for all relevant potential fire conditions. Thereby it is possible to identify potentially critical conditions to be investigated in more detail.

By means of 1D simulation it is possible to investigate in short time a large number of fire scenarios. All relevant real-life effects, including traffic volume, composition and evolution, fire development, fire detection as well as ventilation and traffic management, can be accounted for in a very realistic manner. A description of the particular model used herein can be found in Bettelini (2006). Its peculiarity is the capability of modeling smoke propagation due to thermal stratification in an approximate manner, which increases significantly accuracy and reliability in simulation.

Two illustrative results are presented in Figure 6. It was shown that the fire ventilation performs generally in a satisfactory manner in case of “standard” 30 MW fires. In case of atmospheric pressure differences between the portals or increasing fire intensity smoke confinement is not complete anymore and part of the smoke “escapes” from the 600 m long smoke-extraction zone. As stated in chapter 4, this is a consequence the combination of the limited smoke extraction rate and the lack of an effective mastering of longitudinal velocity.

7 THREE-DIMENSIONAL SIMULATIONS OF FIRE SCENARIOS

CFD (Computational Fluid Dynamics) is an advanced simulation technology, which allows for very detailed three-dimensional simulations of fire scenarios. In the design-verification phase, CFD can offer an invaluable help in assessing the effectiveness and relative merits of different smoke-management options. The additional insight to be gained is in particular related to:

– Visibility conditions;
– Concentration of smoke and poisonous gases;
– Temperature and radiation.

In the case of the Branisko tunnel CFD was used for verifying the assessment on smoke-confinement capabilities originally based on 1D simulation. In this case 3D simulation fully confirmed the previous results, therefore providing an excellent confirmation of the capabilities of the 1D technology adopted for this investigation.

8 EXPERIMENTAL VERIFICATION OF SMOKE-EXTRACTION RATE

Because of the importance of smoke-extraction rate for tunnel safety and because of some uncertainties related to leakages, it was decided to conduct a specific measurement campaign in the Branisko tunnel.

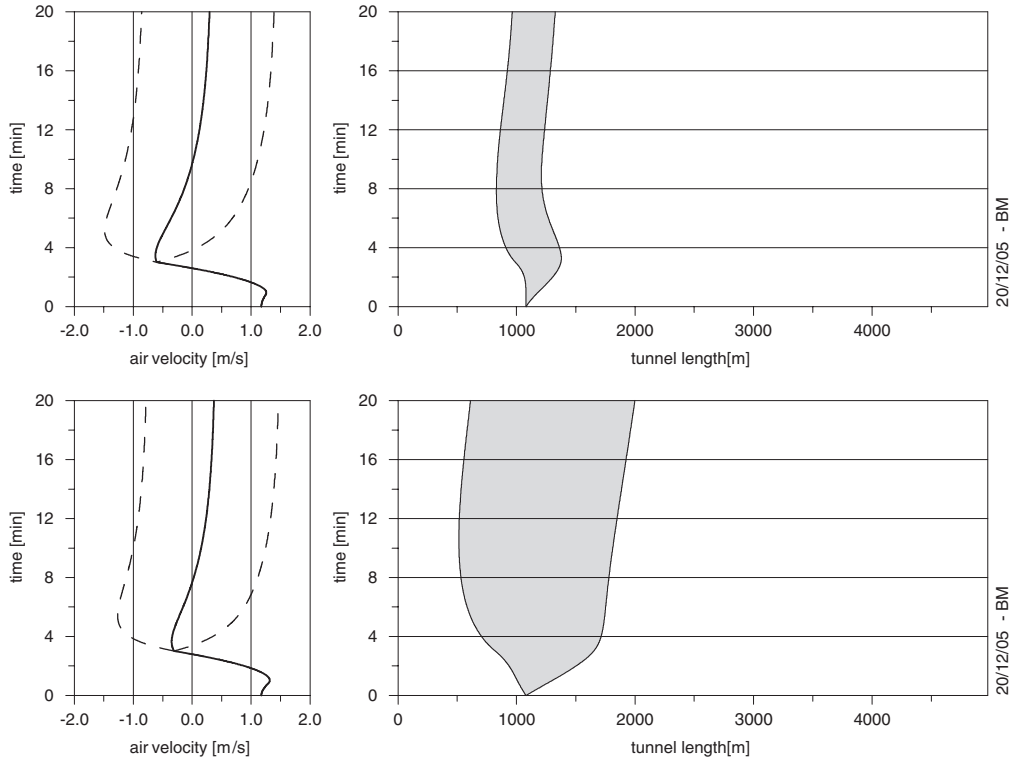

Figure 6. 1D simulation of fire scenarios. Fire location 1,080 m from the western portal, smoke extraction over 600 m, no fresh air, 600 vehicles/h in every direction, 25% HGV, no atmospheric pressure difference, fire detection after 3 minutes. Top: fire intensity 30 MW; Bottom: fire intensity 100 MW. The pictures on the left show the evolution of the longitudinal velocity (fire location as well as 300 m aside) with time. Smoke propagation is presented in the pictures on the right.

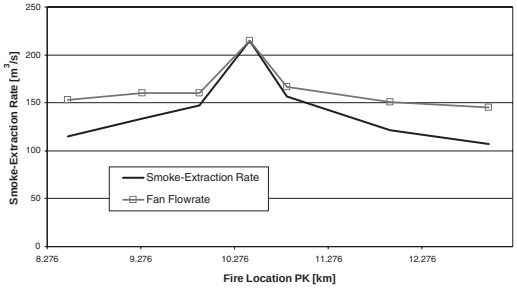

Figure 7. Results of the measurements of smoke-extraction rate (15–17 May 2006).

The measurements were carried out based on SF6 injection and concentration measurements, precision anemometers, pressure gauges and the built-in fan flowrate measuring devices.

The results presented in Figure 7 allowed for an accurate determination of the effectively available smoke-extraction rate. They also allowed confirming the presence of very substantial leakages, of the order of 25% for fire locations in the vicinity of the portals.

9 EMERGENCY EXITS

The main tunnel is connected to a parallel emergency escape gallery by means of 13 cross connections located every about 360 m. Fire doors separate the main tunnel from the cross connections.

The ventilation consists mainly of two fans installed at the entrances, where interlocked doors are installed for preventing pressure losses in case of transit.

The ventilation system is simple but effective and allows for an adequate safety level. Because of its fundamentals safety role, thorough periodic verifications are a key element of the whole safety system.

10 CONCLUSIONS AND RECOMMENDATIONS

The safety analysis of the Branisko tunnel included a thorough investigation of ventilation performance in normal operating conditions and in case of fire. The main findings are summarized below.

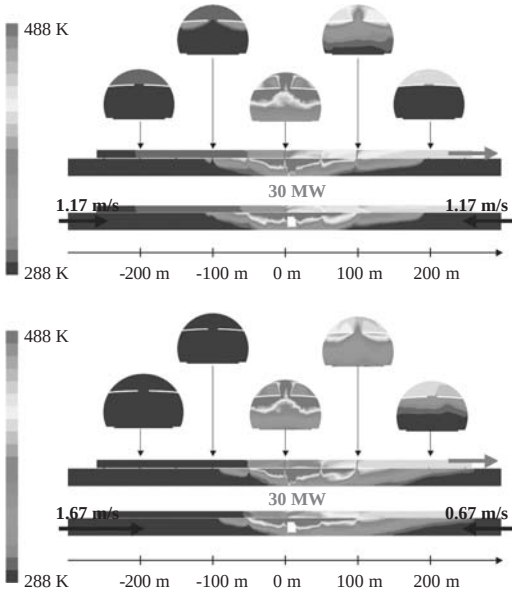

Figure 8. 3D simulation of fire scenarios. Fire intensity 30 MW. Top: full control of longitudinal velocity; Bottom: partial control of longitudinal velocity.

The comparison with the EU directive and with some leading European national guidelines showed that:

– The layout of the ventilation system is correct.
– The currently available smoke-extraction rate is in line with the national guidelines for fires in the central part of the tunnel, but is significantly lower close to the portals. This is partly due to leakages.
– The longitudinal velocity in case of fire cannot yet be properly controlled in an automated manner.

The smoke-extraction rate could be verified by means of dedicated test campaign. This allowed confirming the high leakage rate.

The performance analysis of the ventilation system in normal operating conditions was based on numerical simulation and on the analysis of the operational data. It can be concluded that:

– The system's layout and key design parameters are basically correct.
– Isolated episodes with locally very high opacity values occur periodically. They are mainly related to a small number of highly pollutant vehicles.
– Because of the heterogeneity of the vehicle park, the requirements on ventilation control in normal operating conditions are very high.
– In normal operating conditions large amounts of fresh air are injected through the dampers, in the upper part of the tunnel. In case of fire this could lead to a rapid loss of smoke stratification.

The system's performance in case of fire was evaluated by means of the simulation of a large number of fire scenarios, using both 1D and 3D (CFD) simulation techniques. This part of the investigation led to the following conclusions:

– Under ideal conditions the fire ventilation performs satisfactorily.
– The comparatively low smoke-extraction rate, coupled with the inadequate mastering of longitudinal velocity lead to an incomplete management of smoke propagation.
– "Disturbances", such as atmospheric pressure differences, high fire intensities, particular fire locations etc.) can have a dramatic impact on system performance.
– Initial "disturbances", such as highly asymmetric traffic volumes or slow fire detection, lead to a rapid smoke propagation in the very first phase of the fire, whose compensation is slow.

The main recommendations issued from this investigation are as follows:

– Ad-hoc adjustments to the control algorithms for normal operation can help reducing frequency and amplitude of the high-pollution episodes observed during 2005.
– Leakages shall be reduced.
– The currently available smoke-extraction rate is too small and should be increased to about 200 m^3/s.
– The implementation of an automated tool for mastering the longitudinal air velocity in the tunnel in case of fire is highly recommended.

Globally the Branisko tunnel risk analysis showed that the tunnel represents a minimum risk. The ventilation represents clearly the weakest link in its safety chain. If this deficiency is removed and some other minor measures are put into operation the Branisko tunnel shall fully comply with the up-to-date safety requirements.

The ventilation verification presented goes well beyond a mere normative comparison. The results showed that only a very focused analysis of the effectiveness, based on a large number of realistic fire scenarios, allows for a realistic assessment of ventilation performance.

The Branisko tunnel risk analysis has been the first risk analysis prepared for a Slovak road or railway tunnel. It contains a suitable methodology to be used in Slovakia in the future.

Safety doors in the world's longest tunnel under the Gotthard: Outstanding requirements and performance. Feed-back from the bidding phase and results from the testing phase on selected prototypes

Davide Fabbri & Christina Strassl
Lombardi Engineering Ltd., Minusio, Switzerland / Mechanical Equipment GBT
member of the Joint-Venture Gotthard Base Tunnel South (Lombardi Engineering Ltd., Amberg Engineering Ltd., Pöyry Infra Ltd.)

Simon Peggs
AlpTransit Gotthard Ltd., Lucerne, Switzerland / Mechanical Equipment GBT

ABSTRACT: The 57 km Gotthard Base Tunnel (GBT) will be the world's longest railway tunnel. The tunnel is the central part of the new transalpine rail line in Switzerland. The two single-track tubes are linked by 178 cross passages approximately every 325 m, and two multifunctional stations with an emergency stop station for each tube located one-third and two-thirds along the base tunnel.

During regular operation, high speed passenger trains with a top speed of 250 km/h as well as slower freight trains (160 km/h) will run through the tunnel. In the worst case scenario e.g. a fire on a passenger train, the doors of the cross passages and those of the emergency stations will be essential elements of the safety concept.

This paper gives a short presentation of the safety concept in the case of fire on a passenger train and an overview of the most important requirements of the different door-types. It also includes the state of progress of the special procedure for the commissioning and feed-back from the tests on selected prototypes.

1 INTRODUCTION

A high safety level is a very important premise for the operation of a railway tunnel and as well an economic exigency. After tragic fatalities in existing long traffic tunnels public opinion is especially sensitive to tunnel safety: clients and project managers were called upon to undertake every reasonable effort to increase tunnel safety.

In order to ensure long service (long durability, no revision of the doors in the first 20 years after the installation), the required fire protection (90 minutes at a temperature of 1,000°C) and efficiency in the case of evacuation, very high and stringent regulations have been set for the delivery of doors for the cross passages of the Gotthard Base Tunnel.

Based on former experience, especially on the commissioning of the doors for the Lötschberg Base Tunnel (34.6 km long, also part of the New Alpine Transverses in Switzerland) and in consideration of the unique, extremely harsh conditions of the Gotthard Base Tunnel, the development of a special technical solution is essential; these doors will not be a "standard" product.

The client – AlpTransit Gotthard Ltd. – decided to adopt a special procedure for the commissioning as well as for the evaluation by means of prototypes. A selective bidding procedure with pre-qualification was started on January 2005.

The Joint-Venture Gotthard Base Tunnel South has been charged to carry out the bidding procedure.

2 HIGHLIGHTS OF THE SAFETY CONCEPT

2.1 *Safety requirements*

A fire on board a passenger train in the Gotthard Base Tunnel is the "worst case": the probability of such an incident is very low. However, the following requirements have to be met in the case of an accident:

1. Availability during an event. In the case of fire on board a passenger train, the safety of passengers has first priority. In order to ensure this, the availability of the tunnel has to be maintained as long possible, as passengers should be able to reach a safe place.

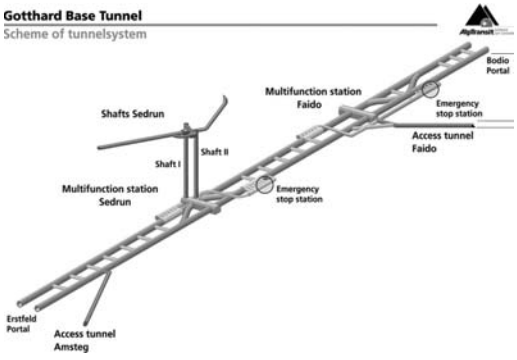

Figure 1. Gotthard Base Tunnel (GBT), the tunnel system [7].

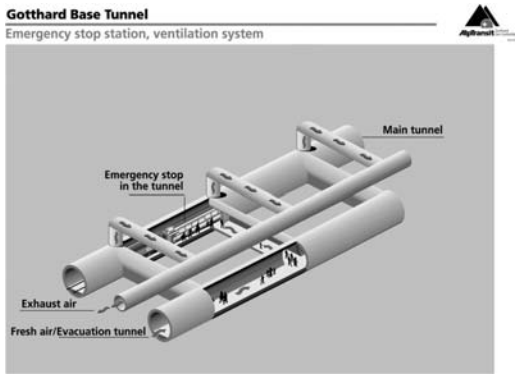

Figure 2. GBT, evacuation in an emergency stop station [7].

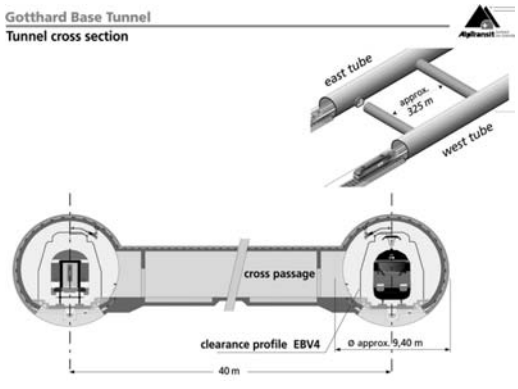

Figure 3. GBT, evacuation through a cross passage [7].

This is a must! In consideration of the fire/life safety system this means:

The tunnel has to maintain operation for 90 minutes after an alarm.

2. Availability after an event. In the case of fire, the interruption of tunnel traffic has to be as short as possible. After evacuation, the reopening of the railway line has first priority. In order to ensure this, constructive fire-protection measures have to be taken:
   - To exclude major damages or collapse of the safe tube,
   - To reduce resulting damages, time and costs for the repair of the burned tube.

2.2 *Overview of the fire/life safety system*

The tunnel system (Fig. 1) mainly consists of two single track tunnels with two train-crossover sections in the so called multifunctional stations. Along the tunnel, cross passages are located approximately every 325 m; the horizontal distance between the tube axes varies between 40 and 70 m.

In the case of a fire on board a passenger train, the procedure of the safety concept depends on the position of the train in the tunnel. Three cases have to be taken into account:

1. The train is running in the last section of the tunnel (after the second multifunctional station): the train has to reach the portal and stop outside the tunnel.
2. The train is running in the first or in a intermediate section of the tunnel: the train has to reach the next multifunctional station and stop there to let passengers be evacuated (Fig. 2). After the fire-alarm, prior to the arrival of the train, the lights of the emergency station will be turned on, the sliding-doors of the escape ways will be automatically opened and the ventilation system will start the extraction of exhaust air from the traffic tube trough the middle of the seven fire dampers. The passengers reach the "sheltered area" of the emergency stop station within 3 to 5 minutes.

   After evacuation from the train – without using stairways or elevators – passengers will wait at the emergency stop station of the opposite tube for evacuation by train.
3. Fire occurs on board a train and it is not able to reach the next multifunctional station or to exit the tunnel. In this case the train will stop at any position in the tunnel and evacuation will have to take place there. On a 1 m-wide side walk escaping passengers will be able to reach the next cross passage through which they will reach the safe tube (Fig. 3). In the opposite tube the speed of the trains is immediately reduced after the alert. In this case, the process of the external rescue proceeds in the same way as if the train had stopped in an emergency stop station.

For case nr. 3, object of the present paper, doors will provide fire-protection of the escape way and the technical equipment inside the cross passages. The ventilation system will ensure overpressure

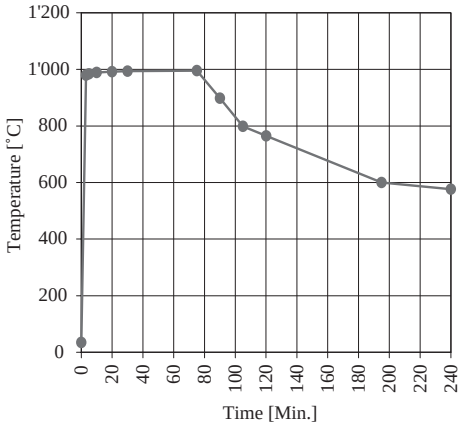

Figure 4. Goods train fire curve ATG (direct flame application).

conditions in the safe tube to avoid smoke entering the safe tube.

3 REQUIREMENTS FOR THE DOORS

3.1 *Main requirements*

According to the stringent requirements of the safety concept and for durability of the tunnel system, very high requirements have been set for the doors of the cross passages. The most important ones are:

- Resistance in case of fire: 90 minutes with AlpTransit temperature-time-diagram (Fig. 4), maximal average inside temperature of the door-panels of 200°C.
- Resistance for high pressure/suction loading due to the passage of trains: ±10 kPa in each running tube, resulting pressure difference on the door of 20 kPa.
- Serviceability: a conceptual solution for the guarantee of operational safety and impervious sealing is especially requested. A maximal necessary force for manual door opening of 100 N (mechanical support driving mechanism permitted) and serviceability in case of interruption of energy supply, as well as a max. air-leakage rate through the door sealing of 50 m^3/h (according to the ventilation system) are fundamental requirements.
- Durability: 100 years for the structure, minimum 20 years for electronic devices and for replaceable parts.

3.2 *Other requirements*

A 16 page long list of requirements, properties and conditions divided into 45 relevant themes, including the main requirements. Every single requested property or prescribed condition has to be fulfilled: some of them are now the object of direct verification with selected tests on prototypes doors. All others have to be certified or plausibly described in the offer.

4 THE BIDDING PROCEDURE

4.1 *The lots*

For the commissioning of the doors of the cross passages AlpTransit Gotthard Ltd. decided on the procurement of 2 separates lots:

- Lot A "Doors for the cross passages of the GBT" for the development, staggered fabrication, delivery and possible installation of steel doors in the tunnel.
- Lot P "Tests and verifications of prototype steel doors for the cross passages of the GBT" for the examination of the proposed solutions of lot A.

4.2 *Selective bidding procedure for Lot A*

The suitability of the contractor had to be determined by a selective procedure based on weighted suitability criteria in accordance with the Swiss Federal Law on Government Procurements (BoeB). For this reason, the selection procedure for Lot A is currently carried out according to the following 9 stages (at the time of the submission of the paper to the editor, stage 5 has been reached):

1. Invitation to tender / Invitation to participate at the prequalification. On January 10th 2005.
2. Prequalification of applicants according to the weighted suitability criteria. Reduction of the number of bidders to a maximum of 8.
   AlpTransit Gotthard's decision was published on June 9th: 2005, the applicants were admitted to the next stage.
3. Bidding phase. From Mai to September 2005: five bids were handed in.
4. Choice of offers based on the additional criteria: reduction of bidders to a maximum of 4. Based on the evaluation of the Engineers-JV, on December 7th 2005 AlpTransit Gotthard Ltd. called all 5 bidders for prototyping and testing.
   Facilities for testing the prototypes are carried out by an accredited testing institution chosen by AlpTransit Gotthard Ltd. This stage started on March 2006 and is in progress at the present time (September 2006).
5. After testing phase: discussions with the individual bidders for the improvement of the technical solution based on the results of the examination. Expected in Winter 2006/2007.
6. Revision of the submission documents.
7. Technical and financial revision of the offers. Expected in Winter/Spring 2007.
8. Revised evaluation of offers and supplements based on the additional criteria.

9. Opening of the supplements / Conclusion of the procedure / Signing of contract. Expected in Summer 2007.

4.3 *Suitability criteria for Lot A*

Suitability criteria were used at stage 2 to evaluate the basic qualifications of a contractor or a bidding consortium to carry out the project. Only suitable bidders were invited to submit an offer. The following suitability criteria were applied:

- Criterion 1: Experience with the production of doors with high technical requirements and with the installation of doors under difficult conditions (weighting: 60%, minimum score 3).
- Criterion 2: Sufficient personnel and technical capacity to fulfill the scheduling and qualitative requirements (weighting 20%, minimum score 3).
- Criterion 3: Sufficient financial capacity for the execution of the job (weighting 20%, minimum score 3).

4.4 *Additional criteria for Lot A*

To evaluate the offer of a contractor or a bidding consortium, the following additional criteria were applied at stage 4 and will be applied again at stage 8:

- Criterion 1: concerning a plausible declaration that the required quality, serviceability and durability will be guaranteed (weighting 30%, minimum score 3 / score scale: 1 to 5, scale division 0.5), i.e.:
  - Fulfillment of fire resistance requirements (partial weighting 10%).
  - Fulfillment of the requirements for high pressure/suction loading due to the passage of trains (partial weighting 10%).
  - Fulfillment of the requirements for serviceability, especially: conceptual solution for the guarantee of operational safety and impervious sealing (protection from dust and noise) (partial weighting 5%).
  - Fulfillment of the requirements for durability (life expectancy) (partial weighting 5%).
- Criterion 2: Price level (weighting 30%, minimum score 3).
- Criterion 3: Appropriateness of the installation concept (weighting 20%, minimum score 3), i.e.:
  - Appropriateness of the underground installation concept. Conceptual solution to guarantee simple and timely installation deadlines (partial weighting 5%).
  - Appropriateness of the underground storage concept (partial weighting 5%).
  - Appropriateness of the packing concept (partial weighting 5%).
  - Appropriateness of the underground transport concept (partial weighting 5%).
- Criterion 4: Guarantee of meeting deadlines (weighting 10%, minimum score 3), i.e.:
  - Reliability of the planned underground installation schedules (partial weighting 4%).
  - Flexibility of the delivery of the doors (high availability and large capacity during production, adjustment of the production schedule as a function of modified deadlines in the tunnel lots) (partial weighting 3%).
  - Plausibility of the tendered services (production and delivery times) (partial weighting 3%).
- Criterion 5: Guarantee of appropriate maintenance (weighting 10%, minimum score 3), i.e.:
  - Maintenance concept. Conceptual solution to guarantee simple and timely maintenance during the construction phases and in service (partial weighting 5%).
  - Possibility for replacements (partial weighting 5%).

5 TESTS ON SELECTED PROTOTYPES

5.1 *Installation tests under tunnel conditions*

To observe and evaluate the installation of the prototype doors – manufactured and mounted by the bidder of the separate Lot A – the contractor of Lot P (the joint-venture PQ: VSH Sargans & Berner Fachhochschule Biel) has been commissioned for the establishment of the conditions corresponding to the simulated tunnel conditions (Fig. 5 and 6).

5.2 *Functionality tests under tunnel conditions*

For the verification of the prototype doors according to the prescribed requirements (i.e.: observance of

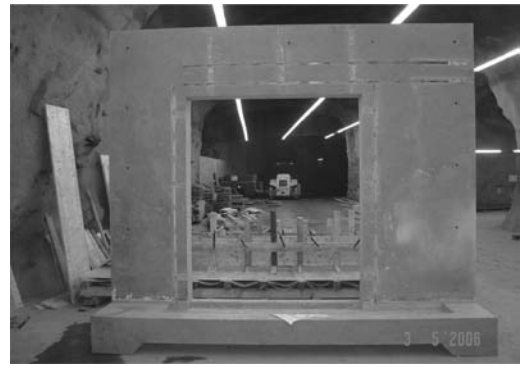

Figure 5. Simulation of the tunnel conditions: the wall [7].

the maximum permissible weight and dimensions for transport, door operation and opening, duration of the opening and closing operations, maximum necessary force for manual door opening of 100 N, verification of the door surveillance apparatus, verification of the function and storage capacity of the mechanical support driving mechanism) the contractor of Lot P has been commissioned for the establishment of the conditions corresponding to the simulated tunnel conditions:

- Execution of opening and closing operations with an overpressure of 0.5 kPa, performed by a robotic arm (Fig. 7), under similar tunnel climatic conditions (temperature and humidity).
- Verification of the air-leakage rate through the door sealing (max. 50 m^3/h during 24 hours, difference of pressure inside/outside of 100 Pa). The fulfillment of this condition is very important to allow the cooling effect inside the cross passage by the ventilation system (air recirculation). Operational equipment requires a max. air temperature during service of 35°C.

Figure 6. Simulation of the tunnel conditions: the lining [8].

Figure 7. Functionality tests, robotic arm [8].

5.3 *Endurance test under tunnel conditions*

For the verification of the prototype doors according to the prescribed pressure and suction loading during train passage and simulation of single pressure shocks (resulting pressure loading of 20 kPa and suction loading of 10 kPa, 500,000 loading cycles, 1 cycle every 2 seconds, 1 cycle = 1 pressure + 1 suction loading, functionality tests every 100,000 loading cycles and at the end of the endurance test) the contractor of Lot P has been commissioned to design and assemble a testing facility (Fig. 8, the so called "Mjöllnir"), to simulate the tunnel conditions:

- Loading by air pressure (no mechanical contacts between testing equipment and prototype doors), verification of the behaviour of the doors including the sealing.
- Very quick increase of the loading (shocks).

5.4 *Fire tests under tunnel conditions*

For the verification of the high fire protection resistance prototype doors the contractor of Lot P has been commissioned to design and assemble a testing facility (Fig. 9), corresponding to the simulated tunnel conditions in the case of a fire in front of the door:

- Freight train fire (250 MW, max. air temperature 1,000°C after the first few minutes, 90 minutes resistance required, see Fig. 4). After a major fire in the tunnel the functionality of the door is no longer required and a replacement is necessary.
- Overpressure on the side of the cross passage of about 100 Pa (reduced amount vs. real conditions) to simulate the air-leakage through the sealing to the "burning tube" during the fire, avoiding smoke and significant heat propagation in the cross passage. Overpressure is assured by the ventilation system in emergency mode.

Figure 8. Endurance tests equipment, the "Mjöllnir" [8].

Figure 9. Fire tests equipment [8].

A maximum average temperature of the inside face of the door during the fire load of 200°C is a must. A single sensor on the inside face of the door should not measure more than 240°C. These requirements are a condition to limit the inside air temperature of the cross passage at 45–50°C, permitting the functionality of the electrical equipment during a fire.

During an evacuation the functionality of the doors of the cross passage has to be assured up to an air temperature of 90°C in the "burning tube". This requirement can be tested in a preliminary phase of the fire test.

6 FIRST FEED-BACK FROM THE TESTS

At the present time (September 2006) the installation test, the functionality tests and the endurance tests have been completed. In October 2006 the fire tests will be carried out and the final reports of the tests should be completed before the end of the year. According to the bidding procedure, and respecting the copyright of the prototype doors disclosure of the results of the tests is not yet permitted.

First feed-back from the tests confirm the correct decision of the AlpTransit Gotthard Ltd. and of the engineers for a selective bidding procedure, with separate procurement of an independent certified contractor for the design and assembling of the testing equipment as well as for test processing. The extreme loading in the Gotthard Base Tunnel, endurance test and the verification of the air-leakage rate through the door sealing represent a real challenge for each bidder. After the completion of the tests, the following revision of the submission documents and technical / financial revision of the offers, based on the very interesting and significant results of the tests, will represent the next important challenge for the choice of a central element of the fire/live safety system of the Gotthard Base Tunnel.

7 CONCLUSIONS

The Gotthard Base Tunnel (GBT) will be the world's longest railway tunnel, with a length of 57 km. It will be unique. This is the reason why no standard solution or products can be adopted to reach the prescribed requirements in the case of an accident. Only "on mass tailored" solutions or products are able to meet all requested properties and prescribed conditions: The know-how of some of the best door manufacturers and the chances given by the new technologies are the mixture for success.

ACKNOWLEDGMENT

The authors would like to thank the AlpTransit Gotthard Ltd for permission to publish this paper.

Information on the outcome of the remaining phases of the selective bidding procedure for the Lot A "Doors for the cross passages" can be obtained under: www.alptransit.ch. http://www.alptransit.ch/pages/e/portrait/submission.php

Mechanical equipment in long, high-speed rail tunnels – Specification and operational experience of doors, cabinets, containers and other elements in the Loetschberg Base Line

R. Haldimann, S. Nyfeler & P. Reinke
HBI Haerter Ltd., Consulting Engineers, Berne, Switzerland

ABSTRACT: The Loetschberg Base Line (LBL) includes the 35 km long Loetschberg Base Tunnel (LBT) and the 3 km long Tunnel Engstlige. Several elements of the mechanical equipment of these tunnels were newly designed. "Non-catalogue" solutions were needed to meet the specific requirements of these long, high-speed rail tunnels. The specific requirements are characterized by uncommon climatic conditions, by the need for safety and reliability during normal and emergency operation, by the specific requirements of single-track, double tube tunnels with cross-passages and by the need for cost-efficient maintainability and fast and simple installation. The special features for a variety of elements such as the doors in the cross-passages, the large doors in the rail tunnel, the cabinets in the cross-passages and the containers in the technical equipment caverns are presented. The methodology to define, to select and to test the equipment during the tendering phase (prototype-based selection and utilisation of a test site in the tunnel) is illustrated. The requirements to manage the various technical interfaces of these elements with other lots of equipment in the tunnel are shown. The experience gained from the design, installation and commissioning phase of the LBL are presented.

1 INTRODUCTION

1.1 *Tunnel system LBL*

The Loetschberg Base Line (LBL) is a principal element of the new cross-alpine rail links (NEAT) in Switzerland which are an integral part of the European high-speed rail network. Central parts of the LBL are the Loetschberg Base Tunnel (LBT; drill and blast, TBM) with a length of approximately 35 km and the Tunnel Engstlige (TE; cut and cover) with a length of approximately 3 km.

The Loetschberg Base Tunnel will be built in stages. The first stage will be taken in operation in 2007. During this first stage, only the southern part of LBT will be a single-track, double-tube system. The northern section will be operated using one tube in bi-directional mode (see Figure 1). At the final stage, the tunnels consist of 2 single track tunnels which are connected with accessible cross-passages approximately every 330 m or emergency exits. In addition, the base tunnel system will include multifunctional stations (MFS) with crossovers and emergency train stations.

During normal operation, passenger trains will run at velocities of up to 250 km/h and freight trains at max. 160 km/h. Freight trains can reach a length of up to 1,500 m.

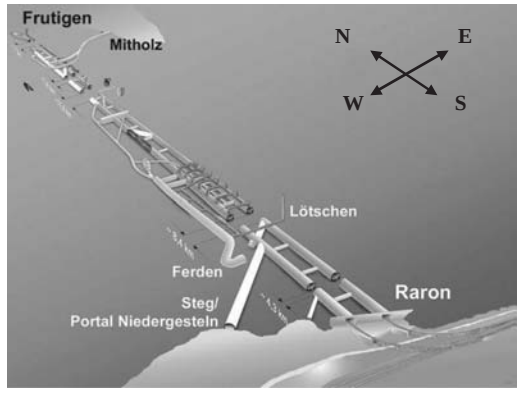

Figure 1. System overview of the Loetschberg Base Tunnel.

There are demanding requirements regarding the lifetime reliability, availability, maintainability and safety of the mechanical equipment. Several "non-catalogue" solutions were needed to meet the specific requirements of these long rail tunnels. These tunnels are characterized by extreme climatic conditions (e.g. significant pressure fluctuations, wide range of temperatures, humidity, dust, salt), by an extended need for safety and reliability during normal and

emergency mode, by specific requirements of single-track, double-tube tunnels with cross-passages, by the need for high availability and durability, by efficient maintainability and the requirement for fast and simple installation (see Ravn & Reinke, 2004).

1.2 *Rail equipment of LBL*

Numerous rail technology systems are needed to ensure smooth rail operations throughout the Loetschberg. Well over a quarter of the total project costs are related to the rail technology. Rail technology as defined for the Loetschberg project includes lots such as:

- track way
- train power supply (16.7 Hz) and catenary
- train control (ETCS 2)
- power supply of the electrical equipment (50 Hz)
- operational control and communication
- mechanical equipment
- ventilation (preliminary and permanent)
- logistics of installation and of rail technology

Above all, the rail technology must meet stringent safety requirements and guarantee reliable operation of the railway. To minimise failures, only the most essential equipment is installed in the rail tubes. All other systems are housed in air-conditioned technical rooms and containers, in the cross-passages or outside the tunnel system.

1.3 *Mechanical equipment*

Mechanical equipment as defined for the Loetschberg project includes elements as listed in Table 1. They make up approximately 15 to 20% of the costs of all rail equipment.

Other elements could be considered as "mechanical equipment" as well. However, these were allocated to other lots (ventilation fans, dampers, cross-passage ventilation, fire water supply, several steel structures, etc.).

Table 1. Mechanical equipment of LBL (approximate quantity refers to first stage of operation of LBL).

Mechanical equipment of LBL	Approx. quantity	Prototype lot	Part of this paper
Doors in cross-passages and emergency exits	173	Yes	Yes
Electrical cabinets	1443	Yes	Yes
Containers for electrical equipment in the operation centres inside the tunnel	136	Yes	Yes
Large doors (in tunnels for train operation)	2	No	Yes
Various other doors for air locks, equipment rooms, entrances of tunnels, etc.	>100	No	No
Heating, ventilation, air-conditioning of equipment rooms (HVAC-systems)	12 caverns	No	No
Handrails	56 km	No	No
Signage	3000	No	No
Various stairways, railings, crane systems, false floors	Various	No	No

2 REQUIREMENTS AND BOUNDARY CONDITIONS FOR MECHANICAL EQUIPMENT

The requirements of the mechanical equipment result from various domains:

- train operation in tunnel
- protection of equipment during normal, maintenance and emergency mode
- escape route network
- tunnel ventilation (see Rudin & Crausaz, 2005)
- connection to power supply (50 Hz)
- connection to tunnel and train control system
- civil design
- logistics of installation

In the following, only an overview of the requirements can be given, highlighting the specific requirements of a rail tunnel such as the LBT. Such tunnels are characterised by the following features:

- single track, double tube
- high-speed trains
- mixed traffic (passengers, freight and shuttle trains)
- increased tunnel length
- high rock overburden
- intense traffic load
- stringent occupational health regulations
- increased requirements for fire safety

These boundary conditions apply to various other rail tunnels as well, for example to Brenner, Ceneri, Gotthard, Guadarrama, Koralm, Loetschberg, Lyon-Turin and Pajares which are being planned or built at the moment. However, none of these are in operation yet, i.e. at the beginning of 2007. Some of these boundary conditions are new in comparison to existing long rail tunnels (Channel tunnel, Seikan tunnel, Simplon tunnel) or existing high-speed rail tunnels (e.g. in Japan, France, Germany, Italy, Spain).

The specific boundary conditions of the LBT, which lead to consequences as illustrated with the examples in Table 2, may apply only locally and/or temporarily.

Further to the specific requirements of the Loetschberg project, various other non-tunnel specific requirements need to be fulfilled. However, these will not be further addressed here.

Table 2. Boundary conditions and interacting consequences for mechanical equipment of LBT.

Boundary conditions of LBT	**Consequences for mechanical equipment**
Long tunnel	– Restricted access due to dense traffic – Long distances for installation and maintenance – Limited air-exchange resulting in accumulation of heat, humidity, salt and dust over a long distance
Limited space	– Demand for detailed transport planning and scheduling throughout the rail equipment installation phase and operation phase – Stringent requirements on the logistic and maintenances – Fast replacement of standardised elements necessary (e.g. cabinets)
Limited access for service and maintenance	– As few as possible equipment in tunnel – High availability and reliability of equipment and short maintenance times necessary
Extreme pressure fluctuations due to high speed trains and single-track tunnels	– Robust, pressure-tight elements or pressure compensation in equipment (e.g. for cabinets) – Extreme pressure difference between tubes, i.e. robust design required (e.g. on cross-passage doors)
Extreme temperatures due to heat release from trains (increased traction power in tunnel, many trains), heat release from technical equipment, heat ingress from rock	– Temperature robust design – Passive or active cooling of equipment
Increased humidity due to ingress from tunnel lining, trains and drainage; humidity accumulation due to tunnel length	– Non-corrosive materials – Air-tight design of certain elements
Reduced air-quality (dust and salt accumulation due to tunnel length)	– Design insensitive to dust, salt or pollution
Handling of fire and other incidents	– Fire-resistance or fail-safe behaviour – Requirement for remote monitoring and operation
Tunnel ventilation	– Remote operation of certain mechanical equipment (doors of cross-passage) to provide proper ventilation functionality – Support of ventilation objectives by pressure resistance, reduced leakage rates, etc. – Necessity for doors in rail tunnels – Adapted design of cross-passage ventilation/closures

3 DESCRIPTION OF THE VARIOUS ELEMENTS OF THE MECHANICAL EQUIPMENT

In this chapter, the doors of cross-passages, the large doors in the rail tunnel, the electrical cabinets and the containers for electrical equipment in the operations centres inside the tunnel are described.

3.1 *Doors of cross-passages – Requirements*

At the entrances to the cross-passages, emergency exits and escape tunnels, a total of 173 sliding doors are being installed. Cross-passage doors play an important role among the tunnel equipment elements:

– In the case of emergency operation cross-passage doors provide the interface to the safe non-incident tunnel. Any problems concerning the doors will have a major impact to safety and may harm the escape conditions.
– The doors help to capsulate the cross-passages and to protect all the equipment inside against aggressive and dusty tunnel air.
– The doors provide a safe egress along the escape route, particularly, with respect to taking into account the risks of incidents in one tube and high-speed traffic in the parallel tube. The doors protect maintenance staff.
– The doors support ventilation especially during the emergency operation. The lack of cross-passage doors would cause a major air short-circuit and disable for certain emergency ventilations concepts.
– The doors help to provide adequate climatic conditions in the tunnel system since they prevent

internal re-circulation of warm air within the tunnel.

Hence, the choice of an adequate cross-passage door is of particular importance.

3.2 *Doors of cross-passages – Specifications*

As a consequence of the above mentioned requirements the doors of the cross-passages need to fulfil major specifications as listed in Table 3.

The door system chosen for the LBL is shown in Figure 2.

3.3 *Doors in rail tunnels – Requirements*

Large rail tunnel doors are installed in both tubes of the base tunnel. These allow for the closing of the rail tunnels (partially or completely). Closing the rail tunnel allows the air-exchange conditions inside the tunnel system to be optimally controlled and monitored. This helps to provide a regulated tunnel climate during service and maintenance work.

The following specific functions need to be fulfilled by the rail tunnel doors:

- robust to aerodynamic forces (pressure, wind loads)
- robust to climatic boundary conditions (temperature, etc.)
- highest reliability class for locking of doors (SIL 4), i.e. part of the rail safety equipment
- connected to the tunnel and train control system
- minimum maintenance requirements and complete maintenance possible in "open"-position

3.4 *Doors in rail tunnels – Specifications*

The improper use of doors in rail tunnels may endanger the train traffic significantly. Hence, it has to be ensured imperatively that no rail traffic occurs when the opened door is not locked in the "open"-position or even closed. This safety requirement leads to control systems between the large doors, the door driving system and the train signalling system.

In addition, any door needs at least one separate escape route in order to ensure a safe escape route towards the exterior of the tunnel. This is of major importance, if trains stop in the vicinity of the door.

As a consequence of the above mentioned requirements, major specifications for the large doors need to be fulfilled as listed in Table 4.

The door system chosen for the LBL is shown in Figure 3 and Figure 4.

3.5 *Cabinets in tunnel climate – Requirements*

The cabinets, being exposed to the tunnel climate, contain equipment for the power supply system, working and emergency lighting, data transmission, door controls, fire detection systems, and safety and radio systems. They are mainly placed in cross-passages, which are not air-conditioned. For safety and maintenance reasons all of the electronic equipment will need to be capsulated, hence, it must be installed inside a cabinet.

Cabinets have to fulfil several basic functions, such as:

- fitting different technical equipment inside
- enabling a safe and reliable railway system and operation

Table 3. Major specifications of the doors of cross-passages.

Construction	– Sliding door (one part) mounted inside cross-passage – Pressure resistance 30 kPa in both directions (mainly due to anticipated shuttle trains) – 2 m wide and 2.2 m high in cross-passages (3 m wide in emergency station) – Lock and unlock mechanism working error-free, also during electrical power cuts – Uninterruptible power supply for the driving system and control technology – Reliable operation in a temperature range of $-15°C$ to $45°C$ and sudden temperature changes (partly temporal or local)
Fire protection	– Fire resistance of the door for 90 min (T90) – Reduced heat transfer through door in order to prevent heat-up of cross-passage during fire – Air-tight design to prevent leakage of smoke – Air-tight design to prevent leakage of false air, i.e. unnecessary air-losses of the ventilation system
Maintenance	– Easy replacement for parts suffering mechanical wear – Quick replacement of a whole door should be possible
Operation	– Default position closed and locked – Local and remote controlled door operation (lock and unlock) – Local door operation prioritised – 'Jam protection'; if automatic operation effort exceeds a certain force – Opening and closing time at automatic operation shorter than 15 s – Force to open the door manually <100 N – Position monitoring of the doors – If trains approach at high speed: Doors locked on cross-passage side – If the doors are unlocked or open: Train speed limitation to 40 km/h

Figure 2. Door of cross-passage.

Figure 3. Large door in rail tunnel partly closed.

– protecting electronic equipment against dust, salt, thermal and aerodynamic loads, humidity, smoke and heat
– providing flexibility concerning number and size of cables entering cabinet

For maintenance reasons only one type of cabinet is used in the tunnel (i.e. outside air-conditioned spaces). However, this type is flexible with respect to mounting of different equipment inside and different cooling requirements of the electrical equipment.

The cabinets have to withstand similar climate and aerodynamic conditions as the cross-passage doors, particularly with regards to:

– extreme temperatures, humidity
– rapid variations in the temperature
– dry environment

Table 4. Major specifications of the large doors in rail tunnel.

Construction	– Sliding door (two part) mounted in niches outside free tunnel envelope – Pressure resistance 30 kPa in both directions (mainly due to shuttle trains) – Uninterruptible power supply – Reliable operation in a temperature range of 10°C to 45°C
Fire protection (only if used to separate tubes)	– Fire resistance of the door for 90 min (T90) – Air-tight design to prevent leakage of smoke – Air-tight design to prevent leakage of false air, i.e. unnecessary air-losses of ventilation system
Maintenance	– Easy replacement for parts suffering mechanical wear – Quick replacement possible
Operation	– Default position closed and locked – Local and remote controlled door operation (lock and unlock) – Local door operation prioritised – 'Jam protection'; if automatic operation effort exceeds a certain force (probably a person is jammed)

– train induced pressure variations and wind loads
– high dust and salt concentration and iron particles in the air
– depending on installation and maintenance concept: allowing rapid installation and replacement and repairs outside tunnel

In addition, each cabinet should have different sensors for local and remote signalling of the cabinet internal temperature and humidity, status of air conditioners (if applicable) and the cabinet door status (open, close). In case of exceeding heat or humidity limits, as well as in case of electronic failures, a local and remote alarm shall be provided. Hence, the maintenance staff can rapidly locate the affected cabinet.

3.6 *Cabinets in tunnel climate – Specifications*

Major specifications of the cabinets are listed in Table 5.

Different equipment and temperatures depending on the location in the tunnel lead to different thermal power losses. Additionally, the temperature range for the equipment inside the cabinet might vary. Hence, different ventilation and cooling equipment might be used, preferable at the back of the cabinets.

A deepened socket provides space for a cable entry system. With the deepened socket combined with

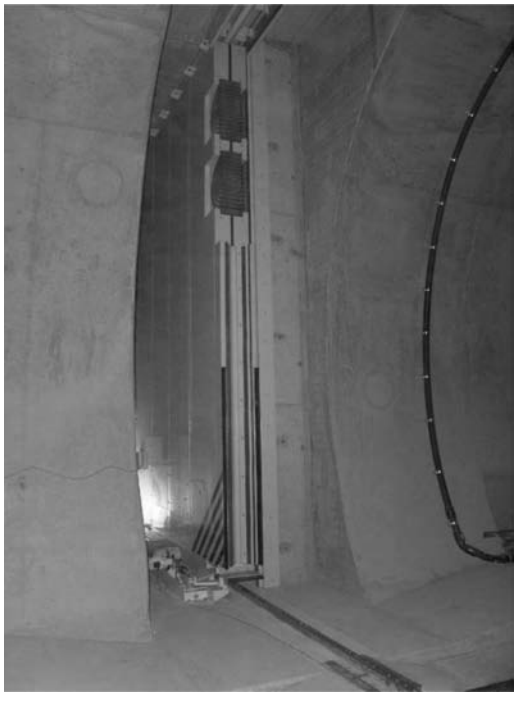

Figure 4. Large door in rail tunnel: Opened door in niche of tunnel.

a flexible system of the cable entry the following mounting procedure can be achieved:

1. installation of socket in cross-passage
2. installation of all cables
3. fitting the cables with plugs
4. placement of cables in sockets and closure of the socket with preliminary cover
5. final installation of cabinet, which is open at the bottom, on the socket and connection of cable plugs with the sockets in the cabinets.

The cabinets chosen for the LBL are shown in Figure 5. The cable entry in the socket mounted in the false floor is shown in Figure 6. The system allows for the pre-installation of cables and sockets before the instalment of the cabinets.

The cabinets were assembled and fitted with the electronic equipment outside the LBL, in order to provide unnecessary site traffic. The cabinets were assembled and pre-tested at a central place.

3.7 *Containers – Requirements*

The mechanical equipment also includes 136 containers, equipped with various control systems, which are installed in the technical caverns. Similarly to the cabinets, the containers protect equipment for the power

Table 5. Major specifications of the cabinets in tunnel climate.

Construction	– Simple and durable construction – Protection against corrosion – 19″ fixtures and fittings to fit standardised equipment – Cabinet dimensions depth/width/height 600/800/2000 mm (including socket) – Single placement on false floor – Maximum pressure loads +/−5 kPa – Air tight design (no filters) – Thermal power loss per cabinet to be specified [kW] – Protection class IP 65
Fire protection	– Temperature control inside – Air-tight design
Maintenance	– Parts suffering by mechanical or thermal wear shall be replaced easily – Simple and fast mounting and exchange procedure – All cable connections by sockets/plugs
Operation	– Simple lock and opening mechanism – Local display of the cabinet interior temperature – Local display of the cabinet interior humidity – Error warning sign exterior of the cabinet (e.g. lamp, diodes, etc.)

Figure 5. Cabinets in cross passage exposed to tunnel climate.

supply system, working and emergency lighting, data transmission, fire detection systems and safety and radio systems. They house the systems required for train control and air-conditioning as well.

Containers have to fulfil several basic functions, such as:

– fitting of different technical equipment inside
– enabling a safe and reliable railway system and operation

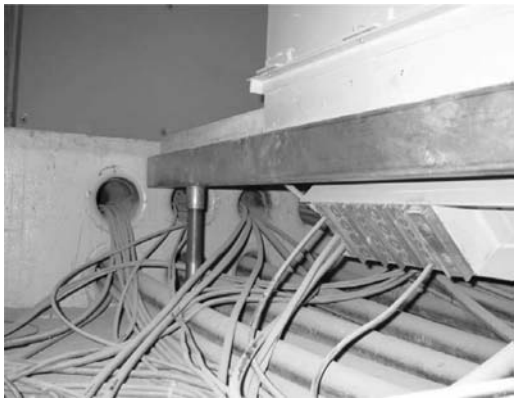

Figure 6. Flexible cable entry system at the cabinet socket.

Table 6. Major specifications of the containers.

Construction	– Simple and durable construction – Transportable 20' ISO-container on road and rail – Different assembly and connection possible – Walls insulated – Pressure resistance ±2.5 kPa – Protection class IP 65 – Equipped with false floor if necessary – Air tight design and air-conditioned
Fire protection	– Fire resistance F30 of walls – Fire extinguishing systems
Maintenance	– Parts suffering by mechanical or thermal wear shall be replaced easily – Simple and fast mounting and exchange procedure – All cable connections by sockets/plugs

– protecting electronic equipment against dust, thermal and aerodynamic loads, humidity and smoke
– providing flexibility concerning number and size of cables entering the container.

For maintenance reasons only one type of container is used in the tunnel.

3.8 *Containers – Specifications*

Major specifications of the containers are listed in Table 6.

The container system chosen for the LBL is shown in Figure 7. A technical cavern where containers are installed is shown in Figure 8.

The containers were manufactured, pre-assembled and equipped outside the tunnel (see Chapter 4.3).

Figure 7. Containers for technical caverns.

Figure 8. Underground technical cavern with containers.

4 SPECIAL METHODOLOGIES AT LBL

Some specialities of the methodology to select, to test and to install the mechanical equipment in the LBL are highlighted in the following sections:

– Prototypes as part of tendering process and evaluation
– Test section in tunnel and tests
– External pre-assembly of equipment in containers and tests in assembly hall
– Management of interfaces of mechanical equipment with other lots (rail equipment, civil, further lots).

4.1 *Prototypes as part of tendering process and evaluation*

In difference to the other equipment, in lots of the mechanical equipment the manufacturing of prototypes was an integral part of the tendering and selection process. The cross-passage doors, the cabinets and the containers were selected in this way. The choice of

the contractor for these elements was organized in 3 stages:

1. Offer for equipment based on written documents
2. Pre-selection of 2 to 3 companies and order to manufacture, deliver and test of prototypes
3. Final selection of company for delivery of the most qualified and economical solution

Reasons for test of prototypes were as follows:

– The components are of major importance for the availability, economy and for the safety of the tunnel system.
– The components are built in large number, i.e. deficiencies of these elements of large number must be firmly excluded.
– Regarding the expected specific boundary conditions in the tunnels of the Loetschberg, no "catalogue solutions" of the above elements (doors, cabinets, containers) existed and experience was lacking.

The objectives for the production of prototypes were:

– to collect systematically suitable solutions for the different elements
– to test selected solutions
– to optimize the prototypes
– to choose from optimized solutions the most economical offer

4.2 *Test section in tunnel and tests*

At a central base point of the LBT, one section of the west tunnel, still at the carcass construction stage, was used as a test section. The test section is hundred metres long. Of this, 62.5 m have the profile of drill and blast excavation and the remaining 37.5 m have the tunnel boring machine profile. The test section also incorporates a cross-passage.

In the test section, the entire interior was applied on a trial basis, in order to obtain important findings on the construction technology and rail technology systems at an early stage. All the constituent elements of the equipment which were finally installed in the tunnel and in the cross-passage were "test installed" in the test section and checked for the installation methodology and ease of maintenance.

4.3 *Pre-assembly of equipment in containers*

The equipment in the technical caverns inside the tunnel was installed in containers, pre-tested and only then installed in the tunnel. Once the rail equipment was installed in the tunnel, it was tested before the actual commissioning work started. Figure 10 illustrates the container installation and assembly of containers for the different technical caverns in the tunnel.

Figure 9. Test section of LBT.

Figure 10. Pre-assembly and installation of equipment in containers in assembly hall outside of the tunnel.

The major advantages of using containers and preparing them outside the tunnel are as follows:

– shortening of actual installation time in tunnel
– allowing tests of various complete electrical systems before installation in the tunnel
– facilitated access to work space – containers of all technical caverns in one hall

4.4 *Management of interfaces to other lots (rail equipment, civil, further lots)*

As in any other complex infrastructure project, civil design, the construction works and the various lots of the technical equipment need to be co-ordinated. This is true for both, the planning and the execution of the works. Since several companies were contracted for the various lots, special measures were required to arrange and control the interface schedules.

Among other measures, an extensive and permanently updated list of interfaces was established. The list identified for example:

– the content of the interface
– the lots being involved
– the responsible lot
– the technical solutions of the interface

During the detail planning phase of the contractors, these several hundred interfaces became systematically addressed and defined. For every single technical interface a document was created stating the technical solution and responsibilities. Each document had to be signed by the two or more contractors who were involved in the interface.

5 CONCLUSIONS

The particular features of modern, long, high-speed, single-track, double-tube rail tunnels lead to new challenging demands for the mechanical equipment being installed in such tunnels.

Technical solutions were found in interdisciplinary teams. Prototypes and extensive tests allowed for a smooth transition from installation to operation of the LBL.

Study on the behavior of smoke from a train fire based on the track gradients in railroad tunnels equipped with a forced ventilation system

D.-H. Kim, Y.-J. Jang & J.-J. Moon
Korea Railroad Research Institute, Kyounggi-Do, Korea

ABSTRACT: This study carried out three-dimensional computerized numerical interpretation for some cases of fire outbreak in tunnels whose inner section measures 70 m^2 and with a 0.75 km extension. Specifically, numerical interpretation was conducted in each of the three cases of varying tunnel gradients after installing and operating a ventilation hole near the entrance and exit of the tunnel under the same conditions.

1 INTRODUCTION

The realignment of railroad tracks and use of the existing railroad lines for the high-speed train service resulted in the growing demand for long railroad tunnels in Korea. A train will likely be unable to get out of a long tunnel in case it catches fire; hence the need to examine the safety of passengers trying to escape in a situation wherein the train stops at a certain location deemed to be most dangerous in the tunnel in case of train fire.

This study sought to derive the design factors for the concept design of new tunnels incorporating disaster prevention facilities such as guide routes, escape routes, service tunnels, etc., through which all train passengers can escape safely from the toxic smoke in case of fire in a tunnel with a track gradient and equipped with a forced ventilation system. The behavior of hot air rising from a fire in a railroad tunnel has been studied intensively by conducting a variety of experiments and computational numerical analysis. Kajiyama and Tanemoto (1998) examined the relationship between the tunnel gradient and speed of hot air in case of fire in a railroad tunnel using model experiments and numerical simulations. On the other hand, Miles & Kumar (1999) verified the results of a full-scale fire experiment conducted on the Memorial Tunnel in the United States through computational numerical analysis and performed research on the behavior of hot air rising in case of fire in road tunnels based on the results. In Korea, Kim et al. (2002) conducted research on the behavior of smoke from a train fire based on the tunnel gradients. Likewise, Lee et al. (2002) conducted at a reduced scale a model experiment on smoke behavior under the influence of natural ventilation in case of fire in a tunnel.

This study examined the behavior of smoke from a train fire in single-bore double-track tunnel whose inner cross section measures 70 m^2 and equipped with a ventilation hole at the 1/5 and 4/5 points of its extension and gradients of −10‰, 0, and +10‰. The examination of smoke behavior per case aimed at understanding the spreading direction of smoke and its characteristics by distance and including them in the design concept of disaster prevention facilities such as escape routes for passengers, etc.

2 SUBJECT TUNNELS FOR THE ANALYSIS AND FIRE SCENARIOS

For the numerical analysis, tunnels whose inner cross section measures 70.0 m^2 and whose design has recently been applied to newly built single-bore double-track tunnels and with a 0.75 km extension (refer to Figures 1 and 2) were considered. Numerical analysis was performed by applying computational fluid dynamics based on the assumption that a fire broke out in a train car on one of the double tracks. Specifically, three-dimensional numerical analysis was performed for the fire simulations on a real-time basis, covering the outbreak of a fire and

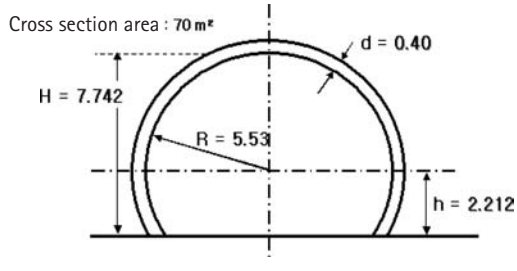

Figure 1. Specifications of the cross sections of the subject tunnels for interpretation.

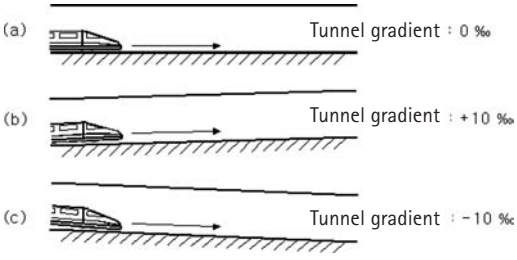

Figure 3. Analysis conditions for tunnel depending on track gradients.

Table 1. Classifications for numerical analysis in tunnel fire.

Classification	Tunnel Extension	Cross Sectional Area	Tunnel Gradient	Operating Condition for the Ventilation Hole
Case 1	0.75 km	70.0 m^2	0‰	A: Air supply B: Air exhaust
Case 2	0.75 km	70.0 m^2	+10‰	A: Air supply B: Air exhaust
Case 3	0.75 km	70.0 m^2	−10‰	A: Air supply B: Air exhaust

its progress given track gradients of −10‰, 0‰, and +10‰ as shown in Figure 3. Table 1 lists the conditions for each case.

The height from the bottom of each subject tunnel to its ceiling was 7.742 m; for purposes of calculation, the concrete lining of its inner wall was assumed to be 0.4 m (Figure 1). The physical properties presented in Table 2 were used for the calculation under the assumption that the inner wall of the tunnel was made of concrete.

2.1 *Source of train fire and heat release rate*

For purposes of calculation, the fire was assumed to have come from a train car located at the 2/3L point from the entrance of the tunnel. Figure 5 shows the specifications of the train fire as used for this study. Ota & Horiuchi's report (2001) suggests a fire-size design of 5 MW for cars, 20 MW for buses/trucks, 30 MW for vehicles used to transport heavy goods, and 100 MW for petroleum tank lorries. Assuming that the fire-size design is the largest for the vehicle

Table 2. Physical properties for numerical analysis.

Classification		Physical Properties
Tunnel Extension		750 m
Air	Density	1.198 kg/m^3
	Viscosity	1.82 × 10^{-5}kg/m·s
	Specific Heat	1000 J/kg·K
	Conductivity	0.02637 W/m·K
Concrete	Density	2300 kg/m^3
	Specific Heat	840 J/kg·K
	Conductivity	1.6 W/m·K
Heat Release Rate		30 MW

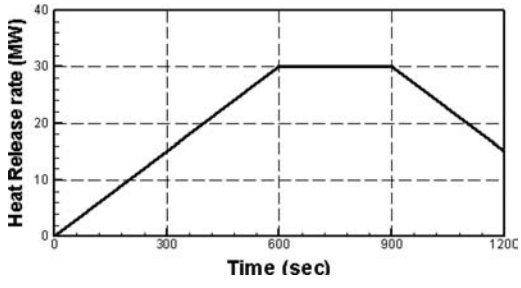

Figure 4. Heat release rate used for numerical analysis.

(b) Grid in the x-z plane

Figure 6. Grid system used for three-dimensional, computational numerical analysis.

transporting heavy goods, this study assigned a heat release rate of 30 MW for the numerical analysis as shown in Figure 4.

2.2 *TUNFIRE fire simulation code and grid generation*

This study used TUNFIRE Code (2001) the computational analysis program for tunnel fires developed recently by a British fire experiment and research institute. The program enables designing fire safety using the numerical method of computational fluid dynamics for the quantitative prediction of the flame spread and smoke flow in the tunnel.

The same grid system was used for the respective conditions for the numerical analysis of Case 1 ∼ Case 3 (Table 1). Figures 6(a) and (b) show the grid system around the source of the train fire. The direction of x denotes the progress direction of the tunnel, with y and z defined as the directions of its width and height, respectively. The number of grids used for the computational numerical analysis in the entire area of analysis was $46 \times 37 \times 35$, which is equivalent to 59,570.

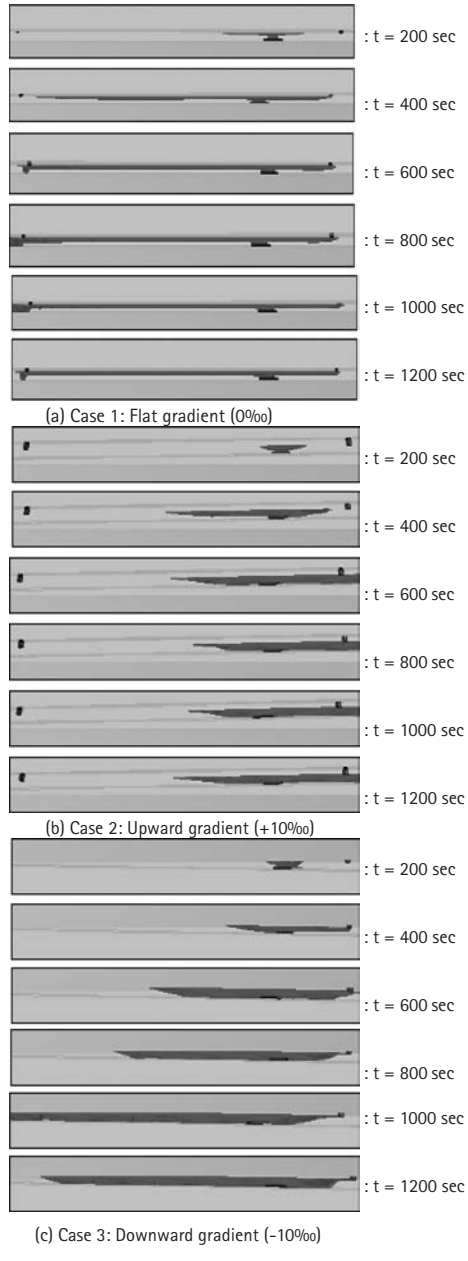

Figure 7. Smoke distribution inside the tunnel over time.

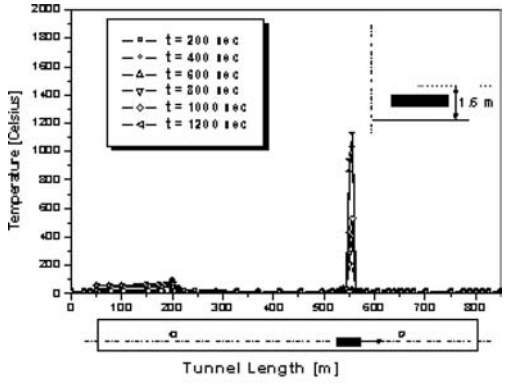
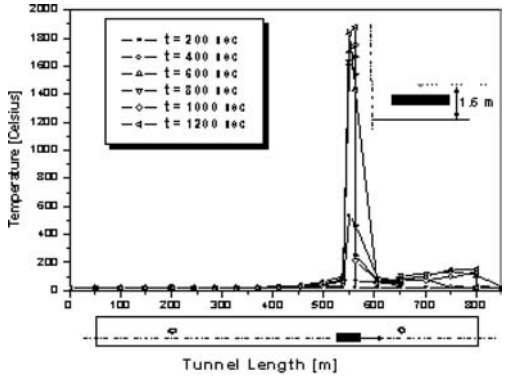
3 RESULTS AND DISCUSSION

The study performed three-dimensional computational simulations for the case wherein a train was unable to get out of the tunnel and was forced to stop inside it after a fire occurred. Figures 7(a) ∼ (c) each show the smoke distribution inside the tunnel on a



real-time basis following the outbreak of a fire, accounting for the result of each numerical analysis.

Only the distribution of smoke at 65°C or higher is shown in Figures 7(a)∼(c) in accordance with the NFPA (National Fire Protection Association) standards, i.e., exposure to smoke at 65°C for more than five minutes is fatal to the human body. In particular, Figure 7(a) shows the smoke distribution inside a tunnel with a flat gradient over time in case of fire. Note that the smoke consistently spread toward the entrance and exit of the tunnel because of the flat gradient. As shown in the figure above, smoke had already occupied over two thirds of the tunnel 400 seconds after the outbreak of fire and spread to most areas of the tunnel 800∼1000 seconds later. 1200 seconds after the occurrence of fire, however, the amount of smoke decreased. The smoke started to spread around the vertical ventilation hole located at the entrance of the tunnel 600 seconds after the outbreak of fire, suggesting that it spread toward the tunnel ground due to the outside air coming into the tunnel through the ventilation hole in air supply mode. In this case, passengers are likely to feel discomfort when they try to escape through the tunnel entrance due to the smoke spreading from the entrance area to the entire section of the tunnel. Figure 7(b) shows the smoke distribution inside a tunnel with an upward gradient of +10‰ over time in case of fire. Note that most of the smoke spread toward the exit of the tunnel under the influence of the upward gradient, starting to move down to the ground near the fire source around the tunnel exit 400 seconds after the outbreak of fire and to the ground almost everywhere around the exit 600 seconds later. On the other hand, minimal smoke spread toward the entrance not only because of the upward gradient but also due to the vertical ventilation hole in cool air supply mode installed at the entrance. Specifically, the outside cool air coming into the tunnel through the ventilation hole pushed the smoke toward the exit. In this case, if a jet fan is installed in the middle of the tunnel, an escape route can be easily secured at the entrance. As shown in Figure 7(c), a much larger amount of smoke spread toward the exit under the influence of the downward gradient. 400 seconds after the outbreak of fire, the smoke had already moved down near the ground in the direction of the entrance, moving down slightly to the middle height of the tunnel in the direction of the exit. 600 seconds later, the smoke moved down to the ground both before and behind the fire source and continued to spread toward the entrance and exit of the tunnel. Note, however, that the smoke already moved down to the ground and continued to spread almost everywhere toward the entrance 400 seconds after the outbreak of fire, moving down to the ground in only a small area toward the exit. The distribution area of smoke at more than 65°C near the tunnel entrance gradually decreased 1000 seconds after the outbreak of fire. Therefore, if a downward gradient is installed, the ventilation hole at the entrance should be set to air exhaust mode instead of air supply mode.



Figures 8(a)∼8(c) each show the temperature distribution inside the tunnel over time in case of fire for each case. The reference point for the temperature comparison was the point 1.6 m high from the ground, i.e., the tunnel bottom, passing the center of the track where the fire source was located. Note that the height for temperature comparison was set at 1.6 m based on the assumption that the average breathing height of Oriental people is 1.6 meters. Figure 8 (a) shows the temperature distribution inside a tunnel with a flat gradient. As shown in Figure 7(a), the temperature distribution was relatively low everywhere at a height of 1.6 m from the tunnel bottom except around the fire source owing to the minimal smoke moving downward. Note, however, that the temperature of about 100°C was distributed between the tunnel entrance and the ventilation hole, possibly due to the spread of smoke under the influence of air coming through the ventilation hole (Figure 7 (a)). Figure 8 (b) shows that the temperature around the tunnel exit was much higher than that around the tunnel entrance. In particular, the temperature around the fire source was about 2000°C, although an almost normal temperature was distributed around the entrance of the tunnel. As shown in Figure 8(c), the temperature around the tunnel entrance was much higher than that around the exit due to the influence of the downward gradient. 400 seconds after the outbreak of fire, the temperature around the fire source was about 2100°C; around the exit of the tunnel, smoke at high temperature spread by moving along the tunnel ceiling before it was released from the tunnel through the ventilation hole. In this case, the temperature fell, resulting in the distribution of an almost normal temperature. Around the entrance of the tunnel, high temperature (about 200°C) was distributed up to the ventilation hole area through which outside air entered, contrary to the tendency shown in Figure 8(b) wherein distribution at about 200°C was concentrated around the exit due to the influence of the tunnel gradient.

Figures 9(a)∼(c) each show the concentration distribution of carbon dioxide (CO_2) inside the tunnel over time in case of fire for each case. Note that the same reference point for comparing the temperature was used to compare the concentration distributions of carbon dioxide, i.e., 1.6 m from the ground. A carbon dioxide concentration of 4.3% or higher is considered hazardous to the human body as shown in Feizlmayer (1976).

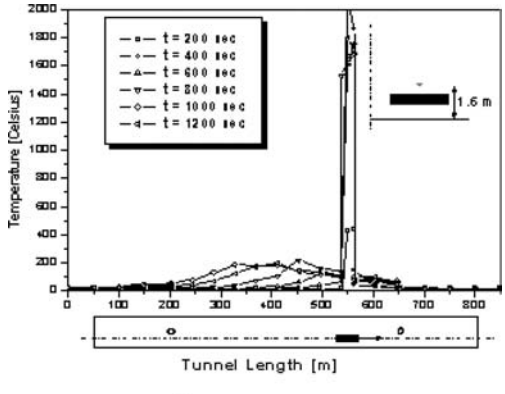


Figure 9(a) shows the concentration distribution of carbon dioxide produced from a fire makes up about 1% of the entire tunnel in case of the flat gradient of a tunnel. As shown in Figures 7(a) and 8(a), smoke did not move downward to the height of 1.6 m from

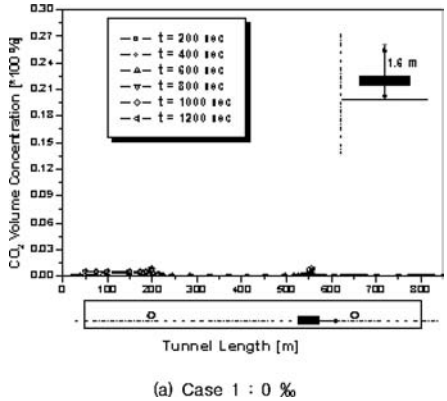
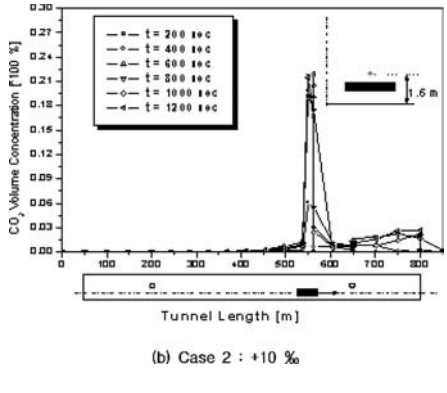
(a) Case 1 : 0 ‰



(b) Case 2 : +10 ‰



(c) Case 3 : -10 ‰

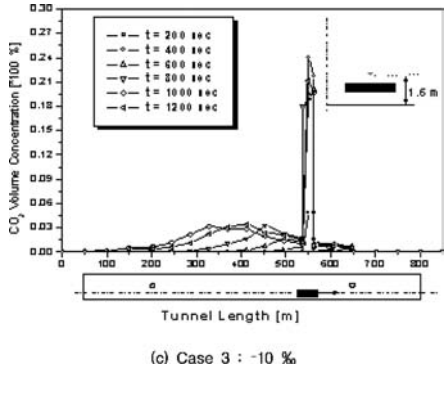


Figure 8. Temperature distribution inside the tunnel over time.

(a) Case 1 : 0 ‰

(b) Case 2 : +10 ‰

(c) Case 3 : -10 ‰

Figure 9. Concentration distribution of carbon dioxide (CO_2) inside the tunnel over time.

the ground 1200 seconds after the outbreak of fire in the tunnel with a flat gradient. Carbon dioxide concentration was slightly over 20% around the fire source in the tunnel with the upward gradient (Figure 9(b)); note, however, that the temperature distribution was about 3% around the tunnel exit due to the influence of the upward gradient. For the tunnel with a downward gradient as shown in Figure 9(c), carbon dioxide distribution tended to be similar to that in the tunnel with an upward gradient around the fire source. Around the tunnel entrance, however, carbon dioxide distribution was about 4%, which was the opposite of the case of

the tunnel with an upward gradient. Therefore, for tunnels with gradients installed based on the results of the abovementioned numerical interpretations, there is a need to set up an escape route in the direction of the entrance in the case of a tunnel with an upward gradient and in the direction of the exit in the case of a tunnel with a downward gradient. This way, loss of lives can be minimized.

4 RESULTS AND DISCUSSION

This study carried out three-dimensional computerized numerical interpretation for some cases of fire outbreak in tunnels whose inner section measures $70\,m^2$ and with a 0.75 km extension. Specifically, numerical interpretation was conducted in each of the three cases of varying tunnel gradients after installing and operating a ventilation hole near the entrance and exit of the tunnel under the same conditions.

First, in terms of the smoke behavior based on the tunnel gradient, more smoke was found to spread toward the tunnel exit due to the effect of buoyancy in the case of the upward gradient (+10‰). Likewise, the smoke moved down to the tunnel bottom faster around the exit than around the entrance. In the case of the tunnel with a downward gradient (−10‰), however, a lot of smoke spread toward the tunnel entrance. Moreover, a lot of toxic gas was distributed around the entrance rather than the exit of the tunnel. In addition, this study found that smoke usually moved down to the tunnel ground 400∼800 seconds after the outbreak of fire. Carbon dioxide (CO_2) distribution also reached a height of 1.6 m from the ground, which is the breathing height of passengers.

This study applied the same ventilation conditions for air supply and exhaust to the two ventilation holes, i.e., one installed at the tunnel entrance and the other at the tunnel exit. In the case of the tunnel with a flat gradient, smoke was likely to have spread already throughout the tunnel 600 seconds after the outbreak of fire due to the air entering through the ventilation hole at the entrance; thus possibly hindering passengers from escaping out of the tunnel. In case of the tunnel with an upward gradient, however, the air entering through the ventilation hole at the entrance prevented the smoke from spreading toward the entrance, thereby helping passengers escape out of the tunnel.

During a train fire inside a tunnel, the most serious problem is about the ventilation of toxic smoke generated from the fire. The results of the three-dimensional computational numerical interpretations imply that the movement of smoke and toxic gas in a tunnel with a gradient varies based on the direction of the gradient. Based on such information, how an escape route should be set up in the tunnel can be predicted.

The results of this study suggest the need to equip each tunnel with ventilation and smoke control equipment suitable for its conditions as well as to develop ways of securing a proper time period for passengers to escape safely from the tunnel in case of a train fire.

ABSTRACT: In road tunnel safety design, most important factor is safe evacuation of people. In case of road tunnel fire, for the sake of smoke control ventilation fan must be operated. But in such a case cross passage doors are opened for egress to opposite tunnel, tunnel pressure balance easy to break. So this phenomenon cause failure of smoke control or smoke influx to opposite tunnel through cross passage. To avoid this phenomenon proper smoke control fan operating mode must be developed. Generally, it is difficult to estimate of tunnel pressure distribution curve by calculation on various cases. In this study, an experimental method is used to assess the proper fan operating mode. This result will use effectively in long tunnel smoke control system by basic data.

1 INTRODUCTION

Road construction is important part of nation's industrial competition. So, new road construction is occurred consequently. Tunnel occurs by a road network expansion. With this fact, it is coming to be long by excavation technique and maintenance management technique gradually.

As length of tunnel is longer, frequency for fire accident in tunnel is coming to be increased. Tunnel fire accident is brought about serious material-human damage. When initial countermeasure and fire preventing equipment is insufficient, social expense loss will come to be increased.

If fire break out in tunnel, evacuation of drivers or passenger occur firstly, and fire extinguishing works is progressed.

If fire were to break out in tunnel, for the sake of safe escaping uni-directional traffic tunnel, cross passages are installed every 200–300 m. Fire door should be equipped as a cross passages. Generally, cross passages are classified with two types; for only passenger, for vehicles and passengers.

In case of fire accident, safety designer must assumed that all fire door behind of fired car will opened to escape to opposite tunnel. With this situation, pressure balancing could be broken because both tunnels are connected with each other. Also fans in fire tunnel are operated to evacuation of passenger safety, and opposite tunnel fans are operated for prevent a fire smoke inflow.

When fans in opposite tunnel operate for pressurization, there is a possibility of fire smoke inflow. It is necessary to prevent a smoke control mode to prevent a smoke inflow to opposite tunnel.

The purpose of this study is to develop a smoke control mode system through the scale model test.

2 FIRE SAFETY DESIGN IN TUNNEL

2.1 *Smoke movement in tunnel*

In such case that fire accident of running vehicles in uni-directional road tunnel is occurred, the initial smoke flows to running direction of vehicles. If ventilation fans should be stopped, inertia force of air movement will lower after the lapse of time, and smoke should be divided to bi-directional flows.

The back-layering velocity of smoke is varied according to slope, tunnel cross-section and fire heat release rate. As fire heat release rate is larger over time, also back-layering velocity of smoke is faster.

The smoke what flows upper part of tunnel crown that goes down to bottom of tunnel by both heat loss and a turbulent flow, and to height of breath level.

An appropriate control is to regulate the smoke so that passenger could escape safety and to prevent a smoke inflow in opposite tunnel.

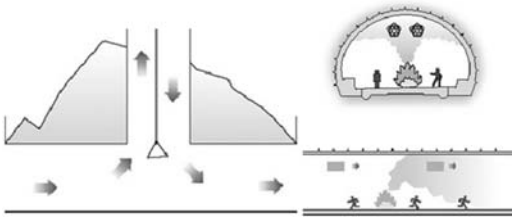

Figure 1. Longitudinal system.

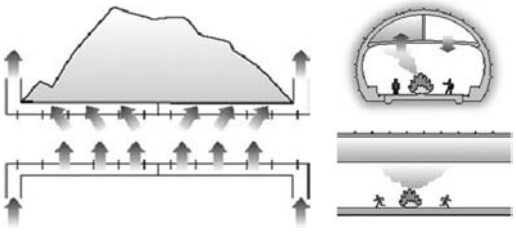

Figure 2. Transverse system.

2.2 *Smoke control system*

The effective smoke control is accomplished controlling through sufficient air volume and pressure. The smoke control must use mechanical equipment. Also long tunnel generally is furnished by operating fan for normal ventilation. Accordingly this ventilation fan is also used to smoke control.

Therefore there is correlation between smoke control system and ventilation method of tunnel. Consequently it uses method of smoke extraction or smoke control is used to type of ventilation system.

2.2.1 *Longitudinal system*

Longitudinal system is method that itself of tunnel is used for smoke moving pathway. If fire accident occurs, main evacuate direction is backward of running direction of vehicles. Also control direction for fire smoke has a same direction of vehicles. Namely, passengers must evacuate to entrance of tunnel, and smoke will be extracted to opposite direction.

2.2.2 *Transverse system*

Transverse/Semi-Transverse System is method that the duct of tunnel crown is used for movement of smoke. When fire break out, transverse system can use a duct port for smoke extraction, so smoke path-way is duct itself. The passengers can evacuate through both side.

3 MODEL EXPERIMENT

3.1 *Characteristic of model experiment*

It's very important to understand that how fire grows in tunnel fire. For the purpose of predict fire condition, full-scale test, model test, and numerical methods are available. Full-scale test is restricted actually. Accordingly, model test can be a best method to predict, and proper method to measure an inside pressure distribution, in safety design.

Such as model test need to be applied right scaling rule to output the correct data. And it is important to install a measure-sensor on the proper point to observe airflow.

Table 1. Applied specification in the scaled model.

Item	Actual size	Scaling size
Extension (m)	880 m(220 m × 4 blocks)	17.6
Cross section (m^2)	72.03	0.028812
HRR	30 MW	1.70 kW
Velocity (m/s)	3.17	0.448
Time proportion	7.07 sec	1.00 sec

3.2 *Scaling*

3.2.1 *Scaling of heat release rate*

The model and full-scale heat release rates Q_{model} and $Q_{full\text{-}scale}$ are related by eqn(1)

$$\frac{Q_{model}}{Q_{full-scale}} = \left(\frac{L_{model}}{L_{full-scale}}\right)^{5/2} \quad (1)$$

Where H_{model} and $H_{full\text{-}scale}$ are the respective length scales, in this case the heights of the model and full-scale tunnels. It is relatively easy to see that the scaling must have this form if one considers the low velocity limits. In this case, dimensional arguments suggest that the distance from the fire at which the temperature takes a given value is proportional to $Q^{2/5}$.

3.2.2 *Scaling of velocity*

The model and full-scale inlet velocities V_{model} and $V_{full\text{-}scale}$ are related by eqn(2)

$$\frac{V_{model}}{V_{full-scale}} = \left(\frac{L_{model}}{L_{full-scale}}\right)^{1/2} \quad (2)$$

3.2.3 *Geometrical scaling*

In this study, the scale of reduced scale model is applied to 1/50.

3.3 *Test model and condition*

3.3.1 *Test model*

In this study, production of model and installation of measuring instrument is composed by Figure 1.

Sensors are adopted anemometer, thermocouple, manometer in this model.

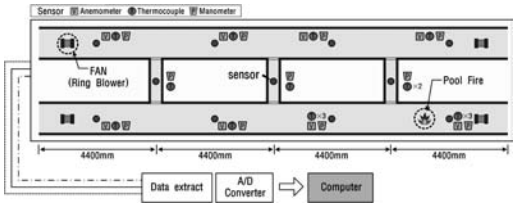

Figure 3. Description of model.

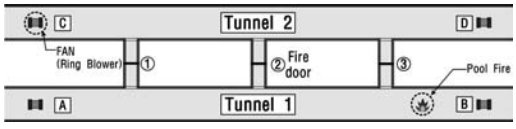

Figure 4. Description of test.

Table 2. Case of test.

	Test condition					
					Fire door	
Case	Tunnel 1		Tunnel 2		①	②	③
1	A:→	B:→	C:×	D:×	closed	closed	closed
2	A:→	B:→	C:×	D:←	closed	closed	opened
3	A:→	B:→	C:→	D:←	closed	opened	closed
4	A:→	B:→	C:→	D:←	opened	opened	opened
5	A:×	B:×	C:→	D:←	opened	opened	opened

3.3.2 *Realization of fire situation*

VVVF inverter(Variable Voltage Variable Frequency Inverter) is applied to control inside velocity of tunnel, which can control an aim velocity exactly. In this experiment, the fire source is applied by Pool Burner which fuel is gasoline. And burning efficiency of fuel is 0.7. It is because that the evaporated fuel doesn't burn in 100%.

4 RESULTS

4.1 *Experiment case*

When the fire breaks out, normal fan operating system can has a possibility that happen to smoke inflow opposite tunnel. Accordingly, experiment cases are selected to prevent smoke inflow to opposite tunnel 1 by the pressurization effect the experiment cases are selected.

4.2 *Case 1*

Fire on/off test is done under all fire doors closed to estimate how much pressure rise by fire in tunnel.

According to experiment results, when the fire break out, pressure is higher than opposite tunnel 1.

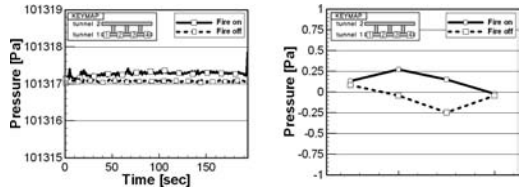

Figure 5. Tunnel pressure of Case 1.

Table 3. Pressure data of Case 1.

Pressure [pa]	1	2	3	4
Tunnel 1	0.1332	0.2733	0.1515	−0.0206
Tunnel 2	0.084	−0.0423	−0.247	0.0432

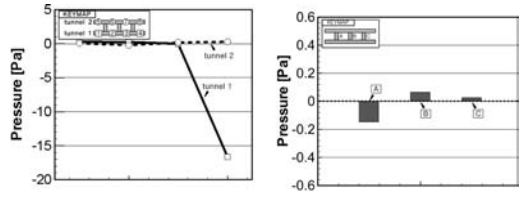

Figure 6. The tunnel pressure of Case 2.

Table 4. The pressure data of Case 2.

Pressure [pa]	1	2	3	4
Tunnel 1	0.2966	0.2437	−0.024	−16.6356
Tunnel 2	0.0706	−0.2254	0.188	0.2856

Table 5. The pressure difference data of Case 2.

Pressure [pa]	A	B	C
Pressure Difference	−0.1499	0.0642	0.0259

It's because of heat buoyancy made by fire. If it has opened doors, it suppose that smoke can inflow into opposite tunnel.

4.3 *Case 2*

Fan D is operated operation under fire door ③ opened in order to prevent spreading smoke into opposite tunnel. In order to know of smoke controlling capability, this test are performed.

According to the experiment result, pressure difference where both side of opened fire door ③ is 0.0259[pa]. The smoke spreading is stopped. It's

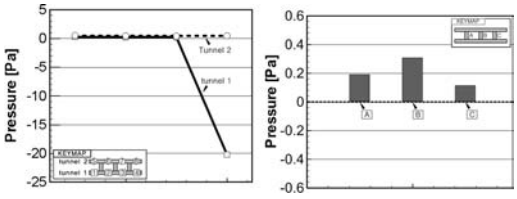

Figure 7. The tunnel pressure of Case 3.

Table 6. The pressure data of Case 3.

Pressure [pa]	1	2	3	4
Tunnel 1	0.2716	0.2404	0.2498	−20.1893
Tunnel 2	0.5159	0.4551	0.4368	0.466

Table 7. The pressure difference data of Case 3.

Pressure [pa]	A	B	C
Pressure Difference	0.1901	0.3073	0.1143

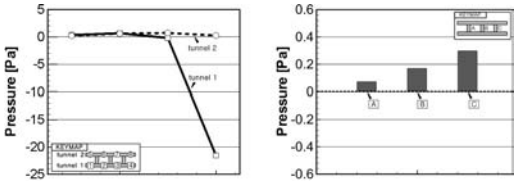

Figure 8. The tunnel pressure of Case 4.

because that the pressure in opposite tunnel is a little high.

4.4 *Case 3*

Fan C and D is operated pressurization under fire door ② opened in order to prevent spreading smoke into opposite tunnel. It's in order to know whether the fan can prevent smoke spreading into ② fire door.

In order to maximize of tunnel pressure, new fan operating mode is tested. Namely it is operated to fire point of tunnel both side.

The differential pressure through cross passage is 0.3073[pa]. Accordingly smoke inflowing is prevented. Because of pressure in tunnel 2 is higher than tunnel 1.

4.5 *Case 4*

All of cross passage is opened. And then Fans are operated pressurization.

Table 8. The pressure data of Case 4.

Pressure [pa]	1	2	3	4
Tunnel 1	0.3468	0.6726	−0.1821	−21.5364
Tunnel 2	0.2351	0.6135	0.7336	0.2519

Table 9. The pressure difference data of Case 4.

Pressure [pa]	A	B	C
Pressure difference	0.0718	0.1697	0.2975

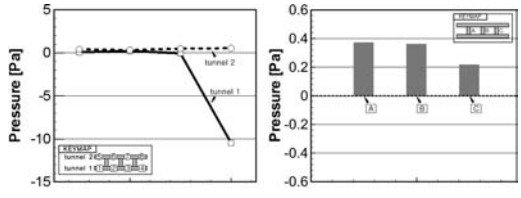

Figure 9. The tunnel pressure of Case 5.

Table 10. The pressure data of Case 5.

Pressure [pa]	1	2	3	4
Tunnel 1	0.0687	0.2159	−0.0572	−10.4422
Tunnel 2	0.4098	0.3166	0.4873	0.5363

Table 11. The pressure difference data of Case 5.

Pressure [pa]	A	B	C
Pressure Difference	0.3733	0.3629	0.2187

The pressure difference the opened fire doors is measured positive. So it is estimated that opposite tunnel pressure is higher than tunnel 1. Therefore smoke doesn't spread to opposite tunnel.

4.6 *Case 5*

Case 5 is assumed that fan in tunnel 1 can't be operated. And opposite tunnel fan is operated the pressurization under all cross passages are opened.

The smoke back-layering occurs constantly. Because the fired tunnel fans can't be operated. But, the possibility of smoke spreading is few. Due to the pressure is more than opposite tunnel.

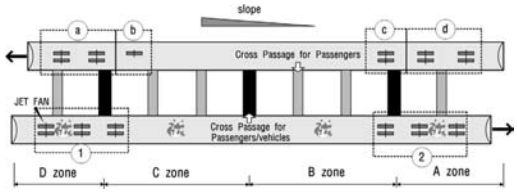

Figure 10. Description of fan operating matrix.

Table 12. Operating matrix 1.

Fire Zone	Fire tunnel ①	Fire tunnel ②	Opposite tunnel a	Opposite tunnel b	Opposite tunnel c	Opposite tunnel d
A	→	→	×	×	×	←
B	→	→	→	→	→	←
C	→	→	→	×	×	←
D	→	→	→	×	×	×

4.7 *Result of experiment*

The road tunnel fire model experiment is performed by many cases of scenario. The purpose of this test is to select and examine the pressurization mode.

It is examined that the differential pressure of cross passage to establish basic data. When it is pressurized by control operating mode, the differential pressure is accomplished. Accordingly, the smoke spread toward opposite is prevented.

Fire experiment is performed for various fire scenario. And the smoke flow is estimated by these fire scenarios.

Finally, the level of differential pressure which is made by pressurization is different by the length between cross passage and fan.

5 FAN OPERATING MATRIX

On the base of these test results, fan operating matrix for smoke control are developed by fire zone in tunnel. And these operating matrix can prevent of smoke spread through cross passage, so it is possible to escape to safety area.

5.1 *Fan in fired tunnel: able to operate*

This operating matrix is supposed that the fan in fired tunnel is not operated.

Table 13. Operating matrix 2.

Fire Zone	Fire tunnel ①	Fire tunnel ②	Opposite tunnel a	Opposite tunnel b	Opposite tunnel c	Opposite tunnel d
A	×	×	→	×	×	←
B	×	×	→	×	×	←
C	×	×	×	←	←	←
D	×	×	→	→	←	←

5.2 *Fan in fired tunnel: unable to operate*

It is supposed that the fan in fired tunnel can not be operated. Namely, this matrix is composed that is only using fan in opposite tunnel.

6 CONCLUSION

Experimental fire test study carried out to establish proper fan operating mode to prevent a smoke spread to opposite tunnel. Results of this study are as followed;

In order to analyze a pressure distribution of tunnel in case of vehicle fire, Scaled model test are used.

Owing to buoyancy effect of fire, pressure of fired tunnel is higher than other tunnel. So in order to prevent a smoke inflow to opposite tunnel, higher pressure are necessary than fired tunnel. As Pressure in tunnel is changeable due to fire-time situation, through various tests, analyzing is performed in case of various pressure patterns.

As a result of this test, fan operating matrix which satisfies the condition is developed. On the base of these results, fan operating matrix guidelines for road tunnel are developed. And this matrix can be adapted in road tunnel safety design and maintenance.

ABSTRACT: The effectiveness of one dimensional critical velocity method for evacuation environment at 10MW fire size in a railroad tunnel has been investigated in this paper by three dimensional CFD method. It was performed to evaluate the evacuation environment in terms of temperature distribution, visible distance distribution and CO concentration at some tunnel inlet velocity, 1 m/s, 2 m/s(near critical velocity), and 3 m/s. At all inlet velocity, passenger should give away downward the flow direction because the inlet velocity can not afford to sufficient evacuation environment for passengers. In case of 3 m/s inlet velocity, however, the evacuation environment for passengers is better than the other cases. To provide more safe evacuation environment on fire situation, tunnel inlet velocity should be larger than critical velocity.

1 INTRODUCTION

Korea is a country surrounded by sea on three sides. Approximately 70% of its land is steep mountainous with great geological variation. Tunnels play an important role in developing new road networks and the number of road tunnels in Korea has continually increased rapidly over many years. This is because of recent developments of road networks through mountainous ranges, and also because of the reduction of tunnel construction costs. In addition, with improving construction technology, tunnels have been adopted as an increasingly cost-effective engineering solution to traverse urban areas with minimum local environment impact.

Fires in tunnels occur no more often than elsewhere, but because of the restricted space and enclosed atmosphere, the consequences can be far more severe. Indeed, a fire may result in extremely damaging situations (e.g. Channel Tunnel fire) or even dramatic events, such as the fire which occurred in March 1999 in the Mont-Blanc Tunnel.(1–3)

When a fire occurs in a tunnel, the most hazardous factor for the users is not fire itself, but the combustion smoke is likely to spread into the tunnel rapidly. That smoke will reduce visibility and can cause deaths by asphyxiation.(4,5)

In case of a fire in a tunnel, the major concern then consists in controlling the smoke propagation by using the ventilation systems set up in the tunnels as efficiently as possible. The essential objective of fire ventilation in tunnels with longitudinal ventilation systems is that of ensuring smoke-free conditions throughout the tunnel cross-section upstream the fire to permit safe escape and rescue of persons and safe fire-fighting. With an inadequate air velocity, however, the smoke layer would also spread against the direction of air flow. A minimum air velocity must be assured, in order to avoid this. Knowledge of such so-called critical air velocities is therefore necessary for planning and design of the fire ventilation in tunnels. Wu etc(6). carried out experimental tests of tunnel fires using tunnels of different cross sections. They reported that different cross sections of tunnel have a small effect on critical velocity. Also, Tetzner(7) etc. pointed out the error for critical velocity equation by Kennedy(8) and proposed beta coefficient, which make up for the weak points in its equation. In case of a fire in a tunnel, however, it is important to consider the distribution of air flow, temperature and smoke in evacuation environment.

Therefore, the purpose of this paper is to identity the availability of one dimensional critical velocity method applied in design of disaster prevention system using three-dimensional Computational Fluid Dynamics. And then we would evaluate that the ventilation equipment designed by the critical velocity equation ensure the safe evacuation environment of passengers throughout the distribution of air current, temperature, visible distance and harmful gas.

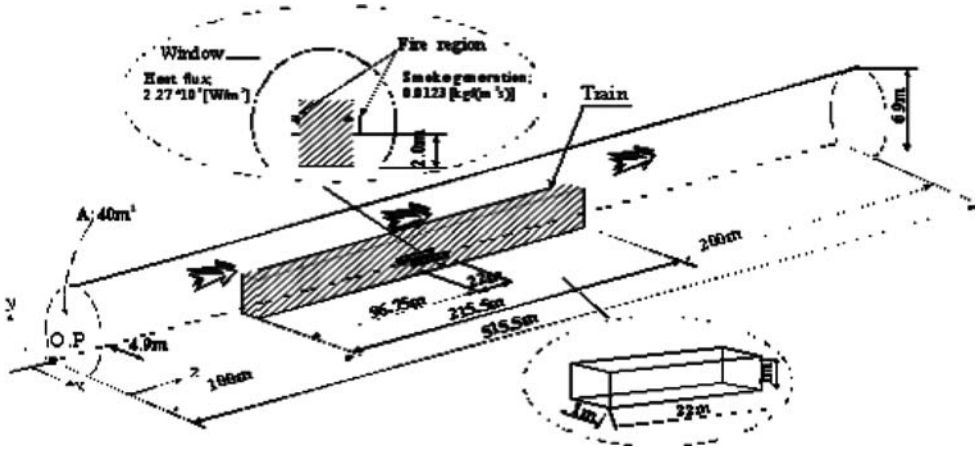

Figure 1. Approximation of tunnel model.

2 THE SAFETY STANDARDS OF EVACUATION ENVIRONMENT

This study checked the safety by applying following details considering foreign standards because there is no Korean standard for stability of evacuation environment.

(i) Air temperature: It must be sustained average temperature below 60∼80°C[9,10] for safe evacuation of passenger. And it must be sustained average temperature below 49°C for the case below 60°C within maximum some seconds or after the lapse more than 6 minutes.[11]

(ii) CO concentration: It must be sustained the density below 200 ppm within maximum some seconds, 1500 ppm within 6 minutes, 800 ppm within 15 minutes and 50 ppm after 15 minutes.[11]

(iii) Visible distance: It must be able to distinguish at least 10 m of wall and door.[11]

3 ANALYSIS MODEL

To investigate the inside environment of railroad tunnel by a train fire in this study it analyzed the case that the train of 210 m stopped by fire as shown in Figure 1. For convenience, it set the origin point to the lower left of the figure, the z-axis to the moving direction of the train, the x-axis to the bottom of tunnel, the y-axis to the height. The entrance of tunnel is the lower left of the figure. The fresh air is flowed into the tunnel through the entrance by the ventilation system. The cross section area of tunnel, A is 40 m^2, the height of tunnel, H is 6.9 m and the hydraulic diameter D_h is 6.88 m. The analytical range is total 515.5 m inclusive of train length[gear train(22 m) + passenger train(176 m) + power train(17.5 m)] and 200 m of the front and 100 m of the rear. The center position of the both windows in fired train is 2.5 m away from y-axis and 207.75 m away from z-axis. And the cross section area of that is 22 m^2. The heat of 10 MW fire size is delivered into the tunnel through the both windows of train in constant heat flux. It assumed the smoke is generated from the virtual volume space of 22 m^3 adjacent to the both windows.

4 THE COMPUTATION OF ONE-DIMENSION CRITICAL VELOCITY

It serves the evacuation of the passenger by sending the fresh air to fired space at fire situation. The phenomenon which the fresh air returns to the inflow direction names back layering. And that is unsafety. The minimum of inflow velocity to prevent back layering names critical velocity, and following equation is the computed equation of Kennedy's one-dimensional critical velocity $V_c^{(8)}$ that applies generally.

$$V_C = K_g\left(\frac{gHE}{Fr_C \rho_\infty c_P A T_f}\right)^{1/3} \quad (1)$$

$$T_f = \frac{E}{\rho_\infty c_P A V_C} + T_\infty \quad (2)$$

$$K_g = 1 + 0.0374\gamma^{0.8} \quad (3)$$

A : cross section area of tunnel [m^2]
C_p : specific heat of air [J/(kg·k)]c
E : fire size [W]
Fr_c : critical Fr number [4.5][12]
g : acceleration of gravity [m/s^2] Fr_c
H : height of tunnel [m]
ρ_∞ : air density except fire range [kg/m^3] k_g

Table 1. Governing equations.

Continuity equation;

$$\frac{\partial}{\partial \chi_i}(\rho u_i) = 0$$

Momentum Equation;

$$\frac{\partial}{\partial x_i}(\rho u_j u_i) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\{(\mu + \mu_t)(\frac{\partial u_j}{\partial x_i} + \frac{\partial u_i}{\partial x_j})\} + \rho g_i \beta (T - T_m)$$

Turbulent Kinetic Energy Equation;

$$\frac{\partial}{\partial x_i}(\rho u_i k) = \frac{\partial}{\partial x_i}\{(\mu + \frac{\mu_t}{\sigma_k})\frac{\partial k}{\partial x_i}\} + G_k + G_b - \rho\varepsilon$$

Dissipation Rate Equation of Turbulent Kinetic energy;

$$\frac{\partial}{\partial x_i}(\rho u_i \varepsilon) = \frac{\partial}{\partial x_i}\{(\mu + \frac{\mu_t}{\sigma_\varepsilon})\frac{\partial \varepsilon}{\partial x_i}\} + C_{1\varepsilon}\frac{\varepsilon}{k}(G_k + C_{3\varepsilon}G_b) - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k}$$

Energy Equation;

$$\frac{\partial}{\partial x_i}(\rho u_i T) = \frac{\partial}{\partial x_i}\{(\frac{\mu}{\sigma_l} + \frac{\mu_t}{\sigma_t})\frac{\partial T}{\partial x_i}\}$$

Concentration Equation;

$$\frac{\partial}{\partial x_i}(\rho u_i C_s) = \frac{\partial}{\partial x_i}\{(\frac{\mu}{S_l} + \frac{\mu_t}{S_t})\frac{\partial C_s}{\partial x_i}\} + S_c$$

$$\rho = (\rho_{ref} T_{ref})/T$$

$$\nu = -0.49467910^{-5} + 0.45839410^{-7} T + 0.8097410^{-10} T^2$$

where,

$$\mu_t = \frac{c_\mu \rho k^2}{\varepsilon},\ G_k = \mu_t(\frac{\partial u_j}{\partial x_i} + \frac{\partial u_i}{\partial x_j})\frac{\partial u_j}{\partial x_i},\ G_b = \frac{\mu_t g_i \beta}{\sigma_t}\frac{\partial T}{\partial x_i}$$

$$C_\mu = 0.09,\ C_{1\varepsilon} = 1.44,\ C_{2\varepsilon} = 1.92,\ C_{3\varepsilon} = 1.0,\ \sigma_k = 1.0,\ \sigma_\varepsilon = 0.9,\ \sigma_l = 1.0.$$

$$\sigma_t = 1.0,\ S_t = 0.68$$

T_f : combustion gas temperature [K] T
$\boldsymbol{T}_\infty$: air temperature except fire range [K]
γ : slope of tunnel [%]
K_g : grade factor [-]

Critical velocity is computed by iterating both equation (1) and (2). In this study that is computed at 2.0 m/s on the assumption that air temperature is 17°C.

5 GOVERNING EQUATION AND BOUNDARY CONDITION

5.1 *Governing equation*

The flow under consideration is three dimensional and turbulent, and has a steady state. The governing equations solved include those expressions for conservation of mass, the momentum, the turbulent kinetic energy, the dissipation rate of turbulent kinetic energy, and the thermal equations are illustrated from table 1. Energy equation and density equation is governing equation for analyzing each distribution of temperature and pollutant in table 1. It selected the sign of each equation by the example of general literature, it selected k-ε model[13] considered buoyancy to analyze turbulent flow.

5.2 *Boundary condition*

To obtain the physically meaningful solution to the problem in question, we must specify the thermal and flow conditions of tunnel inlet, outlet, wall and fire informations. Boundary conditions in this calculation to solve governing equation is illustrated from table 2. u, v and w is the velocity for the direction of x, y and z in table 2.

Heat release rate, the generation value of smoke and the generation value of CO by fire size supposed

Table 2. Boundary condition.

Tunnel inlet	$u=0,\ v=0,\ T=290K,\ C=0,\ w=1m/s,\ 2m/s\ and\ 3m/s$ $k=0.015\times w^2,\ \varepsilon=C_\mu\times k^{1.5}/(0.5\times D_h)$
Tunnel outlet	$\frac{\partial u}{\partial z}=\frac{\partial v}{\partial z}=\frac{\partial w}{\partial z}=0,\ \frac{\partial k}{\partial z}=0,\ \frac{\partial \varepsilon}{\partial z}=0,\ \frac{\partial C}{\partial z}=0,\ \frac{\partial T}{\partial z}=0$
Tunnel wall	$u=v=w=0,\ \frac{\partial T}{\partial x}=\frac{\partial T}{\partial y}=\frac{\partial T}{\partial z}=0,\ \frac{\partial C}{\partial x}=\frac{\partial C}{\partial y}=\frac{\partial C}{\partial z}=0$

to 10 MW, 0.541 kg/s and 0.055 kg/s from previous study[3,14]. It supposed that heat is delivering to tunnel inlet for heat flux $2.27\times 105\ W/m^2$ through right and left window at the fire part of train from that. Also it supposed that the smoke and CO is generated 0.0123 [kg/(m^3.s)] and 1250 ppm from the virtual volume space adjacent to the both windows.

It analyzed three case of tunnel inflow velocity, 1 m/s, 2 m/s(critical velocity) and 3 m/s in this study. The temperature of inflow air is 17°C.

The exit of the tunnel applied for outflow condition and the wall applied for viscosity condition and adiabatic.

5.3 *Numerical analysis method*

In the present study, PHOENICS[15], a general-purpose commercial code, was used to analyze the air flow, the temperature distribution, the CO distribution, and the tunnel environment in the space. To fit the irregular shape of the tunnel, the body-fitted coordinate system was adopted; i.e., the grid lines were arranged to match the physical bounding surfaces. There are $15\times 16\times 90$ grid cells used in the present study.

6 RESULT AND CONSIDERATION

It may ensure to sufficient evacuation environment for passengers at the aspect of flow distribution, temperature, visible distance and harmful gas distribution, to evaluate the effectiveness of one dimensional critical velocity method applied to design disaster prevention system for railroad tunnel.

On fire situation, the passenger got on the upward flow direction from the fire position can evacuate to the upward without passing the fire position. But the passenger got on the downward should pass through the fire position to evacuate to the upward. In fact, it is impossible. Therefore the downward passenger should evacuate to the downward, it must be evaluated the stability for evacuation environment of the downward. For that, it investigated each distribution for x-z section (the region of 186 m~400 m for z direction) that is 1.5 m away from y direction for the bottom of tunnel. This section is breathing height of passengers, it expected to influence on the evacuation of passengers at fire situation. It called breathing section in this study.

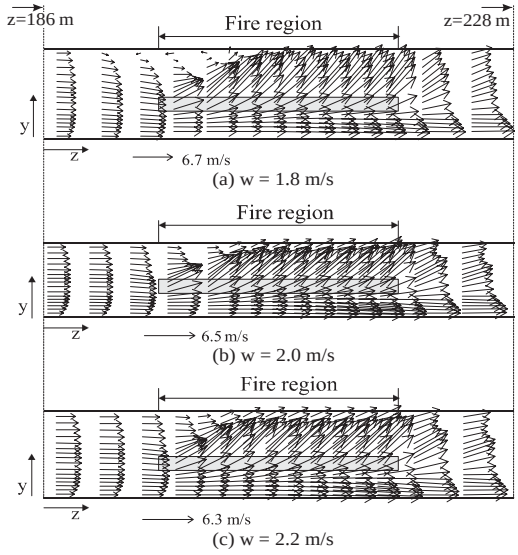

Figure 2. Tunnel inlet velocity distributions by changing inflow velocity.

6.1 *Consideration effectiveness at the aspect of air distribution*

It considered the air flow of the evacuation route (x = 1 m) section to verify the effectiveness of computing critical velocity(2 m/s) by equation (1) with changing inflow velocity, 1.8 m/s(90% of the critical velocity) and 2.2 m/s(110% of the critical velocity).

To check generation of the back-layering at the fire zone, Figure 2 show the flow distributions of the y-z section at the around fired train. Figure 2(a) shows that back-layering generate from fire zone to the evacuation direction of passengers. It generate maximum 6.5 m/s updraft from fire zone, it does not generate back-layering in Figure 2(b). Also it generate maximum 6.3 m/s updraft from fire zone, it does not

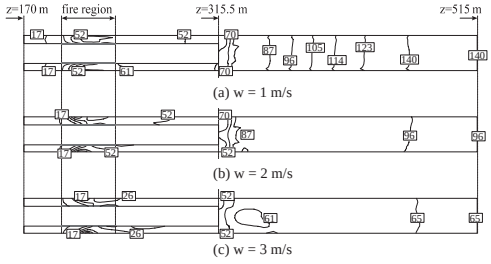

Figure 3. Tunnel inlet temperature distribution by changing inflow velocity [unit. °C].

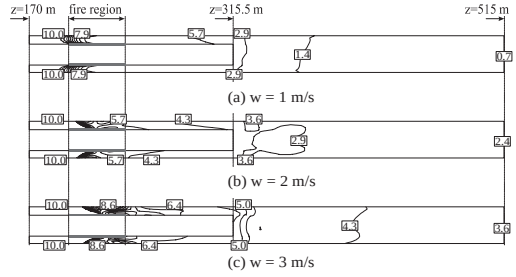

Figure 4. Tunnel inlet visible distance distribution by changing inflow velocity [unit in].

generate back-layering as the occasion of inflow velocity, 2 m/s in Figure 2(c). Therefore, it is considered that one dimensional critical velocity method applied to predict back-layering is comparatively appropriate.

6.2 *Consideration for availability at the aspect of temperature distribution*

Figure 3 shows the temperature distributions of breathing section by changing inflow velocity. In occasion of inflow velocity in tunnel is 1 m/s, the temperature of air is illustrated maximum 140°C by gradually rising from fire zone to inflow downward in Figure 3(c). It is considered that the evacuation environment of passengers at the downward is very poor. It shows that maximum temperature of downward direction is 96°C higher than allowable standard temperature 80°C in Figure 3(b) of inflow velocity 2 m/s. Indeed, it shows that the evacuation environment of passengers is ever poor though tunnel inflow velocity is kept 2 m/s by one dimensional critical velocity equation.

It is considered that the evacuation environment is not appropriate though critical velocity is minimum velocity to prevent back-layering.

Figure 3(c) of inflow velocity 3 m/s shows that the maximum temperature in the downward direction of fire zone is 65°C ower than allowable temperature. It is considered that 150% of critical velocity makes the sufficient evacuation environment for safe evacuation of passengers.

6.3 *Consideration availability at the aspect of visible distance distribution*

It is illustrated visible distance distributions computed by the smoke concentration distribution of at Figure 4 to evaluate the evacuation stability of the passengers. The visible distance distribution applied for following empirical formula and coefficient proposed by Steiner.

$$L_v[m] = \frac{D_s \cdot \ln(A)}{K \cdot Y_s \cdot C_s \cdot \rho_\infty} \tag{4}$$

A : Sight insurance distance [=10 m]
C_s : Smoke concentration of pollutant [-]
D_s : Optical density [-]
K : absorption area [m^2/kg]
L_v : Visible distance [m]
Y_s : Solid particle ratio [-]

Figure 4(a) shows that visible distance being lower suddenly to less than a meter by generating smoke at the place 150 m away from fire zone to flowing downward. It is considered that it need the additional ventilation equipment to make sure visible distance for evacuation because it is very poor for evacuation environment of passengers. Visible distance is elevated as compared with Figure 4(a) in Figure 4(b) increased to 2 m/s. However, it does not provide the visible distance to ensure safe evacuation environment of passengers. Although visible distance increased to 3∼4 m as Figure 4(c) increased to 3 m/s, it doesn't also ensure safe evacuation environment of passengers.

It is expected that it does not provide safe evacuation environment of passengers at the aspect of visible distance, in occasion of choosing ventilation equipment by critical velocity as visible distance distribution. Accordingly it considered to need additional ventilation equipment to ensure safe evacuation environment of passengers.

6.4 *Consideration availability at the aspect of harmful material distribution*

Figure 5 shows CO concentration distributions at the height of breathing section to evaluate stability of evacuation environment of passengers at the aspect of concentration distribution. It shows that CO concentration increase to 350 ppm by moving to downward direction in Figure 5(a) of inflow velocity 1 m/s. Considering Figure 5(b) Inflow velocity is 2 m/s, the maximum concentration of tunnel exit range is 300 ppm. and it doesn't be large different for the case of inflow velocity 1 m/s. however, it shows 225 ppm at the large range by the rising mixing of CO and air with increasing air velocity.

In Figure 5(c) of inflow velocity 3 m/s, the maximum concentration for evacuation road downward range is 250 ppm. And CO concentration greatly

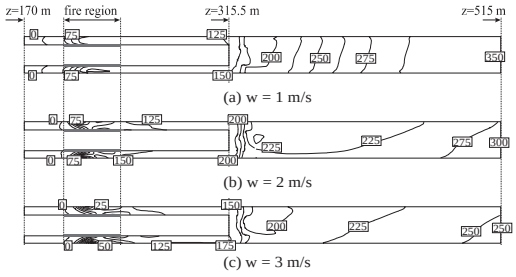

Figure 5. Tunnel inlet CO distribution by changing inflow velocity [unit: ppm].

decreases than the two case. It is considered to be able to provide some time in fire situation required prompt action. In the case of three inflow velocities, CO distribution is far lower than 800 ppm, average concentration for 15 minutes. But it is considered that passengers must evacuate to the position supplied fresh air within 15 minutes. Because CO distribution is far higher than 50 ppm required in evacuation over 15 minutes.

7 CONCLUSION

It studied that the ventilation equipment designed by one dimensional critical velocity equation can ensure to sufficient evacuation environment for passengers at the aspect of air distribution, temperature, visible distance and harmful material distribution, to evaluate the effectiveness of one dimensional critical velocity method applied to design disaster prevention system for railroad tunnel. It is obtained following conclusion.

(1) It is considered that one dimensional critical velocity method at the aspect of air current is reasonable because it doesn't occur back-layering at more than 2 m/s.
(2) It indicate that evacuation environment of passengers is poor at the aspect of temperature distribution in occasion of 1 m/s or 2 m/s. Consequently it is able to provide safe heat evacuation environment in occasion of 3 m/s.
(3) Visible distance is made better by increasing inflow velocity at the aspect of visible distance distribution. However, it is considered to need additional ventilation equipment to make better visible distance because it is expected that it doesn't provide enough visible distance.
(4) It is considered that passengers must evacuate to the position be supplied with fresh air within 15 minutes because CO distribution is far higher than 50 ppm required in case of evacuation time more than 15 minutes, though it is far lower than 800 ppm of average concentration for 15 minutes at the aspect of CO distribution.

Visiting Professor University of Tokyo, Kajima Corporation, Tokyo, Japan

ABSTRACT: A fire disaster prevention system using a water screen(WS) was developed for potential fires in underground spaces. This system is aimed at securing the occupants' evacuation from the fire by partitioning the fire zone using a water screen and also at the safety of a structure by reducing damage due to the fire. Because WS is composed by fogged drop of water discharged from the special nozzle continuously arranged under the ceiling, WS is possible to be a compartment of the fire zone even in a large and complex space. Moreover, because WS doesn't disturb the traffic of the people and the vehicle, it is suitable for in the subway station, the road tunnel and so on where a lot of passengers use.

To understand the performance of WS, fire experiments were conducted by using 1/2-scale models of a road tunnel. As a result, it was quantitatively confirmed the performance of WS for cooling the hot flow and washing soot particle off. Additionally, a numerical simulation method by CFD that was able to analyze the effect of WS was developed through the verification with results of the experiments. By this developed method, it has been possible to predict the flow of heat and smoke when WS operated. In addition, the occupant' safety at a fire can be confirmed by considering their behavior.

By this method, the fire safety was analyzed in two kinds of structures. 1st analytical case was assumed a fire in the road tunnel with the section having two lanes and the longitudinal slopes of 6%. The sprinklers and WS were assumed as disaster prevention equipments. The origin of fire was assumed 20 MW (corresponding to one large-scale bus) with gasoline in the center of the road. The distance from the fire origin to the shelter entrance as a safety zone was assumed to be 400 m. As a result, in the case of no equipment and only sprinklers, it was concerned that occupants' view was interrupted with the diffusing smoke before they got to the shelter entrance. By operating WS at the early stage of fire, occupants' was able to get to the entrance safely. 2nd analytical case was assumed a fire in the subway station. The fire origin was assumed 5 MW with gasoline in a train(corresponding to an arson). A smoke curtain (A small wall hung from the ceiling, height of 50 cm) and WS were assumed as equipment that prevented smoke spread at the evacuation route. As a result, in the case of no equipment and only a smoke curtain, it was concerned that the smoke was filled in not only the platform but also the evacuation route. But by operating WS, occupants' view was secured if they passed through WS.

1 INTRODUCTION

With big fires such as those which broke out in a tunnel in Daegu city in Korea (2003), the Mont Blanc Tunnel (1999) in Europe and the Tauern Tunnel (1999), interest in fire disaster prevention in tunnels has increased. The occurrence of fires can be attributed to various causes such as arson, accidental ignition and human error. Regardless of the cause, the common result is that a number of people may be killed or injured and that a great deal of time and labor is required for restoration work. With the promotion of highly developed utilization of such deep underground spaces as the Aqualine, the Metropolitan Expressway Shinjuku Line and the Outer Loop, how to secure safety in cases where fires break out in tunnels is an important problem which must be confronted. We have been developing water screens (hereafter referred to as WS) as well as investigating their applicability to the civil engineering field since 2002. The basic performance of the WS was established in large-scale fire tests using a 1/2 scale tunnel model. At the same time, a numerical analysis system for estimating the behavior of heat and smoke was developed in order to influence the compartmenting effects of the water screen.

Furthermore, evacuation simulation during a tunnel fire has been made possible by combining the predicted movements of occupants during evacuation and the safety standards for the occupants. This paper describes the effectiveness of the WS as well as introduces examples of the evacuation simulation for the road tunnel and the subway station.

2 WATER SCREENS

Waterdrops with a diameter of 200 μm which are sprayed from special nozzles arranged in rows on a wall create water screens. This fire disaster prevention system can restrain the diffusion of heat and smoke and secure the safety of occupants by collecting and washing out harmful floating particles. Moreover, this system can minimize the degree of damage to structures. Photo. 1 shows the WS when activated.

3 CFD (COMPUTATIONAL FLUID DYNAMICS)

The CFD, which is a system for a numerical analysis of the behavior of fluids and gasses such as water and air, has recently been applied in the field of fire safety design in tunnel spaces. Although fire tests are effective for the understanding of physical phenomena, a great deal of expense and labor are required in order to satisfy conditions for different sectional shapes according to structures, ventilation wind speed and fire source types. It is also difficult to carry out measurements and visualize flows. On the other hand, the CFD can help us understand any fire's behavior changing according to the aforementioned conditions quickly and from different angles. In our development, the FDS (Fire Dynamics Simulation: Developed by the National Institute of Standards and Technology of US Department of Commerce), which has been employed in many evacuation safety inspections around the world, was selected from among a number of CFD systems in order to build a function for analyzing the effects of the WS. The analysis accuracy of the FDS has already been verified through comparing the analysis results with the fire test results.

Photo 1. WS which are activated.

4 EVACUATION SIMULATION

In order that occupants may take refuge in safety during a fire in a tunnel, they must reach an emergency exit while avoiding fire induced heat and smoke. The evacuation simulation is carried out so as to judge whether or not the environment for the occupants satisfies the established safety standards until they reach the exit by comparing the behavior of heat and smoke obtained from the CFD with occupants' evacuation speed.

4.1 *Evacuation speed*

In inspecting the safety of evacuation, speeds at which occupants can escape are established according to different conditions in various literature references. The walking speed for a person who can walk unaided on a level surface (without stairs) is set at 1 m/s in most cases. In this study, it is assumed that occupants escaping from a fire source reach an exit with a walking speed of 1 m/s just after the occurrence of a fire.

4.2 *Safety standards*

4.2.1 *Safety standards for heat*

One literature reference indicates that humans can tolerate a temperature of 50°C and a humidity of 100% in the atmospheric condition surrounding their bodies for a period of only several minutes. Therefore, a temperature of less than 50°C at the height of an average human body can be regarded as a safe condition.

4.2.2 *Safety standards for smoke*

The light limiting smoke concentration under which occupants can take refuge in safety without missing visual directions is regarded as $Cs < 0.1 \sim 0.4$ for an attenuation coefficient of light. According to a literature reference, it is simpler and more straight forward to specify an evacuation direction for a tunnel structure than for an ordinary structure. Therefore, in the case of the attenuation coefficient of light at the height of an average human body being $Cs < 0.4$ occupants can be evacuated in safety. And for a subway station, in the case of the attenuation coefficient of light at the height of an average human body being $Cs < 0.1$ occupants can be evacuated in safety.

5 ANALYSIS EXAMPLE

5.1 *The cases of the road tunnel*

5.1.1 *Analysis conditions*

Analyses were carried out for a two-way traffic tunnel corresponding to class 2 for the Road Standard Type 1. The vertical section gradient of the tunnel was set as 6% in order that a traffic accident could easily occur and heat and smoke may rapidly spread. The fire protection rating for this traffic tunnel equipped with an emergency exit as well as water sprayers was classified as AA. Analysis conditions are shown in Table 1 and Fig. 1.

Table 1. Analysis conditions.

Fire source	Gasoline (Heat release rate 15 MW) (corresponding to one bus)	
Tunnel structure	Sectional shape	Inside diameter ϕ 10.8 m (Upper part of the road surface for the circular shield tunnel)
	Longitudinal length	L = 740 m
	Vertical section gradient	6% (maximum gradient of the subjective tunnel)
Water spraying equipment (WSE)	Nozzle	5 m/each (150 L/each/min)
	Compartment	Sprayed in two compartments with a length of 50 m (Sprayed in a 100 m length)
Compartmenting equipment (WS)	Nozzle	20/section (10 L/each/min)
	Compartment	50 m/each (Sprayed to both end sections in a WS compartment)
Ventilation equipment	Natural ventilation (primary wind speed 0 m/s)	
Emergency exit	510 m away from a fire source	

5.1.2 *Analysis cases*

Analyses were carried out in 6 cases shown in Table 2.

5.1.3 *Analysis results*

The results in both cases of S-2 and S-3 where the noticeable effects of the WS were discernible among all analysis results are compared with each other in Fig. 2,3. In the case of S-2 where the WS was not activated, smoke with Cs $\geqq$ 0.4 (red color in the figure) descended to the height of a human body 7 minutes after a fire broke out. On the other hand, in S-3 where the WS was activated 3 minutes after the outbreak of fire smoke concentration decreased and the smoke did not fall to the height of a human body even after 8.5

Table 2. Analysis cases.

Case no.	Analytical object	WS	Water spraying equipment (WSE)
T-1	Heat (Temperature)	Without	Without
T-2		Without	Activated 10 min after a fire broke out
T-3		Activated 3 min after a fire broke out	Activated 10 min after a fire broke out
S-1	Smoke (Attenuation coefficient of light)	Without	Without
S-2		Without	Activated 10 min after a fire broke out
S-3		Activated 3 min after a fire broke out	Activated 10 min after a fire broke out

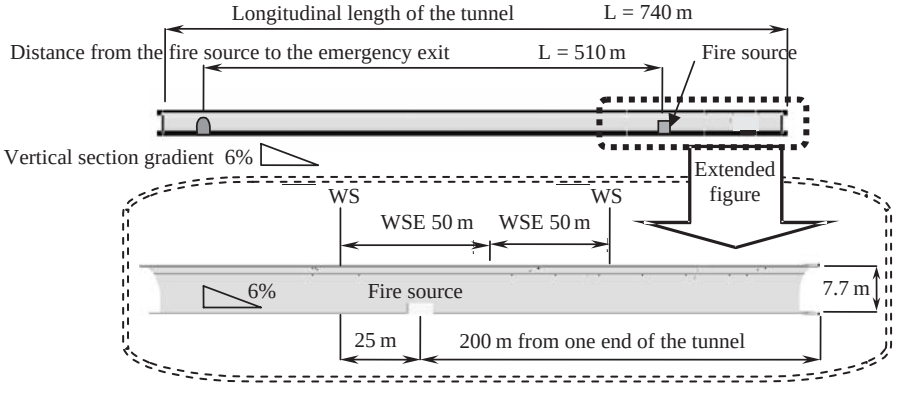

Figure 1. Analysis model.

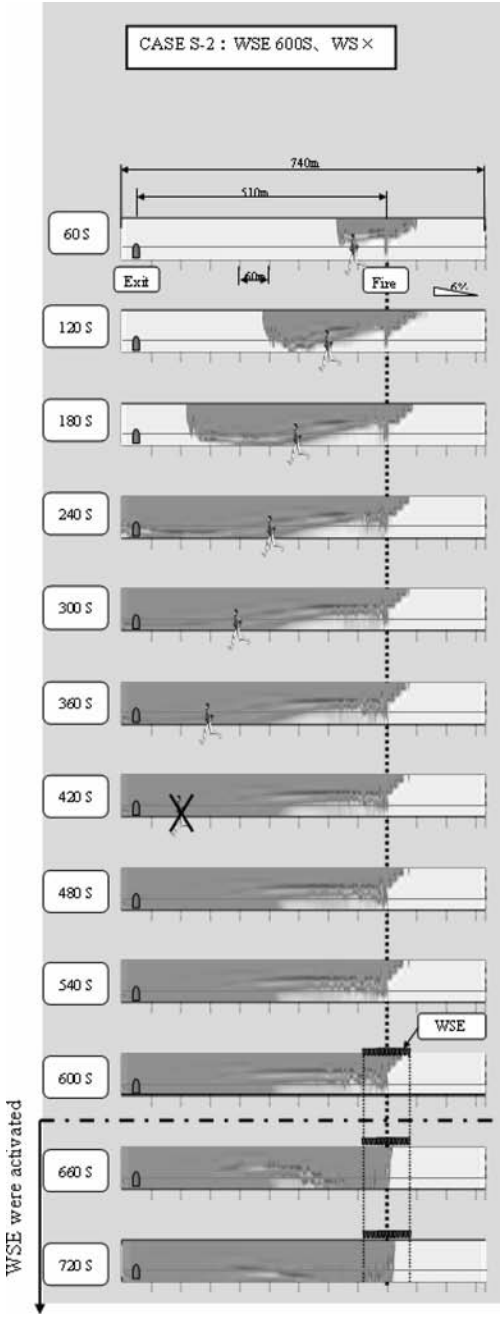

Figure 2. Evacuation simulation results for smoke (S-2).

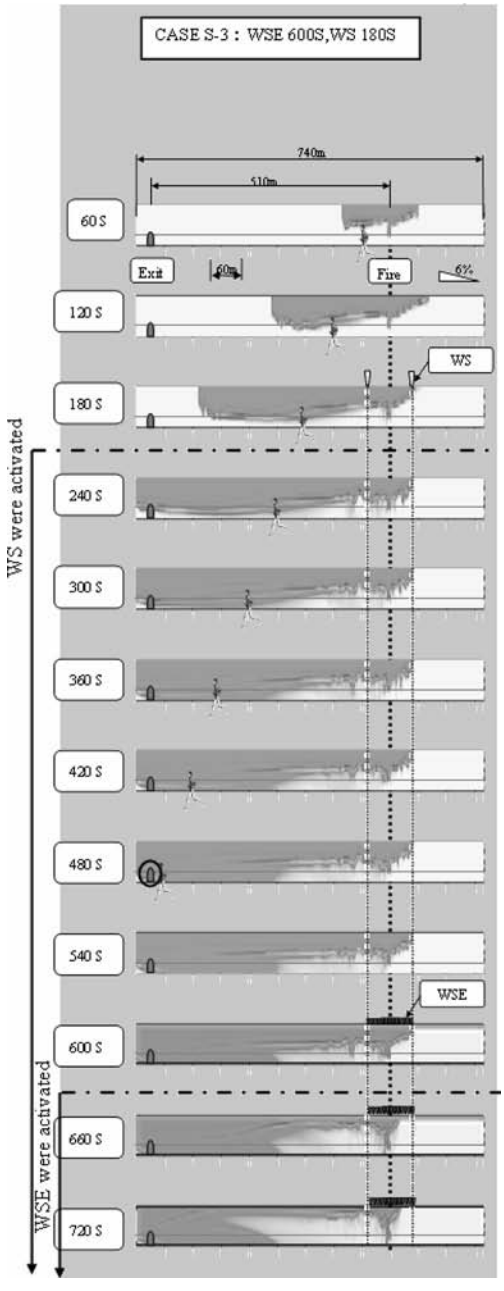

Figure 3. Evacuation simulation results for smoke (S-3).

minutes, in which time occupants reached the emergency exit. It was made clear that the WS contributes to the improvement of the safety for evacuation from fires. The same results were obtained from the WS for heat.

With regard to fire disaster prevention systems for tunnel spaces, the criteria prescribed after the occurrence of a fire in the Nihonzaka Tunnel are still applied. However, it can be thought that new studies on WS and evacuation simulation will be regarded as important in the future.

Table 3. Analysis conditions.

Fire source	Scale	A fire of a train caused by an incendiary: gasoline fueled large fire source * Calorific value Q: 5 MW * Burning time t: 3 min * Burning area A: 5 m^2 [1]
	Fire position	On the train in front of the ticket gates
Evacuation	Evacuation passageway	Trains → Platform → Ticket gates → Stairs → Stairs above the surface
	Time to finish evacuation	7.8 min (To refuge on stairs above the surface)[2]
Environment	Wind	Windless
	Temperature	20°C

[1] On the assumption that a fire breaks out in trains and flames as well as smoke are emitted from windows. (The total window area is 5 m^2 with 3 m^2 windows on the side of the platform and 3 m^2).
[2] According to the method for calculating the time required to take refuge prescribed in the "manual for evacuation safety in the case of fires breaking out in subway stations."

5.2 *The cases of the subway station*

5.2.1 *Analysis conditions*

Analyses were carried out for a subway station. Analysis conditions are shown in Table 3 and Fig. 4.

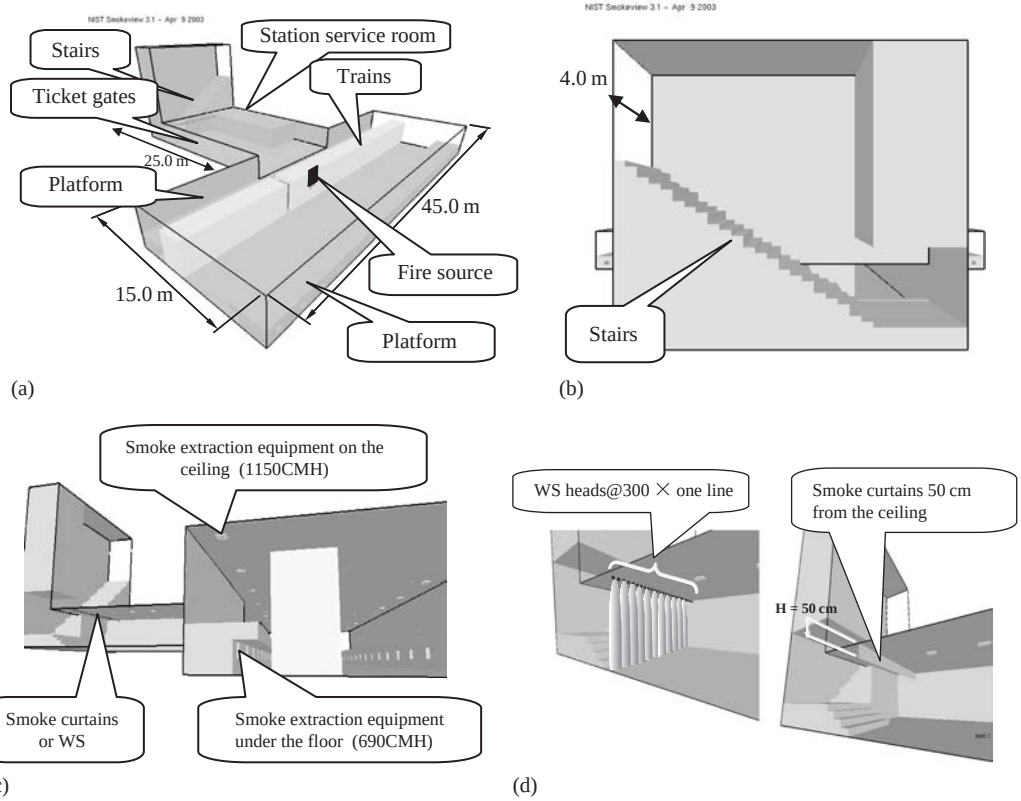
- Smoke extraction equipment of both up and down lines are activated simultaneously with the outbreak of a fire according to the judgment made by station service room staff.
- Water is sprayed simultaneously with the outbreak of a fire.
- Water is sprayed over 10 minutes.

5.2.2 *Analysis cases*

Case 1: Without any countermeasure
Case 2: Installation of smoke curtains
Case 3: Installation of WS (Water Screens)

5.2.3 *Analysis results*

Smoke flows and evacuation conditions are shown. It was confirmed that smoke is prevented from flowing compartments due to the effects of water out of fire screens and that the water screens functions the same as fire doors and fire shutters. Smoke easily climbs



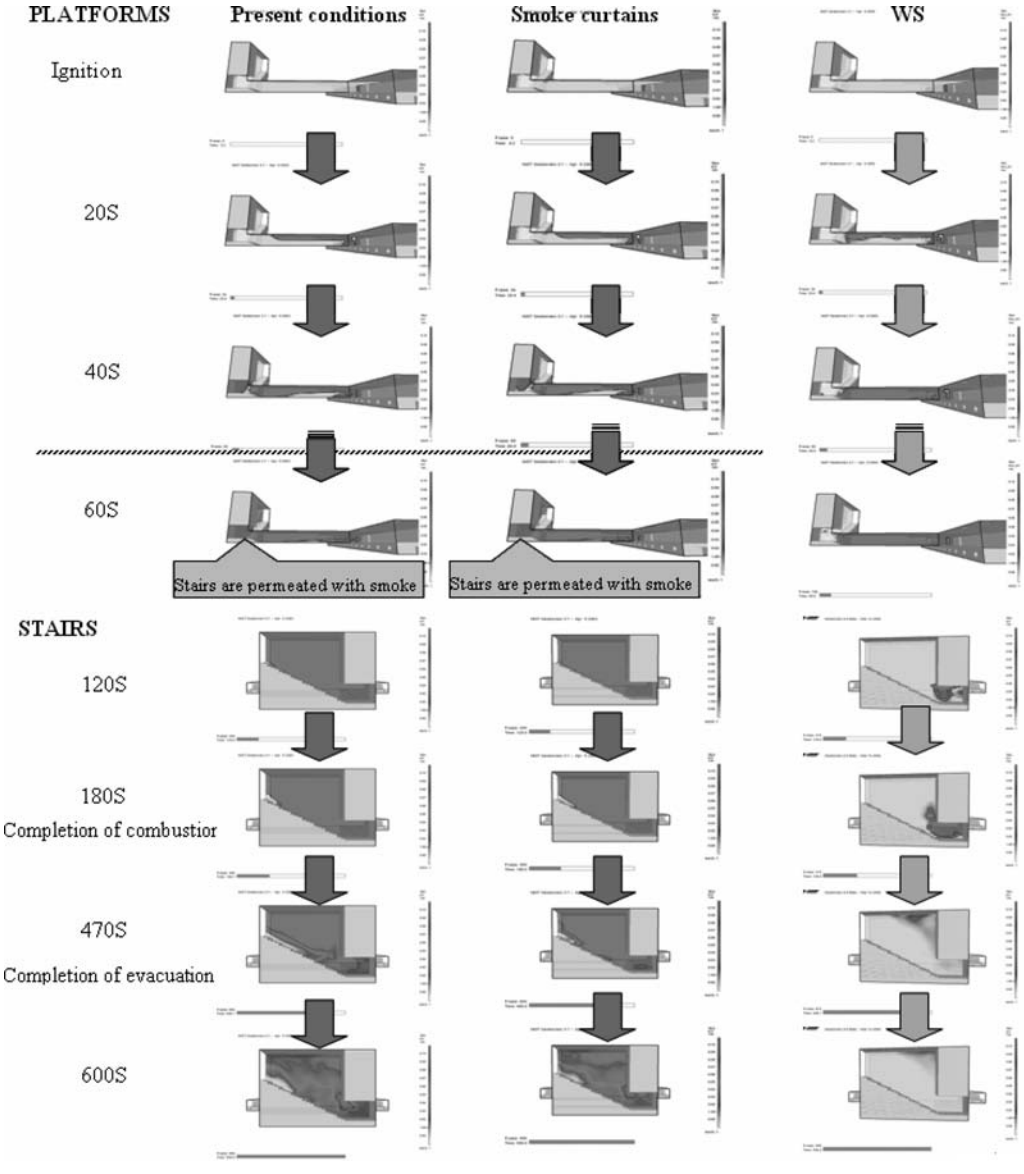


Figure 4-1. (a) The layout of the subway station. (b) Stairs. (c) Emergency facilities (Smoke extraction). (d) Emergency facilities (Smoke spread prevention).

over the smoke curtains in a shaft. Outflow conditions of smoke are not so different from the present conditions. It can not truly be said that smoke extraction equipment functions effectively in the case of explosive combustion immediately after the outbreak of a fire caused by a large fire source.

Road tunnel equipment

M. Novák, V. Misárek & D. Benda
Metroprojekt Praha, Prague, The Czech Republic

ABSTRACT: The article deals with equipment which is installed in road tunnels. The development of new motorways, expressways and the Prague City Ring Road cannot cope without construction of road tunnels. Road/motorway tunnels pose an increased risk for drivers, primarily in the case of a fire due to an accident in the tunnel. Road tunnel equipment improves operational safety and reduces potential consequences of accidents to a minimum. The designing of tunnel equipment in the Czech Republic is controlled by TS 98 Technical Specifications: Road Tunnel Equipment, which was issued after a revision in 2004. The other regulation with which tunnel equipment must comply is the EU 2004/54/EC Directive of the European Parliament and of the Council on minimum safety requirements for tunnels in the Trans – European road network. The structural design and requirements for safety equipment of road tunnels are solved in ČSN 73 7507 standard: Design of Road Tunnels (reissued in 2005). The requirements for safety equipment of road tunnels were incorporated into the design of new tunnels on the D8 motorway, namely the Panenská tunnel and the Libouchec tunnel, which were opened to traffic at the end of 2006.

1 INTRODUCTION

A design of a road/motorway tunnel must solve the equipment which provides for uninterrupted and safe traffic in the tunnel. In addition, the equipment significantly reduces the risk for drivers in the case of an accident and a fire in the tunnel, and makes safe escape of passengers from the tunnel to the surface possible. Designers working in the Czech Republic must conform mainly to the following fundamental regulations:

TS 98 Technical Specifications: Road Tunnel Equipment (revision 2004)

EU 2004/54/EC on minimum safety requirements for tunnels in the Trans – European road network (2004 issue)

ČSN 73 7507 standard: Design of Road Tunnels (reissued in 2005).

A total of four tunnels have been designed for the D8 motorway leading to neighbouring Germany via northern regions of the Czech Republic: the 2115 m-long Panenská tunnel and the 535 m-long Libouchec tunnel in the motorway section between Trmice and the border with Germany; the 620 m-long Radejčín tunnel and the 270 m-long Prackovice tunnel in the section between Lovosice and Řehlovice. The Panenská and Libouchec tunnel were opened to traffic at the end of 2006. The Lovosice – Řehlovice motorway section containing the Radejčín and Prackovice tunnels found in the České Středohoří highland are under preparation; the completion is planned for 2009–2010.

2 EQUIPMENT OF THE PANENSKÁ TUNNEL ON THE D8 MOTORWAY

The 2115 m-long Panenská tunnel on the D8 motorway section between Trmice and the border with Germany is currently the longest motorway tunnel ever brought into service in the Czech Republic. It is a twin-tube tunnel with two traffic lanes in each tube. The western tunnel tube is on a 3.22 per cent longitudinal gradient; the eastern tube is on a 3.28 per cent gradient. The traffic flow is anticipated at 12,500 vehicles per 24 hours per one tunnel tube; of that, 15 per cent is made up by lorries. The maximum speed allowed in the tunnel is 80 km/h; the average tunnel altitude is 590 m a.s.l.

The tunnel tubes are interconnected by ten cross passages, escape routes for passengers, every 200 m. The cross-passages No. 3 and 7 in addition allow the passage of small emergency vehicles, and the cross-passage No. 5 is passable for big vehicles of rescue units. Eight cross passages house small distribution substations for electrical equipment installed in the tunnel. The substations are fire separated from the respective escape routes.

2.1 *Tunnel ventilation*

A longitudinal ventilation system has been designed for the uni-directional tunnel tubes, with jet fans installed under the tunnel vault. The designed longitudinal ventilation, which is operated in the direction of the traffic, guarantees that the required limits

Table 1. Typical values of limits for noxious substances set for various traffic states.

Traffic state	CO-concentration [ppm] y. 2000	CO-concentration [ppm] y. 2010	Opacity Coefficient K $[10^{-3} . m^{-1}]$
Fluent peak traffic v = 50–100 km.h	100	70	5
Daily congestion, Stop and Go	100	70	5
Exceptional congestion	150	100	7
Longer maintenance work under traffic	30	30	3
Tunnel closure	250	200	12

of concentration of noxious substances produced by vehicles will be met. The limits have been set for Carbon Monoxide (CO), Nitric Oxide (NO_x) and opacity in the tunnel. The allowable concentrations of the noxious substances, which have been set on the basis of the Technical Specifications TS 98, are contained in the above table.

The recommended nitric oxygen maximum allowable concentration value is 20 $mg.m^{-3}$.

It follows from results of calculations that, at normal traffic volume and the speed of vehicles ranging from 30 km/h to 80 km/h, both tunnel tubes are sufficiently ventilated by the piston effect of vehicles passing through the tunnel. The jet fans installed under the tunnel crown are step-by-step started up in the case of traffic congestion in the tunnel or extraordinary climatic conditions (weather inversion, fog, windstorm etc.), depending on the situation, on the basis of the data provided by CO and opacity sensors, measurement of velocity and direction of airflow in the tunnel. When traffic in the tunnel is stopped, drivers are asked through a message sign to turn the engines off.

The complete ventilation system will be automatically switched on in the relevant tunnel tube in the case of an accident, a fire in one tunnel tube, approximately 6–7 minutes after the fire initiation. During this time the smoke is kept by the heat under the tunnel crown and an about 2.5 m high zone above the roadway remains free of smoke (under the condition that the longitudinal velocity of the airflow in the tunnel is less than 2 m/s). The fans are run in the direction of traffic so that escape of passengers found before the accident scene in the tunnel is possible. The fans are switched on stepwise, from the exit portal toward the entrance portal. Fresh air flows counter the direction of escape of passengers. Passengers found ahead of the fire can get out of the tunnel in their vehicles. The ventilation system in the other tunnel tube which is not affected by the fire is run in the reverse direction so that the airflow direction is identical with that in the tunnel tube with the burning vehicle. A total of four fans are switched on at the front end of the tunnel (viewed in the airflow direction – the reverse direction) and run in the reverse direction, whereas two fans on the opposite end of the tunnel are run counter the airflow (the main direction); thus the fans create positive pressure in the tunnel tube, which prevents drawing of the smoke which blows from the portal of the incident tunnel. The ventilation of the cross passages is also switched on, in the respective direction. The purpose of the ventilation is to allow passengers to escape to a smoke-free space via the cross passages or through the portal to the open air. The jet fans are capable of providing longitudinal airflow at the minimum velocity of 3 m/s even if as many as four fans fail to work.

Figure 1. Jet fans under the Panenská tunnel crown.

The fire ventilation is designed according to TS 98, to a norm fire size of 30 MW; the fans must keep operating at a temperature of 400°C for 90 minutes.

According to the design, the western (descending) tunnel tube will contain seven pairs of jet fans (14 pieces in total). Six pairs of jet fans are designed for the eastern (ascending) tunnel tube (12 in total). Parameters of one jet fan:

A high-pressure axial-flow fan, size 1000, with silencers, reversible, suited for temperatures until 400°C/90 min. The thrust produced by the fan in the main/reverse direction is 875 N; a 30 kW/400 V electric motor.

The ventilation system will be controlled from the tunnel control centre and locally, from respective switchboards.

2.2 *Tunnel lighting*

2.2.1 *Adaptation lighting of the tunnel*

The adaptation lighting of the tunnel is designed to illuminate the threshold and transition zones in the entrance section of the tunnel at a luminance level corresponding to the ability of driver's eye to adapt. In the tunnel entrance section, it consists of two rows of counter-beam asymmetric discharge lamps installed

below the ceiling of the respective tunnel tube. The rows of the luminaries are installed above the centre lines of both traffic lanes. The adaptation lighting is divided into zones; it corresponds to the maximum speed limit set for the tunnel at 80 km/h. The adaptation lighting is fed partly from an uninterruptible power source and partly from a source without a backup.

2.2.2 *Stand-by lighting of the tunnel*
Stand-by lighting of the tunnel is activated during extraordinary operating states, for example in case of a failure of normal power supply. The stand-by lighting consists of selected sections of luminaries of the adaptation lighting, which are fed from the uninterruptible power source. In the case of a failure of the normal power supply, the stand-by lighting keeps working; the maximum operating speed is reduced to a maximum speed limit of 60 km/h.

2.2.3 *Interior tunnel lighting*
The interior tunnel lighting is designed for the illumination of the internal part of the tunnel; it consists of one row of double-source symmetric discharge lamps installed below the ceiling, on the centre line of the respective tunnel tube. The lights are fed from an uninterruptible power source.

2.2.4 *Emergency lighting of the tunnel*
The emergency lighting of the tunnel is designed to illuminate escape routes in the case of a fire in the tunnel. The emergency lighting consists of LED-type luminaries with a source, which are embedded in recesses provided in the lining. With a view to the possible smoke logging of the upper space of the tunnel, the luminaries are installed at a height of 90 cm above the walkways. The luminaries are installed at 12 m spacing. The intensity and variation range of the emergency lighting must meet the values prescribed. The emergency lighting is fed from an off-line backup source.

2.3 *Electrical installations – the heavy current distribution system*

2.3.1 *Distribution substations, 22 kV*
The 22 kV distribution substations are divided into an inlet part with a separate entry for SČE (the power supplier), and an outlet part with a separate entry for the ŘSD (the tunnel operator). The inlet part of the substation in the Operating and Technical Services Building (OTSB) South will be built as a part of the tunnel construction. The inlet part of the substation in the OTSB North will be built as a part of a separate subsequent structure. The substations have been designed in the metal-clad version, with SF6 insulation. The inlet part of the substation in the OTSB South consists of three cabinets with disconnecting switches. The inlet part of the substation in the OTSB North consists of four cabinets with disconnecting switches. The outlet parts in both OTSBs consist of three cabinets (cabinet 1 – measurement (air space insulation); cabinets 2 and 3 – outlets to transformers with motor-actuated disconnecters and trip coils and fuses. Cabinet 2 contains, in addition, a capacitance voltage sensor with a remote signalling transducer. The inlet parts have been designed in a way allowing the use of T-connectors for cable connections; they are equipped with surge voltage protectors.

2.3.2 *Transformers*
Each OTSB will contain two 1000 kVa transformers; each transformer will be installed in a separate cell. The transformers are of the oil-cooled, air-tight type. Part of the supply of the transformers will be index pointer thermometers with contact outlets: temperature lower – warning, temperature lower – shutting down.

2.3.3 *Measurement of power consumption*
Each OTSB will have an independent commercial measurement system. Universal measuring boxes will be installed in the inlet part of each 22 kV distribution substation. The ratio of the current measurement transformers in the consumer's (ŘSD) outlet parts of the 22 kV substations corresponds to the agreed technical maximum, i.e. 25/5A.

2.4 *The traffic and equipment management system*

The management system controls traffic in the tunnel in relationship with an external motorway information system. It consists of switchboards fitted with programmable logic controllers, input and output circuits, and a link to the management and stand-by control centre. The stand-by control centre is located in the portal building, and the management centre, which is common for the Libouchec tunnel and Panenská tunnel, is in the SSÚD Řehlovice.

2.5 *The fire alarm and detection system*

The fire alarm and detection system (FADS) comprises FADS switchboards located in the portal buildings, fire sensors, manual call points and a linear heat detection system including cable connection. The FADS switchboards are connected to the management system and, via a direct communication line, to the fire rescue management centre and the other elements of the Integrated Rescue System. The following equipment will be controlled on the basis of the assessment of the FADS signals:

– emergency lighting
– fire ventilation
– traffic signs
– CCTV camera system

Figure 2. An SOS cabin in the Panenská tunnel.

– public address
– wireless communication

2.6 *Emergency announcement system*

SOS cabins are provided at maximum intervals of 150 m. The fundamental requirement for the SOS system is that nonverbal announcing of an emergency must be possible by pressing a relevant button (medical aid, Police, fire, defective vehicle). In addition, verbal communication with the police controller is possible. First aid tools and means (rescue tools, fire extinguishers and a first aid kit) are stored in SOS niches.

2.7 *The closed circuit TV camera system*

The video surveillance is solved by means of an independent closed circuit TV camera system (CCTV), which allows the police and technical-administrative controllers to visually check traffic in the tunnel. In addition, the CCTV system allows automatic video detection of specific traffic states. The CCTV control centre including the automatic video detection switchboard are located in the portal building, and are interconnected with the tunnel management system. The locations of the cameras guarantee that the entire tunnel is monitored, with a special focus on the SOS cabins and their neighbourhood, entrances to the escape galleries and their interior. The video surveillance is used by the traffic operators to check the traffic in the tunnel, and allows them to timely respond to an emergency situation in the tunnel or in front of tunnel portals. The automatic video detection system further improves effectiveness of the performance of traffic controllers and, in the case of an exceptional failure of the human factor, provides an automatic response to the emergency state detected in the tunnel, including a vehicle fire. This system is currently the fastest to detect crisis situations originating in the tunnel. Part of the CCTV system is the recording of the video signal provided by the cameras.

2.8 *Wireless communication*

The wireless communication system spreads radio signal inside the tunnel for selected users, as for example:

– the SSÚD
– the Fire Rescue Service
– Ambulance
– the Police of the Czech Republic
– mobile operators' services (an independent investment project organised by mobile operators)
– local FM radio providing traffic information broadcasting and the RDS.

2.9 *Public address*

In the case of emergency in the tunnel, drivers can be informed through the Public Address system. In principle, it is a low frequency signal distribution between the switchboard and loudspeakers installed in the tunnel and escape galleries. The public address system makes an entry of controllers possible, according to the allotted priorities (the Police, a traffic controller, the person in charge of a rescue intervention).

2.10 *Telephone for controllers*

The system of telephones for controllers is installed to make co-ordination and communication between the tunnel maintenance and operation control system components possible. The telephones are installed in all technical services rooms existing in the tunnel.

2.11 *Traffic lights and signs*

Traffic in the Panenská tunnel is controlled by means of variable traffic signs. The signs are used for the control of traffic in individual traffic lanes. The entry to the tunnel is closed by means of double-chamber light signs. The variable traffic signs are controlled by command signals from the tunnel traffic control room on the basis of control algorithms.

2.12 *Road signalling system*

The road signalling system must be understood as a complex consisting of fixed and variable traffic signs, including traffic lights, both in the tunnel and on the adjacent road sections (usually the intercrossing sections).

There are four gantry structures carrying variable traffic signs before each tunnel entrance, which make gradual reduction of speed of vehicles possible, to the speed at which the vehicles can be stopped by a red light. The gantries are further used for informing drivers about emergency situations in the tunnel.

2.13 *Vehicle height checking*

The height of vehicles is measured on carriageways of the motorway, at a distance from the tunnel portal

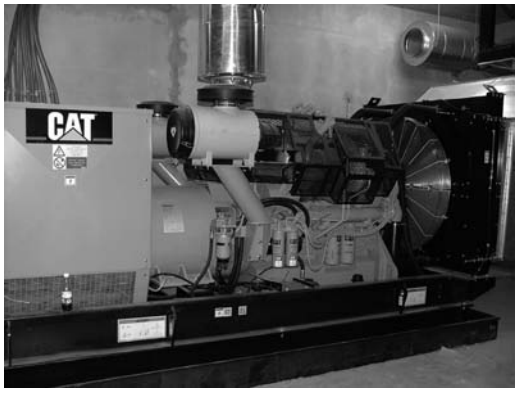

Figure 3. A 900 kVA diesel generating set – the stand-by power source in the northern portal building at the Panenská tunnel.

sufficient for stopping an oversize vehicle. The dimensions are checked by a detector based on the principle of and infrared barrier combined with an inductive traffic loop detector. The signal is transmitted from the infrared barrier to processor stations through the control system, which actuates the variable traffic signs in front of the tunnel. At the same time, the control system sends a message to the traffic control centre.

2.14 *The stand-by power source*

The supply of power for selected items of equipment in case of a failure of power supply from the public network is provided by rotary stand-by sources (SBS), i.e. diesel generating sets. The appliances for which the uninterrupted operation is required are backed also by rotary UPSs (RUPSs).

The sets of stand-by power sources, including the RUPSs, are installed in a common machine room, in the respective Operating and Technical Services Building (OTSB) at both portals. The OTSB North houses a 900 kVA SBS + a 250 kVA RUPS. The OTSB South houses a 750 kVA SBS + a 250 kVA RUPS. The sets are in the version comprising a frame, with elastic support of the motor and the generating set. The SBSs will be switched on automatically at a power failure, or on a command from the control room. The operation of the diesel generating set is interconnected with the RUPS, which guarantees uninterrupted operation of selected items of equipment and, in addition, aids the starting system of the diesel generating set, thus enhances reliability of the equipment.

3 CONCLUSION

The Panenská tunnel equipment guarantees a maximum possible level of the required safety of traffic and safety in the case of an accident and a fire in the tunnel. Early detection of an emergency situation, a fire etc. gives passengers a good chance of escaping to protected spaces and out of the tunnel. Early intervention of the elements of the integrated rescue system will not only protect the health of passengers, but it also will diminish a contingent damage to tunnel structures and equipment.

Site ventilation of a long deep tunnel: The lot Bodio of the Gotthard base tunnel

M. Oberaigner
Lombardi Engineering Limited, Minusio, Switzerland

F. Romerio
Consorzio Tunnel AlpTransit – Ticino, Bodio, Switzerland

ABSTRACT: In the future several very long tunnels with a high overburden are going to be built in Europe and all around the world. These structures mostly consist of two parallel running tunnels plus cross passages at regular distances. Generally all of these constructions are divided into several lots and consist of a combination of TBM or shield drives together with NATM drives. The automated drives tend to achieve 10,000 meters in length and beyond, cross passages or other special cross sections are usually carried out by NATM.

Thus they comprise a huge challenge regarding the supply of fresh air. Fumes of the drill-and-blast-sections, exhaust gases, any dust created through excavating or mucking, etc. have to be extracted and fresh air has to be brought up to the TBMs heads. Due to the extreme lengths and the need to simultaneously casting the inner lining the application of flexible ventilation ducts to carry the fresh air from the exterior to the tunnel head is almost impossible. Therefore a recirculation ventilation system is established during construction.

1 INTRODUCTION

1.1 *Short review of tunneling in the Alps*

The construction of tunnels with lengths of 10,000 m and beyond have a long tradition in the European Alpine countries. The first of these was the Mont-Cenis-Railway-Tunnel (also-called Fréjus-Tunnel) under the Franco Italian border between Modane and Bardonecchia in the Western Alps. Construction period of this originally 12,233 m long tunnel last from 1857 through 1871. The estimated construction time of some 25 years could be cut to around half by the introduction of pneumatic drill-hammers.

Based on the innovations made on the Mont-Cenis-Railway-Tunnel the Swiss Confederation decided to build the 14,982 m long Gotthard-Railway tunnel from 1871 through 1881. Ventilation was accomplished through the compressed-air ducts. After blasting the fumes of the explosives were cleared away by the air supplied by these ducts.

1.2 *The simplon tunnel*

After the completion of the Gotthard-Railway tunnel the Swiss decided for another railway line further west, connecting Brig in the Vallais canton in Switzerland and Iselle di Trasquera in the Italian Piemont region. For military reasons an alignment with the national border exactly in its half was chosen. This alignment led to a length of tunnel of almost 20,000 m, thus being one of the longest tunnels in the world until the late 1970s. An overburden of up to more than 2000 m at the highest summits, drive lengths of some 10,000 m and rock temperature of up to 42°C presented new challenges to the engineers.

For ventilation purposes two parallel tunnels were driven for the first time in history. While the eastern tunnel was excavated to its final cross-section, the western parallel drive was redimensioned to a small adit of some 2.5 m in diameter, which generally did not dispose of any inner lining. These two tubes were linked by cross passages at regular distances of 200 m. Fresh air for the main drive, the supply with pressurized water as well as the draining of seepage water happened through the parallel-adit, while the main drive was used for mucking.

This very advanced concept of having two parallel drives – one of which brings the fresh air to the tunnel head, the other evacuating the used air – is also applied for the long drives of the Gotthard base tunnel.

2 THE GOTTHARD BASE TUNNEL

2.1 *Gotthard base tunnel project overview*

The Gotthard base tunnel of 57 km consists of five sections, with a variable length between 7 km and 16 km. It is a system with two parallel single-track tubes with

an excavated diameter varying from 8.8 m up to 9.5 m. There is no parallel safety gallery, but 180 cross passages, with some 300 m of distance between one and another, link the two tubes. Considering all accessory works like access tunnels, shafts, multifunctional stations and by-passes, the whole length of excavation totals 153 km. Almost two thirds of it have been achieved by August 2006.

To shorten construction time and for ventilation purposes, the tunnel is driven from several sites simultaneously. Excavation in the five sections takes place from the two portals as well as from three intermediate attacks.

2.2 *The Bodio section*

The Bodio section is the very southernmost lot and consists of an open cut section, an excavated section under a rock-fall mass at the portal and the drill-and-blast section until the assembly-caverns, which was driven from an by-pass adit. This by-pass adit joins the main tunnel at a so-called crossing-cavern and was driven in order to evade the rock-fall mass situated at the portal zone of the tunnels' alignment, thus allowing an earlier start of the assembly works an launching of the TBMs. This latter TBM-section is the so-called main-lot.

This main-lot comprises the construction of the two running-tunnels starting at the assembly-caverns of the open TBMs some one and a half and two and a half km from the tunnel portal for the western and the eastern tube respectively. The eastern drive reaches a chainage of 15.97 km, the western one has its break-through point at 15.70 km from the portal. Furthermore a total of 50 cross passages have to be constructed.

The inner lining is cast some way behind the TBMs at the so-called "worm" installations on either drive of the tunnel. This installations are some 600 m long and encompass the revision of the excavated cross-section, laying of the seepage water drainage pipes and impermeability sheet, casting and curing of the vault concrete and all the necessary auxiliary equipment.

2.3 *Ventilation of the main lot in the Bodio section*

The SUVA (Swiss Accident Insurance Fund) defines clear rules for underground work in a hot and humid climate. The air temperature in and around the main working places must never exceed 28°C dry temperature (given 100% air humidity). In this way, acute heat affected diseases during an 8-hour shift of hard underground work can be avoided.

The site ventilation system ensures that maximum working point concentrations are retained by replacement of the used air and dilution of the toxic substances produced underground – although not air conditioning as such. The cooling function produced by the construction ventilation system does, however, represent a welcome side effect.

A recirculation system is set up in the Bodio section to provide fresh air for the parallel tunnel drives and the cross passage drive. For all work sites a total of 120 m^3/s of fresh air has been determined.

2.4 *Function of the recirculation system*

The tunnel's mouths are situated at some 30 m one from each other. The west portal is hermetically closed with a sliding door in it to allow passage to the train traffic. Two fans extract the air from the western tube and create a depression in the full section of the this tube, sucking the air from the interior of the tunnel. In order to avoid recirculation at the portals the fresh air is blown until the crossing-cavern through the by-pass adit, having its mouth some 200 m from the main portals.

From the crossing-cavern the air flows into the eastern tunnel in its full section, passing by the worm east, where the final lining of the eastern drive is cast.

Past the worm east the air passes on to the ventilators situated at the cross-passage QSx-3 (Figure 1), thus supplying the to TBMs with fresh air by means of flexible ventilation ducts. 45 m^3/s are delivered to each TBM, the remainder of the 120 m^3/s continue to the ventilator at the cross-passage QSx-2. This ventilator the blows the rest of the fresh air straight into the western tube, thus diluting the used air of the TBMs passing at this position an going further on to the worm west, where the inner lining of the western tube is cast.

The ventilator at the cross-passage QSx-1 evacuates the used air returning from the TBM-East to the western tube, where it joins the used air from the TBM-West. The exhaust air from the TBM-East jointly clears the fumes of the drill-and-blast drive at QSx.

These ventilators at the last cross passages care for a depression in the eastern tube, thus helping to suck in the fresh air from the outside of the eastern tunnel, and create an over-pressure in the western tube, pushing the waste air towards the ventilators at the portal of the western tube. These two ventilators help to strengthening the system and maintain it more reliable.

To granting the full flow of air to the deepest of the tunnel and obstructing ventilation short circuits all the cross passages have to be equipped with hermetically

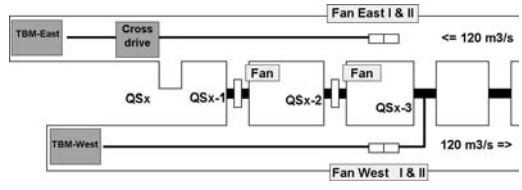

Figure 1. Overview sketch of the ventilators in the cross passages at the deepest of the tunnels.

leak-proof locks with a door in it, allowing staff to cross from one tube to the other when necessary.

2.5 *Work in progress*

Steady advance of the different work sites creates the necessity of disassembling and substituting these locks.

The first type of lock is mounted on the eastern side-wall of the western tube, right after the break-through of the new cross passage QSx. Once the invert of this cross-passage is finished a steel lock is mounted in the center of it. This lock later allows the attachment of the ventilators providing for the flow of air from the eastern to the western tube at QSx-1 and QSx-2.

After completion of a further cross passage these ventilators have to be advanced to the next cross passage. Thus this they give way for the worm west to proceed.

The western mouth of the cross passages is cast at the worm west, which is some three cross passages ahead of the worm east. Given an advance rate of some 500 m per month, casting of a mouth of a cross passage takes place every 20 days. The impermeability sheet and the seepage water drainage pipes have to be laid in the cross passage.

Therefore the lock in the center of a cross passage has to be dismantled and the cross passage is sealed with a different type of lock on the western side-wall of the eastern tube. When the shutter is needed the lock is placed aside, the shutter for the mouth is inserted from the eastern side of the cross passage and the lock is set back in place.

When the shutter is needed for casting the mouth of the next cross passage the lock has to be moved aside again. The shutter is moved to the eastern tunnel, loaded onto a train and transported to the next cross passage, where the before mentioned procedure is repeated. The lock at the cross passage the shutter stood before is closed with an again different type of lock on the eastern side of the cross passage adit.

By the time the worm east is ready to cast the mouth of that same cross passage the shutter is moved in form the western tube. A lock on the western edge of the cross passage is mounted, the lock on the eastern side is dismantled and the shutter is pulled in place through the cross passage.

When the shutter is needed for casting the mouth of the next cross passage the lock on the western side is dismantled, the shutter is loaded onto a train on the western tube and transported to the next cross passage, where the before mentioned procedure is repeated. The lock on the eastern edge of the cross passage is reestablished and the inner lining of the cross passages is cast at a later stage of work.

These locks will be only removed when the two final lock-wall will be cast on each side in a later work stage.

3 CONCLUSIONS

Maintaining the recirculation ventilation system functioning – assuring that all the work sites may advance in its pace – is a complex task, however it is inevitable to ensuring that the limits for the maximum working point concentrations are observed.

In the current project the depicted procedures guaranteed to keeping concentrations to the lowest possible and warranted good working conditions for all the staff involved.

Ventilation of cross-passages in long rail tunnels: Requirements and possible solutions with a passive or an active ventilation system for the Gotthard Base Tunnel

D. Portmann, P. Reinke, B. Hagenah & A. Busslinger
HBI Haerter Ltd., Consulting Engineers, Berne, Switzerland

ABSTRACT: The Gotthard Base Tunnel will be a main part of the new railway links crossing through the Swiss Alps. It will have a length of 57 km. A total of 180 cross-passages will connect the two single-track tubes. The cross-passages provide escape routes in case of emergency to the parallel tube and they house technical equipment for the operation of the train traffic. Due to the heat release of this equipment and the high rock temperatures, the cross-passages need to be ventilated. A passive ventilation system ("pitot-tubes") and an active ventilation system are described within this paper. Both concepts may provide an adequate cross-passage climate. In the specific case of the Gotthard Base Tunnel, the active ventilation is to prefer because of the demanding reliability and availability requirements and the challenging climatic conditions. However, the passive system was found to be suitable for many cross-passages with the advantage of low maintenance, low failure risk and low operation costs.

1 INTRODUCTION

1.1 *General*

The Gotthard Base Tunnel (GBT) forms a major element of the new Swiss alpine rail tunnels. It consists of 2 single track tunnels of 57 km each which are connected with accessible cross-passages (CPs) approximately every 330 m. In addition, the base tunnel system includes 2 multifunctional stations (MFS) with 2 crossovers and 2 emergency train stations each, see Figure 1.

Three different modes of operation must be distinguished for the GBT:

- normal operation
- maintenance operation
- emergency operation

During normal operation, the trains run from north to south in the eastern tube and from south to north in the western tube. The tunnel ventilation system is not in operation, since the train-induced airflow is sufficient to provide an adequate tunnel climate. The air-exchange of the CPs must be considered separately. Since the CPs accommodate equipment with considerable technical heat release (up to 7 kW per CP) and the initial rock temperatures reach up to 50°C, specific ventilation measures have to be provided.

Maintenance operation in the GBT takes place during the night time in one tube while in the other tube trains run alternately from south to north or from north to south. The tunnel ventilation system will provide fresh air for the maintenance teams. The ventilation of the CPs is needed during this phase.

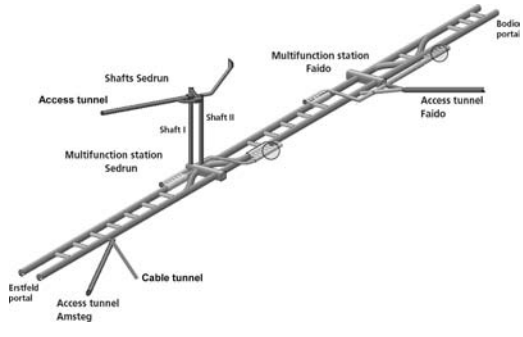

Figure 1. System overview of the Gotthard Base Tunnel.

In the case of an emergency in the tunnel, the incident train is supposed to leave the tunnel or to stop at a MFS. The tunnel ventilation system will provide smoke-free areas for escaping passengers along the rescue paths in the MFS. In the unlikely event of a train stopping in the tunnel but outside a MFS, the tunnel ventilation system will provide an overpressure in the non-incident tube. This results in a smoke-free non-incident tube, even if escaping passengers open the CP doors. During an emergency the CPs that are not opened by passengers must be ventilated to protect the equipment enabling the evacuation of the passengers.

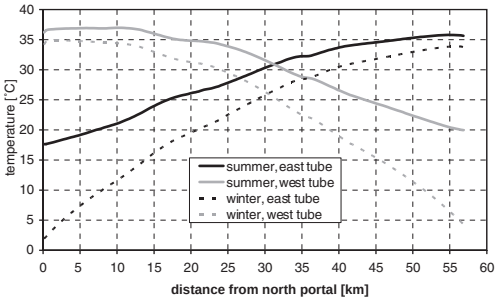

Figure 2. Expected tunnel temperature in the GBT from Busslinger et al.

Table 1. Classification of warmer and cooler tunnel sections.

Tunnel	North portal – km 30	km 30 – south portal
East	Cool	Warm
West	Warm	Cool

1.2 *Tunnel climate*

In order to ensure the proper operation of the base tunnel, an acceptable tunnel climate must be maintained. If the tunnel air is too warm or too humid, technical installations may fail or their lifetime will be reduced. Additionally, maintenance teams shall meet acceptable working conditions.

The expected temperatures along the base tunnel are shown in Figure 2. The temperature will rise from the entrance portals to the exit portals.

Figure 2 allows a classification of the tunnel into warmer and cooler sections. These are shown in Table 1.

While the climate in the train tunnels is mostly relevant for passenger comfort (air-condition systems on board depend on the outside temperature) and the maintenance teams the CP climate is crucial to the reliability, since they include most of the technical equipment. Additionally, the CP climate must fulfill requirements for maintenance teams. Tunnel and CP climate are strongly connected to each other because the fresh-air supply of the CPs will be provided from the tunnels.

1.3 *Cross-passage ventilation*

The CPs are located approximately every 330 m and are connecting the two single-track tubes. Their length is about 40 m, the free cross-sectional area is about 11 m^2. Each end of a CP is equipped with a door that separates the CP from the adjacent tube. For maintenance reasons or during an emergency the doors may be opened.

The CPs have two purposes:

- The main purpose is to provide evacuation paths in case of an incident with stop of the incident train in the tunnel but outside a MFS
- house technical equipment important for the operation of the tunnel

The technical installation in the CPs consists of:

- transformers
- telecommunication equipment (fix, mobile)
- traction current supply
- 50 Hz power supply

This equipment may emit during peak-times waste heat of up to 7 kW per CP.

2 OBJECTIVES OF CROSS-PASSAGE VENTILATION

To provide a safe, reliable and economic tunnel system, basic climate requirements must be fulfilled in the CPs. In the following sub-chapters the ventilation objectives of the CPs are stated for the different modes of operation.

2.1 *Normal operation*

The ventilation objectives for normal operation in the CPs of the GBT are as follows:

- temperatures shall not exceed 35°C
- relative humidity shall not exceed 70%

An exception of this rule is given for the CPs in the vicinity of the portals where meteorological conditions dominate and can not be controlled.

2.2 *Maintenance*

During maintenance the climatic conditions in the tunnel system including CPs have to meet the regulations of the Swiss Accident Insurance Fund (SUVA), i.e.:

- The maximum temperature shall not exceed 28°C (preliminary requirement which, possibly, will be changed to 28°C WBGT-temperature in the future).

Furthermore, the maintenance teams in the CPs must not experience severe pressure changes generated by trains travelling in the non-maintenance tube:

- The maximum pressure fluctuation during a 4 s-time period shall not exceed 1.5 kPa.

2.3 *Emergency*

During an emergency, most of the CP equipment is supposed to work reliably enabling the trains in the tunnel to leave the system and, at a later stage, allow

the entrance of an evacuation train. This results in the following requirement:

– The temperatures in the CPs shall not exceed 40°C for at least 90 min after the beginning of an emergency.

Furthermore, if CP doors are opened by escaping passenger, the following objective shall be met:

– The velocity of air in open CP doors shall inhibit smoke propagation into the non-incident tube (>2 m/s) and allow a safe escape (<11 m/s).

3 POSSIBLE CONCEPTS

3.1 *Basic principles*

To accomplish the objectives as defined above, some basic principles for the CP ventilation of the GBT may be introduced.

During normal and/or maintenance operation the following principle is favourable for the CP climate:

– Both, the fresh air supply and the waste air removal are achieved with the cooler tunnel tube.

One side of the CP is closed (closure to the warmer tube) and an aerodynamic decoupling of the tubes is established. This arrangement reduces non-favourable pressure fluctuations across the CPs and internal re-circulation of waste air. Additionally, it supports the efficiency of the tunnel ventilation system during emergency (less leakage).

During an emergency, another principle is taken into account:

– Air-supply is provided from the non-incident tube (not necessarily the cooler).
– Air removal is directed to the incident tube.

In this case, an air flow from the non-incident tube to the incident tube will result. Thus, the propagation of hot, smoky air into the CP can be prevented, even if a burning train is located just in front of a CP.

In the following sub-chapters, two selected solutions based on these principles will be described.

3.2 *Passive cross-passage ventilation*

The passive CP ventilation is driven by the train traffic. The trains in the GBT travel with speeds of up to 250 km/h and induce during normal operation a mean air velocity of about 7 m/s along the tunnels.

Parts of this air flow are guided into and out of the CP by “pitot-tubes” as shown in Figure 3.

The main principle of this ventilation concept is as follows: Due to the dynamic pressure there is a pressure difference between the tunnel openings of pitot-tube 1 and 2. This pressure difference generates an air-flow through the CP.

The pitot-tubes have a length of 2 m (tube 1) or 40 m (tube 2) and a diameter of 0.4 m. They will be installed

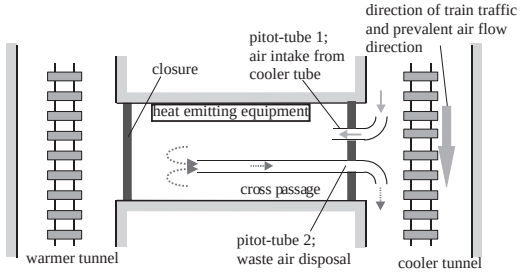

Figure 3. Ventilation of cross-passages with pitot-tubes during normal operation.

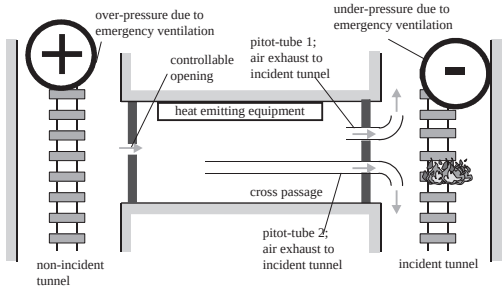

Figure 4. Passive cross-passage ventilation during an emergency in the cooler tunnel.

above the CP door to exclude any constraints for passenger escape (cf. Figure 6). The warm waste air will be guided through the longer tube 2 in the vicinity of the warm ceiling climate of the CP to increase the cooling efficiency. The length of tube 2 provides longitudinal flow of air along the whole CP. The concept allows for both flow directions in the rail tunnel even though the opposite of the presented flow direction leads to a smaller air-exchange.

Figure 3 is typical for normal operation and maintenance (if maintenance is taking place in the warmer tube). Three more modes have to be addressed therefore. These are:

– maintenance in the cooler tunnel
– emergency in the cooler tunnel
– emergency in the warmer tunnel

During maintenance in the cooler tunnel, no train traffic will induce air-flow. However, the maintenance teams have to be supplied with fresh air. In this case, the air will be supplied by the tunnel ventilation system. So, an air-flow will be guaranteed.

Due to the symmetric arrangement of the pitot-tubes on the tunnel side, air will be lead into the CP independently of the flow direction in the rail tunnel.

Figure 4 shows the situation during an emergency in the cooler tube. The tunnel ventilation system generates an over-pressure in the non-incident and an under-pressure in the incident tunnel, mainly to

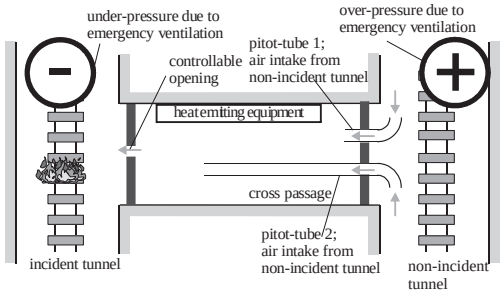

Figure 5. Passive cross-passage ventilation during an emergency in the warmer tunnel.

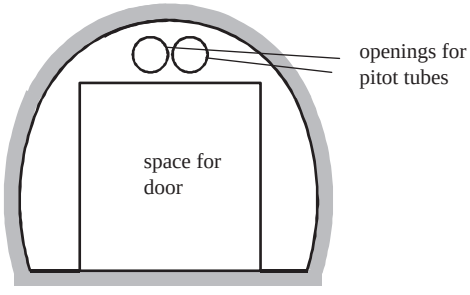

Figure 6. Front view of cross-passage with arrangement of openings for pitot tubes.

provide an air-flow through the opened CPs (by escaping passengers). CPs with closed doors would be endangered to be filled with warm and smoky air via the pitot-tubes, if no further measures would be taken. Dampers in the pitot-tubes might prevent this, but on the other hand, no more cooling air-circulation in the CP would take place. Additionally, they would reduce the ventilation power due to additional flow resistance. As a consequence, overheating and failure of equipment in the CP, especially with a train fire nearby, can be assumed. Therefore, a damper in the wall opposite the wall with the pitot-tubes of the CP must be foreseen. During an emergency, the damper will be opened. The pressure difference between the tunnels will lead to an air-flow through the CP and provide a minimal ventilation to enable the tunnel operation until all the passengers are evacuated.

In the case of an incident in the warmer tunnel as depicted in Figure 5, one could keep the controllable damper closed, since no warm air could enter the CP via the pitot-tubes. For the following reasons it still is advisable to open the damper:

- No decision of the operator concerning opening of the dampers is necessary, independently in which tunnel the incident takes place.
- The CPs are always minimally ventilated.

The installation of the pitot-tubes will preferably be above the CP doors (see Figure 6).

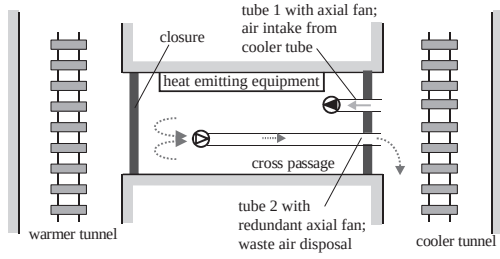

Figure 7. Active cross-passage ventilation during normal operation.

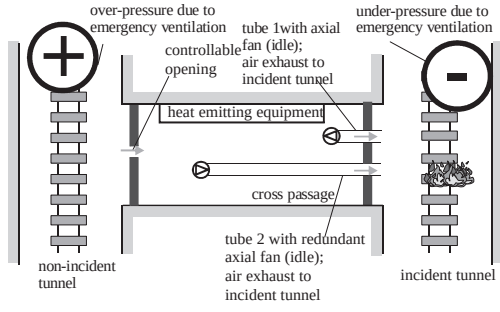

Figure 8. Active cross-passage ventilation during an emergency in the cooler tube.

3.3 *Active cross-passage ventilation*

In contrast to the passive CP ventilation, the active CP ventilation is only sparsely dependent on train traffic in the tunnels. The concept of the active CP ventilation system is shown in Figure 7.

A fan mounted on tube 1 will lead air from the cooler tunnel in the CP. The waste air will be disposed via tube 2 by the idle redundant fan. The situation just described is valid for normal operation and maintenance.

During an emergency, the tunnel ventilation system will create an over-pressure in the non-incident tunnel and an under-pressure in the incident tunnel. The fans in the CPs will be turned off and the above described damper on the opposite side of the CP will be opened. This allows a pressure driven ventilation of the CPs, automatically in the right direction, as shown in Figure 8 and Figure 9.

4 SIMULATION RESULTS

In this chapter, it will be shown that the described concepts are feasible.

4.1 *Passive cross-passage ventilation*

The following parameters determine the air-flow in a passively ventilated CP:

- air velocity in the railway tunnel

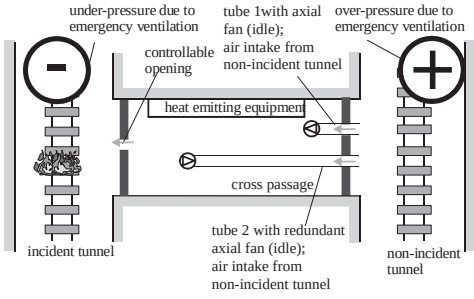

Figure 9. Active cross-passage ventilation during an emergency in the warmer tube.

– diameter of the pitot-tubes, i.e. the flow resistance of the system CP and pitot-tubes
– position of the pitot-tube in the tunnel

Based on aerodynamic predictions for the GBT it is known, that the mean air velocity in the tunnel during normal operation will be about 7 m/s (mean value during normal schedule). The inner diameter of a pitot-tube is supposed to be 450 mm. Measurements carried out in a CP test site have shown, that a volume flow of about 0.4 m^3/s can be achieved with an optimal position of the pitot openings in the tunnel.

To estimate the cooling effect of the passive CPs ventilation, the subsequent parameters need to be known:

– air temperature and humidity of tunnel air
– heat release of CP equipment and rock
– size of CP, i.e. air that has to be replaced and CP surface in contact with the air
– water ingress through CP lining

In Table 2 and Figure 10 the results for the air temperature calculation are listed and depicted, respectively. The initial rock temperature has a major influence on the temperature in the CPs. Furthermore, the expected heat emission by technical equipment is of relevance. For the calculations, a minimal water ingress through the CP lining was assumed.

It is apparent, that as soon as the rock temperature is in the region of 45°C, the passive ventilation system will no longer be effective.

4.2 *Active cross-passage ventilation*

With active CP ventilation the volume flow through a specific CP can be chosen by installing an adequate fan.

In section 4.1 it was shown, that not for all thinkable combinations (rock temperature, heat emission, tunnel air temperature, etc.) the requirements to the CP air temperature can be met. In the Table 3 and Figure 11 is shown, what air volume flow is required to meet the design objectives for the CPs.

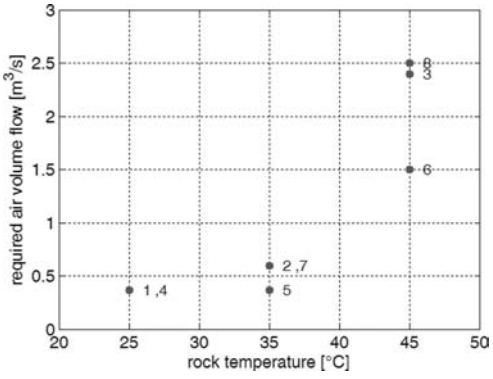

Figure 11. Required air volume flow to keep cross-passage below 35°C.

5 COMPARISON

The passive and the active CP ventilation should be compared on a qualitative level. The following criteria are relevant:

- During normal operation or maintenance:
  - *Climate control*: Low temperatures and low relative humidity shall be achievable in the CPs.
  - *Ingress of dust*: Ingress of dust in the CPs shall be as small as possible.
- During maintenance:
  - *Maintenance availability*: The ventilation of the CP shall also be possible during maintenance.
- During an emergency:
  - *Escape path*: The CPs shall be kept smoke free. Furthermore, no obstacles shall constrict the path of escape.
  - *Robustness*: The CP ventilation elements shall be operable as long as possible.
  - *Operability of CP equipment*: The temperature increase shall be as small as possible.
- Special conditions and general aspects:
  - *Ventilation during special situations*: The effort for the CP ventilation during situations that differ from normal schedule shall be as low as possible.
  - *Reliability and availability of CP ventilation*: The probability of failure or malfunction of the CP ventilation as well as the maintenance effort shall be as small as possible.
  - *Life-cycle cost*: The investment, the maintenance costs as well as the energy input shall be as low as possible.

In Table 4 the passive and the active CP ventilation were compared to each other, whereas "+" means good, "0" means neutral and "−" means poor.

Table 4. Comparison of passive and active cross-passage ventilation.

	Ventilation type	
Criteria	Passive	Active
Climate control	+	+
Ingress of dust	0	+
Ventilation during maintenance	0	+
Escape path	0	+
Robustness	−	−
Operability of CP equipment	+	0
Ventilation during special situations	−	+
Risk of CP ventilation failure	+	−
Life-cycle cost	0	−

Table 4 shows that for the GBT, the active CPs ventilation features more positive aspects. On the other hand, the passive system shows fewer weaknesses.

6 CONCLUSIONS

Depending on the specific boundary conditions of each tunnel, the active, the passive ventilation or a combination of both concepts are thinkable.

In the case of the GBT, a tunnel with high heat loads in the CPs and high rock temperatures, an effective control of the CP climate may not be guaranteed at all locations and at all operating conditions with a passive system. To achieve homogenous CP ventilation in all situations, an active CP ventilation system is required. It allows reliable CP ventilation in all possible operation modes, at the costs of frequent maintenance intervals and a non-optimal cost-benefit ratio.

The passive CP ventilation represents a robust solution, depending on adequate rock temperatures and moderate heat releases in the CPs. It is not suitable for the GBT. In case of uni-directional traffic, i.e. a specific air-flow direction in each tunnel tube, the passive CP ventilation is a feasible and cost-effective solution.

ACKNOWLEDGEMENT

The authors wish to thank AlpTransit Gotthard Ltd for permission to publish this paper. AlpTransit Gotthard Ltd decided for the active CP ventilation in 2004. In December 2006 the tendering for the Lot B1 "CP Ventilation" will be published. For information regarding the current active CP ventilation design contact AlpTransit Gotthard Ltd.

Fire test in the Mrázovka tunnel and its impact on the ventilation control systems in tunnels Mrázovka and Blanka

J. Pořízek, M. Hanfová & L. Šajtar
SATRA, spol. s r.o. Prague, Sokolská, The Czech Republic

ABSTRACT: Risks, which are related with fires in road tunnels, will be always decisive for the choice of technological systems that enable a safe escape from tunnel. The biggest life hazard is the hot toxic smoke that is released during combustion of hydrocarbon fuels and flammable materials. Considering smoke behavior and laws of conservation, then the system of forced ventilation, which exhaust heat and smoke from tunnel, is the most effective method. It is possible to predict the smoke behavior in tunnel of a concrete geometry and location by the appropriate choice of initial and boundary conditions. One of the most effective methods for understanding the smoke behavior and for design of safety measures is the real fire test in tunnel with the using of the hot smoke. On the basis of results of these fire tests it is possible to determine or modify the strategy of ventilation control system. Several tests with cold and hot smoke were realized in the Mrázovka tunnel. The heat release during the combustion of hydrocarbon fuels was always only 5 MW. Different methods of forced smoke exhaust and other safety equipments in the tunnel were examined during fire tests. Fire tests in the Mrázovka tunnel proved the efficiency of the designed system and they have produced new knowledge about the smoke behavior. In the SATRA engineer's company these results are integrated into algorithmic rules of ventilation control systems.

1 INTRODUCTION

Especially in cases of long tunnels there are necessary devices for smoke exhausting. In urban tunnels, there can be increased a number of users during fire so it is necessary to provide smoke exhaust from short tunnels too. Potential sources of fire inside tunnel are vehicles, materials and equipments in tunnel or in technical area.

The most dangerous for tunnel users are fires of vehicles. Fire can arise anywhere in tunnel and for every type of vehicles and loads. Fire characters are very different from case to case. Heat release of real fire is in range from 2 to 200 MW (and sometimes even more).

For determination of temperature resistance of construction it is possible to issue from normative curves showed in figure 1.

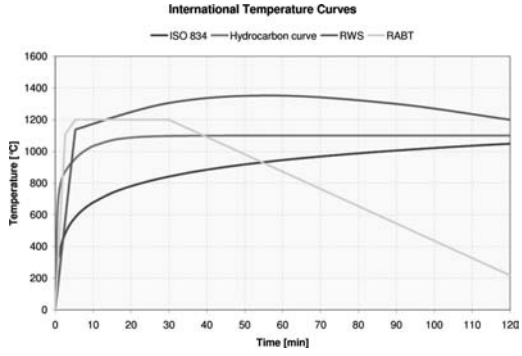

Figure 1. Temperature fire curve.

Normative temperature curve ISO 834 was derived for fire in underground buildings and it can be used for examination of the fire resistance in tunnels.

Hydrocarbon temperature curve is used where can be fire of cistern with petrol, crude or chemicals.

RABT temperature curve was derived in Germany within the bounds of several research plans. This curve corresponds with heavy goods vehicle fire.

RWS temperature curve is based on assumption of the worst fire with heat release 300 MW. The curve is result of many tests executed in the Netherlands in the late seventies of previous century. The RWS curve describes burning in closed area where a chance of smoke and heat spread to outside area is minimized.

The most used characteristic of fires for design of the ventilation systems are showed in table 1. These fires were chosen on purpose, because they include majority of real incidents.

The most important for determining of smoke volume, which is needed to exhaust from road tunnel is a

Table 1. The most frequently design parameters of fires.

Vehicle type	Heat release [MW]	Smoke production [$m^3 \cdot s^{-1}$]
1 Passenger car	5	$\leq$20
2 to 3 Passenger cars	8	$\leq$30
Heavy lorry (bus) without dangerous goods	20–30	60–80
HGV with fuel and oil (petrol tanker)	$\geq$200	>300

fire of heavy goods vehicle that cannot be extinguish by users and whose heat release exceed 20 MW is [7].

If a normative fire has been defined, than it has to be determined the exhausted flow of the air (smoke) from a tunnel during fire. The theme of this article is the fire test in the Mrázovka tunnel and some examples of requirements on determining of volume flow, which has to be forcedly exhausted from tunnel, according to directives of some EU states are shown here. These volume flows were determined for fires of heat release 20 to 30 MW. Documentation published by association PIARC issues from these nationally directives and it shows, that positive exhaust flow rate can set like three-fold of tunnel cross section. By fire with heat release higher than 100 MW it may be until fifth-fold.

Basic indicators for determining capacity of ventilation system are: type and length of tunnel, traffic density and first of all conceptual design of ventilation (longitudinal, transverse, semi-transverse or their combinations).

France
For design capacity of transverse system with eliminated dangerous goods vehicles is assumed fire heat release from 20 to 30 MW. In the case of tunnels with clearance profile over 3.5 m it is taken into account with 80 $m^3 \cdot s^{-1}$ of smoke volume. In the case of concentrated smoke exhaust from tunnel, the minimal volume flow can be determined like volume of produced smoke plus 1.5 multiply of longitudinal velocity in tunnel.

Germany
In ground of solution the minimal exhaust volume is determined like 1.5 multiply of smoke production.

Austria
This directive report that the minimal exhausted volume flow rate during fire must be at least 120 $m^3 \cdot s^{-1}$ over the length 150 m

Czech republic
In this directive, the flow extracted from three-lanes tunnel (cross section 65 m^2) in the case of transversal exhausting is determined to 195 m^3/s through a length,

Figure 2. Stratified smoke layer during fire test in tunnel Bruyères [13].

which is not defined. This value is based on the older Swiss directive [8].

Switzerland
In the directive of 2004, the minimal flow of extracted air has to be counted as three-times of the tunnel cross section. In the case of forced air supply, the flow of supplied air has to be added to this exhausted volume.

Following documents are obligatory in most of cases for the design of technological equipments in road tunnels and their operating in Czech Republic:

- TP98 – Technological equipments of road tunnels: 2004
- TP154 – Operation, management and maintenance of road tunnels
- ČSN 73 7507 – Road tunnels designing
- European Directive 2004/54/EC – minimum safety requirements for tunnels in the trans-European road network.

2 ABOUT THE VENTILATION SYSTEM IN THE MRÁZOVKA TUNNEL:

The smoke extraction in Mrázovka tunnel was designed for the fire of one heavy goods vehicle and for no danger goods vehicles. According to data that were used for the design, the heat power of a heavy goods vehicle fire will be 20–30 MW and flow of smoke will be 60 m^3/s [3]. In that time, requirements on extraction of 80 $m^3/s \cdot km$ for two-lanes section [4] seemed to be insufficient. Opinions on increasing of extraction were different for different theories 110–190 m^3/s.

The system of the transversal smoke exhausting, with slots in ceiling, was designed additionally for the fire in tunnel in the case of congestion. This method consists in prolonging of the time, in which the extracted smoke stays under the ceiling and when users may safely escape the tunnel. This system shall ensure zone of stratificated smoke (see Fig. 2) and thus the efficiency of longitudinal ventilation will be higher.

Transversal fire exhausts in cut and covered sections, which have shorter distance between the ceiling and the road, are other elements of the ventilation system in the Mrázovka tunnel, that increase security of users in the case of fire.

The power for transversal extraction was designed 150 m^3/s through the length 400 m. This value has been verified for specifics conditions in the Mrázovka tunnel on 3D model by means of CFD simulation, where was different traffic densities, different fire locations and different operating modes simulated.

3 THE FIRE TEST IN THE MRÁZOVKA TUNNEL

The aim of the fire test was to verify the designed system of ventilation, fire detection EPS etc. Test was realised in two localities in Eastern tunnel according to the location of smoke outlet and according to the technical equipment in airways for the smoke extraction.

On the basis of the requirement of Prague's firebrigade, which follows from their attitude to the project of the Operating documentation for the Mrázovka tunnel, there had to be the test of smoke extraction completed before putting the tunnel into operation. This test had to be completed with the participation of representatives of Prague's fire brigade. According to realisations of fire test in new or reconstructed tunnels, the attitudes to methods of fire tests are becoming unitary in EU. Examples of these tests are: Mont Blanc tunnel (France-Italy), Platsbush (Austria) and Rennsteig tunnel (Germany). Fire tests of real fires (5 MW) were realised in all these tunnels. The power 5 MW was achieved by lighting up of 20 litres of petrol in containers with the area about 2–4 m^2.

The method of realization of the fire test in the Mrázovka tunnel is based on the results of the project of EU: COST N˚ OC G3.40 "SMOKE SPREAD IN THE CASE OF FIRE IN ROAD TUNNEL", which worked out SATRA company in co-operation with VUT Brno in 1999–2003.

This project was aimed to problems of smoke spread in road tunnels immediately after ignition of fire. Problems were studied by means of Euler-Lagrange model of CFD.

The project of fire test, which came out from results and recommendations of fire tests in tunnels Mont-Blanc, Platsbush and Rennsteig, was modified and filled in after the consultation with KRASO company and Technical Institute of Fire protection, who were participated in fire test.

3.1 *Test preparation*

Fire tests with cold and hot smoke in Mrázovka tunnel were effected in 13. -15.8. In all cases was the fire of passenger car simulated and it correspond to heat

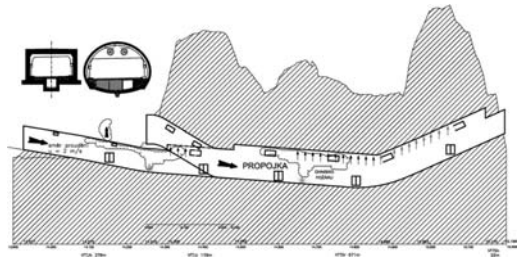

Figure 3. Scheme of fire tests (fire on the left – cut and covered two-lanes section – cross section 56 m^2, fire on the right – driven three-lanes section – cross section 93 m^2).

power about 5MW. For the test were used 40 l of petrol and 10 l of oil for visualisation of the thermal field with the smoke. This mixture was lighted up in the tank with the area about 2 m^2. The container was situated in the axis of cross section at a height 1,5 m under the road.

3.2 *Preventive measures*

The surface of the road round the tank was protected at the distance 2 m on both sides (cca 30 m^2) with panels of insulating material ROCKWOOL, which are made of miner wool. Protection of distribution system (lighting, EPS, antenna, cables) on ceiling was ensured at the distance 25 m on both sides with material of ROCKWOOL with an ALS foil LAROCK 65 ALS at thickness 120 mm.

4 COURSE OF THE FIRE TEST

4.1 *Initial conditions*

Before igniting of the fire the similar conditions to those, which are in the tunnel during the normal operation (average flow velocity 2 m/s and more) were simulated by means of jet fans. The flow velocity was measured by the air flow sensor FLOWSIC 200 (in the three lane section – u_{VTS}, in connected entrance ramp – u_B).

4.2 *Fire test in the three-lanes section*

The seat of the fire for the first test was chosen in the downward part of three-lanes section in the driven tunnel (see fig. 3 – Fire in the right part), before the section with the slope 4,5% in the direction of upward.

This test was effectuated to verify the efficiency of the exhaust slots in the ceiling of the driven tunnel and assurance of the smoke stratification under the ceiling.

Slots are end elements of the channels, which are in the tunnel lining and which joins to the smoke duct under the road (see Fig. 7). It is possible to close every channel with the remote control damper, which is situated at the connection with the smoke duct. The distance of the slots is 20 m. In the case of

Figure 4. *The test with a hot smoke* (driven three-lanes section).

Figure 5. The test with a cold smoke.

fire detection in the section with transversal smoke exhaust, 20 dampers are opened at the length of 400 m and 150 m^3/s of the hot smoke is exhausted.

The test with a hot smoke (see Fig. 4) was repeated more times. Before the ignition of the fire the exhaust ability of slots was several times tested (see Fig. 5). Behaviour of the cold smoke was and will be for every time different from the hot smoke.

The cold smoke starts to fill the whole section and fall towards the road immediately after the ignition, whereas the hot smoke rise up and form a stratificated zone of the smoke "pillow".

The cold smoke was spread in the whole section of the tunnel. Exhaust range of the slots is substantial only in their proximity and thus the cold smoke was not almost exhausted. During this test it could seem, that the system is ineffective. In the case of hot smoke test, the smoke stay under the ceiling and slots exhaust nearly all the smoke.

4.3 *Fire test in the two-lanes section*

The aim of the second fire test was to verify ability of the system to avert the back layering and assurance of the smoke stratification in the downward part. The other aim was to verify functionality of the natural exhaust of the smoke by the flue, which is situated at

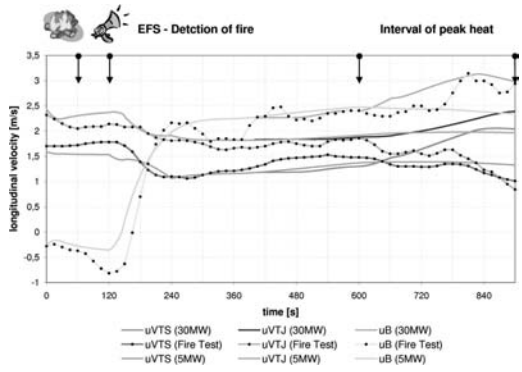

Figure 6. Behaviour of the longitudinal velocity.

the boundary of the driven and cut and covered part. And the last aim was to verify the efficiency of the parallel functioning of transversal smoke exhaust by the slots and control of the longitudinal flow. The seat of the fire was chosen in two-lanes cut and covered section of the Eastern tunnel with the slope −2% (see Fig. 3 – Fire in the left part).

4.4 *The airflow in the tunnel*

On the Fig. 6 is the shape of longitudinal velocity in the three-lanes section during the fire test. The direction and the size of longitudinal velocity are decisive factors for assurance of conditions for the save evacuation of users during the first phase of fire. On the figure is the velocity in the section with a fire (u_VTS) and the velocity in the connected entrance ramp (u_B). On the figure, there are the shapes of measured velocities and shapes of velocities, which were numerically calculated during the simulation of the 5 and 30 MW fires. The shape and the size of the flow velocity for the 5 MW fire correspond satisfactorily to values, which were measured during the test. If there will be a fire in upward part of the tunnel (represented by the calculation of 30 MW fire), the flow velocity will increase about twice. In the case of downward unidirectional tunnels, there is the danger of the back layering of the smoke above cars and users, which are escaping the tunnel.

For the calculation was used the development of a passenger car fire with power about 6 MW (according to results of fire tests of Eureka project) and the development of a fire of goods vehicle with flammable load with power about 30 MW (according to [9] or by modification of results of the fire test in Runehamar tunnel).

The mathematical calculation was based on the solution of the system of dynamic equations of the one-dimensional non-stationary flow of incompressible fluid and on the solution of continuity equations.

During the simulation of the fire in tunnel it is important to include the pressure loss, which is induced by the fire, into the calculation. This pressure loss depends on the heat power, on the shape of cross section and on many others factors. This loss can be correctly calculated only by the numerical calculation of three-dimensional models by means of CFD. By the analysis of results of many studies, realised in CETU and during which the velocity was between 1,5 and 3,5 m/s, the following approximate relation was founded:

$$\Delta p_F = c.\frac{Q.10^6}{u.D_H^2}\,[\mathrm{Pa}] \qquad (1)$$

where $c \approx 9.10^{-5}$.

5 ASSESMENT OF THE RESULTS OF THE TEST

In all cases the fire was detected between 55 and 60 seconds by means of thermo line detector Cerberus® FibroLaser II. Thus the requirement for fire detection in one minute was verify. Immediately after the detection the relevant emergency sequence, whose part is the smoke extraction too, was putted into action.

Immediately after the detection of the fire all the equipments of the ventilation are stopped and at the same time, jet fans or fans of the transversal exhaustion by slots, are put into operation according to the location of the fire. The power for exhausting may be concentrated into the area, where the smoke is going and where it could endanger escaping users, thanks to the possibility of closing or opening of dampers of the slots.

The highest temperatures, which were measured by the thermo line detector during the test, were 60–70°C in the three-lanes section and 80–90°C in the two-lanes section. (the highest expected temperature on the ceiling is 150°C in the case of fire in three-lanes driven tunnel and 250°C in the case of fire in the two-lanes cut and covered tunnel). At these conditions the smoke stayed under the ceiling of the tunnel. In the three-lanes driven section, the smoke filled the space in tunnel, because of low temperatures of the smoke and because of fast getting cool of diluted smoke in the cross section (93 m^2). In the two-lanes cut and covered section (about 56 m^2) the smoke formed an ideal layer of stratification under the ceiling, which has never get cool so that it started to fall into the escape zone.

5.1 *It can be claimed that*

1. The fire will be detected in one minute and since the stopping/starting of partial equipments the airflow in the tunnel will be steady in 3–4 minutes. During this time the smoke's behaviour is natural and the smoke stays safely under the ceiling.
2. At the using of the thermo line detector FibroLaser II, the reliability of EPS is very high.
3. When the heat rate of the fire is higher and the conditions are similar, the smoke temperature will be higher and the time for getting cool of smoke will be longer, so the smoke will stay at the ceiling for longer time and the space under the smoke will be diluted sufficiently.
4. For ensuring of smoke stratification, it is necessary to keep the move of the smoke in one direction and the flow velocity in the first phase of evacuation should be 1,5 m/s. This can be achieved by the control of the flow by means of jet fans.
5. Its suitable simplification and particularization of others eventualities of ventilation control system by nonscheduled smoke behavior.
6. It is important to differentiate between the faze of evacuation and that of firefighting. During the evacuation is the ventilation in automatic smoke control mode, when is desirable not to stir the smoke with high air flow velocities. During the fire fighting faze the ventilation is in the manual control, operated according to the needs of firefighters.
7. Algorithm design methodology of automatic ventilation system must be make on events passing in the time before and after fire detection.

Results of the COST project are available on www.satra.cz.

6 SYSTEM OF VENTILATION IN THE OTHER TUNNEL IN PRAGUE CITY RING

The Prague's City ring is very important part of traffic infrastructure of Prague. The main object of City ring is to ensure the fluid transit through Prague. One of the most important parts of the City ring is the Blanka tunnel considered. Length of this tunnel is about 6 km and the system of smoke and heat exhaust is nearly the same like in the Mrázovka tunnel (combination of exhausting from cut and covered and driven sections.

6.1 *The ventilation control in the case of fire*

A few minutes after outbreak of fire it is important to keep the visibility in tunnel as long as possible. In the case of non-exhausting of smoke, the whole cross section is filled with smoke in 3–5 minutes. This time can be lengthen by longitudinal velocity and smoke extraction regulation.

The smoke extraction from driven sections is by means of slots in the ceiling. The shape of slots was designed to minimize a non-uniformity of extraction (see Fig. 7). The transversal system exhausts the volume, which corresponds to three times cross section and its value is 240–300 m^3/s. The distance of slots is about 85 m. It is possible to close every channel with

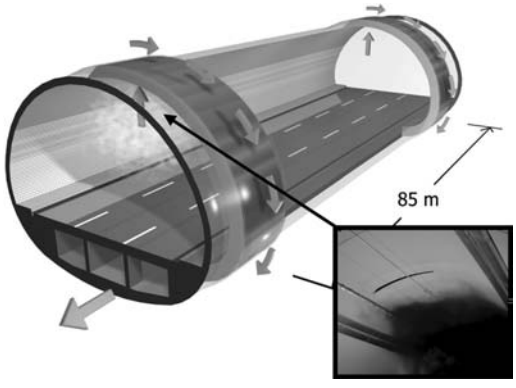

Figure 7. The channel in the lining of the driven tunnel with a detail of the slot in the ceiling.

the remote control damper, which is situated at the connection with the smoke duct, this enable to concentrate the power for exhausting.

The level of security in cut and covered sections (extraction in every 300–500 m) is lower than in driven sections (extraction every 85 m) in the case of fire during the congestion in the tunnel. In that case, jet fans in cooperation with local exhaust have to control the longitudinal velocity in value 1,5 m/s (according to the location and power of fire) during the phase of evacuation and it is necessary to exhaust the smoke according to the flow in the tunnel in order not to increase longitudinal velocity of the flow and smoke. Every increase of the longitudinal velocity may disturb the smoke stratification, which enable the visibility near the ground also behind the fire (in the sense of flow).

Optimization of tunnel system based on ITS architecture

P. Přibyl
ELTODO EG, Prague, The Czech Republic

ABSTRACT: Road tunnels consist of several very complex sub-systems (safety, ventilation etc.), which have to be integrated in terms of transport telematics principles. The article describes a web-oriented tunnel safety architecture based on the European KAREN project and standards elaborated in the CEN/TC278 technical committee. Upon the choice of a user needs connected with tunnel safety (non mandatory equipments or systems) is generated automatically a set of functions and information flows between them in a form of ITS architecture. This system restricts both any useless functions to be implemented and any failure to install important functions and tunnel is equipped on an optimal way.

1 INTRODUCTION

The tunnel and its technological equipment is surely a very comprehensive system consisting of many sub-systems and equipments. As a scheme the tunnel may be shown as an equilateral triangle with corners "Safety", "Economy" and "Ecology" in the focal point of which is traffic. It concerns a transport system, which must be reasonably safe, appropriately built in terms of cost and ecological considerations as may be required. As regards ecology, there is almost never any problem because a tunnel usually replaces a longer and serpentine road on which drivers brake and accelerate more frequently. From the safety point of view it is much complicated because there is not only the cost of the original safety systems investment but also the cost of operation. This is the reason why a balance between a safety and a price of safety systems shall be searched.

This article describes the tunnel system in connection with and from the viewpoint of transport telematics. And the tunnel is really such a system because by using methods usual in transport telematic systems it integrates a number of heterogeneous systems in one target function, which is safe and smooth traffic. We can see very often that there are several equipment and systems installed in tunnels, which are not interoperable in full and thus their characters may be not used to the fullest. In order to provide for full integration of complex systems it is useful to model them in the form of architecture, which precisely defines functions and information flows of all sub-systems and equipment. Within several European projects (KAREN, FRAME) frameworks and rules for the establishment of architecture have been prepared. Similar processes are even standardised at the European level in technical committee CEN/TC278 "Road Transport and Traffic Telematics" and its working group WG13 "Architecture and Terminology".

The article describes the architecture of tunnel systems, which is to be used for the optimisation of any tunnel. The recommended procedure has been developed and tested within the national project of science and research OPTUN (Road Tunnel Optimisation) supported by the Ministry of Transport Czech Republic.

2 TUNNEL AS A TELEMATIC SYSTEM

A road tunnel, both in a city and in a rural area, is a component of a communication network, and traffic conditions in a tunnel correspond to traffic conditions on any road. The tunnel is, however, a specific traffic structure in terms of higher investment and operating costs. Tunnels must be viewed as integral parts of the communication system. It is always necessary to seek optimisation of economic, social and environmental impacts. An investor also has to pursue relations beyond the scope of a simple cost-benefit analysis.

These technical systems work with a large quantity of data which is often very different because a group of traffic parameters is measured as well as weather and ecological conditions, and besides, it is necessary to transmit verbal information reliably, for example from SOS boxes or telephones of road users while TV supervision is of great importance. A large data file is connected with safety and security systems in use (emergency buttons, fire alarms) and in addition,

there is a large group of data to control and monitor the technological systems such as ventilation, lighting, and charging batteries etc.

The tunnel must be seen as a part of the transport system in the area given and that is why it is necessary to communicate mutually with transport centres, police, rescue service and fire department hot lines but it is also necessary to provide for respective relations and links from the viewpoint of controlling, e.g. traffic signals near the tunnel have to react to any queuing in the tunnel.

The road tunnel equipped with the respective technology is a typical telematic system and, as such, must be integrated into a more general transport-telematics system of a city, region or district. There are several definitions of telematics, the first is from 1997, Pribyl 2003, see the simplified form below:

> The systems which may be classified as telematic systems used for the improvement of population mobility both *tele*communication and infor*matics* equipment. All necessary information is available for both any sub-system and equipment because everything is connected in one global telecommunications environment.

However, the sole connection of telecommunications and transmission is not enough because these systems are launched just and only for the purpose to ensure the common target function which, in case of a tunnel, may be providing for "smooth and safe traffic with minimum ecological impact and optimisation of operating costs". It means that e.g. to install a proper tunnel regime requires a transport sub-system with a ventilation sub-system so that tunnel users benefit from optimum conditions and that tunnel is operated safely and effectively. All co-participating sub-systems are connected at the information level so that they execute just such functions which are necessary. In case of fire in the tunnel other functions, prepared in advance, are activated which execute other processes. As the tunnel is to be deemed as a telematic system its model in the form of an ITS architecture can be prepared.

2.1 *Approach to tunnel system model preparation*

Before the approach to the preparation of architecture is described it is necessary to define the term "system" because the definition of the system is a basis for creating architecture. A real object which is a general transport telematic system and which is subject to "investigation" is composed of a number of entities mutually connected. The investigation may be understood in many ways. However, the preparation

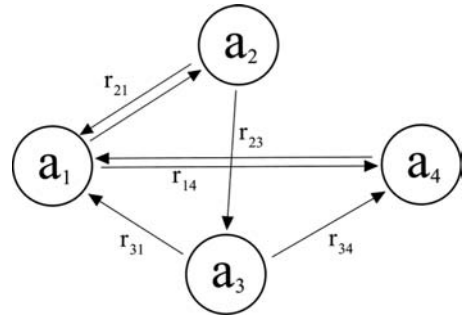

Figure 1. System structure of relations between elements.

of architecture is characterized by grouping entities into *elements* while a set of *relations* is established between them. The selected point of view concurrently determines the degree of investigation, which is a distinguishing level. Generally it applies that system S is made of a couple of sets A and R

$$S = [A, R]$$

Where A is a set of elements and R is a set of relations (links) among them:

$$A = \{a_1, a_2, ..., a_i, ..., a_n; n \in N\},$$
$$R = \{r_{ik} | r_{ik} = (a_i, a_k), \quad a_i, a_k \in N\},$$

this has certain characteristics (N is the set of natural numbers). Elements are particular fundamental entities of the system, Figure 1.

Interaction of elements is to be interpreted also that each element a_i fulfils within the system as a whole certain functions $f_{i1}, f_{i2}, \ldots, f_{ij}; j \in I$, which constitute a basis for creating architecture making. Graph G(A, R) is a structure of system S. Thus the term system is an abstraction which is the form in which the object is shown. In our conception the term system is understood as transport-telematics object which provides for the pointing out of his system characteristics. A realistic system is then a system installed in a concrete real object, for example concrete tunnel. Thus the real system becomes a model which the observer creates in the process of monitoring, investigating and describing the object given.

2.2 *Definition of architecture*

The tunnel system is a typical transport-telematics system because in addition to its primary function – transport it must provide for suitable lighting, good ventilation, safe traffic etc. It is a heterogeneous system consisting of several sub-systems of which each executes its macro-function. All macro-functions

execute one target function. The architecture of the tunnel system enables the complex sets to be described, which cannot be designed by exact methods, for example a safety system via a model which is sufficiently available to persons who are not extra specialists in the field given. The tunnel system architecture is to be defined as set out below:

From the transport telematics point of view the tunnel system architecture is described on the basis of user needs in the form of complex model made by a functional, information, physical, organisational and telecommunication model.

In making a model of telematic system in the form of architecture it is necessary to use suitable methods. The basic method how to approach the preparation of architecture is its breakdown into simpler pragmatic models. Their structure and division arise from experience of the European architecture KAREN, lit. Franco 2000 or at the level of the Czech Republic from the "ITS Architecture CR" lit. Svítek 2002. The architecture of systems in transport telematics is to be classified as:

Functional – creates and defines particular functions of elements, modules and subsystems including relations between them and thus it enables applications to be made.

Information – defines the principles of creating the structure of the respective information sub-system including requirements for allocation, encoding and transmission of information.

Physical – defines physical devices, which perform particular functions so that functions of applications are ensured i.e. allocation of particular elements, modules and sub-systems defined in functional architecture by relevant physical equipment.

Communication – describes transmission of information in the system in relation with physical architecture.

See graphical form of this breakdown on Figure 2. The tunnel system at the bottom level is presented by physical reality: own tunnel, communication, buildings, building sites. . .

In the second layer more detailed breakdown into physical systems and equipment is to be distinguished: transport system is made of sensors and actors, the control system consists of computers in the tunnel and control room etc. Based on this breakdown it is possible to form a vision how a physical model may look like. But it should not be connected with concrete elements or suppliers but should be as general as possible. The abstract description is placed at the highest layer, where functions (function architectures) are allocated to physical entities, relations between functions are defined (information architecture), information flows help define communication architecture and the whole activity is ensured by organisation layout, from which information architecture is formed.

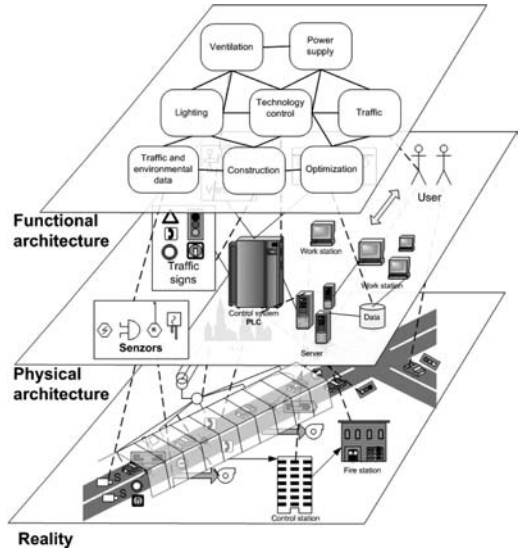

Figure 2. Distinguishing the architecture of systems in transport telematics.

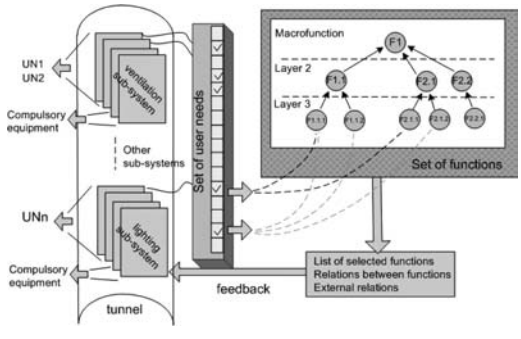

Figure 3. Making architecture scheme.

3 MAKING THE ARCHITECTURE OF THE TUNNEL SYSTEM

The conception how to develop the architecture is shown by scheme, see Figure 3. It is evident there from that the tunnel is divided into *n* sub-systems (Lighting, Ventilation etc.). Part of technological, transport or safety and security equipment in the tunnel installation is compulsory because it is stipulated in standards and given by technical conditions (in the Figure 3 it is marked as "compulsory equipment", which may include, for example, accommodation lighting or the position and performance of ventilators. There are accurate methodological instructions how to design them. Thus the tunnel may be equipped with devices which are not unambiguously required but are recommended or proven to be good in other tunnels. This

equipment required by the user (investor, future operator, security technician, IES units etc.) is marked as User Need/UN., see Chap. 3.1.

The user will specify user needs, which he would like to be satisfied in the tunnel and functions, which execute them, are allocated just to these selected needs. They are accurately defined and concurrently information flows between functions are unambiguously defined, or between functions and ambient conditions. The whole process is automatically executed within a database and web oriented interface.

Fundamental benefit is that a user who does not need to be any extra specialist in the field will get a list of functions and relations, which execute his needs and thus it cannot happen that any function or relation is forgotten or vice versa that he does not buy also functions which are not necessary for its execution. To get orientation in all functions which the chosen system is to execute or in relations which must exist in order to be integrated into the tunnel system in full is nearly impossible for the "lay person" or ordinary user. In particular in such cases various lobby pressures start to occur which may cause the system to be disproportionately much expensive or complicated. Just in these situations the role of architecture of the tunnel system is not substitutable.

3.1 *User needs*

As regards a general tunnel system user needs have been defined such as a set of functions (macro functions) providing for higher security of operation, improvement of comfort for the user, improvement of the quality of processes etc. As a representation of user needs for a security sub-system of the tunnel is Table 1. The main User Need *U*1 *Security* is broken down into fifteen concrete user needs ($U1.1 - U1.15$), which specify optional requirements for the equipment of the tunnel in detail.

The user chooses one or more User Needs from the list offering just those which will help him solve the problem given.

3.2 *Function and information architecture*

Thus the function architecture "fulfils" user needs. The user need is executed via functions, which belong to it. Functions of the system are divided into several group according to their character. There are functions which provide for security, ventilation, lighting, control etc. Functions are organised in hierarchy at three levels, at the lowest level there are the so-called elementary functions, see Figure 4.

Functions of the first level are the global functions (macro-function), functions of the second level give more details and only the functions of basic level of the function tree execute concrete requirement(s) of the system, execute user needs in part (measurement, control etc.) An example how to describe a function for a subsystem security is available at Table 2.

A sub-output of the program is an automatically generated list of all functions of one or several user

Figure 6. Display web application for user needs definition.

needs. In the next step automatically all relationships between functions *UP*, between functions of the tunnel and external relations are defined while convention UML is used, all to be shown in Figure 5.

3.3 *Presentation of architecture*

The architecture of tunnel systems is presented at interactive websites. The display and keeping defined architecture is based on the XML language. The document in XML represents both the databases maintaining descriptive information about the architecture of tunnel both with use of suitable templates shows architecture in the required form. The application platform for web application is ASP. NET with programming language VisualBasic. The architecture is available in Czech at www.eltodo.cz.

4 CONCLUSION TO THE ARCHITECTURE OF THE TUNNEL SYSTEM

The tool developed within the OPTUN project is an interactive environment for co-operation of the investor or future operator in the preparation of a conception of the tunnel system. The user may potentially select the equipment or systems according to actual needs of the tunnel. The architecture of the tunnel based on user needs reliably generates functions and their relations for optimum design of the subsystem given. Thus it is guaranteed that the system is not equipped in excess, or on the other hand is not insufficiently equipped. The equipment and systems are unified to a certain extent, independently of suppliers. In addition, the system outlined as said above meets the conception of tunnel as telematic system.

Increasing industrial safety and climatic conditions by the use of spray nozzles

A. Rudolf & O. Gloth
ILF Consulting Engineers SA, Switzerland

P. Schürmann
AxEnergy Ltd., Switzerland

ABSTRACT: One system can cope with fire safety, dust separation and cooling requirements at once: waster mist. These requirements must be considered thoroughly during construction, installation and later for operation of a tunnel in order to meet modern standards for health and safety. It is claimed that a water mist system is a multi-purpose system which should be incorporated as a fixed part in the basic construction of a tunnel structure such as cable ducts and drainage systems already are. Further, it is claimed that a water mist system is an uncommonly versatile and cheap system which requires only little installation space.

In this paper, the basic guidelines for design and dimensioning of such a system are outlined. In particular, the required water flow rates, the distance of water mist installations, droplet size as well as systemic requirements are discussed.

1 INTRODUCTION

During the construction of a tunnel, fire safety, dust separation and cooling are important aspects to meet modern standards for health and safety at work. Later, during the installation phase and during operation these aspects continue to be important in order to meet security standards and ambient requirements. In long alpine tunnels, these issues are particularly critical.

Fire and smoke are usually dealt with by a ventilation system. If no escape path is nearby, fire suppression systems and shelter areas are required additionally.

Dust is typically deposited by mechanical filters or water sprays where solid particles adhere to water droplets.

Cooling is most commonly achieved by heat exchangers with heat dissemination by water pipes. These pipes are large, thus they incommode installation works and hamper logistics. Besides, the mere temperature increase of the backflow water represents an environmental problem, which is sometimes difficult to overcome.

The required systems are often temporarily installed, even though their costs are in the same order of magnitude as the final installations. In this paper, it is shown that fire suppression systems may be used for cooling and dust separation during construction. In some cases, they may even be planned so that their use can be continued after regular operation has commenced.

A system which combines all the three functions is based on the use of spray nozzles which produce water mist with varying properties suitable for the specific function. It is a cost efficient, versatile, low profile and extremely effective measure.

The paper outlines the advantages of the use of spray nozzles during tunnel construction and thereafter in order to increase the safety level as well as the environmental conditions during construction and operation. It is also emphasized that cost effective synergies may be sought between different phases of the constitution of a tunnel if such a system is included in the basic tunnel structure as draining systems and cable ducts are nowadays.

2 SUGGESTED INSTALLATIONS

There are several possibilities to position pumps and nozzles and to provide the required infrastructure. After careful consideration of these options, the suggested configuration is outlined below.

2.1 *Water supply*

It is suggested to install a low pressure water pipe in the side-strip of the tunnel tubes with sufficient capacity to

cover fire and smoke suppression in an incident as well as to settle dust and to cool during normal operation.

2.2 *Central high-pressure pumps for fire suppression*

For the fire suppression system, high pressure pumps should be installed section-wise to cover larger tunnel portions or the entire tunnel. It should be considered to integrate a high pressure tube with regular T-pieces in the concrete lining as well in order to avoid hindrance of further installations works. Optionally, the high pressure pipe can be positioned along the tunnel lining.

2.3 *Distributed installation of high pressure pumps for dust suppression and cooling*

For dust suppression and cooling applications, the high pressure pumps should feed on the low pressure water line. They are positioned at the locations of the atomizing water nozzles. The dust suppression and cooling applications can be installed at arbitrary locations along the entire tunnel.

2.4 *Electricity*

The standard power supply can be used, as the high pressure pumps have fairly low power consumption (ca. 1–4 kW). If required, remote control data cables can be placed in cable ducts along the tunnel shoulder.

3 CHARACTERISTICS OF A DROPLET

In the sequel, the most popular mean and characteristic diameters, their definitions, and their most appropriate uses, are discussed (see Figure 1). Drop size terminology can be found in ASTM Standard E1296–92 [2,3].

DV0.5: Volume Median Diameter (also known as VMD or MVD). A means of expressing drop size in terms of the volume of liquid sprayed. The VMD is a value where 50 percent of the total volume of liquid sprayed is made up of drops with diameters larger than the median value and 50 percent smaller than the median value.

DV0.9: is a value where 90 percent of the total volume of liquid sprayed is made up of drops with diameters smaller or equal to this value. This diameter is best suited when complete evaporation of the spray is required.

*D*32: Sauter Mean Diameter (also known as SMD) is a means of expressing the fineness of a spray in terms of the surface area produced by the spray. The SMD is the diameter of a drop having the same volume to surface area ratio as the total volume of all the drops to the total surface area of all the drops. This diameter is best suited to calculate the efficiency and mass transfer rates.

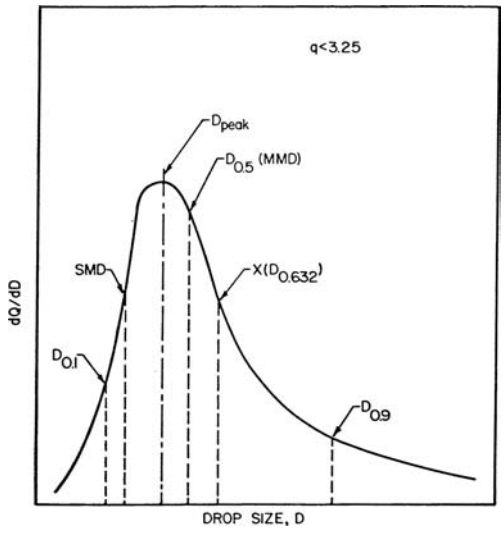

Figure 1. Statistical droplet distribution in water spray according to Rosin Rammler with indication of characteristic sizes of the droplet spectrum.

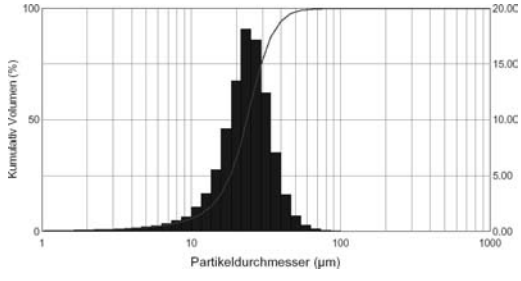

Figure 2. Volumetric distribution over particle size.

The typical droplet distribution of a high pressure atomizer is best described by the 2 parameter Rosin Rammler Function:

$$Q = 1 - \exp\left[-\left(D/X\right)^{q}\right] \quad (1)$$

where:

Q	::	fraction of total volume contained in drops smaller than D
X	::	empirical constant
q	::	empirical constant indicative of spread of drop sizes

Figure 2 shows a typical volumetric droplet distribution of a high pressure water atomizer nozzle, with a DV0.9 of 40 µm & D32 of 17 µm.

4 FIRE AND SMOKE SUPPRESSION

In the sequel, several advantages of a fire and smoke suppression system using water mist are discussed.

4.1 *Reduction of heat load*

With the beginning of the water discharge, the fire development can be significantly delayed, the spreading of the fire to other vehicles or combustible material avoided and thus the maximum heat load reduced. Consequently, the smoke production rate is, particularly in the first minutes, reduced.

The reduction if the smoke is of utmost advantage for the self-rescue, which is still a major key to tunnel security.

As the heat load and the smoke production rate are determining the sizing and the control of the ventilation system, additional security margins are generated.

4.2 *Reduction of structural damage to the tunnel*

The adiabatic cooling of the surrounding of the fire results in significantly reduced surface temperatures. As Wetzing and Reichsthaler, 2003 have shown, the following temperature criteria can be met or undercut:

- $<50°C$ at a distance of 20 m from a burning truck, this way the fire brigade can close in on the fire.
- $<250°C$ at a distance of 5 m from a burning truck; this avoids spreading of the fire to combustible material nearby.
- $<100°C$ at 10 mm depth in the concrete structure; this ensures stability of the concrete.

5 DUST SUPPRESSION

To get an efficient dust suppression system the water droplet spectrum has to be in the proper range. As shown in Figure 3, the droplet should be in the same magnitude as the dust particle to get a maximum effect for dust suppression.

Experience gained over the years with water sprays has established the following facts:

- for a given spray nozzle, the collection efficiency for small dust particles increases as the pressure increases.
- at a given pressure, the efficiency increases as the nozzle design is changed so as to produce smaller droplets.

The conclusion is clear-cut: the smaller the water droplets, the better dust particles adhere to them.

This can be demonstrated by considering a water droplet about to impinge on a dust particle, or what is aerodynamically equivalent, a dust particle about to impinge on a water droplet (see Figure 3).

If the droplet diameter is much greater than the dust particle, the dust particle simply follows the air stream

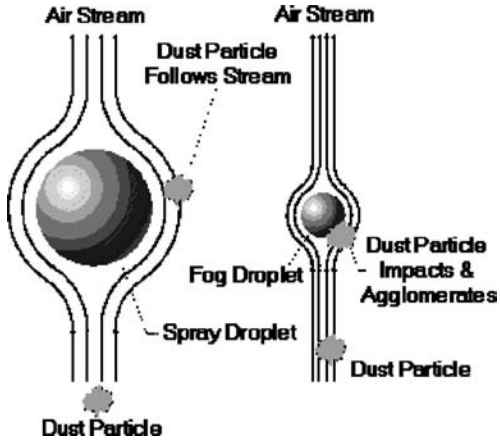

Figure 3. Airflow around a large water droplet prevents dust particles from colliding with water droplet. Flow around smaller droplets allows dust particle to cross the streamlines and to adhere to the water droplet.

lines around the droplet. Little or no contact occurs. In fact, it is difficult to impact micron-size particles on anything. This is the whole reason why inertial separators do not work well at these sizes. If, on the other hand side, the water droplet is of a size comparable to that of the dust particle, contact occurs as the dust particle tries to follow the streamlines. Thus the probability of adherence increases with smaller water spray droplets.

With these facts in mind, we are led through the logical extension of our approach to smaller droplet sizes, all the way to the vapor phase, extending the relative humidity above 100% and condensing the water directly onto the dust particles. In this way, the particles can be made to grow, under the proper conditions, to a size where they will either fall out or can be removed by sprays.

As soon as we take this step, we are in an area of physics known as “cloud physics” and can draw on the tremendous volume of scientific research results that exists in this area. For example, for over 20 years, the US Atomic Energy Commission has studied the basic processes by which radioactive fallout from bombs and reactor accidents is naturally removed from the atmosphere. The fundamental processes involved are nucleation and condensation.

Nucleation is the process by which raindrops are formed in clouds. There are two categories: homogeneous, where no foreign particles are present; and heterogeneous, wherein the droplet formations take place on foreign particles. The efficiency of the latter depends on many factors, such as particle solubility, wettability (hydrophobic or hydrophillic), the presence of hygroscopic salts, temperature, electric fields, charge and others.

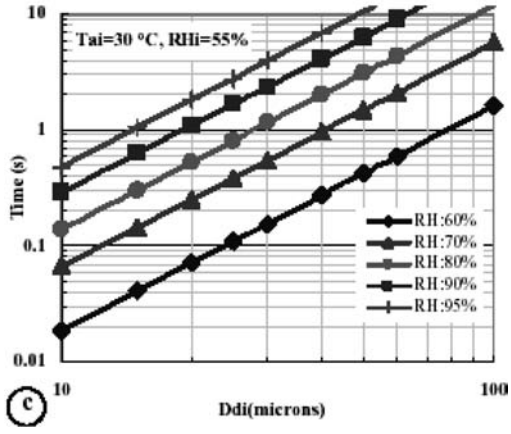

Figure 4. Time for evaporation over droplet size with relative humidity as a parameter (Chaker, 2003, p. 11).

6 COOLING

For a fast and efficient cooling effect, the water mist has to fulfil the following criteria.

6.1 *Duration of evaporation:*

The water droplets have to be small enough to evaporate in a given time. This time depends on the available evaporation distance and air velocity in the evaporation duct as shown in Figure 4.

At 30°C and 55% relative humidity a droplet starting at 20 μm diameter will need approx 2s to evaporate to a target humidity of 95%.

6.2 *Droplets must follow the air flow*

The water droplets have to be small enough not to collide with any obstacles within the evaporation duct. For a typical diameter of 10–20 μm, the viscous forces acting on a water droplet dominate the inertia forces. Thus, a droplet of this size will follow the air stream and will not collide with any obstacles.

The droplet size for large industrial adiabatic cooling units is in the order of 20 μm. With high pressure pumps capable of delivering up to 200 bar operating pressure and ceramic nozzles, a long life time for the industrial applications (up to 8700 operating hours per year) can be guaranteed. Only stainless steel materials are being used in these systems to meet the demanded service life of more than 25 years.

6.3 *High water quality*

The water quality has to meet high quality criteria. For most applications, a reverse osmosis water treatment system is recommended resulting in a conductivity of less than 1 μS/cm. This water quality guarantees the least amount of deposits left over from evaporated water, that the system will not be clogged by impurities in the water and that it is also safe for humans to breath in the cooled humidified air. Especially when used in a working environment, the absence of bacteria, especially Legionella, and respirable dust from minerals must be ensured.

Table 1. Yearly running costs for adiabatic cooling versus mechanical chillers w/ cooling power of 15 MW.

Adiabatic Cooling		
Needed cooling power	15'000	kW
Amount of water needed (approx.)	23	m^3/h
Electrical power rating of the system	120	kWe
Power factor (cooling power/ power consumption)	125	–
Operating hours per year	8,700	h/a
Electrical cost: CHF/kWh	0.30	CHF
Water cost: CHF/m^3	1.00	CHF
Cost of power consumption (power rating * operating hours)	1,044,000	kWh/a
Cost of water consumption (water cost * operting hours)	200,000	CHF/a
Total running costs	1,244,000	CHF/a
Mechanical Chiller		
Needed cooling power	15,000	kW
Electrical power rating of the system	5,000	kWe
Power factor (cooling power/ power consumption)	3	–
Operating hours	8,700	h/a
Electrical cost: CHF/kWh	0.30	CHF
Power consumption (power rating * operating hours)	43,500,000	kWh/a
Total running costs	13,050,000	CHF/a

6.4 *Life cycle costs*

In order to evaluate the life cycle costs, the running costs must be added to the installation costs of all required equipment.

The cost of the equipment is in most cases clearly in favor of adiabatic cooling as no backflow pipe is required and the water flow is significantly lower than the backflow of the mechanical chillers. Also, the required electrical installations and machinery is much smaller.

This is why in Table 1, only the typical yearly running costs for a total cooling power of 15 MW of an adiabatic system is compared to the costs of mechanical chillers.

The water costs have been estimated to 1 CHF/m^3, a rather high value as compared to actual projects. It

Figure 5. Fogging of air intake at gas turbine.

may vary depending on the conditions how water can be obtained. It must be added that only little costs for waste water treatment is necessary for cooling, as most of the water evaporates.

No water costs are considered for mechanical chillers as the water is circulating in this case and is not consumed.

Thus, from Table 1 it becomes obvious, that life cycle costs are in favor of adiabatic cooling.

6.5 *Typical cooling applications*

6.5.1 *Cooling of intake air for gas turbines*

A minimum in droplet size is recommended due to the very short evaporation time given in the air intake systems.

Not evaporated droplets may impinge on the turbine blades causing erosion.

6.5.2 *Adiabatic cooling system for tunnels*

For applications in the tunnel a compromise in droplet size (respectively in visibility) and evaporation efficiency (resp. in droplet travelling distance) had to be made. A typical droplet size if 40–50 μm was selected to be the optimal choice.

This first choice has been based on simplified estimates for particle traveling distances and visibilities. The falling velocity and hence the traveling distance for given tunnel conditions can be computed with (2).

$$v_{fall} = \frac{D^2 \rho_W g}{18\eta} \tag{2}$$

The visibility in meters can be estimated by equation (3), where LWC is the liquid water contents in g/m^3 and N_d the number density in 1/cm^3.

$$Vis = \frac{1002}{(LWC \cdot N_d)^{0.6473}} \tag{3}$$

This equation can be found in Gultepe a.o., 2006.

Figure 6. Water mist station in a tunnel environment with high ambient rock temperatures and significant technical heat.

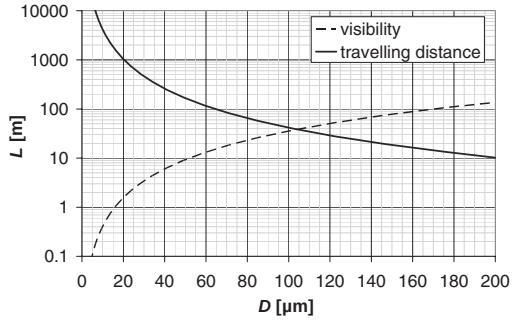

Figure 7. Distance traveled and visibility for different particle diameters (2.5 m/s flow velocity and 5 m ceiling height).

7 OPTIMAL DROPLET SIZE

Based on an air velocity of 2.5 m/s and ceiling height of 5 m, with nozzles located in the tunnel ceiling, Figure 7 illustrates the dependency of visibility and traveling distance on the particle diameter for a flow velocity of 2.5 m/s and a ceiling height of 5 m.

For droplet sizes of 40–50 μm a good compromise between visibility and traveling distance is expected from this simplified approach. Measurements of both, the traveling distance and the visibility, have to be carried out in order to gain confidence in the choice of droplet size.

(a) The visibility is in the order of 10 m, which is sufficient for the self rescue for the people trapped in the fire zone.
(b) The droplets in the range of 40–50 μm will travel at least 200 m within the tunnel.

8 CONCLUSIONS

This paper covered the combined use of a water mist system for fire and smoke suppression, dust separation and cooling during construction, installation and operation of a tunnel.

Due to its unique versatility and low expenses, it is suggested to incorporate a low pressure water tube in the basic design of a tunnel cross-section and to add a high-pressure tube in sections where fire suppression is required.

Based on travel distance and visibility, an optimal droplet size of 40–50 μm is suggested, subject to project-specific verification.

Towards tunnel facility management: Applying asset management to the operation and maintenance of tunnels within infrastructure networks

J. Ruiter
Centre Applied Research Underground Space (CARUS) Zeeland University, Vlissingen, The Netherlands

ABSTRACT: Until now rational maintenance of tunnel constructions was not the foremost field of research due to which insufficient information was available to professionalise Tunnel Facility Management. Tunnel Owners (managers) have in the past underestimated the complexity of maintenance and related costs. A managerial approach is needed to professionalise the maintenance of tunnels.

The main objective of this paper is the professionalising of current maintenance practice towards Tunnel Facility Management so decisions can be taken based on facts rather than on implicit knowledge. The theoretical approach takes as starting point the managing of the asset and tries to learn from asset management. The Asset Management Theory can be used for the model creation of Tunnel Facility Management. Tunnel Facility Management will provide the framework within which the information can be used to take sound and economic based decisions as part of a total lifecycle approach to managing and maintaining tunnels as important assets within infrastructure networks.

1 INTRODUCTION

Until now rational maintenance of tunnel constructions was not the foremost field of research due to which insufficient information was available to professionalise Tunnel Facility Management. Tunnel Owners (managers) have in the past underestimated the complexity of maintenance and related costs. A managerial approach is needed to professionalise the maintenance of tunnels. In this paper the related fields of tunnel facility management will be discussed.

1.1 *Developments*

A recent study undertaken by the Centre Applied Research Underground Space (CARUS), concludes that the need to professionalize maintenance management of tunnels (and underground installations) will become more and more important from a social perspective. Also the introduction of private ownership of tunnels rather than public ownerships calls for a rethink on inspection and maintenance as part of often lifecycle based investments. Both developments underline the necessity to study Tunnel Facility Management with practice or action-based research so that maintenance of tunnels can develop into a more professional and economic based profession in the future.

There are also a number of developments in the public domain which have increased the awareness for a rational and economic based approach to maintenance. The focus nowadays moves from new development to maintenance of infrastructure because:

- Infrastructure networks are growing as economies worldwide continue developing
- Infrastructure networks are constantly ageing
- Requirements to be met by infrastructure networks are growing
- The impact of bad maintenance practice and management on the total network is enormous

1.2 *Objective paper*

The main objective of this paper is the professionalising of current maintenance practice towards Tunnel Facility Management so decisions can be taken based on facts rather than on implicit knowledge. The theoretical approach takes as starting point the managing of the asset and tries to learn from asset management. The Asset Management Theory can be used for the model creation of Tunnel Facility Management. The operation of a tunnel is part of the operation of an infrastructure system. It is impossible to see tunnel operation and infrastructure network operation in general as separate entities. The operation of the infrastructure network provides the framework and prerequisites of the operation of the tunnels. In reverse, the operation and the availability of tunnels has a major impact on the operation and availability of the total infrastructure network.

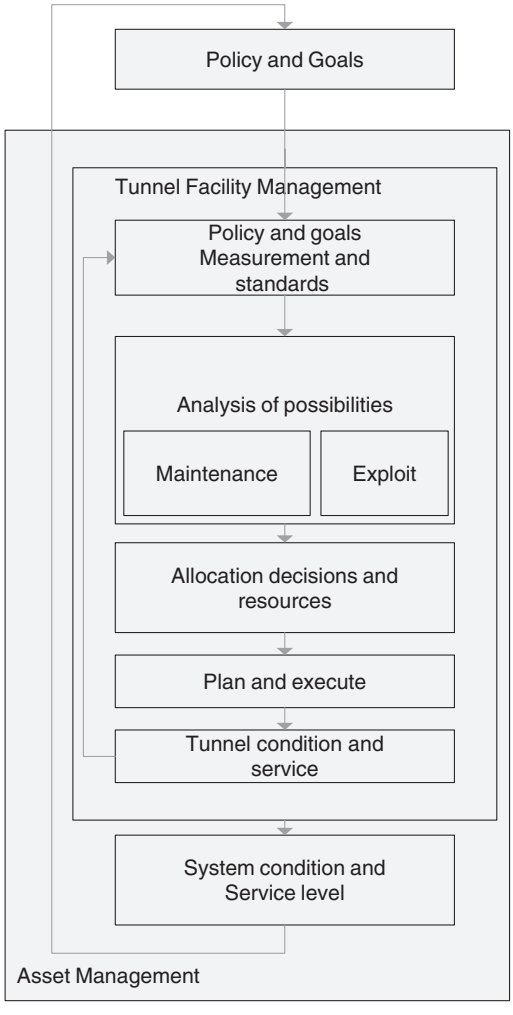

Figure 1. TFM model.

1.3 *Modelling Tunnel Facility Management*

The theoretical approach takes as starting point the managing of the asset (asset management). The asset management theory can be used for model creation of Tunnel Facility Management. During the study figure 1 is used.

1.4 *Policy*

The integral policy for infrastructure addresses on the infrastructure system as whole. The integral policy encompasses the mission, the policy view, the goals and the strategy. The most important part of the integral policy is formed by the mission. The mission will indicate the direction what the infrastructure system is going to achieve. In the policy's view is indicated how the manager handles with the developments that are outlined by the influences of the environment. The mission and policy's view will be worked out in integral objectives. Finally the strategy will be set up.

To make steering on functionality and quality possible, there has to be a link between the present policy and the to maintain objects.

- Environmental influences; a part of the policy is formed by the environment influences, i.e. influences from outside the organisation. The environmental influences will indicate which (future) developments need to be considered by the tunnel manager.
- The integral policy will be divided into feasible goals per object and the way to achieve these object specific policies.
- The object goals with the accompanying standards have to meet the following requirements:
  - Specific
  - Measurable
  - Acceptable
  - Real
  - Time dated

Both the objectives and complying standards have to be SMART.

The object specific policy needs to be checked against the functional requirements of the current policy goals. The core activity of maintenance is to maintain the quality during the rest of the lifecycle at a desired level. Measures are necessary when the desired goals and standards can not be met. RAM(S) thinking is introduced from the industry sector. No longer only safety and technology are important. Under societal pressure a shift is taking place towards availability and reliability as criteria to be met in the operation of infrastructure. In other words the optimisation of the RAM(S)-indicators is the goal which needs to be achieved. RAM(S) stands for the terms Reliability, Availability, Maintainability and Safety.

- Reliability is the probability that an object fulfils its function during the operational phase.
- Availability is the interval where an object fulfils its functions in both a normal operational situation and during emergencies.
- Maintainability can be divided into two categories:
  - Minimizing the maintenance by optimizing during the design phase.
  - Achieving accessibility for maintenance works.
- Safety can be divided in four categories:
  - Fulfilling Health & Safety requirements.
  - Structural safety.
  - Detection (gas, water electricity).
  - Unauthorized access.

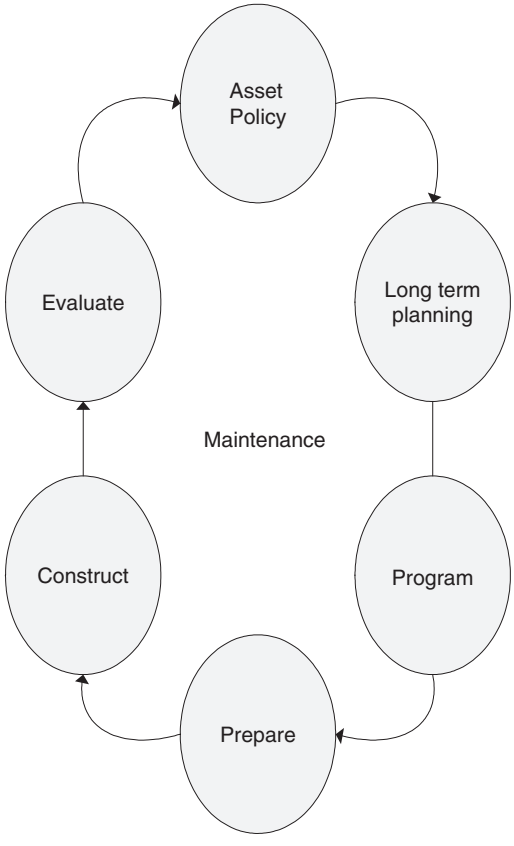

Figure 2. Maintenance Cycle.

1.5 *Maintenance & RAMS*

Maintenance has to focus on functionality and quality. The steering on functionality: Reliability, availability, maintenance and safety (RAMS), is based on checking the current asset to the expected and desired functionality. The maintenance of the asset has to be set from a technical approach to a managerial approach. The aim of this approach is to achieve accountability of maintenance based on budgeting and forecasts (see figure 2).

The maintenance process is top-down. Although there is also feed back to the policy level. This is necessary for self reflection of the policy maker and to ascertain if the goals are achieved.

1.6 *Operation*

The operation of a tunnel is part of the operation of an infrastructure system. It's impossible to see tunnel operation and infrastructure separate. The operation of the infrastructure provides for frameworks and preconditions for the operation of the tunnels. The operation of tunnels has influence on the operation of the infrastructure.

Successful accomplishment of the operational task relies on accurate and recent information on the condition of the tunnel.

- traffic management is aimed at an optimal flow of the traffic within the boundaries of the capacity of the infrastructure and the number of traffic participants.
- traffic information management consists of managing the traffic by monitoring the traffic.
- incident management consists of the multi-stage-plan and co-ordination process to signal traffic accidents.
- weather conditions management consists of acquiring information about current and up-coming weather conditions. Composing information about current and upcoming road conditions to support managers in their task to plan and execute maintenance. Prediction of traffic flow and giving traffic information. As well as formulating strategies for emergencies.
- Work location management consists of formulating strategies and adjusting to minimize obstruction as a result of maintenance works and to assure the safety traffic participants and workers.
- Emergency management consists of assuring an effective response of the infrastructure network in case of emergency, such as natural disasters, large traffic incidents and terrorist attacks.
- Transport management consists of activities which assure an efficient, safe and guaranteed transport of all categories.
- Ventilation management consists of activities which assure an efficient and safe air circulation.

1.7 *Life cycle management*

Life-cycle-management is a tool for decision support for the accomplishment of the policy-goals. "Sufficient Life Cycle Management" is not an autonomous goal. With regard to Life Cycle Management (LCM) it is not possible to set any functional requirements with exception of one, which is that for all decisions during the lifespan a LCM-analysis must be used for decision support. Therfore we can conclude that LCM is a tool and not a goal for policy decisions.

2 CONCLUSION

Successfully managing the operation of tunnels depends first and foremost on accurate and current information on the condition of the tunnel. Tunnel Facility Management will provide the framework within which the information can be used to take sound and economic based decisions as part of a

Figure 3. Tunnels form an integral part of modern infrastructure networks.

total lifecycle approach to managing and maintaining tunnels as important assets within infrastructure networks.

International Tunnel Control System – Introduction and experiences from realization

Jiří Řehák
ELTODO dopravní systémy s.r.o.

ABSTRACT: International Tunnel Control Central (ITCC) was developed by international group of engineers inside Siemens Intelligent Traffic System Division. Engineers were originally from Czech Republic (ETODO dopravni systemy s.r.o.), Germany, Austria, Switzerland and Nederland. The main goal of the system is to unify tunnel control system software approaches used in each involved country to improve efficiency and reliability of new system together with increasing of total tunnel safety. The structure of ITCC system and system features is demonstrated including examples of software control modules. Special consideration is focused on traffic, mechanical and electrical modules. The experiences with ITCC on real project are presented. The approach to design and realization of complex tunnel control system on Sitina tunnel in Slovak Republic is discussed as the first example and the control systems for Turkish highway tunnels Bolaman-Persembe and Giresun-Espiye as the second example.

1 INTRODUCTION

Up to date road tunnels matching to requirements to mechanical and electrical system safety resulting from requirements of tunnel standards have to be equipped by tunnel control system. A tunnel control system represents the key integration component in the tunnel. In case of occurring of emergency situation the control system is a component which failure less functionality can decide about seconds needed for evacuation and safety of endanger people inside of tunnel. Proper functionality of control system turns on many factors. Between most important factors defining overall reliability of control system belong especially:

(a) design
(b) used components
(c) reliability of software equipment
(d) testing

This article will discuss in the following text new approach to design of software equipment of tunnel control system. On the beginning of article there will be a short prompt to basic requirements to tunnel control system. Recommendation of Czech standards TP98 – "Tunnel technological equipment" will be shown as example requirement. Czech standard TP98 in parts of tunnel safety equipment and control system belongs to one of the sharpest standards in the world. This standard has been taken as one of the fundamental standards for architecture proposal of new tunnel control system ITCC.

2 TP98 STANDARD REQUIREMENTS FOR TUNNEL CONTROL SYSTEM

The requirement of TP98 for integration of all control system components to one integrated system is one of the fundamental stones of the standard. This requirement applies mainly for controlling of traffic and mechanical & electrical tunnel equipment.

As it is shown on the Figure 1 TP98 standard defines control system as one entity to which has to apply also system of control. The systems of control of traffic and mechanical & electrical equipment has so shared set of common data that splitting of control of traffic and mechanical electrical equipment into two separated systems could lead to significant decreasing of overall system reliability.

Next TP98 define in detail requirements for hardware and software architecture of control system. Both these standpoints have been taken into account during ITCC system development. Hardware architecture of control system according TP98 defines hierarchical organization of control system from point of view of its structure in frame of high level telematical system as it is for example city or large regional traffic control management. The standard defines for each control level basic functional assumptions including definition of types of communication protocols. Main emphasis is focused on optimal usage of redundancy. Control system response and reaction time is required in real time with minimum system delay.

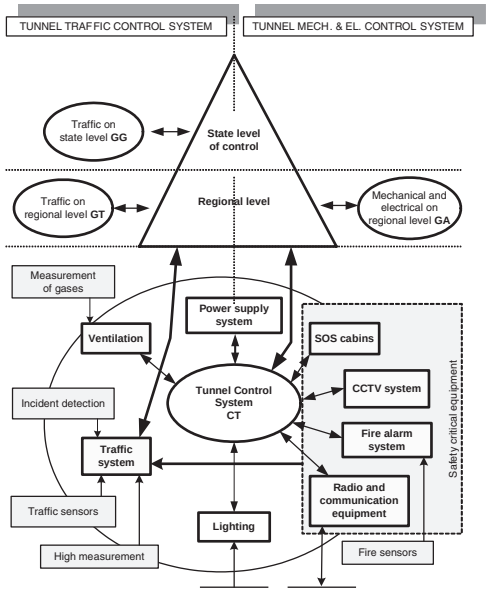

Figure 1. Integrated tunnel control system according TP98.

Table 1. List of tunnel operational status according TP98.

Name of tunnel status
Normal mode
Exceptional mode without necessity of emergency units
Exceptional mode with necessity of emergency units

TP98 takes into special account requirements to software design. For each level of control the standard defines a set of functions, which have to be implemented for proper function of tunnel control system. From operational point of view it is important that TP98 has direct reference to other Czech standard TP154 – "Operating of Road Tunnels". Both standards work with the same set of basic tunnel statuses. The set of tunnel status as it is described in TP98 is very important input for designing of software equipment of tunnel control system (Table 1).

3 TUNNEL CONTROL SYSTEM IN SIEMENS BEFORE 2003

In the frame of SIEMENS group number of software application for tunnel control has been developed in 90th of last century. Regional groups in SIEMENS has been pressed for development of own systems because of absence of central product. These systems have been prepared according local standards of each

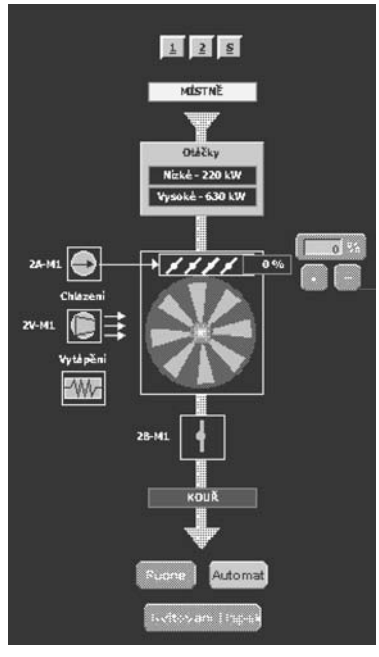

Figure 2. Sample of Kerberus GUI.

region. In the Czech Republic this development has been provided by ELTODO dopravní systémy s.r.o. ELTODO dopravní systémy s.r.o. developed complex tunnel control system with the name Kerberus. Kerberus is software equipment consisting from number of universal control modules intended to different control levels (for example SCADA level, level of main redundant PLC, level of field PLC) – see Figure 2 as example. Each successively tunnel application is than build from these modules step by step to required software structure.

Similar systems as Kerberus were also realized in Austria, Germany, Netherland and Switzerland. All of these systems were incompatible and were mostly related to national (regional) standards. Each system had different style of Graphic User Interface (GUI) and different style of control mode. The algorithms inside of software modules were prepared in different style, documentation to systems was written in different languages. Exchange of information and sharing of experiences between regional development teams was not possible.

4 ITCC – INTERNATIONAL TUNNEL CONTROL SYSTEM

The idea to realize new product built on base of existing regional software products arouse in year 2003.

Table 2. Overveiw of ITCC responsibilities.

Country	Responsibility
Austria	Traffic Manager (TM)
Czech Republic	Electrical and Mechanical Equipment
Germany	Project Coordination, Automatic Incident Detection
Netherland	Documentation
Switzerland	Traffic Manager (TCE)

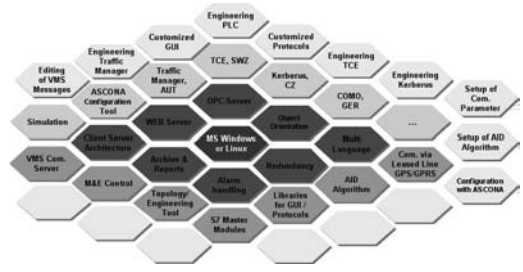

Figure 3. ITCC system structure.

Detail functional analyze of particular systems preceded technical realization of new system. The goal was to use maximum knowledge from existing systems. Special benchmark method for evaluating of existing system was used. Technical and economical parameters were used as inputs for evaluation. Based on the result of evaluation the development of new system was split to regional groups of developers as it is shown on Table 2.

Development of new control system had following main targets:

- Jointly coordinated development in five countries (Austria, Germany, Czech Republic, Switzerland and Netherland) with optimum utilization of know-how and account being taken of the requirements of all regions and customers
- Use of tried-and-tested industrial middleware and thus concentration on the know-how of Siemens ITS in the area of traffic and operations control
- Modular design of the software blocks with defined communications interfaces
- Centrally developed and updated software modules as product building blocks for the core functions of all tunnel systems
- Creation and configuration of the control centers from the product building blocks and the middleware in the region – therefore flexible in design to satisfy local customer needs (for example: graphic user interface, logs and statistics, control model)
- Platform-independent use under Windows and Linux
- Integration of different control models enables selection according to country-specific requirements.

5 ITCC KEY-FUNCTION BLOCKS

ITCC system was split to four different levels (Figure 3). The 1st level is the level of operating system – Microsoft Windows or Linux. On the 2nd level there is so called middleware i.e. SCADA system (in case of ITCC it can be PVSS or WinCC), database engine, system of redundancy and OPC interface. The 3rd level consists from developed control modules of ITCC system. It is for example module for Traffic Control (Traffic Manager and Traffic Control Engine), automatic incident detection module (AID) and software modules for controlling and monitoring of mechanical and electrical equipment. The integration software intended to particular realized tunnel is on the 4th level.

6 ITCC – STANDARDIZATION OF FUNCTIONAL BLOCKS

Maximum standardization of particular software modules was one of main targets during development of new ITCC system. Detail preparation preceding implementation of modules was necessary. For particular software block detail design specification was prepared – i.e. functional specification and specification of communication interfaces (Figure 4). Interface was defined in the way to ensure compatibility between software modules. Each module was split to two parts – Graphic User Interface part (GUI) and Programmable Logic Controller part (PLC). The list of elementary ITCC functional modules developed during the first stage of development is summarized in Table 3.

In the frame of ITCC Architecture listed elementary function modules are controlled in manual mode or are grouped to upper level function modules as it is for example Traffic Manager. Mechanical and electrical modules are grouped according particular requirement of realized application to complex algorithms on the level of PLC (for example automatic lighting functions, automatic ventilation functions, reaction of tunnel equipment on fire etc.). Standardization of software modules during ITCC development phase significantly increase speed of realization of final software equipment for tunnel control system.

7 SYSTEM TESTING

Testing phase of final ITCC system was a part of development. Special simulation environment for simulation of responses of real tunnel was prepared for this purpose. Special design documentation describing

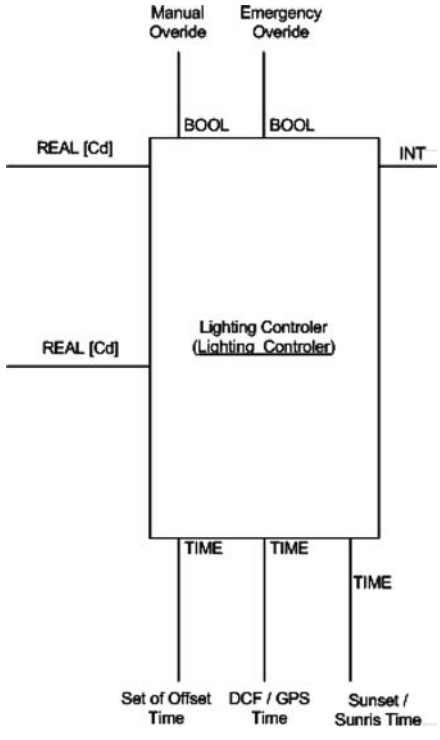

Figure 4. Sample of ITCC elementary module.

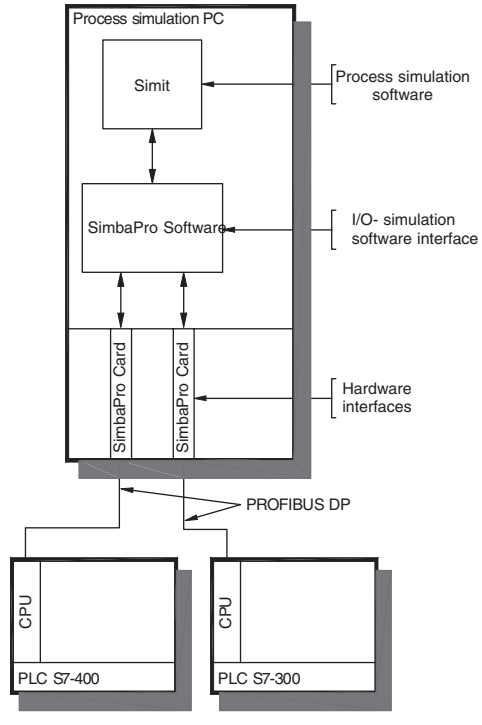

Figure 5. Simulation environment.

Table 3. List of ITCC elementary modules.

Function group	ITCC module
Lighting	Controller Astro Clock Contact Conversion
Power	Breaker Forecast KWH conversion
Ventilation	Selector Jet Fan Damper
Pump	Comparison

simulated tunnel was created. Simulated tunnel was implemented to process simulation PC, which was connected on PLC of ITCC system. Structure of simulation environment is shown on Figure 5. Simulation process was provided according prepared time schedule. Results were recorded to protocols and were subsequently evaluated. Several diagnosed failures were fixed and simulation process repeated. This process ensured 100% functionality of software modules in case of safe critical events in tunnel.

8 EXAMPLES OF REALIZATION OF ITCC CONTROL SYSTEM

ITCC system was at first time used in Sitina tunnel in Bratislava in Slovak Republic and next time in projects Bolaman-Pershembe and Gyreshum-Espyie in Turkey.

8.1 *Tunnel sitina*

Construction of two tube 1,4 km length tunnel Sitina in Bratislava in Slovak Republic started in 2004. The central control system is delivered as the part of mechanical and electrical equipment. The system is designed in ITCC environment. Sitina control system consists from four redundant layers (lighting, ventilation, traffic, power supply + auxiliary), which are fully integrated on level of SCADA system. Sitina control system is based on SIAMTIC S7 PLC, SCADA system PVSS is used.

8.2 *Bolaman-Pershembe and Gyreshum-Espiye tunnels*

System of two tube tunnels Bolaman-Pershembe and Gyreshum-Espyie in Turkey is constructed on the highway on Black Sea seaside near towns Samson, Odru and Trabzon. Control system is distributed into huge area. Control system manages 23,5 km highway including 9 tunnels. The longest controlled tunnel is 3,8 km length Neffise Akcelik Tunnel. Control system is based on SIAMTIC S7 PLC, SCADA system WinCC is used.

9 CONCLUSION

The new tunnel control system approach has been introduced in the article. The new tunnel control system with the name International Tunnel Control Central (ITCC) has been developed by joined group of engineers from five countries using their experiences with tunnel control systems. The system structure has been shown on all levels of control. Problems of development and testing of new universal tunnel control system has been described. Two examples of tunnel control system based on ITCC control system from tunnel realization in Slovak Republic and Turkey have been shown.

System of traffic control on Prague inner city ring

Jiří Štefan
ELTODO dopravní systémy s.r.o.

ABSTRACT: This article describes the system of traffic control of the inner city ring in Prague with emphasis on control systems of tunnel constructions. A new control system is introduced, which is responsible for safe and continuous traffic flow, not only on highway parts of the ring, but also on adjacent roads. The main emphasis is put on safe operation of the tunnel in conditions of city environment. The Mrázovka tunnel – the key component of the inner city ring – was opened in August 2004 after six years of construction. The Mrázovka tunnel is the middle section of the tunnel system, which can be used by drivers for easy and safe passage between northwest and south part of Prague. The Mrázovka tunnel is one of the best technologically equipped tunnels, which is controlled by a sophisticated control system integrating automatic control algorithms for traffic, mechanical and electrical equipment. As a part of the construction of the Mrázovka tunnel, the integration of control of existing tunnel constructions to one "Supervising control system" had to be solved. This "Supervising control system" was developed by the Czech engineering group of the ELTODO dopravní systémy s.r.o. The system was put into operation at the same time as the Mrázovka tunnel.

1 INTRODUCTION

Fundamental decisions of tunnels are made already in the design phase, where the following matters have to be optimized: the building part and the technological equipment. Generally, the cost of technological part is much smaller than the building part, but the technology is able to significantly improve safety in the tunnel. The Mrázovka tunnel is one of the best technologically equipped tunnels and one part of its technological equipment – the section of speed control – has improved the discipline of drivers to an extent that cannot be reached by means of the building part, e.g. by building "sleeping policemen".

2 THE MRÁZOVKA TUNNEL AS THE COMPONENT OF THE TRAFFIC FLOW IN THE INNER CITY RING

The Mrázovka tunnel (the nickname ATM) is in the middle of the tunnel system of the Prague inner city ring. It is connected with the Strahov tunnel on its northern end, and with the Zlíchov tunnel on its eastern end. The Strahov was built as the first tunnel in the city ring.

The Mrázovka tunnel, especially its control system, has to make allowance for the traffic in these adjacent tunnels. In addition, all tunnels are placed close to the city center, on a built-up area. There are several multilane roads and traffic lights are placed close to the tunnel portals.

Let us spend a few words about the philosophy of the tunnel control systems. According to the Czech technical conditions (TP 154), each control system of tunnels involves, apart from the technology inside the tunnel, also further technological parts outside of the tunnel and traffic signs in the clearway (the space in front of tunnel). The technology on these clearways is controlled and powered from the tunnel. Especially the power system uses interrupt power supply. Clearways are equipped with variable traffic signs, traffic lights and pikes. In case of emergency, this technical equipment must be able to stop vehicles in front of the tunnel portals and switch to a state allowing for the fastest possible evacuation of the tunnel.

Because these tunnels are in the city, the case of gated tunnel (or tunnel with restricted operation – this condition occurs much more frequently than tunnel out of order) have influence to the urban traffic in the neighborhood. Traffic lights outside of the tunnel and their key elements – traffic controllers – have direct connection to the control system. One of the most difficult tasks was the design of the intersection 573. As can be seen on the picture nr.1, the traffic controller receives commands from the two tunnels – Mrázovka and Strahov. Furthermore, close to this intersection there is the shopping centre Tesco (KOC) with its big parking place. The commands that are created in the control system of the Strahov tunnel (SAT), Mrázovka

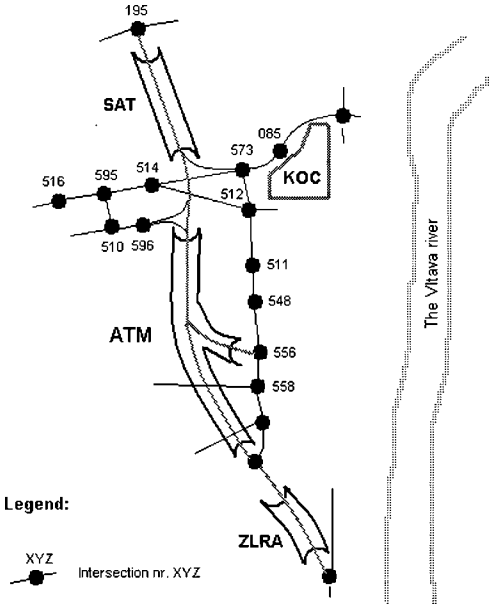

Figure 1. General situation.

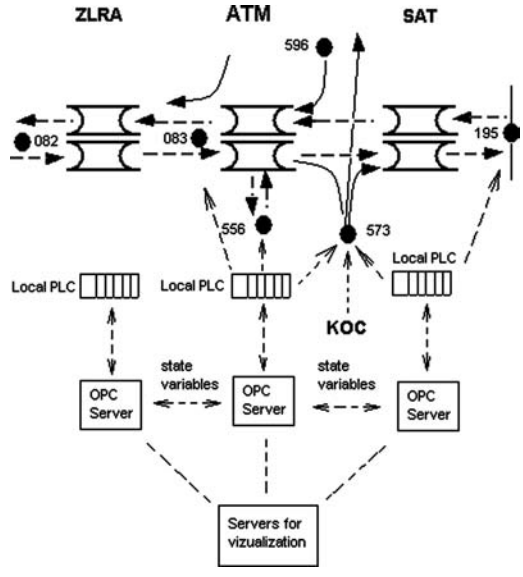

Figure 2. Relationships.

tunnel (ATM) and in the control system of the Tesco parking place are transmitted to the traffic controller nr. 573 are summarized in the following table.

I suggest, to implement a dynamic control system of the intersections placed on the inner Smíchov circle that would allow for the preference of public transport vehicles and high priority vehicles, and that would be connected to the central traffic control system.

The second problem was the interfacing between the control systems of these tunnels. The Strahov tunnel has used the control system made by G.E. Fanuc and tunnels Mrázovka and Zlíchov have used the Siemens control system. Therefore designers made a proposal to use a hardware-independent solution. The data exchange system is based on the OPS technology.

These state variables represent the states of the variable traffic signs. It can be seen that a small amount of state variables can represent all possible traffic situations in the tunnels.

On this chapter I would like to show that the traffic problems are much more complicated if the tunnel is built in the city than if it is built out of the city area. On the other hand, there is no problem with a sufficient electric power supply.

3 CONTROL SYSTEM OF MRÁZOVKA TUNNEL

The base conception of this control system is determined according to the category of the tunnel. In the Czech Republic, there are 3 categories: TA, TB and TC. The Input criteria are the length of the tunnel tube, and the traffic load (in vehicles per day). Tunnel Mrázovka has two tunnel tubes and the maximum length of 1300 m (the west tunnel tube). The traffic density has been over 4 000 vehicles per day. Therefore the tunnel Mrázovka belongs to the most intensive category TA.

4 WHY DO WE NEED A CONTROL SYSTEM?

From time to time, people ask this question. The Mrázovka tunnel contains 14 440 input/output points – sources of information or commands to action elements. Analyzing these amounts of information in each second is only if we use the computerized control system. The system analyzes the current events in the area of the Mrázovka tunnel, and issues commands to the underlying technology, but the human dispatcher has the higher priority to control. The regulation of such stochastic systems is increasingly dependent on computers, but a human dispatcher still has his own place in this process.

The base element of control system is a Programmable Logic Console for industry use (located in the control room) and the distributed I/O modules located by the technology. This solution was designed with regard to physical dimensions of this control system, according to the Czech regulations and, at least, to make the cost acceptable by the investor.

But this solution request to use very safe communication lines. We designed dual optical ring to connection among main control system and distributed I/O modules.

Table 1. List of variables to the intersection 573.

ATM	SAT	KOC	Description
x			Exit ATM across the 573: steady green.

SAT east tunnel tube left line closed:	ATM west tunnel tube left line closed:
SAT east tunnel tube closed:	ATM west tunnel tube closed:

Two optical rings are laid in the different cable shafts. As can be seen on the figure 3 there are 4 communication ways. The decision of which way has to be used is made fully automatically. The operator obtains only warning information in case of a defect. The second key element, the main station, has been built as hot standby redundant system. Both main PLC station (the first PLC operates as a master and the second PLC as a backup) are located in the different rooms, in the different fire segments. The optical synchronization bus guarantees the on-line data synchronization between master and backup PLC systems.

The problem of power supply is important as well. The power supply system uses two equivalent inputs for each important cabinet and the switchover is controlled by the control system. Each cabinet containing

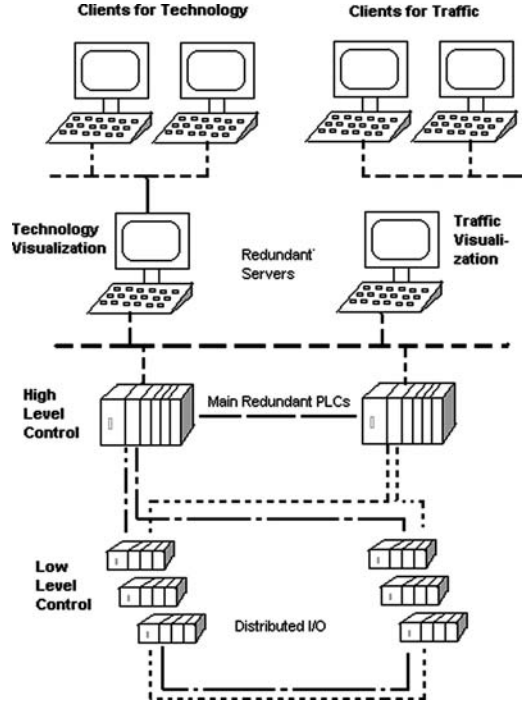

Figure 3. Structure of ATM control system.

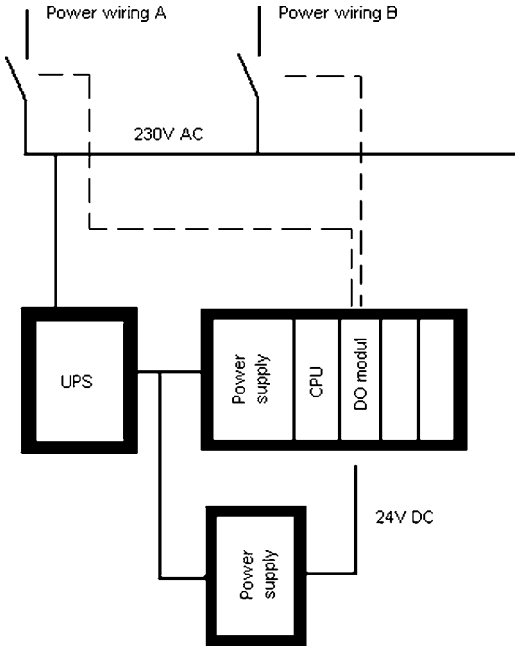

Figure 4. Layout of process station.

involving components of the control system has a dedicated UPS. Its capacity is 30 min. It is sufficient time for a service team to reach this locality and to fix the defect.

The control system is divided into two parts – transport control (dispatching Praha 2. ul Na bojišti – police works as traffic dispatchers) and control room of technology (Strahov, the civil staff). During ordinary operation the main control centre of ATM communicates with the superior control centers of tunnel and technology. The traffic flow in the ATM is controlled based on the received information (video control, traffic lights, phone communication, SOS and video-detection). The control system Kerberus was used. Its product has been developed for more than 10 years. It is a product of ELTODO dopravní systémy and has been used in 7 tunnels in the Czech Republic and in 4 tunnels in Turkey. It is independent on the type of the PLC equipment and also the tools for the integration with the city system (bindings to traffic information centre etc.) are available.

Table 3. Main features of Kerberus system.

Mode	• On – line Control • Simulation
Control	• Automatic Sequential • Manual
Options	• User Defined Traffic States and Sequences • Check Conflict Before Command

This system has these main features:

As was said before, the traffic system is of a high complexity. Therefore it is very useful to use the Simulation mode and options Check Conflict Before Command for the training and preparing of the human dispatchers.

Facility management methods for an improved serviceability of traffic tunnels and their application to tunnel drainage problems

M. Thewes
Institute for tunneling, pipeline construction and construction management, Bochum, Germany

F. Heimbecher
Federal highway research institute (BASt), Bergisch Gladbach, Germany

G. Vollmann
Institute for tunneling, pipeline construction and construction management, Bochum, Germany

ABSTRACT: In order to be long-term effective and cost-effective for the operator transportation infrastructural buildings need very high service availabilities. This applies especially to tunnel buildings in the context of road networks and railway systems. Service availability problems often result from design errors or from inadequate realisation during the construction phase but may also occur as a result of wrong planned maintenance and refurbishment. A definition that is adapted to modern requirements therefore must include all three classic phases of the life cycle – planning, construction and operation – on an equal footing. In addition a precocious acquisition of specific data and its transfer through all phases of the life cycle has to be guaranteed in order to secure the service availability of the building. In the paper the problem, which has been introduced before, will be pointed out considering German traffic tunnels as example and in the progression of the paper a method of resolution will be presented that is identifying the possibilities of effective facility management for the international tunnel operators. Subsequently first genuine realised methods of resolution are presented on the basis of the problem of "tunnel drainage", which may lead to large expenses on traffic tunnels for the operating companies. Concluding, the mechanisms that form the basis of the developed concept are transferred to other sectors of tunnelling and tunnel operation and thus the specific possibilities of TFM are demonstrated.

1 INTRODUCTION

Traffic tunnels usually are located where no adequate alternatives for traffic are available or at least are connected with considerable disadvantages. Independently of the traffic mode they are used in, they in most cases represent highly needed key elements of the infrastructure network they belong to. That said high service availability is always a main target for the operator. Securing high service availability is thereby strictly connected to an efficient operating strategy, whereas methods of facility management are a useful help in the way they are exercised in the modern real estate economy. Especially taking a holistic approach for evaluating a specific building – thus regarding all phases of a lifetime, as there is planning, construction and operation up to the dismantling of the building – has to be considered as a reasonable method.

Regarding German road tunnels these reflections do not only have an influence on the German national economy. Because of Germany being a country which is highly frequented by transit traffic, especially regarding its location for the European community, these problems are of a serious concern for the EU-wide infrastructural network. Therefore a conclusive and efficient lifecycle strategy has to be carried out to insure high service availabilities for those buildings. In addition, it can be expected that the fields of operation and maintenance will in future take up a far greater share of the pending tasks for research and development. (Thewes, 2006).

In this paper, possible strategies for generating an efficient facility management for tunnels are described while taking German road tunnels as an example. During operation of such structures a large variety of factors has to be considered, out of which within this paper a first focus is given to the detail aspect of permanent drainage systems. Throughout the last years there has been a significant progress regarding draining systems, determined by a large amount of analyses and research (Maidl et al. 1999, Maidl et al. 2002, Maidl et al. 2004 unpublished). As a result a new guideline for planning, construction and operation of draining systems for road tunnels has been issued, which will

be released in the near future by the BASt, on behalf of the German Ministry for Traffic, Construction and Urban Development.

After a short and general introduction regarding methods of facility management and after some remarks concerning the operation mode of road tunnels, some of the methods of the guideline for drainage will be introduced to the reader. Those methods provide a holistic and lifecycle oriented approach to operation of drainage system.

2 FACILITY MANAGEMENT AS A METHOD TO REDUCE LIFECYLCE COSTS

Facility management (FM) regards a building in holistic way and relates to its complete lifecyle.

Thereby the main target is to reach a higher level of benefit, a higher productivity, more profitability and a conservation of the facility's value throughout its whole lifetime. During this process the benefit of the specific building should be increased, while the expense for maintenance will be constantly reduced. This fundamental approach to operating a facility is increasingly necessary due to the fact that in the last years an obvious change regarding the ratio of new constructions to the refurbishment of existing ones occurred. This development is shown in figure 1.

It can be assumed that this trend will proceed throughout the next years. Therefore it is obvious that maintenance and repair of a specific building will furthermore be a vital part of its operation phase and therefore needed expenses will rather increase then diminish. That said two central perceptions can be derived:

1. According to the higher meaning of the lifetime of a specific building and its extension due to sustainable refurbishment, an operation strategy has to be derived that allows to optimize the lifecycle costs by reducing the maintenance effort and the resulting expenses.
2. Thereby the operation strategy has to include methods of maintenance and repair which are preventive and proactive and allow an extension of the lifetime and a decrease of efforts for maintenance and – in a long term view – efforts for repair and refurbishment (Figure 2).

For determining the profitability of a specific building all influences on the facility from outside and from within have to be considered in the scope of an extensive analysis, while reduced expenses due to proactive measures have to be included. Generally therefore the following procedures need to be evaluated and to be included in the calculative approach:

– aspects of sustainability
– actions on structures

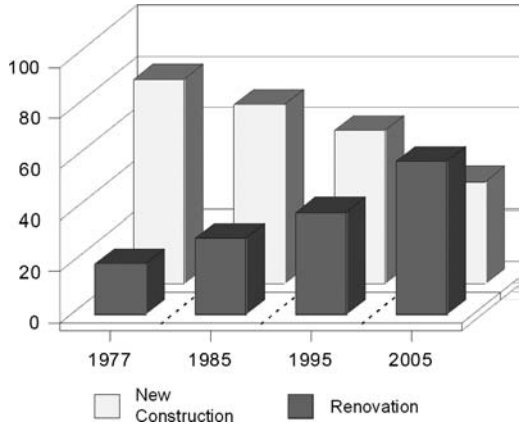

Figure 1. Ratio of new construction compared to renovation in Germany the last 30 years (Peil & Hosser, 2005).

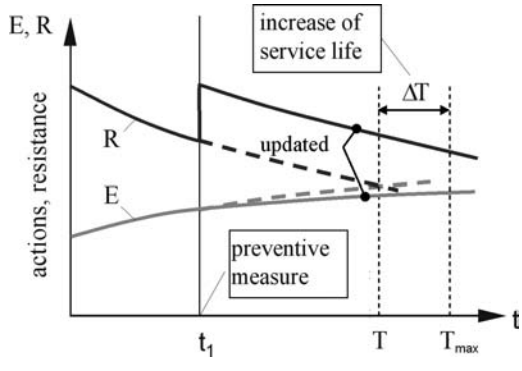

Figure 2. Increase of service life through protective and proactive measures and actions.

– accessibility and exchangeability of individual components or entire structures (inspection-oriented design and construction)
– component and structure characteristics
– lifecycle costs
– risk analysis
– energy and environmental performance over the entire lifecycle.

3 FACILITY MANAGEMENT OF TUNNELS: POSSIBLE AREAS OF APPLICATION AND PERSPECTIVES

3.1 *Points of operation of traffic tunnels and their influence on the cost structure*

Due to the specific common carriers traffic tunnels feature different points of operation, which are of vital importance regarding to the facility's function

within the transport network. A structured and efficient facility management needs to be focussed on these points. Regarding road tunnels the following points of operations can be pointed out:

- Ventilation
- Lighting
- Communication technology
- Systems for fire safety
- Systems for traffic surveillance, traffic guidance and signalling
- Drainage installations for road surfaces and (in case of permanently drained tunnels) for ground water.

In addition, the integrity of the inner lining and i.e. the roadsurface needs to be inspected frequently. However, the before labelled points of operation are subject to a higher frequency and intensity of maintenance and repair and naturally do have a shorter span of lifetime. This applies especially if the inner shells or the tracks of a tunnel are built due to high requirements regarding construction and durability.

All these points of operation do have in common that they first require an initial investment during the construction phase and that they generate operational costs during the operational phase of the building of a non substantial amount. This also includes costs for energy supply and cleaning. During later phases of the facility's lifecycle parts and components of theses systems need to be exchanged due to ageing, failure or wear. The influence of these matters on the facility's cost structure needs to be considered for generating a lifecycle cost-model (LCC-model) for road tunnels.

Furthermore all points of operation do have in common that their maintenance and repair, even if it's only on parts of the structure, will generate obstacles and handicaps for the utilization of the building, which results in a decrease of the facility's service availability. This has to be factored into the considerations. At some point the blocking of one track is necessary, at another point a complete tube or the tunnel as a whole has to be taken out of service. Expenses for the general public result here from.

In addition costs of general upkeep will occur, for instance due to cleaning of the inner shells or the track marks.

3.2 *Inspection, monitoring and damage detection*

For being able to maintain all points of operation efficiently, a substantial surveillance and detection of deterioration is needed. At this time mostly visual inspections and failure detection which is inherent to the specific system (for instance as function control for ventilation or illumination) is used for German road tunnels.

Naturally visual inspections are subject to fluctuations which depend on the conducting person. A deterioration, for instance to a draining system, isn't necessarily categorized in the same way by two different persons. On this account visual inspections need to be standardized as far as possible. To achieve this goal deterioration categories can be developed based on experiences from the past, which can be consulted during an assessment. In doing so the variance is reduced. However visual inspections do always have the disadvantage that only deterioration which has already und fully occurred can be recognized and not their development process. Therefore visual inspections in many cases only allow reactive and not preventive measures and actions.

Another large part of deterioration detection is carried out by non-destructive testing methods, for instance as a measurement for the integrity of the inner shell. The procedures with the biggest area of applications are the Impact-Echo-Method and the Ultrasonic-Method, which are already used to a large extent for inspections during the acceptance period of a construction and for the surveillance of existing facilities.

In a long term view it has to be expected that a surveillance of tunnels with monitoring-systems and -procedures will be exercised more widely. Especially deformations of the inner shell (convergence measurement) allow being collected and displayed by sensorial measurement and data logging. But even other applications are imaginable, for example tension detection on rock anchors, measurement of bedrock pressure, leakages, corrosion of the concrete or the range of sight and the exhaust development inside the tunnel. Hereby the advantage of monitoring procedures is that every measurement value logging can be conducted without any interference of traffic and therefore without any decrease of the service availability of the facility. The amount of data has to be collected and archived centrally in a control centre, and has to be used for optimizations of the operation.

3.3 *Measures of facility management as guidelines for planning, construction and operation*

As already mentioned, the primary centre of action of an efficient facility management has to be the operation phase of the lifecycle. This is essential for tunnels in comparison to other engineering works, due to the length of their lifetime, which has already reach about 150 years for some rail tunnels. In addition several points of operation are in need of maintenance with high intensity and frequency. The aimed quality of maintenance has to be clearly defined and to cope with adequate measures during the cause of action. Especially for the example of tunnel draining system studies have shown impressively, that wrong facilitated maintenance could be followed by an increase of maintenance costs (Maidl et al. 2002, Maidl et al. 2004

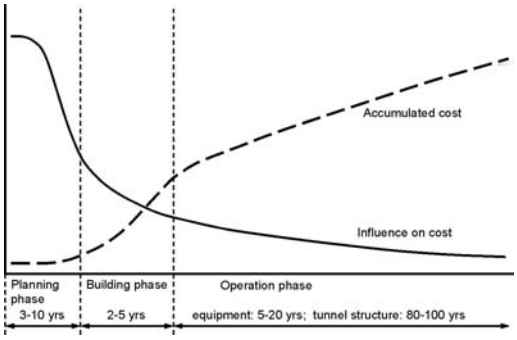

Figure 3. Tunnel project phases: Accumulated cost and corresponding influence on cost (PIARC, 2005).

unpublished). In addition, maintenance and repair are no static processes, but the necessary extent of maintenance changes throughout the lifetime due to wear of operational items or the change in operational boundary conditions of the building. Therefore a continuous adaptation of the extent of maintenance to the change in boundary conditions has to be carried out based on expertises from the phase of maintenance.

That said it doesn't cope with the problem to create a basis of action with modern methods surveillance, on which the operation staff may act in an arbitrary manner. Strictly defined maintenance measures are vital, as far as an accurate definition and description of maintenance documentation during its operational phase. This is essential especially for recognizing changes in boundary conditions at an early stage and for realizing an adequate reaction. The formulation of such clear guidelines for instance could be implemented by a explicit building management system, such as it is established by the BASt in Germany at the moment. (Haardt, 2004).

But also during the phases of planning and construction maintenance and repair have to be a vital part of the considerations in terms of a holistic approach. Studies of the PIARC have proven that a substantial part of expenses for maintenance and repair are determined by mistakes and errors which have occurred during design and construction phases. Most of the time this is influenced by the fact that those who are involved in the design and construction process have only little experience with the problems of maintenance and its costs. This becomes furthermore problematic, because the possibilities of taking an influence on matters during the operational phase, whose cost developments are directly linked to decisions taken in the planning or the construction phase are quite limited. The relationship between the cost of maintenance and the level of influence exercised on these costs can be depicted diagrammatically, as shown below (Figure 3).

4 INFRASTRUCTURE MONITORING AND OPTIMIZATION OF OPERATIONS WITH THE EXAMPLE OF TUNNEL DRAINAGE

4.1 *General*

In the following it is shown how a sustainable cost reduction can be achieved with methods of facility management, by following a holistic strategy, which comprises the design, the construction and the operation of particular details. Using the example of a drained tunnel, a problem which is specific for drainage systems is shown, which can is encountered at new road tunnels in Germany with a holistic strategy. This strategy is described by specifying measures from the areas of planning, construction and operation.

4.2 *Operational problems with drainage systems*

The permanent draining of tunnels during the operation phase is a solution, which is easier to build and which considerably reduces the construction costs in comparison with a tunnel with waterproofing. Over the service life of a tunnel, however, the effort for maintenance caused by a permanent drainage can become quite large. The result of a comparative LCC-analysis might therefore be that a waterproofing of the tunnel in spite of higher construction costs still is the more cost-efficient solution over the tunnels lifecycle. The main cause for this outcome could be lime deposits, which have to be cleared from the drainage pipes requiring a high technical and logistical and therefore costly effort. The mentioned lime deposits develop from precipitating calcium carbonate ($CaCO_3$) previously dissolved in the drained ground water and they partially are quite tough and resistant against cleaning. The $CaCO_3$ either originates from the temporary lining, where it is eluted from the groundwater contact with the shotcrete, or it caused by geologic limestone formations, which are passed by the drained ground water. Depending on the applicable case of origin for the $CaCO_3$ the lifecycle-oriented strategy for the design of a drained or undrained tunnel has to be developed. The main factors in this consideration are that the lime deposits caused by shotcrete linings are likely to become less with time whereas geologically caused lime deposits could continuously be problematic during the whole service life of the tunnel.

The mentioned causes for lime deposits principally can be differentiated regarding their hydrochemical and their hydromechanical origins. The hydrochemical causes have been extensively been investigated (Maidl et al. 2004 unpublished, Vollmann 2005, Girmscheid et al. 2003) and will not be discussed further at this point. However the hydromechanical causes of lime deposits always are closely depending on decisions and actions from the design, construction and operation phase of a tunnel (Maidl et al. 2002,

Maidl et al. 2004 unpublished, Vollmann 2005) and can be summarized as follows:

a) design: conception of the drainage system regarding the use of unsuitable components, i.e. unsuitable drainage pipes or filter materials
b) construction: placement of the drainage system with a lack of quality, i.e. placement of defect pipes or destruction of components of the drainage system
c) operation: application of unsuitable inspection and maintenance methods, unfavourable maintenance intervals

Together, these factors can cause a substantial maintenance and repair effort, which in the past in many cases was largely underestimated. In order to illustrate the resulting operational problem there are three main areas of influence which have a significant effect on the development of the operational cost:

a) the removal of deposits (i.e. with high pressure cleaning vehicles) and the resulting cost for the operator of a tunnel
b) the reduction of the service life of drainage pipes caused by the highly abrasive cleaning methods and the resulting cost for repair and for early replacement
c) the necessary (partial) closing of the tunnel for cleaning of the drainage system and the necessary traffic diversions and the resulting cost for the operator including a possible reduction of toll income

These factors have to be covered by a LCC-analysis even though the economic effort caused by the removal of deposits (a) is very difficult to quantify during the design phase of a tunnel. This is due to the difficulty of making a prognosis for the development of lime deposits before the tunnel actually goes in operation. The enormous problems caused in this context are illustrated by the decision of the German Railways (Deutsche Bahn) who in their building regulation, RiLi 853 (Deutsche Bahn AG, 2003) do not normally allow for the application of drained tunnels anymore but require full waterproofing of new tunnels. This is mainly due to the fact that train tunnels during maintenance are not available for service, causing the delay of trains at high cost because the rail network usually does not allow for equivalent detours.

4.3 *Constructive and operational solution approaches*

For the application field of German road tunnels extensive research has been performed on behalf of the Ministry for Traffic, Construction and Urban Development resulting in constructive and operational solution approaches aiming at the reduction of all deficits from design and construction which correlate with the development of lime deposits. The chosen approach

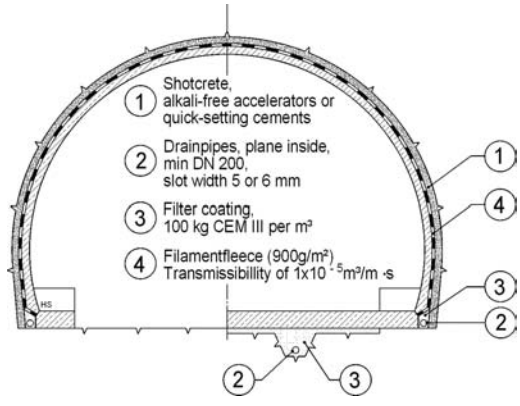

Figure 4. Deposit depleted ground system according to ZTV.-Ing.T5 (BMVBW, 2006).

led to the development of basic system of individual components with a reduced disposition towards developing lime deposits (Figure 4) proven by research projects (Maidl et al. 2002, Maidl et al. 2004 unpublished, Vollmann 2005). This basic system became mandatory in the national building regulation for road tunnels, ZTV-Ing. part 5 [11].

In case of a strong tendency towards the development of lime deposits, the basic system project-specifically can be enhanced by using components with an even further reduced disposition towards lime deposits. These components can be studded sheets in case of high local water inflow or uncemented gravel filters in connection with a special drainage pipe. Other solutions for handling drainage water with a high inclination towards lime deposits are available.

Finally, all data about the development of lime deposits will have to be collected and transferred to the operator for evaluation and for prognosis of deposit development during the operation phase. With this data it will become possible for the operator to optimize the strategy for inspection and maintenance and thereby reduce the operational cost for permanent drainage substantially.

4.4 *Proactive measures for maintenance and documentation*

Based on the data from the construction phase the operator can develop an optimized maintenance program for an individual drainage system adapted to its specific need for inspection and cleaning. Further, guidelines for the concept of a maintenance programme have been developed, consisting of the following points:

– data collection about the disposition toward the development of lime deposits at the inspection shafts

– camera inspection of the drainage system for the detection of the development of lime deposits using a unified classification method
– general recommendations for suitable cleaning methods of drainage systems in case of lime deposits
– tools for the collection, representation, evaluation and the archiving of data about the drainage system.

The use of a standardized method for classification and evaluation of inspection data the chance for arbitrary inspection results has considerately been lowered and the data becomes valid for long-term comparative evaluation of different tunnels and different drainage systems. This approach aims at the development of a central database for the drainage of German road tunnels leading to improved recommendation in future.

5 CONCLUSIONS AND OUTLOOK

It was shown that by a specific examination of the deterioration mechanisms and by the development of adequate measures a structured general program for operation and maintenance of a drainage system of a traffic tunnel can be developed. This on one hand will facilitate a reduction of the life cycle costs and on the other hand guarantee the highest possible availability of this individual point of operation and the whole tunnel. Further it was shown, that these systems can be flexible enough to be adapted to specific requirements of particular tunnels.

Similarly programs for the operation and maintenance of other points of operation are developed and will be integrated in a holistic overall approach for the facility management of traffic tunnels. For this a particular goal will be the collection of all relevant data for operation over the whole lifetime of tunnels and the subsequent optimization of adapted concepts for operation and maintenance regarding future changes of boundary conditions.

Fire protection concept for the Ceneri Base Tunnel

S. Čufer
Edy Toscano AG, Engineering & Consulting, Chur, Switzerland

ABSTRACT: The Ceneri Base Tunnel, two single-track tunnels with the length of 15.4 km, is the south continuation of the Alptransit Gotthard transalpine rail route. This tunnel will allow, together with Gotthard Base Tunnel, fast and economical freight and passenger transportation service trough the Swiss Alps and assure optimal connections in both the Swiss and European timetable systems. In the same time, in the built-up areas, the regional rail system (TILO) will cut journey times to half of today's duration.

Report "Safety in Swiss railway tunnels" of BAV (Swiss traffic state authority) from 2001 shows that safety in the railway traffic is considerable bigger then safety in the road traffic. Although the probability of an accident in the railway tunnels is small, the consequences of the damages are massive and the rescue conditions, especially in the long tunnels, are very limited. The safety level in the newest base tunnels in Swizerland meets requirements of the European high-performance traffic routes.

This paper deals with the concept of the tunnel safety and fire protection system for Ceneri Base Tunnel based on the experience of the AlpTransit Gotthard. To meet fire protection requirements, the safety and protective measures have to be defined. These measures include railway facilities, ventilation system, drainage and tunnel structure. The focus of this paper is on the requirements for the fire protection of the tunnel inner lining.

1 CENERI BASE TUNNEL

The Ceneri base tunnel stretches from Vigana in the north to Vezia in the south. It consists of two parallel single-track tunnels which are linked by cross passages approx. every 320 meters. The rock cover of the tunnel is 400–800 m in the north and approx. 100–300 m in the south, see Fig. 1/Fig. 2.

The tunnel is embedded in the crystalline bedrock of the Southern Alps. The zone is complex and heterogeneous, which consists of various geological rock layers. Bedding of different rock formations runs inclined to the tunnel axis, see Fig. 1. The axis-center distance of the 2 single-track tunnels is approx. 40 m. Multifunctional analysis has shown that this tunnel system is the most suitable for long alpine tunnels. The Sigirino intermediate point of attack represents the central logistic base for the construction of the tunnel. It mainly embraces the Sigirino access tunnel (2.5 km), and the existing Sigirino exploratory tunnel (2.9 km), as well as the installation caverns located at the foot of the access tunnel.

The Sigirino access tunnel represents the main opening for the excavation of the installation caverns during construction phase and in the operation phase will be used for ventilation purposes. The installation caverns will be excavated in part sections by drill and blast method. Sigirino access tunnel will be excavated by open TBM. The main tunnels will be driven from the installation caverns in both directions. The Ceneri north tunnel section will be excavated by drill and blast method.

The southern section of the tunnel will be driven parallel with the construction work in the northern part of the tunnel. The south tunnel tubes will be excavated by drill and blast method over a distance of approx.

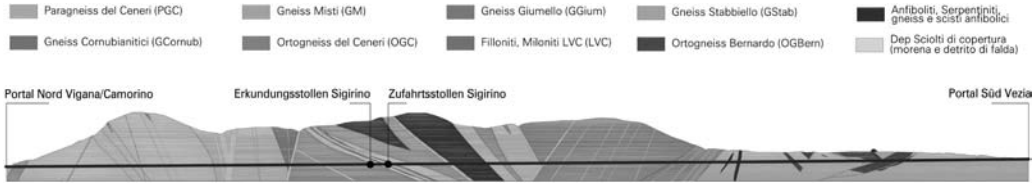

Figure 1. Geological longitudinal section.

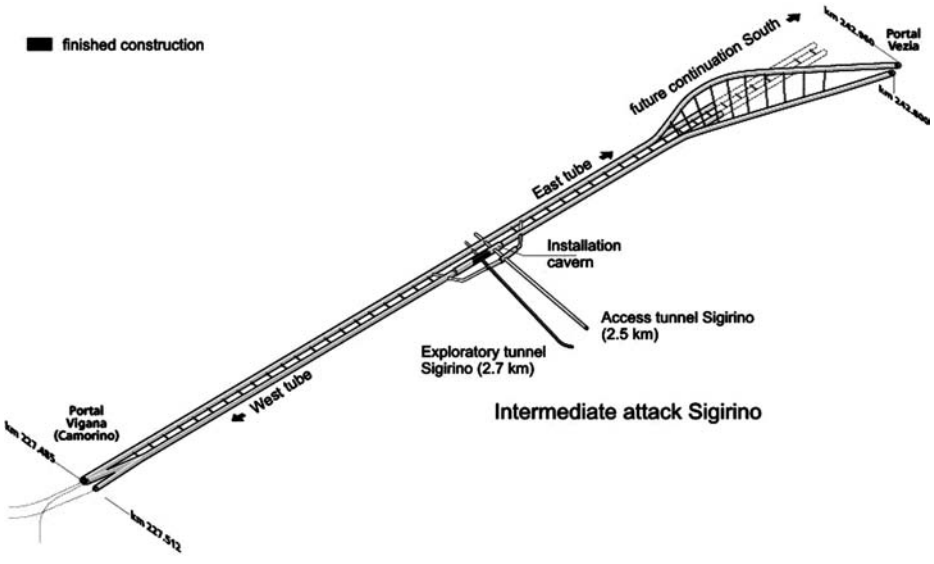

Figure 2. Ceneri base tunnel, length 15.4 km.

2 km to "Linea Val Colla" (LVC, approx. length of 600 m), one of the most geological challenged zones of the entire Ceneri Base Tunnel. The section after LVC will be excavated by TBM. The bifurcation caverns in Saré are located approx. 2 km from the southern portal, which provides the prerequisite for a future extension of the AlpTransit line to the south, in direction Milan, see Fig. 2.

2 PURPOSE AND FOCUS OF THIS PAPER

The aim of this paper is to provide a better understanding of a tunnel safety and fire protection design of the long railway tunnels. The following subjects will be discussed:

- Tunnel safety concept,
- Fire protection concept,
- Use of the fire protection standards,
- Fire scenarios,
- Concrete behavior during the fire,
- Requirements for the fire resistant inner concrete lining

3 SAFETY CONCEPT

The main elements of the Ceneri Base Tunnel are shown in figure 2.

The tunnel system is based on a twin tube system. Tunnel tubes are connected by cross passages approx. every 320 meters.

In emergency case the passengers can escape through the cross passages to the opposite tube where the evacuation measures from the tunnel take place. It is not planed to use the access tunnel in Sigirino for evacuation purposes. Since the evacuation of the passengers in an emergency case is based on the rail transport, the access route in the opposite tube must be free. To control traffic in the tunnel in the regular and incident mode, the Ceneri Base Tunnel will be equipped with modern signaling system.

In case that the burning passenger train can't reach the portal and has to stop in the tunnel, following operational regulations have been defined:

- All trains outside the tunnel have to be stopped before they enter the tunnel,
- Trains in front of the incident train leave the tunnel with normal speed,
- Trains behind the incident train have to be stopped immediately,
- Speed of the trains in the opposite tube is reduced generally to 80 km/h,
- Evacuation of the passengers is carried out using a rescue train in the opposite tube.

4 REQUIREMENTS FOR FIRE PROTECTION CONCEPT

The fire of the passenger or freight train in the Ceneri Base Tunnel can cause large damage of the tunnel structure following by extreme costs of the renovation works. Service breakdown in one or both tunnel

tubes can last several months. This subject have been analyzed by the safety department of the AlpTransit over the last years and following main requirement is defined: "During fire of the passenger or freight train in one tunnel tube, the operation safety in the other tube shall be as high as realistically possible."

Additional to this main requirement following requirements are defined:

– Availability during fire (passenger safety): The safety of the passengers during the fire has to be ensured. The tunnel must be in the service until the evacuation of the passengers is finished (compelling criteria).
– Availability after fire: A service breakdown of the tunnel shall be as short as possible.

5 CONSTRAINTS

5.1 *Availability during fire*

Following requirements for the availability during fire are determined:

a. Fire of the passenger train: availability of the accident tube: 45 min
b. Fire of the passenger train: availability of the opposite tube: 90 min
c. Fire of the freight train: availability of the opposite tube: 90 min

First requirement ensures that the passengers leave the burning train and accident tube through the cross passages. This requirement is valid for tunnel areas in the accident tube near to the source of fire. In these areas, explosive spalling of the concrete elements is not allowed.

Second and third requirement ensure that the trains, which are located in the tunnel and not affected by the fire, can leave the tunnel without damage, including evacuation of the passengers from the burning train. These requirements can be also applied for tunnel areas in the accident tube which are not in the immediate vicinity of the source of fire.

5.2 *Availability after fire*

In regard to reduce total renovation costs, protecting measures have to ensure that after fire, service in at least one tunnel tube begins as soon as possible. Evaluation of the protecting measures is based on their efficiency and costs.

The conditions for the service of the one tunnel tube after fire are determined as follows:

– Passenger traffic in not affected tube is possible if the ventilation system is in the service; one or two cross passages and the accident tube in the area of these cross passages may not be available.
– Freight traffic in not affected tube is possible when maximum four cross passages or ventilation system are not in service. It is not allowed to use an accident tube in the area of the damaged cross passages.

6 APPLICABILITY OF STANDARDS

The temperature-time curves for the case of the burning passenger or freight train in the long railway tunnels are not yet developed and standardized. Therefore, safety department of AlpTransit developed own temperature-time fire curves which are used for the fire protection design of Gotthard and Ceneri Base Tunnel. These temperature-time fire curves widely correspond to the international standardized curves, but they show longer duration of the fire.

– Fire of the passenger train with maximum value of the fire power* of 40 MW,
– Fire of the freight train with maximum value of the fire power* of 250 MW.

*The actual fire is described in terms of the rate of heat (or "fire Power") expressed in Mega-Watts (MW) which depends upon the rate at which the combustible materials burn. For example, in a tanker, the fire power depends very much upon the opening produced by an accident through which the fuel leaks, as well as on the capacity of the tunnel drainage system.

7 FIRE SCENARIOS

Following assumptions for the calculation of the fire temperature are defined:

– Basic air flow in tunnel is 2 m/s in the direction of travel,
– When train stops, the fire is already developed (20 min after begin of fire),
– Train burns down from the end to the begin of the train composition,
– Passenger train has 10 cars (250 m),
– Freight train has 32 cars (750 m),
– Temperature is evenly distributed in the tunnel cross section (simplified assumption).

7.1 *Fire of passenger train*

Maximum fire power is 40 MW. The source of fire is 125 m long (a part of the burning train). Each part of the train is exposed direct to the fire for 120 min and after 6 hours entire train is burnt down. A reverse current of the hot air is not expected, whereby, upstream of the source of fire, the air will be not heated. Downstream of the source of fire, the air will be cooled down through the heat exchange with the tunnel wall.

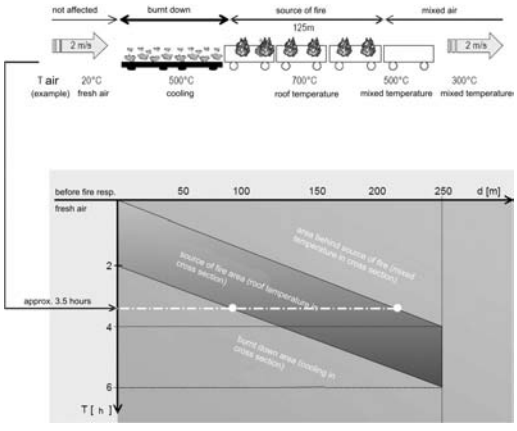

Figure 3. Assumption of the fire of the passenger train.

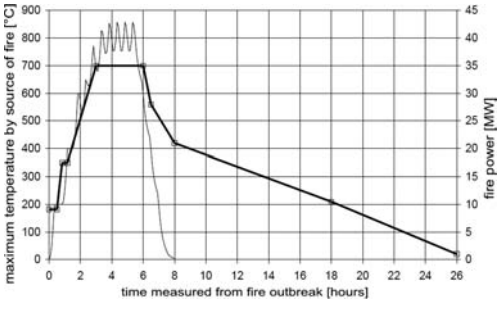

Figure 4. Maximum temperature of the passenger train by the source of fire incl. cooling. Right scale and fine diagram curve: fire load based on the fire standards.

Figure 4 shows a temperature flow in the tunnel cross section in the source of fire, in case of passenger train fire. During 6 hours, the source of fire moves along the entire train.

7.2 *Fire of freight train*

Maximum fire power of 250 MW will be used for all kind of freight trains, incl. the trains transporting dangerous materials. The source of fire is 200 m long (a part of the burning train). Each part of the train is exposed direct to the fire for 45 min and after 4 hours entire train is burnt down. Hot air can flow back 150 m against the basic air flow. Further upstream, the air will be not heated. Downstream, 25 m behind the source of fire, the air will be cooled down through the heat exchange with the tunnel wall.

Figure 6 shows a temperature flow in the tunnel cross section in the source of fire, in case of freight train fire. During 4 hours the source of fire moves along the entire train.

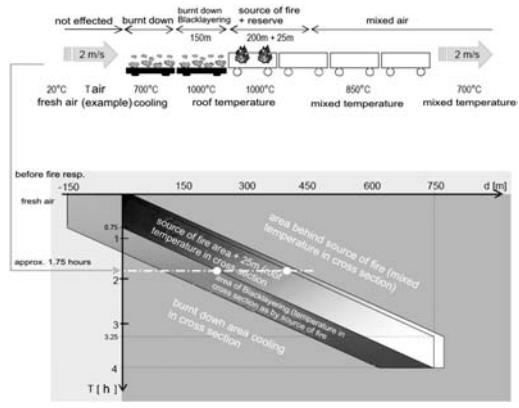

Figure 5. Assumption of the fire of the freight train.

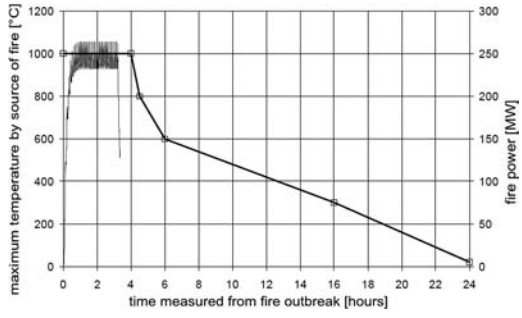

Figure 6. Maximum temperature by the fire of the freight train by the source of fire incl. cooling. Right scale and fine diagram curve: fire load based on fire standards.

8 CONCRETE BEHAVIOUR DURING FIRE

Fire impacts upon concrete structures insofar as it generates a heat flow into the concrete's exposed surface, producing temperature, moisture and pore pressure gradients within the concrete mass. Thermal strains, stresses and cracking develop within the heated structure and explosive spalling of the concrete takes place. The concrete and steel, as well as the bond between them, experience strength losses.

There are two problems of concrete in fire. These are: deterioration in mechanical properties as temperature rises, caused by physicochemical changes in the material during heating; and explosive spalling, which results in loss of material, reduction in section size and exposure of the reinforcing steel to excessive temperatures. Consequently, both the separating/insulating and load-bearing functions of the concrete member could be compromised.

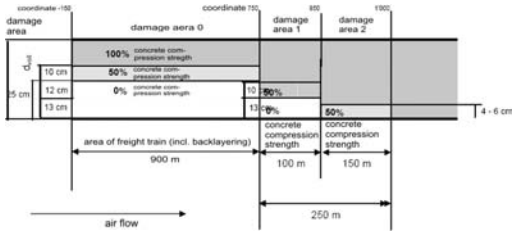

Figure 7. Damaged model of the concrete element without fire protection.

Table 1. Simplification of the damages in different areas of the concrete element.

Damage area	Distance (m)	Destroyed (cm)	Damaged (cm)
Area 0	−150 to +750	25	10
Area 1	+750 to +850	13	10
Area 2	+850 to +1000	0	5

8.1 *Concrete failure model without fire protection*

Explosive spalling:
Explosive spalling takes place when the concrete reaches temperature of 180°C. Based on the temperature-time fire curve and progress of the source of fire, the concrete element in the area up to 100 m downstream of the burning freight train, will be heated to 180°C in 6 cm concrete depth.

Strength loss:
By temperature of 380°C, the concrete strength decreases, caused by physicochemical changes in the material. Based on the temperature-time fire curve and progress of the source of fire, the temperature of 380°C occurs in 10 cm depth of the concrete element. Damaged model of the concrete element without fire protection measures is shown in Figure 7.

Damaged model:
Damaged model of reinforced concrete:
– Concrete cover of 5 cm is assumed,
– Explosive spalling will occur in the depth of the reinforcement,
– Reinforcement will be badly damaged (strength loss caused by high temperature),
– Damaged reinforcement stabilizes first fully weakened concrete layer, which ensures the thermal isolation of the underlying concrete layers,
– Strength loss and destruction influence can not go deep into the concrete element,
– Behind the reinforcement, first concrete layer of 10 cm is 100% and following 10 cm, 50% weakened.

Temperature- time process in source of fire:
(a) 45 min. after begin of the fire:
  – Heating of the concrete surface to the temperature of 930°C. With temperature rise of 3°C/min, the critical limit of the explosive spalling will be reached in 10 cm depth of the concrete element. In humid environment and under consideration of the progressive damage of material, 10–15 cm deep explosive spalling occurs in non-reinforced concrete areas,
  – Temperature of the inner reinforcement (in the areas of the fault gauges and by the cross passages) is min. 450°C (causes a significant strength reduction in the reinforcement).

(b) 90 min. after begin of the fire:
  – Temperature on the concrete surface is still approx. 900°C,
  – In 6 cm depth of concrete element the temperature reaches max. value of 500°C,
  – In the depth of 10 cm is the temperature approx. 270°C (still rises). It comes to the additional spalling, indeed with lower intensity as in the first 45 min. Total spalling is in the range of 10–20 cm. It comes to significant strength reduction in the following 5 cm of the remained structural concrete,
  – Temperature in the area of the inner reinforcement exceeds 600°C and the reinforcement shows only an insignificant bearing capacity.

(c) 16 hours after begin of the fire:
  – Slow cooling to the temperature of 250°C in the whole concrete cross section,
  – Additional spalling of the weakened area as a result of the temperature expansion,
  – After cooling: Strength loss as a result of the spalling in the whole cross section of the non-reinforced concrete element. In the reinforced areas, demolition of the concrete, caused by spalling, will be reduced (presence of the reinforcement).

(d) Banquets and cable protection pipes:
  – Cable protection pipes located in the banquets are exposed to the temperature of 150°C after 45 min. and to the temperature of 280°C after 90 min. The cable protection pipes have no fire protection function.

9 FIRE TESTS

Objectives of the fire tests are to:
– verify assumed depth of the spalled and weakened areas of the concrete lining in consideration of the project specific constraints incl. high compression stresses in the concrete element section,

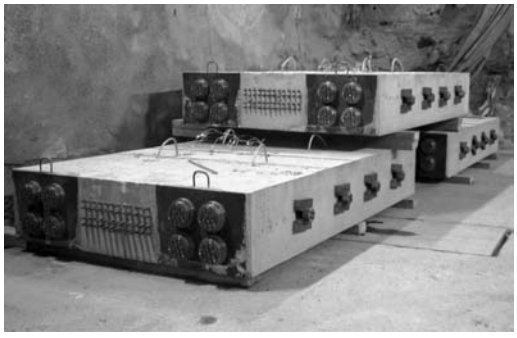

Figure 8. Test samples for the fire tests.

– optimize concrete cover in the bending tension stressed structural member,
– determine the temperature spread in the concrete cross section in order to verify used calculation models,
– optimize the concrete mix (aggregate, cement, W/C factor, mixing time,…),
– determine fire protection measures.

10 CONCLUSIONS

With planned fire protection concept described in this paper, the key principles of the safety philosophy related to the Ceneri Basis Tunnel can be achieved.

General requirements for the fire resistant concrete:

– Fire resistant concrete must have the same mechanical characteristics as a conventional concrete. Strength, strength development, long-term behavior (shrink, creep), frost resistance, tightness have to comply with given requirements,
– Fire resistant concrete must show high fire resistance, i.e. concrete may not show tendency of production of the deep spalling, based on the fast increasing and longer acting of the heat ($>1000°C$).

Special requirements:

Concrete strength:
Fire resistant concrete must reach the strength characteristics given by the Engineer based on the structural requirements.

Heat penetration after 45 minutes:
During the fire tests it has to be proven, that at the minimum cover depth (5 cm), the temperature after the first 45 minutes of fire exposure will not exceed 350°C.

Explosive spalling:
During the fire tests explosive spalling of the fire resistant concrete isn't allowed. After the fire tests the maximum depth of the concrete spalling should be at maximum 3 cm.

Cracking, resp. concrete surface condition after the fire:
Based on the temperature-time fire curve of the AlpTransit, the concrete surface after the fire has to be solid ("knockproof"). Cracking has to be fine distributed (crack size max. 0.3 mm). In the next 24 hours after the fire tests the concrete surface may not be changed.

Newest issues of integrated road urban tunnel fire protection system

N.F. Davydkin
INTERSIGNAL Scientific/Production Coordination Centre, Moscow, Russia

S.N. Vlasov
Russian Tunnelling Association, Moscow, Russia

ABSTRACT: Brief analysis of fire danger, fire load quantitative and qualitative indices, ignition sources, fire temperature regimes, as well as time needed to safely evacuate people from the tunnel is provided in the article. Integrated road urban tunnel fire protection system developed in INTERSIGNAL and discussed in the article consists of the following sub-systems:

– fire prevention;
– passive fire protection;
– active fire protection;
– management and technical measures;
– fire liquidation and people rescue by operative teams.

The system makes it possible to duly provide for the safety of people, to preserve material values, to reduce fire risks and to liquidate fires at minimal losses.

In spite of considerable progress, contemporary engineering does not have absolutely safe construction and operation techniques or methods and means that would make it possible to forecast certain probable emergency situations determined as outwardly sudden events characteristic with uncertainty and difficulty of decision-taking and associated with sharp conflicts and stresses experienced by people, with social, ecological and material losses, especially life losses, resulting in considerable manpower, material and time expenses required to carry out evacuation and rescue activities and to liquidate the catastrophic consequences.

In case of fire in a road tunnel, transport vehicles, steel structures and equipment of the works become metal thrash. Structural components including tunnel lining (steel, reinforced concrete, etc.) get broken, loose their carrying capacity and collapse. This is particularly dangerous in case of urban tunnels running under existing structures, since tunnel collapse may result in forming a major surface cavity with catastrophic consequences (Davydkin et al. 1998; Strakhov et al. 2000; Koshmarov 2002; Haak 1999; Welzig 2000).

Well known are tragic consequences of fires in Baku metro (1995), under Mont Blanc 25 March 1999, in Capron funicular tunnel (11 November 2000) with more than 150 lives lost, in the approach part of the Freju tunnel (28 May 2001), in the 17 km long Sent Gotthard tunnel (24 October 2001) (Domke 1999).

Any fire in a tunnel results in operation of the whole transportation system of an urban region, a major city or even a country's part paralysed.

It is a strategic task to provide for safety of the people, for normal operation of road underground tunnels in major cities.

Since tunnels are long confined space structures of variable depth containing a good deal of flammable substances and materials as well as various ignition sources, they are much more dangerous in terms of fire rise and development in comparison with surface highways.

In case of a jam at the tunnel exit, quantities of flammable materials concentrated. In the space of a 3 km long three-lane tunnel, and attributed only to cars (6 m long with intervals, no gas vehicles) will make as follows (Davidkin et al. 2004; Davydkin 2002; ADAC 2000; Brux 1999):

– petrol: 61200 l;
– flammable liquids: 15300 l;
– rubber: 91800 kg;
– plastic: 30600 kg;
– synthetic materials: 61200 kg.

The figures may increase provided mixed traffic is taken into account.

As a matter of fact, tunnels are huge underground storages of easily ignitable liquids, flammable substances and materials with each vehicle being a bomb stuffed with incendiary mixture ready to ignite or blast any moment.

In case of fire, burning temperature of easily flammable liquids, plastic and other materials may reach 1100–1300°C an to last for a long time (up to 2–3 days) (French-Italian Commission 1999). For people happened to be in the tunnel, the situation becomes critical in 3 to 5 minutes from the moment of fire beginning (Shoigu et al. 1997; Grushevski et al. 1985), the figures determining the required people evacuation time.

Given the above mentioned temperature levels, it becomes practically impossible for emergency and rescue teams to enter the tunnel to liquidate the fire, provided this was not stipulated by design solutions beforehand.

Smoke escaping in the course of fire contains up to 70 types of chemical compositions poisonous for people (Shoigu et al. 1997; Davydkin et al. 1997 a, b, c, d, e; Toudos 2001; Day 1999).

Professor Pokrovsky and other researchers have established that combined impact of temperature and toxic gases to people increases as temperature rises. Carbon dioxide toxicity increases as fume and humidity of the environment rise resulting in synergic effect when combined impact of the factors exceeds that of the same individual factors.

Psychologically, the impact of fume is expressed in the form of fear people experience to enter into the visible fume environment.

If traffic jam gets formed at the tunnel exit, minimal number of people present in the vehicles and subject to be evacuated in case of fire will make approximately 2 thousand. This is why provision for people safe evacuation in case of man-induced catastrophes and fires in road tunnels is of priority while taking fire safety design solutions. Given psychological condition of a person facing emergency situation, the process proves to be fairly challenging.

Vitality of fire safety issues for operation of road tunnels determines the fact that in the course of their design and construction, sophisticated engineering solutions should be developed.

Having examined respective standards and codes of practice effective in Russia, USA (*Fire Protection Engineering*, SPPE, 2002), France, Germany, Italy, Switzerland, Japan, etc., and having generalised practical world experience gained in the course of road tunnel design, construction and operation, INTERSIGNAL RPCC supported by Russian Tunnelling Association and research and design companies developed an integrated road urban tunnel Fire Protection System (FPS) (Davydkin et al. 1999; Davydkin et al. 2000; Davydkin 2001; Davydkin 2002; Davydkin et al. 2002; Davydkin et al. 2004). Authors' rights for FPS integrated system development are protected.

FPS is an amalgamation of different interrelated most complex engineering solutions grouped in the following individual sophisticated autonomous systems: Fire Prevention System, Passive Fire Protection System, Active Fire Protection System, Management and Engineering Measures System, Fire Fighting and People Rescue System.

Described approximately, Fire Prevention System provides for elimination of one of the three main fire causes (that is for prevention of forming any fire situation), i.e. combustion and ignition sources, fire load (flammable substances and materials), entry of oxygen or other oxidizing agent. This is a very brief explanation of a broad complex of fire prevention and protection measures. Among subsystems there are:

- prevention of forming an inflammable environment;
- prevention of forming ignition sources in inflammable environments;
- elimination or restriction of oxidizer to inrush;
- making it inadmissible to arrange A and B fire/blast danger category premises in tunnels;
- gas (CO, CO_2, NO_3, etc.) control;
- lightning protection for buildings and structures.

Passive Fire Protection System is optimised for design and estimation documents made at various project development stages by all design process participants (Client – Designer – Examination body – State supervision bodies – Contractors).

PFPS comprises a complex of technical fire-protection solutions and determinations related to architectural and structural parts of the design including:

- solutions related to plans and master plans;
- solutions related to external water supply for fire-fighting needs;
- transportation and pedestrian flow ways;
- fire-protection space and plan parameters;
- allowable area of fire niches and sections;
- required (normative) and actual fire-resistance properties of tunnel structures;
- fire-protection membranes;
- blast-protection measures;
- integrated smoke-protection measures;
- fire-fighting technical measures;
- structures and plans of evacuation ways/exits/emergency staircases;
- fire-protection power-supply technical measures;
- distribution and transformer substations;
- continuous power supply facilities.

Calculation of fire resistance and fire protection properties of tunnel structures is a key fire safety

factor, since structures used for road tunnels at present are usually large and complex in terms of their design and space form.

For example, fire-protection technical solutions to be taken while developing plans and master plans will relate to:

- tunnel alignment;
- junctions to rail projects as well as to coach terminals and to parking lots;
- availability and parameters of: gas pipelines and underground reservoirs;
- oil product pipelines grouped to those carrying quickly inflammable, carrying inflammable liquid products or raw oil;
- other objects dangerous in terms of fire and blasting;
- underground storages of liquefied gas/flammable liquids/oil/petrol stations' tanks;
- other product pipelines;
- special-purpose underground works;
- other strategic utilities;
- routes of emergency and rescue teams.

Active Fire Protection System **(**AFPS) is an information and management part of FPS used to automatically implement the functions, examine information parameters, take adequate decisions on fire detection and warning subsystems, warn people on the fire and manage their evacuation from the tunnel, exercise running of integrated smoke-protection and automatad fire-fighting systems operated on the basis of foam, water, powder or gas devices.

Three priority levers are distinguished in AFPS Automated Management System (AMS) (Topolski 1997):

- top priority is given to subsystems providing for fire and blast prevention and to those responsible for continuous/discrete operation of the automated management system;
- first priority level is attributed to subsystems providing for safety of the people, of the project and of the personnel of emergency and rescue teams;
- second priority level is attributed to subsystems responsible for fire and blast safety of individual premises and works, provided their putting out of operation results in no catastrophic consequences and no danger for people.

Algorithm and software shall be developed for each subsystem, integrated algorithm and integrated software being developed then for AFPS AMS on the whole.

Central AFPS AMS remote control desk usually placed in the central master station together with AMSs for life-support and for road tunnel operation is a sophisticated complex of engineering and technical devices centrally operated in automatic regime.

Here is a list of main AFPS subsystems:

- automatic fire detection and warning;
- TV supervision over transportation and tunnel safety zones;
- people warning and evacuation from transportation and tunnel safety zones;
- telephone and radio communication of emergency and rescue teams;
- management of integrated smoke-protection system;
- internal fire-fighting water pipeline/taps;
- automatic foam fire extinguishing in the tunnel traffic carriageway space;
- drainage of water used for fire-fighting;
- automatic gas-type fire extinguishing in service premises;
- automatic powder fire extinguishing into power cable pipelines;
- aerosol fire extinguishing;
- robotic fire-fighting devices.

Management and Engineering Measures System comprises several algorithms and software sets developed and used to integrate AFPS AMS with other AMS (life-support, traffic control, unsanctioned approach, etc.) as well as with other algorithms, texts, manuals, maintenance schedules, etc. Other main components of the system are listed below:

- AFPS subsystems operation manual;
- testing and maintenance schedules for AFPS subsystems;
- technological automatics;
- manual on fire safety measurements;
- creation of fire safety supervision committees;
- creation of voluntary fire-fighting teams;
- instructive documents on fire danger.

Fire Fighting and People Rescue System serves as basis for mathematic simulation of parameters of probable fires in road tunnels and for two-dimensional calculation of fire areas at different points along the tunnel alignment. The calculations make it possible to assess tactical capabilities of fire-fighting teams and rescue services as well as to determine the types and the number of special equipment and the number of personnel required to extinguish the fire (Broushlinski et al. 2000). The fire liquidation and people rescue system makes it possible to comply as much as possible with recommendations regarding development of fire fighting and people and valuables rescue plans.

The system of liquidation of emergency events and fires and people rescue by efforts of mobile subdivisions consists of the following basic components:

- operative extinguishing plan;
- people rescue plan;

– provision for people rescue technical solutions and means;
– provision for fire fighting technical solutions;
– interface between fire-fighting teams and traffic police services while fighting the fire;
– automatic redistribution of traffic flows;
– automatic and remote control of traffic flows using traffic lights;
– restriction to park vehicles, to place equipment and devices near fire hydrants and tunnel exits;
– interface with other emergency and mobile services in conformity with fire-fighting plans.

The integrated FPS system developed by INTERSIGNAL SPCC has been approved in the course of design, construction and operation of the Volokolamsky, Kutuzovsky, Soushchevsky and Gagarinsky road and rail tunnels as well as the Lefortovo complex of the deep tunnel and the tunnel/viaduct route options.

Professional interest has been shown towards the integrated FPS for road tunnels on the part of leading foreign specialists in tunnel design and construction.

At present, INTERSIGNAL SPCC cooperates with many foreign companies in examining fire-protection technical solutions needed to provide for the safety of people and property in existing and future tunnels in Europe.

The integrated approach makes it possible to bring design, assemblage and start-up of a fire protection system of the whole project to higher standards, to duly provide for safety of the people and safe-keeping of the property, to optimise the expenses, to diminish the risk of catastrophes and to liquidate their consequences at minimal loses if occurrence took place in an operated tunnel.

– Taking into account the major functional aim of the integrated fire protection system, its importance in terms of provision for the safety of people and the works on the whole, the multidirectional nature of the tasks, the complexity of its social and engineering instruments, the authors are well aware of the fact that it is hardly possible to cover the problem in a single article.

Creation of advanced technologies in the generation of electrically safe flows of finely dispersed water for fire protection of underground installations

A.S. Chirko
"Mosinzhproekt", Moscow, Russia

A.V. Karpyshev & M.D. Segal
The Research Institute of Low Temperatures at the Moscow Aviation Institute (NIINT), Moscow, Russia

ABSTRACT: Specificity of fires in underground installations provides rigid requirements to fire fighting systems: fire extinguishing agents must be safe to people, fire fighting system shall provide a quick temperature drop and combustion products precipitation, fire suppression must not result in flooding of installation and engineering compartments. Special attention should be paid to fighting fires in alive electrical equipment which is of great importance for cable collectors and underground subway installations. Experts believe that the most effective way of fire fighting in specific conditions of underground facilities is use of finely dispersed water. Moscow specialists have made fundamental investigations in the field of generation of finely dispersed flows and experimental study of their conductivity on special electric stands. As a result of these researches, the advanced fire fighting systems based on finely dispersed water have been successfully tested and implemented, among them there are portable units and fire extinguishers for alive electrical equipment.

Improvement of city underground infrastructure safety system is aimed at fighting of technogeneous disasters and mitigation of high fire risk related with possibility of massive deaths, failures of city life support systems and transport communication lines.

Fires occurring at megapolis underground installations are especially hazardous. They are characterized by fast temperature growth, lockout of evacuation ways from underground facilities, adjoining ground areas and buildings by toxic combustion products, structural damage and their possible collapse.

Specifities of underground installation fire impose strict requirements to fire extinguishing systems: extinguishing agents shall be safe for people, fire protection systems have to ensure fast temperature decrease and combustion product deposition, fire extinction shall not result in installation and engineering room flooding. Special attention should be paid to a possibility of extinguishing live equipment, which is very important for metro cable collectors and installations.

According to expert opinion, atomized water application is one of the most efficient ways to extinguish underground infrastructure items. Specialists of Moscow Aviation Institute made fundamental research of atomized water flow generation, determination of their extinguishing capacity and dielectric test performance at special authorized electric test bench. On the basis of these investigations, they developed, successfully tested and reduced to practice advanced atomized water fire protection systems, both portable and mobile, able to extinguishing live equipment.

United metro tunnel network, high day and night passenger traffic that makes about 40% of the total city population results in dramatic negative consequences escalation caused by fire, electric trains tunnel blocks , and passenger evacuation prior to megapolis transport collapse.

Fire evolution in metro train carriages, at passenger platforms, escalators, railways and metro installations of vital importance is characterized by the following features:

- space restriction, great number of people present, and passenger evacuation difficulties caused by the above reasons;
- high degree of general fire load different for every carriage series exceeds 50 kg/m^2 and may include a great amount of materials releasing toxic combustion products;
- great number of $\sim$10 kV power cables in metro tunnels;

– presence of live equipment fastened on metro trains;
– impetuous temperature growth up to thousand degrees and even higher; actually in 3–5 min after a fire starts, the situation for the people becomes critical, therefore several hundreds of people have to be promptly evacuated from the tunnel;
– possibility of fast spread of smoke over the evacuation ways and the metro underground space;
– great difficulties and sometimes impossibility to deliver extinguishing agent supply to the underground installation fire;
– possibility of general panic arising among passengers.

Smoke pollution is admitted to be the major hazard for metro passengers in case of fire. People, as a rule, die of asphyxia and intoxication with combustion products dangerous for breathing.

As it has been already mentioned, the specificity of fires in underground installation and tunnels puts strict requirements at extinguishing systems:

– extinguishing agents applied in carriages, passenger platforms and escalators shall be safe for the people;
– fire-fighting system shall provide fast operation including tunnel traffic lockout;
– fire protection system shall ensure people's safety on trains, at platforms and escalators;
– fire protection system shall provide fast temperature decrease and combustion product fall out;
– fire extinction technique shall not result in flooding of metro tunnels, cable cradles and engineering rooms;
– fire protection system shall lockout smoke release areas, absorb smokes and fire heat emission;
– negative consequences of false actuation shall be negligible.

Similar problems are typical for other megapolis underground infrastructure items – motor transport tunnels, particularly of great length, underground parking lots, and trading centers.

Higher degree of fire hazard and difficulties of people evacuation from the city underground transport systems and metro facilities require fast operating and highly efficient fire protection system, safe for the passengers operating staff, and environment.

Atomized water fire protection technology application allows to extinct fires with utmost efficiency, faster operation and minimum water consumption. The greatest advantage of these systems is fire extinction with no current shutdown.

On the basis of the latest aerospace technology achievements, specialists of Moscow Aviation Institute developed efficient atomized water fire protection technologies superior to prior art devices and designed number of functioning well-proven units .

At present, there is some experience of implemention of atomized water in fire protection systems design, manufacture and service as part of automatic, portable, mobile and fixed fire extinguishing systems protected by dozens of patents issued in industrial countries of Europe, the USA, and Japan.

In recent years, a backpack firefighting unit RUPT-1-0.4 designed at the Institute for timely suppression of solid combustible, inflammable liquid and gas fires as well as live equipment fires has come to light.

Functioning of the unit is based on gas dynamic principles of atomized two-phase water-and-air flow acceleration, with an average water droplet diameter of 100 microns that allows to suppress fires fastly and efficiently.

The unit features small dimensions and modest weight (its gross mass is less than 20 kg); it is easy and reliable in service, always ready for operation. The extinguishing liquid is water or water and additives of about $9 \cdot 10^{-3}$ m^3 capacity. The unit operation is activated by pressurized air bottle of 30 Mpa operating pressure and $2 \cdot 10^{-3}$ m^3 capacity used in fire fighters' breathing systems. The RUPT unit operation is particularly efficient for suppressing fires in metro tunnels and engineering communication collectors. A curtain of fine water spray allows to block a smoke-filled area of up to 4 m diameter in the tunnel and ensure fire fighters' way to the fire. The second mode of extinguishing agent delivery allows to obtain atomized water jet up to 12 m long.

While running unit approval tests in Russia and abroad, it was confirmed that the unit could be used for the following purposes:

– Class 55A solid combustible fire extinction (under EN-3) that corresponds to fire area of approximately 60 m^2 including smoldering fires;
– Class 233 B inflammable liquid fire extinction (petrol, kerosene, heptane, different oils, etc.), herewith in the course of the unit approval tests it was shown that $9 \cdot 10^{-3}$ m^3 water and foam capacity was sufficient to extinguish about $200 \cdot 10^{-3}$ m^3 of burning petrol or heptane;
– up to 36V live equipment fire extinction from the distance of more than 1 m (approved by a jet breakthrough test at special electric test bench).

These features of the system make its application highly promising for underground infrastructure installations due to the following effects obtained:

– timely beginning of the fire suppression prior to fire crew arrival;
– exclusion of tunnel or any other room flooding by great quantity of water and complete avoidance of collateral damage;

– extinguishing of fire with personnel present in the fire area;
– extinguishing of fire with no voltage preswitched off.

Special firing tests conducted showed that a burning car was completely suppressed within 165 seconds by $3{,}5 \cdot 10^{-3}$ m^3 of extinguishing liquid only.

On the basis of statistical data on fire area by the moment of fire crew arrival, we may believe that 90% of all fires may be successfully suppressed by RUPT unit allowing to avoid great damage to property.

The design was patented in several industrially developed countries of the world, awarded Golden Medals at the 49th World BRUSSELS-EURIKA-99 Exhibition and the 28th International Exhibition (April 2000, Geneva), and the Prize of Government of Russian Federation for the year 2000. License for its manufacture was bought in Germany.

One of the latest designs is an air-emulsion extinguisher generating a jet of atomized extinguishing agent (EA) for timely suppression of initial comparably small fires.

Extinguisher EA capacity ($6 \cdot 10^{-3}$ m^3) is sufficient to suppress Class 34À fire under EN-3 (burn area is about 32 m^2) or Class 183B fire (approximately 180 litres of any inflammable liquid on a 2,7 m diameter tray). The gross weight of this extinguisher is 9 kg. An atomized EA jet range is 5–7 m, liquid flow rate is $0{,}3 \cdot 10^{-3}$ m^3/sec.

In the course of special approval tests at the electric test bench it was confirmed that the extinguisher could be reliably used to suppress Class E fires (live equipment) with the voltage up to 1 kV.

These features of the extinguisher allow to suppress such fires typical for metro and other underground infrastructure item fires as sleeper fire (including smoldering burn), tunnel cable fires as well as car fires.

To confirm a possibility of reliable extinguisher application for Moscow Metro installation, series of firing tests was conducted under the operating voltage on 825 V direct current rail. A kerosene cloth prepreg (50×40 cm in size) was ignited directly under the contact rail.

Fire suppression was effected by an operator at the distance of 2–3 m from the fire. The operating voltage of the contact rail at the end of fire suppression was 825 V.

In the process of test fire suppressing by the above extinguisher the operator wearing cotton gloves on his hands did not experience any discomfort related to the high voltage effect. The fire was completely suppresseds within 15 seconds.

An actually recorded atomized agent jet breakthrough value at each operating mode of the extinguisher amounted to 0,2 microampere, which is considerably less than the tolerance admitted by Russian Standards in force.

One of the most important objectives of stable functioning and evolution of a megapolis is communication collector fire protection improvement. City collectors house important communications vital for city life support, e.g., power cables, communication and telecommunication cables.

According to the current Standards, collector fire suppression may begin only on official information receipt of the voltage switch off. This procedure may take a few hours. Hence, the most actual systems are those of collector fire protection engineering design requiring no voltage switch off.

Analysis showed that special spray nozzles generating atomized water streams may serve as the above systems.

Specialists of Moscow Aviation Institute developed and tested highly efficient atomizers, their performance considerably surpassing the best foreign analogs, the application of which is desirable to consider while designing collector fire protection systems.

Apart from other systems, the spray nozzles with an operating water delivery pressure of about 8 MPa, MAI-designed highly effective atomizers operate at water delivery pressure of about 0,6–1,2 MPa and generate an atomized water stream, an average size of droplets being 150–200 mcm.

Electric tests at special test bench under the operating voltage of 36 kV showed that the atomized water jet of the above parameters had a break-through value considerably less than those admitted by the Standard requirements.

It should be noted that gas, powder and aerosol fire protection system application is very dangerous in a closed space with the people present. Atomized water application is not only efficient bur also safe for people. Fine water droplets intensively absorb heat release and adsorb chemically harmful and toxic substances, thus protecting people from hazardous fire factor effect and creating local safety areas.

In long tunnels with rare evacuation exits and joints it is advantageous to use SAFE-POINT unit that means group protection equipment in tunnel facilities. This joint development of MAI and “Mosinzhproekt” is especially efficient in the city deep tunnels as a compensation and additional safety measure designed to protect people who were not evacuated from the fire point. tests showed that the SAFE-POINT provides heat release protection from the surface area of not more than 65 kWt/m^2 and maintains oxygen contents in the protected area not less than 15%. The unit is easy to assemble, remotely and manually controlled. The SAFE-POINT is fitted with an advanced audible and light beacons system allowing to detect fire within the visual range not less than 0.8 m at the distance of

50 m. The unit is of high functional level, it may be integrated with automatic fire protection systems.

Hydraulic and fire tests of this equipment have shown their high efficiency in fire extinguishing, ability to decrease the fire temperature within the shortest possible time (of the order of a few seconds) and deposit the combustion products.

Institute for High Energy Density Russian Academy of Sciences, Moscow, Ru

ABSTRACT: Methods for physical modeling and experimental investigations for fire tunnel accident are described. Development of experimental and numerical techniques in the IHED RAS allows reproducing most part of blast and fires impacts in laboratory experiments.

Urban structure development is followed by expansion of tunnels and communications system. Fires and explosions in the communications may cause significant victims and damages. Reasons of initial fire may be very different, for example, electro explosion of conductor. Now development of experimental and numerical techniques in the IHED RAS allows reproducing most part of blast and fires impacts in laboratory experiments.

The first facility [1] consists of a diaphragm shock tube with 72×72 mm square cross section with length of 5 m., connected to a vacuum chamber (Fig. 1). This shock tube is equipped with optical windows and piezo-electric pressure transducers. Different tunnels can be angle mounted at the end of the shock tube. It is possible to obtain images in two directions of view perpendicular to each other. The post shock flow pattern can be recorded by IAB-451 schlieren device. The schlieren movie will show the time evolution of the process with intervals of 5–10 μs. The exposure is 1 μs. The single frame size is 60×60 mm^2. To obtain 72 images in one experiment, a high-speed opto-mechanical device VSK – 5, with the frame size 16×22 mm^2 can be used. New electronic device is used to obtain the high-speed digital imagines.

The detonation formation in front of the propagating flame in channel with the combustible gas mixture can be observed (Fig. 2). Flame front turbulisation leads to its acceleration and shock wave formation.

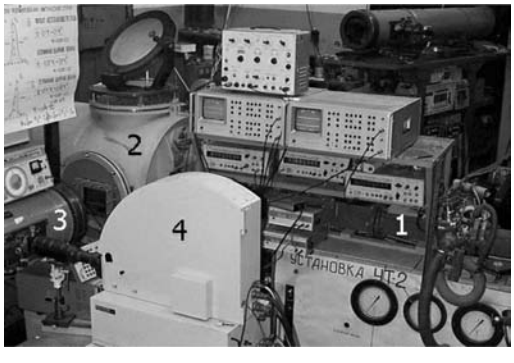

Figure 1. Experimental set up for explosion in tunnels investigation. 1 – Detonation/shock tube, 2 – Receiver/Vacuum chamber, 3 – IAB-451 schlieren device, 4 – High-speed photo-registration camera.

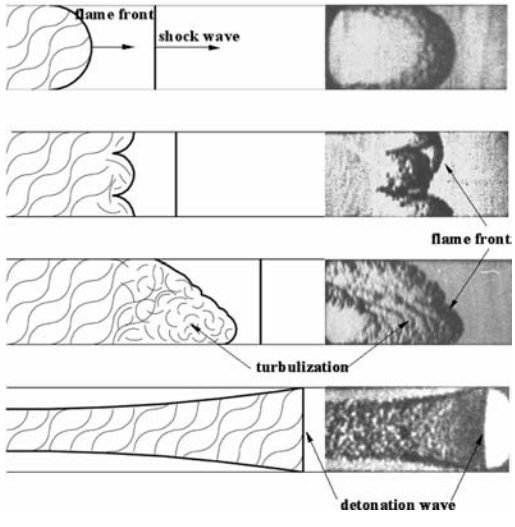

Figure 2. The detonation formation in front of the turbulent flame.

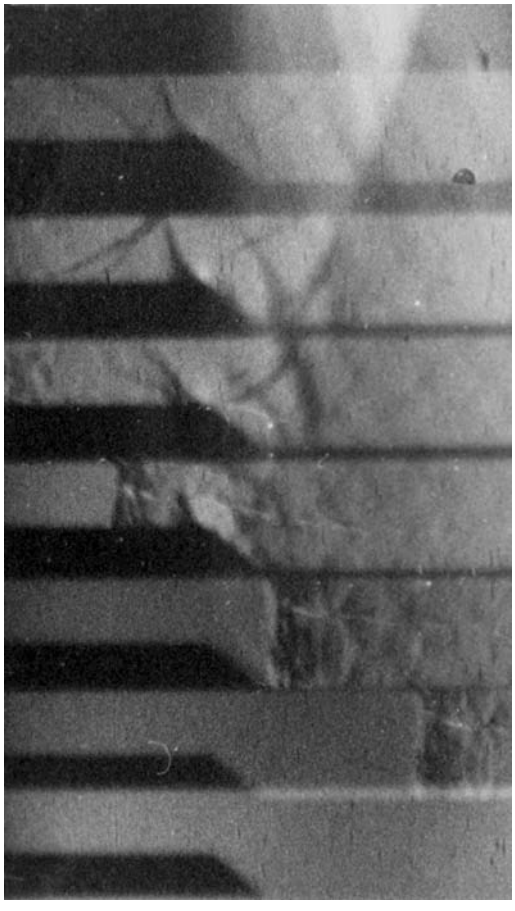

Figure 3. Gas ignition at the convex step.

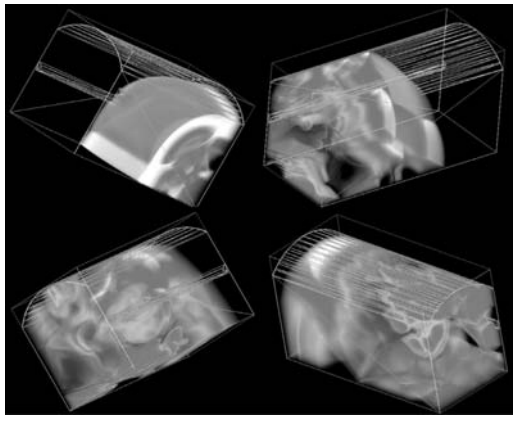

Figure 4. Pressure distribution after 3 kg TNT-charge explosion.

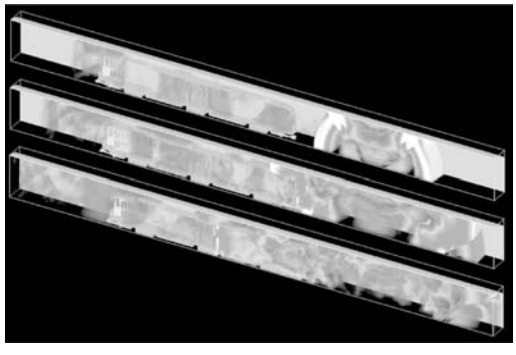

Figure 5. 3D-Pressure distribution after TNT-charge explosion in the railway tunnel.

The shock wave intensity is high enough to generate the detonation. In the channel.

The weak shock wave can initiate the detonation of the combustible mixture near the channel wall with a convex step (Fig. 3). The intensity of weak shock wave is not sufficient to ignite the gas. Near the step the reflected wave is formed, producing an additional sharp temperature rise in the gas. Ignition accompanied by bright gas glow is initiated.

The attenuation of shock wave produced by explosion of hexogen charge after sand-cement barrier destruction was observed.

The second shock tube allows us to carry out the large-scale experiments by exploding a massive charge to generate a powerful blast wave. The shock tube is of about 100 m in length and it consists of four sections with different lengths and diameters up to 5 m. Explosive charges of up to 20 kg TNT may be used for the blast wave generation. The object under investigation is located in the shock tube channel. The test complex is equipped with piezo-electric pressure transducers mounted along the wall. Moreover, the complex possesses a video observation system.

A high-performance CFD-code that provides a non-stationary 3D explosive problem solution has been developed [2].

The code allows operation with a number of explosive types: FAE (Fuel-Air Explosives), HE (High Explosives), LDE (Low Density Explosives), multiphase compositions (CHON-type fuel and metal particles).

For example in Figs. 4 and 5 the pressure distribution after 3 kg TNT-charge explosion and after TNT-charge explosion in the railway tunnel are shown. Euler equations for dilute-limit two phase flow with solid and gas phase chemical reactions are solved. There are three submodels differing by chemical reaction peculiarities of solid and gas phases: (1) metals reacting according to the type of aluminum; (2) metals reacting according to the type of magnesium; (3) metals reacting according to the type of aluminum boron.

The code is available on both SP, multiprocessor and cluster systems with Linux and Windows operating systems. The number of cells in domain is up to 50 million for a conventional PC with 2Gb of RAM. This enables calculating complex shock wave phenomena with the domain geometry close to the real one. Results of blast and fires impacts in laboratory experiments are necessary for fire and blast safety improvement of existing and projected tunnels. Also it allows designing effective emergency rescue system and elaborate new procedures of tunnels testing and maintenance directed to exploitation safety enhancement.

1 CONCLUSION

Development of experimental and numerical techniques allows reproducing most part of blast and fires impacts in confined volumes in laboratory experiments. Investigation of initial reasons of fire with following 3D-scenario of tunnel accident also is possible.

Fire test to characterize fire-induced damage of concrete lining in NATM tunnel

Soon-Wook Choi, Soo-Ho Chang & Gyu-Jin Bae
Korea Institute of Construction Technology, Goyang, Gyeonggi, Korea

Jong-Wook Kwon
NOWENG Co., Ltd., Seoul, Korea

ABSTRACT: Since the NATM (New Austrian Tunnelling Method) is the most popular tunnelling method in Korea, the fire-induced damage of the concrete lining or secondary lining should be assessed to propose the optimum fire-proofing method and the repairing method after a fire accident. This study is to evaluate the fire-induced damage of concrete lining by using a laboratory furnace. The concrete specimens were tested under the RABT fire scenario in which the maximum temperature was 1,200°C and a RWS fire scenario in which the maximum temperature was 1,350°C. From the tests, the loss amount of concrete materials under the RWS scenario was slightly bigger than under the RABT fire scenario. Especially, under the RWS fire scenario, the loss of concrete materials was mainly induced by melting. In contrast, it was proved that the material loss under the RABT fire scenario was mainly induced by explosive spalling.

1 INTRODUCTION

As tunnels and underground facilities become longer and deeper, the disaster management in underground spaces becomes more important. Especially, fire in an underground space can cause severe structural damage as well as heavy casualties (Haack, 1998). It is very essential to characterize the fire-induced damage of construction materials in underground structures to protect the underground structure and passengers from fire. However, it is almost impossible and uneconomical to carry out a full-scale fire test in a tunnel that is in use. Moreover, fire in underground space has rapid temperature gradient and relatively long duration time.

In this study, a high-temperature furnace was manufactured to easily evaluate the fire-induced damage of underground structure materials. Its biggest advantage is the capability to simulate fire situations in underground space, and to carry out fire tests on various construction materials at the laboratory. By using the furnace, it was intended to characterize the fire-induced damage in an un-reinforced concrete lining used in a NATM (New Austrian Tunneling Method) which is the most popular tunneling method in Korea. Fire scenarios applied in this study included the RABT (Richtlinien für die Ausstattung und den Betrieb von Straßentunneln) and the RWS (RijksWaterStaat) fire curves used in Germany and Netherlands respectively (Beard and Carvel, 2005). It was also intended to compare different fire-induced damage characteristics of NATM concrete lining materials under the RABT with those under the RWS scenarios.

2 FIRE TEST

2.1 *Fire scenarios*

Khoury(2002) pointed out that the structural behaviors after a fire are governed by the characteristics of a fire such as temperature gradient, maximum temperature, fire duration time and cooling time. Those characteristics can be expressed by the time-temperature curve applied in the surface of a structure.

In general, since a tunnel is a structure isolated in underground space, the maximum temperature during the fire in a tunnel is much higher than in other conventional structures. Moreover, a fire accident in a tunnel continues much longer because it is not easy for fire fighters to have a rapid access to the accident location. As a result, a fire scenario in a tunnel should be different from a general fire curve (ISO 834) used in conventional structures (Beard and Carvel, 2005). Figure 1 shows two representative fire scenarios in a tunnel. In the RABT scenario, the temperature reaches 1,200°C only after 5 minutes elapsed since the fire ignition, and is maintained for 30∼90 minutes. The scenario is known to be very close to a real fire situation in a tunnel. In the RWS scenario, the temperature

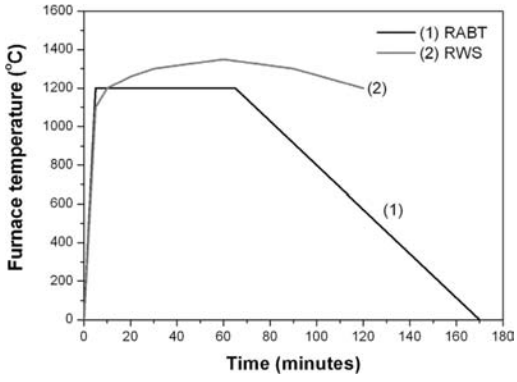

Figure 1. RABT and RWS fire scenarios.

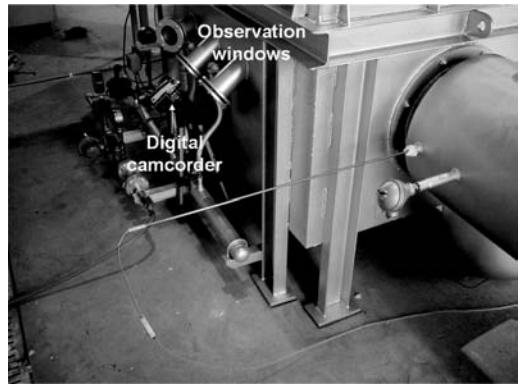
reaches 1,100°C and 1,350°C after 5 minutes and 60 minutes elapsed since the fire ignition respectively. The RWS scenario is generally applied to simulate a catastrophic accident in a tunnel. In this study, it was intended to compare different fire-induced damage characteristics of NATM concrete lining materials under the RABT with those under the RWS scenarios.

2.2 *High-temperature furnace and specimens*

The maximum capacity of the two burners on the furnace was set to 580,000 kcal/hr enough to simulate the rapid temperature increase in the initial heating stage of RABT and RWS fire scenarios. The furnace also had the two-way directional windows for observing the states of the fire room and the specimen surface during the fire tests (Figure 2(a)).

Table 1 shows the mixing proportion of the concrete with the design strength of 24 MPa. The maximum size of aggregates, water/cement ratio, slump and air content were 25 mm, 50%, 15 cm and 4∼6% respectively. The concrete specimens for fire tests were 1,400 mm long, 1,000 mm wide and 500 mm thick.



For each concrete specimen, seven K-type thermocouples with the diameter of 6.4 mm were embedded in the depth of 5 cm, 10 cm, 15 cm, 20 cm, 25 cm, 30 cm and 40 cm from the initial specimen surface. The used K-type thermocouple was a sheathed thermocouple with the maximum range of 1,370°C and the accuracy within ±2.5°C.

In addition, a number of cylindrical specimens were used to measure the changes of mechanical properties of concrete at different temperature conditions. The diameter of the cylindrical specimen is 100 mm and the ratio of the diameter to the length was set to 1:2.

2.3 *Experimental procedures*

After installing the concrete specimen as shown in Figure 2b, the specimen was tested under a RABT and RWS fire curves. During a test, the acquired temperature data from each thermocouple were saved at an interval of one second. Simultaneously, the surface of the specimen was observed with a digital camcorder.

For the cylindrical specimens to evaluate the alteration of mechanical properties at different temperature conditions, the maximum target temperature was from 300°C to 1,000°C at the interval of 100°C. The heating gradient to each target temperature was 450°C/min, which was almost as close as to the initial heating gradient of RABT and RWS fire curves. The target temperature was kept during one hour as soon as the room temperature reached it. After one-hour heating

and successive natural cooling, mechanical properties and loss weight of the damaged concrete specimens were measured.

3 RESULTS OF FIRE TESTS

3.1 *Time-temperature histories*

Figure 3 shows the measured temperatures in the concrete under the RABT fire curve. Furnace temperature was shown to correspond to RABT fire curve well. In the initial stage, it was deduced that the concrete up to 10 cm from the surface exposed to fire was fallen off at intervals of about ten minutes. After 90 minutes elapsed, the maximum temperature at the depth of 15 cm from the surface exposed to fire reached 360°C by the heat accumulated in the concrete block. It is generally well known that concrete can experience significant strength loss at temperature above 300°C and is unable to carry sustained load at temperature in excess of 550∼600°C (Khoury, 2002). From such a reason, it was judged that the concrete nearby 15 cm from the initial surface exposed to fire should be investigated more precisely.

Figure 4 shows the severely damaged concrete surface after a fire test under the RABT fire scenario. The maximum depth of concrete loss amounted to 11.76 cm. It was observed that the original concrete block was grey but the surface exposed to the fire turned brown. In addition, the melting on the concrete surface was rarely observed.

Figure 5 shows the measured temperatures in the concrete during a RWS fire test. Furnace temperature was well controlled and corresponded with the RWS fire curve well. The loss of concrete material under the RWS fire curve was larger than that under the RABT fire curve. However, the speed of concrete loss up to the depth of 10 cm from the surface exposed to fire was slightly lower than that under RABT fire curve.

Figure 4. Damaged surface after fire (RABT).

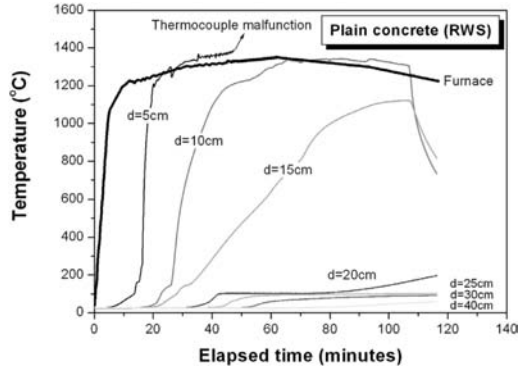

Figure 5. Temperature distribution in a concrete block under the RWS fire scenario.

Figure 6. Damaged and melted surface after fire (RWS).

Figure 6 shows the fire-induced damage after a RWS fire test. The maximum depth of concrete loss was 13.76 cm. We easily found the evidence that the whole area exposed to fire melted. Through a digital camcorder recording during a test, it was verified that

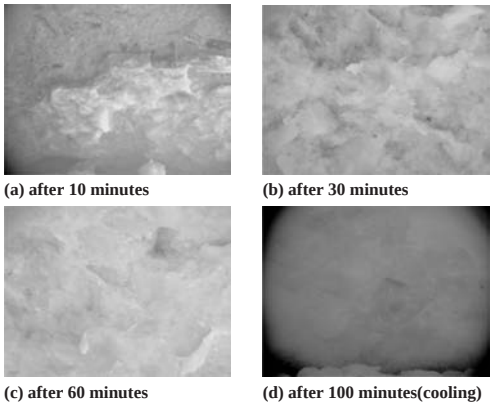

Figure 7. Concrete surface exposed to fire (RABT).

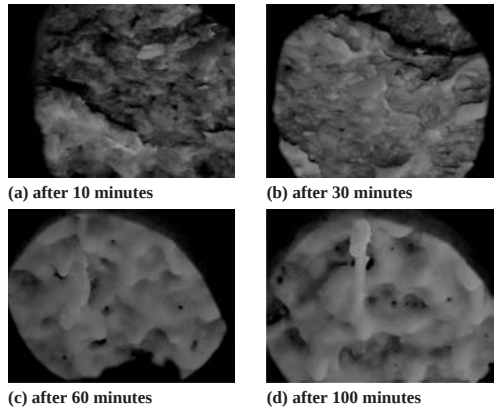

Figure 8. Concrete surface exposed to fire (RWS).

concrete materials became to melt just after the room temperature within the furnace reached over 1,200°C. The reason is why the melting temperature of concrete materials is 1,200°C or more (Khoury, 2002).

It is analogized that the melted material influenced the loss of concrete during the test and the transmission of heat. In other words, it is regarded that a layer of melted concrete materials interrupted the transmission of heat to the remaining concrete part. Nevertheless, the reason why the loss of concrete under RWS fire curve was larger than that under RABT fire curve is that high temperature over 1,200°C accelerated the loss of concrete materials by melting them rapidly.

Figure 7 and Figure 8 show the states of an exposed surface at different recording time conditions under RABT and RWS fire scenarios respectively. From them, it is possible to easily verify the effects of temperature levels on the deterioration and the loss of concrete materials.

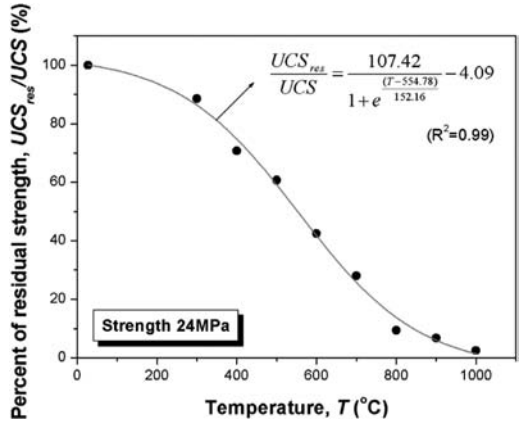

Figure 9. Relationship between residual strength and temperature.

3.2 *Alteration of mechanical properties under high temperature*

Extracting cylindrical core specimens from the large concrete block is inconvenient, time-consuming, and able to do damages on them during coring procedures. Therefore, specimens cured in the cylindrical moulds were used to evaluate mechanical properties of concrete under high temperature condition. They have the same mixing proportion as concrete blocks used in fire tests.

Figure 9 shows the average uniaxial compressive strength of concrete specimens after heating to each target temperature. As the temperature increases, the uniaxial compressive strength is prone to decrease. The relationship between temperature and uniaxial compressive strength can well regressed by the Boltzmann function. It is also found that uniaxial compressive strength rapidly decreases at the temperature range between 300°C and 700°C. In other words, uniaxial compressive strength starts to decrease at the temperature near 300°C. Therefore, the temperature of 300°C can be considered as a critical temperature level and a threshold for fire-induced damage on concrete.

Figure 10 shows the average elastic modulus of concrete specimens after heating to each target temperature. It is shown that as the temperature increases, the elastic modulus also decreases proportionally. Similar to uniaxial compressive strength, the critical temperature where the elastic modulus starts to decrease rapidly is considered as 300°C. At the temperature conditions over 600°C, residual elastic modulus after fire becomes less than 20% of the original property.

From the results, it is suggested that the critical temperature to judge whether concrete is damaged or not should be 300°C. In addition, it is considered that the recovery or the structural ability of a concrete material cannot be expected at the temperature level over 600°C

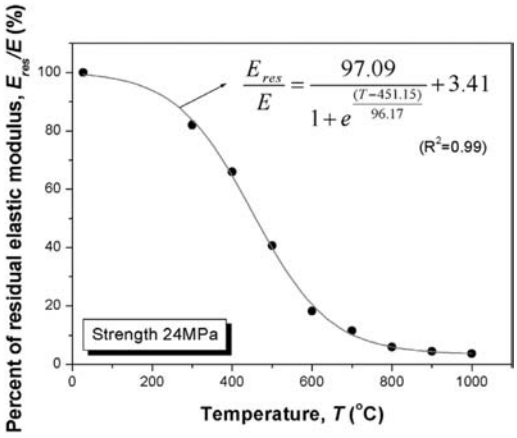

Figure 10. Relationship between residual elastic modulus and temperature.

or 700°C. It is highly expected that these two critical temperature thresholds can be utilized usefully for the optimum rehabilitation works after a fire accident.

3.3 *Proposal of a simple damage prediction model*

In this study, it was intended to propose a simple experimental model for the prediction of a temperature history within a concrete lining and its corresponding damage characteristics.

First, based on the experimental results shown in Figure 3 and Figure 5, the relationships between the elapsed time and the distance from the initial exposed surface were regressed. From the regression analyses, it was revealed that the relationships could be well approximated by the negative exponential functions:

$$T = a + b \times e^{(-t/c)} \quad (1)$$

where T = the temperature within a concrete lining; t = elapsed time after fire ignition; a, b, c, d = regression constants.

Figure 11 and Figure 12 show the regression models to predict the temperature distribution within a concrete lining at RABT and RWS fire scenarios respectively. The prediction results depend upon the distance from the initial exposed surface.

Finally, two simple diagrams (Figure 13) to predict temperature distribution within a concrete lining as well as its corresponding mechanical properties were proposed by combining Figure 9, Figure 10, Figure 11 and Figure 12.

It is expected that when the application of CFD(Computational Fluid Dynamics) analysis is limited or impossible, the diagrams can be usefully utilized to approximately estimate time-dependent

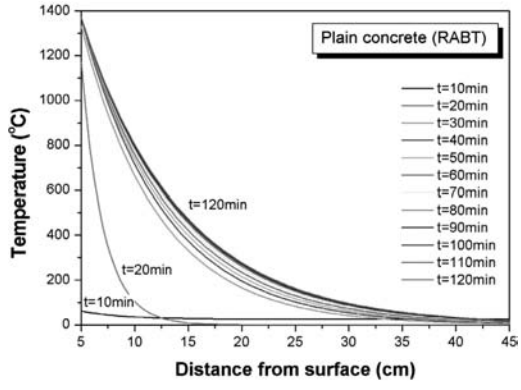

Figure 11. Temperature distribution within a concrete lining depending on the distance from the initial exposed surface (RABT).

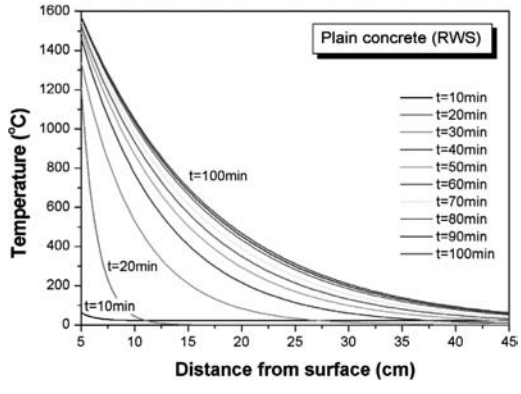

Figure 12. Temperature distribution within a concrete lining depending on the distance from the initial exposed surface (RWS).

temperature distribution within a concrete lining as well as its corresponding mechanical properties.

4 CONCLUSIONS

In this study, a high-temperature furnace was utilized to easily evaluate the fire-induced damage of underground structure materials. The concrete specimens simulating the concrete lining used in a NATM tunnel were tested under the RABT and the RWS fire scenarios. Under the RABT scenario, the maximum depth of concrete loss amounted to 11.76 cm and the maximum temperature at the depth of 15 cm from the initial surface exposed to fire reached 360°C. Under the RWS scenario, the maximum depth of concrete loss was 13.76 cm. In addition, it was easily found that the whole area exposed to fire melted. From a real-time camcorder recording, it was verified that

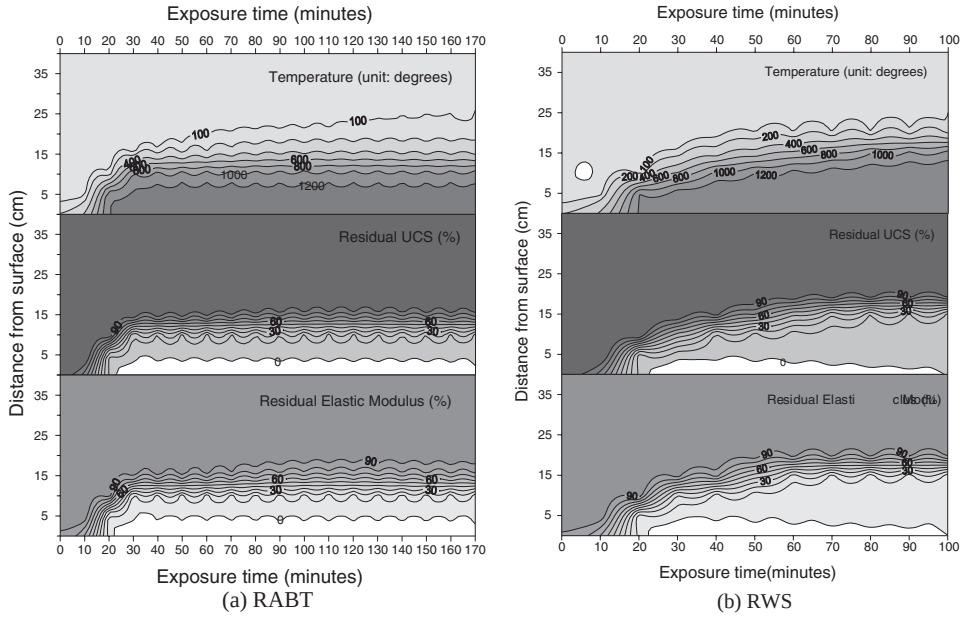

Figure 13. Proposed diagrams to predict temperature distribution and mechanical properties.

concrete materials became to melt just after the room temperature within the furnace reached over 1,200°C. The reason is why the melting temperature of concrete materials is 1,200°C or more.

The deterioration of mechanical properties of the concrete material was measured between 300°C and 1,000°C at the interval of 100°C. From the experiments, it was suggested that the critical temperature to judge whether concrete is damage or not is 300°C. In addition, it was considered that the recovery or the structural ability of a concrete material cannot be expected any more at the temperature level over 600°C or 700°C. It is highly expected that these two critical temperature thresholds can be utilized usefully for the optimum rehabilitation works after a fire accident.

Finally, two simple diagrams to predict temperature distribution within a concrete lining as well as its corresponding mechanical properties were proposed. It is expected that when the application of CFD analysis is limited or impossible, the diagrams can be usefully utilized to approximately estimate time-dependent fire-induced damage to concrete lining.

Large scale fire tests with different railway overhead systems – experience by the test center

Sven J. Seirer & Volker Wetzig
VSH – Hagerbach Test Gallery Ltd., Sargans, Switzerland

ABSTRACT: Numerous tunnel fires in recent years in Europe ended in disaster and sensitized politicians and the public. It resulted in a high level of safety in tunnels. In a railway tunnel the probability of a fire disaster, caused by an accident, is far smaller than in a road tunnel. Authorities, railway companies and the industry are asked to appropriate measures to limit the risk of fire in rail tunnels or to cut one's losses. The most important task is to bring the train out of the tunnel, and this is (only) possible if the train wagons are operational and if there is an electric power supply as long as possible. Caused on the thermal impact and the load (tension) a conventional overhead wire elongate, and if the temperature is to high the probability of a failure is very high. An overhead conductor rail, without any tension load, should have a quit better behavior in case of fire in a tunnel. In summer 2004 Furrer + Frey Ltd., Bern, Switzerland, commissioned the VSH-Hagerbach Test Gallery Ltd. (www.hagerbach.ch) to carry out large scale fire tests to verify that assumption.

1 INTRODUCTION

The catastrophic fire disasters in European tunnels during the very recent past have raised awareness of tunnel safety among policymakers and the general public. Although the probability of accidents in a rail tunnel is lower than in a road tunnel, the consequences can also be catastrophic in a rail tunnel. This creates particular requirements for the authorities, the rail operators and industry. These sectors are seeking active and passive measures to prevent fire accidents in tunnels or to limit their consequences. One of the most pressing and important points is that the burning train must travel out of the tunnel whatever the circumstances. Most important of all, as well as rolling stock that is capable of functioning, the power supply from the overhead line must remain guaranteed for as long as possible. Under the influence of heat, the contact wires (- tensioned with a force of 10 to 30 kN -) become elongated, and it is even possible for constrictions or line tears to occur at the location of a fire.

On the basis of the installation method without tensile force for roof-mounted conductor rails developed by Furrer + Frey, and the substantially larger cross-section (8 to 12 times) as compared to the overhead lines, it was supposed that a roof-mounted conductor rail would remain functional for substantially longer.

In order to confirm this, Furrer + Frey Ltd. commissioned VSH-Hagerbach Test Gallery Ltd., to carry out large scale fire tests. The aim was to provide experimental confirmation of the theoretical consideration that the roof-mounted conductor rail from Furrer + Frey retains its mechanical functioning capability for longer than the conventional contact wire systems.

2 OVER HEAD SYSTEMS

2.1 *General*

All the systems were installed approx. 95 cm above the carriage roof, with a length of approx. 20 m each. In addition to the interception and securing fixtures at the ends, each system was additionally secured in the middle of the carriage.

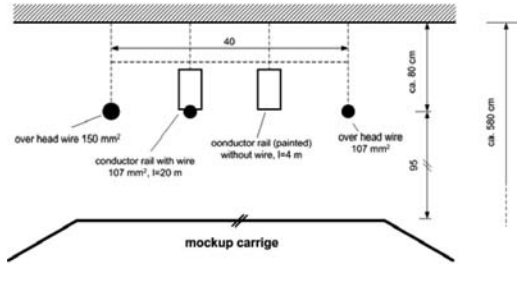

Figure 1. Cross-section from the test set up (not drawn to scale).

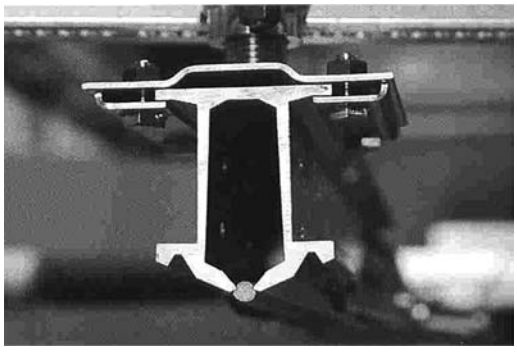

Figure 2. Conductor rail by Furrer + Frey Ltd.

Only the ≪fourth system≫ had a length of just 4 m and was fixed solely by the securing fixture in the middle of the carriage. The two overhead line wires were tensioned with a transmission ratio of 1:2. No power flowed through the lines during these tests.

2.2 *Conductor rail*

This is a box-shaped aluminium profile with a contact wire inserted without tensile force. It is a positive-type connection and both copper and aluminium of up to 161 mm^2 can be used as the contact wire. For this series of tests, a contact wire of 107 mm^2 was used.

The standard length is 12 m, and the system can be used for track radii ≥120 m without any special measures.

2.3 *Overhead wire*

Contact wires of 107 mm^2 and 150 mm^2 were used in these tests. In test 1, both cross-sections were tensioned with 900 kg and in tests 2 and 3 the weight was increased to 1250 kg for the 150 mm^2 cross-section. The transmission ratio was 1:2 for both cross-sections.

3 DESCRIPTION OF THE TESTS

3.1 *Test location at VSH*

The tests were carried out in an access tunnel of the ICST in the VSH-Hagerbach Test Gallery Ltd. (www.hagerbach.ch). The test area was approx. 25 m long and approx. 6.9 m wide, and it had an average height of approx. 5.8 m. The walls in the test area had a rough surface of rock or sprayed concrete.

3.2 *Mock-up carriage*

The mock-up carriage, manufactured from steel profiles and steel plate, was built by VSH according to the client's specifications. Up to a height of 2.62 m, the dummy was left open at the sides, thus simulating the window glass which is present in a railway carriage. Above 2.62 m, the entire surface area of the dummy was sealed with steel plate (t = 2 mm).

After test 1, it emerged that the steel plate represents a very major thermal barrier in the upward direction, in relation to the overhead line systems. For this reason,

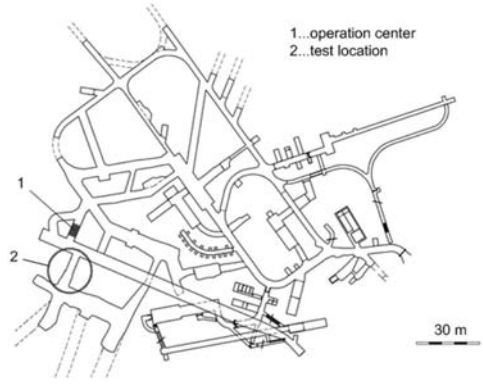

Figure 3. Plan of the tunnel test facility VSH-Hagerbach Test Gallery Ltd.

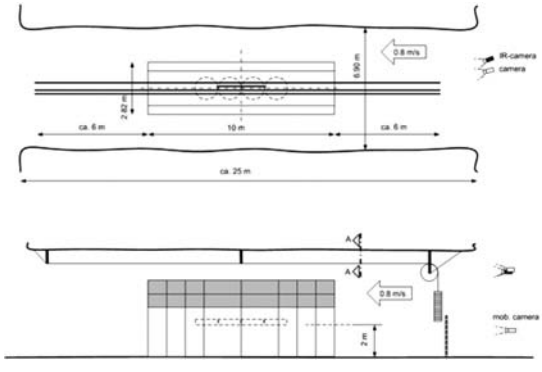

Figure 4. Sketch of the test location (not drawn to scale).

Figure 5. Construction of the mock-up carriage.

after consultation with the client, twelve openings were cut in the horizontal area of the carriage roof prior to test 2. Each slit was 70 cm long and 15 cm wide, providing an open area totalling 1.3 m^2. The distance between the slits was also 15 cm.

3.3 *Pool fire*

In order to carry out the tests, a fire seat was set up with four circular pools. These pools, with an internal diameter of 1.15 m and a height of 0.3 m, were manufactured from steel plate. The total area of combustion was therefore approx. 4 m^2. The fuel used was normal commercial heating oil with the following characteristics. The average heating capacity of one fire trough was approx. 1.4 MW, with a pyrolytic decomposition of some 0.034 kg/s. The total heating capacity of all four fire troughs was approx. 5.4 MW. The fire troughs were secured to the dummy carriage with a steel frame. In tests 1 and 2, the height of the fluid level at the start of the test was approx. 2 m, and for test 3 this figure was approx. 2.4 m.

3.4 *Test procedure*

The same climatic conditions prevailed in the test area for all three tests. An air flow is present in every tunnel due to differences in air pressure at the portals, mechanical ventilation or traffic (piston effect). As the tests were to be conducted under the most realistic conditions possible, an air flow of approx. 0.8 m/s was created in the test area.

For each test, one litre of heptane was added per fire trough as a fire accelerator, in order to speed up the ignition process.

3.5 *Data recording*

The MDA-600 multi-channel measuring and monitoring system was used for central recording of the measured data. One or more limit values can be assigned to each channel. All the data are stored in an indelible, error-proof memory.

The MDA-600 was accommodated in the central measurement technology unit and was protected against power failures by a UPS.

3.6 *Temperature sensors*

Due to the fuel used and a minimum air flow in the test area, maximum temperatures $<1000°C$ could be assumed. For this reason thermo couples of type K (NiCr-Ni) were used. These allow temperatures of up to 1200°C to be measured.

A total of 16 sensors (nos. 11 to 26) were affixed – four to the carriage roof and 12 to the overhead line systems. The positioning of the sensors is shown in Figure 8. The measuring point for the sensors was

Figure 6. Picture from the infra-red (IR) camera at test 1.

fixed on the underside of the copper wire in all the systems. One exception was the short rail (no overhead line); in this case, the sensor was fixed laterally on the aluminium.

All the sensors were designed as cased thermo couples with a diameter of 3 mm. Each sensor was connected with the data recording system in the operation centre via a shielded type K compensating data line.

3.7 *Video recording*

To provide optical monitoring of the overhead line systems during the testing, three cameras were installed in the fresh-air zone. The special camera and the thermal imaging camera were connected with analogue recording devices in the operation centre.

A special camera (fixed installation) for tunnel light conditions was used at a height of 4.5 m. This camera was designed for a minimum illuminance of 2 Lux and was equipped with a variable focus (7.5–75 mm). A thermal imaging camera (fixed installation) was also mounted at a height of 4.5 m and on approximately the same optical axis as the normal imaging camera. A Bullard® TIx thermal imaging camera, as normally used by fire brigades for fire- fighting, was used for the tests. Independently of the other two cameras, a DV Handy-Cam was installed at a height of approx. 1.3 m. The time progression of the elongation of the contact wire was recorded optically with the mobile video camera and a vertical yardstick next to the tensioning weights.

4 RESULTS

4.1 *Elongation*

Based on an optical evaluation of the video recordings, the reduction of the tensioning weights (Δs) for the two overhead line wires was determined. Since all the

Figure 7. The elongation was measured by a yardstick and video records.

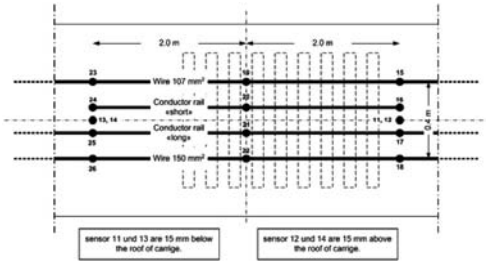

Figure 8. Location of the thermo couples. The sensors were fixed direct on each overhead system.

contact wires were tensioned with a transmission ratio of 1:2, the change in length (Δl) of the contact wire was half of the reduction in the tensioning weights (Δs). In test 1, both contact wires were tensioned with 900 kg, so the different cross-sections also gave rise to different tensions in the wire. In tests 2 and 3, the tensioning force on the 150 mm^2 contact wire was increased so that the tensions were the same.

In test 1 (closed carriage roof), the change in length (Δl) for the two contact wires – despite the difference in cross-section – was approx. 4 cm. None of the contact wires tore during this test.

In test 2 (slits in the carriage roof), the maximum elongation (Δl) of the 107 mm^2 contact wire was approx. 36 cm and the figure for the 150 mm^2 contact wire was approx. 16 cm. The wire with a 107 mm^2 cross-section tore 6 minutes and 35 seconds after ignition.

In test 3 (slits in the carriage roof, fire troughs at 2.4 m), the maximum elongation (Δl) of the 107 mm^2 contact wire was approx. 20 cm and the figure for the 150 mm^2 contact wire was approx. 36 cm. The contact wire with the 107 mm^2 cross-section tore 3 minutes and 18 seconds after ignition, and the contact wire with the 150 mm^2 cross-section tore 7 minutes and 12 seconds after ignition.

4.2 *Temperatures*

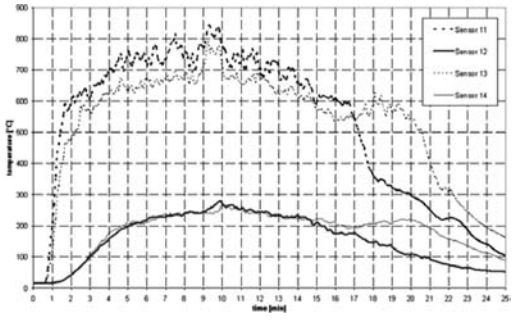

Figure 9. Temperature plot (example) from sensors 11, 12, 13 and 14. The peak at the end of the test is due to wind velocity change.

5 CONCLUSION

- The test results basically confirm the supposition that the conductor rail stays intact for longer than the conventional contact wire systems in case of a fire.
- The tests were not conducted with electrical power.
- The conductor rail heats up more slowly than overhead wire, probably due to its larger cross-section and its consequently higher heat conductivity.
- The conductor rail also remained mechanically intact at temperatures of 450°C.
- The results are valid for rail carriage made of steel.
- Test 1 showed that the closed steel roof shields temperatures in such a way that temperatures of "only" the level occurring during normal operation were measured on the overhead line systems. Slits were cut in the carriage roof for tests 2 and 3.
- Verification of electrical functioning capability was not a subject of this investigation.

6 OUTLOOK

All the system components used in the tests were dismantled and were subjected by the client to further testing in the laboratory (material technology and electrical).

Special attention should be focused on the carriage material, because it has a decisive influence on the progression of the fire. Modern carriage systems, of the sort that are already in frequent use and which will probably be used even more often in future, consist of aluminium or composite materials (plastics). The importance of tests with materials of these kinds is very great, and they would lead to highly relevant and important findings.

Another question which must be answered is: How does the locomotive system behave during a fire in a tunnel? An overhead wire system that is able to function is of little use if the power cannot be taken off by the locomotive, for example because the power take-off system is no longer functioning.

A further highly important aspect is the functional behaviour of the systems which separate the current carrying components from those which do not carry current (isolators) because here too, a failure leads to an interruption of the power flow.

The tests which were conducted were of great importance. In turn, however, the systems that were examined form a module in a larger and even more complex system, and the expected behaviour of a subsystem cannot be used as the basis for conclusions about the behaviour of the higher-level system.

The requirement specified by the rail operators, the authorities and the safety experts is that the train must travel out of the tunnel. In order to meet this demanding requirement, it is necessary for the entire system to be able to function.

For these reasons, we regard more extensive fire tests on system components as highly appropriate, or rather we consider tests on the complete system to be indispensable.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to Mr B. Furrer, CEO from Furrer + Frey Ltd. (www.furrerfrey.ch), Bern, Switzerland, for his permission of publishing this paper. Special thanks also to all staff of VSH for their total commitment during this project.

The research on countermeasure of fireproofing and rescue for long highway tunnel

Wang Yong-dong; Xia Yong-xu; Deng Nian-bing
Highway College, Chang'an University, China

ABSTRACT: In view of laws of the occurrence and development of fire, countermeasure system of fireproofing and rescue for long highway tunnel can be divided into eight parts such as its guiding ideology, fire safety grade, propagandas and education, traffic management, ventilation control, monitoring and fire control, building materials and ancillary establishments, and system of fire rescue. Each subsystem has a detailed fireproofing countermeasure. Based on each fire safety grade, the fireproofing facilities and traffic control table to transport dangerous goods are put forward. Organizational process of fireproofing and rescue for highway tunnel is improved, and the principle, the content and the material program of studying the counterplan are put forward.

1 INTRODUCTION

With the rapid development of transportation in the world in the last 20 years, the grade of highways becomes higher and higher, the scale of highway tunnel becomes bigger and bigger, and the length becomes longer and longer. Nevertheless, many traffic safety problems have also emerged, and fire is one of them.

We can see from a large number of statistics[1][2], the probability of highway tunnel fire is 20–25% more than railway tunnel; there is one fire each 50 million vehicles per kilometers in the tunnel, in view of the Component of Common vehicles in the tunnel. Although the trucks only take 15% of the all highway transport vehicles, 30% of the fires were caused by trucks. In China, there was about one fire each 70 million vehicles per kilometers in shanghai Dapu Highway Tunnel from 1981 to 1988. In addition, to resume operation after the tunnel fire would take a very long time. For example, to resume the operation of Austria's Tauern tunnel after fire spent three months. France & Italy's Mont Blanc tunnel takes three and a half years to resume, and resuming the operation of the Swiss St. Gotthard tunnels takes one and a half year. Therefore, when a fire happened in the tunnel, economic losses were incalculable, it will also have a serious impact on society. Based on the analysis of available information of the world and the development trend of the tunnel safety, with the increase of traffic and the transportation of hazardous materials, number and the length of tunnels year by year, and the serious increase of terrorism, it can be sure that the probability of highway tunnel fire will go upward, therefore the traffic fire in tunnel has become an international concern.

Although China has built many long highway tunnels, but there are no management standards of long highway tunnel. Research of fireproofing and rescue for long highway tunnel is also still in its infancy, Many management departments do not know much about the relief and fire countermeasures. Therefore, it is important to research on countermeasure of fireproofing and rescue for construction, management and the constitution of management plans in fire of long highway tunnel.

2 CHARACTERISTICS AND CAUSES OF FIRE IN HIGHWAY TUNNEL

2.1 *The characteristics of fire in highway tunnel*

According to a large number of investigations and studies of fire in highway tunnel, there are several distinctive features:

(1) Randomness. The time, location, scale, morphology of fire is random.
(2) Disaster time is short. The time of fire broke out from vehicles generally between 5 and 10min, and the fire development process is quickly. The fire duration, which has relation to the environment of the tunnel, is generally between 30 minutes and a few hours.
(3) Smoke, and high temperature. Because of the tunnel is confined to a airtight space, in case of fire, smoke can not be ventilated naturally, so a lot of smoke inside the tunnel, the tunnel can not disperse heat easily. Fire makes the temperature inside the tunnel rise quickly, usually amounted to hundreds

or even thousands centigrade, for example, the fire temperature of Tauern tunnel is above 1300°C.

(4) To fight the fire is hard. The fire in tunnel may undermine the tunnel lighting system greatly which makes the fighting difficult. Moreover, because of the high temperature, to put out the fire source is difficult to the firemen.

(5) Difficulties in evacuation. Because the section of tunnel is small, it is almost impossible to evacuate personnel and material completely.

(6) To cause serious harm. As the fire in tunnel developed quickly, to put out the fir is difficult, it often causes huge casualties and property losses and has a bad effect on the society.

2.2 *The causes of the fire in highway tunnel*

There are many causes of the fire in highway tunnel. Common causes of the fire are : ① the burning of car carburetor; ② the brakes catches fire when the emergency brake; ③ traffic accidents; ④ inflammable goods in vehicle catch fire; ⑤ electrical lines or electrical equipments are short in tunnel.

3 THE COUNTERMEASURES OF FIREPROOFING AND RESCUE FOR HIGHWAY TUNNEL

3.1 *The guiding ideology of the countermeasures of fireproofing and rescue for highway tunnel*

The countermeasures of fireproofing and rescue in highway tunnel should follow the principles that prevention is primary combining with rescue. The basic idea should be to make people escape mainly and to protect property supplement. It mainly depends on the firemen of management department of tunnel.

3.2 *Fire safety grades of highway tunnel*

Considering the importance of the tunnel in traffic network and harm extent of fire, the tunnels are divided into several grades based on a certain safety standard system. Because of the different safety grade, the countermeasure of fireproofing and rescue, and fire safety equipment are different. Based on the technology development of highway tunnel and the national conditions, fire safety grade of highway tunnel in China is given, which can be divided into five grades: I, II, III, IV, V, the minimum length of the tunnel corresponding to the fire grade is 0.5 km, the characteristic lengths of tunnel of different fire grades safety are 1.0 km, 5.0 km and 10.0 km, the minimum traffic of each section is 10000 veh/d, Fig.1.

3.3 *Propagandas and education*

Propagandas and education are primary work to prevent fire of highway tunnel. The objects of education

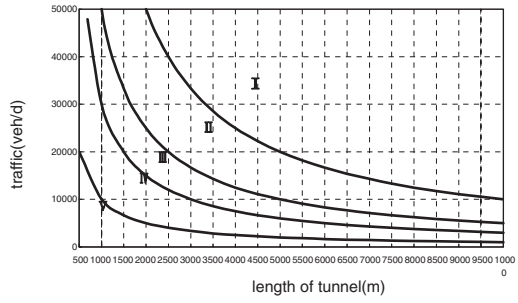

Figure 1. Fire safety grade of highway tunnel in China.

are users, tunnel maintenance and management staffs. Through education people can help themselves and minimize fire hazards. The means of propagandas and education are training, the dissemination of pamphlets and VCD. Education include: ① the characteristics of highway tunnel structure; ② the regulates of vehicle speed, overtaking and the distance between vehicles through the tunnel; ③ the alarm system of highway tunnel; ④ the extinguish facilities of highway tunnel; ⑤ the fire law of highway tunnel; ⑥ fire hazard of highway tunnel; ⑦ the escape system of highway tunnel; ⑧ the fire countermeasures of highway tunnel.

3.4 *Traffic management of highway tunnel*

3.4.1 *Normal operation and management of highway tunnel*

The main task of normal operation and management of highway tunnel is to control the traffic inside the tunnel, and limit the smallest distance and the maximum speed of the vehicle, so that to prevent congestion and accidents.

3.4.2 *Fire grade of vehicle in tunnel*

Fire grade of vehicle indicates the capability of fire resistance of vehicle. Fire grades of vehicle are classified A1, A2 and B by France. In those standards, only vehicle with A1 can be allowed to go through the tunnel. Fire grades of vehicle are classified A-A, A and B by Japan's transport department. The fire grade of vehicles through tunnel must be reached the highest-grade A-A. In management and operation of the tunnel, limiting the low grade vehicles to go through the tunnel or taking some control measures (such as escorting, allowing at night) will greatly reduce the probability of the fire occurrence of the highway tunnel.

3.4.3 *Management of dangerous goods in highway tunnel*

Currently, there is no corresponding standards and management system for the transport of dangerous goods in China. But with the increase in highway tunnel, these problems have to be resolved. The work must

Table 1. Traffic control table to transport dangerous goods in highway tunnel.

Traffic control	Grades				
	I	II	III	IV	V
Speed(km/h)	Design data-20	Design data-20	Design speed	Design speed	Design speed
Vehicle distance(m)	500 ~ 1000	400	300	300	300
Ultrahigh	Prohibit	Prohibit	Prohibit	Prohibit	Prohibit

overlong	Escorting passed at night	Escorting passed	Escorting passed	Escorting passed	Escorting passed
Flammable liquid	Escorting passed at night	Escorting passed	Escorting passed	Escorting passed	Escorting passed
LPG	Escorting passed at night	Escorting passed	Escorting passed	Escorting passed	Escorting passed
Chemical item	Escorting passed at night	Escorting passed	Escorting passed	Escorting passed	Escorting passed
Explosives	Prohibit	Escorting passed at night	Escorting passed at night	Escorting passed at night	Escorting passed at night

Notes : If it is motorcade with dangerous goods, the distance must be kept at 1 ~ 2 km, or only allow one go through tunnel at a time.

be do to Enact strict transport laws about noxious, inflammable and explosive goods, which clearly regulate that which kinds of vehicles are permitted, limited or prohibited to use the tunnel. Management department can also consider the problem that which kinds of Vehicles carrying inflammable or explosive goods can be allowed to go through the tunnel or bypass the tunnel from the economic, security, society and other aspects.

Based on specific circumstances of highway tunnel in China, traffic control table to transport dangerous goods in highway tunnel with corresponding fire safety grade is put forward, Tab.1.

3.5 *Fire ventilation control of highway tunnel*

Fire ventilation control of highway tunnel is particularly important in the extinguishing process. Ventilation system of highway tunnel must be achieved aim: ① offering the minimum wind speed to prevent smoke going in the opposite direction; ② ventilating the smoke from the tunnel as soon as quickly; ③ lowering the temperature inside the tunnel; ④ providing fresh air for escape channel and refuge; ⑤ providing fresh air for firemen.

3.6 *Monitoring and fire control system of highway tunnel*

3.6.1 *The monitoring system of the highway tunnel*

The purposes of setting up monitoring system in highway tunnels are to make full use of the traffic capacity of the tunnel, ensure safety, meet environmental requirements and reduce disasters in highway tunnel. Tunnel Monitoring System is composed of the following parts: ① tunnel traffic control signal; ② ultrahigh -detection device in the both entrances; ③ detection loop of vehicle in the tunnel; ④ fire and smoke alarm device; ⑤ CO concentration detector; ⑥ visible detector in smoke; ⑦ brightness monitor in the both entrances; ⑧ closed-circuit television surveillance; ⑨ computer Auxiliary control system.

3.6.2 *Fire alarm system of highway tunnel*

(1) Fire detection system
There are three types: ① emergency phone; ② manual annunciator; ③ fire detector.

(2) Emergency alarm devices
There are three types: ① alarm display ② flash light, alarm light; ③ audio signal generator.

3.6.3 *Tunnel fire facilities*

There are four types: ① fire extinguisher; ② extinguishing hydrant; ③ water offering hydrant; ④ spraying facility.

3.6.4 *Other facilities*

In order to provide security for staffs and vehicles in emergency, other facilities are installed. Other facilities should include: ① some ancillary facilities to ventilate smoke; ② transfer channel and refuge for escape; ③ the car park in emergency situations; ④ asylum-oriented facilities used for evacuation of vehicles and staffs in disaster; ⑤ I.T.V; ⑥ emergency lighting facilities; ⑦ emergency power-supply facilities.

3.6.5 *Selection and installation of fireproofing facilities in the tunnel*

3.7 *Fireproofing of construction materials and ancillary facilities of tunnel*

3.7.1 *Fireproofing of construction materials*

Fireproofing of construction materials mainly includes the fire-resistance of waterproof material, fireproofing of concrete and other burning-retardant lining material such as fireproofing paint layer.

3.7.2 *Fireproofing of ancillary facilities*

Fireproofing of ancillary facilities includes fireproofing of the fan, the lamps, detection equipment, monitoring equipment, power supply facilities.

3.8 *Fire rescue system of highway tunnel*

3.8.1 *Rescue echelon of highway tunnel*

Rescue echelon of long highway tunnel can be divided into three teams, the first team is composed of vehicle drivers and passengers in fire areas, the second team includes tunnel management staffs, non-professional firemen and policemen, and the third team includes professional firemen and doctors. The early tunnel fire fighting work is implemented by the first and second teams, and the latter part of work is finished by the third team. Based on some typical examples and the fire experiments, the time of the arrival of the professional rescue team should not exceed 10 minutes, otherwise they will lose the best chance to rescue and putting out the fire.

3.8.2 *The organizational process of putting out fire in highway tunnel*

Once the tunnel is on fire, in order to avoid of the deterioration of the rescue environment, it must be put out the fire as soon as possible to prevent the tunnel full of smoke. At the same time, the fire alarm must be provided to prevent vehicles driving to the scene of the fire and give the right guidance to the drivers so that they can leave the fire tunnel. Fire rescue work can be organized and implemented according to the Fig. 2.

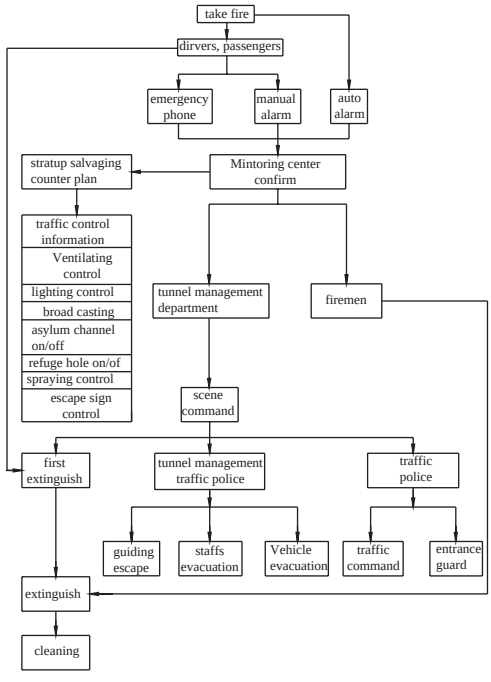

Figure 2. Organizational process of putting out fire and rescue in highway tunnel.

3.8.3 *Salvaging counterplan for fire of tunnel*

Salvaging counterplan for fire of tunnel is a kind of plan which is carried out when the tunnel is on fire. Various countermeasures are given based on different fire conditions (fire scale, the location, the type of fire, etc). If the tunnel is on fire, it is the important guiding principles to reduce greatly the time and prevent confusion and mistakes in operation.

Salvaging counterplan for fire of tunnel should be formulated based on safe, feasible and economic principles. The counterplan includes: tunnel sections divided in the fire, traffic control, lighting control, ventilating control, communication control, fire extinguishing, escape, evacuation and rescue. The startup model is an important step of the counterplan, if it is not carried timely after the fire, the counterplan will lose its meaning. The best way is to store the counterplan in the computer. If the tunnel is on fire, the monitoring equipment will judge the specific circumstances and corresponding countermeasures will be initiated. Of course, the fire condition also can be judged by the tunnel management operators, but the startup process should be simple to operate. Salvaging counterplan for fire of tunnel should be researched specially with numerical simulation, physical simulation and field experiment.

4 CONCLUSION

The research on fireproofing and rescue for long highway tunnel is a long-term and arduous task. This article presents basic countermeasure of fireproofing and rescue, the fireproofing facilities and traffic control table to transport dangerous goods based on each fire safety grade. Organizational process of fireproofing and rescue for highway tunnel is improved, and the principle, the content and the material program of studying the counterplan are put forward. These productions establish theoretical and technical basis for construction and research of counterplan of long highway tunnel.

Experimental study on mechanical behaviors of tunnel lining under and after fire scenarios

Z.G. Yan & H.H. Zhu
Tongji University, Shanghai, China

ABSTRACT: To evaluate the fire safety of tunnel lining under and after fire scenarios, a series of reduced-scaled experiments on mechanical behaviors of tunnel lining were carried out. Three types of concretes that are reinforced concrete, steel fiber reinforced concrete and polypropylene fiber concrete are employed in the experiments. The results indicate: a) mechanical properties of lining materials especially uniaxial compressive strength, elastic modulus and impermeability deteriorate significantly after high temperature; b) comparing with normal temperature condition, high temperature result in significant decrease of load-bearing capacity and significant increase of displacement of segments and joints; c) because of material deterioration, thermal damage and thermal stress due to high temperature, the load-bearing capacity and reliability of tunnel lining system decrease heavily. Moreover, large displacement of lining system may affect the safety of surrounding substructure and surficial buildings.

1 INTRODUCTION

There are a number of fire accidents with high peak temperature, rapid heating velocity and long duration in traffic tunnels. These fire accidents resulted in not only lose of property but also severe damage to tunnel linings in term of concrete spalling, deterioration of physical-mechanical property and reduction of load bearing capacity. For example, the Mont Blanc Tunnel fire in 1999 and St. Gotthard Tunnel fire in 2001 both cause severe damage to tunnel lining (Haack 2002).

To evaluate the fire safety of tunnel lining under and after fire scenarios, a series of reduced-scaled experiments on mechanical behaviors of tunnel lining, which include three levels tests i.e. lining material testing (FT1), segment (joint) testing (FT2) and lining system testing (FT3) were carried out in Tongji University. The scopes of the researches involve: a) the variation of uniaxial compressive strength, elastic modulus and impermeability with high temperature; b) mechanical behaviors of lining segments (joints) under and after different thermal-mechanical conditions; c) mechanical behaviors of lining system under and after different thermal-mechanical conditions and d) method to protect lining concrete from spalling without large decrease of impermeability durability.

This paper briefly introduces the experiments and main results from these experiments.

Table 1. Parameters of the Concrete, steel fiber and polypropylene fiber used in the experiments.

Items	Properties
Concrete	C50
Steel fiber	Hooked steel wire fiber, L = 50 mm, L/d = 55, Blend capacity = 60 kg/m^3
Polypropylene fiber (PP fiber)	Dispersed monofilament fiber, L = 12 mm, d = 18 μm, Melting point = 160°C, Blend capacity = 2 kg/m^3

2 EXPERIMENTAL SETUP

Three types of concretes that are reinforced concrete(RC), steel fiber reinforced concrete (SFRC) and polypropylene fiber concrete (PPFC) are employed in these three tests, as shown in Table 1.

In FT1, the temperature varies in the range of 20°C–1100°C, and the heating velocities are 50°C/min and 5°C /min in the testing furnace. In FT2 and FT3, two thermal-mechanical conditions i.e. Load case 1 and Load case 2 are considered (Fig. 1). And a standard HC curve with duration of 0.5 h or 1 h is used to simulate defined fire scenarios (Fig. 2). At the same time, in order to simulate the surrounding environment of tunnel lining, single face heating are conducted and the lining are covered by soil layer (Fig. 3, 4).

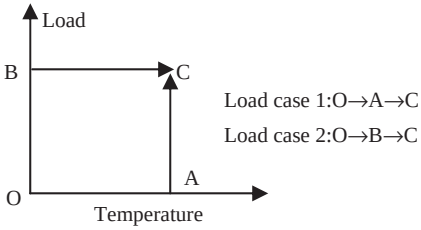

Figure 1. Two thermal-mechanical conditions in the FT2 and FT3.

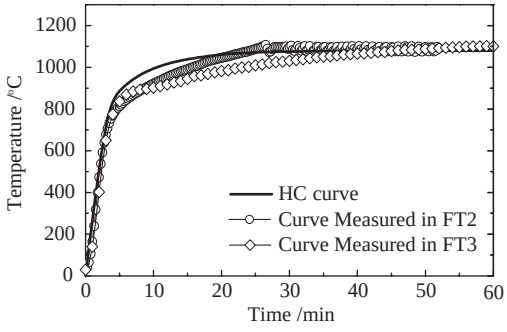

Figure 2. Temperature-time curves measured in the fire experiments.

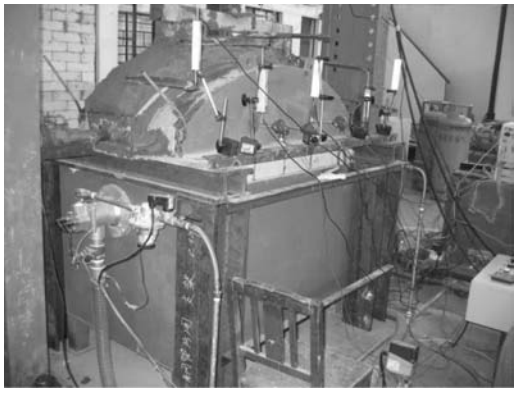

Figure 3. Experimental setup on mechanical behaviours of segments and joints during and after high temperature (FT2).

3 EFFECTS OF HIGH TEMPERATURE ON PHYSICAL-MECHANICAL PROPERTIES OF TUNNEL LINING MATERIAL

As shown in Figure 5, both uniaxial compressive strength and elastic modulus of three types of concretes decrease with suffered temperature after fire because of dehydration of cement paste, disharmony of heat expansion between cement paste and aggregate and

Figure 4. Experimental setup on mechanical behaviours of lining system during and after high temperature (FT3).

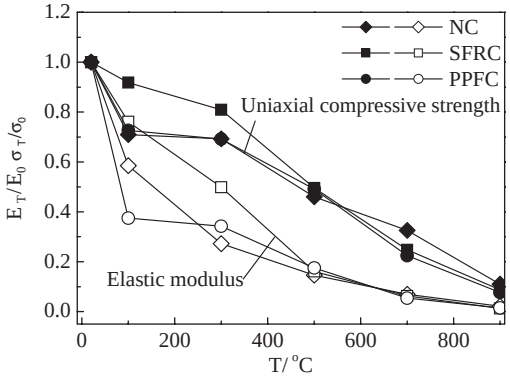

Figure 5. Variation of relative elastic modulus and uniaxial compressive strength of three types of concretes after high temperature.

cracking of aggregate. Owing to long duration of tunnel fire and high peak temperature, heavy damage to tunnel lining will occur in terms of deterioration of mechanical characteristics and reduction of load bearing capacity. These deteriorations may seriously affect the safety of tunnel lining.

Figure 6 shows variation of permeability of three types of concretes after high temperature, which is represented by relative permeability coefficient S_k. It shows that all the relative permeability coefficients of three types of concretes increase significantly after high temperature. Especially for PPFC, the relative permeability coefficient after high temperature of 300°C increases by 259 times of the value in 20° C. The increase of relative permeability coefficient means deterioration of impermeability durability of tunnel lining concrete. Because tunnel linings are embedded in surrounding soil and water, it is important to maintain sufficient impermeability durability in their lengthy service period.

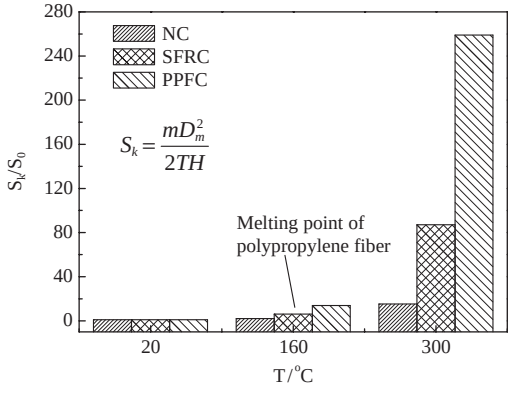

Figure 6. Variation of the relative permeability coefficient S_k of three types of concrete after high temperature.

It is noticed that addition of polypropylene fiber will results in severe decrease of impermeability durability of concrete although concrete spalling can be avoided successfully.

4 MECHANICAL BEHAVIORS OF LINING SEGMENTS (JOINTS) AND LINING SYSTEM UNDER AND AFTER HIGH TEMPERATURE

Because of material deterioration, thermal damage (e.g. concrete spalling), asymmetric thermal-stress, asymmetric deterioration of material properties within tunnel lining (result from asymmetric temperature distribution, as shown in Fig. 7) and resisting force of surrounding ground, the load-bearing capacity and reliability of segments (joints) or tunnel lining system deteriorate heavily. And comparing with the SFRC lining the load bearing capacity of RC lining is higher at same thermal-mechanical condition (Fig. 8).

Furthermore, because of recovery of strength and elastic modulus of reinforcement bar, the load bearing capacity of RC lining after high temperature is higher than the value during high temperature (Fig. 8). However, for SFRC lining the load bearing capacity after high temperature is lower than the value during high temperature because of development of cracks during cooling process.

At the same time, comparing with normal temperature condition, high temperature results in significant increase of displacement of segments (joints) or lining system besides significant decrease of load-bearing capacity. For example, the rotation angle and expending distance of joint increase significantly because of deterioration of mechanical properties of concrete and bolt (Fig. 9, 10). This increase of displacement of segments (joints) or lining system may affect the safety of surrounding substructure and surficial buildings.

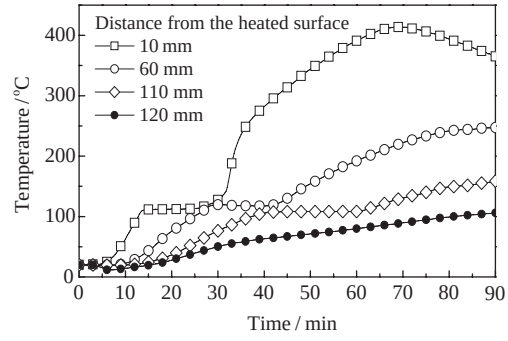

Figure 7. Temperature distribution in the section of segment in HC curve.

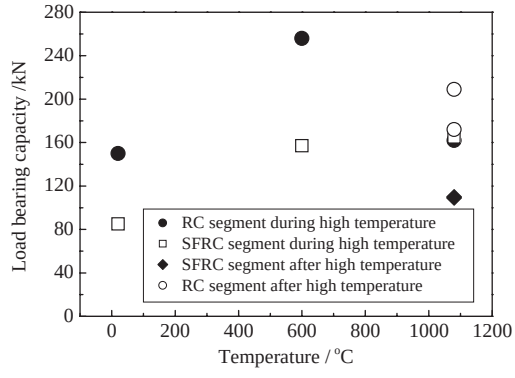

Figure 8. Load bearing capacity of segments under and after different thermal-mechanical conditions.

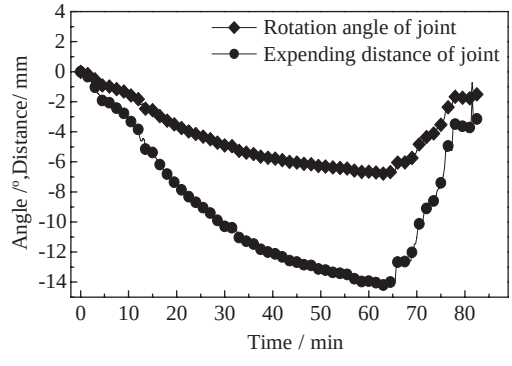

Figure 9. Rotation angle and expending distance of joint owing to high temperature.

Moreover, it is noticed that rubber sealing rod may be destroyed by high temperature if expending distance of joints reach to a certainvalue under fire scenario.

Figure 10. Large expending distance of joint owing to high temperature.

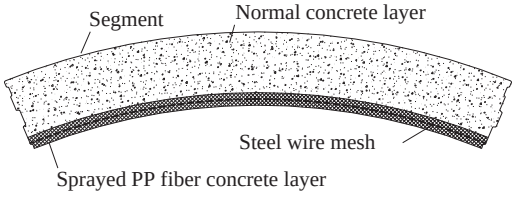

Figure 11. Schematic view of the new segment with ability to prevent spalling during high temperature.

5 A NEW METHODS TO PROTECT TUNNEL LINING FROM SPALLING

Because of rapid heating velocity, high compressive stress and low permeability of tunnel lining concrete, numerous fire accidents indicate that spalling is one of the most severe damage to tunnel linings (Kirkland 2002). Furthermore, due to continuous spalling reinforcement bar may be exposed to high temperature and quickly lose strength and elastic modulus leading to collapse of lining system.

Adding polypropylene fiber to entire concrete mixture is a general method to prevent lining concrete from spalling during high temperature. However, as shown in Figure 6, this method will make the impermeability durability of concrete reduce significantly.

A new method is established in the experiment of FT2 and a new prefabricated segment is designed. In this new method, polypropylene fiber is just mixed in defined thickness near to the inner side of the lining (Fig. 11). And based on spalling temperature of 250°C–420°C and spalling time (generally within the extension of 20 min from fire ignition) (Hertz 200, Khoury 2000), the required thickness of polypropylene fiber concrete layer is summarized in Table 2 according to temperature of hot smoke and time from ignition through FEM simulations. As shown in Figure 12, no spalling is found in the inner surface of the specimen

Table 2. The required thickness of the sprayed PP fiber concrete layer according to temperature of hot smoke/mm.

	Temperature of hot smoke/°C				
Time/min	600	800	1000	1200	1400
15	9–22	17–28	22–32	26–35	29–38
20	10–25	19–32	25–37	30–40	33–44
25	12–28	21–36	28–41	33–46	37–49
30	12–30	24–40	31–45	36–50	40–53

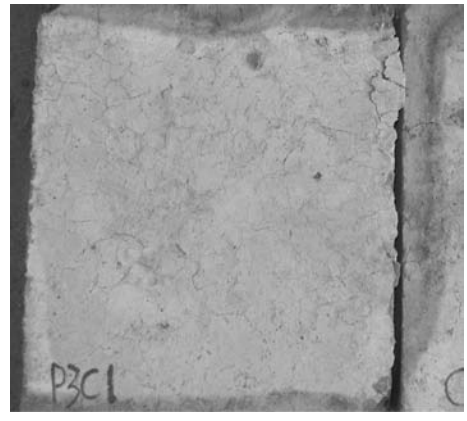

Figure 12. No spalling in the surface of the testing specimens.

with 3 cm polypropylene fiber concrete layer. These results indicate that adding polypropylene fiber to partial concrete mixture is feasible to prevent spalling and to prefabricate segments of shield tunnels.

Comparing with adding polypropylene fiber to entire concrete mixture, this new method will not reduce impermeability durability significantly because polypropylene fiber just is mixed in the thin concrete layer near the inner surface of lining.

6 CONCLUSION

Based on the experiments i.e. FT1, FT2 and FT3, the conclusions can be summarized as follows:

1. Mechanical properties of lining materials, which include uniaxial compressive strength, elastic modulus and impermeability deteriorate significantly after high temperature. This deterioration will seriously affect the safety and reliability of segments (joints) and lining system.
2. Because of material deterioration, thermal damage and thermal stress due to high temperature, the load-bearing capacity and reliability of segments

(joints) and lining system decrease heavily. Moreover, large displacement of lining system may affect the safety of surrounding substructure and surficial buildings.

3. It is important to reduce the deterioration of impermeability durability of lining concrete by high temperature besides preventing spalling. According to the results of the fire experiments mentioned in this paper adding polypropylene fiber to partial concrete mixture is a feasible method to prevent lining concrete from spalling and to control deterioration of impermeability durability.

M. Bettelini
INELMEC SA, Minusio, Switzerland

ABSTRACT: The Branisko tunnel is the first motorway tunnel in Slovak Republic. It was put in operation on June 29 2003. The tunnel system consists of a single tunnel tube with bidirectional traffic and a parallel emergency escape gallery transversally connected to the main tube. The administrator of the Branisko tunnel decided to conduct a risk analysis according to the EU and EC Directive 2004/54/EC on minimum requirements for tunnels in trans-European road network. The final report of the safety analysis includes the applied definitions, descriptions, assessment methods, safety and risk analysis results and recommendations for measures (structural, technical and organizational measures) to improve the safety of the tunnel Branisko. Future risk analysis and safety assessments for road tunnels in the Slovak Republic can apply the mentioned methodology, which fulfils the requirements of the EU/EC 2004/54/EC directive and has been used in other European countries as well.

1 INTRODUCTION

The nature of traffic tunnels and road traffic as such predetermines risk occurrence resulting in critical situations. Due to constantly increasing traffic density it is vital to monitor the current status of traffic safety, although, based on statistical data the accident rate in tunnels is lower that in open roads. Any traffic problems in relation to the confined space in the tunnel induce risk. As the most fatal result of such risk is fire, the fire safety is crucial. Safety assessment includes a variety of factors, therefore, a risk analysis using mathematical statistical methods and theory of probability seems a suitable tool for an objective and systematic assessment.

National Motorway Company, a.s. (NDS, a.s., Bratislava) as the administrator of the Branisko tunnel authorized the consortium Inžinierske združenie AGB which comprises AMBERG Engineering Slovakia, s.r.o., ASIT AG, INELMEC SA and BUNG Ingenieure AG as an independent consultant to perform the following task: "Preparation of risk analysis including ventilation simulation of the Branisko tunnel" a part of which has been the task to prepare tunnel safety documentation and a proposal of a detailed and appropriate methodology, for future use on a national level, corresponding to the best applicable practices (according to the EU and EC Directive 2004/54/EC on minimum requirements for tunnels in trans-European road network).

Figure 1. Western portal of the Branisko tunnel.

2 THE BRANISKO TUNNEL

The Branisko tunnel is the first motorway tunnel in Slovak Republic. It was put in operation on June 29 2003 (Fig. 1).

Figure 2. Escape exit.

Figure 3. SOS-box in an emergency lay-by.

Basic data typical for the tunnel structure:

- Total length of the tunnel: 4974.626 m (including the portals),
- Tunnel system: a single tunnel tube with bidirectional traffic; a parallel emergency escape gallery (clearance profile 2.50×2.50 m) transversally connected to the main tube,
- Longitudinal gradient: (from the west) $+1.2\%$ in length 4550 m, -1.65% in length 425 m,
- Transverse gradient: 2.5%,
- Traffic surface area: 47.68 m^2,
- Width of roadway between curbs: 7.50 m (2 traffic lanes),
- Left and right shoulder (service walkways), each 1.0 m wide,
- Transverse connections to the tunnel tube (Fig. 2) and emergency escape gallery (total number 13, each 360 m apart), whereas one transverse connection in the middle of the tunnel is designed for motor vehicles,
- Lay-bys: 6, out of which 4 single-sided and 2 double-sided (each 700 m),
- Emergency stations each 240 m,
- Ventilation shaft at a distance of 2050 m from the West Portal.

Technological equipment of the tunnel consists of the following devices:

- Ventilation devices: half-transversal system of ventilation with fresh air supply through axial ventilators located in the portal objects or longitudinal ventilation with fresh air supply through portals with ventilation shaft exhaust; louver ventilation flaps controlled by electric actuator are located each 50 m in the ventilation shaft (total number: 90, flow profile: 2.0 m^2);
- Technological equipment of the escape gallery: fire-proof doors with supervision, air condition indication, smoke detectors, lighting equipment, ventilation, wireless radio connection;
- Safety devices in the tunnel: emergency call system by means of emergency box (Fig. 3), system of closed video monitoring, system of wireless radio connection;
- Central controlling system;
- Measurement of physical quantities: opacity measuring devices, CO concentration measuring devices, air circulation speed and direction measuring devices, pressure differential measuring devices;
- Electrical fire signalisation (EPS): automatic fire alarms (point and linear thermal alarm), button fire alarms, stationary fire extinguishing devices;
- Lighting devices – standard, substitute and fire emergency.

3 BRANISKO TUNNEL SAFETY AND RISK ANALYSIS

Component parts of the analysis were the following:

(a) Identification of relevant hazards and scenarios, definition of the relevant operation scenarios at different operational regimes, during maintenance and other incidents, as well as the definition of traffic loading and the assessment of the procedures in case of emergency.
(b) Comparison of actual and prescribed safety measures, with regard to all relevant safety issues and standards in relation to substantial documents, such as Slovak and European safety regulations with particular reference to the Directive of EU and EC 2004/54/EC concerning essential issues of the various parts of the tunnel.
(c) Ventilation analysis (the actual state in relation to the air supply and comparison of the prescribed and actual state), simulation with regard to relevant operational and emergency scenarios, ventilation assessment.

Table 1. Typical values of vehicle fires.

	Min (%)	Max (%)	Special cases
Motor cars	2.0	2.0	2.0
Trucks/buses	1.5	4.5	13.5
Out of this not under control	0.5	1.5	4.5
Vehicles transporting hazardous goods	0.5	1.5	4.5
Out of this not under control	0.2	0.6	1.8

(d) Proposal of a detailed and appropriate methodology, for future use on a national level, corresponding to the best applicable practices. Due to the fact that at the time of developing of the risk analysis, an appropriate methodology valid in Slovak Republic was not yet selected, the task of the author of the risk analysis was also to propose a detailed and appropriate methodology in cooperation with all the concerned parties (i.e. the Ministry of Traffic, Posts and Telecommunications of the Slovak Republic, the Ministry of Internal Affairs, the Fire Brigade and Rescue Head Office, etc.).

(e) In the Branisko tunnel risk analysis, the OECD/PIARC model QRAM (Quantitative Risk Analysis Model) was used whose application is recommendded by PIARC and EU. The QRAM model has been evaluated by several national road and motorway authorities. The risk is visualized by means of a F-N-curve (frequencies versus consequences). The QRAM simulation considers also (apart from the traffic data) various structural and technical features of the tunnel in addition to the air-supply conditions and the smoke extraction of the tunnel ventilation system.

(f) Preparation of the final report as well as the "safety documentation" according the EU-Directive with all definitions, descriptions, assessments results, safety and risk analysis results, with recommendation of additional measures (i.e. structural, technical and organizational measures) and further proposals for improvement of safety and minimization of risks.

3.1 *Qualitative analysis of hazards and risks*

Basically fires in the tunnels are rare. Table 1 gives typical values for vehicles fires per 100 million kilometers (according to CETU 2003).

The minimum value is valid for motorway tunnels and/or municipal motorway tunnel without any specific gradient of access roads. The maximum value is valid for the sections with high longitudinal gradient and turnings or for state roads. The ratio of special cases is valid for tunnels with difficult access roads. So-called "fires not under control" represent such cases when the drivers were not able to extinguish the fire, thus the vehicle and the load was completely destroyed.

Table 2. Vehicle fires after collisions.

	Motorways	State roads
Motor cars	0.007	0.2
Trucks/buses	0.05	4.5
Vehicles transporting hazardous goods	0.5	1.5

Table 3. The most important hazards for persons and environment.

Hazard indicator	Hazard	Cause
Inhabitants (road users, other inhabitants)	Mechanical hazard	Collision, crash, stay in the tunnel
	Danger of fire or explosion	Fire, explosion after accident, technical defect
	Contact with chemical and substances dangerous to life	Leakage of chemicals, smoke after collision, technical defect or fire
Environment: Ground water/ Surface water	Pollution due to leakage of chemicals	Leakage of dangerous substances after collision, technical defect or fire

Only a small number of vehicle fires in the tunnels were primarily caused by a collision (only one vehicle fire out of ca. 30). Table 2 shows the values for fires in the tunnels after collisions for different types of roads (value for 100 million kilometers, CETU 2003).

Based on the CETU values the following fire frequency rates are valid for the Branisko tunnel for traffic frequency 6 000 vehicles per day and a length of 4 975 m:

- Motor cars: 0.7626675×10^{-3}/year.
- Trucks/buses: 5.447625×10^{-3}/year.
- Vehicles transporting hazardous goods (ADR): Transport of hazardous goods is not allowed.

As a part of analysis there are defined relevant hazard scenarios based on the potential hazard assessment. They are to be incorporated into the concept safety documentation/safety management of motorways in Slovakia. Subsequently the most important hazards and risks were determined.

The most important hazards for persons (road users, personnel or inhabitants) and environment adjacent to the D1 Motorway in the Branisko tunnel area are stated in Table 3.

Based on the CETU 2003 methodology the following significant trigger reactions were determined for

the Branisko tunnel (road tunnel with allowed passage of trucks, however, not allowed transport of hazardous goods):

(a) Truck fire (e.g. 20 MW) -> B1
(b) Truck fire transporting liquids or slightly liquefied substances with high heating power (e.g. 100 MW) -> B2

3.2 *Hazard and risk assessment*

The frequency of dangerous events occurrence is displayed in Table 4 (see CETU 2003 for categories) and the extent of the damage is shown in Table 5.

Qualitative risk categories as to the acceptability of risk:

– Unacceptable risk: must be excluded.
– Undesired risk: can be accepted if reduction of risk rate is not practically feasible and the approval by a competent safety authority has been submitted.
– Tolerable risk: accepted subsequent to control and approval by the tunnel administrator.
– Acceptable risk: acceptable without any further approvals by the tunnel administrator.

Subsequently the risks have been evaluated as to the risk acceptance.

Based on the above risk assessment it is possible to scale serious events such as a truck fire (B1) and a fire of a truck with big heating capacity (B2) as follows:

a) B1: C (occasional occurrence) – III (critical extent) = undesired (risk category);
b) B2: D (infrequent occurrence) – IV (serious extent) = undesired (risk category).

The risk for both fire scenarios is considered as undesired based on the proposed system. Therefore it is necessary to implement such measures in order to minimize the risks and the risk is to be monitored (periodic review and evaluation by the safety management).

Table 4. Frequency of dangerous events occurrence.

	Category	Definition	Frequency per km of tunnel/year
A	Very frequent	Very frequent occurrence	>0.1
B	Frequent	Frequent occurrence	0.1–0.01
C	Occasionally	Occasional occurrence	0.01–0.001
D	Infrequent	Infrequent occurrence	0.001–0.0001
E	Very infrequent	Very infrequent occurrence	0.0001–0.00001
F	Unlikely	Occurrence is unlikely but possible	<0.00001

Table 5. Extent of damages.

	Category	Definition	Quantity
I	Insignificant or zero	Material damage, minor injuries only, no death cases	0 dead, a few minor injured
II	Significant	A single death case and/or serious injury	0–1 dead, <5 injured
III	Critical	Several death cases and/or several injuries	2–10 dead, 5–10 injured
IV	Serious	Numerous death cases and numerous injuries	10–50 dead, 10–20 injured
V	Catastrophe	Great many death cases and injuries	>50 dead, >20 injured

3.3 *Quantitative risk analysis with QRAM*

3.3.1 *Introduction*

The OECD methodology was used for personal risk quantification using the software tool QRAM. Thus it is possible to determine individual risks for users due to the transport of dangerous goods (based on model scenarios) in tunnels and in the open route (risk cumulative curve). In addition it is possible to calculate two purely fire scenarios (for 20 MW and 100 MW fire). The individual risk for people is documented in the risk cumulative curves (F-N curves, frequency/fatalities). Environmental risks cannot be analyzed with QRAM.

It is to be emphasized that the QRAM software has been developed to mutually compare the risks of various alternative routes (including tunnels) for the transport of dangerous goods. The model has not been designed for assessment of specific measures to be taken for risk reduction. In the present risk analysis the QRAM version 3.5.1. was used. The QRAM model is partially restricted as to the simulation of certain parameters optimally. Ventilation parameters, for example, have a relatively considerable impact on the results of the model. Based on the hitherto experience with simulations using QRAM (for Swiss tunnels) the results for traffic roads seem correct and acceptable.

3.3.2 *Individual risk quantification for the Branisko tunnel*

The average daily traffic frequency rate in the tunnel is 6 000 vehicles per day, out of which 25% are trucks. The following crisis situations were used for QRAM analysis:

- Perfect fire scenarios:
  – 20 MW fire,
  – 100 MW fire.

- Despite the fact that the transport of dangerous goods is not allowed in the Branisko tunnel at present, three scenarios for dangerous goods were calculated:
  – Fire (pool fire),
  – Explosion (BLEVE propane),
  – Leakage of dangerous gas (e.g. ammoniac).

Calculations of the scenarios with dangerous goods were based on the distribution of ADR classes according to the "Handbook III, Transport routes" of the Swiss ordination "Protection against major accidents" for the transport of dangerous goods (DG).

The diagram in Figure 4 shows the cumulative curve of the fire scenario risks (20 MW and 100 MW fire) in the Branisko tunnel (probability per 100 m of a reference section in one year).

Figure 4 gives risk assessment criteria from Switzerland and Austria. Limit 1 represents the limit of acceptance; limit 2 represents the limit of insignificancy. It is obvious that considerably stricter risk criteria apply in Switzerland.

A 20 MW fire does not mean any substantial hazard according to the QRAM calculations; therefore it is not displayed in the diagram. The ventilation simulation for the Branisko tunnel showed that a 30 MW fire is normally (no pressure differences between the portals) without any problems. A 100 MW fire in the tunnel can be fatal (more than 15 death victims), e.g. the Gotthard tunnel fire (October 2001). Such fire, based on a high frequency rate, represents a considerable potential risk. If compared with the Swiss regulations such risk is not acceptable. If compared with the Austrian regulations the measures are to be inspected.

The transport of dangerous goods is not allowed in the Branisko tunnel. For the sake of completeness three other scenarios for the transport of dangerous goods in the Branisko tunnel were modelled.

The diagram in Figure 5 shows the cumulative risk curve for the scenarios with dangerous goods in the Branisko tunnel, apart from the Swiss and Austrian risk assessment criteria (limit 1 represents the limit of acceptance and limit 2 represents the limit of insignificancy).

Figure 5 shows the cumulative curves of risks of the respective crisis situations with dangerous goods and also the total cumulative curve of risks for the Branisko tunnel. The quantitative risk analysis clearly proves that when transporting dangerous goods the collective personal risk curve (total cumulative risk curve) for the current ventilation system does not fall within the acceptable scope of the Swiss assessment criteria for the Ordination "Protection against major accidents" (OPMA). Similarly it does not fall within ALARP scope of the Austrian assessment criteria.

The location of the overall cumulative curve of risks is dominant as to the "pool fire" scenario: it clearly expresses that for the current traffic frequency rate and for the current ventilation system such a situation constitutes a great risk. The tunnel user in case of a fire has a restricted chance of escaping to the protected or safe area in time. A high number of death victims is to be assumed. The previous modelling of a 100 MW fire without any transport of dangerous goods came to similar conclusion. The cumulative curve of a crisis situation when considering an explosion shows a high number (up to 60) fatalities and it passes through a transitory area according to the Swiss ordination. In such situation there is no chance to escape (short time factor).

The cumulative risk curve points to the fact that the Branisko tunnel is not without fault when assessing personal risk. Most significantly, the ventilation system based on the cumulative risk curves of a 100 MW fire (e.g. truck fire with high fire power without any transport dangerous goods involved) and a pool fire (in case of DG scenarios to be considered) has negative effects on fire scenarios.

In this regard it is also very important to implement recommendations as to the rescue planning and (operational) rescue plans.

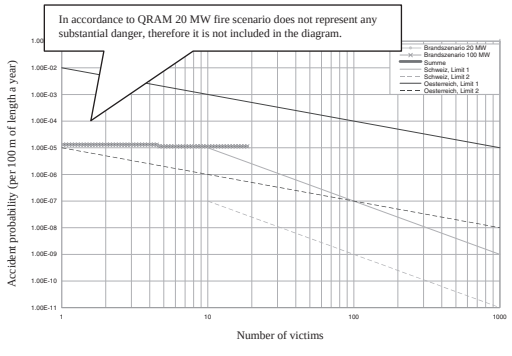

Figure 4. F-N curves of fire scenarios without DG for the Branisko tunnel.

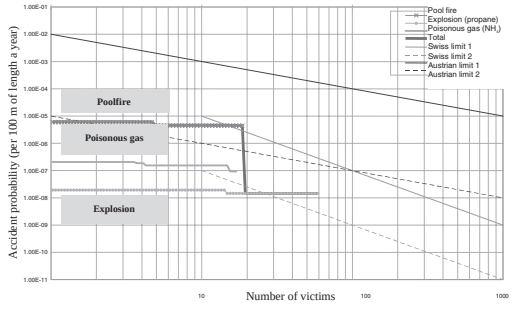

Figure 5. F-N curves of dangerous goods scenarios for the Branisko tunnel.

QRAM modelling demonstrated that the 100 MW fire scenarios and those of pool fire with dangerous goods show similar F-N curves results.

Safety measures are designed to remove a high potential risk in case of major fire events. In particular in case of fires with high radiation (more than ca. 100 MW) the insufficient output of exhaust fans has a negative impact on the cumulative curves of risks for fire scenarios.

3.4 *Level of measures assessment*

A system of assessing the level of the existing safety measures (level of safety measures) with reference to the safety technology condition (STC) has been proposed, using four categories:

1. Very good level of safety measures + STC fully attained (fully-fledged/total conformity with the EU Directive or with the practice of other states).
2. Good level of safety measures + STC partially but prevailingly attained (partial conformity with the EU Directive or partial conformity with practice of other states).
3. Critical level of safety measures + STC prevailingly not attained (low conformity with the EU Directive or only partial conformity with practice of other states).
4. Bad level of safety measures + STC not attained (no conformity with the EU Directive or no conformity with practice of other states).

Additionaly the real conditions and effectiveness of safety measures regarding risk relevance were assessed too and additional measures were recommended for the relevant issues regarding infrastructure (construction, technology equipment) and tunnel operation.

4 CONCLUSION

The Branisko tunnel risk analysis has been the first risk analysis prepared for a Slovak road or railway tunnel. It contains a suitable methodology to be used in Slovakia in the future.

The Branisko tunnel risk analysis showed that the tunnel in general represents minor risks. However is has to be pointed out that the current ventilation system is insufficient for adequate safety conditions for all operational regimes of the tunnel. This is due to its exhaust capacity in case of a fire. If the above deficiency is removed and some other minor measures are put into operation the Branisko tunnel shall fully comply with the up-to-date safety requirements.

ITA-Committee on operational safety of underground facilities – COSUF: Role and objectives

A. Haack
STUVA e.V., Cologne, Germany; Former President of ITA

ABSTRACT: The tragic tunnel fires of the past years have lead to discussions of experts in Europe and around the world. In many European countries they have caused a complete revision of the national safety guidelines for road and rail tunnels. The European Commission has developed directives concerning the minimum safety equipment of road tunnels as well as of railway tunnels. This action is supplemented by intensive domestic and international research activities. The Second International Symposium on Safe & Reliable Tunnels gives special focus on the objectives and important findings of this most recent research programme. The two projects UPTUN and SafeT being just in their final stage form together with COSUF – the ITA Committee on Operational Safety of Underground Facilities the main topic. The Committee is joining 8 research and network projects launched within the 5th and 6th Research Programme of the EU. It is aiming at a world-wide exchange of views, ideas and experience in the field of safety and security regarding traffic tunnels and other underground facilities.

1 INTRODUCTION

Fires in transport tunnels can cause catastrophic disasters. The accidents in the French/Italian Mont Blanc Tunnel (March 24, 1999), in the Austrian Tauern Tunnel (May 29, 1999), in the Swiss Gotthard Tunnel (October 24, 2001; Fig. 1), in the subway system in Daegu/South Korea (February 18, 2003; Fig. 2), in the Swiss Baregg Tunnel (April 14, 2004), in the French Fréjus Tunnel (June 4, 2005; Fig. 3) and most recently in the Swiss Via-Mala-Tunnel (September 16, 2006) have made this more than clear. The detailed analysis of the cause and progression of these fires have yielded new insights that had not been expected or calculated to this extent before. The only comparable experience before has been the fire in the Nihonzaka Tunnel in Japan of 1979, which involved a total of 189 vehicles.

One insight pertains to the extremely rapid development of truck fires with an enormous rise in temperature of up to 1000 degrees Celsius and above. Experience has also shown that large amounts of fire gases are released within a short time, starting in a very early phase of the fire development.

The fire in the Mont Blanc Tunnel also showed that heated gases are capable of setting other vehicles on fire even at distances of 200 meter and more with no vehicle in between. The third and especially frightening aspect is the behaviour of the tunnel users. Too many of them did not recognize the danger they were exposed to. When they finally realized what was happening, it was frequently too late for a successful escape. In the context of subway fires, the example of Daegu also showed how crucial the impact of railcar engineering and equipment, operational organization and safety training of train conductors and station managers can be. Severe shortcomings in these criteria were a crucial factor in the tragic outcome with 196 fatalities.

Figure 1. Burning lorries in the Gotthard Tunnel (Switzerland) on 24.10.2001.

Figure 2. Arson attack in the subway of Daegu/South Korea on 18.2.2003.

Figure 3. Fire accident in the Fréjus Tunnel (France) on 4.6.2005.

2 SAFETY RELATED EUROPEAN RESEARCH

In consequence of the devastating fire accidents the European Commission issued in April 2004 directives regarding the minimum fire prevention equipment of road and rail tunnels. In addition, a number of important research projects were initiated. These are seven multinational projects that have already been awarded and funded in conjunction with the fifth and one project with the sixth Research Framework Programme of the EU briefly described by Haack in 2005 and as follows. They are more or less linked with each other as well as with national projects like a puzzle.

- **DARTS** (**D**urable **A**nd **R**eliable **T**unnel **S**tructures) started in March 2001 and ended in early 2004. The initiative included eight European partners and was structured into six technical work packages. It was primarily dedicated to the problem of exceeded cost during the construction of underground transport facilities. Furthermore, the quality and lifetime of tunnels as the most cost-intensive component of the entire traffic infrastructure was to be improved. For more information see www.dartsproject.net.
- **FIT** (**F**ire **I**n **T**unnels) was established in March 2001 and limited to four years. This "thematic network" included 33 partners from twelve European countries. The project was to gather information from all over Europe and around the world about existing research results and general experiences with fire prevention and mitigation in transport tunnel facilities. For further details visit: www.etnfit.net.
- **UPTUN** (Cost-effective, sustainable and innovative **UP**grading methods for fire safety in existing **TUN**nels) is a RTD project, running from 2002–2006. UPTUN is being performed by 42 partners from 18 European countries. UPTUN comprises research work of approx. 950 man months. Detailed information on UPTUN and its partners can be found at www.uptun.net.
- **Safe Tunnel (Safe**ty in Road **Tunnel**s) began in September 2001 and was designed for a project term of three years. The project involved nine partners. The main focus was to reduce the extent and number of fire accidents in road tunnels. The web address of this project is: www.crfproject-eu.org.
- **SIRTAKI (S**afety **I**mprovement in **R**oad& Rail **T**unnels using **A**dvanced Information Technologies and **K**nowledge **I**ntensive Decision Support Models) was initiated in September 2001 for a term of three years. The initiative was shared by twelve European partners. The main focus of the project was to reform operative concepts with regard to safety and emergency management. Further details are available at: www.sirtakiproject.com.
- **Virtual Fires** (**Virtual** Real Time Emergency Simulator) was started 2001 for a duration of three years with eight partners from five European countries. The objective was to develop a suitable and practical simulator to train firefighters in confining and fighting fires in tunnels. A computer model is used to create virtual simulations of fires in tunnel situations. For more information visit: www.virtualfires.org.
- **Safe-T** (**Safe**ty in **T**unnels) represents another thematic network with a three-year term that was started in the fall of 2003. The primary objective is

to harmonize the European requirements regarding tunnel safety. Experiences gathered at the national level are to be compiled and assessed in such regulations. Given the background of the negative experience with the former operative concept of the Mont Blanc Tunnel, special emphasis will be on cross-border operative concepts. The experience of regional authorities, firefighters and emergency rescue services are of special importance for this project. Further details are available from the website at: www.safetunnel.net.

– L-SURF (Design study for a Large Scale Underground Research Facility on Safety and Security) as a research project on safety and security in enclosed underground spaces is of outstanding importance as most recent incidents (tunnel fires, terror attacks in metros etc) have shown. However currently the competence related to safety and security in Europe is largely unstructured, fragmented and mostly national oriented. Especially missing is a large scale research facility. For more details see www.L-Surf.org.

3 STEP INTO FUTURE

These eight projects mentioned before came to the conclusion that their joint capacity and the momentum gained by the intensive research work conducted during the last couple of years present a great chance for an ongoing future research work and global exchange of knowledge. They therefore looked for a worldwide well reputed international umbrella organisation which could offer a basis for coming activities to develop a better safety level for all kinds of underground facilities. ITA – the International Tunnelling Association – with its 53 member nations worldwide was ready to play that role in close cooperation with PIARC – the World Road Association. Finally the eight projects came to an agreement with ITA and established the ITA **C**ommittee on **O**perational **S**afety of **U**nderground **F**acilities (COSUF; Fig. 4). This committee was installed in May 2005 at the occasion of the ITA World Tunnel Congress 2005 in Istanbul, Turkey. Although starting from the 8 European projects listed above COSUF is open for all institutions, companies, consultancies, governmental organisations etc. world-wide which are active and interested in the field of safety and security regarding underground facilities.

4 SCOPE AND OBJECTIVES

The scope of COSUF concerns safety in tunnels and other underground facilities. It is limited to safety in operation and not during construction This subject is covered by ITA Working Group No. 5: “Health and Safety”. Security will also be covered and is considered as part of safety.

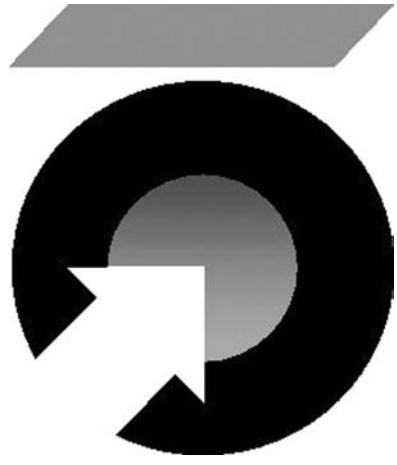

Figure 4. Logo of COSUF.

Within this scope the following objectives as basis for all the future activities of COSUF are defined:

– maintain and develop a network to:
  - exchange knowledge
  - encourage collaboration
  - facilitate the creation of dedicated teams and groups to perform specific (research) activities
– facilitate cooperation worldwide
– enhance research and development activities through combining of national, European and international funding and promoting support
– promote safety (and security) by:
  - fostering innovation
  - raising awareness of current and newly developed safety (and security) issues amongst decision makers, professional end-users, financers, risk managers, international forums and other stakeholders
– supporting the development of improved regulations

5 ACTIVITIES AND BASIC STRUCTURE

Considering the aforementioned objectives COSUF will follow the below listed activities as described by Haack in 2006. The list gives examples but does not claim to be complete. In detail the activities will include:

– networking and coordination meetings, at least once a year, possibly linked with other events
– to take part in international standardisation

– actions towards focussing international research programmes to include tunnel and underground safety (and security), e.g. in the EU framework programmes, European Technology Platforms or other international activities
– developing and maintaining a website, based on the FIT-website, which will promote its activities and disseminate its findings
– (co-)organising workshops and conferences
– to form groups and ad-hoc task forces inside the Committee to address issues related to the scope of the Committee and its objectives

For conducting the manifold activities COSUF has formed three Activity Groups (AGs):

– *Activity Group 1*: Interaction with European and international initiatives; coordinated by Ben van den Horn, Rijkswaterstaat, The Netherlands
– *Activity Group 2*: Regulations and best practice; coordinated by Dr. Marc Tesson, CETU -Centre d'Etudes des Tunnels, France
– *Activity Group 3*: Research and new findings; coordinated by Prof. Dr.-Ing. Markus Thewes, Ruhr University of Bochum, Institute for Tunnelling, Pipeline Technology and Construction Management, Germany

These AGs are described to more details further down. They generally aim at collection of information, creation of syntheses and recommendations, dissemination of information, identification of current and future needs for research and development giving direction as well as specific initiatives, and other related activities.

The AGs themselves do not carry out studies, research or similar activities of commercial value which could be done by institutes or companies. Instead of that they should develop to be centers of excellence for exchange of information and know-how with regard to safety and security of tunnels and other underground facilities.

The general objectives of the AGs are:

– sufficient safety and security for tunnel users, employees and rescue personnel
– cost efficient solutions for safety and security
– a strive for optimality taking into consideration life-cycle cost and socio-economy and societal demands
– improvements of tunnel safety and security by fostering innovation and with a vision of future possibilities and needs

The three AGs must interact to avoid duplication in their work. Thus their activities have to be coordinated by the SB. The AGs will establish task groups and ad-hoc groups which shall deal with specified sub-items.

The Activity Groups are controlled and receive advice in a strategical and political sense by the Steering Board (SB) of COSUF, which consists of representatives from the 8 research projects. The SB is chaired by a chairman as representative of ITA – the International Tunnelling Association and a vice chairman as representative of PIARC – the World Road Association. Both are responsible to the annual General Assembly of ITA.

6 WORK PROGRAMME OF THE ACTIVITY GROUPS

6.1 *Activity Group 1: Interaction with European and international initiatives*

AG 1 will take and keep contact with other external institutions, groups and projects in order to receive relevant information, to co-operate for avoiding duplication of activities, to give information about activities in COSUF to external groups and possibly influence the initiatives.

The relevant external groups and initiatives can include for example:

– European Construction Technology Platform, Focus Area Underground Construction (as far as COSUF is concerned)
– European Technology Platform on Industrial Safety "ETPIS"
– other international committees like: ACUUS, ISO, ISTT, ITP, PIARC, fib, RILEM, UIC etc.
– national or international organisations funding research
– existing and completed European research projects others than the projects founding COSUF, for example EuroTAP and TUNCONSTRUCT
– other research, commercial, national or international projects
– testing programmes
– large construction projects
– other relevant initiatives, groups or similar

The areas considered in Activity Group 1 are complementing those mentioned below for Activity Groups 2 and 3. The activities in Activity Group 1 consist e.g. of:

– identifying relevant initiatives outside COSUF
– attracting COSUF members from the initiatives or appoint liaison responsible COSUF members
– liaison with initiatives outside COSUF
– reporting to Activity Groups 2 and 3 about the results and findings of activities outside COSUF
– reporting transparently to relevant external groups and initiatives about the ideas and results of COSUF
– ensuring that safety and security is given proper priority in initiatives concerning underground facilities
– influencing initiatives to include safety and security aspects in line with the ideas of COSUF

– bringing COSUF ideas to life as projects either as part of existing initiatives or as new separate projects

Participants should come from the 8 projects, but should also be representatives from projects, committees, groups, and institutions outside of COSUF. If not otherwise possible a COSUF member could be appointed to be the liaison officer for those projects.

6.2 *Activity Group 2: Regulations and best practice*

AG 2 will cover regulations, the state-of-the-art and best-practices in various countries world-wide. The state-of-the-art can monitor the current practice and experience with various design methods for different tunnel systems. This includes discussion and comparison of regulations and best-practice procedures from different owners, networks, projects and the experience gained by them.

By doing this it is aimed to collect and distribute information on existing national and international regulations and recognised recommendations as well as to establish the best-practice for tunnel safety (and security). As a result it can be identified that

– there is a need of improvement or harmonisation considering regulations in different countries, between networks, between different projects etc.
– the regulations are not up-to-date compared with the recent activities and achievements in practice
– state-of-the-art or state of practice is deviating significantly from region to region, from industry to industry or from institution to institution.

The findings can result in requirements for new regulations; they can also contribute to disseminate the knowledge from region to region or from industry to industry, from institution to institution and identify areas for which new research is needed.

Ideally the work in this Activity Group is part of establishing a global state-of-the-art for tunnel safety (and security) and the regulatory tools to control that an adequate safety (and security) level is achieved.

All underground facilities are covered by these activities. This includes underground facilities for transportation like road, rail and metro tunnels, as well as underground facilities such as underground shopping malls, underground stations, places for other purposes e.g. for concerts, sports, exhibitions, production facilities, underground technical facilities, etc. For these areas there might be a need for establishing the best practices and the necessary up-to-date regulation.

The activities should cover all safety related aspects such as (at least):

– safety objectives
– basic methods of technical approach (prescriptive and performance-based approaches)
– protection of the structure
– methods for risk assessment
– safety systems and equipment
– interaction with human behaviour
– operation and maintenance
– intervention

These above-mentioned activities may be distinguished for the different types of underground facilities (road, rail, metro and other underground use) or may be considered together. For all activities it will be relevant to discuss both the side of best-practice and the side of regulations and to compare the two sides.

The area of security may be highlighted specifically, since there may be a need for establishing the state-of-the-art also in this field. Security deviates from safety particularly with respect to the prevention, whereas the reaction consequence side may be similar to those which are resulting from evaluation and analysis of accidents or so. These prevention activities will involve regulations of control, enforcement, and similar.

The participants will be mainly engineers, scientists, fire brigades, rescue teams, and other professionals with experience concerning safety in design, operation and rescue in various areas related to underground facilities. For security the professionals may include the police. Public servants and others involved (on project, regional, national, supranational (EU) and international basis) in developing and reinforcing regulations can significantly contribute to these activities. Also researchers and other professionals with knowledge of the most recent achievements and findings may contribute to the identification of needs and demands for the design process and its regulation.

The participants should also include representatives from Activity Group 1 and of current research projects, committees, organisations involved in developing and studying tunnel safety and security.

6.3 *Activity Group 3: Research and new findings*

The scope of AG 3 is to motivate to research and to use research results and other new findings for the benefit of safety (and security) in underground facilities in general. The activities include.

– collection of results of research and collection of new findings
– evaluation of events, results and new findings
– dissemination of the results and new findings among COSUF members
– synthesis of results and new findings into best practices (in collaboration with AG 2)
– collection and evaluation of ideas for research
– identify needs for the future and give directions for future research

The actual launch of new research projects is initiated outside COSUF by liaison through AG 1.

The aim is to make aware all relevant professionals of new findings and recent results of research in the safety and security related activities regarding underground facilities, to discuss these results and other ideas and to process them into specifications of needs of new research into recommended best practices.

In order to fulfil these aims it is necessary to:

- identify safety (and security) related activities for underground facilities
- identify relevant research activities and their results
- identify relevant new findings
- process into best practices (in cooperation with AG 2)
- evaluate the results and the findings
- receive and develop ideas for research
- communicate the results and findings
- identify new needs and requirements for research
- outline the basis of new ideas for research
- liaise with Activity Group 1 for the launching of projects outside COSUF

The sub-items considered cover all safety (and security) related activities. These areas could include the following, but the list may be modified and extended during the work, depending on the available information and the interests and qualification of the members of AG 3:

- new/innovative equipment in tunnels and new materials
- processes, analyses and design procedures integrated design procedures, risk analyses as part of the design, fire design techniques etc.
- IT tools in the tunnel design and operation
- test programmes using standardised techniques
- operation and maintenance monitoring
- safe intervention, evacuation, fire fighting etc.
  planning
  training
  simulation
- interface tunnel, users, operators and rescue services (human behaviour etc.)
- experience from tunnel incidents, accidents and near misses
- tunnel safety related data collection
- specific security related problems for underground facilities

For research and new findings it may be also relevant to divide into the types of underground facilities: road, rail, metro and other underground use, as mentioned for AG 2.

The possible number of a crosswise combination of items, sub-items, activities and types of facilities is high. The AG will have to organise itself and to prioritise the activities.

The participants in the activities are mainly researchers with activities in the field of safety (and security) of underground facilities and engineers, scientists and other professionals with experience in safety design in various areas related to underground facilities. Furthermore, other professionals involved in design, operation, rescue etc. of tunnels, and particularly the safety (and security) related side of these activities can significantly contribute to the activities. Public institutions and representatives of formulating research and funding institutes would also be highly relevant as participants in the work.

In addition representatives from AG 1 and of current research projects, committees, organisations involved in developing and studying tunnel safety and security outside of COSUF should also become participants of this AG.

7 MEMBERSHIP

COSUF invites all parties world-wide interested in the field of operational safety and security of tunnels and other underground facilities to become member and to co-operate within COSUF. There will be exceptionally corporative members, no individual ones. The membership in COSUF has to be confirmed by the General Assembly of ITA, but is not bound to membership in ITA or vice versa. Of course, a membership in both is possible and welcome.

The annual membership fee will be as follows:

- public organisations and educational institutes: EUR 250
- all others: EUR 500

Interested parties can subscribe membership at the occasion of the 2nd International Symposium Safe & Reliable Tunnels on May 30-31, 2006 in Lausanne, Switzerland or online using the form given on the ITA webpage www.ita-aites.org.

A numerous and wide-ranging membership will certainly help to improve and standardise the safety and security level in traffic tunnels and all other underground facilities.

8 OUTLOOK

The tremendous research efforts of the European Commission described here to improve the safety in traffic tunnels are an essential prerequisite for the highly needed all-European harmonization in this field. Here COSUF forms a platform to continue the activities even after finalising the research projects and in the same time presents a forum for a world-wide exchange of views, ideas and experience in the field of safety and security regarding underground facilities. This appears especially important as tunnels are an indispensable

part of the trans-European traffic network. Given this background, the research activities are delivering a crucial contribution to guarantee the mobility of persons and goods, which represents a high political priority.

Optimisation of road tunnel safety based on risk analysis

M. Holický
Klokner institute, Czech Technical University in Prague, The Czech Republic

J. Smolík
SUBTERA, Ltd., Prague, The Czech Republic

L. Šajtar
SATRA, Ltd., Prague, The Czech Republic

ABSTRACT: Optimisation of operational safety of road tunnels is based on the probabilistic methods of risk analysis taking into account societal and economic consequences and possible safety measures contemplated in design. The total consequences of alternative tunnel arrangements are assessed using Bayesian networks supplemented by decision and utility nodes. It is shown that the optimization of the total consequences may provide valuable information enabling a rational decision concerning effective safety measures. A general procedure is illustrated by the optimization of a number of escape routes considered in design of road tunnels. It appears that the optimum number of escape routes is significantly affected by the discount rate and specified life time of a tunnel. Further investigation of relevant input data including societal and economic consequences of various hazard scenarios is, however, needed.

1 INTRODUCTION

Tunnel structures usually represent complex technical systems that may be exposed to hazard situations leading to unfavourable events with serious consequences. Minimum safety requirements for tunnels in the trans-European road network are provided in the Directive of the European Parliament and of the Council 2004/54/ES. The Directive also gives requirements concerning risk management, risk assessment and analysis.

Methods of risk assessment and analysis are more and more frequently applied in various technical systems (Melchers 1999, Steward & Melchers 1997) including road tunnels. This is a consequence of recent tragic events in various tunnels and of an increasing effort to take into account societal, economic and ecological consequences of unfavourable events (Holicky & Šajtar 2005, 2006). Available national and international documents (NS 5814 1991, CAN/CSA 991, ISO 2394 1998, ISO/IEC Guide 73 2002, ISO/IEC Guide 51 1999, ISO 9000 2000) try to harmonise general methodical principles and terminology that can be also applied in the risk assessment of road tunnels.

The submitted contribution, based on previous studies (Brussaard & Kruiskamp 2004, Ruffin et al. 2005, Vrouwenvelder et al. 2001, Vrouwenvelder & Krom 2004, Kruiskamp et al. 2001, Worm et al. 1998) and recent PIARC working documents, attempts to apply methods of probabilistic risk optimization using Bayesian networks supplemented by decision and utility nodes (Jensen 1996). It appears that Bayesian networks provide an extremely effective tool for investigating the safety of road tunnels.

2 PRINCIPLES OF RISK ASSESSMENT

Risk assessment is an essential part of the risk management as indicated in Figure 1 (based on CAN/CSA 1991). The diagram in Figure 1 indicates the main components of risk management and relevant basic terms. The whole process of risk management includes the risk assessment and risk control. The risk assessment further consists of the risk analysis and risk evaluation. The risk control consists of the risk decision and risk monitoring. Figure 1 also indicates an important part of the whole risk management, i.e. risk communication concerning an unavoidable exchange of data between the risk assessment and risk control. Obviously other types of risk communication may be required in case of the risk management of complex tunnel systems.

The main components of the whole risk management consist of the risk assessment and risk control.

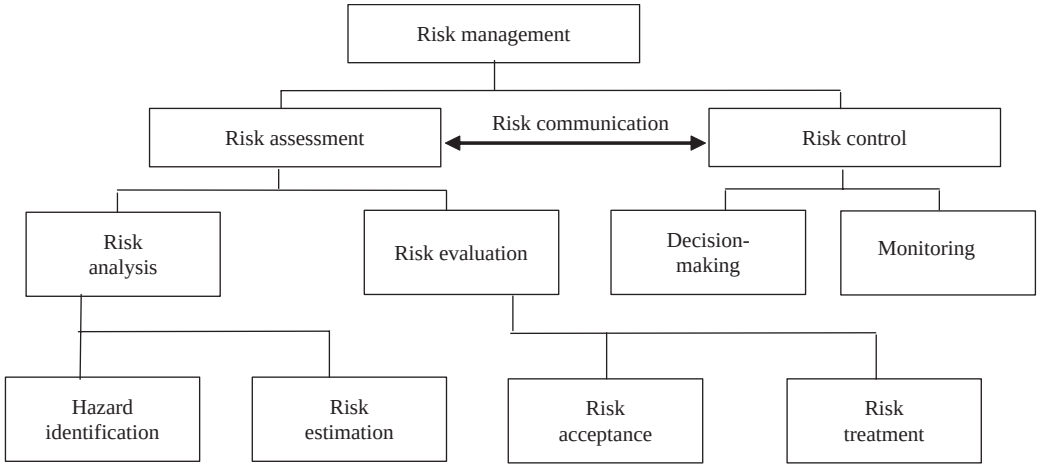

Figure 1. A framework for risk management (adopted from CAN/CSA 1991).

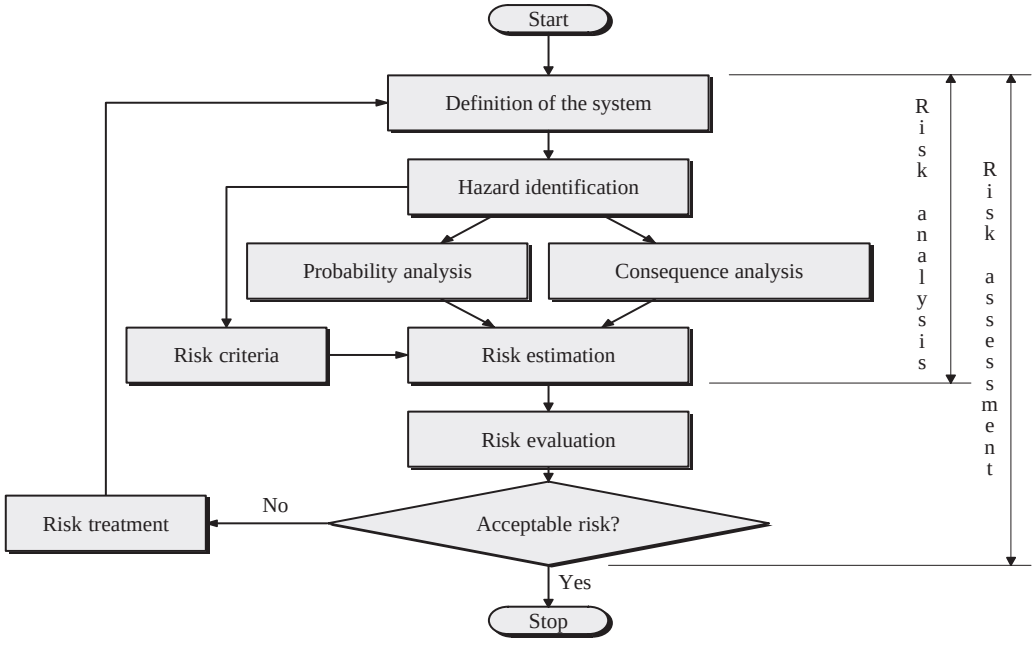

Figure 2. Flowchart of iterative procedure for the risk assessment (adopted from ISO 1999).

The risk control is outside the scope of this paper. A general procedure of risk assessment is shown in Figure 2 indicating the main steps. The flowchart is adopted from ISO 1999 and recent working materials of PIARC/C3.3/WG2. Two key steps of the risk analysis, probability and consequence analysis, and subsequent risk estimation are shortly described below.

3 PROBABILITY ANALYSIS

Probabilistic methods of risk analysis are based on the concept of conditional probabilities $P_{fi} = \mathrm{P}\{F|H_i\}$ of the event F providing a situation H_i occurs (Melchers 1999). In general this probability can be found using statistical data, experience or theoretical analysis of the situation H_i.

If the situation H_i occurs with the probability $P(H_i)$ and the event F during the situation H_i occurs with the probability $P(F|H_i)$, then the total probability P_F of the event F is given as

$$P_F = \sum_i P(F \mid H_i) P(H_i) \tag{1}$$

Equation (1) makes it possible to harmonize partial probabilities $P(F|H_i)$ $P(H_i)$ related to the situation H_i.

The main disadvantage of the purely probabilistic approach is the fact that possible consequences of the events F related to the situation H_i are not considered. Equation (1) can be, however, modified to take the consequences into account.

4 RISK ESTIMATION

A given situation H_i may lead to a set of events E_{ij} (for example fully developed fire, explosion), which may have societal consequences R_{ij} or economic consequences C_{ij}. It is assumed that the consequences R_{ij} and C_{ij} are unambiguously assigned to events E_{ij}. If the consequences include only societal components R_{ij}, then the total expected risk R is given as

$$R = \sum_{ij} R_{ij} P(E_{ij} \mid H_i) P(H_i) \tag{2}$$

If the consequences include only economic consequences C_{ij}, then the total expected consequences C are given as

$$C = \sum_{ij} C_{ij} P(E_{ij} \mid H_i) P(H_i) \tag{3}$$

If criteria R_d and C_d are specified, then acceptable total consequences should satisfy the conditions

$$R < R_d \text{ and } C < C_d \tag{4}$$

that supplement the traditional probabilistic condition $P_f < P_{fd}$.

When the criteria are not satisfied, then it may be possible to apply a procedure of risk treatment as indicated in Figure 2. For example additional escape routes may be provided. Such measures might, however, require considerable costs, which should be considered when deciding about the optimum measures.

5 RISK OPTIMIZATION

The total consequences $C_{tot}(k, p, n)$ relevant to the construction and performance of the tunnel are generally expressed as a function of the decisive parameter k (for example of the number k of escape routes), discount rate p (commonly about $p \approx 0,03$) and life time n (commonly $n = 100$ let). The decisive parameter k usually represents a one-dimensional or multidimensional quantity significantly affecting tunnel safety.

The fundamental model of the total consequences may be written as a sum of partial consequences as

$$C_{tot}(k,p,n) = R(k,p,n) + C_0 + \Delta C(k) \tag{5}$$

In equation (5) $R(k, p, n)$ denotes expected societal risk that is dependent on the parameter k, discount rate p and life time n. C_0 denotes the basic of construction cost independent of k, and $\Delta C(k)$ additional expenses dependent on k. Equation (5) represents, however, only a simplified model that does not reflect all possible expenses including economic consequences of different unfavourable events and maintenance costs.

The societal risk $R(k, p, n)$ may be estimated using the following formulae

$$R(k, p, n) = N(k)\ R_1\ Q(p, n),$$
$$Q(p, n) = \frac{1 - 1/(1+p)^n}{1 - 1/(1+p)} \tag{6}$$

In equation (6) $N(k)$ denotes number of expected fatalities per one year (dependent on k), R_1 denotes acceptable expenses for averting one fatality, and p the discount rate (commonly within the interval from 0 to 5%). The quotient q of the geometric row is given by the fraction $q = 1/(1 + p)$. The discount coefficient $Q(p, n)$ makes it possible to express the actual expenses Z_1 during a considered life time n in current cost considered in (5). In other words, expenses Z_1 in a year i correspond to the current cost $R_1 q^i$. The sum of the expenses during n years is given by the coefficient $Q(p, n)$.

A necessary condition for the minimum of the total consequences (5) is given by the vanishing of the first derivative with respect to k written as

$$\frac{\partial N(k)}{\partial k} R_1 Q(p, n) = -\frac{\partial \Delta C(k)}{\partial k} \tag{7}$$

In some cases this condition may not lead to a practical solution, in particular when the discount rate p is small (a corresponding discount coefficient $Q(p, n)$ is large) and there is a limited number of escape routes k that can not be arbitrary increased.

6 STANDARDIZED CONSEQUENCES

The total consequences given by equation (5) may be in some cases simplified to a dimensionless standardized form and the whole procedure of optimization may be generalized. Consider as an example the optimization of the number k of escape routes. It is assumed that

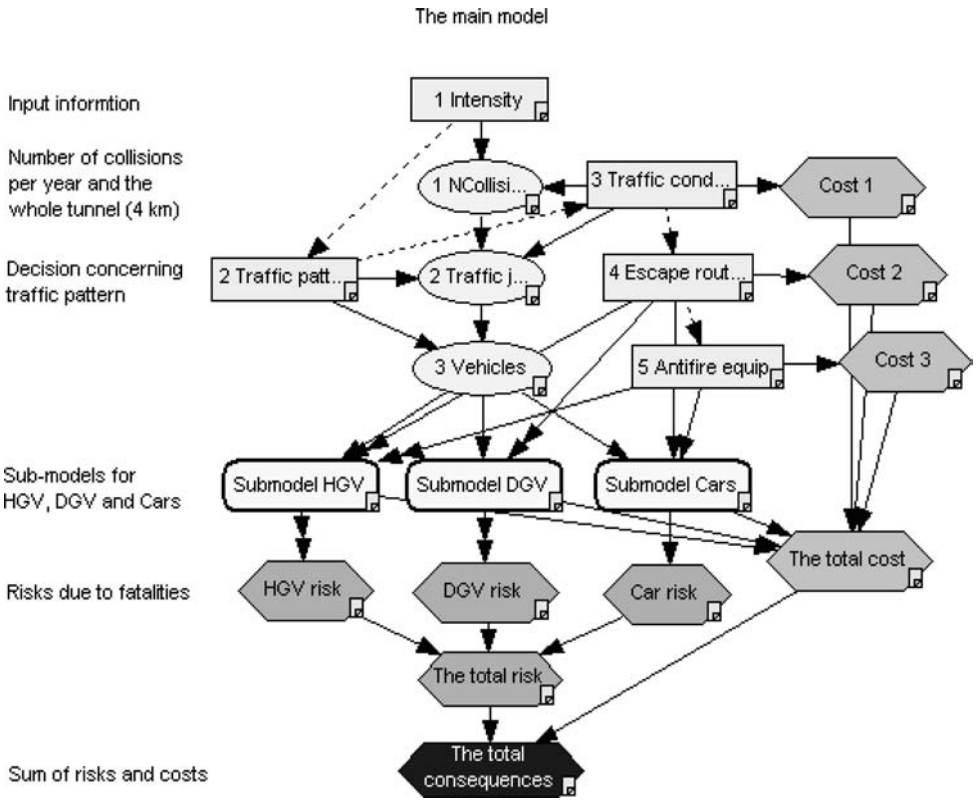

Figure 3. Main model of the tunnel.

involved additional costs $\Delta C(k)$ due to k may be expressed as the product $k\ C_1$, where C_1 denotes cost of one escape route. If C_1 is approximately equal to R_1 (assumed also by Vrouwenfelder & Krom 2004), equation (5) becomes

$$C_{\text{tot}}(k,p,n) = N(k)\ C_1\ Q(p,n) + C_0 + k\ C_1 \tag{8}$$

This function can be standardized as follows

$$\kappa(k,p,n) = \frac{C_{tot}(k,p,n) - C_0}{C_1} = N(k)Q(p,n) + k \tag{9}$$

Both variables $C_{\text{tot}}(k,p,n)$ and $\kappa(k,p,n)$ are mutually dependent and have the extremes (if exist) for the same number of escape routes k. A necessary condition for the extremes follows from (7) as

$$\frac{\partial N(k)}{\partial k} = -\frac{1}{Q(p,n)} = -\frac{1-1/(1+p)}{1-1/(1+p)^n} \tag{10}$$

An advantage of standardized consequences is the fact that it is independent of C_0 and C_1. It is only assumed that $C_1 \approx Z_1$ is a time invariant unit of the total consequences.

7 MODEL OF A TUNNEL

The main model of a road tunnel is indicated in Figure 3. The tunnel considered here is partly adopted from a recent study (Vrouwenfelder & Krom 2004). It is assumed that the tunnel has the length of 4000 m and two traffic lanes in one direction. The traffic consists of heavy goods vehicles HGV, dangerous goods vehicles DGV and Cars.

The total traffic intensity in one direction is 20×10^6 vehicles per year (27 400 vehicles in one lane per day). The number of individual types of vehicles is assumed to be HGV:DGV:Cars = 0,15:0,01:0,84. The frequency of serious accidents assuming basic traffic conditions (that might be modified) is considered as 1×10^{-7} per one vehicle and one km (Vrouwenfelder & Krom 2004), thus 8 accidents in the whole tunnel per year. The Bayesian networks used here need a number of other input data. Some of them are adopted from the study (Vrouwenfelder & Krom 2004) (based on event

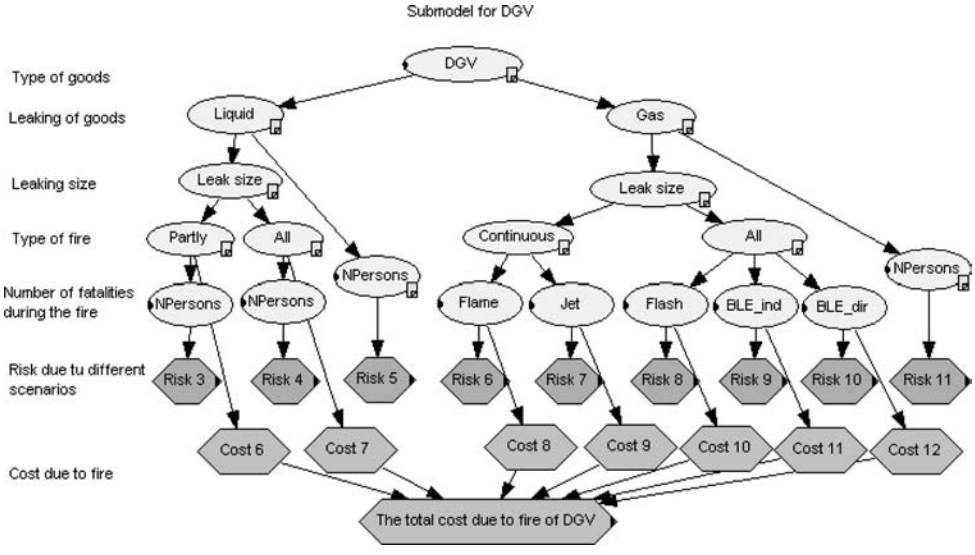

Figure 4. Sub-model for dangers goods vehicles DGV.

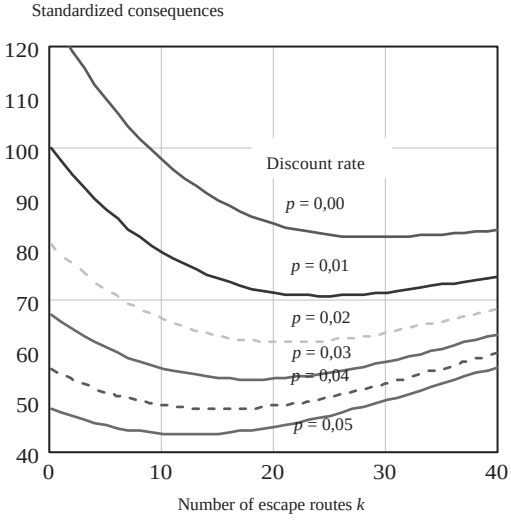

Figure 5. Variation of the standardized total consequences $\kappa(k, p, n)$ with k for selected discount rates p and the life time $n = 50$ years.

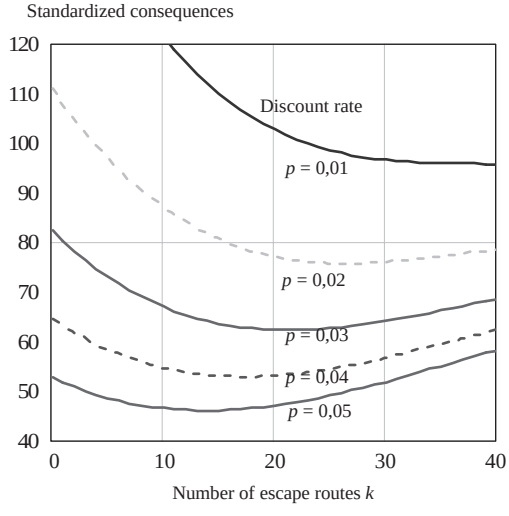

Figure 6. Variation of the standardized total consequences $\kappa(k, p, n)$ with k for selected discount rates p and the life time $n = 100$ years.

tree method), the other are estimated or specified using expert judgement.

The main model includes three sub-models for heavy goods vehicles HGV, dangerous goods vehicles DGV and Cars. Figure 4 shows a sub-model for dangerous goods vehicles DGV. Note that different types of hazard scenarios are distinguished as they may cause different consequences. Similar sub-models are used also for heavy goods vehicles HGV and Cars. Detailed description of the main model, sub-models and required input data is outside the scope of this contribution.

8 RISK OPTIMIZATION

Risk optimization of the above described tunnel is indicated in Figures 5 and 6 showing variation of

the standardized total consequences $\kappa(k, p, n)$, given by equation (9) with number of escape routes k for selected discount rates p (up to 5%) and life time n (=50 and 100 years).

Figure 5 shows the variation of the standardized total consequences $\kappa(k, p, n)$ with k for selected discount rates p and the life time $n = 50$ years only. Figure 6 shows similar curves as Figure 5 but for the expected life time $n = 100$ years (common value).

Figures 5 and 6 clearly illustrate previous finding that the discount rate p affects the total consequences $\kappa(k, p, n)$ more significantly than the number of escape routes k.

9 CONCLUSIONS

Similarly as in case of other technical systems the risk assessment of road tunnels commonly includes

- definition of the system
- hazard identification
- probability and consequences analysis
- risk evaluation and possible risk treatment

Probabilistic risk optimization based on the comparison of societal and economic consequences may provide valuable background information for a rational decision concerning effective safety measures applied to road tunnels. However, as tunnels are commonly design for a long life time (100 years), discount rate must be taken into account. It appears that assumed life time and the discount rate may affect the total consequences and the optimum arrangements of the tunnels more significantly than the number of escape routes.

The following conclusions may be drawn from the submitted study of probabilistic risk optimization of road tunnels using Bayesian networks:

- The optimum number of escape routes may be specified from the requirement of the minimum total consequences covering both the societal and economic aspects.
- The optimum number of escape routes depends generally on discount rate, required life time and the ratio between the cost for one escape route and acceptable expenses that a society is able to afford for averting one fatality (societal compensation cost).
- The total consequences are more significantly affected by the discount rate than by assumed life time, cost ratio and the number of escape routes.
- Bayesian networks supplemented by decision and utility nodes seem to provide an effective tool for risk analysis and optimization.

Correct specification of discount rate and required life time is essential for making proper decisions. Further investigations of input data concerning conditional probabilities describing individual hazard scenarios and models for their societal and economic consequences are needed. In particular cost of various safety measures and acceptable expenses for averting a fatality are required for advanced optimization of road tunnels.

ACKNOWLEDGEMENT

This study is a part of the project GAČR 103/06/1521 "Reliability and Risk Assessment of structures in Extreme Conditions" supported by The Grant Agency of the Czech Republic.

Austrian risk analysis for road tunnels development of a new method for the risk assessment of road tunnels

B. Kohl & K. Botschek
ILF Consulting Engineers, Linz, Austria

R. Hörhan
Ministry of Traffic, Engineering and Technology, Vienna, Austria

ABSTRACT: For the Austrian Risk Analysis for Road Tunnels (TuRisMo) a set of different methodical tools are used to analyse the whole system of safety relevant influencing factors; the method consists of two main elements:

- Quantitative frequency analysis: event tree approach for calculating the frequencies of defined accident scenarios
- Quantitative consequence analysis:
  - mechanical accidents: estimation of consequences based on tunnel accident data
  - fire accidents: modelling of consequences by combining a ventilation model with an evacuation simulation model

The risk model covers the personal risks of tunnel users. The result of the risk analysis is the expected value of the societal risk of the tunnel investigated.

Risk evaluation is done by relative comparison of the tunnel investigated to the risk of a reference tunnel (tunnel of the same length, type and traffic characteristic, fully complying with the minimum safety requirements as per EC Directive).

Keywords: Tunnel safety, quantitative risk analysis, risk reducing effects, safety measures.

1 BACKGROUND

In April 2004, the EC Directive on road tunnel safety (Directive 2004/54/EC) was issued. Article 13 of this Directive obliges every member state to develop a method for a risk analysis on a national level. Therefore, the Austrian ministry started a design process to develop a methodology which meets the specific requirements of Austrian Road Tunnels. The work process was coordinated with an expert group of tunnel safety and ventilation experts.

The Austrian Risk Model focuses on frequently occurring mechanical accidents and fire accidents with small and medium sized fires. For a more thorough investigation of accidents involving hazardous goods, the DG-QRA model developed by OECD/PIARC shall be used in Austria.

2 TuRisMo – TUNNEL RISK MODEL FOR ROAD TUNNELS

2.1 *Database of risk analysis*

Due to the great number of tunnels in Austria and the extensive collection of data on accidents, the risk analysis is done based on Austrian data and experiences.

Data were collected from accidents with personal injury in tunnels on motorways and expressways for the years 1999–2003. In addition to Austrian data, foreign data sources are used for comparison and completition.

2.2 *Methodical approach*

2.2.1 *General consideration*

The risk analysis aims to investigate the risk to tunnel users (personal injuries and fatalities); as relevant

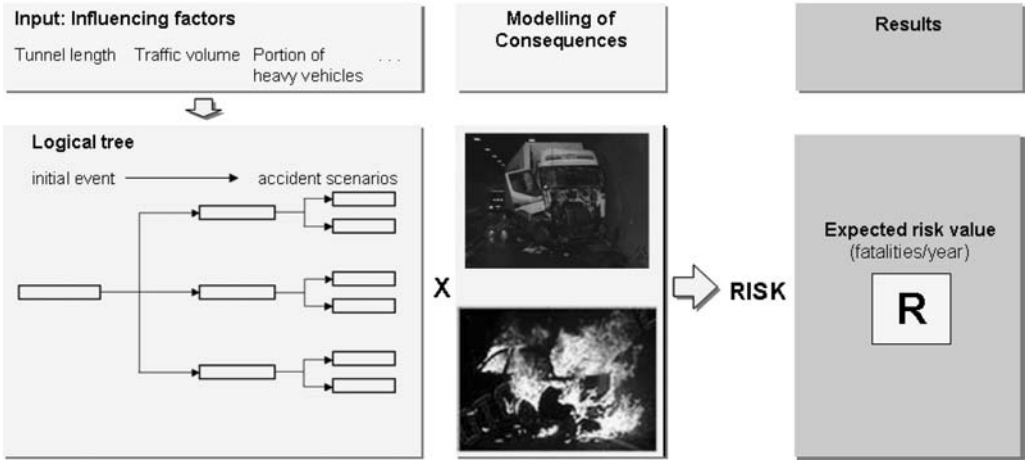

Figure 1. Sequence of risk analysis.

reference value the societal risk (fatalities per year) of the tunnel is calculated.

The methodical approach consists of two basic elements:

– a quantitative frequency analysis (event tree approach) and
– a quantitative consequence analysis (evaluation of statistical accident data for mechanical accidents and modelling of fire accidents)

The sequence of the risk analysis is shown in Figure 1.

2.2.2 *Influencing factors*

The following main influencing factors and their interrelations were identified and taken into account in

– traffic volume
– uni-directional or bi-directional traffic
– additional points of conflicts such as ascending and descending ramps
– dangerous goods (amount and composition – general approach only)
– portion of heavy vehicles (> 3.5 tonnes)
– portion of busses
– tunnel length
– ventilation system
– length of escape route to emergency exits
– operational components (fire detection, etc.)
– longitudinal gradient in tunnel
– longitudinal gradient in front of tunnel
– frequency of traffic jams
– cross section type

2.2.3 *Event tree analysis*

An event tree analysis is performed to calculate the frequency of defined accident scenarios. The event trees distinguish between accidents (with personal injury) and breakdowns. Starting from an initial event leading to a set of damage scenarios, possibly ensuing damage events are developed through the individual branches of the event tree. These damage scenarios differ significantly from each other as regards type of accident, vehicle involvement, involvement of dangerous goods and influence of fire. Taking into account the framework conditions of the tunnel infrastructure (e.g. distance between emergency exits), the extent of damage is estimated for the respective damage scenario.

The level of detail for an event tree is defined in such a way that the available data material can be used appropriately.

The input data of the event tree – accident rates and relative frequencies – are calculated based on an evaluation of data from 81 Austrian motorway tunnels (60 with uni-directional, 21 with bi-directional traffic). The accident rates are modified in dependence of tunnel length and traffic volume.

Table 1. Basic values of accident rates (own evaluation board upon Robatsch et al. 2003).

	Bi-directional tunnel [fat./Imio. vechicle-km]	Uni-directional tunnel [fat./Imio. vehicle-km]
Accident rate in Austrian road tunnels (on motorways)	0,077	0,112

2.2.4 *Consequence analysis*

For each damage scenario in the event tree the corresponding extent of damage is estimated.

– Estimation of extent of damage of mechanical accidents:

Figure 2. Part of event tree the risk analysis.

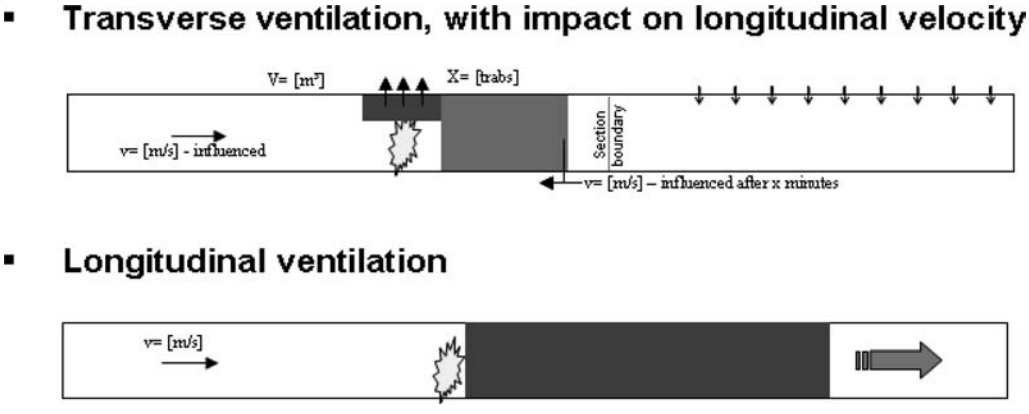

Figure 3. Basic principle of ventilation model.

The damage scenarios differ in terms of type of accident and vehicle involvement. The consequences of each damage scenario are estimated based on an evaluation of accident consequence data of 447 tunnel accidents with personal injuries (same database as for frequency calculation).

– Estimation of extent of damage of accidents involving fire:

The extent of damage of fire is estimated with the support of an evacuation simulation model in combination with a one-dimensional ventilation model.

2.2.4.1 *Ventilation model*

In the ventilation model two different scenarios (5 MW, 30 MW) und two different ventilation regimes can be selected (Fig. 3)

– longitudinal ventilation
– transversal ventilation, with impact on longitudinal air velocity

They are valid for standard situations. However, the model also makes it possible to investigate non-standard ventilation systems and non-standard situations, but this requires more work to compute this data.

The smoke release rates of fires are defined and smoke concentrations in dependence on time and location in the tunnel are calculated. The design of the model allows a detailed investigation of the performance of the ventilation system in combination with the corresponding evacuation procedures.

2.2.4.2 *Evacuation simulation model*

For the evacuation simulation the software package "buildingExodus 4.0" (Galea 2000) is used, which takes into account the effects of smoke gases according to the FED model (FED – Fractional Effective Dose) of Purser [2]. The influence of temperature, HCN, CO, CO_2 and lack of O_2 is included. The calculation is done for individual persons with individual characteristics.

In the evacuation simulation model, the location of the accident in the tunnel, the location of the emergency exits, the constellation of the vehicles on both sides of the accident, the propagation of smoke, the reaction of the people and their evacuation in the tunnel towards an emergency exit (a tunnel portal) are taken into account. This approach makes it possible to

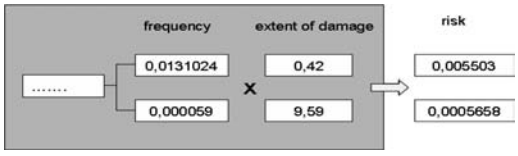

Figure 4. Combination of frequency and extent of damage.

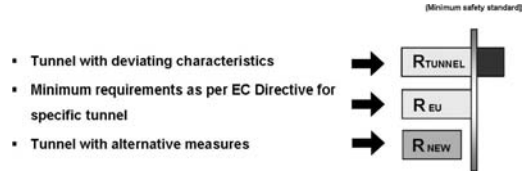

Figure 5. Risk evaluation in accordance with EC Directive (assessment through relative comparison).

investigate all influences, which may effect the lapse of time concerning the interaction of propagation of smoke and self rescue, such as

– fire alarm/start of ventilation
– reaction of people
– walking velocity with/without smoke
– walking distances
– congestion effects, etc.

The results of the evacuation simulation show, depending on the time elapsed, how many persons reach the "safe area" and how many persons are unable to get to safety due to the given framework conditions (length of escape route, start of evacuation, atmospheric conditions).

Based on these results, various accident locations in the tunnel are investigated, and an expected value of the extent of damage for every damage scenario is calculated; this expected value is implemented in the event tree.

This element of the risk model can be used for the consequence assessment of defined fire scenarios (calculating a risk value) as well as for a detailed scenario investigation.

2.2.5 *Risk calculation*

As reference value the expected value of societal risk (fatalities/tunnel and year) is calculated by combining incident frequencies and consequence values for defined scenarios in the event tree; a distinction is made between risks from car accidents with mechanical effects only, from fires and from accidents involving hazardous goods.

2.3 *Results of risk analysis and strategy of risk evaluation*

In Austria no quantitative risk criteria are defined. The EC Directive defines the minimum safety standard of a tunnel by laying down requirements for tunnel design and tunnel equipment in a prescriptive way. But the EC Directive allows limited derogations for these requirements, on the condition that the same safety level can be achieved by alternative risk reduction measures. For this reason risk evaluation is done by relative comparison of the risk of the tunnel investigated with the risk of a reference tunnel. A tunnel of the same length, type and traffic characteristic, fully complying with the minimum safety requirements as per EC Directive, is used as reference case. The identified divergences can be assessed in terms of risk. Alternative measures to offset the divergences can be evaluated; the risk reducing effects of the different safety measures can be investigated in a similar way. The safety assessment of safety measures can be completed by a cost-effectiveness analysis.

3 EXPERIENCE IN PRACTICAL APPLICATION

3.1 *Case study*

Design and equipment of an existing tunnel are in line with the requirements of the EC-Directive, only the share of heavy goods vehicles exceeds the reference value of 15%; according to Annex I, article 1.3.2 the respective additional risk has to be assessed.

The additional risk shall be compensated. Therefore several possibilities of upgrading of the existing tunnel by additional safety measures shall be investigated by calculating their effects on risk.

Definition of the system:

– Existing single tube tunnel, length 5,5 km
– Bi-directional traffic, 9.500 vehicles per day, 25% heavy goods vehicles
– Emergency exits: every 500 m
– Ventilation: transversal ventilation, extraction openings with dampers every 100 m – in line with Austrian guide lines
– Automatic fire detection system

Additional safety measures to be investigated:

– cross passages every 250 m to an already existing parallel evacuation gallery
– reduction of velocity of heavy goods vehicles from 80 km/h to 60 km/h
– construction of a second tunnel tube

As reference value the expected value of the societal risk is calculated (fatalities/year); a distinction is made between risk due to car accidents with mechanical effects only, due to fires and due to accidents involving hazardous goods.

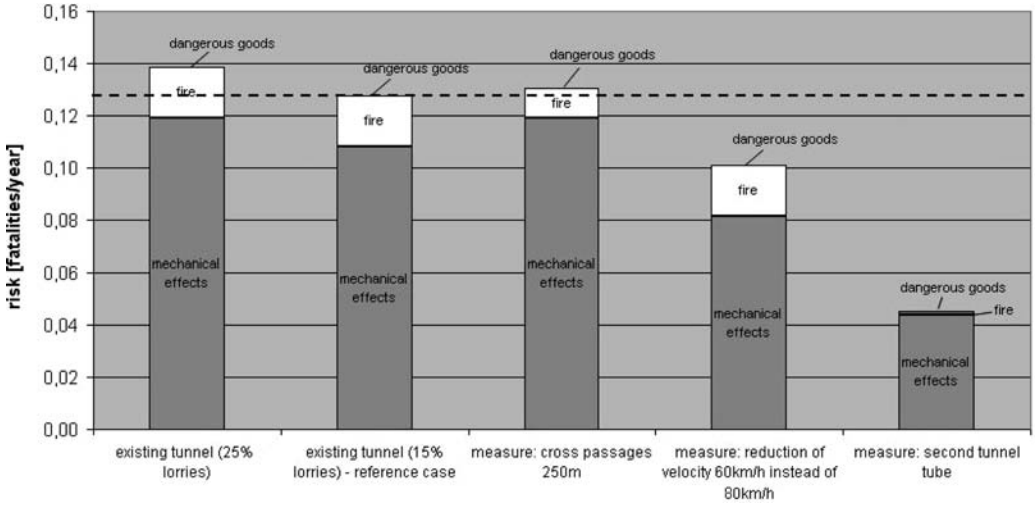

Figure 6. Graphical survey of results of case study.

Table 2. Results of risk analysis.

	Societal risk – expected value (fatalities/year)	Relative share in risk		
		Mechanical effects (%)	Fire (%)	Hazardous goods (%)
Existing tunnel (25% heavy goods vehicles)	0,139	86	14	< 1
Existing tunnel (15% heavy goods vehicles reference case	0,128	85	15	<1
Measure: cross passages every 250 m	0,131	91	9	<1
Measure: second tunnel tube	0,045	97	<1	3
Measure: reduction of velocity 60 km/h instead of 80 km/h	0,101	81	19	<1

For the tunnel investigated the following results are obtained (Figure 6):

Risk evaluation is done by relative comparison, mainly by comparing the tunnel as it is to the situation as it should be (reference case).

– The high portion (25%) of heavy goods vehicles causes an increase of risk of about 9% compared to the reference value according to the EC-Directive

The additional safety measures envisaged contribute to risk reduction as follows

– cross passages every 250 m can reduce risk by about 6%; this is almost the same order of magnitude as the additional risk, caused by the high portion of heavy goods vehicles; however, this measure considerably reduces fire risk but does not influence the risk portion due to accidents with mechanical effects
– reduction of velocity of heavy goods vehicle from 80 km/h to 60 km/h can reduce risk by about 38%, thus reducing it far below the risk value of the reference case. This measure considerably influences the risk due to mechanical effects of car accidents (which is dominated by the heavy goods traffic), but influences fire risk only to a small extent
– a second tunnel tube considerably reduces the risk level of the tunnel to about one third of the initial value, strongly influencing both, the fire risk as well as the risk due to mechanical effects.

The measure reduction of velocity of heavy goods vehicles can be realized within short term and causes only low costs, whereas additional cross passages are much more expensive and much more time consuming in terms of realization. Although very effective in terms of risk reduction, for cost-benefit reasons a second tunnel tube can only be justified, when the traffic volume is expected to increase considerably (up to 20.000 during the next 15 year – with reference to the EC-Directive, Annex I, article 2.1.2).

Therefore – if the effects on traffic flow are acceptable – the speed limit for heavy goods vehicles is recommended for cost benefit reasons as short term measure. If the traffic flow increases considerably, as long term measure a second tunnel tube should be envisaged.

3.2 *Range and limitations of application*

In general the model is applicable to all tunnels with mechanical ventilation; for specific situations (e.g. unconventional ventilation systems) the model can be used, but must be adapted. The advantages of the model are

- the high flexibility of the individual methodical elements, so that it is applicable to almost every tunnel, ventilation or traffic configuration
- the possibility of changing the most relevant input data very easily; thus new information can be implemented quickly in many cases
- its capability to include the effects of almost every important safety relevant influencing factor in a quantitative way; one of its key elements is the modelling of the complex interaction of smoke propagation in the tunnel and the procedure of self rescue in the situation of a fire, which allows the investigation of all influences on the lapse of time within this process
- its simply, clearly understandable and easy comparable results.

The model can be used for a wide field of different applications, such as safety assessment of new or existing tunnels, support of the decision-making process for a selecting safety measures (new tunnels) or upgrading measures (existing tunnels), definition of priorities for upgrading measures, etc.

However, the results of the model (expected value) do not include information about the distribution of different accident consequence classes (such as F-N-curves); therefore the model is not suited to specifically investigate accidents with very low probabilities and very high consequences. Hence, the model is not suitable for a more thorough investigation of the effects of accidents involving hazardous goods.

ABSTRACT: Integration of the safety requirements for the Lyon-Turin Rail link project.

1 INTRODUCTION

The Lyon-Turin rail link between France and Italy, crossing the Alps, is one of the major projects in Europe. This high speed link is an important connection in the pan-European railway network. In 2015 the first trains will run. The link will be used by high speed passenger trains, freight trains and "Autoroute Ferroviaire" (trucks on the train) and will consist of a 53 km long tunnel crossing the border between France and Italy as well as the 12 km long Bussoleno tunnel. For such a project, the safety expectations are very high. Before starting the detailed design of the tunnel, it is therefore of importance which safety measures are to be integrated in the tunnel to meet the defined safety principles.

2 INCIDENT TREATMENT PRINCIPLES

Different kinds of incidents have to be potentially treated on the LTF section. They have to be identified and the specific constrains of the project have to be considered, in order to face them.

The topic of "Incident treatment principle" specific study is a global one which includes a lot of parameters and hypothesis coming from other studies.

The following paragraph details only the principles. Specific topics concerning equipment, dangerous goods and railway motorway are described below.

2.1 *Reminder of the project previous phases conclusions*

The two single-track tubes will be linked by cross passages every 400 m. A safety station will be provided at each extremity of the link (in the open air), in the middle of the tunnel (underground space close to Modane) and also on the Val Cenischia viaduct between the main tunnel and the Bussoleno tunnel. These emergency stations will be able to receive every type of train (AF, freight or passenger) and will be built for dealing with the possible incidents. Three additional underground intervention stations will be situated in the main tunnel for dealing with the incidents concerning the railway motorway and freight trains only. These emergency and intervention stations are to be designed and equipped to ensure the safety of users, even in the case of an incident.

2.2 *Events to take into account*

The identification of the events to take into account has been carried out in collaboration with the studies in charge of the global risk analysis of the project called "Safety principles". The main elements for identifying the potential incidents are:

- The infrastructure has to be designed for several kind of trains (passengers, freight, railway motorway);
- The infrastructure will consist of a 53 km long tunnel crossing the border between France and Italy

as well as the 12 km long Bussoleno tunnel and a viaduct;
– The freight train and the railway motorway may carry dangerous goods.

Consequently, the following events have been studied:

– Breakdown of each type of train in different locations;
– Fire on a passenger train in several locations in the tunnel or in the open air;
– Fire or explosion on a freight train or a railway motorway in several locations in the tunnel or in the open air.

2.3 *Major elements concerning incidents treatment*

In case of an incident, the goal for the concerned train is to reach an adapted place in order to treat the event (emergency station or intervention station). However, in case of a breakdown in the current section of the tunnel, the safety concept has to also to allow the treatment of this incident.

The trains behind the stopped train will have to stop and to reverse. The trains in front will have to continue their route with an adapted speed.

The behavior of the trains in the other tube will depend on the nature and the position of the incident train.

2.4 *Use of ventilation means*

In case of a fire on a train, there are two possibilities:

– All people on board are on the same side of the train;
– People on board are separated by the fire.

In the first case, the ventilation system is used in order to push all the smoke on the side where nobody is present. The minimal distance between two trains has been calculated in order to maintain the following trains free of smoke.

In the second case, the ventilation system is used in order to provide an environment compatible with an evacuation of the train passengers.

2.5 *Procedure in case of a fire on a freight train*

In case of a fire on a freight train, the driver has to stop the train in a safety or intervention station.

The ventilation system and the fire mitigation system are switched on in order to protect the train driver. He goes down the train and waits emergency services in a safe place.

In case of stop inside the tunnel, he waits in a cross passage.

2.6 *Procedure in case of a fire on a railway motorway train*

In case of a fire on a railway motorway train, the driver (located in the "Sonia" with all the truck drivers on board) has to stop the train in a safety or intervention station.

The ventilation system is switched on in order to protect the "Sonia". The driver start the diesel propulsion and separate the "Sonia" from the rest of the train in order to drive away from the burning convoy and exit the tunnel.

2.7 *Procedure in case of a fire on a passenger train*

In case of a fire on a passenger train, the driver has to stop the train in a safety station.

In the open air, users are directly taken care of by rescue teams.

In the tunnel, the train passengers wait for an evacuation train in the not-affected tube, which will bring them outside.

2.8 *Elements concerning rescue teams*

Elements concerning rescue teams are specific to the infrastructure:

– First line of intervention, with a very rapid response, because they are located permanently nearby the access to safety and intervention stations;
– Second line of intervention, which is organized by the public services.

Their vehicles will be both "road-rail"-vehicles together with traditional rolling stock for the more heavy logistics. The road-rail engines are rapidly put on rail and can operate in bad conditions (presence of smoke or high temperatures).

3 EQUIPMENTS

In order to provide for the required level of safety in the tunnel, several security systems and security equipment has been foreseen in both tunnels (Tunnels du base and the Tunnels du Bussoleno).

3.1 *Emergency philosophy*

The emergency philosophy for trains with a fire onboard has to, if possible, continue to a "safe haven" and to evacuate all passengers there. For all other trains not directly involved in the incident the rule is to a) leave the tunnel(s) as quickly as possible or to b) stop before entering the tunnel.

3.2 *Emergency installations and equipments*

The following emergency installations are used in the tunnel and connected areas:

- Detection equipment for:
  - Smoke and fire
  - Derailment
  - Train stop
  - Gage
  - Fumes and gasses
- Containment and extinguishing equipment in case of fire:
  - Ventilation systems in tunnels, inter tube tunnels
  - Ventilation of safe areas
  - Ventilation of technical rooms
- Control systems:
  - Lighting system
  - Video system (CCTV)
  - Central command post (PCC)
  - Communication equipment
  - Telephone system
  - HF communication system

The following equipment is foreseen in the tunnels, intervention stations and safety stations and surrounding elements:

- Evacuation of passengers:
  - Emergency platforms:
    - In the tunnels (min. 1.2 m width)
    - In the emergency stations and station (3.0 m width, 750 m length)
  - Cross passages (every 400 m, in Modane station every 50 m)
  - Collection rooms for the injured in every intervention and emergency station
  - Directions signs for emergency escapes
  - Audio system
- Accessibility and equipment for emergency services:
  - Emergency accesses at the highest point of every emergency tunnel, connecting to local infrastructure. The accesses are provided with a helicopter platform, parking space, and a command post
  - Emergency tunnels
  - Fire extinguishing equipment:
    - Hydrants (6–10 bar, every 133 m, French and Italian system)
    - Fire mitigation system in every intervention station and in the safety station
  - Automatic fire extinguishing system in technical rooms

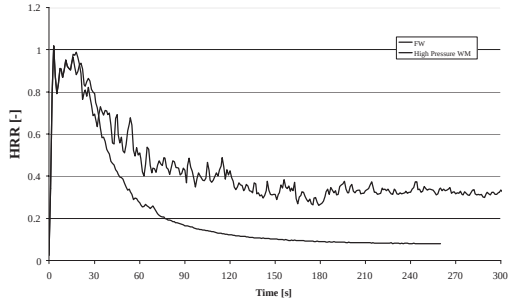

Figure 1. Test results from Foam Water and high pressure Water Mist systems to a 50 MW fire.

  - Emergency water reservoirs (with a capacity of 120 m^3) in each station.
  - Central command post (PCC), one in France and one in Italy.
  - Drainage system liquids (alpine water, extinguishing water)
  - Storage tanks for dangerous liquids (6 in total, storage capacity 240 m^3 per tank)

Three systems in particular will be described in following paragraphs, namely the foam water system, the emergency tunnels and the drainage system.

3.3 *Fire mitigation system*

Fires with a capacity of 50 MW can occur in the tunnel, due to the properties of transported goods and air speeds in the tunnel. These fires cannot be reached physically by fire fighters and therefore cannot be put out in a traditional way. For this reason, all goods trains will have to make a safety stop at an intervention station or safety station when exiting the tunnel is not an option. Each intervention and emergency station in the tunnel is provided with a sprinkler like system, using a specific mixture with water onto the fire from nozzles located on either side of the tunnel roof. Two systems have been modeled and tested: a Foam Water system and a high pressure Water Mist system. With a ventilation speed of 2 m/s, the following results are found.

The figure shows that the FW system reduces a fire to 20% of its original intensity within 70 sec and to 10% within 150 sec. The WM system mitigates a fire to 40% and 35% for the same time intervals respectively. These results are obtained when the system is called into action immediately after the start of a fire. There are however scenarios in which it takes up to 15 min before a train is located in an intervention station provided with a FM or WM system and the system is switched on. This way, 100 MW fires cannot be excluded.

3.4 *Emergency tunnels*

The intervention stations of Saint-Martin, La Praz and Venaus, as well as the emergency station of Modane are connected to the outside world by means of emergency tunnels. In total there are 4 emergency tunnels, with a diameter of 10 m and lengths varying from 500 to 4,500 m. The emergency tunnels will be used by emergency services in case of an emergency. The enormous length of the emergency tunnels led resulted in a one-way regime for traffic, with passage sites every 400 m, dividing each emergency tunnel into sections. The passage sites have a length of 200 m and a width of 20 m. Traffic lights will be used to indicate a free passage per section.

3.5 *Drainage system*

In the tunnel, a drainage system is applied to drain the alpine water from the tunnel the slope of the system is 2%, following the tunnel slope. In case of fire in a goods train leaking dangerous liquids, extinguishing efforts with water will result in a pool fire, possibly increasing the capacity of a fire. Therefore, the drainage system consists of lateral and longitudinal canals that collect in central collection points with siphons, to prevent progression of a fire in the closed drainage system. The liquids are collected in storage tanks, located at every station and at the heads of the tunnel.

4 DANGEROUS GOODS

One of the reasons the tunnels are being constructed is the transport of freight. From current transport of freight we know that a substantial part of the international transport can be classified as dangerous goods. Effects of an incident with dangerous goods in the tunnel may be serious for both persons present and the structure of the tunnel. Before allowing transport of dangerous goods in the tunnel, it has to be determined whether the possibility of an accident in relation to the effects is acceptable.

4.1 *The methodology*

The UN working group WP15 on the transport of dangerous goods has been developing a methodology to categorize tunnels. Through tunnels of different categories, different groups of dangerous goods are allowed for transport. For the LTF project this methodology has been the base to define safety measures and to determine whether transport of dangerous goods can be allowed in the tunnels. For each group is determined whether the possibility of an accident in relation to the effects is acceptable and if safety measures can be taken to ensure that the required safety level is reached.

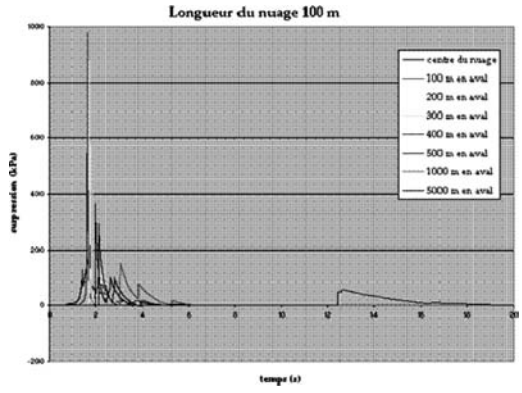

Figure 2. The blast effects after ignition of a cloud with a length of 100 meter.

4.2 *Possible effects and proposed safety measures*

4.2.1 *Group A*

Dangerous goods in this group are prohibited for transport and are therefore not analyzed in the studies for the project Lyon Turin Ferroviaire.

4.2.2 *Group B*

4.2.2.1 The effects

Dangerous goods in this group can provoke a big explosion. LPG is the product most transported good within this group. For this reason the effects of an accident with LPG are taken as normative to analyze the effects of a possible incident with goods of this group.

Two types of incidents have been considered: a leak of limited size leading to a vapor cloud explosion after ignition and a catastrophic failure of a LPG vessel leading to a BLEVE (Boiling Liquid Expanding Vapour Explosion).

A combination of a steady leak and steady ventilation flow may result in a homogeneous cloud in the tunnel downstream of the leak. For stoichiometric clouds of 10, 20, 50 and 100 meter length (it is never certain when a cloud may be ignited), the blast effects up to a distance of 5000 meters on either side of the cloud have been modeled.

A vapour cloud explosion as simulated can generate a blast that can cause victims up to 4200 metres.

4.2.2.2 Proposed safety measures

The prognostics show a large amount of possible transport of flammable gases. For this reason, both protective and preventive measures are proposed for the tunnel.

Since effects of an explosion reach up to 4,200 meters in the tunnel, the first measures is to keep a distance of at least 4,200 meters between a train carrying this products and a train with passengers. Furthermore the truck train combination is not allowed for

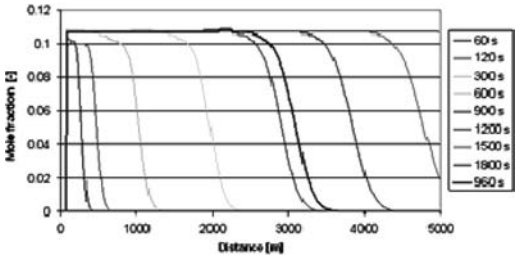

Figure 3. Dispersion of chloride in the tunnel after a leak (50 mm) of a vessel (ventilation speed 3 m/s).

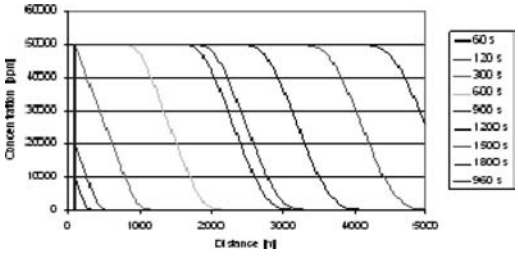

Figure 4. Dispersion after a leak (50 mm) of ammonia (taken ventilation speed 3 m/s).

this group since there are too many drivers present in the train, thus within the 4,200 m range.

4.2.3 *Group C*

4.2.3.1 The effects

Dangerous goods in group C are goods that can provoke an explosion or a toxic leak in the tunnel.

To analyse possible effects of possible incident with goods in this group, dispersion of ammonia and chloride in the tunnel is modelled.

With the probit function (probit functions give the mortality rate depending on concentration and exposure time) for chloride it is calculated the toxic cloud reaches up to 3,500 meters from the incident after 16 minutes.

The lethal concentration of ammonia will not reach as far as the chloride cloud.

Toxic vapour clouds from toxic liquids have also been analysed. Since evaporation from a liquid pool is a lot slower than evaporation of a pressurized gas, effects will not carry as far as the effects of pressurized gases.

4.2.3.2 Proposed safety measures

Since some of the goods in this group can provoke an explosion, a distance of at least 4,200 meters (3,500 m for truck-trains) between a train carrying this products and a train with passengers is introduced.

To reduce toxic effect of gases, the ventilation system should be able to influence the velocity and the direction of a toxic cloud.

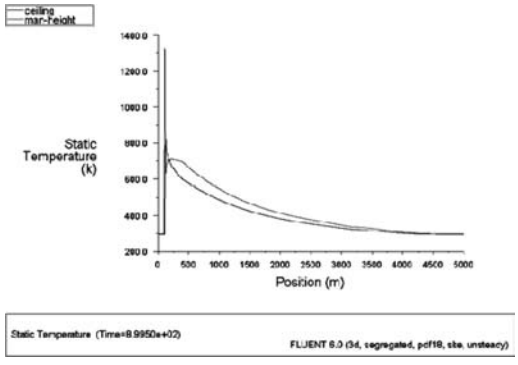

Figure 5. Temperature of 100 MW in relation to distance in the tunnel.

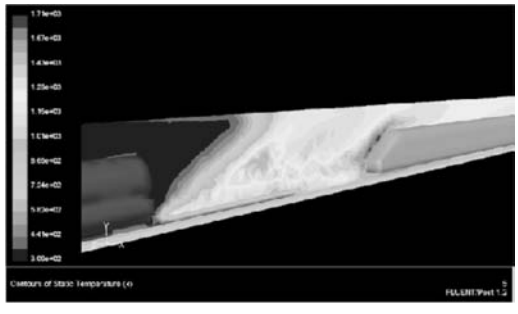

Figure 6. Simulation of a major fire next to a passenger train.

To reduce the effect of toxic liquids it is proposed to limit the surface of a possible pool to minimise evaporation. As for the flammable liquids a maximum of 100 m^2 is proposed (see above). The evacuation system has the possibility to separate toxic liquids and water (they can provoke a chemical reaction in some cases).

Further on, the ventilation systems of trains passing through the tunnel should be closed unless toxic clouds can be detected before trains with groups of passengers enter the tunnel.

The Sonia vehicle does also have this possibility to ensure that drivers of the trucks can get away in this vehicle.

4.2.4 *Group D*

4.2.4.1 The effects

Dangerous goods in groups D are those that can provoke a major fire. To analyse possible effects of possible incident with goods in this group, the effects of a fire of 100 and 200 MW in the tunnel have been modelled.

Furthermore the effect of a fire in case of another train present was analysed.

It has been concluded that the temperature reaches up to 50°C at 3,500 meter after 15 minutes. Since the air in the tunnel will be moist, this the level which can be dangerous to persons present in the tunnel.

4.2.4.2 Proposed safety measures

Since temperature and smoke can reach dangerous levels up to a distance of 3,500 meters, this distance should be kept between a train carrying flammable products and a train with passengers. The interdistance of 4,200 m caused by group B makes this one oblivious.

To prevent a fire from growing to fast and to limit effects, the ventilation system should be able to influence the velocity and the direction of the air in the tunnels.

To make sure a pool fire will be limited in magnitude, the surface of a possible pool should be limited to a maximum of 100 m^2 (gasoline generates about 2 MW/m^2).

The Sonia vehicle must be able to leave as fast as possible after an incident, before the effects of a fire reach the vehicle where the drivers are present.

4.2.5 *Group E*

Since the products in group E are either less dangerous or transported in smaller quantities this group has not been analysed. Measures taken to reduce risks for the other groups are supposed to be efficient enough to take away the risks of this group.

5 RAILWAY MOTORWAY

5.1 *Introduction*

The rail-motorway has to allow the HGV transport between France and Italy by rail. It should offer a new service that goes beyond conventional carriage and combined transport. The principle is that complete heavy goods vehicles (tractor + semi trailer) are carried through the Alps on wagons. The service includes a comfortable carriage for drivers.

The railway motorway trains to be designed to link Lyon and Turin are a new type of rolling stock compare to existing trains (Eurotunnel, *Modalohr* in France and Italy, *Petites roues* in Switzerland and Italy). According to the current rules, it is necessary to demonstrate the safety level of this new type of train by risk analysis. With this study the choice of the most adapted prevention and mitigation measures, to reach the safety level required, was taken.

5.2 *Description of the rail motorway*

A dense traffic of rail motorway trains per day is supposed to circulate in each direction. It allow the transport of 600 000 to 1 200 000 PL.

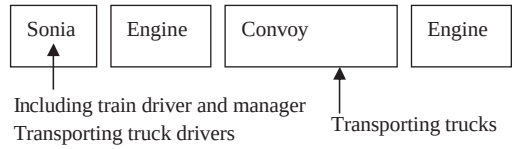

Figure 7. Composition of a railway motorway train.

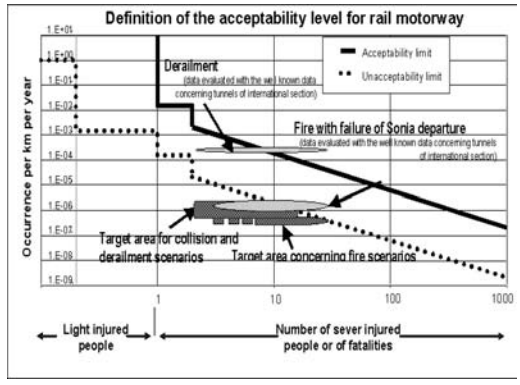

Figure 8. Safety level.

Trains are 750 meters long. The possibility to design 1,500 meters long train has been studied.

The train will be compound of several elements:

In this configuration the first vehicle, the "Sonia", is transporting all people on board and is equipped with a diesel propulsion to drive away from the burning convoy in case of a fire on a truck or on an engine. The complete safety procedure in case of an incident is described in paragraph 2.

5.3 *Result of the risk analysis*

5.3.1 *Prevention and mitigation measures to take into account*

Prevention and mitigation measures are introduced on several fields, like rolling stock, infrastructure, exploitation and emergency interventions.

Some of them are additional to measures concerning dangerous goods. The main conclusions are the following:

- The Sonia vehicle will necessitate a lot of adaptation of rolling stock;
- Because of the configuration of the train (with the Sonia vehicle in front of it), special care is required concerning collisions;
- A lot of verification will have to be proceeded before the departure of the train;
- Rolling stock will have to be tested frequently and safety elements will have to be used during maintenance;

– The distance between 2 trains have to respect the elements given by the “Safety principles” and the “Dangerous Goods” studies.

5.3.2 *Safety level*

The demonstration of the safety level has been carried out by the way of scenario analyses including failures, collision or fire events. The grid was elaborated by the “Safety principles” study. The target level was validated by the international governmental commission (CIG).

6 CONCLUSION

The safety studies have been carried out in order to determine the Functional Requirements Specifications of all safety measures in the tunnels to minimize the risks. The outcomes have been served as input for further technical studies of the project.

Operational safety of road tunnels: Safety reviews of tunnel projects and existing tunnels

N. Seifert
ASIT Ltd., Berne, Switzerland

R. Siegenthaler
ASIT Ltd., Berne, Switzerland

ABSTRACT: Proprietors/operators of road tunnels are responsible for the safe operation. Therefore the safety of road tunnels has to be reviewed in all life cycles.

Regarding the new Swiss regulation SIA 197/SIA 197/2 the safety planning in a tunnel project is performed as a stand-alone process. This concept is briefly introduced on the basis of an application example.

The safety assessment and planning for existing tunnels in exploitation can be performed using the approach described in the EU-directive 2004/54/EC. Using the example of the Bransiko tunnel in Slovakia a two-step approach combining different elements of safety and risk analysis methods is shown.

From the experience of the expert the conclusion can be drawn, that the integration of the safety analysis issue in the early stage of a tunnel project will have advantages also for the exploitation phase.

1 INTRODUCTION

1.1 *The responsibility of the proprietors or operators*

The proprietors and operators of motorways have the responsibility of a safe operation of the infrastructure. During the life cycle of roads and tunnels the safety measures have to be kept up-to-date under consideration of the economic constraints.

The users of road tunnels, the public and also political institutions demand a high level of safety for tunnel operation. It is necessary to control the relevant aspects for the operational safety for road infrastructure and particular tunnels directly in the design phase and periodically during exploitation.

The need to establish a safety management, which is responsible for the safety planning and the implementation of all necessary safety measures, is obvious. In practice the lead of the safety management refers directly to the top management of the responsible operational organization.

1.2 *Regulations and guidelines*

For the accomplishment of the operational safety of roads and road tunnels, the most important fundamentals are prescribed in the according regulations and guidelines (e.g. national technical regulations, national guidelines, EU directive 2005/54/EC for TERN roads), in laws (e.g. Swiss ordinance on the protection against major accidents) as well as in management system regulations (e.g. EN ISO 9001).

Theses prescriptions give the most important design and safety requirements for roads and road tunnels and are based on technical experience, safety and risk assessment results and research.

1.3 *Safety standards versus state-of-the-art of safety*

On one hand the operator of a road tunnel has to fulfill all design requirements, which are given by safety standards, which are updated in the range of several years. They can be considered as the common “Rules of Technology” (Engineering rules).

On the other hand there may be (legal) requirements to be followed as well, which claim the implementation of a so-called “State-of-the-Art of Safety Measures”. The latter represents a higher safety level becoming necessary because of a special risk situation and also depends on the risk acceptance of the public opinion. The level of the “State-of-the-Art of Safety Measures” can be higher than the rules of technology (Fig. 1). In the course of time, the gap between the levels of the rules of technology (safety standards) and the state-of-the-art of safety measures increases and can become considerably high.

Figure 1. Rules of Technology versus State-of-the-Art of Safety Measures.

Therefore a periodic review of safety and risk aspects is advisable.

It is important that the responsible proprietor/ operator distinguishes the mentioned aspects and is aware of the necessary relevant level of safety.

1.4 *Safety analysis in all life cycles of a tunnel*

The safety of road tunnels has to be reviewed and assessed in all life cycles of the infrastructure (design – realization – exploitation/operation/maintenance – removal). Reviewing the relevant safety aspects already in the planning phase of the project has considerable advantages, e.g. regarding cost – benefit considerations for later life cycles, especially for the operational phase.

Basically, the safety assessment/safety review of tunnels has to be carried out:

- During the design in the different project planning stages (preliminary studies, general project, detail project, regulatory approval project),
- In the construction (detail) project,
- During tunnel exploitation/operation and maintenance (e.g. prior to restoration)

The important means of the safety assessment/review lead to an optimization of the planning and are a decision support for the decision makers in the safety management on side of the tunnel proprietor or operator.

2 THE SAFETY CONCEPT AND SAFETY MANAGEMENT

Due to the fact that the proprietor/operator is responsible for the safe operation of the road or the tunnel, he would be well-advised to constitute a safety management, which works according to the principles of a safety concept or safety case and is the basis for all safety related activities. It comprises:

- The safety policy and the objectives;
- The safety organization (the management units, and the description of responsibilities, tasks, and interfaces to other players);
- Safety analyses (various studies and levels of detail adapted to the needs at the actual stage);
- Comprehensive and transparent documentation of all basis information, organizational framework, all analyses and assessments, planning material as well as concepts relevant for the safe operation of the road and tunnel infrastructure.

For the improvement of the operational safety of motorways and motorway tunnels it is essential and indispensable to establish an institutionalized collaboration between the safety management of the operator and the safety experts, road design experts and electromechanical experts. Only like this the operators can attend to their responsibilities in a complex environment with constantly changing boundary conditions and effectively protect the tunnel users from the consequences of catastrophic event scenarios.

3 SAFETY REVIEW AND PLANNING IN THE DIFFERENT STAGES OF A TUNNEL PROJECT

3.1 *The Swiss standard regulation SIA 197 and SIA 197/1 for tunnel projects*

The standard SIA 197 is the superior regulation concerning the design of tunnels and is amended by two more standards: SIA 197/1 for railway tunnels and 197/2 for road tunnels.

Amongst the documentation of project elements, constructive fundamentals, design issues, safety relevant issues, safety measures for different tunnel types and informative basics (e.g. exploitation duration, fire characteristics and curves, examples of normal tunnel profiles) the principle is described how a safety analysis with stage-specific content during all stages of a tunnel project has to be executed.

3.2 *Application example*

In the Swiss project of a new motorway exit and feeder road to the city of Geneva, the “Tunnel des Nations” has been assessed concerning the safety aspects even in a very early first preliminary study.

In this stage, the line management of the feeder road and the tunnel had been discussed in different possible variants, taking into account the connection with the city road network and the urban characteristics of housing in the area. It was crucial to consider the possible tunnel length with the requirements concerning escape routes for tunnel users, ventilation system and access for fire fighters from outside.

The design of the connection to the motorway A1 with its passage near the Geneva exhibition center and the Geneva airport area (with high density traffic in rush hours) was also introduced regarding the specific risks.

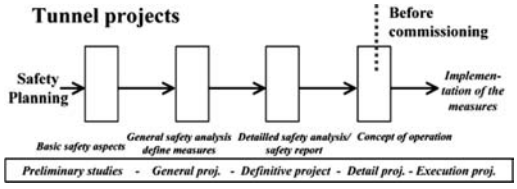

Figure 2. SIA 197 regulation – Safety planning during the different design stages.

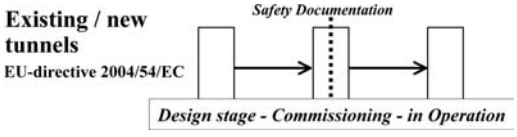

Figure 3. EU-directive – Risk analysis and safety documentation during the different stages.

In the next stage of the project the selected variants will be investigated more in detail till in further stages a complete and detailed safety analysis (safety report) will be available (Fig. 2).

4 SAFETY ASSESSMENT AND PLANNING FOR AN EXISTING TUNNEL IN EXPLOITATION

4.1 *The EU-directive 2004/54/EC for TERN roads*

The mentioned directive gives a prescription about the minimum safety requirements for tunnels in the trans-European road network (TERN) for tunnel design and tunnels in exploitation.

Different positions of the safety management and their tasks have to be defined: the administrative authority, the tunnel manager, the safety officer and the inspection entity.

Also it is required to execute a risk analysis and to elaborate the elements of the safety documentation in the design stage, the commissioning and the operation of the tunnel (Fig. 3) including among others a dangerous goods transport risk assessment, a hazard investigation and an emergency response planning.

4.2 *Application example*

For the existing tunnel of Bransiko (motorway D1, Slovakia: one tube – bidirectional traffic, safety gallery) a two-step analysis was carried out:

1. Prescriptive safety analysis: A wide set of different safety relevant issues had been investigated concerning the conformity of the existing safety measures with the safety level required by the EU-directive. If for specific issues a gap had been recognized between the current condition and the required safety level, recommendations were made together with an evaluation of the found safety level (1 = very good; 2 = good; 3 = critical; 4 = bad). All results are documented in a large listing to be the base of the decisions concerning safety measures planning.
2. Risk based analysis: A qualitative hazard analysis was carried out based on distinct incident scenarios. The frequencies and consequences were analyzed and a risk acceptance criteria matrix was proposed. The base results were also introduced to the safety documentation (see EU-directive).

   Then using the QRAM model of OECD/PIARC fire scenarios (20, 100 MW) were simulated for the Bransiko tunnel under consideration of the existing tunnel ventilation. It can be shown that with the 100 MW fire scenario the FN-curve reaches a zone, which, based on Swiss acceptance criteria, will be nearly unacceptable. Regarding other acceptance criteria however (ALARP) the risk curve reaches the transition zone.

   Also three DG-scenarios (pool fire, explosion, toxic gas release) have been simulated. The FN-curve of the pool fire scenario corresponds with the 100 MW fire.

The safety and risk analysis of the Bransiko tunnel has shown a modern tunnel with a mostly good safety level concerning the EU-directive requirements. There are however some improvements to be implemented. With the results of the detailed analysis the responsible safety management of the proprietor/operator has the necessary evaluation basics available to take decisions about additional safety measures.

5 EXPERIENCE AND CONCLUSIONS

ASIT has a great experience with safety and risk analysis of road tunnels. Tunnels of different types have been assessed or reviewed in the last years (one tube with bi-directional traffic; double tubes with one-directional traffic) and during different project stages or exploitation (Table 1).

Our experience clearly indicates that a well-organized safety management of a road tunnel who takes the responsibility seriously can avoid safety lacks and protect tunnel users from severe consequences. Introducing the safety analysis issue early in project stages can economize the financial resources in the later project stages and even in the exploitation phase.

Experiences and (in)effective application of QRA for assessing tunnel safety in The Netherlands

C.J. Soons [1,2], J.W. Bosch, P.H.A.J.M. van Gelder & J.K. Vrijling
[1]*Delft University of Technology, Faculty of Civil Engineering, Delft, The Netherlands*
[2]*Horvat & Partners, Rotterdam, The Netherlands*

ABSTRACT: Since 2006, it is compulsory in the Netherlands to use Quantitative Risk Assessment (QRA) for assessing tunnel safety. But previous to this legislative directive, risk analysis had already been applied to new tunnels for about ten years, but not all for the same reason or in the same manner. Therefore it is investigated in what manner QRA had been applied and what can be improved, all in order to eventually value QRA as an effective application for assessing tunnel safety. This research ends with a list of recommendations, from which can be concluded that QRA, up till now, has not been applied appropriately, some exceptions left.

1 INTRODUCTION

1.1 *Background*

Since the Alp fires around 2000, tunnel safety has become a major point of interest in the Netherlands. In May 2006, new legislation regarding tunnel safety has become valid. Safety standards for road and rail tunnels are set. In the legislation, the methods (i) scenario analysis and (ii) quantitative risk analysis (QRA) are referred to as the obligatory methods to use. But these methods to calculate the safety level in order to compare them to the set standards, are not established yet (2006).

There are some problems regarding these proposed risk analysis methods. For scenario analysis in road and rail tunnels, directives are set up in 2005/2006. These are obviously not completely finished (first set-up), but it is decided to review the documents in 2008, using comments/remarks from practice to develop an accepted scenario analysis method. Regarding QRA-modeling in road tunnels only the Rijkswaterstaat QRA-model is present for assessing tunnel safety. But for rail and metro tunnels no such method is present; only project based QRA-models exist. Further some stakeholders involved in the tunnel safety process (local government, emergency services etc) think the Quantitative Risk Assessment of tunnel safety is an ineffective application to approach tunnel safety. The question can be asked whether the stakeholders are right.

Therefore the goal in this research is to make sure the QRA method can be valued as an effective tool for assessing tunnel safety. To reach this goal the current use of QRA for assessing tunnel safety will be researched leading to a list of improvements.

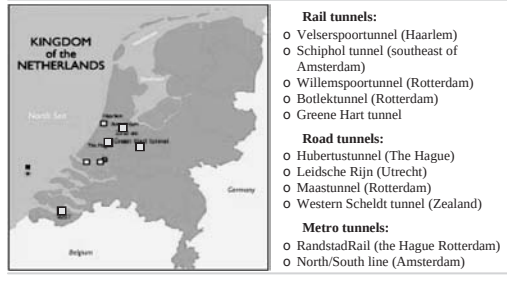

Figure 1. Dutch tunnels investigated.

Further the remarks must be made that the QRA-model is focused on the internal safety of personnel and passengers and that QRA should always be used together with Scenario analysis (SA) in order to assess tunnel safety thoroughly.

1.2 *Investigated Dutch Tunnels*

In this research several Dutch tunnels were assessed (road, rail as metro, both old as new tunnels), as shown in figure 1.

1.3 *Reader*

The analysis of the use of QRA for tunnel safety has been executed by applying an evaluation framework, see chapter 2. The analysis of each tunnel (type) is

described in chapter 3. At the end, the conclusions and recommendations for further research are provided.

2 EVALUATION FRAMEWORK FOR QRA

In order to evaluate the applied QRA in tunnel projects, a (theoretical) evaluation framework needs to be set. Then it is possible to compare the use of QRA in Dutch tunnels to the theoretical approach. The demands for a thorough QRA-model, can be divided in three aspects; (i) input, (ii) model and (iii) output. But to make sure the QRA-model is applied properly, also demands must be set for the organization and the process. In order to make all stakeholders (including politicians) understand the QRA-modeling and increase the confidence in QRA-modeling, it should be insightfully set up.

This results in the following evaluation framework:

A. Input (data)

Conditions to the input of the QRA-model are that (i) the data must be valid and (ii) the input must be as complete as realistically possible (f.i. human factors or tunnel technical systems).

Data are considered valid if the source (guarantee transparency), the context (correct use) and reliability (prevent 'wrong/filthy' data), are known. Input can be considered complete, if all input variables are identified and if the uncertainty of the parameters is known and clear.

B. Model

To make sure the QRA-method is valued as an effective method to determine the safety level of a tunnel, also the modeling itself is point of attention. It should be reliable ('comparable/usable' for the real situation), clear (no black box), flexible (future use) and complete (as possible).

Regarding the completeness of modeling the following issues should be taken into account, (i) all scenarios, (ii) modeling steps taken in each scenario, (iii) modeling steps taken for self rescue/emergency services/fire departments/human actions and (iv) relation QRA-model and procedures.

C. Output (Results)

The results of the model must be presented in such a way that they are understandable (for all stakeholders), unambiguous (to prevent discussions) and reproducible (increases confidence).

D. Organization

In QRA-modeling with 'THE organization' is meant all involved stakeholders. They should be aware of the limitations of QRA-modeling and have the knowledge in what manner the QRA-model is set up. Further should they be aware of the connection between the QRA-model and the procedures to be drawn and executed by personnel (driver, maintainers, operators).

Table 1. Overview of QRA studies per tunnel.

	QRA? (year)	stage
Rail tunnel		
Velserspoor-tunnel	Yes, to determine and improve safety level before a change of owner. (LREHC, 2003)	expl.
Schipholtunnel	No, evacuation study	expl.
Willemsspoor tunnel	No, qualitative risk analysis for changing security system	expl.
Botlektunnel	Yes, for external safety (1997), and sprinkler discussion (RWS, 2003)	design/ construction
Greene Hart tunnel	Yes, for assessing internal safety (2000)	design
Road tunnel		
Hubertustunnel	Yes, for assessing internal safety but QRA under embargo	design
Leidsche Rijn	Yes, for deciding on design alternatives (location of explosion holes) (RWS, 2002)	design
Maastunnel	No.	expl.
Western Scheldt tunnel	Yes, distance in between cross passages (Bouwdienst (1999)) & safety level during maintenance (TNO, 2005)	const/ expl.
Metro tunnel		
RandstadRail	Yes, for assessing internal safety (GWR, 2002)	design
North/South line	Yes, for assessing internal safety (North/Southline 1998/2002)	design

E. Process

To determine whether the QRA-process has been executed thoroughly and accurately, the following points should be addressed: (i) stage, (ii) reason to execute a QRA, (iii) relation to scenario analysis and (iv) decision process.

3 SAFETY ANALYSIS OF DUTCH TUNNELS

3.1 *Introduction*

The safety approach applied in several Dutch tunnels is researched. In table 1 an overview is provided of the use of QRA (reason, stage).

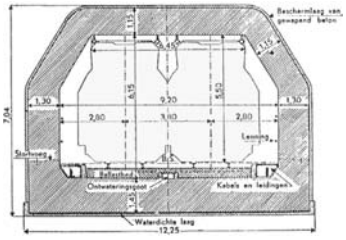

Figure 2. Cross section of Velserspoortunnel (crossing the NorthSea channel, west of Amsterdam).

In the following sections, it will be explained in what manner QRA has been applied in rail, road and metro tunnels together with the safety process.

3.2 *Rail tunnels*

The ownership and exploitation of the Velserspoortunnel (passenger/(dangerous) freight transport, opened in 1957), was transmitted from Rijkswaterstaat to ProRail in 2001. Therefore it was necessary to determine the safety level before handing over the tunnel. Another reason was that the existing safety level of the tunnel in the exploitation stage needed to be improved. QRA is used to make a comparison between three alternatives (LREHC 2003). SA is also executed by other stakeholders (RailNed 2003). Self rescue is the main focus in this studies.

Considering the input of the QRA study, the remarks can be made that there is a good overview of input parameters, the uncertainty of variables is clear, but the background of probabilities of failure is not clear.

Considering the model, it can be noted that all incorporated and remaining scenarios are clear. But the modeling of consequences, smoke and heat development is not explicitly taken into account. The uncertainty of QRA-modeling is clear when looking at the output (framework).

Finally it can be concluded that the QRA approach is clear, but the consequence modeling and background of probabilities of failure is not elaborated.

For the Schipholtunnel (opened in 1978/1990s) no QRA study has been executed, solely an evacuation study (ProRail 2006a) after an incident in 2001. Four trains were stopped inside the tunnel for several hours, due to a fire in the power supply room. This incident was researched by the Safety Board (RVTV 2003), issuing the improvement of the cooperation of all stakeholders.

It can be concluded that the evacuation study is a bit meager because not the complete system (rolling stock, organization, infrastructure) is taken into account, only the route is taken into account and no link was made to possible smoke and heat development, for instance the possible safety measures to prevent haltering of trains in the tunnel or to improve the organization.

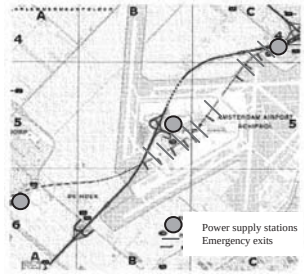

Figure 3. Overview of Schiphol rail tunnel underneath Schiphol airport, including emergency exits (two rail tunnels with each two tracks), (∼7,5 km)).

Figure 4. Interior Botlektunnel [S1].

The Willemsspoortunnel (crossing the river Meuse ∼3 km, opened in 1993) is used for both passenger as freight transport (dangerous goods). From 2007 this tunnel will also be used by HSL-trains. Because of current and future capacity problems, a qualitative risk analysis has been executed (ProRail 2006b) in order to provide a base on which the decision can be made that the security regime could be changed.

It can be concluded that not the whole system is assessed (capacity, type of transport etc.), no integral safety approach is conducted while changing the security regime (trias, stages and scenarios).

In the Botlektunnel (two bored tunnels part of the Betuweroute, open in 2007), two QRAs were executed; one in the design stage to assess the external safety and one in the construction stage (Bouwdienst 2003). The influence of sprinklers, heat resistant plaster, ventilation and detection on the safety level and the related costs were assessed in this study, issued by political discussion.

Further primarily qualitative safety studies were executed, due to the fact only personnel is involved in the tunnel. Most of the studies are executed in the construction stage and are described in the Integral Safety Plan of the Betuweroute (V&W 2004).

It can be concluded that the QRA is more used as a verification tool, rather than a design tool. The process of safety related studies is non-transparent, ad hoc and is not executed in the design stage but mostly in the construction stage. When considering the fact that the Green Book (BZK and V&W 1997) is set as a condition for gaining a construction permit it can be said

Figure 5. Cross section Green Hart (land tunnel) – one tube divided by wall (∼7 km) [S2].

that there was bad communication and cooperation amongst stakeholders.

The Green Hart tunnel is bored underneath the Green Hart (rural centre of the Randstad) and is solely used for public transport . It is part of the High Speed Line, and will be opened in 2007.

The QRA was used in the design stage as a design tool. Several safety committees were set and safety plans were set., including an integral safety plan (HSL-Zuid 2000, 2001), of which the QRA was part of (TNO-MEP 1998, 2000b).

It can be concluded that there was good communication from the design stage involving all stakeholders, setting up several safety committees. The QRA was used as a design tool and is executed in an integral manner (including SA).

Further all possible variables are implemented into the QRA model (trias), including human factors. The background of probabilities of failure is described. Several scenarios are considered (complete modeling), the modeling is clear and the steps taken are understandable. Good consequence modeling has been applied because the relation between the fleeing speed of the passengers and the smoke-heat development is taken into account.

But maintaining the designed safety level during the construction stage is a difficult issue.

Finally, considering rail tunnels, it can be concluded that in existing rail tunnels no/little attention is paid to the present safety level of the tunnel. Most of the safety studies are problem steered instead of a thorough integral approach. In rail tunnels owned by ProRail, uptill 2006, no integral QRA is executed in order to assess the safety level in the exploitation stage.

In new tunnels, attention is being paid to safety, but this has been worked out better in the Green Hart tunnel than in the Botlektunnel, probably having to do with the communication in the safety process. For rail tunnels no standard QRA approach is available.

3.3 *Road tunnels*

For the Hubertustunnel (two bored tunnels underneath rural and residential area, currently under construction) both SA and QRA were executed. The safety process already started in the design stage and several stakeholders were involved from the start and a safety concept is set-up. The QRA is under embargo and the SA is a qualitative research (Haaglanden 2005), so no valuation of input variables, but 9 scenarios have been analyzed qualitatively. The required time of each incident is compared to the demands set for self rescue, emergency services, traffic development and control of incidents.

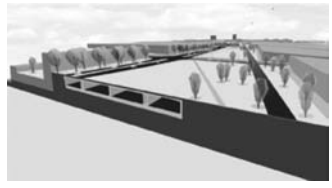

Figure 6. Cross section of Leidsche Rijn tunnel (land tunnel, in order to prevent barrier in between two urban areas).

It can be concluded that the start of the safety process is good (organization, safety studies), but the follow-up is unknown. And considering the scenario analysis the following remark can be made that whether each scenario complies to these set criteria is vague, due to the assumptions made of which no background is available.

For the Maastunnel project (immersed tunnel crossing the river Meuse) no QRA was executed. It is the oldest road tunnel in the Netherlands (1942).

Still TNO has executed a safety study (after the Alp fires), but this is under embargo. But all recommendations made are taken along in a maintenance plan for many years. The safety level of the Maastunnel will be as high as possible, but it must be taken into account that it is impossible to change the lay-out of an existing tunnel. It is built in a time, there was no policy regarding tunnel safety, therefore it is impossible to reach the safety level as set in the tunnel safety Directive (Tunnelsafety 2003).

In the Leidsche Rijn, both QRA as SA were executed in the design stage. The tunnel is designed according to the VRC-directives (Bouwdienst 2004) and this is the base of the RWS-QRA model. By executing a QRA a comparison is made between the design alternatives.

It is noted that not all safety measures are implemented in the QRA model, because the safety measures described in the VRC-directive are seen as 0-alternative. But human factors are incorporated (minimal).

The model itself incorporates 4 scenario types and the steps taken are clear. But the consequence modeling is inadequate and not the complete system incorporated in the modeling. Both internal as external risk are calculated due to multiple space use. But still there is no clear consideration between the two.

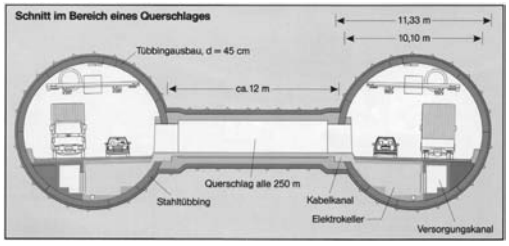

Figure 7. Cross section of Western Scheldt tunnel [S7].

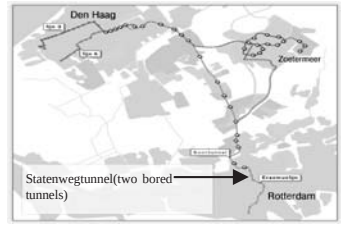

Figure 8. Layout of RandstadRail track [S5].

RWS executed the QRA and TNO executed the SA. In the SA it is mentioned that a partially opened tunnel is better for the internal safety compared to a completely closed one. Both studies had different conclusions regarding the alternatives. But these studies were not used in parallel, because in the decision-making process, only the QRA study was shown to the Committee Tunnel Safety and the SA was left out. Due to limited access of documents in the decision-making process, 'wrong' decisions are made (non transparent process).

In the Western Scheldt project (two bored tunnels opened in 2001) two QRA were executed; one in the design stage (to determine the hart-to-hart distance between the cross section – RWS-QRA) and one in the exploitation stage to compare alternatives of traffic diversion routes during maintenance of one closed tube (TNO 2005). This study was executed after an lethal accident has happened in 2001 during maintenance works (RVTV2004). In the design stage several stakeholders were involved. But this could not prevent the discussion on the distance in between the cross passages (500/250 m), for which the first QRA was executed by the Bouwdienst.

It can be concluded that no QRA is executed in the exploitation stage to assess the safety level integrally. The interaction with the fire department in the exploitation stage is good and the procedures are (regularly) updated and communicated.

In the TNO study, several scenarios are incorporated, but the validity of data is unknown. The modeling itself is not completely described, so it is not transparent. In the safety study the best possible alternative of traffic diversion routes during maintenance of one tube (closed) can be chosen.

Finally it can be concluded that in Dutch road tunnels mostly the QRA-RWS model (Rijkstunnels) Not all safety measures are implemented in the QRA model, because the VRC-directive is seen as 0-alternative. QRA is not properly used as a design tool, and in the exploitation stage it is not used in an integral manner. In municipal tunnels and old tunnels no such studies are executed.

3.4 *Metro tunnels*

The RandstadRail LightRail project is currently under construction and the Statenwegtunnel is being bored in Rotterdam. QRA is executed in the design stage to determine the safety of the Statenwegtunnel in case of fire. In this QRA study not all scenarios are incorporated, but the set up is clear. The uncertainty of the probabilities of failure is clear because of the division in classes. The QRA is used to determine the effect of distance between the cross sections, and therefore it is not used in an integral manner.

Further several other safety studies have been executed in the construction stage (RandstadRail 2004a, 2004b, 2004c, 2005, 2006a, 2006b). In these safety studies not a QRA approach is applied but it is solely based on existing frequencies without taking into account possible other causes which has not occurred until now. But SA is also executed.

Early on in the design stage, several stakeholders are involved. A safety concept is drawn, in which the main focus of self rescue and the Safe. Local government accepts the safety demands officially; increasing the compliance. And at the finalizing stage of the construction a Safety Case is executed.

It can be concluded that the safety process has started in the design stage, setting up an integral safety study. Several safety studies have been executed, but the QRA is not executed in an integral manner as a design tool incorporating all scenarios. And the safety studies are executed in the construction stage to check the safety level instead of in the design stage to gain a good design.

The North/South line metro project is currently under construction in the city of Amsterdam (two bored tunnels, underneath the old city centre).

Early on the design process several stakeholders are involved, evaluating safety studies. But there are people opposing the metro line and questioning the safety. The question is whether it is not communicated well or people do not want to understand. The Safety concept is an integral qualitative study in which the Safe-haven principle and self rescue are main focus (North/Southline 1998 and 2002a).

QRA for tunnel safety (North/Southline 2002b and TNO-MEP 2000a) is used to determine the effect of

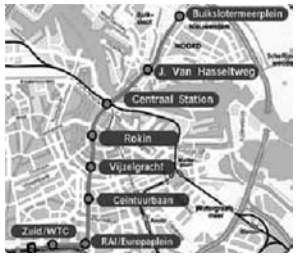

Figure 9. North/Southline track [S3].

distance between the cross sections. Besides the QRA for fire safety inside the tunnel, also a QRA for the underground station is executed. QRA is not used in an integral manner.

As input of the modeling the trias is applied (organization, infrastructure and rolling stock), including human factors. Not all scenarios are incorporated, but the set up of the model is clear. Consequence modeling takes relation between fleeing speed and smoke development into account.

It can be concluded that in metro tunnels, QRA is being used, but not in the integral manner as set in the evaluation framework. The safety process has been set up early on in the design process, but the safety documents do not all contribute to a thorough design. Some are more execute to verify the eventual safety level.

4 CONCLUSIONS

In this chapter, conclusions can be drawn on the use of Quantitative Risk Assessment in Dutch tunnels. As said in the evaluation framework, QRA can be valued as an effective application tool if:

- An integral approach is applied (trias, all scenarios).
- QRA is used as a design tool (comparing alternative designs, safety measures etc.)
- QRA is used together with Scenario Analysis (SA) in a probabilistic way to guarantee that all issues (traffic handling, self rescue, emergency services) are covered.

However, after the analysis in chapter 3, on the use of QRA in Dutch tunnels, it can be concluded that:

(A) No integral approach is used for executing QRA-modeling:
  (1) Tunnel safety is often assessed in a more *problem steered way* instead of a systematic approach, resulting in a shredded approach.
  (2) The *modeling of QRA* for assessing tunnel safety is inconsistent (trias, incorporated scenarios, elaborating each scenario, probabilities of failure, human factors, evacuation).

(B) The reason for executing quantitative analysis varies, increasing the suspicion of stakeholders;
  (1) Verification tool instead of design tool
  (2) Resolving problems ad hoc instead of systematically.

(C) Difference between internal and external safety is rather difficult, when considering multiple space use projects causing difficulties in decision-making:
  (1) The dividing line between internal and external safety is rather thin.
  (2) Are all effected areas taken into account for each main scenario; these can vary per scenario.

(D) As-built problems; After the construction stage the structure must eventually comply to the demands set in the design stage, but because several stakeholders are necessary to reach that goal this is a rather difficult issue.

(E) Process; good initial cooperation in several new projects, but in few projects it leads to a thorough and structured process. And the responsible stakeholder for safety is not always clear.

5 RECOMMENDATIONS

It is recommended to further investigate the use of QRA of the mass-transit systems and not of road tunnels, because in the Netherlands this field is already covered by the Bouwdienst of Rijkswaterstaat (RWS-QRA model). By developing QRA for mass-transit systems enables to make comparisons and as a consequence improve the trust of stakeholders in QRA-modeling.

But it is recognized that no standard QRA-model for 'all' tunnels should be developed, but a standardized QRA-approach. Several divisions need to be made because of the project specific conditions, location (land/water tunnel), type of tunnel (bored/immersed tunnels/in situ), geometry, multiple space use, type of transport.

By setting a standardized approach the modeling will be flexible for all locations and for future use. Therefore the goal is to incorporate all possible input variables, forcing the analyst to make considered choices (and describe those as well), resulting in a fit for purpose QRA-model for different types of underground mass-transit systems.

In the following sections recommendations are made regarding the improvement of the safety process, the organization and regarding the QRA-modeling itself.

5.1 *Recommendations regarding QRA application in Dutch tunnels*

(1) Use QRA and SA together; QRA should be used to check whether all steps are taken along in the SA and if all needed safety measures are taken. But then again, QRA should be used to determine safety level and as input for CBA.
(2) Create a link between the initial and actual conditions to guarantee the safety level in (i) the construction and (ii) the exploitation stage.
(3) Determine the stage and the situation in which QRA can be applied. QRA must be used as a steering tool for designing the tunnel and to maintain the safety level in the exploitation stage.
(4) Responsible stakeholder should be known and should manage the safety process structurally.
(5) The standards set for tunnel safety should be researched (background, relation to costs like dike safety, unit, relation to other safety related fields).
(6) Develop QRA approach for multiple space use.

5.2 *Recommendations regarding QRA modeling in Dutch tunnels*

To improve QRA-modeling the following issues should be improved:

(1) Classification of probability of failures: Ascribe each safety measure to a certain class (a/b/c).
(2) Prevent black box modeling.
(3) Incorporate human factors in a groupwise manner (professionals or not)
(4) Improve the modeling of self rescue (smoke and heat development and related consequences).
(5) Fully incorporate rolling stock.
(6) Incorporate the link between the QRA and the procedures (calamity plan, safety control plan).

If all these recommendations are researched, hopefully the stakeholders will recognize the effective application of QRA-modeling.

Emergency egress provisions and their guidelines

Magdalena Vasilovska
Parsons Brinckerhoff, Sydney, Australia

M. Reedman
Parsons Brinckerhoff, Brisbane, Australia

ABSTRACT: The paper provides an overview of the egress provisions currently applicable in various countries around the world, and the recommendations by PIARC, NFPA, and the recently published Directive 2004/54/EC of the European Parliament. Presently, egress locations vary from 100 m up to 500 m, and with egress door widths varying between 0.815 to 1.4 m. If the guideline recommendations are strictly followed without limited performance based assessment, tunnel designs are at risk of ending up with either inadequate emergency egress facilities or surplus facilities that affect the sustainability of road tunnel projects, especially tunnels of relatively short length (<750 m). This paper mainly focuses on egress passage locations and dimensions as required by various guidelines for two-tube unidirectional urban tunnels. Egress analyses using SIMULEX have been performed for selected representative scenarios to compare the egress time of various international designs, with commentary on the results provided.

1 INTRODUCTION

1.1 *General*

The frequency of egress passages has an impact on the occupants egress time and safe evacuation, and the rapid implementation of fire fighting activities by the fire brigade required for extinguishing fires to save life and provide property protection in case of a fire incident within a road tunnel. On the other hand, they add considerable costs to the construction, fit-out, and maintenance of road tunnels.

Historically, there has been considerable debate within the fire-protection and tunnel engineering communities on the provision of acceptable fire prevention and protection facilities in road tunnels, including frequency of egress passages. Currently, there is no uniform position on the distance between egress passages in road tunnels internationally.

In addition to a brief overview of the egress passage requirements as defined in the internationally accepted guidelines such as PIARC, NFPA, EU Directive, and AFAC, this paper also provides a brief overview of the adopted guidelines in selected countries. Comparison of the predicted egress times in each tunnel by performing egress analyses using PB's version of the computer program SIMULEX has been performed. The egress time referred to in the paper is the actual movement time measured from the time the occupants decide to evacuate to the time when occupants have reached a place of safety The delay time (measured from the start of the fire until the time when occupants decide to evacuate) has not been included in the egress times as there are no set values and is another complex research topic.

2 GUIDELINES FOR ROAD TUNNELS

2.1 *PIARC 1999 recommendations (PIARC, 1999)*

Section VI.2.3.2 Tunnels with unidirectional traffic (two tubes or more):

> *. . .The most common escape route in two-tube tunnels is a connection (cross passage) between the two tubes. The distance between connections should depend on traffic density and emergency rescue scenarios, for instance 100–200 m in cities. This distance should be designed so that people can walk to the nearest exit before smoke reduces visibility.*

2.2 *Fire safety guidelines for road tunnels 2001*

AFAC (AFAC, 2001)

> *. . .It is not possible to provide a general recommendation for the distance between egress points and such details should be developed for each individual case after consideration of the conditions within the tunnel.*
> *. . .Required exit points depend on a number of factors such as the types and volumes of vehicles*

and the ventilation and smoke management systems within the tunnel. . . . Occupants must be provided with a means by which they can escape to a place of safety prior to smoke reducing visibility or creating untenable conditions.

2.3 *PIARC (PIARC, 2007)*

A second, or new report entitled 'Systems and Equipment for Fire and Smoke Control in Road Tunnels' is being prepared by PIARC Working Groups 6 and 2. This report is yet to be published and will complement the 1999 report and supplement, not replace the material contained in the earlier publication. Its view on egress provisions is:

. . .Emergency exits in enclosed road structures addresses the issue of emergency exits for evacuation, escape and rescue including consideration of the types and characteristics of emergency exits in road tunnels including how to deal with disabled people. Also included is the consideration of the necessary spacing between exits according to people behaviour and tunnel ventilation including escape modelling.

2.4 *NFPA 502 (NFPA, 2004)*

Section 7.17.7 Cross Passageways:

. . .Where tunnels are divided by a minimum of 2-hour fire-rated construction or where tunnels are in twin bores, cross passageways between the tunnels shall be permitted to be utilized in lieu of emergency exits. The following requirements shall be met:

(1) Cross passageways shall not be further than 200 m apart. . .

(3) An emergency egress walkway with a minimum clear width of 1 m shall be provided on each side of the cross passageways.

2.5 *DIRECTIVE 2004/54/EC of the European Parliament, 29 April 2004 (European Parliament, 2004)*

Section 2.3: Escape routes and emergency exits:

. . .In any event, in new tunnels, emergency exits shall be provided where the traffic volume is higher than 2000 vehicles per lane. . . Where emergency exits are provided, the distance between two emergency exits shall not exceed 500 m.

2.6 *Summary of egress requirements*

The egress provisions as defined in the guidelines above are summarized in Table 1 below:

Table 1. Summary of international guidelines egress provisions.

	Spacing (m)	Passage Width (m)	Door-width (m)
PIARC	100–200	1	0.8
AFAC	N/A	N/A	N/A
NFPA 502/101	200	0.915	0.810
EU-Directive	<500	N/A	N/A

3 EMERGENCY EGRESS REQUIREMENTS IN SOME INTERNATIONAL GUIDELINES

Various countries around the world have developed and adopted their own national guidelines that define the minimum safety provisions applicable to new tunnels including maximum distance between egress points. In some cases, they even define the minimum passage and door widths. Egress passage requirements defined in various national guidelines and considered in the egress analyses in this paper are summarised in the table below:

Table 2. Selected International Road Tunnel Cross passage Requirements*.

	Spacing (m)	Passage Width (m)	Door-width (m)
Australia^	120	1	0.8
France^	200	1.8	1.4
Germany	350 m	N/A	N/A
Netherlands^	100–250	1.2	0.85
Sweden^	100	1.2	0.9
UK^	100	Various	0.914
USA^	200	0.915	0.81

^SIMULEX modelling performed for these requirements

* Requirements sourced from: Australian Standards (2001); Interministry Circular (2000); RABT (2002); MTPW (2004); SNRA (2000); The Highways Agency (1999); NFPA (2004); NFPA (2006).

4 MODELLING OF ROAD TUNNEL EGRESS

4.1 *Description of SIMULEX*

The emergency exiting analysis was done using the computer program SIMULEX (Integrated Environment Systems Ltd., 1998) that models the emergency exiting of people from large complex geometries to a point of safety. SIMULEX allows the user to create a 3-D model of a building by using a number of CAD-designed floor plans, connected by escape passages or stairways. To do this the program assigns a body dimension, position, angle of orientation, occupant type, and a walking speed to each person. The

simulation of escape movement includes distance mapping, way finding, overtaking, route deviation, response time, and adjustments to individual speeds due to the proximity of crowd members. The program's algorithms for the movement of individuals are based on real-life data and predict realistic people flow rates.

4.2 *Population mix and walking speeds*

The commuters in the simulations consist of 50% male, 40% female and 10% children. Each commuter type has a body size and normal walking speed. The new versions of SIMULEX offer two commuter mixes comprised of Western countries or people from Asia, who differ in body size. However, the average walking speed for both types is 1.225 m/s. In the simulations performed in this study, people from Western countries have been used corresponding to the countries modelled. The data used is summarized in Table 3 below:

Table 3. Parameters of "commuters" in the SIMULEX* Model.

	Commuter type		
	Male	Female	Children
Average speed	1.35 m/s	1.15 m/s	0.9 m/s
Shoulder breadth	540 mm	480 mm	420 mm
Body depth	320 mm	280 mm	240 mm

* For additional information on SIMULEX modelling of Road Tunnel egress, refer to Li (2001) and Bendelius (2002).

4.3 *Tunnel occupancies*

To minimise the number of variables that can affect the results of the SIMULEX modelling, one set of vehicle fleet parameters was used to determine the tunnel's occupancy loading for all scenarios. In case of tunnel congestion, traffic density of 165 PCU/km/lane was used and 1.167 PCU/vehicle. The average traffic density is 141 vehicles/km/lane. To determine the number of vehicles per lane, this figure is multiplied by the length of road tunnel section (1.5 times the cross-passage spacing). The tunnel occupancies were derived by using fleet ratios and average number of people per vehicle as in Table 4.

Table 4. Fleet ratio and Average number of Passengers per vehicle.

	Fleet ratio %	Average Passengers/Vehicle No.
Car	85.7	2.5
LCV	9.5	2
HCV	4.8	45

A random distribution of 2, 3 and 4 people per passenger vehicle was used in the model, equating to an average of 2.5 passengers/vehicle. The number of occupants used in the egress modelling for 1, 2 and 3 lane tunnels are summarised in Table 5 below. The values in brackets next to each country indicate the distance between cross passages.

Table 5. Summary of number of occupants used in the egress analyses.

	Number of people evacuating a tunnel section		
	1-Lane	2-Lanes	3-Lanes
Australia (120 m)	115	229	343
France (200 m)	191	381	572
Netherlands (100 m)	95	191	286
Netherlands (250 m)	238	476	715
Sweden (100 m)	95	191	286
UK (100 m)	95	191	286
USA (200 m)	191	381	572

Most guidelines suggest that road tunnel egress provisions need to be assessed based on the tunnel length, the type of tunnel (uni-directional or bi-directional), number of lanes, and the traffic density. The focus for this study is based on long, twin tube, (uni-directional only) urban vehicle tunnels, with traffic congestion resulting in highest occupant loadings putting a greater demand on the tunnel emergency egress facilities.

4.4 *Egress analyses of a long, twin tube, uni-directional urban tunnels*

SIMULEX models were created representing the egress provision required by the guidelines for long, dual tube, uni-directional urban road tunnels in Australia, France, the Netherlands (100 m and 250 m distances), Sweden, UK and USA. The models were created using the following assumptions/parameters:

- Fire located next to a cross-passage, making escape into this passage impossible.
- Passengers exit in both directions using the closest unobstructed cross-passage. Due to symmetry, only egress from one side of the incident was required to be modelled, resulting in a model length of 1.5 times the cross-passage spacing
- Congested tunnel (maximum occupancy).
- No deluge system in operation (Australia only).
- 1, 2 and 3 lane tunnel configurations.

Typical tunnel layouts and egress passage geometry used in the model, and a typical egress simulation output layout showing positioning of people in front of an egress passage are shown in Figures 1, 2 & 3 below:

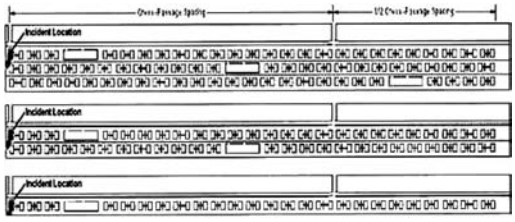

Figure 1. SIMULEX model layout for 1, 2 and 3 lane tunnels.

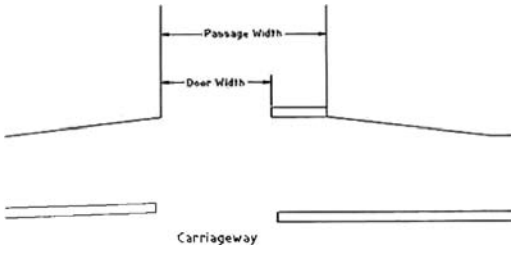

Figure 2. SIMULEX model cross-passage doorway layout.

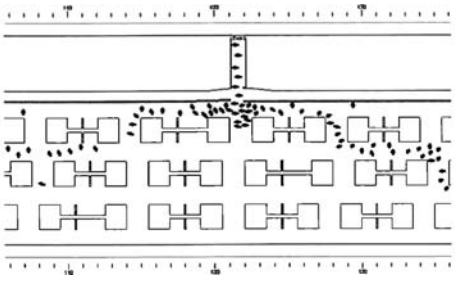

Figure 3. Screen shot of SIMULEX simulation, cross-passage close-up for an Australian 3-lane tunnel.

5 SIMULATION RESULTS

Egress times predicted by SIMULEX for each scenario modelled are summarized in Table 6 below:

Table 6. Summary of simulated egress times (min:seconds).

	Simulated Tunnel Egress Times (min:sec)		
	1-Lane	2-Lanes	3-Lanes
Australia (120)	3:12	3:55	5:00
France (200 m)	5:01	5:05	6:10
Netherlands (100 m)	2:36	3:20	4:50
Netherlands (250 m)	6:14	8:25	11:50
Sweden (100 m)	2:35	3:15	4:40
UK (100 m)	2:35	3:15	4:35
USA (200 m)	5:06	6:55	9:30

The actual progress of the egress during evacuation as predicted by the model for 1, 2 and 3 lane tunnels are shown in Figures 4, 5 & 6 below. The figures indicate the percentage of evacuees that are yet to evacuate the tunnel at any point in time during evacuation. The vertical line indicates the time when evacuation is expected to be complete in an Australian tunnel, and can be used to predict the percentage of people yet to evacuate tunnels designed in accordance with French, US or Netherlands (250 m) guidelines. Australian tunnel design was assumed as a reference point in this comparison.

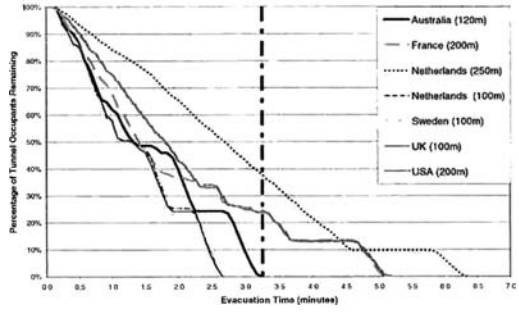

Figure 4. Egress results for 1-lane twin tube, urban road tunnels.

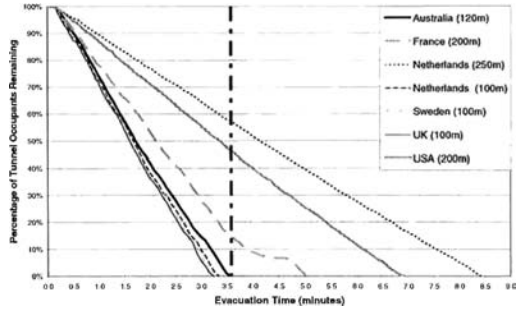

Figure 5. Egress results for 2-lane twin tube, urban road tunnels.

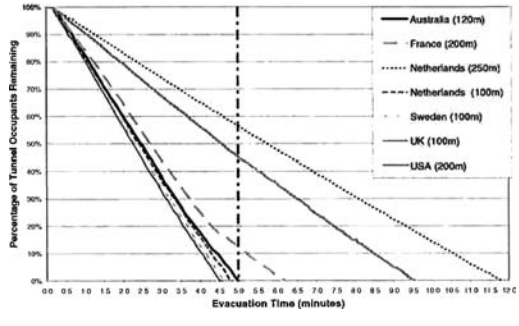

Figure 6. Egress results for 3-lane twin tube, urban road tunnels.

6 SUMMARY

The frequency of the egress passages has an impact on the occupants egress times and safe evacuation and the rapid implementation of fire fighting activities by the fire brigade to extinguish and control fires, therefore protecting and saving life and property. However, currently there is no uniform position on safe distances between egress passages in road tunnels internationally.

Internationally accepted guidelines such as PIARC, NFPA, EU Directive, and AFAC recommend varying egress/cross passage distances. In addition, various countries around the world have developed and adopted their own national guidelines that define the minimum safety provisions applicable to new tunnels, including maximum distance between egress points and, in some cases, the minimum passage and door widths.

SIMULEX models were created with egress provisions for long, dual tube, uni-directional urban road tunnels in Australia, France, the Netherlands (100 m and 250 m distances), Sweden, UK and USA in accordance with the applicable guidelines. The modelling results showed that the UK, Sweden and Netherlands (100 m passages) would achieve slightly better egress times than Australian tunnels, with France, Netherlands (250 m) and US expected to have longer egress times. The egress times ranged from 2 min 35 sec (for egress distances of 100 m) to 11 min 50 sec (for egress distances of 250 m).

7 OTHER PARAMETERS AFFECTING EGRESS

7.1 *General*

In addition to the frequency and size of egress points, there are other components that are critical for safe evacuation of tunnel occupants such as:

- traffic density and occupant loading
- allowance of congested traffic conditions
- occupants reaction (delay) time (greatly dependent on incident detection and advisory provisions)
- walking speed of occupants
- fire size and growth, fuel type, smoke production
- capacity and type of tunnel ventilation system (longitudinal, transverse, semi-transverse)
- smoke management systems (smoke ducts)
- tunnel detection and communication provisions
- fire protection systems (such as deluge)
- adopted emergency rescue scenarios

These components either help to directly shorten the evacuation time or prolong the time available for evacuation within a tenable environment inside tunnels. There are varying views on each component within the international tunnel engineering communities, and further research is required to determine acceptable values.

7.2 *Egress provisions and occupant loads*

Emergency egress provisions in road tunnels vary between countries, as do the occupancy loads. Australia and Japan install deluge systems that have a potential to improve the tenability inside tunnels, and can provide additional property protection. However, Australian tunnels have comparable egress provisions with European countries, but differ from Japanese tunnels.

In addition, new rail tunnels incorporate egress passages at a distance of not greater than 244 m as recommended by the NFPA 130, even though the occupancy level is expected to be a lot higher, (up to 1600 people for an 8 car train) and the egress time can take up to 2.5 hours if all goes well. Expected occupancy levels for the applications discussed are summarized in Table 7 below:

Table 7. Summary of expected occupancy levels.

	Number of people evacuating a tunnel section		
	1-Lane	2-Lanes	3-Lanes
Australia (120 m)	115	229	343
France (200 m)	191	381	572
Netherlands (100 m)	95	191	286
Netherlands (250 m)	238	476	715
Sweden (100 m)	95	191	286
UK (100 m)	95	191	286
USA (200 m)	191	381	572
Japan (700–800)	667	1333	2000
NFPA 130* (244 m)	1600	N/A	N/A

* Applicable to rail tunnels only

7.3 *Occupant reaction time and walking speeds*

The response times of tunnel occupants are highly unpredictable and there are no set values applicable to tunnel environments. Some test data is available and further tests and studies are being undertaken to research human behaviour during emergency evacuation from tunnel environments. Currently PIARC suggests delay times between 2 to 5 minutes. Most guidelines and studies suggest that the first 5–10 minutes after a fire incident are the most critical for safe evacuation, therefore shorter delay times are very critical for safe evacuation.

Occupant walking speeds also vary between various guidelines and the feedback from real tunnel evacuations and tests. Some of the recommended values are summarized in Table 8 below:

Table 8. Summary of recommended occupant walking speeds.

Values in m/s				
PIARC	NFPA 502	SFPE	SIMULEX	Japan
1–1.5	1	1.19–1.25	1.225	1.2–1.7

7.4 *Fire size and smoke production rates*

Fire size, fire growth and the smoke production rates are detrimental to the tenable environment during tunnel evacuation. Various guidelines offer different values. Comparison of current and recommended fire sizes are summarized in Table 9 below:

Table 9. Comparison of recommended fire sizes.

Type of vehicle	PIARC (MW)	NFPA502 (MW)	AFAC (MW)	France (MW)	Ingason (MW)
small car	2.5	5	2.5	–	5
large car	5	5	5	–	5
2–3 cars	8	–	8	8	10
van	15	–	15	15	20
bus	20	20	20	–	30
lorry	20–30	20–30	20–30	30	50
HGV	100–120	–	100–120	–	70–150
petrol tanker	–	100	100–120	200	200+

In addition, latest tunnel fire test results (Ingason, 2006) suggest adoption of increased fire sizes and faster fire growth values, reaching a maximum fire size within 10 minutes. These increases will also lead to new fire smoke production rates that are yet to be determined and will affect tenability inside tunnels.

Using "t-squared" fire growth is the most accepted description of the rate of heat release of accidental open flaming fires and adopted for tunnel fires. The general equation is as follows:

$$Q = \alpha t^2$$

Where: Q = fire hear release rate [kW]
α = coefficient of growth
t = time [s]

Current and future proposed fire growth rates are summarized in Table 10 below:

8 RECOMMENDATIONS

More research and field studies are being performed and new data is emerging on topics related to fire emergency within a tunnel environment such as:

- expected vehicle density and occupancy rates within a tunnel, including traffic control
- human behaviour
- impact of fire detection and communication systems on the occupants reaction (delay) time
- acceptable walking speed
- fuel type, smoke production, fire size and fire growth rates
- fire and life safety provisions including tunnel ventilation, smoke management (smoke exhaust ducts) and water suppression systems
- emergency operation procedures

The outcomes of the latest research results need to be analysed collectively by the worldwide tunnel engineering communities and authorities that have jurisdiction over setting of guidelines for road tunnel designs. As a consequence, the current guidelines and design practices adopted by various countries may need to be reviewed and updated subject to the outcomes of the latest research findings. Collective agreement on the design parameters, or at least an agreed design approach, within the tunnelling communities and project approval authorities is critical in order to guide tunnel designers in delivering safe and sustainable road tunnel projects in the future.

ABSTRACT: At the Slovak territory there are several historical mining towns with extensive underground spaces and construction systems. Nowadays, in aftercare and restoration mining stage, have these abandoned working and spaces systems oft unique character, but also with undesirable geotechnical risk and impact to surrounding in each individual towns.

After several years ago these geotechnical impacts makes itself also as a damages on the surface buildings and objects. First of all in old historical interesting gold and silver mining town Banská Štiavnica, that is except as well the cultural heritage of UNESCO town, they may to be survey some surface geotechnical changes and some destruction. In many case are being this changes straight bellow in the middle of the town near by residential area.

The contribution deals about the in underground developing geotechnical impacts and some new geotechnics situation, there are as a result of groundwater move effect as well as the various tectonic destroy. The geotechnics and environment issues could be considered as a main problems resulting from extraction of minerals in deepness more than 500 m under town. At present has town number thousand solid content of unknown opened underground spaces, there are constantly dangerous for living environment. Therefore the article deals also about the geotechnics methods there could be acceptable by problems solution from geotechnical point of view.

1 INTRODUCTIONS

The Slovakia has a long metal mining history, but at present time with the exception of two metal mines operated by Mining companies Siderit Nižná Slaná,Ltd. and Slovenská Banská spoločnost', Banská Hodruša, Ltd., there are hardly any metal mines still in operation. However a few years ago were on the all territory many that time economically important underground operated metal mines. In most cases they were localities with yearly extraction performance of industry minerals more than 1 Million tons, for example the mining fields in Rudňany and Slovinky on the east part of the country. Except above mentioned two most undergound mines in the region of the present Slovakia they were also the another mines with early very extensive mining activities. In this context they are scores of the time mentioned the oldest mining cities Banská Štiavnica, Kremnica and Špania Dolina, which are situated in the middle part of country, and that also were very closely connected with occurrence of ore deposits as both gold and silver. Alikes to Spiš-Gemer metalic ore-fields with many important rich in copper mines production, with the beginning of mining in 15th century, also Banská Štiavnica silver-gold ore field has belong among 13th and 18th century with its both gold and silver production to the richest in Europe. In a similar manner is to be mention the unique opal deposit and mine Dubnik, that is located in the middle of northen part of Slansky mountains. The beginning of noble opal mining might reach up to 16th century, what at present time shows numerous destroyed and collapsed underground and open pit mine areas.

Despite of all hereby stated facts is significant highlighted, that with the expection of Bansko-Štiavnicko-Hodrušský ore field there is not exist on the present any mining activities on the places, which were once upon in previous time so well-knowed. As it was discussed

above on the all oldest mining localities and also on the all till then operated mines, were aproximetly since of 1998 year the all mining activities stopped and the mines were fully closed in stages.

About present time period its began very strong consider respecting to underground mining spaces utilisation for so called non-mining purposes. The main task was to solve problems with stability of opened underground spaces, because non each of operated mines were closed according to technical requirement. Namely, the all reclamation after finishing or terminating of a mining activity belongs to responsibilities of a organization, to which a mining claim is registered. The reclamation itself is not permitted by a district mining office, but by a county office, division of allotments, agriculture and forest management. The all connecting activities with restoration and aftercare works in Slovakia it has to supply the main state institution, which has the financial purely for the mines in closure phase. However today is an increasing tendency to stipulate such provision for new projects.

At present time is considerable number of old and abandoned mine workings all over the country, that could have need more financial support with regards to the elimination of environmental impacts in connection with geospace and underground water. There is a considerable number of old and abandoned (orphaned) mine workings all over the country, and some of them cause quite substantial environmental impacts, especially in connection with surface run-off or water from underground workings. The Mining Directorate has for more than 15 years managed projects aimed at mitigation of the most severe negative cases. This work has mainly been financed by the Ministry of the Environment. Similar must to be to evaluate the all activity, associated with exploitation waste disposal within waste dumps, tailings, underground spaces and nature rock masses structures, is assumed as mining activity, and for its performance a mining license and a permission by the district mining office, is demanded.

On more mining localities of Slovak territory, e.g. Banská Štiavnica, Hodruša, Kremnica, Špania Dolina, Smolník, Rudňany, Gelnica and next old mining towns, at last 10 years was indicated negative demonstration of Mining activities on surface. This dangerous stage follows from:

- mining methods development
- long term underground exploitation
- unknown mining spaces and objects
- opened and abandoned spaces, which are not signate in any mining maps (there are the object 13th–16th century)
- geomorphological conditions
- progression of building plan in towns
- localization of surface objects by former operating mines.

2 GEOTECHNICAL REQUIREMENTS BY AFTERCARE MINING MANAGEMENT

In case of the termination of old mines, that they are near by settled zones is crucial to evaluate the all geotechnical aspects of abandoned underground spaces, first of all their condition of stability. The above mentioned polymetallic minerals and ore deposit districts at Slovakia territory have formerly belong to the most important localities for the gold, silver, copper and semi-precious stone underground mining. The mining of gold and silver-bearing minerals has been running across several centuries there. New geological exploration and mining works started at 50th years of the last century. Expect in old semi-precious stone opal/ hyalite at the deposit Dubník, on which the mining activities were closed in 1922 year, it went on the mining production by another mines till end–of nineties. In these years were the all polymetallic ores deposits at the territory of Slovakia over definitely closed including of their relatively modern plant processing.

Number of data and corresponding information related to the history of mining, exploration activities, mining technologies, the mineral processing plants, eventually another with mining coupled activities are scattered in separate records room and other institutes. Thus ways they are these data searched and processed uniformly for the subsequent utilisation for detailed studies and for the help to the state and municipial bodies. In Slovakia does these works the institution – Geological Survey of Slovak Republic, which represents an independent contributory organisation of the Ministry of the Environment of Slovak Republic.This institute, as a ministerial scientific research institute, besides its main goals focused to the geological research and exploration, deals also with geotechnical conditions of the territory, mainly for purposes of land use planning and aftercare mining monitoring. By one of his main goal is also the research into geological structures suitable for final waste storages into suitable natural rocks and underground spaces. The institute safeguards of obligations following from the Law of National Council of Slovak Republic No. 52/1988 of the Law Code on geological works and Slovak Geological Office in the wording of the Law of National Council of Slovak Republic No. 497/1991 of the Law Code and from the Law of National Council of Slovak Republic No. 44/1988 of the Law Code on the protection and utilisation of mineral resources, in wording of the Law of National Council of Slovak Republic No. 498/1991 of the Law Code on registers administration, management of exploration territories, administration of attests on exclusive deposits, administration of exclusive deposits resources and balance sources of mineral raw materials, management of register of old mining works, gathering, administration

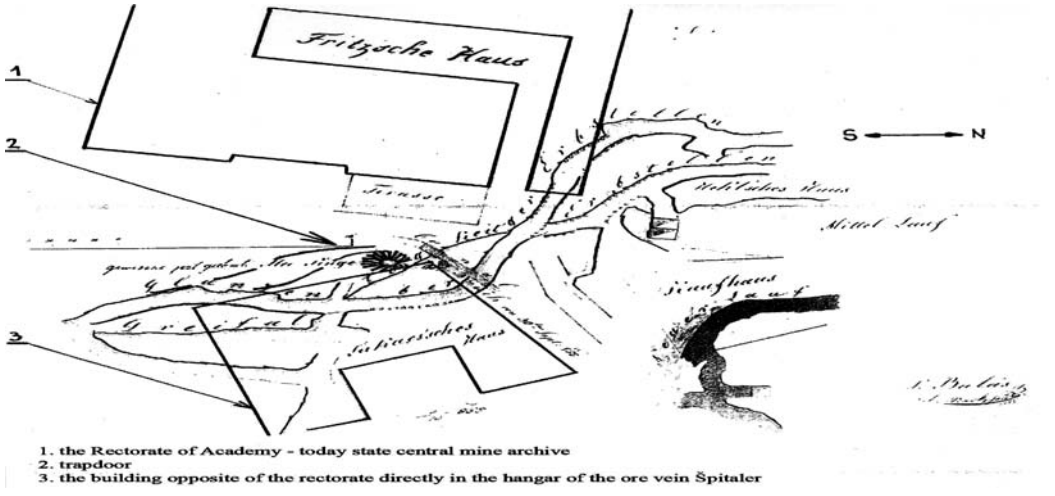

Figure 1. Historical map detail of collapsed mining area in part of old mining town Banská Štiavnica.

and making available of geological works results. In large measurement they are the activities of institute intent on protection and sustainable usage of rock environment and ground waters.

From abandoned underground spaces reemploying point of view is very necessary by evaluation concerning spaces to solve many of geotechnical and old mining technological issues. For the effectual solving of problems is to be go from searching and collecting of records indication at mining area, which are related to the watched mining district out. The same way is needed to have to disposal the database of geographic information from the old underground, in order to be completed the field data from the exploration of terminate mining.

By analyse of all condition of rock massive stability into old exploitation area including opened and abandoned underground spaces it must to be proceed with the respectable **methodology for obtaining of relevant information and** data primarily acquired from various sources. The periods of historical mining and dressing of ores, geological exploration, modern mining and dressing of ores and the period of mine workings closure and reclamation of areas affected by mining lasting up to now will be differentiated between one another.

In many parts of Slovakia underground cavities – corridors, tunnels and mining blocks, created by mining exist under surface areas that are now populated. This has come about because mine maps were not always available, for instance due to uncontrolled mining activities, the loss of mining documents – especially as a result of the not quite well assembling and the fact that some old mines were simply not mapped. Provided the underground mining structure is sufficiently stable, i.e. it is located deep enough with adequate pillar dimensions and provided there is no freshwater inflow into any regions located in different geological formation, then such old mine workings do not pose any danger to the earth's surface. If, however, the overlying rock is too weak or the pillar size is too small, any villages, roads or other structure located above the underground cavities are acutely endangered. This is particularly true for old mine workings or shafts in rock, in which there is an inflow of freshwater and the same time an outflow of brine. To protect urban areas threatened with collapse, large-scale redevelopment work using boreholes for mine filling is necessary to stabilize the underground. However, in order to efficiently position the needed filler boreholes, it is necessary to know accurate details of the underground mining structure. That is not usually possible to access these old structure, the information required can be gained only from exploration boreholes. Implicitly are being also any different techniques how to find the underground open space to identify its. By one of such method is a sonar tool usage to measure the all surrounding underground cavities. One different possible to search the opened spaces in underground after the mines activities is e.g. tomographic geophysical measurement. Namely, scores of the time just then, if its go to be about cases on former mining district nearby small cities damages of surface, that are caused by breakdown of subterranean cavities of mine, which e.g. had been exploited from the 19th century until fiftieth years. In these cases it is needed verified the hazards for surface areas by tomographic method. This measurement technique benefit

the statement building, roads and other public facilities being not endangered by effects of former mining activities.

By all above presented methods it is needful to understand very well the both geotechnical and also hydrogeological conditions at evaluated settlement areas. These requirements are respond to next utilization of abandoned underground spaces in extenso. It depends, whether opening spaces have to be construct for underground waste management or must to be flooded. In second mentioned case will to be needed in closed mines to propose such safety measures, which will help to lose problems with the drainage of minewater in abandoned tunnels (Fig. 1).

3 ENVIRONMENTAL INFLUENCES OF MINES FLOODING

The example of flooding mine in Rudňany at east Slovakia shows to important aspects of environmental part of technical issue solution. Within the scope of the technical part the solution of research works was concentrated first of all on creating the model for judging the overall hydrogeological and geotechnical situation, as well as on modelling some technological underground systems of the Rudňany mine, mainly the system of ventilation and pumping the underground mine waters. A part of the solution at the same time was judging the technical measures of flooding the mine in the relation to the safety requirements of the surface situation and from the point of view of the environmental protection, but also in the relation to the economical evaluation of the realisation of some technical–technological activities underground as well as on the surface.

The closure mine Rudňany was provided by a gradual flooding of individual mining levels. This solution it give not possibilities for the eventually secondary utilisation of abandoned mine spaces. With regard to the existing and fading away mining in above mentioned mine, but also from the point of view of adopted and agreed intention to liquidate the mine by flooding, by the management of the plant in Rudňany was decided to flood the mine in three stages. Individual stages of flooding supposed the total excluding the mine activities on the levels discussed and the following conditions.

The solution of the closure mine by flooding way was aimed at judging and re-evaluating all the aspects, factors, and influences of flooding, first of all from the point of view of the supposed flow and movement of underground water, but also from the point of view of the existing tectonic-geological structures, within the relation to the past as well as existing mining activity. The result of the mining activity at the deposit is a vast extent of mine openings of the whole ore field, which consists of very branched system of mine openings, underground spatial objects and mining blocs on all the underground levels of the mine. The yardage at disposal of these spaces nowadays, mainly in case of mined out exploitation blocks, is difficult to identify, as in the past caving and cut-and-fill technologies of mining were employed. The actual volume potential of existing system of underground spaces of collecting underground water is only supposed and quantified with a certain estimate. The total volume of the free space includes all the open spaces in the eastern and western part of the mine.

The aim of the study was to judge the consequences of flooding active levels of the mine and re-evaluate the sequence of flooding on already stopped levels. The study at the same time draws attention to technical measures and details of flooding, which will affect the geo environment of the mine and ecological components of the life environment on the surface. From the point of view of environmental judging the consequences of flooding the mine were evaluated the decisive factors connected with the underground water level or its flow in the whole space of the mine, as well as with the quality of these waters. When judging the fluctuation of the underground water level it was come out from the idea that the underground of the mine represents a connected system of tanks in which exists the all-directional water circulation. The predicted movements of the underground water were judged in the relation to the precipitation and the subsequent inflow of waters to the underground of the mine. At the same time the static level of flooding of mine on the Rochus tunnel level was determined and the possibility of mixing underground waters with flowing-in surface waters on the basis of the hydrological balance was re-evaluated. The substantial change in the chemist of flowing-out mine and underground waters and its influence on the environmental surrounding was not confirmed even in case of liquidation of oil substances as the residuals after mining technological processes. The influence of the water chemise acting on the hydro technical objects underground was not evaluated as these objects are not supposed to be built.

As grounded was shown the real possibility of weakening tectonically fractured zones by the effect of water flow and forming the area of undermining, caving belts and deformations of the surface mainly around shafts – Mier and 5 RP II. The supposed surface deformations of the terrain were confined by isolines of cavings in the exposed areas of the discussed mining space. The study re-evaluates the influence of the caving areas on important social and ecological objects in the built-on sections of the surface from the point of view of possible permanent movements. The assumption for correct technical solution of flooding the mine was the re-evaluation of the ventilation system on the basis of newly formed situation and the design

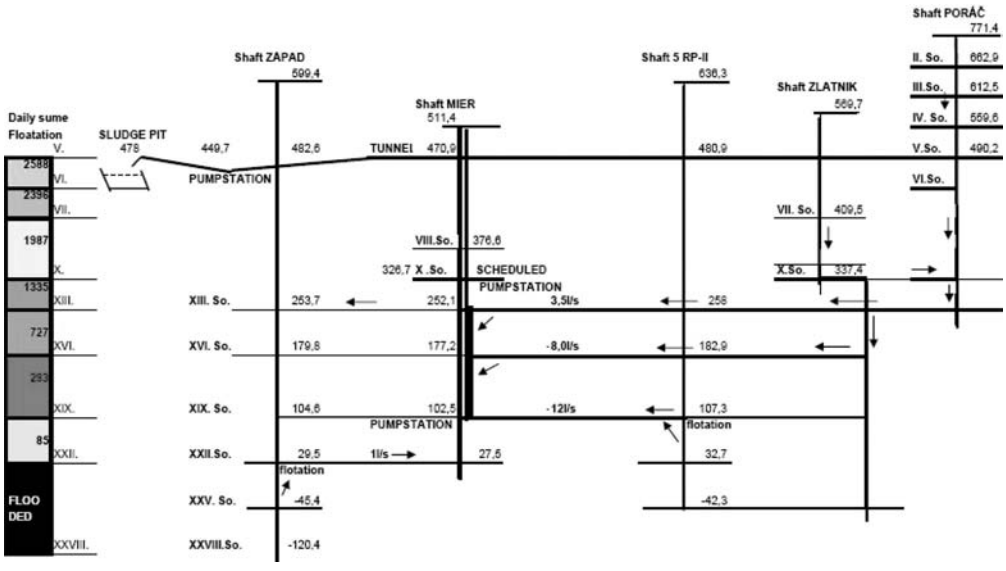

Figure 2. Preparation and building of shaft schema and drainage system mine Rudňany.

of ventilation objects for safeguarding the required regime of ventilation of abandoned and active working places above the 19th level. The study has shown the need of working out the updated ventilation balance as at the flooding a substantial change of the ventilation system is formed. For the system of pumping mine waters in the study there is proposed a pumping station on the 10th level of the Mier shaft. The proposed technical measures are economically judged on the basis of investment demand of the realisation of technical measures and required kinds of works on the basis of the supposed budget. The ecological and mine damage are in the study solved independently. The study analyses negative influences of the process of flooding the Rudňany mine and define possible consequences of these influences, mainly in the relation of the surface subsidence. At the same time proposes concrete technical measures and recommendations to prevent undesirable influences of flooding from the point of view of endangerment of the life environment in all its components (Fig. 2).

4 UNDERMINING OF HISTORICAL CENTERS IN OLD MINING TOWNS

Undermining influences has showed in full extenso to in conditions of gold – silver ore deposits district Banská Štiavnica – Hodruša. Most developed vein structure on deposit was Špitaler vein ore body, which was appeared to surface over the center of town Banská Štiavnica. Mining in 11th–15th century have not left any negative impacts on surface, with except heard quarks which have destroyed all buildings objects of Glanzenberg. In small depth under surface was mining activities directly under building plan of towns and villages in above mentioned ore districts. From surface negative impact are nowadays critical just those mining areas – without disposal mining maps (Fig. 2).

At last 10 years after finishing of extraction in old mining towns, which were mentioned, was 6 serious subsidence process of surface into mining spaces. In most cases handled it about local point depressions over some vertical mining objects as raise and shaft, which where insufficiently supplied by closing mining process. In one individual case in 1995 was large extend in crush about old mine spaces near by Maria shaft on vein Grüner and surface depression was in extend 10×30 meters. This cave-in was just 80 meters from building plan of residential house. Last 30 years was just one case of cave-in on surface of results in mining in 90th years. It was in year 1998 during drift of raise KT-221 on second deposit level of Teresia vein. In mentioned case was surface depression in extending 40×5 meters to depth 15 meters. After destruction of old mining areas in to this raise were outflow of fill materials into this raise (Fig. 3).

Cave-in was decline more and more in this reason was destroyed tourist way, which was just 1 meter from previous cave-in. Reason of building water-supply in town Banská Štiavnica, what is 17 years after cave-in the raise must be solved the effects of this event. In the last time period we can mention cave-in the town street in year 1973 in another place 10 meters far from tunnel

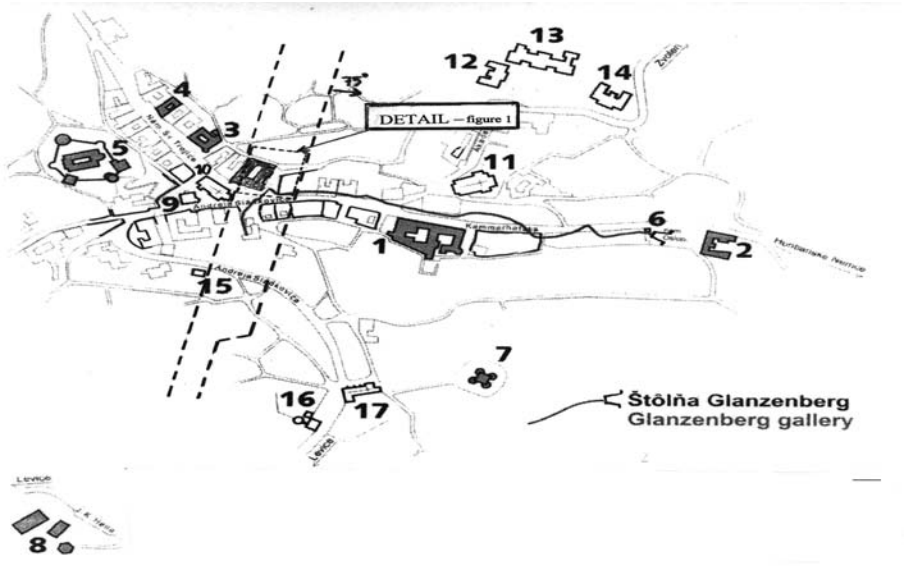

Figure 3. The process of ore vein Špitaler and the mining in depth till 30 m from the surface cross the city center of Báňská Štiavnica. Glazenberg country's gallery copies the main street (Kammerhofská) in length 450 m and in depth 3 m near portal till the depth 34 m in the crossing with sequence corridors.

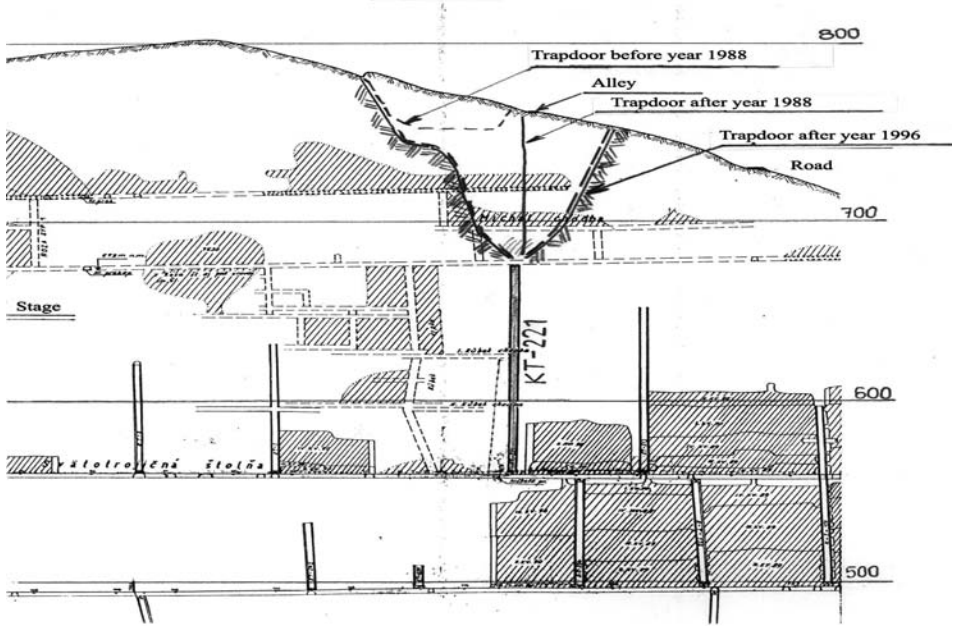

Figure 4. Situation of trapdoor shaft KT-221.

collar Glanzenberg, which was 9 meters under ground. This was solved by inbuilt TH segments of reinforces and concrete rafter of 5 meters long line and filling the surface slot with gravel. From this period since to year 1991 was tunnel not monitored. The tunnel Glanzenberg was first time reconstructed in year 1992. Since this is under consideration general rebuilding of tunnel Glanzenberg. To general repair of tunnel come

in year 2001, when it was reinforced with stone furring. In year 2001 was tunnel opened for visitors in framework with Slovak Mining Museum. Similar in year 2006 was rebuild the shaft Kaufhaus. Here bay where secured the two most critical object directly in the center of the town Banská Štiavnica (Fig. 4)

5 CONCLUSION

In the paper described issues impacts of subsidies in historical centers of old mining towns at Slovakia, will be needed to solve in particularly details. Results from facts in article is visible that after finishing the mining activities will take for some decade as far as the effect of the mining on surface will be eliminated. Favorable solve for all mining districts at Slovakia could be combination of looking for new utilization of old mining spaces and therewith possibility their monitoring respectively reconstructions. It shows that after care mining and closure mine could be one new study field. Till now has no connection with praxis and also haven't sufficient technical support. Therefore we must assume that many in last time realized technical projects could be after some time as inapt.

Results of the excavation works in upgrading the Frejus railway tunnel

P. Grasso, M. Pescara, F. Valdemarin & G. Beccaria
Geodata S.p.A., Turin, Italy

ABSTRACT: In reference to the paper presented to the ITA WTC 2005, concerning the design of the upgrading of the Frejus railway tunnel, this paper reports the excavation activities, the problems faced during the execution of works and the main results achieved to date. The upgrading works in the Frejus tunnel, followed on site by Geodata since 2003, according to the principle of flexible design and construction, are performed maintaining the international rail traffic on one single track, with thus significant constraints on the worksite logistics and safety. Keeping under monitoring the stress-deformation response of the tunnel's structures, the benching under the first track and the excavation of the new niches on the same side of the tunnel have been recently concluded. For effective management of the various construction phases an innovative Web-GIS application has been set-up to centralize all the geological, construction and monitoring data in order to facilitate their interpretation in real-time so as to drive the design optimizations.

1 INTRODUCTION

The Frejus Tunnel, bored between 1857 and 1871, connects Bardonecchia (I) to Modane (F), over the length of 13636 m (6791 m on the Italian side).

The tunnel is double track, with a maximum overburden of 1600 m, and an inclination varying from 1‰ to 30‰; the maximum height a.s.l. is 1296 m at the Border Line. The lining is in masonry, mainly made of stone blocks at the sidewalls and bricks at the crown; the lining thickness varies from 80 cm at the sidewalls to 45 cm at the crown.

The upgrading activities are part of the overall works to empower the historical Turin-Modane line managed by the railway administrations of Italy (RFI) and France (RFF), to allow the transportation of particular trains and to improve the safety endowments of the whole system.

In particular, the ongoing works include:

- adjustment to B1 gauge (Italians side);
- implementation of a more advanced system for managing the train circulation;
- upgrading of the safety system according to the new RFI guidelines for existing tunnels.

With respect to the new shape, it will be obtained by lowering the current rail plane by 60–70 cm and re-adjusting the two tracks in plan. As regards the system's adjustment, the new necessary apparatuses will be placed inside new or adapted niches.

Figure 1. The Italian historical portal of the Frejus Tunnel during benching of the even track.

2 OVERVIEW OF THE DESIGN PHASES

A detailed overview of the design can be found in Grasso et al. (ITA WTC 2005) and hence only some essential information is given below.

2.1 *The geology*

The Frejus tunnel is excavated in the formation of the calceschists of the "Serie Piemontese" (Schistes lustrés), which have been assembled in wide plicative structures.

Table 1. Representative geomechanical parameters of a section and used for the numerical analysis.

E_d	$\sigma_c \approx \sigma_{cm}$				
[GPa]	[MPa]	$m_b(=m_i)$	$s(=s_i)$	m_r	s_r
10	30	10	1	1.017	$8.1 \cdot 10^{-4}$

E_d = deformability modulus;
$\sigma_c \approx \sigma_{cm}$ = compressive strength of the rock mass;
m_b,s, m_r,s_r = constants of the Hoek-Brown failure criterion.

From the geologic-geomechanical point of view the calcschists show a remarkable variability (from almost massive to foliated) essentially due to tectonization, with a tendency of creeping behaviour.

The geomechanical characterization was developed on the basis of various in situ and laboratory tests and confirmed by back-analysis.

Table 1 shows the values of the main parameters derived and used for the numerical analysis.

For the in situ stress, a deficit of the vertical stress was verified, and the values of the k_0 (horiz./vert. stress ratio) quite variable, generally comprised between 0.7 and 1.3.

2.2 *Constraints of the site*

The need to maintain a well defined "respect zone" to guarantee safe exploitation of the tunnel on one track conditioned all the design and later on the construction activities, with sever limitations to the space available for the machinery. For most of the time the activities are undergoing in such conditions because only for few hours each day divided in 2 "windows" a complete interruption is foreseen.

2.3 *The actual tunnel conditions*

The tunnel lining in itself can be considered as still in quite a good condition. Anyway, the presence of a cracks located in the crown and a generally high level of stress in the blocks must be pointed out with an asymmetric distribution inside the arch. Moreover, the inspections of the lining's foundations revealed poor bearing conditions.

The back-analysis calculations, done with the code FLAC, reproduced the actual conditions of stress and strain inside the structure, which can be summarized as characterized by:

- asymmetry of loads;
- high stress values;
- tendency of the structure to converge at the sidewalls with consequent high compression stresses at the intrados of the crown, justifying the existing crack at the crown.

2.4 *The design solutions*

Starting from the results of the above mentioned studies, further numerical analyses were performed to evaluate the effects of the excavation on the existing tunnel structure. Such calculations allowed to define the targets to be reached through consolidation works which should permit the excavation to be done in safe conditions. The specific objectives are:

a. to contrast the lining convergence trend aggravating the compression at the crown, and thus limiting further weakening of the structure;
b. to prevent settlement of the structure due to potential sliding of loose materials underneath the foundation during bench excavation;
c. to completely support the arch in the zones where it will be partially demolished to create the new niches or in particular, delicate sections;
d. to support punctually the masonry arch in correspondence of the portal of any niche.

Hence, the design solution foresaw:

- filling of void at the extrados to re-establish the contact with the surrounding rock mass;
- installing rock bolts at the side walls to contrast the convergence;
- consolidating the foundations where needed to prevent potential settlements.
- to reinforce the whole arch with rock bolts when the niches should be excavated.

3 THE RESULTS OF THE FIRST HALF OF THE WORK

3.1 *The consolidation works*

The consolidation works, prior to every excavation, strictly followed the design, consuming in the period of 2003–2005 the following quantities of materials:

- 60.000 meters of CT-Bolt anchors,
- 9.600 meters of self-drilling bolts;
- 8.950 meters of Swellex Mn24;
- 3.250 tons of dry product injected corresponding to 4000 m^3 of grout mixture.

In accordance with the design philosophy based on a flexible approach, the choice was to achieve a generalized strengthening of the overall arch by making it collaborating with the surrounding rock mass. In the mean while, in collaboration with the Engineer and the Client, a systematic check of some particular conditions were made during the site operation in order to identify any special weak points.

One of these weaknesses was an almost continuous longitudinal crack located exactly at the top of the crown, which proved to be extending for more than 3 km on the Italian side. In October 2004 an unforeseen fall of a block of masonry occurred at Ch. 88 + 030,

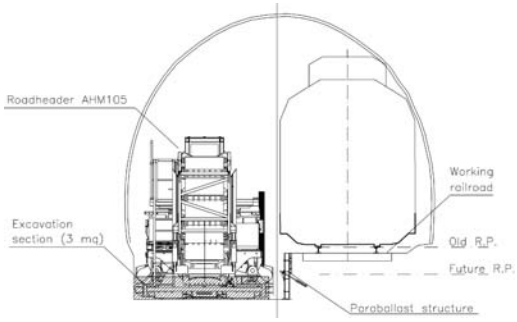

Figure 2. Geometry of the excavation phase.

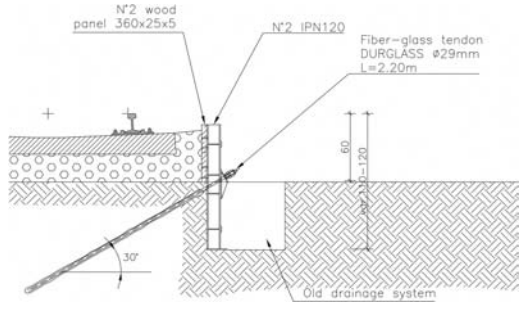

Figure 3. The "paraballast" in good rock, constituted by a continuous structure in wood anchored punctually to the rock by fiber-glass tendons connected to vertical steel beams.

just in correspondence of the crack, and such event, which caused the temporary closure of the railway line, led to the decision to integrate the interventions along an extension of the crack for about 2650 m. It is also probable that no major problem occurred because the basic consolidation work was already done, and thus the section was already partially strengthened.

The integrative works, which forced to postpone the benching activity, consisted of:

- one structural shell, 3 m wide, 8 cm thick, made of shotcrete reinforced with steel mesh (ϕ8 mm 10×10 cm), fixed to the masonry with ϕ18 mm L = 60 cm steel nails (pattern of $0.4\,\text{m} \times 0.5\,\text{m}$);
- complete grouting of the voids located in the crown and at sidewalls extrados with an expansive, light-weight, grouting mixture;
- bolting with CT-Bolt (M22 L = 3 m) in a pattern of $1.3\,\text{m} \times 1.5\,\text{m}$, pre-tensioned to 10 kN, to anchor the new structural shell also to the rock mass.

3.2 *The benching excavation*

Ending the consolidation works, the benching excavation started on the 6th of December 2005 using a Voest-Alpine AHM105 road-header advancing from the Border towards the Italian portal.

This benching operation involves:

- removing all the existing rails and ballasts;
- installing a so-called "paraballast" in between the two rails in order to guarantee the safety of the line in operation (see Figure 3).

Due to scheduling constraints, the benching operation had to be done as fast as possible, through a refinement of the normal driving procedure for the road-header. Thus, the following excavation steps were followed, which could be adopted also because the excavation face in reality was only 0.7 m high and 3.5 m wide (see Figure 2 & 4):

- "forward step": it consists of sinking the head in the front for a depth of $10 \div 20$ cm, with the arm of cutter laterally extended for the maximum width of the foreseen cross-section to be dug;

Figure 4. Road-header in action.

- "cutting step": it is the phase of the real digging, conducted by lateral movement of the cutterhead.

Moreover, in order to create the space for positioning a new central drainage pipe running below the rail level the transversal excavation profile was created with a 2% slope towards the axis of the tunnel.

The particular excavation face geometry and the original way to operate the machine, combined with the need to respect the gauge, forced to integrate the on-board instrumentation with a special monitoring of the road-header's position to reach a better precision of digging and minimize the over-excavations, with the following elements:

- laser system for the continuous excavation level control;
- systematic manual check of the height of excavation using the fixed pins anchored to the lining.

The bench excavation works on the even rail were completed on the 20th of August 2006.

From the point of view of production, the results of the excavation were better in the straight part (more than 6 km), where the benching was constantly driven in compact rocks, than those in the two long curved

Table 2. Main excavation parameters for Frejus road-header.

Parameter	Value	Units
Total excavated volume	27810	bank m^3
Effective net cutting time	49,36	%
Average net advance per hour	10,92	m/h
Average net cutting rate	45,98	bank m^3/h
Av. Spec. pick consumption	0,08	pick/bank m^3

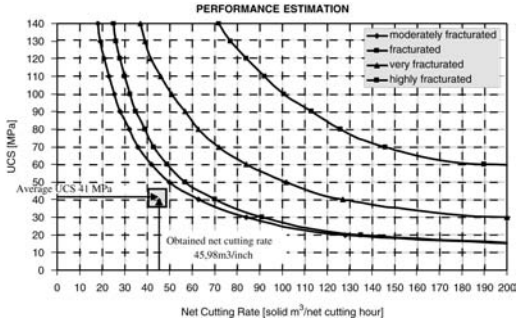

Figure 5. Indicative prediction diagram for NCT (low cutting speed).

sections where some excessive over-excavation were locally observed.

The reduced excavation section of about 3 m^2, permitted a high advance rate (maximum 190 m/day), despite the heavy limitations imposed by the track under exploitation. In fact, the critical activity of the benching was not the digging but the mucking, realized daily using railway wagons during the only 4 hours of total availability of the tunnel.

All the excavation parameters were recorded on a daily basis for analysis; the main parameters are summarised in the Table 2 above.

The comparison of these data with the available literature shows that:

- the net cutting rate (NCR) obtained compared with the results of the VAB studies (Peter Kogler, 2005), indicates that the performance is lower than what could be expected, considering the presence of a "fractured" or "moderately fractured" rock and an average value for the uniaxial compressive strength of 41 MPa.
- the specific peak consumption was slightly higher than the mean reference values given by a CAI value (characteristic abrasivity index) of the rock equal to 2,3 in present case.

The main reasons for this under-target performance (see Figure 5 & 6) were due to the reduced size of the cutting front and partly to the already-mentioned constraints.

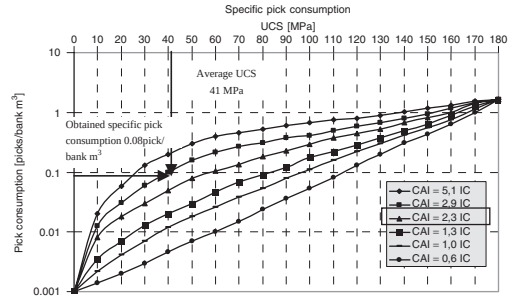

Figure 6. Indicative prediction diagram for specific pick consumption.

For the benching of the odd track, there will be no possibility to further optimise road-header digging, and great effort should be put on reducing the mucking time by, for example, starting excavation from the portal in order to have direct, continuous access to the machine with heavy trucks.

3.3 *The excavation of new niches*

The excavation of the new niches started in November 2004 and ended for the even track side at the end of June 2006.

The particular working conditions required:

- to use equipments not interfering with the track under exploitation;
- to minimize the disturbance to the portion of lining not interested by the digging.

These conditions and the constraints of the time schedule, demanded for a careful and even difficult research of the best excavation method, considering the prohibition to use a D&B technique.

The chosen alternative was a pre-cutting with multidisk saws coupled with a robotized demolisher.

Anyhow, it must be pointed out that this technique showed its limits (production around 2 m3/day), tied up also by the quite high strength in the direction of excavation, which was systematically perpendicular to the schistosity, and by the reduced space available for the manoeuvre.

New excavation techniques have already been tested to increase the productivity and accelerate the excavation of the remaining 51 new niches.

Of particular interest was the first test in Europe of the new CFI (Controlled Foam Injection) technique, which consists of injecting foam at high pressure in a drilled hole in the front, to cause a controlled fracturing of the rock, with a target of 1,5m^3/h of demolished rock. The tests however revealed the low efficiency of the CFI in a fractured-layered rock because of the escape of the foam.

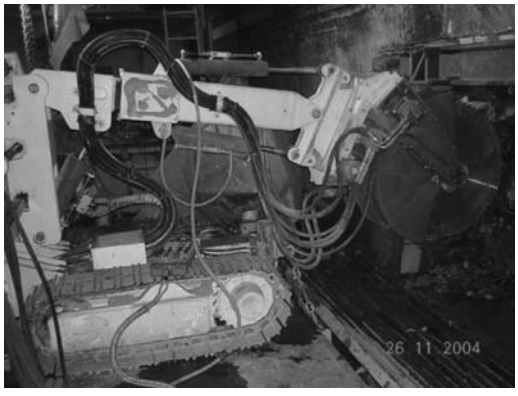

Figure 7. Multi-disk saw at work.

4 MONITORING DURING CONSTRUCTION

The interventions needed for the consolidation of the tunnel structure, for the niches' excavation and for the benching of the tunnel itself justify monitoring starting from the very first stage of the works, in order to guarantee the structural integrity during all the processes or to assure the timely application of pre-defined countermeasures in case of risks.

4.1 *The monitoring plan*

With reference to the targets of the design interventions (see Sec. 2.4), the monitoring scheme during the excavation activities was designed to:

a. quantify the tendency of lining convergence;
b. verify the settlements of the structurs foundations;
c&d. verify the effects induced onto the tunnel lining by the excavation of the new niches;
a&b. verify the effect of the vibrations of the road-header digging on the tunnel structures.

The monitoring system, based on a hierarchical system and divided in three levels, includes:

- the instruments and the topographic targets;
- the data acquisition units;
- the data centralization, management and distribution system (GIS application).

4.2 *The monitoring sections*

In order to achieve the above mentioned targets, two monitoring schemes were used: stress-deformation monitoring and vibration monitoring.

Regarding the stress-deformation monitoring three section-types were applied:

- *Current Section* (SC) spaced every 50 m with only optical reflectors;
- *Special Section* (SP), located along problematic zones (n.10 in total), consisting of five optical reflectors, plus four tangential pressure cells;
- *Niche Section* (SN) in correspondence of the new bigger niches, constituted by a wire extensometer installed to measure the lining settlement immediately above the niche excavation profile.

In the presence of cracks of the masonry in the crown, an electrical rod extensometer was added. In total, a huge number of instruments have been employed: more than 300 optical targets, 45 pressure cells, 5 wire extensomeres, 3 rod crackmeters, 2 laser distometers and 1 load cell on anchors.

Regarding vibrations, coupled with the already mentioned sections, a vibrometrical monitoring was applied during bench excavation: up to four moving sections (SV) that followed constantly the road-header which could potentially produce dangerous vibrations to the lining structure.

4.3 *The acquisition of monitoring data*

All the convergence data (SC & SP sections) and the stress data in masonry (SP sections) were manually acquired in accordance with the advance of the road-header.

Moreover, in order to avoid any problem, especially regarding the most critical points where high deformations and settlement could occur, a real-time monitoring was put in place; such continuous monitoring was applied in two situations:

- in correspondence of the new niches;
- for SV sections where the instruments were equipped with a GSM system to transfer data remotely.

4.4 *The GIS application*

Independently from the typology of the sensor, all the monitoring data (recorded in continuous with data-logger or taken by traditional methods), converged towards an unique management & distribution system, based upon a GIS-Web platform (see Figure 8).

The system allowed real-time monitoring data management and the automatic activation of alarm procedures if over-passing of predefined thresholds occurs. The link in the GIS system of the monitoring measurements with the design data and tunnel survey data, allowed to identify and to understand the instrumentally recorded phenomena and to bring them back to their correct physical meaning.

Thanks to the GIS-Web platform all the monitoring measurements are distributed in real time (with a protected Internet login) to the Contractor, the Client, the Resident Engineer and the Designer, facilitating rapid decision and activation of the counter-measures.

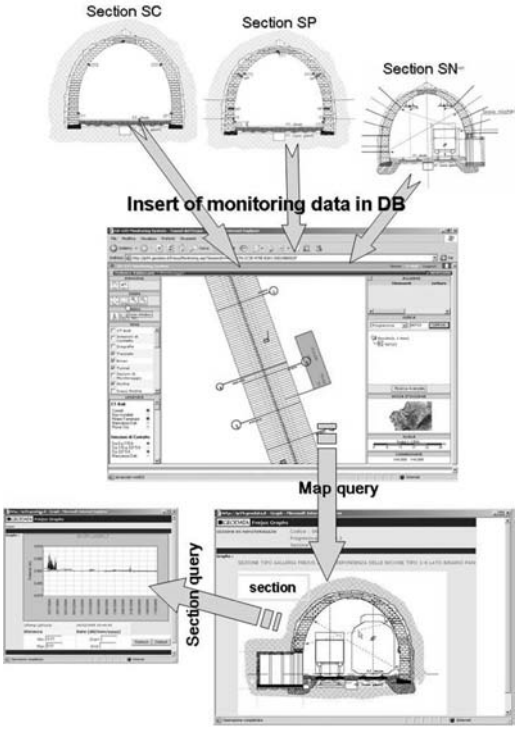

Figure 8. The monitoring with the GIS-Web application.

4.5 *The results*

The results of the stress-deformation monitoring implied very little movements of the tunnel structures during excavation phases. The measured convergences have been compared with the attention and alarm thresholds pre-defined at the design phase.

The maximum topographic recorded convergence was 5,3 mm while the maximum recorded settlement was 7,3 mm, without the evidence of any new damages or cracks.

All the installed wire extensometers on the portal of the niches did not register significant deformations.

Regarding the vibration monitoring, the results in terms of instantaneous speed PVS (Peak Vector Sum) have been compared with attention and alarm limits prudently defined at 8.0 and 12 mm/s. Maximum PVS value recorded during excavation was 15.0 mm at one single section. Also in this case no major effects were found on the structures.

5 CONCLUSIONS

Following the presentation of this challenging project in terms of design (Grasso et al., 2005), the present paper illustrated the first results of the works on site, which are at the half of the schedule.

The main points to be underlined are:

- the need to approach this kind of structure step by step, in order to better investigate, understand it and find the best solutions to assure and/or increase the general stability;
- the importance of the constraints of working inside a tunnel under exploitation;
- the great benefits of a real-time monitoring system, which helps to reduce the presence of personnel inside the tunnel and permits an efficient understanding of the response of the tunnel structure to the bench and niche excavations;
- the importance of the continuous presence on site during the works of a design & construction team able to face and to solve specific and critical problems that could arise.

ACKNOWLEDGMENTS

Monitoring and evaluation after repair and reinforcement of damaged 3-lane Freeway Tunnel located within fault influenced zone

Jia-Song Hou
China Engineering Consultants, Inc. (CECI), Taiwan

Dar-Jen Tseng & Yeou-Herng Lee
Taiwan Area National Expressway Engineering Bureau (TANEEB), Taiwan

ABSTRACT: The Chungliao Tunnel is a twin-tube, 3-lane freeway tunnel located in southern Taiwan having a length of about 1800 m. The tunnel was completed and opened for traffic in February 2000, but after four years of operation, it was evident from the cracks of inner lining walls, the settlement of pavement and the increased flow of drained water, that the tunnel structure conditions were worsening possibly due to the severe earthquake that struck Taiwan in September 1999. Henceforth, it became a priority to (1) rehabilitate the pavement to meet the requirements for driving smoothness, (2) replace the main drain under the pavement and (3) reinforce the tunnel foundation. Furthermore, a detailed monitoring plan would have to be executed to verify the effectiveness of the repair efforts. The scope of the monitoring work covered the measurement of groundwater, ground settlement, etc., while inside the tunnel, monitoring focused on tunnel deformation, profile clearance and crack on pavement and side walls. This paper reviews the data measured from monitoring and further evaluates the cause-effect relationship between the fault and Chungliao tunnel. The results of one year of continuous monitoring and the final report of assessment of measured data are also discussed to determine the next step and whether or not future rehabilitation measures are required.

1 INTRODUCTION

The north portal section of the twin-tube, 3-lane Chungliao Freeway Tunnel features different mudstone and sandstone materials and a heavily sheared fault area. The tunnel is more than 1800 meters long and its dimensions include an excavation width of around 16 meters and excavation height of around 12.5 meters. Because of the wind and rain, the mudstone material is easy-to-erode and the topography of the area is a local representative landmark of the natural landscape of southern Taiwan.

On September 21st, 1999, around two months before tunnel construction was finished, a severe earthquake struck Taiwan. The quake, with its epicenter located in central Taiwan, brought about some damage to the Chungliao Tunnel, but it did not affect the tunnel's forthcoming opening to traffic in February 2000. However, after four years of operation, cracks of inner concrete lining walls, settlement of pavement and

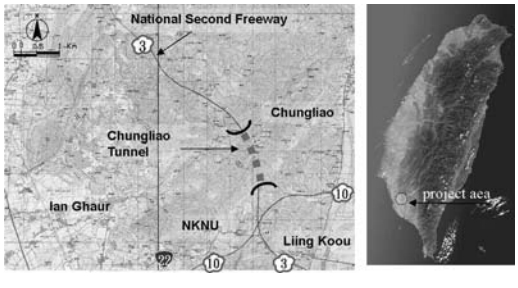

Figure 1. Location of tunnel Chungliao, Taiwan.

Photo 1. Landscape of mudstone topography.

increased flow of drained water became worse and seriously impeded the traffic functions of the freeway. In response, a rehabilitation plan was proposed by the Client, Taiwan Area National Expressway Engineering Bureau (TANEEB). Details of the repair works and the monitoring and evaluation report will be described in the following sections.

2 GEOLOGICAL CONDITIONS OF NORTH PORTAL OF CHUNGLIAO TUNNEL

2.1 *Strata and tectonics*

Based on the drilling results and field mapping, excavation at the beginning of the tunnel from North to South mainly goes through mudstone and sandstone. All rocks are seriously fractured resulting from tectonic events and highly weathered down to varying depths beneath the surface. The fault, which is a thrust fault located at the north portal, represents the tectonic border between mudstone (Pliocene) lying underneath and sandstone (Miocene) above. This fault is marked by fracture zones and mylonites dipping steeply to the south. Also, conjugated and associated fracture zones and gouge were found reaching far into the tunneling area as well as in the northern direction into the mudstone area.

2.2 *Hydrological and hydrogeological conditions*

The precipitation records show one peak of main rainfall. The main period lasts from the beginning of June to the end of August. The maximum value is frequently around 1083 mm in July and the dry season lasts for 9 months with the average precipitation of 20 mm per month.

3 LAYOUT OF TUNNEL STRUCTURE AND DAMAGE RECORDS

3.1 *Layout of tunnel structure*

According to the characteristics of topography and geological conditions, different design concepts were applied to the structure and the north portal sections were divided into 4 different structure sections, including cut & cover (without overburden section), prelining support (excavation along asymmetric slope),

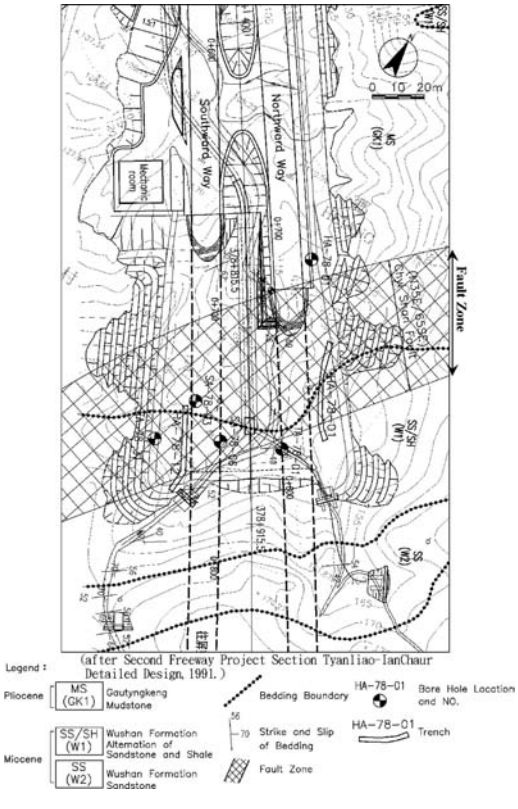

Figure 2. Geological map for north portal of Chungliao Tunnel.

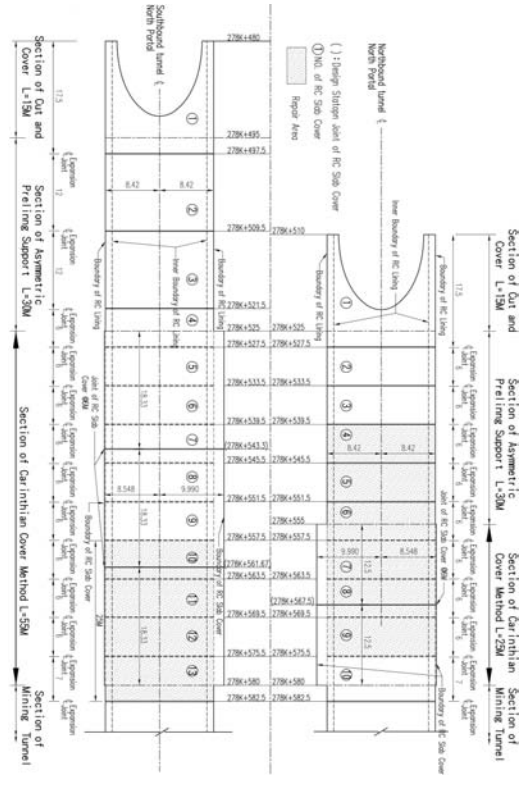

Figure 3. Plain view of structure layout at north portal section.

mining with concrete slab cover (reducing precut earth work), and normal mining tunnel sections (with enough and sound overburden).

In addition, when considering the possible ground movement due to strong earthquake, the concept of flexible concrete linings was applied by installing joints every 6 meters in order to restrain possible damage to a limited damaged area and be able to repair those sections easily in the future.

3.2 *Damage records of tunnel structure*

After four years of operation and the severe earthquake that occurred in 1999, the cracks of inner lining walls, the settlement of pavement and the increased flow of drained water were discovered and seriously impeding the traffic functions of the freeway. Hence, after surface mapping inside the tunnel, the major damage phenomena, including settlement and cavity on road pavement, cracks along inner lining walls and sidewalks, and their locations at both the northbound and southbound tunnels near the north portal were sketched as shown in Figure 5.

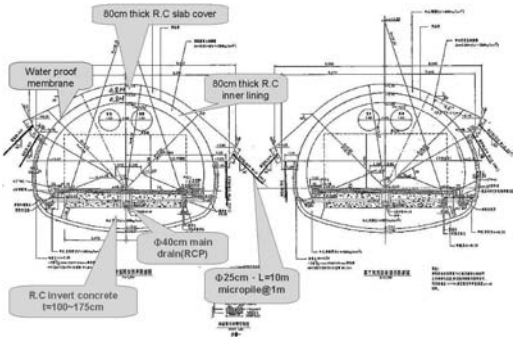

Figure 4. Typical Cross sections of concrete slab cover tunnel (so called Carinthian Cover method).

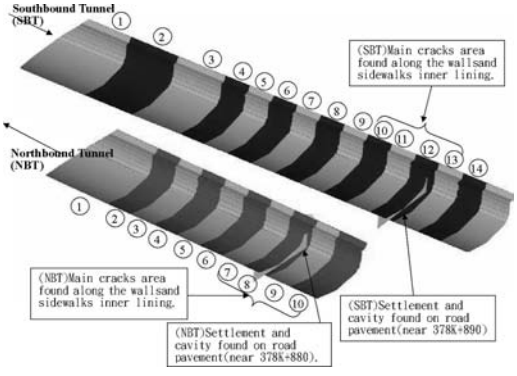

Figure 5. Sketch map of types of damage and location.

4 EXECUTION OF REHABILITATION WORKS AND MONITORING PLAN

Since the Chungliao Tunnel is an important access of the southern freeway system plus a scenic area for tourists, all repair works had to be finished based on a strict time schedule in order to reduce the traffic impact and inconvenience to drivers.

4.1 *Execution of rehabilitation works*

Due to the obvious settlement of pavement and increased flow of drained water, it became a priority to rehabilitate the pavement so that it would meet the driving smoothness requirements, and also minimize the impact during shutdown of the 3-lane freeway for replacing the main drain under the pavement and reinforcing the tunnel foundation. The repair works were executed for both the northbound and southbound tunnels in different stages. The major rehabilitation procedures are described as follows.

4.1.1 *The first stage-northbound tunnel*

(1) Investigation of cavity behind sidewalls and below invert by geophysical survey and core drilling.
(2) Open cut of pavement, removal of backfilled materials above concrete invert.
(3) Installation of 8 grouting pipes along the invert where expansion joint was damaged and grouting with cement.
(4) Replacement of main drainage system (RCP) with HDPE pipe.
(5) Backfilled with 245 kgf/cm^2 concrete instead of aggregates and finished with pavement.

4.1.2 *The second stage-southbound tunnel*

(1) Same as steps (1) ~ (4) for Northbound.
(2) Backfilled with 140 kgf/cm^2 concrete instead of aggregates and finished with pavement.

4.2 *Execution of Monitoring Plan*

The Monitoring Plan has to not only consider whether the effectiveness of rehabilitation works are being achieved, but also, as noted by the Client, whether these damages were caused only by the water problem,

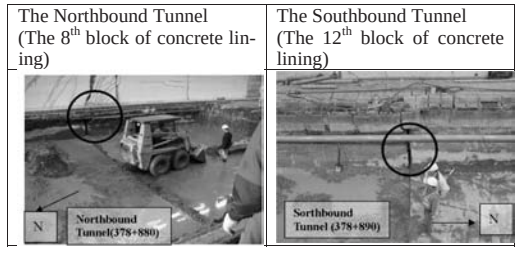

Photo 2. Opening at invert expansion joint for both tubes.

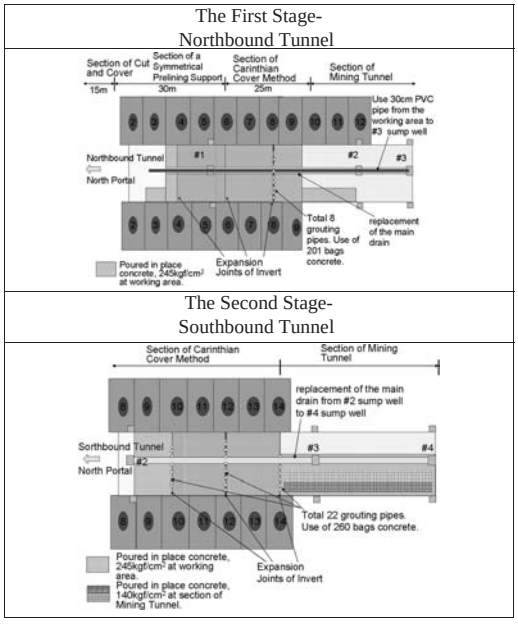

Figure 6. Sketch of major rehabilitation works for both tubes.

or also by the activity of the fault influence zone where Chungliao Tunnel is located.

Thus, a detailed monitoring plan was proposed to be executed to verify the effectiveness of the repair efforts. The monitoring scope covers the measurement of groundwater, ground settlement and surface subsidence, etc., while inside the tunnel, monitoring focused on tunnel deformation, profile clearance and crack on pavement and side walls of concrete lining (Table 1).

Besides this, an additional 7 subsidence measuring points were installed far ahead of the north portal of Chungliao Tunnel in order to check the stability of bench mark (Figure 7).

5 EVALUATION OF MONITORING DATA AND ASSESSMENT OF TUNNEL SAFETY

5.1 *Evaluation of monitoring data after rehabilitation works*

Based on one-year measurements, a summary of the acquired data is given as follows:

5.1.1 *Observation well for groundwater level*

It shows that groundwater level is discontinued because of obstruction by fault gouge.

Table 1. Summary of engineering consideration for monitoring layout.

Item	Objectives
Observation well for groundwater level	Measurement of water level for Up-thrust plane (well no. N-4, N-5, S-7), fault zone (well no. N-2), down-thrust plane (well no. S-1) in order to evaluate the possible change of water level and repairing effectiveness after replacement of main drain pipes.
Inclinometer for ground movement	Monitoring for 5 slope area of southbound tunnel (S-2, S-4), northbound tunnel (N-1, N-4) and upslope above tunnel portal (N-5) in order to evaluate the possible influence of groundwater to slope stability. Besides this, according to the slope moving direction and quantity, the stability of surrounding ground body of tunnel can be verified.
Subsurface settlement points observed well for ground movement	Measurement of the possible movement at different ground elevation (S-3 installed on southbound tunnel, N-3 on northbound tunnel) in order to monitor the influence of groundwater lowering down and the stability of surrounding ground body of tunnel also can be verified.
Subsidence measuring (Surface settlement) points	Focusing on the location of invert opening, 5 Subsidence measuring points (N-6, N-7, N-8, S-6, S-7) were installed to monitor the possible settlement above tunnel crown and surface condition. Also monitor the influence of groundwater lowering down and evaluating the stability of surrounding ground body of tunnel.
Crack measuring meter (Crack gauge)	Mainly installed on the side wall of concrete lining, especially where cracks were found and backfilled. The measured data can be evaluated and compared with other measurement for surface settlement, subsurface inclined and vertical movement.
Tunnel profile clearance and convergence measurement (Reflector prism survey)	The possible influenced blocks of concrete lining were installed with 5 sets of reflector prism. Profile clearance and convergence survey were executed periodically and also were compared with other monitoring data in order to evaluate the influence of groundwater lowering down and the stability of surrounding ground body of tunnel.

(1) Groundwater level, located at hanging wall of fault, almost maintains stable between the tunnel crown and invert.
(2) Groundwater level, located at foot wall of fault and within the fault zone, keeps dropping down and out of measurement because exceeding the depth of observation well (Figure 8).

5.1.2 *Inclinometer for ground movement*
No obvious records related to ground movement.

5.1.3 *Subsurface settlement points observed well for ground movement*
Records show there are differential movements at the depths of 10, 20, 30 meters below ground surface. The possible cause might be the re-organization of softened body around the invert which has slightly deformed with uneven settlement due to the grouting effect. No evidence related to the fault is shown (Figure 9).

5.1.4 *Subsidence measuring point*
Some dropdown settlement records were proved to be caused by construction activity on the surface but some other settlement needs more comparison and evaluation with other monitoring data (not consistent with other monitoring data).

5.1.5 *Crack measuring meter of tunnel walls*
Obvious cracks were recorded mainly on the sidewalk surface along concrete lining blocks No. 8 (Northbound) and Nos. 11 & 12 (Southbound). Only one

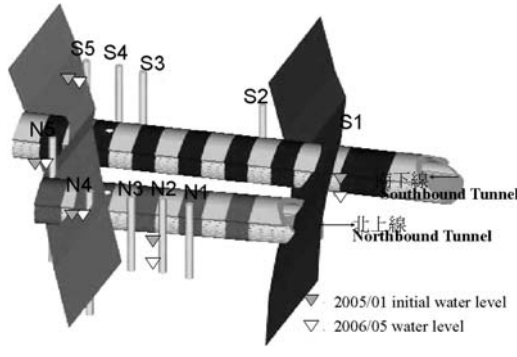

Figure 8. Groundwater level along the tunnel.

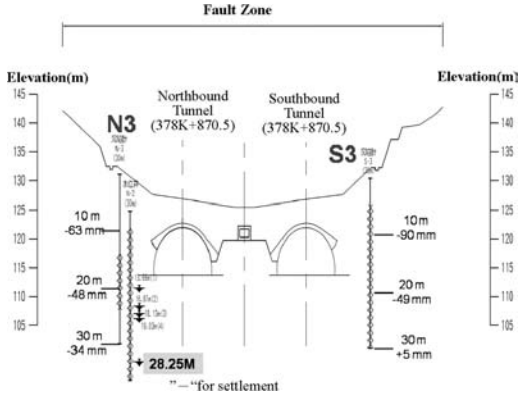

Figure 9. Sketch of measurements for subsurface settlement points observed well.

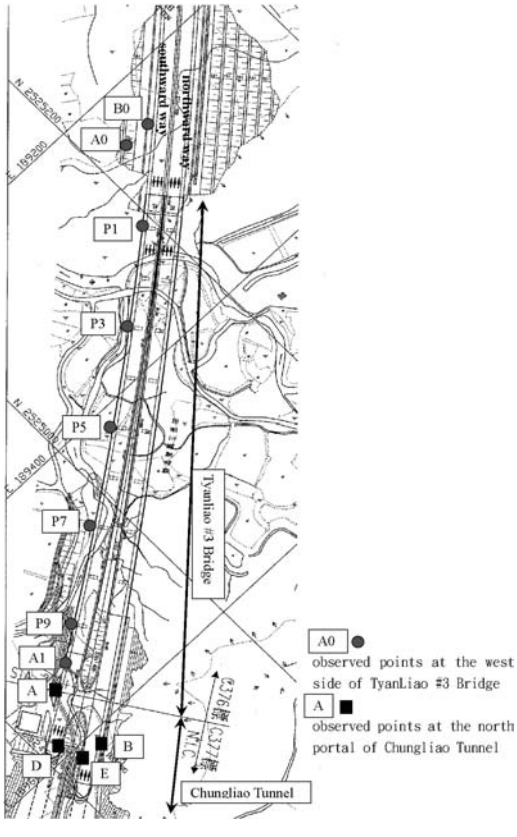

Figure 7. Layout of subsidence measuring points.

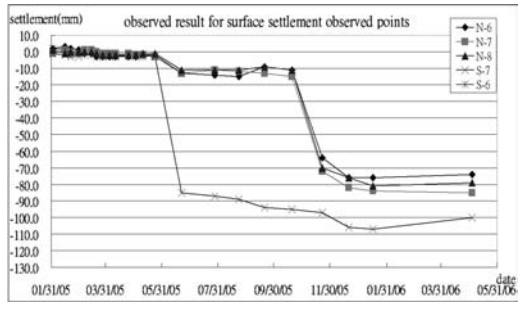

Figure 10. Deformed curve for surface settlement.

obvious crack found on the surface of side wall on concrete lining block No. 11 (Northbound) (Figure 10).

5.1.6 *Tunnel Profile Clearance & Convergence measurement*

The periodical measurement of Tunnel Profile Clearance and Convergence showed that the deformation problem of tunnel structure was not critical.

However, it was evaluated that the whole tunnel structure tilted slightly toward the southeastern direction after grouting below the tunnel invert. This was caused by the differential stiffness of grouted body while the rock mass might have stabilized when some of the muddy area became dry with no more differential settlement occurring.

5.2 *Assessment of tunnel safety*

After examining all measured data, the most problematic sections for both tubes of the tunnel are at the border of changing strata between sandstone and mudstone. It was realized that improvement of the tunnel foundation by grouting especially at sections 378K + 880(NBT) and 378K + 890(SBT) was essential owing to the cavities under the invert of the tunnel.

All the abnormal phenomena, including subsurface settlement, surface subsidence, and cracks measured on concrete lining and sidewalks, and deformation of tunnel profile clearance, had not been proved to be related to the activity of fault. In order to evaluate tunnel stability, a possible softened ground model was developed by senior geologists based on monitoring data and surface mapping. And it was concluded that broken main drain pipes provided leaking water to the bottom of the tunnel through cracks on expansion joint of the tunnel invert. The leaking water made ground beneath the tunnel invert a very soft muddy foundation.

Because grouting works only can be executed through two expansion joints of invert, the quality and effect of grouting work can not be fully assured. It also takes time for the soft ground beneath the tunnel invert to stabilize after cutting off leaking water. However, from the monitoring data, the tunnel structure at this stage is still in sound condition (Figure 11).

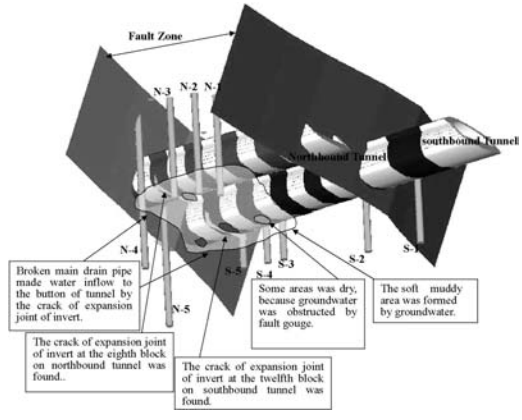

Figure 11. Possible softened ground under the invert for both tubes.

6 CONCLUSION

Using extension joints for every 6 meters in tunnel alignment has been proved to be very effective to reduce possible structure damage caused by strong earthquake. However, a broken main drain with fractured fault zone materials still caused severe deformation of the northern portal section of Chungliao Tunnel. In turns, after four-year operation, a thorough repair work was required and executed.

During the rehabilitation work, the replacement of the main drain pipes indeed cut off leaking water, while at the same time, it seems very difficult to grout the whole weak ground beneath the tunnel invert. But we did manage to partially fill the cavity and consolidate the ground. Later on, a one-year monitoring program has proven the tunnel structure to be stable, but uneven deformation still can not completely be avoided. Despite this unusual behavior and phenomena, the tunnels structure is still safe. It might, hopefully, takes several years for the soft ground beneath the tunnel invert to regain full stability. Hence, further continuous monitoring has been proposed. And, further ground improvement would be recommended if severe tunnel deformations are observed in the future.

Environmentally friendly subway construction in the overcrowded city of Tokyo

K. Irie
Tokyo Metro Co., Ltd.

S. Nishibayashi
Metro Development Co., Ltd.

ABSTRACT: In Tokyo, Japan's capital city, construction of Subway Line 13 is about to reach a peak of activity. This subway line is the last that will be built by the former Teito Rapid Transit Authority (now Tokyo Metro), a Japanese government-affiliated corporation that had built subway lines in the metropolitan area since 1941. Various aspects of this project involve sophisticated technologies. Some are perfections of those developed while the Tokyo Metro was still called Teito Rapid Transit Authority. Above all, this project is wrestling with issues that will inevitably continue to arise in subway construction. These include global warming and resource recycling as part of the general requirement to reduce environmental impacts. This paper describes our efforts to address these issues.

1 OBJECTIVE OF SUBWAY LINE 13

Subway Line 13 will connect three major Tokyo sub-centers, Ikebukuro, Shinjuku, and Shibuya. The plan includes a route connecting Ikebukuro and Shibuya that is separate from the existing Ikebukuro-Shibuya section of the JR Yamanote Line. The main objective is to eliminate congestion at major terminals and to alleviate commuting congestion to points away from Ikebukuro and Shibuya.

The Subway Line 13 route, which is as shown in Fig. 1, has a total construction length of 8.9 km. Connecting at Ikebukuro Station, Tokyo Metro, Tobu Railway, and Seibu Railway operate to the west of Ikebukuro. The Tokyu Toyoko Line provides service southward from the other terminal, Shibuya Station. Together with Subway Line 13, the railways mentioned above will provide through train operation by mutual entry to stations at the ends of the line. When Subway Line 13 opens, a railway axis will be completed over a wide area, from southwestern Saitama Prefecture, through the metropolitan centers, and on to Yokohama in Kanagawa Prefecture.

Much of this route is constructed directly under Loop 5, a road with the greatest traffic congestion in Tokyo. Conversion from automobile traffic to the use of the subway, which will be promoted, is expected to contribute to eliminating road congestion as well as reducing the environmental burden imposed by transportation.

Figure 1. Subway Line 13 route map.

2 ROUTE AND GEOLOGICAL FEATURES

Lined on both sides with high-rise residential and office buildings, Loop 5 runs through the commercial area of Shinjuku, Japan's largest bustling quarter. Therefore, during the work, various difficulties will be encountered, such as the need to avoid worsening the surrounding environment with noise and vibration, and the substantial restrictions imposed on the scope and time allowed for using the road.

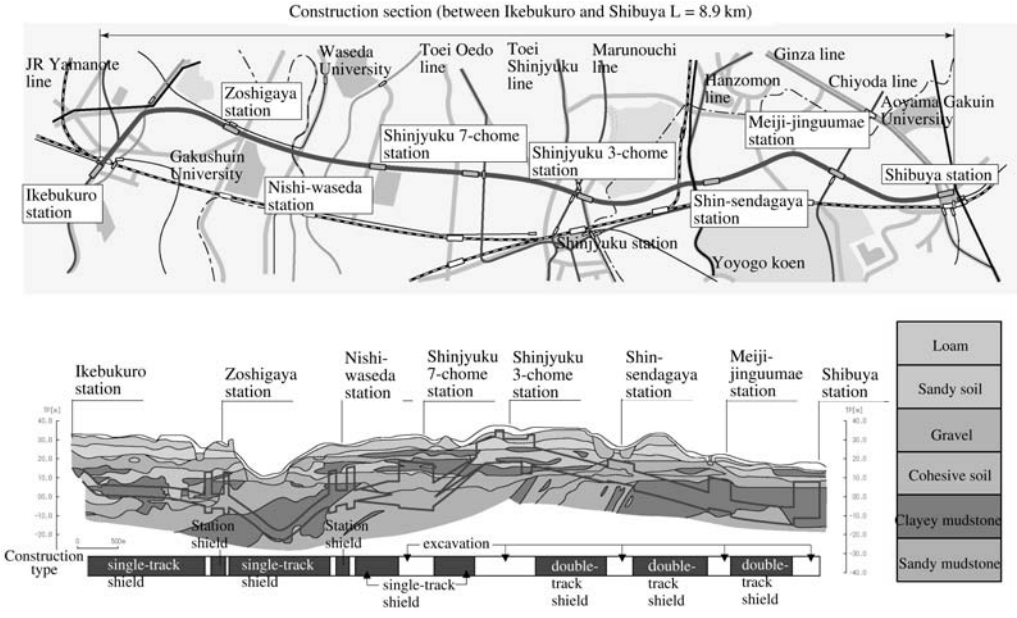

Figure 2. Plan view and geological profile of sections of Subway Line 13.

Horizontal and longitudinal alignments are as shown in Fig. 2. The smallest radius is 180 meters between Ikebukuro and Zoshigaya Stations, the steepest grade is 4.0% between Shinjuku 7-chome and Shinjuku 3-chome Stations, the deepest excavation point is 39 meters below the ground surface at Shinjuku 7-chome Station, and the greatest excavation width is 36 meters at Shibuya Station.

The geographical features of this section, shown in Fig. 2, include a plateau of the Quaternary Pleistocene of the Cenozoic era and a lowland or plateau-dissecting valley filled with sedimentation, which is located 35 to 10 meters above sea level. The plateau has volcanic ash clayey soil and terrace gravel, below which the Kazusa group, which is the foundation of this area, is distributed. In the lowland area, are an alluvial layer of deposited clayey soil and below which the Kazusa group distributed.

Groundwater is shielded against the terrace gravel layer and the Tokyo formation by low-permeability clayey soil, and free water is distributed in each layer. The lowest Kazusa group has a high head due to the existence of artesian water.

3 OUTLINE OF THE WORK

This construction work, which intersects nine existing subway lines, must deal with large infrastructure under the road, including electric power, communications, water supply and sewerage facilities. In this sense, this is a typical large-scale urban civil engineering project that has to be implemented while protecting existing facilities.

The subway line has seven stations along its course. One section with five stations that extends 1.9 km was constructed by the cut-and-cover method. Where station excavation was associated with a large amount of groundwater, a continuous underground wall was used for earth retaining to prevent adverse effects on the surrounding environment. The shield method was employed for the remaining two stations, whose excavation depth was greater. The total length of tunnels connecting these stations was 7.0 km. This was divided into seven sections, each constructed by the shield method.

The slurry shield method and high-density slurry shield method were used for the shield work, to enable recycling the soil discharged from the excavation process, to meet the geological conditions, and to protect neighboring structures.

4 MEASURES ADOPTED TO REDUCE THE ENVIRONMENTAL BURDEN

Subway construction exerts a considerable impact on the environment and requires a huge amount of materials, including concrete, steel, wood, sand, and water. These conditions exist in all stages of excavation. The work includes transporting excavated soil; quarrying, transporting, and refilling with sand in the cut-and-cover method; and shield excavation, transport of excavated soil in the tunnel, and road transport

Photo 1. The electric telescopic clamshell.

in the shield method. In the case of Subway Line 13, the total volume of excavated soil will be as much as 1,600,000 m^3, of which the cut-and-cover method will account for about 1,100,000 m^3, and the shield work will account for about 500,000 m^3. This amount will increase to about 1,700,000 m^3 when the volume of excavated soil for continuous retaining walls, and other work is added to the total.

As subway construction exerts a heavy environmental burden, the following measures were put into practice to reduce the impact as much as possible.

4.1 *Cut-and-cover method*

4.1.1 *Work vehicles*

The 4-ton trucks and dump trucks used for material and equipment transport during the work run on diesel fuel. As this fuel emits PM (particulate matter) during operation, work vehicles with a PM reduction unit were used.

In addition, for 2-ton trucks, compressed natural gas vehicles (CNG vehicles) were introduced. These vehicles are environmentally superior to gasoline-fueled vehicles due to their reduced noise and extremely low emission of black exhaust PM or NOX.

4.1.2 *Excavation machinery*

In the large-scale cut-and-cover work for subway construction, mechanized excavation is to a depth of about 20 meters below the road deck surface. The machine (called a telescopic clamshell) used for this excavation normally uses diesel fuel. However, in order to eliminate exhaust gas and to reduce the surrounding noise, the world's first electric excavation machine (Photo 1) operating on electric power was developed and introduced.

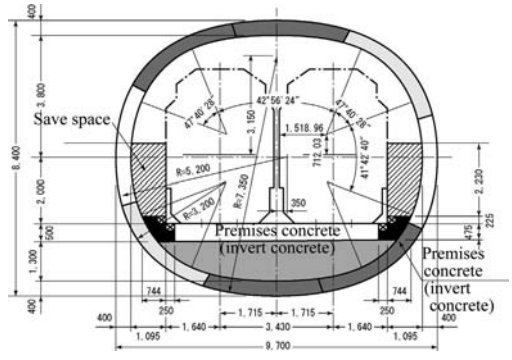

Figure 3. Standard section of composite circular tunnel.

Table 1. Area comparison table.

	Excavated sectional area	Tunnel space sectional area
Circular[A] (φ 9.7 m)	73.90 m^2	46.95 m^2
Composite circular [B] (W9.7 m × H8.4 m)	67.30 m^2	46.05 m^2
B÷A	0.91	0.98

For the same purpose, an electric-drive-type backhoe was selected for excavating and loading soil.

In this way, the PM in the exhaust gas can be reduced by 79% and nitrogen oxides by 24%. It is also estimated that carbon dioxide (CO_2) emissions considered responsible for global warming can be reduced by about 4,800 tons.

4.2 *Shield method*

4.2.1 *Reducing sectional area of shield tunnel*

For the double-track shield tunnel for Line 13 near Shibuya Station, we were able to reduce the volumes of excavated soil and invert concrete by eliminating unnecessary spaces in the upper and lower portions of the tunnel while securing the functions needed in a railway tunnel. We did this by adopting a composite circular section (non-circular section). (See Figure 3.)

The special feature of this type of section is that the cross-section of the tunnel interior space (the space minus the sectional area for concrete, invert, etc.) is nearly equivalent to that provided by a circular section. The composite circular section is formed by combining the radii of several curves.

As shown in Table 1, the interior cross-sectional area of the tunnel, including the maintenance space, can be nearly the same as that provided by a circular section, but the overall sectional area becomes about 10% less than that of a circular section. Invert concrete that has to be placed in unnecessary space can be reduced by about 40%.

Table 2. Environmental load reduction effect through reduction of the tunnel section.

	Circular tunnel	Composite circular tunnel
Real space of the tunnel	100	98.1
Volumes of excavated soil	100	91.1
Volumes of segment concrete	100	93.8
Volumes of invert concrete	100	60.0

Reducing the tunnel section leads not only to less excavation, but also to less use of such materials as segment material (concrete) and invert concrete supporting the subway tracks. As shown in Table 2, this can greatly contribute to effective reduction of the environmental burden.

4.2.2 *Recycling soil discharged in shield work*

The slurry shield and high-density slurry shield methods were used for this work.

In both methods, discharged high-density slurry (the slurry in the case of the slurry shield method) contains a large amount of water. Accordingly, it is designated as industrial waste and subject to legal regulations imposed on its handling. The percentage recycled is a low 45.3%. The material in high-density slurry ‘or slurry) is a substance existing in nature, which means it can only be recycled after it is dewatered.

- Recycling of slurry in slurry shield method
  Tokyo Metro has recycled slurry in the slurry shield method (specific gravity 1.3 to 1.4) by processing it into fluidized soil for refilling in the cut-and-cover method and invert material for the shield tunnel. It was decided that similar slurry recycling by processing it into fluidized soil could be used in the slurry shield method in the Subway Line 13 construction.
  The amount of slurry to be processed into fluidized soil for recycling for refilling in the cut-and-cover method and for tunnel invert material in the Subway Line 13 work is shown in Table 3 below.
- Recycling of high-density slurry in high-density slurry shield method
  The high-density slurry in this method has low water content – 50% to 80%. It is difficult to transport on the road without using special transport vehicles. In addition, the legal determination of whether or not this type of slurry is industrial waste is made at a “time point when the generated excavated material is discharged from the system separating it into soil and water.” Accordingly, we decided to improve and discharge high-density slurry in the rear base, which forms an integrated system with the shield. Improved high-density slurry is to be recycled for reclamation in Tokyo seaside commercial areas and elsewhere.

Table 3. Slurry recycling amounts.

Volumes of slurry	Recycling item	Recycling amounts (m^3)
131,000 m^3	Fluidized soil for refilling in the cut-and-cover method	135,000
	Invert material	26,000
	Total	161,000

Table 4. Volume of landfill embankment material recycled.

Volumes of high-density slurry (m^3)	The volume of high-density slurry recycled (m^3)
334,000	418,000

For improvement, research and development work was done on methods that could be used for physical dewatering for separation of slurry into water and soil according to the idea that the excavated soil could be returned to its natural state. Although practical implementation has proved to be possible, the improvement system is large in scale and the space needed at the rear base is difficult to secure in this project. In addition, improvement that fits in with the shield excavation process is difficult. For these reasons, we adopted the stabilization method described below in which additives are used.

a) Method using plaster neutral solidifying material
   This is a method using water absorption and solidification achieved by adding and mixing plaster-based neutral solidifying material into high-density slurry.
b) Method using sludge incineration ash
   This is a method using water absorption and improvement by adding PS ash from used paper manufacturing.
   Considering the environmental impact of the additives, a requirement was set so that the pH value of the improved soil remains in a neutral range and the soil will not be returned to slurry after improvement (solidification).
   The volume of high-density slurry recycled in the high-density slurry shield method is as shown in Table 4.
   As an example, the method using plaster neutral solidification material is introduced.

- Method using the plaster neutral solidification material
  In this method, high-density slurry discharged to the rear base by a conveyor belt is fed into a mixer.

Table 5. Mixing of plaster neutral solidification material and the cone index of the improved soil.

Additive mixing			Cone index of the improved soil	
Plaster neutral solidification material	Polymer cohesion material	Improvement time	In 2 hours	In 24 hours
86 kg/m^3	1 kg/m^3	60 s/batch	480∼500 KN/m^2	630∼670 KN/m^2

While adjusting mixer rotation speed and stirring, the neutral solidifying materials are added sequentially for instant improvement of soil (the specified strength appears in about five minutes). In this case, the neutral solidifying material and a batch-type 2-axis mixer for stirring are parts of a system used to achieve uniform quality.

The additive mixing rate and the cone index of this method are shown in Table 5.

This improvement technology can be applied for all work in which slurry with high water content must be handled. There is actually an example, in which slurry accumulated in marshes was improved then and there, and the improved soil was used to build a road to resurrect a park beautifully. We believe this technology to be applicable in many fields in view of the importance now placed on environmental protection.

5 SUMMARY

Compared with automobiles and buses as well as other forms of rail transportation, subways, which emit the lowest levels of CO_2 and impose the smallest environmental burden, are viewed very favorably in terms of prevention of global warming.

However, subway construction requires huge amounts of materials such as concrete and sand as well as large construction machinery and many work vehicles. In addition, the quarrying of huge amounts of materials damages mountains, and the utilities required to transport these materials as well as the operation of construction machinery over extended periods of time all exert a considerable impact on the environment. With an eye toward minimizing the use of materials taken from nature and the impact on the environment during the work period, we took up the challenge of recycling resources and reducing the environmental burden imposed by excavation machinery.

The construction work is still under way and we have just begun implementing the measures adopted to reduce the environmental burden. Today, prevention of global warming and resource recycling are unavoidable issues in construction work. We realize that we must continue to engage in research and development to effectively deal with environmental protection issues.

ABSTRACT: From the largest private and public water and power supply utility companies in the world to the smaller municipal water and power agencies and irrigation districts to the oldest water district in California, operations and maintenance of water tunnels has been an important factor and vital link in California's infrastructure. Michael O'Shaughnessy (San Francisco Hetch Hetchy Water Supply System), William Mulholland (Los Angeles Department of Water and Power and Metropolitan Water District of Southern California's Colorado River Aqueduct), John Eastwood (Southern California Edison Big Creek Hydroelectric Project) along with many late 19th and early to mid 20th century pioneers, visionaries, ordinary and extra-ordinary people built large and small water supply, irrigation and hydroelectric tunnels, which have supplied environmentally friendly- water supply and electricity, and uninterrupted service to customers for a burgeoning population and economy. This paper discusses case histories and lessons learned providing enlightenment in the reliability assessment of existing structural conditions of tunnels, repair, and replacement of historic and vital water tunnel projects in California.

1 INTRODUCTION

1.1 *Water tunnels and California sustainability*

California is blessed with natural resources and divided into 11 geomorphic provinces as shown in Figure 1. The Sierra Nevada mountain range, the largest mountain province, and several other major mountain ranges, require crossing with tunnels to feed water to the fertile valleys and major metropolitan areas. Spurred by unprecedented growth and opportunity after the gold rush, agriculture, the post industrial society of World War I, World War II, Cold War, and development of the transistor and the silicon chip, California has grown to be the world's 8th largest economy. The planning, maintenance, operations, and construction of water supply and energy projects (including the conveyance tunnels) since the founding of California has managed to keep pace with suburban growth, baby boomers, and the high technology sector in the information age.

By today's standards, construction of these historic water tunnels was relatively primitive (50 to 100 years before smooth wall blasting, automated equipment,

TBM's, etc.) using mule, drill and blast "spiders", hand mining methods, timber supports, Ford's Model T's, and brute force. For the most part these tunnels have provided uninterrupted service from 50 to over 100 years, but nevertheless, environmental impacts, deterioration of rock and liner conditions, maintenance and repair, and occasional emergency outages have occurred.

1.2 *Some significant water tunnels in California*

Table 1 summarizes some of the significant and historical water tunnels in California by agency/project. From a new world standard, these tunnels are considered to be historical and seminal in contributing to the sustainability of California as a powerhouse economy in both innovation and education.

2 PIONEERS, ENGINEERS, LEADERS

2.1 *William Mulholland, 1855–1935*

Mulholland was born in Belfast, Ireland and came to the USA at the age of 15, first as a sailor, lumberer, dry goods clerk, miner, and finally as a ditch digger for the Los Angeles Department of Water and Power (LADWP). As a self taught engineer, he would ultimately rise to chief engineer, and is credited for bringing Owens Valley water to Southern California. The Owens Valley water project was politically charged for water rights, required over 5000 men (pioneers themselves), and included 164 tunnels (69 km); the entire aqueduct extending 362 km without a pump in the system. In 1913, when the project was completed and water arrived in Los Angeles, Mulholland's famous speech was: "There it is, take it." He also conceived the Colorado River Aqueduct (completed in 1941), which provides the majority of Southern California's imported surface water.

2.2 *John Eastwood, 1857–1924*

Eastwood was born in Minnesota and educated as a civil engineer. He began his career in the Pacific Northwest as a railroad engineer, but soon moved to Fresno, California where he designed flumes for the timber industry. It was during this work that he first began to study the hydroelectric potential of the San Joaquin

Figure 2. Mulholland, Eastwood, O'Shaughnessy.

River (Redinger, 1998) (Figure 1, E). After a short period as Fresno's City Engineer, and Chief Engineer for the San Joaquin Electric Company, he worked as a consulting engineer for Pacific Power and Light Company (PPL). It was in this last position that he surveyed stream flows and elevations of the San Joaquin River, designing the largest hydroelectric (1100 MW) project conceived by one man. This system of water storage dams linked with tunnels became known as the Big Creek Project with construction rivaling the Panama Canal. Tragically, Eastwood never participated in the construction of his project. In 1910, he was forced to sell his stock in PPL to pay his assessment for construction of Big Creek as was required by all PPL stockholders. Eastwood then began a long career in dam design, creating a unique reinforced concrete multiple-arch design that is well suited to remote sites.

In 1987, to honor the designer of Big Creek, Southern California Edison named their underground 200-MW pumped storage plant the John S. Eastwood Powerhouse.

2.3 *Michael M. O'Shaughnessy, 1864–1934*

O'Shaughnessy graduated from the Royal University of Dublin, Ireland, and arrived in San Francisco in 1885. He worked on Alpine dam in Marin County and later was chief engineer of the Southern California Mountain Water Company in San Diego. In 1912 he was appointed City Engineer for the City of San Francisco's Hetch Hetchy project (SFPUC, 2005) (Figure 1 E & F). The project was constructed between 1914 and 1937, and included over 100 km of tunnels. The dam spanning Hetch Hetchy valley provides his namesake.

Like the Owens Valley water, Hetch Hetchy water was also politically charged, and the damming of Hetch Hetchy valley was opposed by the highly esteemed environmentalist, John Muir. The Raker Act signed in 1913 by President Woodrow Wilson secured the rights to build Hetch Hetchy dam. O'Shaughnessy was a man of action at the Senate debate on the Raker Act.

2.4 *Other Pioneers, Politicians and Engineers*

There are numerous other significant pioneers who contributed to providing water to grow and sustain a thirsty and energy needy California. These leaders included men like William B. Matthews, Joseph B. Lippincott, Fred Eaton, Willie Chalfant, Harvey A. Van Norman and many others too numerous to mention (Nadeau, 1997; Reisner, 1993). A few others of note are discussed below.

Frank Weymouth was the Metropolitan Water District's first general manager and chief engineer from 1929 to 1941. He designed and constructed Mulholland's conception of the Colorado River Aqueduct (including the San Jacinto tunnel) at the height of the great depression.

Tunneling's role in the sustainability of California would not be complete without mentioning the Federal, U.S. Bureau of Reclamation's Central Valley Project (CVP) and the State Water Project (SWP). The CVP began in 1935 and continued into the 1980's with significant tunnels being the Pacheco and Santa Clara tunnels. There are many politicians and individuals who tirelessly worked for the SWP and cooperation with the CVP, including former US Secretary of Defense Caspar Weinberger when he was a California Assemblyman (Thomas, 2006). Several engineers who deserve mentioning include W.H. Hall beginning in 1873, E. Hyatt in 1931, A. D. Edmonston in 1950, and H. O. Banks in 1956 who were State Engineers who took part in SWP; and R.B. Marshall in 1919 of the U.S. Geological Survey was the first to conceive of SWP. The SWP significant underground works include the Angeles, Porter, San Bernardino, and Tehachapi tunnels and the underground hydroelectric plant at Oroville Dam.

There are also countless environmental pioneers that helped provide balance between California's population growth and the earth's sustainability starting with John Muir and the Sierra Club, David Gaines of the Mono Lakes Committee, and Tim Such of Friends of the Earth (SFPUC, 2005; Nadeau 1997).

3 CITY OF LOS ANGELES DEPARTMENT OF WATER AND POWER (LADWP)

The First Los Angeles Aqueduct has 164 tunnels totaling 83 km. The Second Los Angeles Aqueduct has 4 tunnels, totaling 1.9 km.

3.1 *Owens Valley Water Tunnels*

These tunnels located in the Eastern Sierra Nevada and Great Basin provinces (Figure 1, E & G) were part of LA's First aqueduct. World record advance rates were achieved on their tunnels, and in 1908 a soft-rock world record for advance of 323 m in a single month was set on the 3.5 km Red Rock tunnel. In 1910, on the 8.2 km Elizabeth tunnel, hard-rock a world record advance rate of 184 m in a single month was set.

To ensure continued operation in the 21st Century, maintenance inspections are performed annually. Repairs are scheduled during these outages based on the previous year's inspection. While the repairs are done in one section by the Construction and Maintenance Group, inspections are performed by the Engineering Group in another section. Once the tunnel is back in operation, the Engineering and Construction groups meet to discuss the following year's repair schedule (Miller et al., 2006).

Typically, relining with shotcrete is used to repair spalls and cracks. Removal and replacement of old concrete walls and floors that have buckled or cracked is sometimes needed. These areas are generally limited to small sections only. Tunnel shutdowns are usually scheduled during periods of low demand, and shutdowns range from 2 months or less during a wet year to 5 months during a dry year.

LADWP uses a special mix of shotcrete to reline the tunnels. On the Elsmere portion of the First Aqueduct, the shotcrete has proven to be dense enough to prevent seepage of naturally occurring crude oil into the tunnel. In some cases if the tunnel section allows, robotic shotcrete arms are used.

3.2 *Stone Canyon projects*

Stone Canyon dam, tunnel and pipeline facilities, located in the Santa Monica Mountains of the Transverse Range (Figure 1, I) were constructed in the 1920's, expanded in the 1950's, and expanded again and repaired in 2000's. The latest expansion was implemented to meet new EPA and California drinking water regulations, which mandated the filtration and disinfection of potable water supplies subject to surface water runoff (Bentwood, et al., 2006).

Bypass Tunnel No. 1 was completed in the 1950's. Inspection revealed the mortar lining was severely deteriorated (Anbessaw, 2005). After high water pressure cleaning, a new 13 to 38 mm shotcrete liner was placed over the 1340 m long by 1.7 m diameter horseshoe tunnel. Troublesome water leaks are panned using formation drain tubes. The work was completed in a round the clock operation in 19 days, 2 days ahead of planned shutdown schedule.

Bypass Tunnel No. 2, consisting of 870 m of 3 m average bore diameter was completed in 2006. The project provided for operations and maintenance flexibility and redundancy in addition to meeting new drinking water standards.

3.3 *Mono Crater's Water Tunnels*

The Mono Craters Tunnel, located in Great Basin province (Figure 1, G) was constructed in 1939. This tunnel is 18.2 km long and connects the Mono Basin to the Owens River Valley. Excavation of the west portal was started in September 1934. The Mono Craters Tunnel was watered up in 1940.

Inspections of the tunnel are scheduled every 3 to 5 years, requiring a shutdown of just a few days. Given confined space and air flow requirements caution is required for entry. Naturally occurring carbon dioxide gases in the area are monitored during inspections. Past inspections indicate that the tunnel is in good condition. These inspections indicate minor mineral deposits, cracks, root growth, some shifting of joints and rough portions of invert. Groundwater inflow into the tunnel is about 25 m^3/minute (417 l/sec) all year round (Miller et al., 2006).

4 METROPOLITAN WATER DISTRICT OF SOUTHERN CALIFORNIA (MWD)

MWD was incorporated in 1928 to provide water for Southern California. One of the two main surface water supplies comes through the Colorado River Aqueduct (CRA) which consists of 29 tunnels totaling 148 km, including most significantly, the 21-km long San Jacinto Tunnel, the 12.1 km long Iron Mountain Tunnel, 29.5 km Coachella Tunnel.

4.1 *San Jacinto Tunnel*

This tunnel is part of the San Jacinto Mountains (Figure 1, I) where extremely large groundwater inflows, usually associated with faults, were experienced during tunnel construction. The San Jacinto Tunnel (Anon. 1940; Thompson, 1966) was constructed by conventional drill and blast excavation from about 1935 to 1939. The 6-m ($\pm$) excavated diameter by 20,983 m long tunnel was constructed predominantly in granitic rocks with some zones of metamorphic rocks (mica schists, quartzites, and crystalline limestones).

The MWD Historical Record (Anon. 1940) indicates that during tunneling, four major faults and about 20 minor faults or fractures were encountered. There were 8 to 10 instances when peak flows of about 1,000 liter/second and associated peak water pressures of 41 bars were experienced with common pressures on the order of 10 to 25 bars. The maximum flow measured from all tunnel headings was about 2,500 liters/second. Tunnel construction records indicate about 190 hm^3(155,000 acre-ft) of water was drained through the tunnel from the surrounding rock. Groundwater that originally fed springs located as much as 11 km from the tunnel was lowered following tunnel construction. The Historical Record further indicates that the large quantities of inflow were associated with sudden surges of flow when tunneling through (impermeable) fault zones, usually major faults, which held back compartments of groundwater under high head. This was especially noteworthy with one

particular major fault, the Goetz fault. However, it should be noted that when crossing another major fault, the Mclnnes fault, the Historical Record indicates:

…Water originally percolating through the fracture zone on either side of the gouge . . . had been drained by the tunnel advancing from both sides. There were many indications that the water had been previously present, yet the quantities remaining at the time of penetration were relatively small. . . . Through the center of the fault the inflow was less than 100 gpm [6.3 l/sec]. *. . . drainage had occurred, perhaps largely through the water course . . ., six months before the Mclnnes fault was reached.*

It appears from examining the Historical Record that the Goetz fault and the Mclnnes fault are two fault zones, which form the boundaries of a groundwater compartment. Large quantities of water were not encountered along the Mclnnes fault because when tunneling through the Goetz fault large quantities of water were drained off from interconnected joints and fractures. It should be noted that grouting was performed as they approached the Goetz fault from the west, while when approaching from the east grouting was not performed because the water had largely drained to the west.

Thompson (1966) indicates another contributing factor or alternate explanation to higher flows when tunneling from the east.

…it was that water occurred in open interconnected fractures and joints in the hanging (northeast) wall of the northwest-striking faults. Out in the hanging wall the rock became increasingly tight away from the actual zone of shearing. When tunnel headings approached northwest-striking and easterly-dipping faults from the east, water under high pressure was generally developed at some distance away from the fault plane in hard but somewhat fractured rock. As the heading neared the fault the open fractures were numerous and volume of inflow increased. Normally by the time the footwall was reached, where gouge and crushed material was present, the hydrostatic head had generally been reduced to the extent that little difficulty was encountered in driving through the soft, faulted material characteristic of the actual planes of slippage. Conversely, when headings were being excavated from the southwest side of the northeasterly-dipping faults, (through their footwalls) large flows of water under very high pressures were freed instantaneously, resulting in strong surges that carried large quantities of broken rock, sand and clay gouge in the tunnel.

A decade later, major repair efforts to grout leaks in the liner were performed in 1947, and repairs to the floor were performed in 1952. To this day there are leaks in the San Jacinto tunnel; two of the leaks are known as the car wash zone and the high-pressure jet (Howser). The San Jacinto Tunnel construction experience is an extreme example of groundwater inflow into tunnels. Many of the tunnels constructed in the past had problematic groundwater inflows (100 to 200 l/sec typically and sometimes more). These tunnels crossed similar water bearing fault traps during construction and the inflows often can be a long term maintenance concern.

A major shutdown of the CRA is required in order to inspect the conveyance system. The inspection frequency for the entire CRA is once every 10 years or longer, with a typical shutdown period of three weeks. Recent inspections occurred in November 2002 (Beikake and Bell, 2003) and January 2005. MWD used a 4 category anomaly rating system for ranking damage, defects, or distress to the liner, with 1 requiring immediate attention, 2 repair be made in the next years inspection, 3 repair be made in two ears, to 4 not likely to be adversely impacted, but monitor for degradation in future inspections. Most fell in the category 3 or 4 anomalies. During the 2005 shutdown, crack monitoring gauges were placed at various tunnel cracks in San Jacinto and Iron Mountain tunnels to provide data on crack propagation behavior. The cracks will be visually inspected for changes in crack growth during the next CRA shutdown (possibly in 2007).

5 SOUTHERN CALIFORNIA EDISON (SCE)

SCE has over 100 km of tunnels, all located in the Sierra Nevada province, including the Kern River and Big Creek projects. SCE inspects their tunnels every 5 years with an average shutdown time of 1 week. Damaged areas and needed repairs are identified and are included in future operation budgets. Because of the long service history of SCE's tunnels a large archive exists that is used for long term trending of damage and repair monitoring.

5.1 *Big Creek No. 2*

Hydropower development of the San Joaquin River region, located in the south-central Sierra (east of Fresno, Figure 1), was begun by Eastwood (Redinger, 1998). Surveys, independently conducted with a string of pack mules, were done from 1896–1899 and again in 1902. By 1910, planning of the "Initial Development" of Big Creek, soon to be known as "The Hardest Working Water in the World", had begun. Development continued throughout the 1920's, the 1950's, and the late 1980's. Table 1 shows a listing of the primary tunnels in SCE's Big Creek system.

Big Creek No. 2 is 6,632 m long by 4 m nominal diameter and was accessed during construction by 9 adits and 2 portals. The project was built in 1912 by drill and blast methods (60 years prior to smooth

wall blasting techniques). The tunnel varies from 4.3 m wide by 4.9 m high horseshoe shaped tunnel cross section to completely enclosed 3.4 m by 3.4 m (ID) arched concrete cross section.

Problems with this tunnel began during construction as it is constructed through highly jointed rock, and some sections suffer from low cover. Consequently, 11 concrete support arches were installed. Many leaks to the surface as well as caveins and reactivation of a landslide have resulted in several repair efforts including reinforced concrete walls and floors, shotcrete, and complete lining of some sections with welded steel pipe.

Leaks to the surface continue to the present. Since 2003, visual inspections, ground penetrating radar (GPR) investigations, underground and surface mapping, and water tracing surveys have identified several leak locations (Willowstick, 2006). SCE is evaluating several repair options including steel liners and stage grouting with reinforced shotcrete.

5.2 *Kern River No. 1*

In the early 1900's the Edison Electric Company (precursor to Southern California Edison) undertook construction of a hydroelectric generation project utilizing the waters of the Kern River. The site is located approximately 190 km north of Los Angeles in the foothills of the southern Sierra Nevada (Figure 1, E). In February 1903, excavation of 19 tunnels that would ultimately form a continuous 12.9 km conduit flowline transporting up to 11.6 cubic meter per second of water from the dam and intake structure at Democrat Hot Springs to the powerhouse were started. The tunnels were advanced by conventional drill and blast methods using air drills.

The tunnels were designed as 2.7 m by 2.7 m rough cross section followed by the placement of a non-reinforced concrete lining to create a 2.4 m wide by 2.3 m high rectangular open channel with a 15 cm high natural rock wall above the concrete wall and a natural rock crown. At several locations a shallow rise unreinforced concrete arch cap with a shallow arch was installed to support areas of poor rock. There are 551 locations where a concrete cap was installed, in various lengths, with a total of amount of concrete cap of about 4,900 m.

During the 98 years that the tunnel system has been in service, there have been eight significant failures of capped sections that blocked the tunnel flow and caused a total outage until the area could be cleared and repairs completed. Other repairs have varied from as little as the removal of fallen material and returning the tunnel to service, to very large efforts involving rock bolting of continuous steel plates on the walls and cap with secondary grouting. The latest such cap failure occurred in July 2002. The full width of a 3.7 m long section of cap with approximately 3.7 cubic yards of rock fell into the tunnel, blocking the conduit and causing an overflow of water that cascaded down and across the highway 800 feet below. A detailed engineering, geological, and geophysical (GPR) survey of the conditions of the tunnel and geological features was performed. This survey was completed in early 2003 and the rehabilitation measures proposed included installation of rock bolts and shotcrete and repair or complete replacement of concrete walls. In tunnel 19, several alternatives were considered including replacement with a new tunnel. The final solution was to install a new thin reinforced concrete structural lining with cellular grout over the existing concrete cap (Fallesen et al., 2006).

6 SAN FRANCISCO PUBLIC UTILITIES COMMISION (SFPUC)

SFPUC has over 125 km of tunnel constructed for the San Francisco Bay Area's water supply from 1867 to present. The Hetch Hetchy system spans from the north central Sierra Nevada through the Central Valley to the Coast Range geomorphic provinces (Figure 1, E-F-B). Rehabilitation and reliability upgrades to the Hetch Hetchy system include tunnels, some of which are described below.

6.1 *Mountain Tunnels*

Located in the foothills of the Sierra Nevada, this 30.8 km tunnel by 3 m diameter tunnel was put into operation in 1925. Since 1925, there have been 11 inspections, 4 for the full length and 7 for a partial length. Even though the condition of the tunnel has continually degraded, there is no indication that any repairs have been made. Deterioration of the tunnel has resulted in increased head loss and a decrease in system capacity. Due to concern of future tunnel collapse and further restriction of flow, a future repair program is being implemented. As the storage capacity within the Bay Area is limited, the outage duration for tunnel repairs is severely limited. To minimize shutdowns, sub-aqueous ROV inspections may be used. Typically, the low demand period is from November to March and planned outages are normally scheduled in that timeframe.

It is speculated that changes in the operation of the Moccasin Powerhouse have led to increased deterioration of the Mountain Tunnel. Since about 1987, the powerhouse has been operated as a peaking plant resulting in large flow changes on a daily basis and causing tunnel pressure fluctuations and surges upon filling and emptying the tunnel.

Possible repair scenarios consider conventional shotcrete and rock bolts installed in less than 3 month outages over a 5 to 8 year period.

6.2 *Coast Range tunnels*

The Coast Range tunnels are divided into the Telsa-Alameda and the Irvington segments. The Telsa to Alameda segment is 40.2 km long by 5 m diameter average bore, and includes two portals and five access shafts used during construction. Early use of shotcrete (1 m thick) was implemented by Engineer Carl Rankin in 1930 to control squeezing ground here on the Telsa-Alameda segment and later on the San Jacinto tunnel (Proctor, 1998). The Irvington segment is 5.6 km long by 5 m diameter.

6.2.1 *Thomas Shaft*

Thomas Shaft, one of the five construction shafts for the Telsa-Alameda segment, is founded in weak sandstone and about 2 m wide by 5.5 long by 107 m deep, lined with 25 cm thick concrete liner with weep holes to full depth. Reinforced concrete struts were installed at regular intervals. In the early 1990's, Lawrence Livermore Laboratory required a water tap into the Coast Range tunnel for some site expansion improvements (ESA, 1990). Prior to the improvements, inspection, condition assessments, and shaft loading analysis were made. Previous borings and construction records from 1926 to 1927 were reviewed and the concrete cored and tested. In general, the shaft was found to be in good condition. Loose concrete was scaled, wrapped, and/or repaired, and struts replaced where required. The tap was done through a massive concrete bulkhead from an adit connected to the aqueduct. Controversy arose over the safety of taping into the bulkhead. Consequently, an extensive grouting program was employed prior to tapping.

6.2.2 *Irvington Tunnel*

Irvington Tunnel has not been inspected in about 40 years. There are no operational alternatives if it is taken out of service; it is a bottleneck. In the event of its failure, Hetch Hetchy water would not reach the San Francisco Bay Area. It is bounded on each side by the Hayward and Calaveras faults, so the reliability of the system is of concern. The length of the tunnel does not make it amenable to ROV inspections. Because the condition of the existing Irvington Tunnel is unknown, it is not possible to determine whether or not a new Irvington Tunnel is required. However, adding a new tunnel provides additional seismic reliability. Planning and engineering are underway for a new parallel tunnel.

7 PACIFIC GAS AND ELECTRIC (PG&E)

PG&E has over 200 km of tunnels in its extensive hydroelectric system located primarily in the Sierra Nevada Mountains. When possible, tunnels are evaluated in a watered condition using head loss, seepage, and discharge of debris as key indicators of condition. Remotely operated vehicles (ROVs) are increasingly used to inspect watered tunnels where their use makes economic sense.

Tunnels are not unwatered on a regular schedule for inspection. Unwatering is avoided unless evaluation criteria suggest a problem, ROV inspection is impractical because of tunnel length, or the tunnel must be unwatered anyway for project maintenance.

7.1 *Drum Tunnels*

There are a number of relatively short, small-diameter tunnels on PG&E's Drum hydro canal system in the central Sierra Nevada east of Sacramento (Figure 1, E). Many of these tunnels are quite old, having been built during the 19th Century as part of a system to bring water to the mining districts in the area. The tunnels take the canal lines under low ridges of granitic and metamorphic rock. In poor ground conditions timber sets were placed and unreinforced concrete liner was later installed, encasing the sets. Because the tunnels are part of a canal system with open channel flow, the timber sets did not remain submerged and eventually rotted.

During the last two decades several sinkholes formed above the lined sections of some tunnels. Inspections during outages for canal maintenance also revealed occasional cracked liners, the rotted timbers, and voids above the crowns of the liners. A systematic program was initiated to characterize the conditions of the tunnels, prioritize them for repairs and then design and construct these repairs.

In addition to visual inspection and sounding the liner with a hammer, the main tool for evaluating liner condition is to drill many small diameter (25 to 50 mm) holes through the liner with a pneumatic hammer. The thickness and condition of the liner, size of void and geologic condition can then be evaluated. Early on in this process large diameter cored holes and geophysical methods (primarily ground penetrating radar) were also tried, but the small diameter holes were found to economically yield the most useful information.

Cracked liner sections with evident bulges or offsets were reinforced or replaced. Repairs that significantly decrease the tunnel cross section cannot be used because the reduction in flow can affect canal freeboard upstream.

Many liner crown sections appear to be in good condition yet are only 75 mm thick. Void spaces above the crown are common. It is not apparent whether these voids were present from the time of construction because of the concrete placement methods in use at that time, or whether they formed during the subsequent decades of operation.

PG&E is in the process of backfilling all void areas with grout. This will eliminate the possibility of flowing water enlarging the voids or collapse of the ground

onto the thin liner. Because of the short duration of the annual outages (one to two weeks), only 100 m long sections of tunnel are backfilled at one time.

The thin unreinforced crown sections are not credited with any structural capacity to support the grout forces. Temporary tunnel supports are installed prior to grout placement. The small tunnel size (about 1 m wide by 2 m high) creates a logistical problem because men, equipment, and material must still have access through the sets and spreader beams. A maximum grout pressure of 0.7 bar is specified. This pressure is found to be sufficient back fill the voids as long as grout holes and grout relief holes are closely spaced and the grouting equipment is closely monitored.

8 CITY OF PASADENA

8.1 *Azusa Conduit*

The Azusa Conduit is a 9.3-km-long water tunnel and box culvert structure in the San Gabriel Mountains in the Transverse Range (I, Figure 1). It conveys water by gravity feed from San Gabriel Dam along the shore of Morris Reservoir to the south abutment of Morris Dam and from there to a forebay where the water drops 100 m through a penstock to a hydroelectric power plant. Much of the conduit was completed in the 1890's by P.G. and E. with various segments consisting of hard rock tunnel, redwood stave flume, or steel pipe armored with native rock and mortar. In the mid-1930's when Morris Dam was built, the old flume and steel pipe was abandoned, most of the conduit was upgraded with concrete encasement, and at least one tunnel section was rerouted deeper into the hillside to avoid deformation and damage caused by a deep-seated creeping landslide.

Much of the downstream half of the conduit alignment below Morris Dam lies high on the side of precipitously steep canyon walls. This portion has been damaged repeatedly by shallow-based rock and debris slides. The landslides and erosion have damaged tunnel access openings, damaged tunnel linings requiring interior repairs and rerouting with new tunnels, and cleaning out of debris. There are several inverted siphons that have had to be cleared of debris and replaced or repaired in the last 20 years. Some segments of the alignment remain very difficult to inspect due to steep topography, unstable slopes, forest cover, and inverted siphons that are obstructed or have impaired ability to drain.

The frequency of conduit condition inspections decreased over the years and overall operational reliability has been good. In 2006, the first complete exterior inspection in several decades was performed. This inspection was undertaken due to estimated water losses greater than 10%, increasing incidence of animal incursions and debris blockages of the tunnel, and greater emphasis on water conservation. The exterior inspection was carried out in two phases: Phase 1 backpacking on foot (5 days) and Phase 2 by boat timed to coincide with the high reservoir water level in the spring for the middle section of the alignment (2 days). All known access points that could be safely reached were inspected, photographed, and plotted on base maps. Coordinates were measured at key locations using a hand-held GPS unit and video recordings were made using a hard-disk camcorder. All hatch covers that could be moved were unlocked and opened, viewed internally to the extent that could be done by looking into the opening, and photographed with a digital camera. Several access points that had not been previously identified were discovered in the field. Findings were plotted aerial ortho-photographic base photos flown and compiled specifically for the project. Preliminary recommendations for repair under consideration for cost versus benefit evaluation include sealing identified point leakages, upgrading flume segments where cover is inadequate, repairing access hatches and ports that have been damaged, overgrown, or buried, armoring or buttressing sections that remain vulnerable to future rockslides, constructing better access to drain an inverted siphon, and performing internal inspections as required.

9 SACRAMENTO MUNICIPAL UTILITY DISTRICT (SMUD)

SMUD has about 38.5 km of tunnels located in the central Sierra Nevada Mountains for hydroelectric generation (Rummel, 2006). Water rights for power and consumptive use are retained by the SMUD and the City of Sacramento, respectively. The most significant tunnels were completed in the 1960's as shown in Table 1. Frequency of inspection is about every 5 years or greater. The tunnels were constructed horseshoe shape by conventional drill and blast in metamorphic and granitic rocks and are predominantly unlined. Those portions that are lined are typically fully lined as a concrete horseshoe with some portions of shotcrete and rock bolts. The Jaybird tunnel was extensively contact grouted to reduce and stop leakage to one of the original construction adits. The Loon Lake shaft and tunnel was grouted to minimize and stop leakage into the underground powerhouse.

10 EAST BAY MUNICIPAL UTILITY DISTRICT

EBMUD, located in Oakland, services the eastern communities of the San Francisco Bay (Figure 1, B). The 5.5 km long Claremont tunnel crosses the active

Hayward fault and is under distress. To provide redundancy and allow for repair of the existing tunnel, EBMUD constructed a 146 m access adit and a 479 m by pass tunnel for reliability and uninterrupted service in a major earthquake event (Caufield et al., 2005).

11 MARIN MUNICIPAL WATER DISTRICT

MMWD, located in Marin, is the oldest municipal water district (non private) in California, having received its charter in 1912. MMWD has eight reservoirs and many pipelines and tunnels, constructed from 1872 to 1982. Bon Tempe reservoir has an intake tunnel constructed in the 1950's (Figure 1, B). The 350 m by 2.5 m diameter tunnel constructed in sandstone housed a smaller diameter intake pipe, which was subject to damage by collapsed and dry rotted timber (ESA, 1992). In general the rock conditions were good, and all the timber was removed and replaced with a shotcrete liner and a new access shaft was added for better and safer maintenance service of the intake valves.

12 CONCLUSIONS

This paper has provided a sampling of tunneling's role in maintaining the sustainability of California as a leading social and economic power in the world today. Early planners and engineers built these tunnels to last. Water tunnels have had an extended service life afforded by the natural environment of being underground combined with the legacy of following generations to perform reliability assessments (inspection and analysis), repairs (maintenance), and replacements, when and where required. Although just one part in the grand scheme of water supply projects, tunnels have played a vital role in providing continuous service to Californians.

ABSTRACT: This paper presents a planning method of maintenance strategy for railway tunnels in Japan. The method adopted in the case study aims to find an optimal maintenance strategy to minimize the expected "Total Cost", which includes costs and risks. In the formulation, the probabilistic state vector consisting of deterioration ranks defines the state of structures. The proposed new planning method is able to indicate the optimal repair timing considering each characteristic of lines. The new approach of tunnel management will provide rational and reliable maintenance for aged railway tunnels.

1 INTRODUCTION

There are thousands of tunnels for railways, highways, and aqueducts for electric power plants in Japan. The total length of them exceeds 10,000 km. Some of them are aged and deteriorated, thus repairs are needed. In addition, a number of defective tunnels will increase drastically in the near future. These tunnels should be maintained properly to be functional more efficiently than ever as it is essential because of social and economical circumstances of Japan. Cost reduction together with maintaining the required level of safety and reliability is a prerequisite for the maintenance. In view of such aspects, we have studied on a planning method for the maintenance of railway tunnels with a risk management technique.

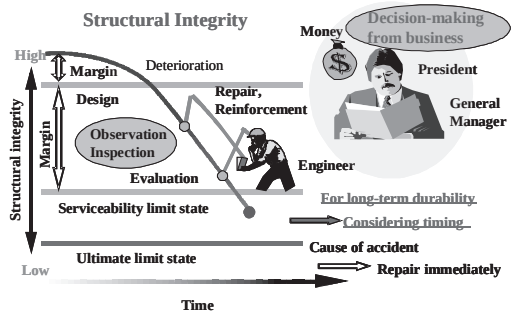

Figure 1. General relationship between maintenance and its structural integrity.

2 RISK MANAGEMENT SYSTEM

2.1 *Risk management for maintenance of structures*

Figure 1 shows a general relationship between the maintenance of a structure and its structural integrity. The vertical axis shows the structural integrity while the horizontal axis indicates time. Figure 1 shows a serviceability limit state and an ultimate limit state. The former signifies the limit state that the structure cannot be serviceable. The latter indicates the limit state that the structure is going to collapse.

Normally structural integrity is designed to be of a higher degree than that of serviceability limit state. Moreover, substantial structural integrity is higher than that of the design stage. Then, the structural integrity is gradually lost as time goes after commencement of operations. A structure engineer in charge of maintenance must understand existing structural conditions through periodic observations and inspections, and then he must consider a need of repair or an alternative measure to deal with substantial condition.

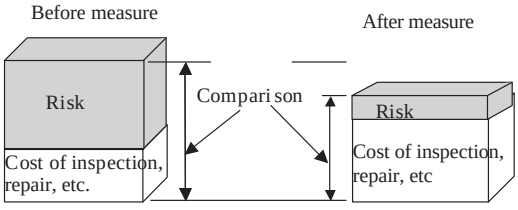

Figure 2. A concept of risk of a structure and management for maintenance.

As the structural integrity was discovered to be inferior to the serviceability limit state, an immediate repair should be made. However, as the degree of structural integrity is higher than the serviceability limit state, appropriate measures to cope with unsatisfactory conditions may be carried out until such time that the structural integrity further reduced to the serviceability limit state. Due consideration are essential in terms of an economical point of view for the following:

1. When will it be repaired? How will it be repaired?
2. Will it be repaired diligently, before the structural integrity degraded into a serious condition?
3. Will a large-scale repair be needed? When the structural integrity degraded into a serious condition?

In the case of an explanatory material, which is a common index between engineers and administrative managers, will be need. It is considered that risk management and asset management are one of the methods in preparing materials.

On a practical planning, many plans regarding inspection method, timing and scale of repair should be taken into account. In either risk management or asset management, the degree and extent of risk and a total cost required should be estimated quantitatively. Throughout the process of material preparation and comparative plans, an optimal plan among them should be selected for application.

The risk is a factor, which gets business worsens due to accidents and disasters. Total cost means the sum of the expenses, which consists of risk converted into money and cost for maintenance, such as inspection and repair. Risk management and asset management will prepare a material source where a total cost and annual risk are described. A manager in charge will make a decision by himself or in coordination with other responsible engineers in some occasions based on the type and quality of material.

2.2 *Procedure for risk management*

The risk management system is one of the methods controlling the risk and minimizing the probable effect caused thereby. It is a characteristic of the risk management to convert the risk into a quantitative loss,

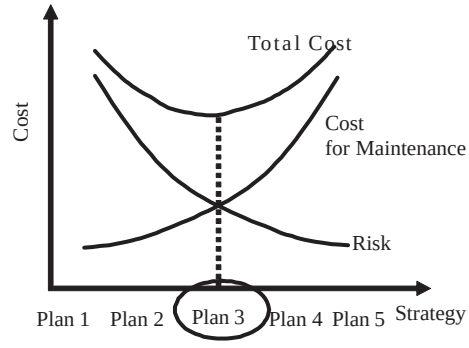

Figure 3. A concept of risk management for maintenance.

for example money, and to deal with quantitatively. In the report, the risk is formulated into Equation 1.

Provisos
Event Probability (P): Probability, which a supposed phenomenon happens
Importance (C): The amount of damage when the phenomenon happens

The method adopted in the case study aims to find an optimal maintenance strategy to minimize the expected "Total Cost", which includes costs and risks shown in Fig. 3.

In case of the investigation, it is important to keep the indispensable safety and reliance due to correctly quantify risks.

A procedure for preparation of a maintenance plan by the risk management is as follows:

1. Draft Preparation (Alternative plans for a period of inspection, method, method of countermeasure, timing of countermeasure, etc.
2. Modeling special qualities of the structure.
3. Extracting risks (With an event tree and scenario)
4. Evaluating for the probability of the risk (With the results of inspection, prediction of deterioration and other factors)
5. Evaluating importance of results (with an event tree and scenario.)
6. Evaluating risks
7. Comparison with the results from (1) stage to (6) stage of each plan

3 CASE STUDIES

3.1 *Subject model*

In the case study, optimal timing of repair was investigated for two imaginary tunnels, based on existing

Table 1. Component of model tunnels.

Item	Route A (A main line)	Route B (A local line)
Location	The old lines	The old lines
Number of trains	20 number/hour	1 number/hour
Length of a route	14 km	65 km
Average number of passengers	65 people/car	12 people/car
Compose of coaches	16 m a six-car train	16 m a three-car train
Length of a tunnel	1008.8 m	1008.8 m
Ground condition	Uniform	Uniform
Proceeds	40 billion yen/year	3.8 billion yen/year

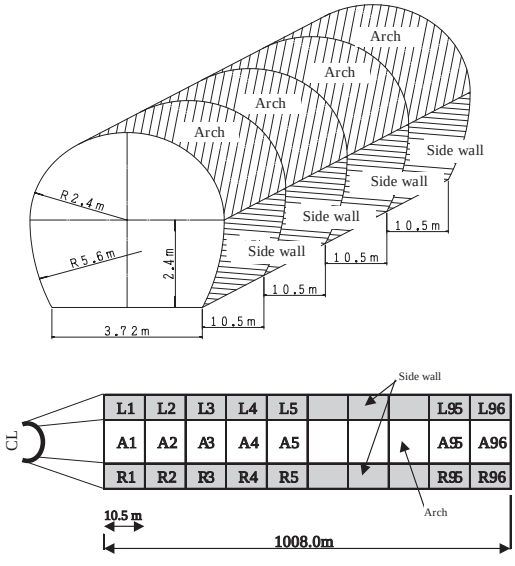

Figure 4. Modeling of tunnel.

data of various actual tunnels applying the above-mentioned method. One is located in a mainline and another is located in a local line as shown in Table 1.

The tunnels are assumed 30 year old. An actual tunnel has various unfavorable problems, for example leakage, deformation, deterioration of material, etc. However, to simplify the problems, only spalling of concrete blocks from tunnel lining was investigated in the case study. We assumed that the size of a concrete block is about 50 cm*50 cm*50 cm. For consideration, we divided a tunnel into many elements as shown in Fig. 4, and finally summed up the results of each element.

3.2 *Calculation of event probability*

A probability of spalling is estimated with a structural integrity classification of tunnel lining (Table 2) applied by many railway companies, because the probability of spalling depends on a condition of a structure. In the case study, the probability of spalling is estimated by previous inspection data assuming that the probability is constant in a similar rank of the integrity classification, as shown in Table 3.

Since tunnel linings are deteriorated due to various causes, the characteristic of deteriorations cannot be necessarily clarified. Accordingly, we assumed that the laws of probability dominate the deteriorating condition of the structure lead by regular inspections is dominated by the laws of probability, and evaluated the characteristic of it. When it is assumed that the state of the structure at time t_n depends on only the state of the structure at time t_{n-1}, (Markov chain), a transfer matrix, which indicates the possibility of the deteriorating progress due to data of past inspections, can be created for the state set up separately, (i.e. ranks from S to AA). Table 4 shows an example of the transfer matrix. The rank of the integrity on a lateral axis shows the condition of one year and it on a vertical axis means the state of the next year. For example, the matrix transfers the state of an element, which is rank S in a year, to the state, which 92.3% of it is rank S and 7.7% is rank C in the next year.

In the report, the transfer matrix was made by inspection data for the previous 30 years of a certain tunnel. In another word, values of the result are for only the tunnel, and other estimation is necessary as for another tunnel.

Figure 5 shows an estimated deterioration curve calculated by the transfer matrix. It indicates the distribution of annual ranks in the structural integrity classification.

In the deteriorating process of a tunnel is modelled by Markov chain. However, if deterioration could be estimated quantitatively due to progress of studying on a mechanism of lining deterioration, the estimation become accurate than it in the report. Next, calculation is made for each element of the tunnel as shown in Fig. 4, and sums the results; and a probability of spalling in the future is calculated.

3.3 *Calculation of importance and risk of event*

When listing facts use either the style tag List signs or the style tag List numbers.

The importance of the event and the damage by spalling cannot be classified easily, because various situations are supposed, for example, “only spalling with no damage”, “hit on a train”, “break signal facilities”, “hit on a person”, etc. However, if the events are verified neither too much nor too little, the amount of damage due to the event cannot be supposed. Moreover, if probability of event and of damage is analyzed enough, the amount of damage due to the event cannot be supposed. Then, with an event tree, we selected all

Table 2. Structural integrity classification of railway structure.

Classification	Influence on driving safety	Deformation	Measure
AA	Danger	Serious	In no time
A1	Danger in time	Progress of deformation and deterioration of performance	Immediately
A2	Danger in future	Apprehension about deterioration of performance when deformation is progressing	In case of need
B	Become rank A when unfavourable state is progressing	Become rank A when unfavourable state is progressing	Observation
C	No problem in the present	Minor deformation	Inspect some point
S	No problem	Nothing	

Table 3. An example of assuming probability of spalling.

Examples of assuming probability of spalling
AA: 3.3%/year*place
A1: 0.33%/year*place
B : *****
An example:
1. Grounds for a probability of spalling in case of rank AA
2. Assuming that four fifth of the spallings happen in case of rank AA
3. Assuming that total length of parts of the rank AA in the railway tunnel is about 300 m
4. Divide into arch and sidewall each 10.5 m
((12/4/300)*(10/3) = 3.3%

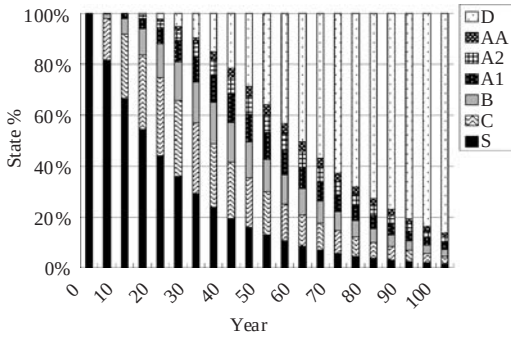

Figure 5. Estimated deterioration curve calculated by transfer matrix.

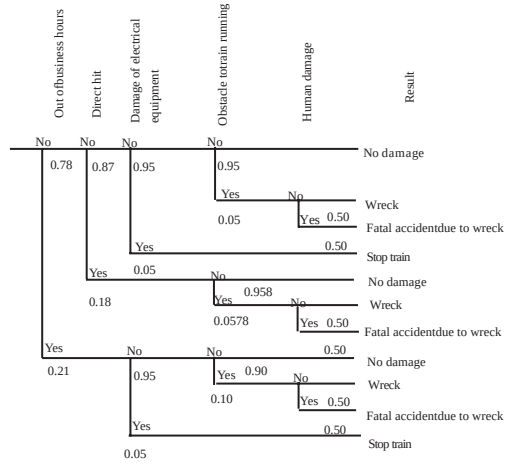

Figure 6. An example of an event tree.

Table 4. An example of transfer matrix.

N / N+1	S	C	B	A2	A1	AA

unfavourable problems due to spalling, and calculated its probability and the amount of the loss.

Next, multiplying the results, we estimated the risk A (predicted loss) due to spalling.

Figure 6 shows an example of an event tree. The event tree is the method picking out all unfavourable problems as follows: set the starting phenomenon on the left end, draw considerable choices in sequence and branch to lead many results. A probability of change is given to each factor changing a phenomenon, and the probability of the phenomenon due to plural factors is connected with the lost cost due to the phenomenon.

Throughout multiplying the risk A by probability of spalling, an annual risk was calculated (Fig. 6).

Incidentally, values themselves in Table 3, 4 and Figure 3 are not important, because the values were led

Probability	A sum of money (million yen)	Risk A (million yen)	Business loss (hour)	Human loss[*3] (%)	Material loss (million yen)
0.62	40		6		
0.02	510	8.34	19		400
0.02	1,000	16.27	19	0.05	400

by a limited data including some assumption. Please refer only to the procedure.

3.4 *Comparative investigation (repair timing)*

In this case study, the difference of risk and a total cost due to various repair timing were investigated. Five plans, which are shown in Table 5, were compared with each other to determine optimal repair timing in proportion to the degree of structural integrity evaluated by regular inspections.

No remedy has been considered for Plan #1. Plan #2 requires a measure (b) in the case of rank A1 and up. A measure (a) is applicable to Plan #3 in the case of rank A2 and up, and a measure (b) is taken in the case of rank 1 and up. The measure (a) is an injection. The measure (b) added a back filling in an emergency to the measure (a).

Figure 7 shows cumulative total costs of the main line. Figure 8 is annual risks of the main line. In view of the foregoing figures, the alternative 5 (the measure (c) taken) is the best among others as shown in Fig. 8 for busy lines if only a decrease in annual risk considered.

However, in the case of 50 years, a cumulative total cost of the plan 4 is the minimum, as shown in Fig. 7.

The risk under the plan 4 is not so extensive to compare with that of the plan 5; the plan 4 can be determined appropriate in general view. The repair cost required for the plan 5 from earlier stage becomes expensive. Where repairs are made on a late timing under the plans 1, 2 and 3 respectively, a higher risk is highly anticipated.

Figure 9 shows a cumulative total cost required for inactive local lines while Fig. 10 shows risk variation anticipated in each year.

Table 5. Each plan for repair timing.

Item	State	Plan#1	Plan#2	Plan#3	Plan#4	Plan#5
Repair timing	S	No	No	No	No	No
	C	No	No	No	No	Measure a
	B	No	No	No	Measure a	Measure a
	A2	No	No	Measure a	Measure a	Measure a
	A1	No	Measure b	Measure b	Measure b	Measure b
	AA	No	Measure b	Measure b	Measure b	Measure b

Measure a: Injection.
Measure b: Added a backfilling in an emergency to the measure (a).

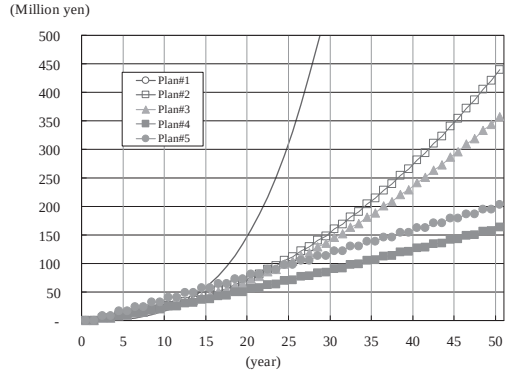

Figure 7. A cumulative total costs of the main line.

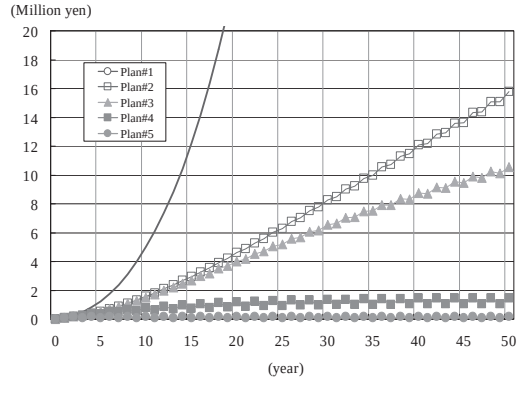

Figure 8. Annual risks of the main line.

For tunnels of inactive local line in terms of 50-year service, it is apparent that the plan 4 is the most appropriate, however, in terms of 20-year service, the plan 3 is another appropriate plan.

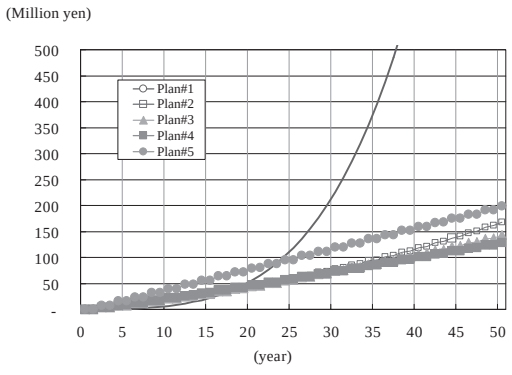

Figure 9. A cumulative total costs of the local line.

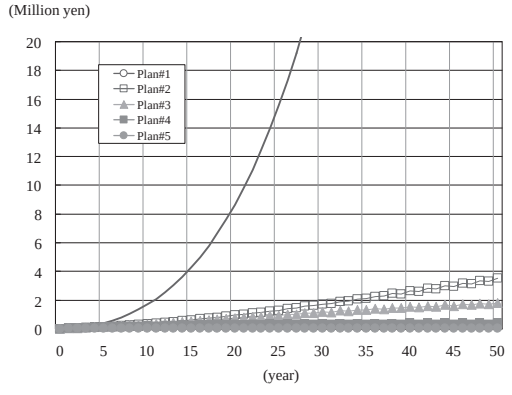

Figure 10. Annual risks of the local line.

4 CONCLUSIONS

We have established a model case based on the concrete results of inspections and repairs, and made a study on a substantial procedure to plan for the tunnel maintenance with the risk management technique. We pay attention to reduce an additional work by applying various data obtained through routine work. We evaluated each plan to compare annual risks and total costs of plans with different repair timings. It is conceivable that we can offer a concrete image of risk management to give examples.

We would like to collect more examples to solve the above-mentioned problems, and improve the accuracy of the method for future application.

Reconstruction of the Jablunkov tunnels

J. Korejčík & J. Růžička
Metroprojekt Praha, Prague, The Czech Republic

ABSTRACT: Reconstruction of two parallel single-rail tunnel tubes had to be designed, as part of the Third Railway Corridor Modernisation Project, in the Czech Republic-Slovakian border section of the corridor. The client wished the old tunnel lining to be replaced and the tunnel clearance enlarged in both tunnel tubes. In view of operational and technical calculations, the authors of the design proved that a single-rail operation mode will be acceptable during the reconstruction period; they designed a new solution, which is based on reconstruction of one tunnel tube only, which is to be rebuilt into a double-rail tunnel with a total length of 612 m. The design reasonably utilises the existing tunnel as an initial excavation sequence, which also allows the part of the rock mass which got loosened after the tunnel destruction during World War II to be improved in advance. In addition, at the time of the top heading excavation, the tunnel will be used for removal of muck by rail. After the new tunnel is put into operation, the old single-rail tunnel tube will be closed.

1 INTRODUCTION

The Jablunkov tunnels are found near the municipality of Mosty u Jablunkova, in the Moravian-Silesian region, in the north-eastern corner of the Czech Republic. The state border with Poland and Slovakia is close to this place. The tunnels were built under a mountain pass lying at the altitude of 552 m above sea level. The pass is hammed in between the crests of the Moravian-Silesian Beskydy Mountains and the massif of the Silesian and Slovakian Beskydy Mountains. The divide between the Black Sea and the Baltic Sea runs along the pass. This location has always represented a connecting line between the northern Moravian industrial region with its coal mining and steel production centre, the city of Ostrava, and north-western Slovakia with its strategic centre, the city of Žilina, which is linked to the capital of Slovakia, Bratislava, from the south and to the industrial centre of eastern Slovakia, the city of Košice, from the east. Despite the splitting of former Czechoslovakia on 1st January 1993, the intensity of traffic on this railway line remains unchanged, today already within the European Union.

The 100-year service life of a pair of single-rail tunnel tubes which were built stepwise to allow the railway to overcome the pass is slowly drawing to the end. The decision to reconstruct the Jablunkov tunnels was given a boost by the fact that the line is part of the railway corridors being developed.

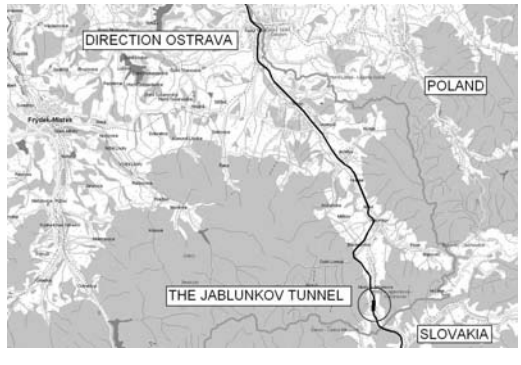

Figure 1. Location of the Jablunkov tunnel.

2 HISTORY OF THE JABLUNKOV TUNNELS

The Jablunkov I (Kalchberg) tunnel was built in 1870 as part of the Košice – Bohumín single-track line, which linked the Ostrava region in northern Moravia with the Košice region in eastern Slovakia. The second track in the Èadca – Jablunkov section was built, in the effort to accelerate and make the operation of the line more financially effective as long ago as 1898, however, without the tunnel. The Jablunkov II tunnel was opened as late as 1917. This construction began

in 1914 using the then modern standard Austrian Tunnelling Method (the Modified English Method) for the entire length of the tunnel. The tunnel was built using Beskydy sandstone from a nearby quarry.

The area of the Jablunkov Pass became the most unsuitable in terms of the vertical alignment of the track; initially, the 16‰ uphill gradient required additional pushing locomotives. In the beginning, coal transport from Ostrava represented nearly 90% of the transport; the transport of grain, rape, fruits, cattle, wood, gravel, ore and other materials started later.

At the beginning of the World War II in1939, charges were set off in both tunnels causing a daylight collapse. A secondary road leading above the tunnel also sank down. The cavity was backfilled and the damaged lining renewed in 1940.

The following years saw the completion of the doubling and electrification of the entire length of the track. The tunnels were partially reconstructed several times, the last time in 1999. Some sections were re-built and some were provided with an invert. Apart from this, drainage boreholes, re-pointing of the masonry and grouting, both into and behind the lining, were carried out. Water collecting drains were installed between some of the tunnel blocks to evacuate water from the external face of the lining. In 1971, the trackbed in the tunnel was replaced by a system with sleepers embedded in concrete. This system, however, had not acquitted itself well. For that reason it was replaced by traditional wooden-sleepers and ballast trackbed in 1987.

3 GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

The bedrock in the north-western part of the area of operations is part of a Cretaceous Silesian unit consisting mainly of the Istebné Sand layers. In the south-eastern and eastern part of the location, the Pre-Quaternary bedrock is formed by Palaeogene Krosněny Member of the Silesian Unit, which means flysch-type alternation of calcareous sandstone and mudstone. Mudstone intercalated with sandstone prevails in the southern part of the location. The interface between the Istebné and Krosněny Members is faulted; the fault passes along the saddle, approximately in parallel to the tunnel centre line.

Due to the terrain configuration, there are several streams flowing down the surrounding slopes to the area of the mountain pass and supplying the area of the tunnel cover with water. The entire length of the tunnel tubes lies in the Palaeogene bedrock consisting chiefly of mudstone with irregular occurrence of clay layers and isolated sandstone intercalations. The cover is an about 2 m to 6 m thick layer of clayey loam, clay, made ground and sand with rock fragments, which is always saturated down to the interface with the Palaeogene bedrock. This means that the tunnel tube is completely submerged under the water table. The water penetrates to this level along faults in the environment which is otherwise little permeable or impermeable. The locations where water seeps to the tunnel structure depth correspond partially with the locations of surface watercourses, or with terrain depressions where long-standing accumulation of surface water occurs. The intensity of seepage follows the intensity of local rainfall with a certain delay.

4 DESCRIPTION OF CURRENT CONDITION

The Jablunkov I tunnel is 606.58 m long. The length of the Jablunkov II tunnel is 608.20 m. Both single-rail tunnels are straight in the ground plan. They are of the summit type, with a maximum gradient of 8.1‰. The overburden thickness reaches 24 m. The clearance height and width of the tunnel tube amount approximately to 6 m and 5.5 m respectively. The safety recesses are provided on both sides of the tunnel, alternately at about 50 m spacing. The portal blocks of the tunnel, including the front walls and wing walls, are made of the Beskydy sandstone, the same as the tunnel tubes.

The tunnel drainage is provided by hand-placed rubble behind the outer surface of the lining. The water is directed from the drains transversally to the main 400 mm-diameter tunnel drainage duct built in the centre of the tunnel bottom. The longitudinal gradient of the duct declines toward both portals. The waterproofing system consists of cement screed spread on the outer surface of the masonry lining, which is covered with corrugated steel sheets. The waterproof covering of the reconstructed sections was provided by asphaltic boards.

The Jablunkov tunnels are electrified; the design speed for the given section is 80 km per hour. The clearance envelope does not comply with the requirements for an electrified track.

5 DEVELOPMENT AND RECONSTRUCTION OF THE TUNNELS

The Jablunkov tunnels are parts of the railway corridor III Cheb – Plzeň – Prague – Česká Třebová – Ostrava – the state border with the SR. In particular they lie in the Dětmarovice – Mosty u Jablunkova – the Slovakian state border section, which is important for the connection of the transit corridor II Warsaw – Vienna with the Slovak Republic. The tunnels will be reconstructed in the framework of the construction lot "Optimisation of the SR state border – Mosty u Jablunkova – Bystřice nad Olší track section". The design documentation for issuance of the zoning and planning decision for this construction lot has been approved and the work on

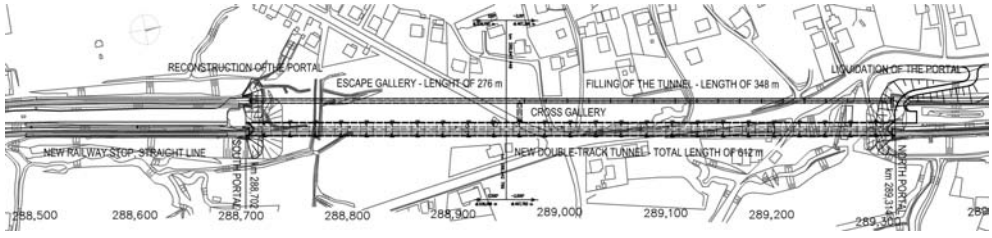

Figure 2. Tunnel layout.

the final design is in progress. The tunnel construction is expected to start in 2008 at the very earliest. The optimisation of this section even places increased demands on the Jablunkov tunnels. The design speed will be increased there to 120–140 km/hour for traditional trains, and to 140–160 km/hour for trains with tilting bodies. The vertical alignment must be modified and the tunnel cross-section enlarged. The overall reconstruction is necessary also because of the unsatisfactory structural condition of the tunnels.

The original solution which was under consideration in the regional planning and technical study assumed that both tunnels would be reconstructed to form a pair of new single-rail tunnels. The liners would have to be removed, then the profile of each tunnel tube enlarged and new liners erected. METROPROJEKT Praha, a. s., the designer, submitted a new solution where the Jablunkov II tunnel was enlarged and relined to form a double-rail tunnel. The Jablunkov I tunnel was proposed to be closed once this tunnel has been brought into service. However, a non-standard requirement for excavation of an escape gallery for the new double-track tunnel was imposed by the Fire Rescue Service of the Moravian-Silesian region during the comments-negotiation period. The client eventually accepted the requirement. According to the redesigned layout, only a part of the single-track tunnel will be closed and the remaining part plus a newly built cross passage will be utilised as the escape gallery.

The advantage of this new solution is, among others, the savings in the time required for the reconstruction of the tunnels, therefore also a shorter time for closing traffic, which will be required only for one track; the problem of staggered closing of the tunnels is thus removed. An economic assessment of the two variants, including associated structures, was carried out with a conclusion that the new solution is nearly by CZK 90 million cheaper. This saving is sufficient to cover the costs of closing the abandoned tunnel and the increased cost of the work on the preportal sections. The extension of the free space at the portals will render better conditions for the development of access roads for emergency vehicles. Owing to the existence of A straight section of the double-rail track in front of the southern portal of the new tunnel, it is possible to develop a new intermediate station Mosty u Jablunkova, which will replace the current intermediate station, which is inadequate because of its position in a curved track section. Another benefit of the new solution is a possibility of utilising a portion of the muck of the current tunnel for the backfill of the tunnel section that is to be closed. This material will be deposited on an intermediate stockpile near the portal, thus the transportation cost will be minimised.

6 THE TUNNEL PROFILE ENLARGEMENT TECHNIQUE

The newly designed Jablunkov double-rail tunnel is 612 m long; it is provided with an escape gallery. The track centre distance is 4 m; the horizontal tunnel alignment is straight. The axis of the new tunnel is shifted toward the other (single-rail) tunnel tube, to a distance of 4 m from the old single-rail tunnel. Regarding the gradient, the tunnel is of a summit type with an uphill and downhill gradient of 2.00‰. The inner radius of the tunnel vault is 5.7 m. There are safety recesses on either side of the tunnel at intervals of 24 m. Because of the rock environment consisting mainly of very weak and squeezing prone mudstone, the invert will be provided along the entire length of the tunnel.

6.1 *The mined tunnel section*

The excavation of the 588 m long mined section of the tunnel will be divided into three phases. The first phase will comprise the excavation of the entire length of the top heading together with the installation of the primary shotcrete support. In this phase, the existing single-rail tunnel will be utilised as the initial partial excavation of the bench. The muck from the top heading can be transported by railway wagons via the old single-rail tunnel up to the final dump. The second phase will comprise stepwise demolition of a major part of the old tunnel structure. It will be carried out concurrently with the excavation of the remaining part of new tunnel profile, while the external side wall of the existing tunnel will be incorporated into the primary lining of the new double-rail tunnel. Subsequently the whole profile will be provided with primary shotcrete support. The closed intermediate

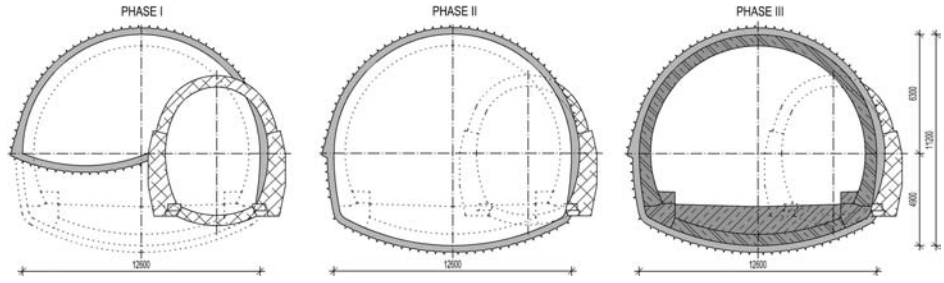

Figure 3. Driven technology of the tunnel.

waterproofing system will be installed and the final tunnel liner cast in the third phase.

The New Austrian Tunnelling Method is designed for the excavation. Application of the drill-and-blast technique is expected for partial operations. Mainly for the demolition of the existing tunnel lining. Weaker mudstone zones will be disintegrated mechanically using tunnel excavators. The excavation will be divided using a horizontal sequence of the headings. The size of the partial excavation faces is sufficient for the operation of high-performance tunnelling equipment. There is an assumption based on the geotechnical survey that the excavation in the mined sections will be categorised as support classes 3, 4 and 5. The theoretical excavated cross-section area ranges from 116.1 m^2 to 129.9 m^2. The primary support consists of C 16/20 sprayed concrete with welded mesh, lattice girders, rock bolts and forepoles. The thickness of the primary lining ranges from 150 mm to 350 mm, depending on the excavation support class. The mined portals are supported a 12 m long pre-support canopy.

The final lining of the mined tunnel, which is provided with an invert, will be constructed in two phases, using a travelling form. The invert will be cast first, the casting of the vault with side walls will follow. The length of the casting blocks is 12 m. The final liner is designed to be made from cast-in-situ reinforced concrete of C 25/30 grade; the thickness ranges from 400 to 600, depending on the excavation support class encountered. It was calculated for the ground water head, therefore there is no need for maintaining a permanent drainage system behind the outer surface of the lining. The concrete reinforcement consists of lattice arches, welded mesh and strap pieces if needed. Tied-up reinforcement is used for the invert, whose thickness is the same as the thickness of the lining. The gap between the invert and gravel ballast is filled with non-structural concrete. The intermediate waterproofing system is designed to be of a closed type, which means that it covers the entire tunnel circumference and no permanent longitudinal toe drainage is necessary. This system, in contrast with an unclosed system of the umbrella type, prevents a long-term impact on the natural regime of ground water in the vicinity of the tunnel. The draining of the tunnel interior is provided by the central drainage duct (a PE pipe 400 mm in diameter), which carries water to both portals. This duct is located in the centre of the tunnel profile, under the trackbed; it is embedded in porous concrete.

Walkways are provided on both sides of the tunnel; steel handrails are fastened to the tunnel lining. The lines of the handrails are broken at the safety recesses. A multi-way PE cable duct is embedded in each pavement. The cable duct is cut by manholes containing outlets for electrical equipment. In addition, there is a dry fire main embedded in one pavement (a 110 mm-diameter PE pipeline), which is fed with water from shafts built in front of the portals.

The numbers of all tunnel blocks, safety recesses and escape routes and their distance from the closest portal or escape gallery will be marked in the tunnel. There are oblique guide-strips interconnecting the neighbouring safety recesses designed with the aim of facilitating safe movement and search for a shelter in the tunnel. The marking will be painted on the internal surface of the final lining. Sign tables will be imprinted into the concrete surface during the casting.

6.2 *Cut-and-cover sections*

Both cut-and-cover entrance sections are designed at a length of 12 m, which corresponds to the length of the portal tunnel block. The sides of the open cuts will be stabilised by shotcrete reinforced with welded mesh. The portal wall of the construction trenches will have additional support in the form of anchoring.

The final lining of the cut-and-cover tunnel sections will be erected after the casting of the mined tunnel blocks has been finished. The same travelling formwork is planned to be used for both the mined and cut-and-cover sections of the tunnel; formwork for moulding of the outer surface will be added in the cut-and-cover sections. The cut-and-cover portal sections which are provided with the invert will be cast using C 25/30 water retaining concrete. The front ends of these sections are slanted and provided with flanges preventing rainwater from spilling over the edge.

Figure 4. Placement of the new double-track tunnel.

The thickness of the lining as well as the invert is 600 mm. Tied-up reinforcement is designed.

The design of the new portals is simple in terms of the style; the slant copies the surface of the grassed over terrain. Their incorporation into the surrounding landscape is very natural and unforced. Access roads will lead to both portals within the framework of the fire protection system. They will terminate at mustering areas provided for fire rescue service equipment and emergency vehicles.

7 CONSTRUCTION OF THE ESCAPE GALLERY AND CLOSURE OF A PART OF THE TUNNEL

All modifications of the existing single-rail Jablunkov I tunnel will be carried out only after the new double-rail tunnel has been commissioned. The beginning of the 276 m long escape gallery is at a safety recess found approximately in the middle of the double-rail tunnel. The escape route leads through the newly built 18 m long cross passage to the unused single-rail tunnel and ends at the southern portal of this tunnel.

The horseshoe shaped profile of the cross passage will be excavated using the NATM, with the primary support consisting of C 16/20 sprayed concrete, mesh, rock bolts and lattice arches. An 8 m long canopy tube pre-support will be installed from both sides of the cross passage.

The main reinforcing elements of the C 25/30 reinforced concrete final lining and invert will be transverse lattice girders and mesh. The vault and side-wall lining is 200 mm thick, while the maximum thickness of the invert is 500 mm. The casting of the final lining of the cross passage is expected in two phases, i.e. casting of the floor and of the vault and side walls. The closed waterproofing system designed is the same as that designed for the tunnel.

A 16.5 m long air-lock chamber will be installed in the cross passage. It is separated from the tunnel by a 2.2 m wide fire resistant door, and from the escape gallery by a steel door with the same dimension. The air lock is positively pressurised by a forced ventilation system independent of the escape gallery ventilation system to prevent smoke entry from the tunnel to the escape gallery.

Regarding the part of the Jablunkov I single-rail tunnel which will be utilised as the escape gallery, the first operation will be the removal of the ballast and proper treatment of the tunnel lining surface. The following phase will comprise installation of a closed waterproofing membrane system and construction of the 350 mm thick C 25/30 final lining. Travelling formwork will be used for casting of the 123 m long tunnel. The escape gallery will be terminated by a concrete bulkhead with a door passable only in the direction of escape.

The interior of the northern part of the single-rail tunnel will be thoroughly filled mostly with the muck from the new tunnel excavation, which will be temporarily stored in an intermediate stockpile. The remaining part of the cross section will be filled with cinder concrete, section by section. The space which will be developed when the process of the cinder concrete setting and shrinkage has been over will be filled by grouting. The drainage effect of the currently existing tunnels will be significantly reduced owing to the grouting and waterproofing membrane; the water table should return to the natural long-standing level.

The final action will be the demolition of the northern portal, including the skew wing walls, and final finishes of the slopes and sowing grass seed. The southern portal with a sign “Kalchberg 1870” will be rehabilitated and maintained as a technical monument for future generations.

8 CONCLUSION

The design expects that the tunnel profile will be enlarged even in adverse geological conditions. It reasonably takes advantage of the possibility to utilise the existing tunnel to serve as the initial partial excavation, which, at the same time, allows transportation of muck from the top heading excavation by rail to direct deposition in other parts of the construction lot in question where new backfill is to be carried out. In addition, this solution allows relocation of the Jablunkov – Mostly intermediate station to a place meeting operational requirements. At last but not least, the design allows deployment of high-performance excavation equipment, thus cutting the construction time. The application of the closed waterproofing system means that the hand-placed rubble drainage behind the tunnel lining can be eliminated. The favourable effect on the natural hydrological regime in the tunnel overburden is obvious.

Upgrading old masonry interceptor sewers to modern sewerage standards

Cezary Madryas, Arkadiusz Szot & Leszek Wysocki
Wroław University of Technology

ABSTRACT: A short history of brick interceptor sewers, surveys of sewer technical condition and analyses of its deterioration and ways of upgrading old masonry interceptor sewers to modern environmental standards and mechanical loads are presented. Both difficulties and benefits of such upgrading are considered. Most of the rehabilitation technologies used in Poland are described in detail in included case studies.

1 INTRODUCTION

A considerable part of the sanitary drainage network in Polish cities is well past its 50-year design service life and the boundary conditions formerly adopted when designing sewers and the associated facilities are much different from the conditions in which the structures serve today. This is especially true of brick sewers built at the turn of the 19th and 20th centuries. In Poland the first comprehensive sewage system design was developed for Gdańsk by the German engineer Friedrich Webe. The project was completed in 1871. But the historical development of sewerage systems in Polish cities should be mainly associated with the engineer William Lindley who designed the basic layout of a water supply and sewage system for Warsaw and his son Sir William Heerlein Lindley, DEng. who implemented the project. Sir William Heerlein Lindley's projects carried out in Poland include designs and their implementations as well as expert opinions relating to the provision of Łódź (1907–1909), Lvov (1909), Radom (1912) and Włocławek (1910–1914) with water supply and sewage systems [5]. Sewerage networks in the Western Territories (incorporated into Poland after WWII), e.g. in Wrocław, developed in a similar way whereas those in the Polish territory formerly under Austrian rule (e.g. in Cracow) developed somewhat differently.

Despite the exceptionally fine workmanship, the sewers are increasingly often damaged due to changed chemical, biological and mechanical loads and the passage of time. This often leads to failures of other structures, e.g. street surface cave-ins and the subsidence of buildings. The external factors causing damage to interceptor sewers are usually stochastic processes which are difficult to define. Predicting changes in their intensity over time is even more illusory than in the case of factors stemming from the sewer service function. Factors adversely affecting sewers include: mechanical (static and dynamic) loads, the chemical aggressiveness of the soil, biological aggressiveness (destructive action of bacteria, tree roots, etc.), the adverse effect of other structures (especially when they fail structurally or are under construction) as well as the effects of warfare, terrorist acts, disasters (e.g. floods) and seismic and paraseismic movements of the surrounding ground.

Surveys of sewers have been conducted by the Department of Urban Engineering of the Institute of Civil Engineering at Wrocław University of Technology since 1968. From the beginning of the 1990s the Department has also been designing trenchless reconstructions of brick sewers.

2 RANGE OF BRICK INTERCEPTOR SEWER INVESTIGATIONS

Sewers can be investigated by means of television cameras (closed circuit television) or by personnel working inside them. CCTV is mainly used in inaccessible non-walkthrough sewerage systems, but sometimes also in large-size interceptor sewers. In the authors' opinion, for all sewers CCTV investigations should be treated as merely tentative. The data acquired from such investigations provide only a qualitative picture of the damage without any quantitative parameters such as the width and depth of cracks or the depth of corroded concrete or mortar zones. By means of CCTV one cannot determine the actual strength or structural parameters and so no static strength analysis can be made. It is often the case, however, that the results CCTV examinations are considered as conclusive and a method of renovating the sewer is selected on their basis or even worse, they are used to dimension the liners. Therefore sewers, especially walkthrough interceptors, should be investigated from the inside and the investigations should include: a technical condition survey with

photographic documentation of characteristic damage (this corresponds to CCTV examinations), determination of the morphology of cracks and the depth of their penetration and determination of the depth of corroded mortar and brick zones; pull-off strength tests performed on the sewer's inside surface; taking samples of structural materials for laboratory tests, including chemical analyses of the composition of the structural materials (to determine the type of corrosion) and determination of their strength parameters; taking sewage, soil and groundwater samples to determine their chemical composition and aggressiveness towards the sewer structure; examination of the ground outside the sewer for voids, an analysis of the actual overburden loading; geodetic surveys of the grade line cross section and fall; geotechnical surveys.

Only on the basis of the data provided by such a wide range of investigations one can formulate a proper rehabilitation programme for the structure, which may cover: protection against the aggressive action of groundwaters, soil and sewage (it is particularly difficult to protect the sewer's outer surface), sealing the structure, strengthening the structure, correcting the grade line, filling in voids in the surrounding ground.

In some cases it may become necessary to replace the interceptor sewer.

3 TECHNOLOGIES OF RECONSTRUCTING BRICK INTERCEPTOR SEWERS

In Poland most of the brick interceptor sewers and associated facilities are in need of repair, which is made difficult by their location – sewers, manholes, connecting chambers and other accessories are situated under roadways. This was not a problem in the past when closing a street or two to traffic did not imply so great disturbance to the latter as today. Considering the congestion in cities and their transport inefficiency, sewerage system repairs are done now using almost exclusively trenchless technologies or techniques which limit excavations to minimum.

The shape, dimensions, technical condition and the current loading of interceptor sewers (including brick ones) usually make it necessary to strengthen their structure (reconstruction) which in Poland is usually done using trolining, short relining or the (close-fit) hardened sleeve technology.

Trolining consists in pulling a two-layered polyethylene sleeve into a sewer under repair. The sleeve's outer layer (preliner) is separated from its inner layer (inliner) by spacers whereby an empty space is created between the two layers. Once the sleeve is inserted, the empty space is filled with special injection compound. Spacer height is adjusted to a given sewer structure. In practice, 10, 13, 17 or 19 mm spacers are used. A modification of this technology consists in making a self-supporting reinforced concrete structure between the polyethylene sleeves, instead of injecting the compound. In this case, the preliner prevents sulphates from penetrating from the sewer structure to the reinforced concrete structure and the inliner provides insulation from the inside. Since the reinforced concrete structure carries loads its dimensions and reinforcement must be adequate to safely carry all the external loads. This modification has all the advantages of the trolining technology.

Short relining consists in inserting modules made (to order) of polyester resins and glass fibre, whose shape adjusts itself to the cross-sectional shape of the sewer under repair. This is very important in the case of brick interceptor sewers since they often have atypical cross-sectional dimensions. Liners made of other materials, e.g. PEHD, are used in sewers circular in cross section.

Through the insertion of a self-supporting lining the hardened sleeve technology allows one to increase the sewer's load-bearing capacity. The linings are made of synthetic fabric impregnated with resin. 'Soft' lining is introduced into a sewer using water column hydrostatic pressure or compressed air. Once inserted into the sewer and pressed against its inner surface, the lining is subjected to thermal (UV radiation) hardening treatment. The lining's load-bearing capacity, which depends on its thickness and fabric and resin parameters, is determined through a static strength analysis.

4 STATIC STRENGTH ANALYSIS

In order to reconstruct brick sewers one must introduce a load-bearing liner into them. Since there are no relevant Polish standards, usually the loads specified by German guidelines ATVA 127 [1] are used in static strength analyses. The authors do such calculations using the finite element method as implemented in COSMOS/M, making assumptions as for brickwork structures [2, 8, 9]. Because of the cross-sectional geometry and load symmetry only halves of the structure, for which the boundary conditions on the axis of symmetry ensure the symmetry of the solution, are considered. Segments of unit length along the sewer's axis are analysed. Systems are modelled by shell elements SHELL 4 with six degrees of freedom at each node. Figure 1 shows exemplary results of static strength computations of a GRP liner for reconstructing an oval brick interceptor sewer. The computations were performed for a 135×90 mm liner and the space between the liner and the sewer wall was filled with an injected compound with compressive strength not less than 5 MPa.

For the assumed liner wall thickness of 25 mm and an undeformable injected compound the following results were obtained:
displacement: the total short-term horizontal contraction in cross-sectional area is $2 \times 1.1 = 2.2$ cm which

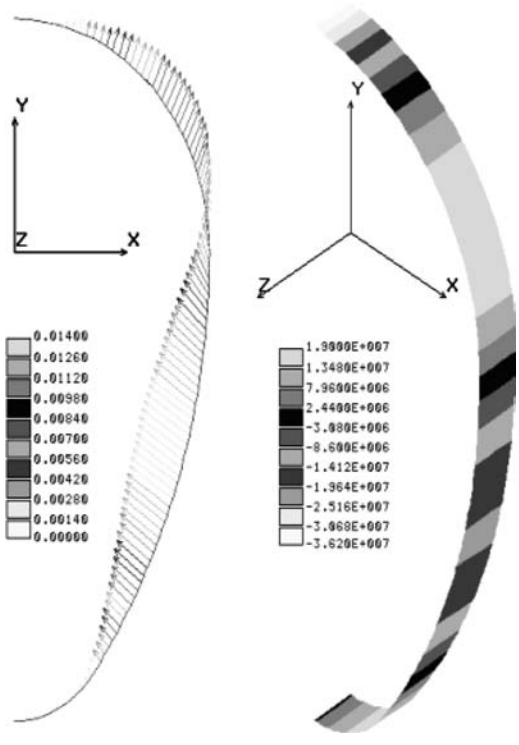

Figure 1. Exemplary calculation results for GRP liner: a – total displacement [m], b – normal circumferential stress [Pa].

amounts to $2.2/90 \times 100\% = 2.4\%$ and the long-term contraction is $2.4 \times 1.6 = 3.8\% < f_{perm} = 6\%$, maximum stress 36.2 MPa.

Special skills are required to design (determine the load-bearing capacity of) close-fit liners. Such liners are highly sensitive to cross-sectional geometric imperfections and on-site installation conditions. The former problem has been much investigated in the Institute of Civil Engineering at Wrocław University of Technology, which led to a PhD dissertation [10] whose selected results were published internationally [6].

5 CASE STUDIES

5.1 *Interceptor sewer in Pułaskiego Street in Wrocław*

Combined sewage interceptor Podwale was built in the second half of the 18th century. It runs in the embankment of the moat which encircles the southern side of the historic city centre. The sewer with a rather uncommon cross-sectional shape of an elevated circle (1.41×1.57 m) carries 500–1100 litres (even more during heavy rains) of sewage per second.

Figure 2. Fracture in interceptor sewer crown with structural displacement and brick loss in walls.

The interceptor sewer was constructed from two layers of brick, with meticulous care typical for sewers built in those times. Cement mortar was used as the binder. The interceptor's invert is 6.0 m underground. Its inspection manholes were also built from bricks and covered with cast iron plates. Because of its long service, the heavy war damage, the very poor quality of post-war repairs, the big change in traffic structure and intensity and the destructive action of roots of the old trees growing there the interceptor sewer had to undergo reconstruction. Pipes with a DN diameter of 1300 mm, made of epoxy resins with GRP fibres, were used as liners in the over 2 km long sewer section which first underwent reconstruction. The space between the old interceptor sewer and the new pipe was filled in stages with lightweight concrete introduced into sections not longer than 3–6 m to prevent the inner pipe from buckling under the pressure of the filler. In order to ensure continuous sewage collection along the interceptor sections undergoing rehabilitation, a floating pipeline made of PEHD was laid in the moat. All the works were supervised by a conservation officer.

The reconstruction went smoothly until May 2001 when during work on the last section of the interceptor sewer in the vicinity of the 1st of May Square it was found that the interceptor was fractured in the crown for a distance of about 25 m (the fracture was as much as 50 mm wide) and deformed to a degree hazardous to both the personnel working inside and the traffic on the roadway situated above the interceptor. In addition, it was found that the mortar in the brickwork joints had been washed out and weakened, the walls were damaged (missing bricks) and the invert was covered with an about 90 mm thick deposit of consolidated sludge.

The most dangerous damage to the interceptor sewer structure is shown in fig. 2.

In that situation reconstruction work was stopped and a temporary support structure for the interceptor was to be immediately designed to prevent it from

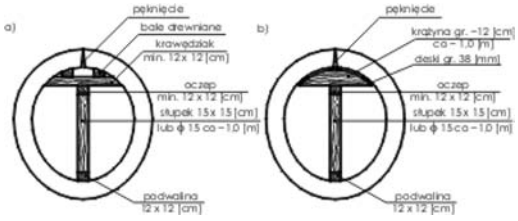

Figure 3. Scheme of temporary protection for interceptor structure. (fracture, wooden beams, square-sawn timber min. 12×12 [cm], capping beam min. 12×12 [cm], 15×15 [cm] post or ϕ 15 at every $\sim$1.0 m, 12×12 [cm] ground beam, $\sim$12 [cm] thick arch centre, 38 mm thick planks).

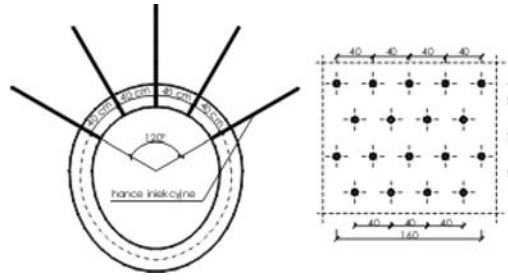

Figure 4. Location of anchors strengthening ground over interceptor sewer (injection lances).

collapsing until further repair work procedures were developed. The present authors were commissioned, via the Institute of Civil Engineering at Wrocław University of Technology, to prepare an expert opinion and to develop technical solutions.

The authors ordered a temporary support structure, consisting of wooden beams or arch centres and supports (wooden or steel posts with adjustable height), to be immediately made. A scheme of the protection is shown in fig. 3.

Before designing permanent protections for the interceptor (after the temporary protections had been constructed) the interceptor structure [4] and the surrounding ground [3] were examined to determine the causes of the damage. In situ investigations, laboratory analyses and calculations showed that the bad condition of the mortar and the bricks was the result of: the long action of sulphate corrosion (the sulphate content in brick amounted to 0.8 % and in mortar to 1.0–1.2%) due to the production of hydrogen sulphide following the decomposition of the organic matter deposited in the invert, the big change in traffic structure and loading in comparison with the 19th century design assumptions, loosening of the ground surrounding the interceptor sewer, in both the floor layer and above the interceptor.

Having analysed the condition of the interceptor and its surroundings and the results of the examinations, we concluded that personnel could work inside the interceptor after closing the street to traffic. Consequently, work was initially conducted only at night. First cavities in mortar and the fracture in the crown were filled in order to strengthen and seal the interceptor structure prior to petrifying (through injection) the surrounding ground to improve the foundation conditions and create a soil-cement vault which by taking over the traffic loading would make it possible to remove the temporary supports and finish relining.

Depending on the results of soil surveys, the subsoil was to be strengthened to a depth of 0.3 m along a distance of about 26 m and to a depth of 0.8 m along a distance of 41 m. The job was done from inside the interceptor by injecting cement slurry (with a predetermined composition) to bind loose sands and to obtain at least a medium subgrade compaction ($I_D \geq 0.5$) after cementation. Semiliquid fractions in local lens of soft-plastic aggradate mud were forced out by the injected cement suspension. It was recommended to perform injection using ϕ 30–40 mm lances (sealed in the interceptor structure) driven into the subsoil at every 1.0 m to a depth of about 20 cm greater than that of the injected zone. The tolerance of lance location in the cross section was set at $\pm 15°$. Slanting boreholes were to be shifted by about 0.5 m relative to the grid of vertical boreholes. Because of the bad condition of the interceptor, boreholes through its wall were drilled nonpercussively using diamond bits and small boring rigs. In total, in accordance with the adopted assumptions, there were to be: in the less deep (0.50 m) injection zone – 50 slanting boreholes and 25 vertical boreholes, with a total length of 37.5 m, which required 75 drillings 50–65 mm in diameter through the interceptor wall, with a total length of 18.75 m; in the deeper (1.0 m) injection zone – 80 slanting boreholes and 40 vertical boreholes, with a total length of 120.0 m, which required 120 drillings 50–65 mm in diameter through the interceptor wall, with a total length of 30.0 m.

Cement suspension with c/w = 1.0–2.0 (the optimum ratio was to be experimentally determined through trial injections) was to be injected. Pump delivery was adjusted to obtain a possibly low injection pressure of $0.1\,\text{MPa} < p < 0.3\,\text{MPa}$ for the set c/w ratio. The amount of cement slurry per borehole was determined on the basis of previous experience at: $0.08 < V < 0.25\,\text{m}^3$ for 0.50 m long boreholes, $0.10 < V < 0.35\,\text{m}^3$ for 1.0 m long boreholes.

The soil-cement vault was to be created along a 30.0 m long section after at least two weeks from the date of completion of subsoil petrification. The 'injection anchor' method was proposed for creating a load-bearing zone over the fractured crown of the interceptor. Such anchors were to be made on a grid with a mesh size of 0.40×0.40 m and shifted neighbouring rows. The location of anchors in the interceptor cross

Figure 5. Installation of liner.

section and a part of the layout of anchors are shown in fig. 4.

Boreholes in the interceptor structure, for introducing injection anchors into the ground, were to be drilled nonpercussively, similarly as boreholes in the floor layer. Their diameter was suitable for inserting steel pipes 0.5″ in diameter and 0.8 long into the ground. After sealing the boreholes cement slurry with an expanding agent (its amount was set in consultation with the manufacturer) was injected. Injection was conducted at very low pump delivery whereby pressure was reduced to $p < 0.3$ MPa. The amount of cement slurry with $c/w = 1.5$–2.0 was set at $0.20\ m^3$ per borehole (the amount was to be verified through on-site trials). Injections were done in the system: every other row and every other borehole in a row. In total, there were to be 6 anchors per borehole, which meant that at the assumed borehole spacing along the vault length of 30 m, 180 anchors had to be made. The temporary protections were to be disassembled two weeks after the completion of vault strengthening work. Only then the interceptor cross section could be calibrated in order to insert a liner into the sewer (fig. 5).

The described damage and the additional work enabling further safe reconstruction (using the relining technique) of the interceptor sewer show how important it is to precisely determine the condition of a sewer structure prior to repair work, especially when repairs are to be done by people working inside the underground structure and when the safety of the users of the streets situated above the sewer is to be ensured.

5.2 *Interceptor sewer in Kazimierza Wielkiego Street in Wrocław*

In July 2005 a part of the road surface of a major traffic artery in Wrocław caved in which made it necessary to close down one traffic lane in the street.

It was surmised that the cause of the damage was the bad condition of the interceptor sewer running under the street. Thus, as it is often the case in sewerage systems, invisible damage to the sewer resulted in visible

Figure 6. Examples of damages of the sewer channel. a. view of inside of interceptor sewer and fracture in its crown. b. view of damage to inside of brick inspection chamber.

damage to another structure – the street pavement. The present authors were commissioned, via the Institute of Civil Engineering at Wrocław University of Technology, to investigate the structures and to design their repairs.

The standard procedure applied in this case consisted in immediately carrying out a survey of the damage and a static strength analysis and determining the causes of the damage and ways of repairing it. The investigations covered the following structures: a reinforced concrete chamber built in the 1970s during the rebuilding of the city's transport system, a brick inspection chamber built at the beginning of the 20th century during the construction of the interceptor sewer, the oval brick interceptor sewer with dimensions $h \times b = 1700 \times 1200$ mm and a wall thickness of 250 mm.

The in situ investigations showed at fig. 6a: 3–7 mm wide fracture in the interceptor's crown, penetrating through its thickness and running along it for at least 55 m; longitudinal cracks in both walls at a height of about 500 mm above the invert, running for about 35 m; weakened mortar in brickwork joints to a depth of about 35 mm in the crown and to about 20 mm in the other part of the interceptor; weakened brick to a depth of about 15 mm; an about 0.14 thick sludge deposit extending from about 20 m from the reinforced concrete chamber to the end of the surveyed section; leaks between the sewers and the chamber; large caverns in the ground around the reinforced concrete chamber; two holes in the brick sewer and a hole 50 mm in diameter in the reinforced concrete chamber; serious damage to the brick inspection chamber: wall fractures with shifts (fig. 6b).

The in situ investigations were supplemented with laboratory tests of the interceptor structural materials' parameters and a static strength analysis of the interceptor structure. It was found that the technical condition of the interceptor sewer along a length of 75.03 m posed a serious construction disaster hazard.

Symptoms of exceeded limit load-bearing capacity, in the form of cracks in the invert channel and in the crown, were found. The cracks were the result of a considerable increase in load relative to the design load and deterioration of the interceptor structural materials due to corrosion processes.

Considering the local conditions, characterized by high traffic intensity, the City Road and Transport Authority gave permission to temporarily close to traffic only one of the three traffic lanes of the south-bound roadway. In practice, this meant that all the construction works, except for reconstruction of the street surface, were to be done using trenchless technologies. Short relining was chosen as most suitable for the reconstruction of the interceptor sewer in the local conditions. Made to order oval GRP modules with 1000×1500 mm inner dimensions were used for this purpose [11]. The short relining technology did not necessitate stopping the flow of sewage and building a sewage pumping installation and made it possible to carry out the works in a very short time. According to the static strength calculations, the liner had to be 27 mm thick.

Similarly as in the case of the Podwale Street interceptor sewer, extensive caverns in the ground around the reinforced concrete chamber had to be filled since they were the direct cause of the fracture and subsidence of the roadway structure. The caverns were filled using the jet grouting technique.

6 CONCLUSIONS

1. Because of their age and changed service conditions most of the brick sewers in Poland need repairs.
2. The brick sewers can be upgraded to current standards provided they are reconstructed.
3. In the case of streets with heavy traffic, sewers should be reconstructed using trenchless technologies.
4. The large number of existing trenchless technologies allows one to select a proper trenchless technology for any interceptor sewer under the present mechanical, chemical and biological loads.
5. The use of trenchless technologies, consisting in the insertion of a self-supporting liner into an interceptor sewer, upgrades the structural parameters of the sewer to its current service conditions.
6. The reconstruction of interceptor sewers should be accompanied by surveys of the surrounding ground and its reconstruction if it has been damaged by sewage exfiltrating and groundwater infiltrating for many years through leaks in the sewers.

The old railway tunnel of Mainz – A design and construction concept for the expansion of two approx. 150 year old tunnels in urban areas

Th. Marcher, G. Braun & F. Jiricny
ILF Consulting Engineers, Rum/Innsbruck, Austria

ABSTRACT: In the City of Mainz, Germany, the railway runs through two approximately 150-year-old tunnels to reach the main station. To update the railway line to European High-speed Railway Standards, the German Railway (DB) decided to expand and reconstruct the tunnels with larger cross sections. The two tunnels, approx. 660 and 290 m long and separated by an approx. 290 m long cut, are located within a very attractive urban area, beneath historical and new multi-floor buildings and hotels with shallow overburden. The underground mainly consists of Tertiary sands and clays, with limestone deposits. The old tunnel masonry and the backfill behind are contaminated due to environmental aspects. This paper presents the design and construction concept of this project under conditions of particularly shallow overburden with sensitive, built-up areas. To protect the buildings at the surface against damaging deformations measures like "push up" injections in the underground or pile walls for deformation limitation are foreseen. The different building protection measures and deformation limiting measures will be presented.

1 INTRODUCTION

Because of the sensitive project conditions the main issue is a design concept which covers all surrounding conditions with respect to the stability of the tunnel tube during excavation and with respect to consistent deformations of the surface. Therefore, the first part of this paper describes three-dimensional FE-calculations which show the varying ground and load-bearing behaviour when simulating various excavation methods (full face versus heading/bench excavation). Stress redistribution due to the relevant excavation procedure will strongly influence the deformations and the load transfer ahead of the excavation face. As a result of the numerical study an optimized excavation concept will be provided which minimizes any additional load on the old masonry tunnel and avoids damaging settlements at the built-up areas. In the second part, emphasis is placed on the construction concept with respect to shallow overburden and a limited time frame of 3 years for realization of the project.

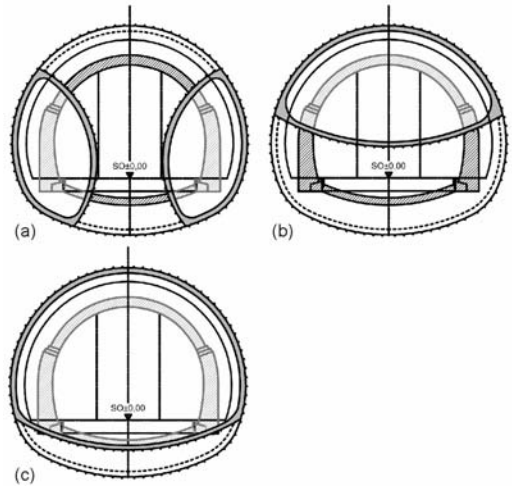

Figure 1. Excavations concepts.

2 EXCAVATION CONCEPTS

During the conceptual design phase various excavation sequences have been discussed. Three of the concepts are illustrated in Figure 1.

The first one considers a "side-drift excavation" followed by the excavation of the core (Figure 1a). The second one assumes a "temporary top heading invert" bedded on backfill to be provided within the area of the old tunnel (Figure 1b). The third concept assumes a "heading/bench excavation" with a quick invert closure, i.e. a full bench excavation is followed by the final invert excavation in a max. distance of 20 m (Figure 1c).

3 ADDITIONAL EXCAVATION MEASURES

Due to the particularly shallow overburden with sensitive built-up areas additional measures like "push-up" injections in the underground to compensate settlements directly above the excavation and installation of pile-walls parallel to the tunnel axis to limit deformations of buildings next to the tunnel axis are required.

4 GEOLOGY

The general stratigraphy comprises artificial fill material of various thickness underlain by tertiary sediments consisting of clay/silt layers, occasionally with silty sand and gravel lenses as well as limestone deposits.

The groundwater level is generally located below the invert.

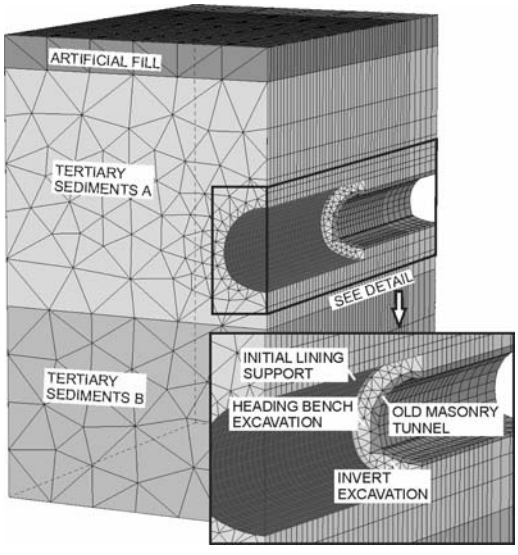

Figure 2. 3D FE-model of excavation concept 1a.

5 NUMERICAL ANALYSIS

5.1 *Tunnel geometry*

The old tunnel built as a "horse-shoe shaped tunnel" approx. 150 years ago was constructed according to the "Old German Tunnel Method". The tunnel has a min. height of approx. 6.5 m and a width of approx. 7.5 m. The tunnel masonry walls have a thickness of 0.6–0.7 m above the crown and increase to 0.8–1.0 m at the abutments. A flat invert arch has been built (approx. 1.5 m below line level). The equivalent tunnel area is 44 m^2.

The new cross section is typical for a single-track train tunnel in Germany. The height is approx. 7.5 m and the width approx. 11 m. The invert arch will probably be approx. 3 m below top of rail. The equivalent tunnel area will be 74 m^2, resulting in a theoretical tunnel diameter of approx. 5 m.

5.2 *FE-model*

The 3D Finite Element program "Plaxis 3D Tunnel" is used for the calculations, Brinkgreve et al. (200l). Because the geometry is symmetric, only half the boundary problem needs to be considered. The circumferential boundaries are restrained in both x and y directions. The ground surface is free to move, the bottom of the model is fully fixed. The dimensions of the FE mesh are chosen in such a way that the impact of the cavity on the edges of the FE mesh has subsided. The length of the model depends strongly on the excavation method and has to be evaluated depending on the relevant excavation phases in longitudinal direction. The ground is modeled with 15-noded wedge elements using the Hardening Soil model. This constitutive model is an advanced model for simulating shear hardening and compression hardening independently of each other. The stiffness is formulated stress-dependent and a distinction is made between first loading and un-/reloading, see Schanz (1998).

The tunnel masonry wall is also modeled with continuum elements using the Mohr-Coulomb model to simulate the masonry behavior. Beam elements are used to model the new shotcrete lining. Rock bolts, steel ribs and steel spiles are not included in the numerial calculations. No support ahead of face is considered.

The final lining is not taken into account as it will be installed after the lining deformations of the initial support have subsided.

5.3 *Calculation sequences*

A "step-by-step" tunneling sequence is applied using the phased analysis option available in the FE program used. The in-situ stress state is followed by the simulation of the excavation of the old tunnel. Next, compensation grouting is simulated using volumetric strains in the FE soil clusters.

Finally the individual excavation phases for heading, bench and invert each with separate application of "young/mature" shotcrete are considered.

5.4 *Ground and material properties*

The properties of the various formations are based on the site investigations carried out and summarized in table 1.

The stiffness parameters are listed for a reference stress of $\sigma_{ref} = 100\,kN/m^2$. A unit weight of

Table 1. Ground and material properties.

	Strength		Stiffness		
	c [kN/m^2]	φ [°]	E_{50}/E_{ur} [MN/m^2]	m [–]	ν_{ur} [–]
Artificial fill	0	27.5	100/–	–	0.3
Tertiary sed. A	20	20.0	25/75	0.5	0.2
Tertiary sed. B	20	20.0	40/120	0.5	0.2
Fill material tunnel	0	37.5	50/150	0.5	0.2

$\gamma = 19$ kN/m^3 is assumed. The initial stress conditions in the ground are defined by the overburden (20 m used for the present calculation section), by the unit weight and by the coefficient of lateral earth pressure at rest $K_0 = 0.5$.

In order to model time-dependent behavior of shotcrete (creep and hardening) two stiffnesses of the shotcrete lining are taken into account, i.e. John et al. (2003). For a short time after tunnel lining installation "young" shotcrete with E = 7500 MN/m^2 is used. For a long-term period "mature" shotcrete with E = 15000 MN/m^2 is applied. This change of lining properties is activated 3–5 round lengths behind the face, which corresponds to a shotcrete age of approx. 2–3 days.

The old tunnel masonry is characterized by an elastic module of 5000 MN/m^2, a Poisson ratio of $\nu = 0.1$, a unit weight of 22.5 kN/m^3 and a cohesion of 4 MN/m^2 (assuming zero for the friction angle φ). The compressive strength which results from this approach fits well to test results. Tensile strength is eliminated by a "tension-cut-off" criteria.

5.5 *Numerical results*

5.5.1 *Stress arching*

Every excavation state implies a change of the stresses and strains around the tunnel. Especially intermediate construction stages are subject to the greatest amount of stress as the disturbance is not yet fully supported by the lining. Generally the pre-existing stresses in the rock mass will be deviated by the tunnel excavation and will be channeled around the tunnel. This redistribution of stresses takes place as (see Figure 3):

(a) arching effect around the tunnel
(b) arching effect along the tunnel axis
(c) Dome effect in front of the tunnel

Arching effects around the tunnel (Figure 3a) are already mobilized due to the excavation of the old tunnel. The widening of the old tunnel increases this effect. The dome effect in front of the new tunnel is affected by the existing old tunnel. The resulting mean effective stresses around the new tunnel lining will

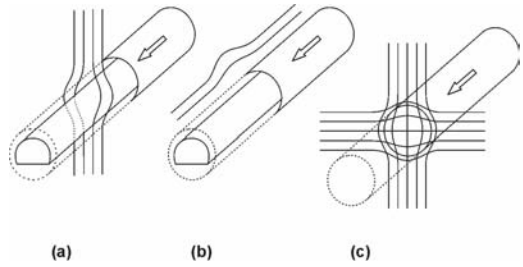

Figure 3. Stress arching effects.

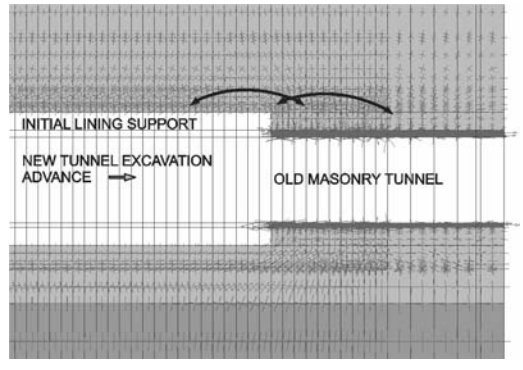

Figure 4. Arching effects along the tunnel axis.

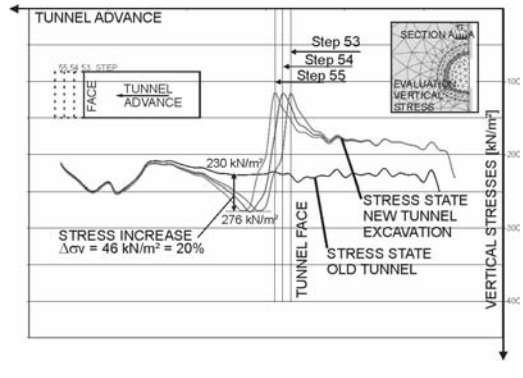

Figure 5. Vertical stress analysis along the tunnel.

be pronounced when considering the option with the "quick invert closure".

Essential for the present tunnel design is the analysis of the arching effect along the tunnel axis (see Figure 4). As evaluated in Figure 5, the old tunnel will be additionally loaded by 20% of the existing vertical load due to the longitudinal stress arching when widening the tunnel. At the same time the horizontal stresses remain almost unchanged (Figure 6).

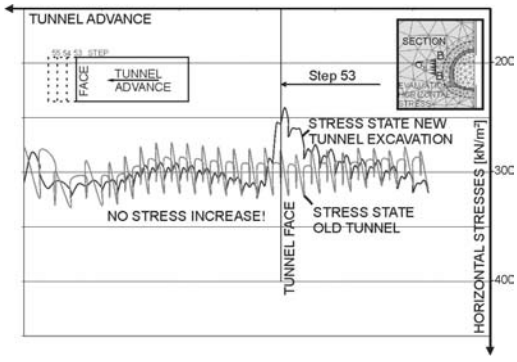

Figure 6. Horizontal stress analysis along the tunnel.

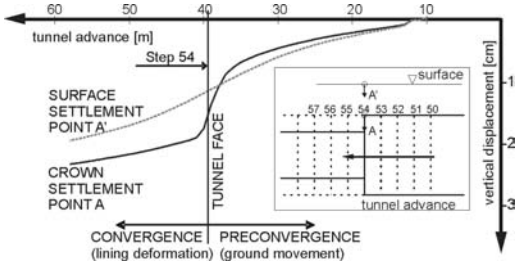

Figure 7. Vertical displacements at the tunnel face.

5.5.2 *Settlement behavior*

Figure 6 indicates that reduced settlements are achieved by the quick invert closure according to concept (1c).

5.5.3 *Bearing capacity of the shotcrete lining*

The calculations indicate that, following concept (1c), a shotcrete lining thickness of 25 cm is adequate for design. In contrast to this concept the side drift walls (concept 1a) and the temporary top heeding invert (concept 1b) are to be executed on a inhomogeneous bedding (partly masonry wall/backfill material and natural ground). High bending moments and shear forces require a strengthening of the shotcrete lining.

5.5.4 *Resulting loads on the old tunnel lining*

The numerical calculations indicate that due to longitudinal stress arching, a vertical stress increase of approx. 20% will develop. The "compensation grouting" procedure will also result in a vertical stress increase of additionally 20%.

Therefore the old tunnel masonry wall has to be improved by application of a shotcrete lining of minimum 10 cm thickness or alternatively by temporary steel girders before excavating the new tunnel.

5.6 *Summary of numerical results*

The most important results of the present study are summarized in Table 2.

Table 2. Summary of vertical displacements.

	Concept 1a [mm]	Concept 1b [mm]	Concept 1c [mm]
Crown settlement:			
Partial excavation	38	44	9
Full excavation	42	53	10
Surface settlement:	55	60	29

It shows that the settlement at the crown is reduced to 30% when applying a "quick invert closure" compared to the other options (concept with sequential excavations acc. to Figure 1a, 1b).

6 CONSTRUCTION CONCEPT

6.1 *Evaluation of the excavation and support concept*

With respect to the reported results of numerical analysis and with respect to other project conditions, namely

- unknown history of stress and strain of the tunnel lining, tunnel backfill and surrounding underground
- shallow overburden
- underpassing of historical and new multi-floor buildings and hotels
- small construction site areas available
- transportation of materials mainly by railway
- project realization time frame of 3 years, given by the owner
- a limitation of the settlements in the tunnel and at the surface
- a sufficient early strength of the shotcrete
- an increase of the bearing capacity of the old tunnel lining,

the usability of the 3 discussed concepts

1. "side drift concept"
2. temporary top heading invert, bedded on an artificial backfill
3. "heading/bench excavation" with a quick invert closure

has been evaluated. The first concept was eliminated because of its assumed construction time and an "unclear stability/settlement situation" at the side drift crown when cutting the temporary side drift wall (see figure 1a). The second concept was eliminated because of the additional masses for the artificial backfill and an "unclear stability/settlement situation" in the invert arch between the old tunnel lining and the artificial backfill (see figure 1b). Therefore the further design was based on the third concept.

With respect to the dimension of the unsupported excavation area and to safety aspects during

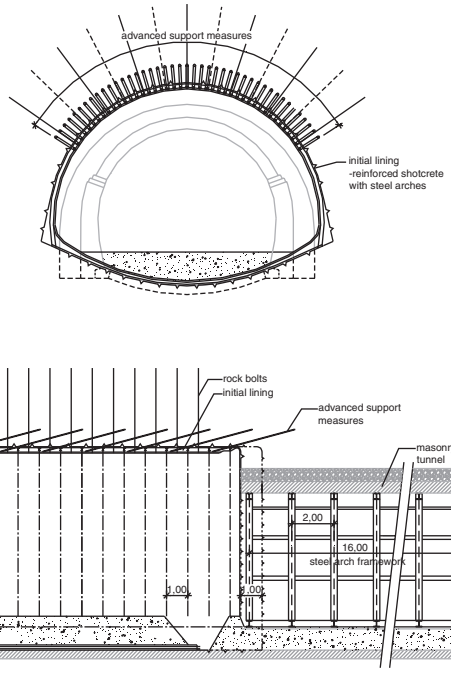

Figure 8. Excavation and support.

construction, the excavation cross section of the third concept was divided into two segments. One segment, the profile, with a temporary invert arch at the level of the existing invert and the other, the final invert (reference is made to Figure 8).

6.2 *Excavation and support*

With respect to these conditions 6 excavation and support types have been designed. All excavation and support types have a 30-cm thick reinforced shotcrete lining with steel arches and rock bolts. The difference between the excavation and support types are the advanced support measures, ranging from no advanced support measures to mortar spiles, steel liner plates and canopy pipes. The advanced support measures mainly serve to limit the excavation volume.

The existing old tunnel lining is generally supported by a steel arch framework construction, with force-closed connection to the lining. The framework is shifted in segments, ahead of the excavation and support procedure. In special tunnel areas such as the area where the surface settlement is limited by "push-up" underground injections, the lining of the old tunnel is stabilized by an additional reinforced shotcrete lining (see above).

The backfill of the old tunnel lining, consisting of small rock blocks, stones, gravel, etc., is stabilized by cement grouting to increase its stability.

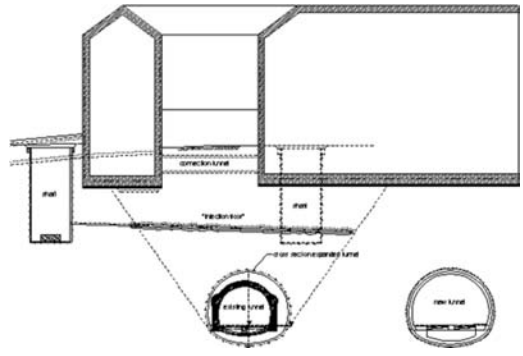

Figure 9. Push-up injection.

The sequence of tunnel excavation is generally designed in the following way:

Saw cuts in the masonry of the old tunnel lining – cut down of the masonry – excavation of backfill and underground – installation of support measures.

A typical excavation and support type is shown in Figure 8. Numerous geotechnical measurements, measuring the deformation of the tunnel lining, the settlement of the surface and the underground behaviour accompanying the excavation and support.

6.3 *Underpassing of buildings*

Because of the shallow overburden of the new tunnel (min. 11 m) and sensitive built-up areas at the surface in some areas (a multifloor hotel partly connected to and built on a historical Roman building) and in addition to the "low deformation" excavation and support concept, auxiliary measures have to be designed for limiting the impact of the excavation and support on the buildings. As reported, several measures have been foreseen. To protect the mentioned hotel and the adjacent buildings, a "push-up" injection is foreseen to control and to limit the settlements. For this the underground beneath the buildings is stabilized with a cement grouted "injection floor", located halfway between tunnel crown and foundation of the building (reference is made to Figure 9). If the buildings settle during the tunnel excavation, they can be pushed up to their original level by additional injections in the "injection floor". This operation can be done several times. The impact on the buildings and the success of the measure will be monitored by horizontal inclinometers in the underground, located between the "injection floor" and the foundation of the building, and with water level measurements in the buildings.

6.4 *Final lining*

The final lining of the tunnel is designed as a watertight reinforced concrete lining. The thickness of the

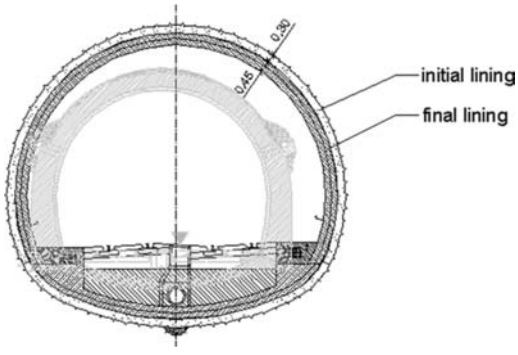

Figure 10. Tunnel cross section with final lining (inside: the existing tunnel).

lining is assumed to be 45 cm. The tunnel cross section is shown in Figure 10. The lengths of the final lining concrete blocks are mainly 9.20 m for equipment reasons. The joints are sealed with tapes.

7 ECONOMIC AFFECTS

The overall project costs are estimated at approximately 52 million €. The total construction costs for the tunnels will be approximately 33 million €. These costs include approximately 3 million € for additional measures to limit the tunnelling effects on the surface. In order not to exceed the project time frame, the 660-m long tunnel has to be driven from both sides.

Compared with the chosen and adapted construction concept "heading/bench excavation" with a "quick invert closure" (costs = 100%) the costs of the "side drift concept" would be approximately 120% and the costs of the temporary top heading invert, bedded on an artificial backfill concept would be approximately 110%.

8 CONCLUSIONS

For the renovation of the "Old Mainz Tunnel" and enlargement of the cross section, and taking into consideration the shallow overburden and sensitive built-up areas at the surface, a careful and comprehensive design was elaborated. With respect to the numerous and various project conditions three construction concepts have been verified and discussed with the Client and his experts.

1. "side drift concept"
2. temporary top heading invert, bedded on an artificial backfill
3. "heading/bench excavation" with a quick invert closure

As discussed above, the three concepts were analyzed by means of numerical simulations in order to get an idea of the interdependence of excavated tunnel, surrounding underground and surface impact. Based on this analysis, the construction concept No. 3 was chosen and designed in detail. Additional measures to protected the built-up areas have been designed, too. The tunnel works were tendered in the autumn of 2006. The start of the construction work is scheduled for March 2007.

Analytical investigation of damaged tunnel linings by the action of excessive earth pressure

H.Mashimo
Public Works Research Institute, Tsukuba, Japan

ABSTRACT: The objective of this paper is to clarify the mechanism of the failure of tunnel concrete lining by the action of excessive earth pressure and establish the method to estimate the direction and magnitude of earth pressure acting on tunnel concrete lining. In this study, field inspection was carried out at two existing road tunnels, which have suffered serious damages on concrete lining, and numerical analysis using two-dimensional FEM, which can take account of development of cracks, was carried out. The results showed that failure patterns of concrete lining obtained from numerical analysis gave the good agreement with those of actual tunnels and the direction and magnitude of earth pressure assumed to act on the damaged concrete lining were obtained.

1 INTRODUCTION

In Japan, there are some existing road tunnels in service that have suffered serious damage such as compression or shear failure on their concrete lining by the action of excessive earth pressure. For these damaged tunnels, some kind of countermeasures such as rock-bolting, inner lining, backfill grouting etc. were adopted to rehabilitate the damaged concrete lining. In order to adopt appropriate countermeasures against the damaged tunnel, it is important to clarify the cause of failure and evaluate the direction and magnitude of the load acting on the concrete lining. However, the mechanism of the failure of concrete lining by the action of excessive earth pressure has not been clarified yet and establishment of the method to evaluate the load acting on the concrete lining is necessary to select the countermeasure most suitable for the condition of damaged tunnel.

In the first part of this paper, field inspection on two existing damaged road tunnels was carried out and an overview of damaged tunnel concrete lining with compression failure at crown or shear failure at invert concrete lining was provided.

In the second, in order to clarify the mechanism of the failure of these damaged tunnels and estimate the direction and magnitude of earth pressure acting on the damaged concrete lining, numerical analysis using two-dimensional FEM, which can take account of development of cracks, was carried out. Furthermore, numerical analysis results were compared with the field inspection results and the mechanism of the failure of concrete lining by the action of excessive earth pressure was discussed.

2 OUTLINE OF DAMAGED TUNNELS

In order to investigate the state of the deformation of existing tunnels, field inspection on the concrete lining surface was carried out at Tunnel A and Tunnel B.

2.1 *Description and inspection of Tunnel A*

Figure 1 shows the state of the deformation occurred in tunnel lining and geotechnical profile of Tunnel A. Tunnel A with a total length of 2,376 m was constructed by steel and logging method about 30 years ago. Tunnel A has a horseshoe shape with a width of 9.7 m and a height of 8.0 m. Its support structure consists of concrete lining with a thickness of 60 cm.

In Tunnel A, passing-through tensile cracks at the shoulders and compressive failure at the crown due to bending moment were observed at the section with a distance of 800 m from portal. The sling that suspended the ceiling boards showed buckling phenomena due to the upheaval of ceiling board. There was void between the ground and concrete lining around the crown. Figure 2 shows the detail of the compressive failure occurred at the crown. The ground at tunnel site and its vicinity, where the tunnel deformation occurred, appeared to be composed of mudstone with the uniaxial compressive strength of approximately 40 N/mm^2. The overburden height at the section where deformation occurred is 320 m.

2.2 *Description and inspection of Tunnel B*

Figure 3 shows the state of the deformation occurred in tunnel lining and geotechnical profile of tunnel B.

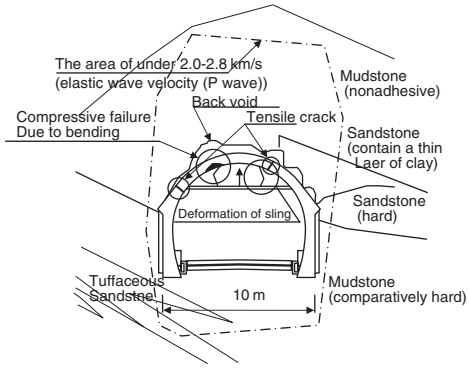

Figure 1. Deformation and geotechnical profile of Tunnel A.

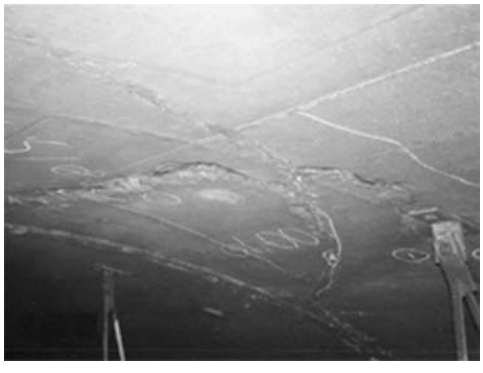

Figure 2. Detail of failure occurred at tunnel crown in Tunnel A.

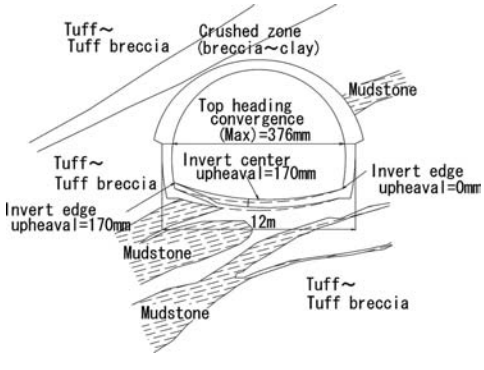

Figure 3. Deformation and geotechnical profile of Tunnel B.

Tunnel B with a total length of 1,013 m was constructed by steel and logging method about 15 years ago. Tunnel B has a horseshoe shape with a width of 11.3 m and a height of 8.9 m, and its support structure consists of concrete lining with a thickness of 60 cm.

Figure 4. Detail of failure occurred at junction between tunnel invert and sidewall foot in Tunnel B.

In Tunnel B, an upheaval of road surface was observed at the middle of the tunnel after about 10 years had passed since the completion of construction of tunnel. Therefore, the state of invert concrete lining was investigated by taking off the road bed material. As a result, it was found that shear failure had occurred at the junction between the invert and sidewall foot and an upheaval with a height of 170 mm had occurred at the invert center. In addition, the top heading arch convergence of 376 mm was obtained by measurement on the inner tunnel space, though no slippage at the construction junction between the top heading arch and sidewall was observed. Figure 4 shows the detail of failure occurred at the junction between the invert and sidewall foot. The ground at tunnel site and its vicinity, where the tunnel deformation occurred, appeared to be composed of mudstone and tuff with the uniaxial compressive strength of 8.4 N/mm^2 and 11.6 N/mm^2, respectively. The overburden height at the section where deformation occurred is 120 m.

3 ESTIMATION OF FAILURE MECHANISM OF DAMAGED TUNNELS

3.1 *Outline of the analysis*

For the purpose of clarifying the mechanism of the failure of damaged tunnels and estimating the direction and magnitude of earth pressure acting on concrete lining, FEM analysis considering the occurrence and development of cracks was carried out. In this analysis, nonlinear finite element method was used and modified Newton-Raphson method was adopted for the solution of nonlinear equations. Plane-stress elements for material and Kupfer's failure criterion were adopted (Mashimo et al. 2004).

Figure 5 shows the stress-strain relation in compression and tension adopted in the analysis. The curve in compression was modified as quadric curve

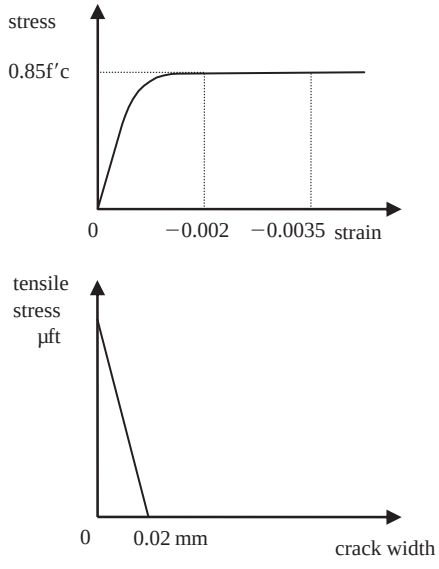

Figure 5. Stress-strain relation adopted in analysis.

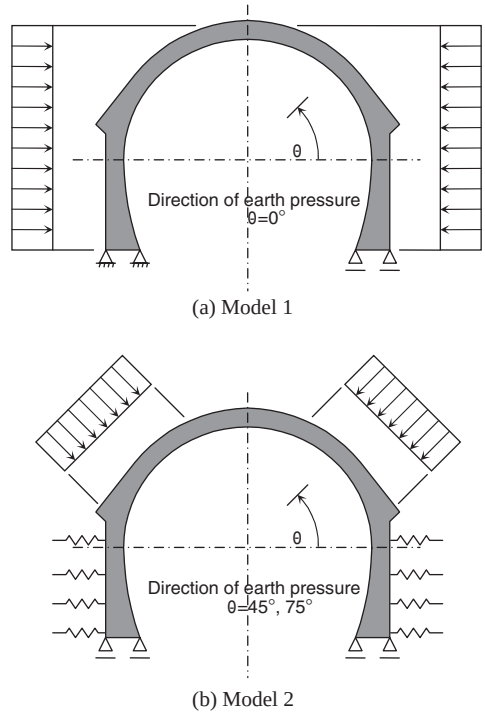
until strain reached the ultimate compressive strain $-3{,}500 \times 10^{-6}$. No stiffness decrease was defined after that. The curve in tension was regulated by tensile-softening curve. The tensile strength f_t was calculated on the basis of compressive strength f'_c as $f_t = 0.23 f'^{2/3}_c$. Allowable crack width and ratio of residual strength μ in concrete was set as 0.02 mm and 1.0, respectively. The interaction between tunnel lining and ground was modeled by a series of spring support outside the tunnel lining, which were assumed to resist only compression and had zero stiffness when subjected to tension. The coefficient k of subgrade reaction was obtained from the following Eq.(1):

$$k = 1/0.3\alpha E(B/0.3)^{-3/4} \quad (1)$$



where α = correction factor(=0.4); E = Young's modulus of ground; B = tunnel height.

The mechanical properties of tunnel lining adopted in the FEM analysis are listed in Table 1.

Figure 6 shows the outline of analysis model of Tunnel A. In the calculation of Tunnel A, for the purpose of estimating the direction and magnitude of earth pressure acting on the concrete lining, two kinds of load condition and the arrangement of subgrade springs were adopted. In model 1, earth pressure acted on the concrete lining throughout the whole top heading arch and sidewall in the horizontal direction and there was no subgrade spring outside the concrete lining because void was found behind the crown. In model 2, earth pressure acted on the concrete lining throughout the top heading arch partially in the direction at an angle of 45 or 75 degree from the horizontal and the sidewall

was supported by subgrade springs. In the calculation, attention was given to tensile cracks at the shoulders and the compressive failure at the crown due to bending moment to evaluate the validity of analysis on the deformation of concrete lining.

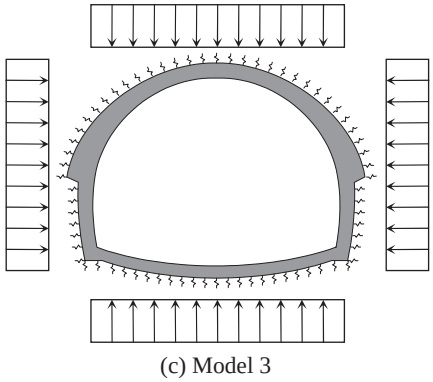

Figure 7 shows the outline of analysis model of Tunnel B. In the calculation of Tunnel B, whole concrete lining with invert was supported by subgrade springs. Construction joint between the top heading arch and sidewall was modeled by interface elements, which consisted of spring element in the normal and tangential direction. Four kinds of load conditions were adopted to estimate the direction and magnitude

(c) Model 2 θ = 75°

Figure 8. State of cracks obtained by analysis on Tunnel A.

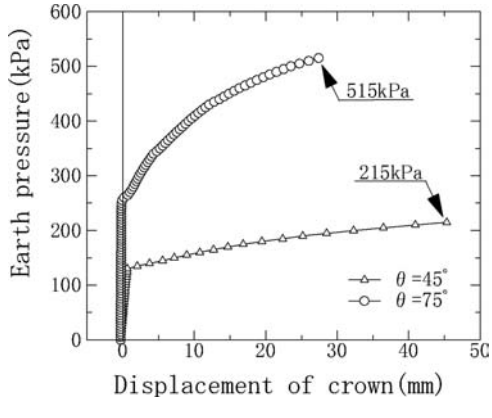

Figure 9. Earth pressure-displacement curve.

of earth pressure acting on concrete lining. In model 1, earth pressure acted on the invert in the vertical direction. In model 2, earth pressure acted on the concrete lining throughout the top heading arch and sidewall in the horizontal direction. In model 3, earth pressure acted on the concrete lining throughout the top heading arch in both the vertical and horizontal direction, sidewall in the horizontal direction and invert in the vertical direction. In model 4, earth pressure acted on the concrete lining throughout the whole top heading arch in the horizontal direction and the sidewall foot partially in the horizontal direction. In this model, the magnitude of earth pressure acting on the sidewall was assumed to be far larger than that acting on the top heading arch. In the calculation of every model, attention was given to the shear failure occurred at the joint between the invert and sidewall foot.

3.2 *Estimation of earth pressure acting on concrete lining*

Figure 8 shows the state of the cracks obtained by numerical analysis on Tunnel A. It can be seen that in the analysis model 1, tensile cracks occurred at the inside of the sidewall and at the outside of the crown. The compressive strains occurred at the inside of the crown showed a value above $3{,}000\mu$ and it was assumed that compressive failure occurred at the crown. However, tensile cracks at the shoulders did not occur. On the other hand, in model 2, tensile cracks occurred at the inside of the shoulders and at the outside of the crown in both cases of $\theta = 45°$ and 75°. The compressive strain occurred at the inside of the crown also showed a value grater than the ultimate compressive strain of $-3{,}500 \times 10^{-6}$ and it was assumed that compressive failure occurred at the crown in both cases. Therefore, it can be assumed that model 2 is more suitable than model 1 for simulating the state of deformation occurred in tunnel A. This means that deformation of Tunnel A was not induced by earth pressure acting on the concrete lining in the horizontal direction, but in the slanting direction.

Figure 9 shows the relationship between tunnel displacement at crown and earth pressure acting on concrete lining obtained numerical analysis using model 2 on Tunnel A. Tensile cracks occurred at the inside of the shoulders when the earth pressure reached approximately 130 kPa and 250 kPa in the case of $\theta = 45°$ and 75°, respectively, and shortly afterward tensile cracks occurred at the outside of the crown. When the earth pressure reached 515 kPa and 215 kPa in the case of $\theta = 45°$ and 75°, respectively, the strain of the inside of the crown exceeded the ultimate compressive strain and it was assumed that compressive failure occurred at these earth pressure values. The overburden height corresponding to these earth pressure values were calculated at approximately 9 m and 20 m by using the

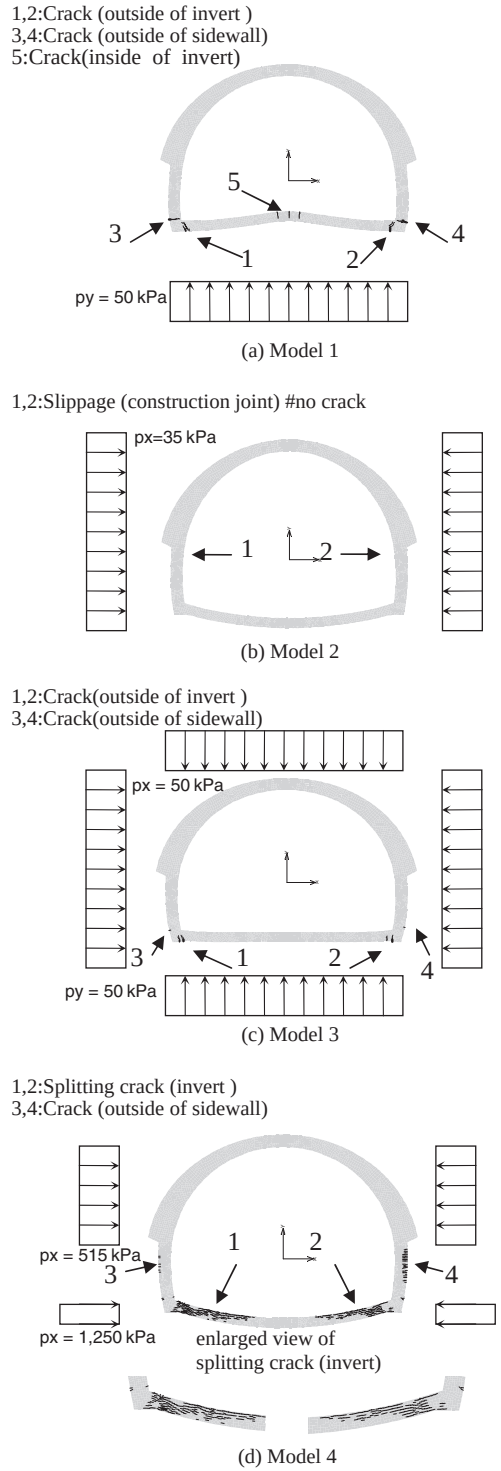

Figure 10. State of cracks obtained by analysis on Tunnel B.

unit weight of ground mass $\gamma = 25\,\mathrm{kN/m^3}$. Overburden height of 9 m in the case of $\theta = 45^\circ$ is almost the same height of loosened area estimated from the elastic wave velocity distribution of the ground.

Figure 10 shows the state of the cracks obtained by numerical analysis on Tunnel B. In model 1, tensile cracks occurred at the inside of the invert center and at the outside of the invert edge and sidewall foot when the earth pressure acting on the invert reached 50 kPa. In model 2, slippage at the construction joint between the top heading arch and sidewall occurred when the earth pressure acting on the concrete lining in the horizontal direction reached 35 kPa, though no tensile crack occurred. In model 3, tensile cracks occurred at the outside of the invert edge and sidewall foot when the earth pressure acting on the concrete lining in both the horizontal and vertical direction reached 50 kPa. In model 4, tensile cracks occurred at the outside of the sidewall and splitting cracks occurred at the invert edge, when the earth pressure acting on the top heading arch and sidewall foot in the horizontal direction reached 515 kpa and 12,500 kPa, respectively. Therefore we can conclude that shear failure occurred at the junction between the invert and sidewall was induced by excessive earth pressure acting on the tunnel sidewall foot in addition to that on the top heading arch in the horizontal direction. However, the earth pressure of 12,500 kPa acting on the sidewall foot is far larger than the overburden earth pressure of 3,000 kPa obtained by using the unit weight of ground mass $\gamma = 25\,\mathrm{kN/m^3}$.

4 CONCLUSION

In this study, field inspection on the damaged tunnels and numerical analysis using FEM were carried out to clarify the mechanism of the failure of concrete lining by the action of excessive earth pressure. The main conclusions obtained from the study are as follows.

(1) Excessive earth pressure acting on tunnel lining could induce compressive failure at tunnel crown or shear failure at junction between sidewall and invert
(2) FEM analysis considering the occurrence and development of cracks is effective in estimating the failure mechanism of damaged tunnel concrete lining by the action of excessive earth pressure.

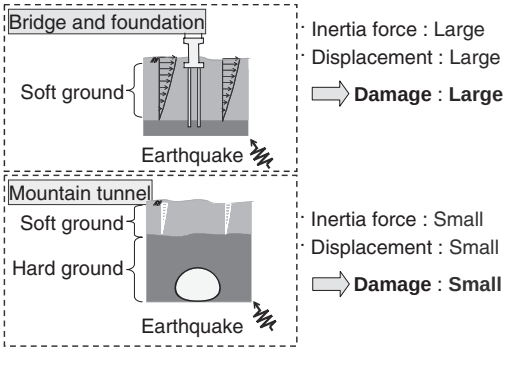
ABSTRACT: Since mountain tunnels are mainly surrounded by stable ground, its displacement upon seismicity is less, therefore, they are structures less susceptible to seismic damage. However, many railway mountain tunnels have suffered damage from the 1923 Kanto Earthquake to the 2004 Mid Niigata Prefecture Earthquakes. This paper shows an outline of the historical damage of mountain tunnels in Japan and result of case studies of damage to mountain tunnels. This paper also shows classification of damage patterns and conditions of damage based on the result of the case studies, and refers estimated causes of damage of the tunnels in the 2004 Mid Niigata Prefecture Earthquakes.

1 INTRODUCTION

Since mountain tunnels are mainly surrounded by stable ground, its displacement upon seismicity is less, therefore, they are structures less susceptible to seismic damage to compare with other structures such as bridges and foundations. (Fig. 1) However, earthquake-resistant tunnels are highly noted since the 2004 Mid Niigata Prefecture Earthquakes occurred. Upon the foregoing earthquake, some tunnels located at disaster area were heavily damaged and have been impediment to reopening of Shinkansen and conventional lines. Especially, a concrete lining of the Uonuma Tunnel of the Jyoetsu Shinkansen located adjacent to the epicenter was heavily damaged and two-month time required for restoration.



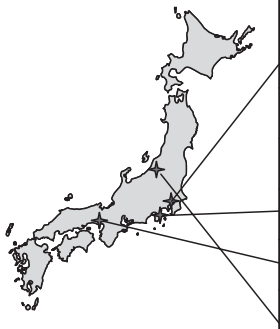


Figure 1. Difference of behavior during earthquake between bridges and foundations and mountain tunnels.

Owing to the progress of construction technology, more and more railway structures are being constructed by the tunneling method, and even tunnels need to have sufficient earthquake resistance. In this paper, we introduce case studies on the historical damage of mountain tunnels, an outline and assumed causes of damage by the foregoing earthquake.

2 HISTORICAL DAMAGE OF MOUNTAIN TUNNELS BY EARTHQUAKE

2.1 *Outline of damage*

Figure 2 summarizes the large-scale earthquakes which caused damage to mountain tunnels of railway in Japan. There are four major earthquakes: the 1923 Kanto Earthquake, the 1978 Izu-Oshima-kinkai Earthquake, the 1995 Hyogoken-nanbu Earthquake and the 2004 Mid Niigata Prefecture Earthquakes. The outline of damage of mountain tunnels will be respectively described below.

Year, Name	Magni -tude	Seismic intensity	Tunnel performance
1923 Kanto	7.9	6	Damage to 93 tunnels 25 tunnels required reinforce
1930 Kita-Izu	7.3	6	Very severe damage to 1 tunnel by a slide of the fault
1948 Fukui	7.1	6	Damage to 2 tunnels 1 tunnel required reinforce
1978 Izu-Oshima-kinkai	7.0	5	Damage to 9 tunnels 2 tunnels required reinforce
1995 Hyogoken-nanbu	7.2	7	Damage to 7 tunnels 5 tunnels required reinforce
2004 Mid Niigata Pref.	6.8	7	Damage to 24 tunnels 5 tunnels required reinforce

Figure 2. Historical damage of mountain tunnels by earthquake in Japan.

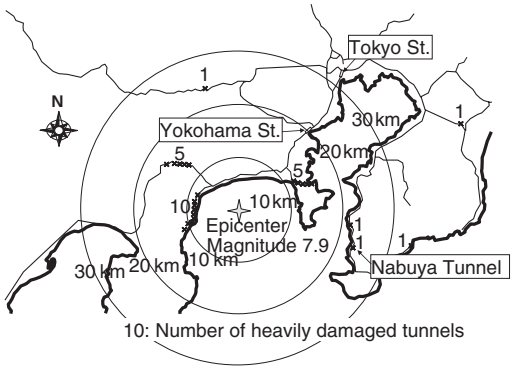

Figure 3. Distribution of heavily damaged railway tunnels upon the Kanto Earthquake.

Figure 4. Collapse of the Nabuya Tunnel.

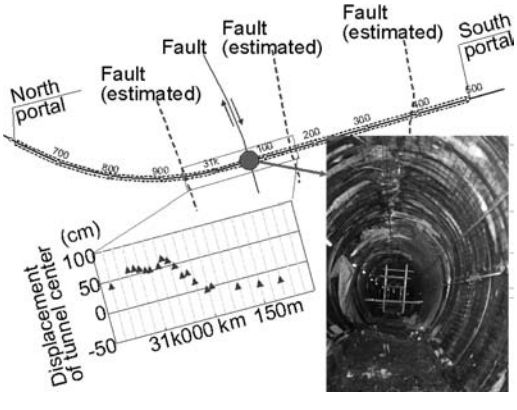

Figure 5. Damage of the Inatori Tunnel.

2.2 *The 1923 Kanto Earthquake*

The 1923 Kanto Earthquake is the earthquake, which caused the largest damage to mountain tunnels. There were 149 railway tunnels located within a range of a 120-km radius area from the epicenter at the time, and 93 tunnels among them were damaged to be reinforced; and 25 tunnels to be reconstructed due to collapse of linings. As an example of the heavily damaged tunnels, Figure 4 shows collapse of the Nabuya Tunnel. It is conceivable that a slide of an earthquake fault or a landslide caused the ground move to the tunnel and destructed a tunnel lining.

2.3 *The 1978 Izu-Oshima-kinkai Earthquake*

Upon the 1978 Izu-Oshima-kinkai Earthquake, nine railway tunnels suffered from damage. The largest damage is that of the Inatori Tunnel. (Fig. 5) A fault crossing the tunnel slid upon the earthquake, a lining of the tunnel collapsed and the track alignment longitudinally displaced. A relative displacement of the fault was 70-cm horizontally and 20-cm vertically according to the results of surveying.

2.4 *The 1995 Hyogoken-nanbu Earthquake*

Upon the 1995 Hyogoken-nanbu Earthquake, seven tunnels among 43 railway mountain tunnels located within a disaster area suffered serious damage, and five tunnels required repair and reinforcement. Figure 6 shows a distribution of heavily damaged railway

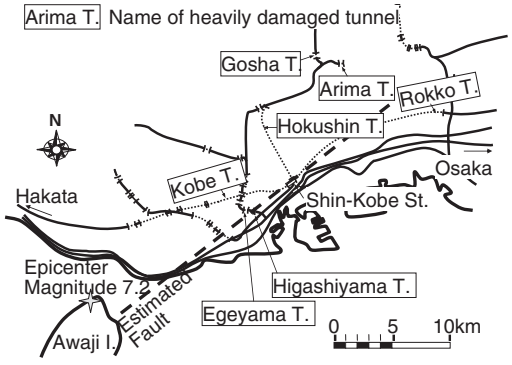

Figure 6. Distribution of heavily damaged railway tunnels upon the Hyogoken-nanbu Earthquake.

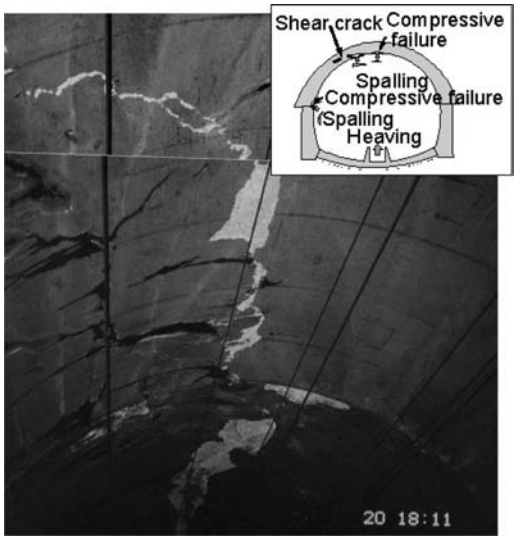

Figure 7. Damage of the Rokko Tunnel.

tunnels. As a typical example, Figure 7 shows the damaged conditions observed at the Rokko Tunnel. Several damage patterns observed at various locations are superimposed in one figure. Typical damage was of compressive and shear failures at the arch of a lining and compressive failures with spalling at joints between the arch and sidewall. Figure 8 shows a longitudinal profile and damaged locations of the Rokko Tunnel. Almost all the damaged locations coincide with faults or fractured zones.

2.5 *The 2004 Mid Niigata Prefecture Earthquakes*

On October 23, 2004, a large earthquake of magnitude 6.8 occurred at latitude 37°17′ N. and longitude 138°52′ E., depth 13-km of Niigata prefecture in

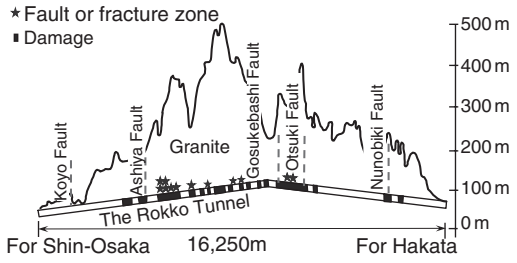

Figure 8. Longitudinal profile and damaged locations of the Rokko Tunnel.

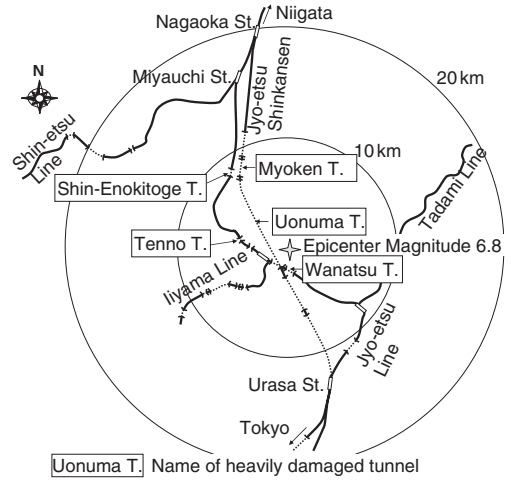

Figure 9. Distribution of heavily damaged railway tunnels upon the Mid Niigata Prefecture Earthquakes.

Japan. Due to this earthquake, a running Shinkansen train derailed and some mountain tunnels suffered from severe damage. Twenty-four railway tunnels had serious damage, and five tunnels (the Uonuma, Myoken, Wanatsu, Tenno and Shin-Enokitoge) required repair and reinforcement of linings. Figure 9 shows distribution of heavily damaged railway tunnels. It is obvious that heavily damaged tunnels concentrated at a limited area of approximately within a 10-km radius area from the epicenter. The most heavily damaged tunnel was the Uonuma Tunnel, which runs nearby the epicenter. The Uonuma Tunnel is a long railway tunnel driven in Neogene's mudstone with a length of 8,625-m. There were three heavily damaged sections in this tunnel. (Fig. 10).

Figure 11 shows a damage situation of the most heavily damaged section. A concrete lining was broken to fall off to a track. The largest concrete block amounted to approximately 2 m^2 (5ton). Other observed damage consisted of reduction of a tunnel diameter, heaving of a roadbed concrete and cracking of an invert. This is the largest disaster among the

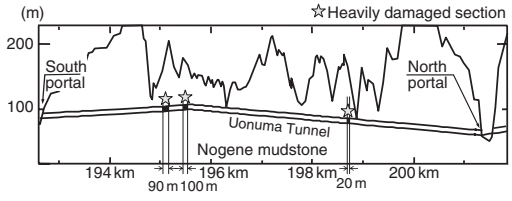

Figure 10. Longitudinal profile and damaged locations of the Uonuma Tunnel.

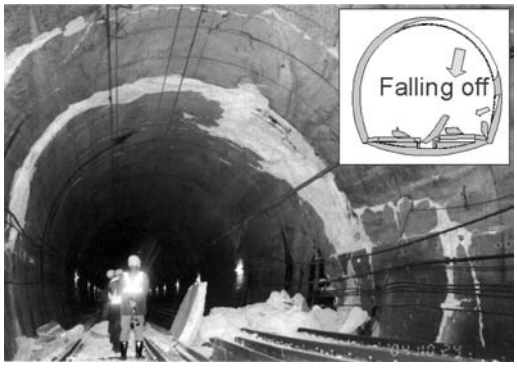

Figure 11. Damage of the Uonuma Tunnel.

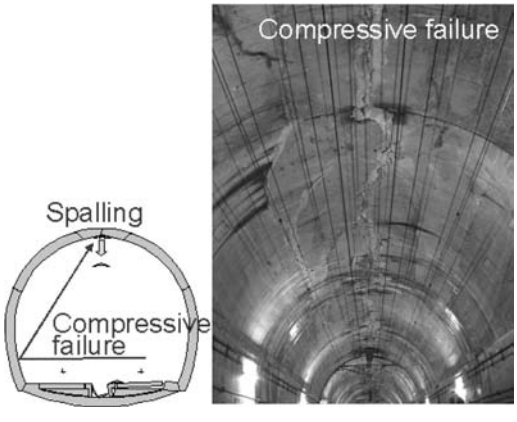

Figure 12. Damage of the Myoken Tunnel.

Shinkansen tunnels after inauguration. The locations were restored by rock bolting, removal of the concrete by breakers, shotcreting, and reinforcement by mortal precast boards; however it became a critical path and took two months until reopening. There was another damage of the Myoken Tunnel of the Jyoetsu Shinkansen. This tunnel had a compressive failure at a crown (Fig. 12) and an invert also heaved like the Uonuma Tunnel. At the Wanatsu Tunnel of the conventional line, there was a compressive failure at

Figure 13. Damage of the Wanatsu Tunnel.

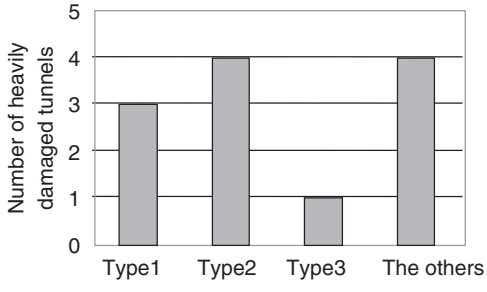

Figure 14. Number of damaged tunnel (respective types).

a crown and large brocks fell off a lining and steel supports of the tunnel were exposed. (Fig. 13) At the Tenno and Shin-Enoki Tunnel, bedrock collapsed and slid above the tunnel and cracks occurred on a lining.

3 CLASSIFICATION OF DAMAGE PATTERNS

Figure 14 shows result of classified damage patterns on the 1978 Izu-Oshima-kinkai Earthquake, the 1995 Hyogoken-nanbu Earthquake and the 2004 Mid Niigata Prefecture Earthquakes, for which various valuable information and data remained. In addition, we classified the damage patterns into three types as shown in Figure 15.

Type 1: Damage of shallow depth tunnels

There are many examples of damaged tunnels in the Type 1. In general, shallow depth tunnels are likely to suffer from earthquake, as they often constructed in the loose ground where a seismic activity is amplified and the ground deforms largely. Cracks in the arch of the lining are characteristic of this type. It is conceivable that tunnels deform like shearing deformation by

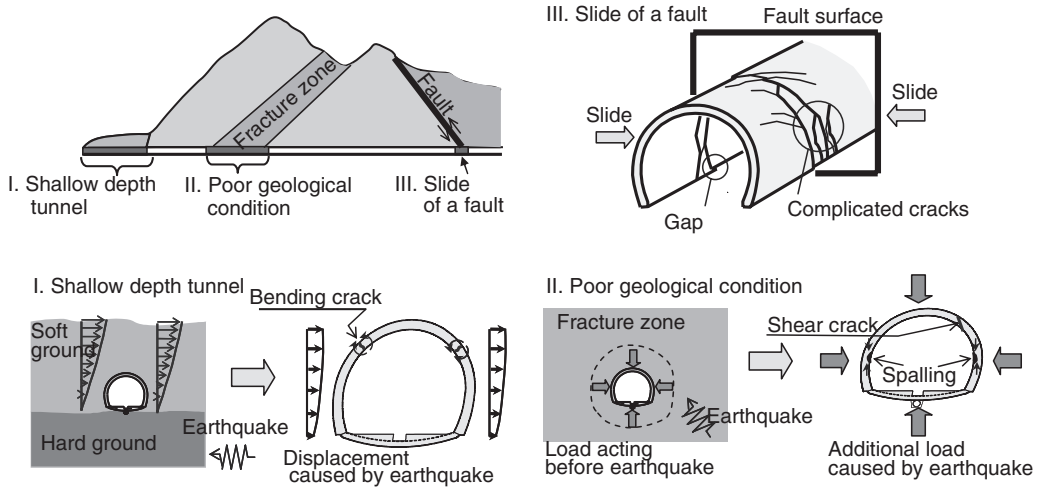

Figure 15. Classification of damage patterns.

displacement of the earthquake and cracks occur at a shoulder part of an arch by bending moment.

Type 2: Damage of tunnels of poor geological condition

This type is visible on tunnels in the soft ground like a fractured zone, sometimes on tunnels of large earth covering. In the fractured zone, the ground is generally soft and displacement in an earthquake becomes large. Furthermore, there have been other loads acting on the lining like loosening earth pressure and plastic earth pressure in the fractured zone before an earthquake. In such a case, the load acting on a lining becomes large and damage by the earthquake tends to be severe.

Type 3: Damage of tunnels by a slide of a fault

Type 3 is a type that an earthquake fault is crossing a tunnel. A slide of the earthquake fault makes various stress such as shear stress, tensile stress and compressive stress on a lining and cause complicated cracks like shear cracks and cracks in round slices.

4 CONDITIONS OF DAMAGE

From such case studies, it is evident that even mountain tunnels suffered damage by an earthquake. Susceptible conditions under which tunnels suffered from damage are provided that:

1. A great magnitude of an earthquake
2. Tunnels located adjacent to an epicenter or an earthquake fault.

Figure 16 shows relation of distance from an earthquake fault, magnitude of an earthquake and number of heavily damaged tunnels. From this figure, we find

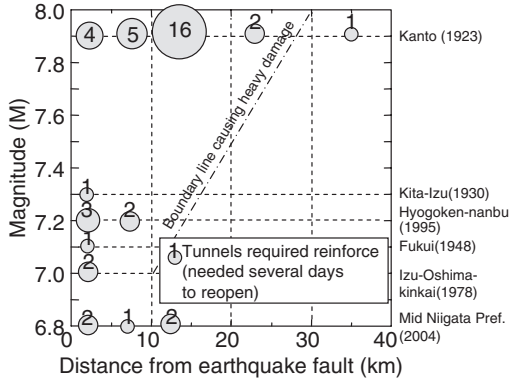

Figure 16. Relation of distance from an earthquake fault, magnitude of an earthquake and number of heavily damaged tunnels.

that a risk of earthquake damage becomes large under on the condition of both 1 and 2. Roughly speaking, tunnels suffered numerous damages at areas within 10 km from an earthquake fault in the case of M7, and areas within 30 km in the case of M8. Figure 17 shows relation between a distance from an earthquake fault and a percentage of damaged tunnels. From this figure, we find that damage that requires reinforcement occurred within 10 km from an earthquake fault. However, these figures have entirely not considered the conditions proper to tunnels such as the ground adjacent to the tunnel and a tunnel structure. It is conceivable that tunnels tend to suffer from an earthquake under,

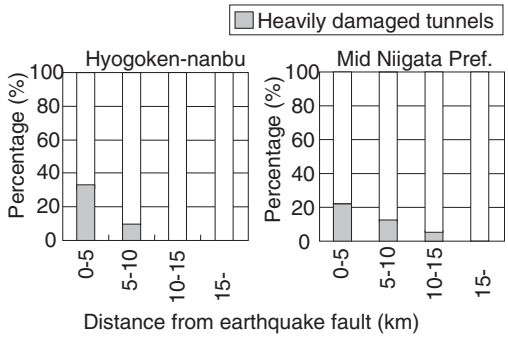

Figure 17. Relation between a distance from an earthquake fault and a percentage of heavily damaged tunnels.

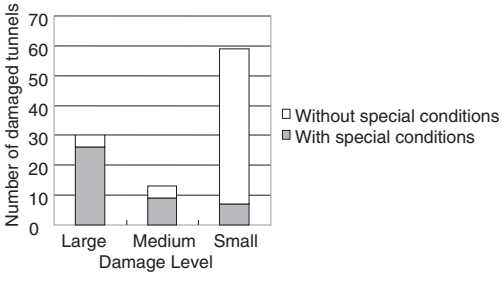

Figure 18. Number of damaged tunnels which have the special conditions (The Kanto Earthquake and Izu-Oshima-kinkai Earthquake).

3. tunnels have special conditions such as;

   a. shallow depth tunnels
   b. poor geological condition
   c. slide of an earthquake fault crossing the tunnel
   d. structural defects of a tunnel lining

Figure 18 shows number of damaged tunnels which have the special conditions. Many of heavily damaged tunnels have some special conditions. Therefore, we can conclude that a risk of earthquake damage becomes large under condition of both 1 and 2, and a level of damage becomes large under condition 3.

5 CAUSES OF DAMAGE OF THE UONUMA TUNNEL

In this chapter, we introduce the causes of damages of the Uonuma Tunnel, which suffered the heaviest damage in the Mid Niigata Prefecture Earthquakes. First of all, this tunnel was within 1-km from an epicenter and an earthquake motion was extremely strong. Secondly, the ground of this area is Neogene's mudstone and relatively soft. We surveyed a geological characteristic and a situation behind a tunnel lining by boring at the heaviest damaged section to find the following

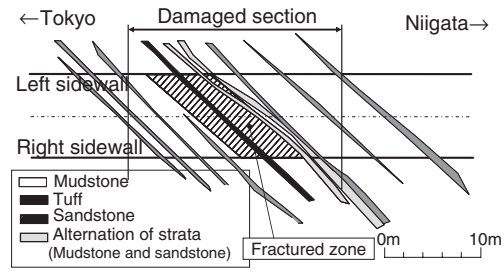

Figure 19. Geological characteristic of the damaged section of the Uonuma Tunnel (a ground plan).

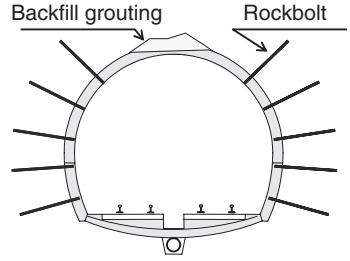

Figure 20. Fundamental countermeasures.

two facts. First, the ground of the damaged section had lower strength than that of neighboring sections, secondly there were voids behind the tunnel lining at an arch and the tunnel tends to deform largely. It is conceivable that the Uonuma Tunnel suffered large damage, because this tunnel was located adjacent to an epicenter, earthquake motion was extremely strong and there was void behind the tunnel lining.

6 COUNTERMEASURES AGAINST EARTHQUAKE OF TUNNELS

We are now planning the countermeasures against earthquake damage. Figure 20 shows countermeasures for existing tunnels. Backfill-grouting to a void behind linings and rockbolting to prevent spalling are fundamental countermeasures. For newly constructed tunnels, we adopt countermeasures to linings themselves. We use fiber reinforced concrete to improve ductility and performance of unti-spalling of linings.

7 CONCLUSIONS

In this paper we showed an outline of the historical damage of mountain tunnels in Japan and result of case studies of damage to mountain tunnels. We also showed classification of damage patterns and conditions of damage based on the result of the case studies.

However, there are many unknown factors on the damaging mechanism of tunnels under an earthquake. It is very important to establish the way to evaluate earthquake resistance of tunnels. We are planning model tests and numerical analyses to evaluate deformation behavior of tunnels under an earthquake and we are going to use the outcome for maintenance of railway tunnels.

Close underpass of ancient tunnels: Methodology and results

Achille Sorlini
Geodata S.p.A., Turin, Italy

Guido Amoretti & Fabrizio Zannoni
"Pietro Micca e dell'assedio di Torino 1706" Civic Museum, Turin, Italy

ABSTRACT: Turin's countermine tunnels represent one of the most famous and extensive underground systems ever realized. *The Citadel*, a fortress built by Francesco Paciotto for the Duke of Savoy in the mid 1500's, saved the city from its enemies on several occasions. The alignment of the new automatic metro (VAL System) line 1 interacts with the ancient tunnel system for at least 1 km. Consequently, subway design was subjected to preservation of the historical underground tunnel network monument. To preserve the historical network, before metro subway excavation, the ancient defensive tunnels were consolidated by filling with sand sacks and grouted. Continuous monitoring of TBM parameters was accomplished for control of settlements. Removal of the tunnel consolidation filling material showed that the defensive tunnels had not been damaged by excavation of the new subway tunnel.

1 INTRODUCTION

The alignment of Line 1 of the new Turin metro (G.T.T. S.p.A., Gruppo Torinese Trasporti is the Metro owner) shared an extent of 1 km with the ancient tunnel system called countermine galleries.

The Citadel, the Turin fortress and its underground network, saved several times the city from its enemies. So the Italian Department of Arts strongly protects these ancient tunnels for their historical value. As a consequence, engineers had to give great consideration to avoid damage to subterranean monument.

Figure 1. Ancient map of *Cittadella* fortress.

2 THE CITADEL COUNTERMINE SYSTEM

2.1 *Historical introduction*

Turin's countermine galleries represent one of the most famous and extensive underground defense system ever realized. It is still existing and accessible. Duke Emanuele Filiberto of Savoy built the pentagonal Cittadella in the 1500s, following the style of modern forehead bastion – the *trace italienne* – invented at the beginning of the same century.

Tunnel construction started in 1572. The underground system was combined with surface fortifications to protect the city using a new, unknown strategy. Between the 1600s and 1700s surface and underground fortification were extended, reaching their maximum extension and efficiency. As a consequence, when French troops attacked the city in 1706, they were defeated.

The defensive network was organized in five large areas, corresponding to the five bastions of the fortress. Each of them had two main galleries placed one above the other, the shallowest between 6–7 m from the surface; the deepest at 12–14 m (just above the water table). The sectors were connected by the magistral gallery: it was the longest tunnel, about 2500 m long around the city. From the above tunnels many smaller branches were driven with small rooms at their end to blast mines below approaching enemies.

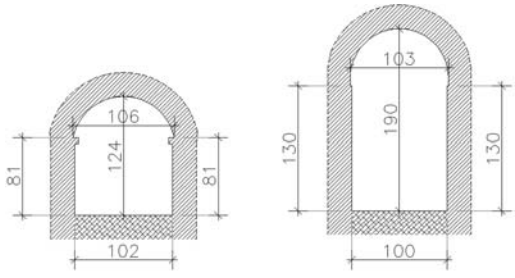

Figure 2. *Cittadella*'s type tunnels.

Around 1850, the city began an uncontrolled expansion which caused the demolition of the surface fortress. Tunnels survived, but they were filled with rubble and waste. New buildings cut connections or destroyed some parts of the network. During the second world war, many parts were reopened and used as air raid shelters. In the 1950s the construction of new buildings in bombed areas brought to the rediscovery of same of tunnels and at the beginning of 1960s the city established the Civic Museum in order to preserve and to recover the ancient galleries.

2.2 *Local geology*

Turin's soil is an alluvial deposit of gravel and sands with local presence of silt (<5%). The alluvial deposit also contains cobbles and rarely 1 m^3 blocks.

Natural cementation of soil varies from low to high. Permeability is at about 10–1 cm/s. Water level is between 15 and 20 m from surface, deeper than the underground network.

2.3 *Old tunnel features*

Ancient tunnel were manually excavated between the second half of 1500s and the end of 1700s. Excavation took advantage of soil cementation for cavity stability. Brick lining and semicircular vaults assured good air circulation and cleaning of galleries, they weren't put in place for support. Most parts of the tunnels have a 1.20 m width and a 1.80 m height; in the working area some lateral branches have a 1.40 m height only.

3 INTERFERENCES

3.1 *Spatial interference*

The Line 1 crosses down the Citadel underground network in the area between the XVIII Dicembre station and the new Porta Susa Metro – Railway station. The low level galleries and the lateral mine branches radial plan increase the number of crossings with the new metro alignment. The distance at the crossings between the crown of the new metro tunnel and the floor of the ancient tunnels is often at only 1.0–1.5 m. The

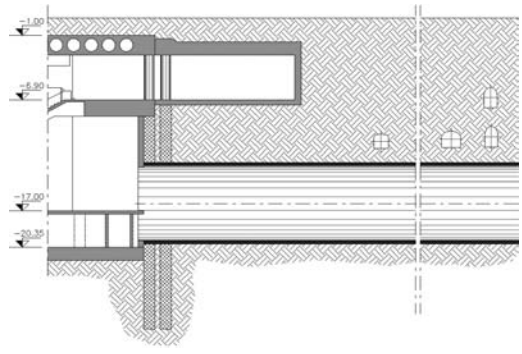

Figure 3. *A longitudinal section along the line: XVIII* December *station on the left, small ancient tunnels on the right.*

diaphragms of XVIII Dicembre station were planned very closed, less than 0.5 m from the historical brick lining of the ancient tunnels.

3.2 *Construction interaction*

Construction interaction with underground network were:

- Excavation and lining of main metro tunnel with TBM EPBS with close underpass of ancient galleries (1.0 m);
- Excavation and concrete filling of XVIII December station diaphragms with hydromill and bentonite slurry;
- Soil drilling and grouting with fluid concrete and chemical products along in/out approaches of TBM to station;
- Ventilation shaft n.11 construction with micropiles and waterproofing grouting.

4 METHODOLOGY TO PRESERVE TUNNELS

4.1 *Underground surveys*

A detailed survey was necessary to plan Line 1 and to locate the works of arts as well. That was accomplished during design. Actually old surveys and documents of the ancient tunnels were available, but they didn't fit to design needs to avoid interaction and to reduce damage risks. Therefore between 1999 and 2000 high quality underground surveys were carried out, some times with help of speleologists, where ancient tunnels were no longer easily accessible.

4.2 *Design criteria*

Aim of preventive protection works was to avoid damages to ancient structures, most of which open to public access from a civic museum.

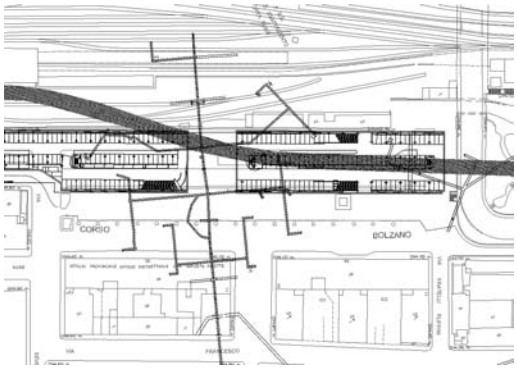

Figure 4. Result of detailed survey: underground network between an underground parking lot and the metro tunnel.

Two risks were considered:

– Soil slab subsidence between metro excavations and galleries pavement (between 5 and 1 m) with soil collapse up to city surface;
– Accidental filling from grouting from surface, not easily removable with consequent loss of gallery section.

Both of these problems were solved by filling systematically the *Cittadella*'s tunnels in the areas where the subway excavation could induce a collapse and where grouting was to take place close to ancient linings.

The filling was carried out with the following elements:

– contrast concrete slab between gallery piers;
– sand sacks and polystyrene blocks to tunnel cap inside a plastic membrane;
– stoppage grouting with cellular concrete.

Filled parts were closed with brick walls. Clinometers to measure settlements were installed inside the filling.

Concrete slab had the purpose of avoiding convergence between piers and of reinforcing tunnel foundations. Filling had to avoid that grouting and chemical or bentonite slurries could enter the tunnel cavity, preferring a designed removable filling, rather than an uncontrolled one.

4.3 *Construction phases*

Works took place in summer 2002. Tunnel filling was driven with manual techniques with some problems of ventilation and accessibility for their small size and positioning. It was necessary to build a new access shaft from surface and to prepare descent adequately to assure safety and rescue for workers.

All operations were supervised by archaeologists, who surveyed filled tunnels and took pictures of different phases. More than 250 m of ancient galleries were filled.

Figure 5. Plastic membrane and sand sacks inside the smallest tunnel.

Figure 6. Grouting of filled tunnels.

4.4 *EPBS excavation control and settlement monitoring*

Underground and surface subsidence measurements, together with TBM excavation monitoring gave evidence of the good results in the preservation of the ancient tunnels. No appreciable settlements were recorded; surface subsidence was of only 2–3 mm.

5 RESULTS

5.1 *Filling removal*

Filling removal operations and tunnel cleaning were carried out one year after TBM underpass and took some months to complete. Closure walls were destroyed and sand sack filling removed with manual tools and instruments. Slab demolition followed and the protective plastic membrane was detached from the

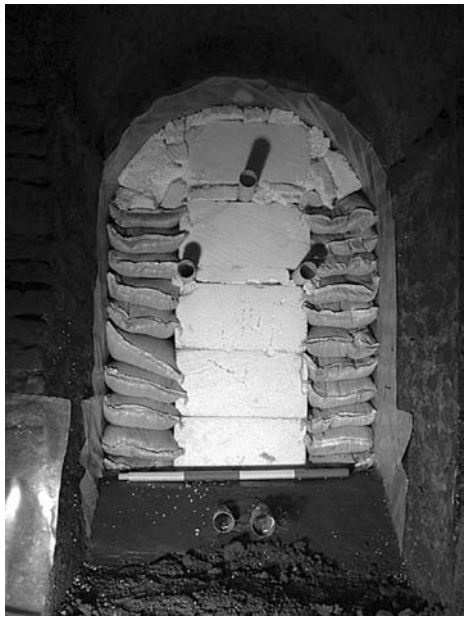

Figure 7. Final filling with polystyrene blocks and injection pipes. The bar is 1 m length.

brick lining. Archaeologists closely monitored each operations.

5.2 *Damage assessment*

Filling removal permitted to survey tunnel conditions. It became very clear that protective works avoided all damages to tunnels, to be caused by TBM excavation: design criteria proved to be correct.

Construction of the metro line had the following effects:

- no structural damage to lining from close TBM underpass or from diaphragm excavation;
- no underground or surface subsidence;
- no collapse;
- accidental drilling was recorded only in two single points of brick vault ;
- local bentonite slurry and concrete infiltration between plastic sheet and lining;
- high permeability chemical patina between plastic sheet and lining.

5.3 *Repair and cleaning*

Cleaning and repairing operations followed the completion of removal works. Brushes and low pressure water jets were the principal tools. Small specialized contractors made few lining reparations.

A new access shaft was kept permanently open and given to the museum in order to improve natural ventilation of the underground network.

Figure 8. Stoppage and filling removed; no damages to brick lining.

Figure 9. Bentonite patina below protection sheet before its removal.

6 CONCLUSION

Design methodology and choices proved to be appropriate to protect the ancient structures and to reduce risks of subsidence and collapse that could have involved buildings above ground level.

The Citadel tunnels were given back the civic museum and today are again open to visitors.

Advanced methods for tunnel assessment

Govind R. Sulibhavi,
Project Engineer, Maryland Transit Administration

William A. Parks, P. E
Chief, Maryland Transit Administration

ABSTRACT: There are numerous tunnels in the country, predominantly in Transit Sector, which needs periodic Inspection, Maintenance for safety and system preservation. Many Transit agencies operate round the clock, which limits the time for assessment. Budgets constraints reduced staff, commercial and environmental pressure to improve the performance of existing tunnels becomes difficult. We need to develop a comprehensive and standard rationale for tunnel assessment, which shall be feasible with time constraints. Present assessment methods are manually intensive, involving cross-referencing of the data, inspecting the tunnels during off-peak hours and recording the data. Maryland Transit Administration (USA) experienced similar problems and decided to utilize the "Three Dimensional Scanning" for tunnel assessment. The paper will describe the present tunnel assessment methods and compare to the evolution of "Three Dimensional Scanning" process as it currently stands and look at the future and where we think this effort will lead.

1 INTRODUCTION

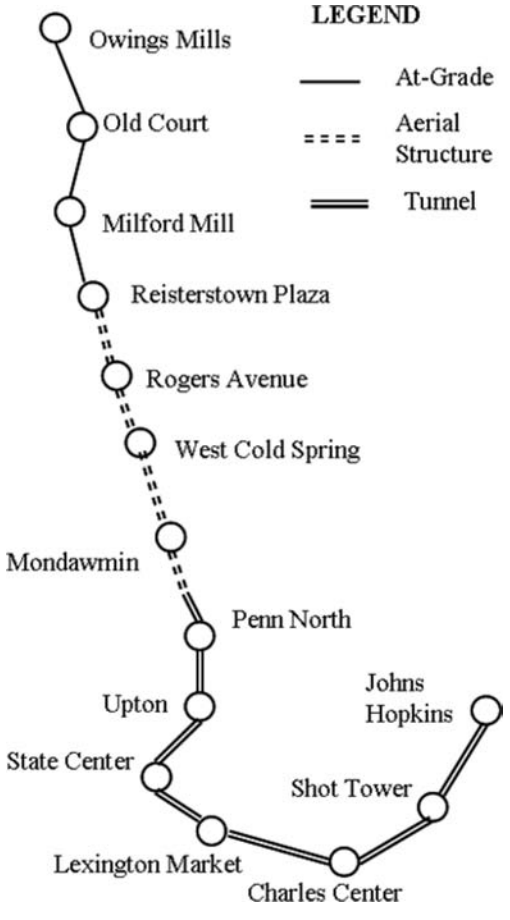
1.1 *Maryland Transit Administration*

The Maryland Transit Administration is a Transit division of the Maryland Department of Transportation providing transportation in various modes. These modes are as follows:

- Metro System – Baltimore Metro System is in operations since 1983 with fourteen (14) Stations
- Bus – Operates more than fifty (50) routes throughout Maryland since 1973. It was known as Baltimore Transit Company (1935 – 1970)
- Light Rail – Baltimore Light Rail System is in operation since 1992 with 32 Stations
- MARC – Maryland Rail Commuter
- Freight – Various Freight Lines in Maryland.

1.2 *Baltimore Metro System*

The Baltimore Metro System operates along a 15.5 Miles (24.8 Km) long route between Downtown Baltimore and Owings Mills in Northwest Suburbs with fourteen (14) stations serving the communities along the line. Part of the Metro System is underground with eight (8) stations and the rest is at- grade and on Aerial Structures. See Map 1. The paper shall discuss the assessment methods deployed for the tunnel portion of Metro System.



2 STRUCTURES ASSESSMENTS

2.1 *Tunnel assessment*

Maryland Transit Administration performs inspection of all the structures once every two (2) years and Tunnels (Underground Metro System) once every five (5) years for Safety and System Preservation. Based upon the Inspection findings, contract documents are prepared and rehabilitation is done. The Metro system Operates from Monday thru Sunday seven days a week. It becomes difficult to get "Track Access". Additionally the due to confined space in the tunnels, inspections cannot be performed during the operation of Metro System. So Maryland Transit Administration System was in search of "Drive through Tunnel Inspection System" which would benefit the Agency. In the process we contacted Takenaka Corporation, Japan, Ensco, Inc., Springfield, Virginia, US and Subterra Company, Germany. Due to various limitations it was not feasible for the mentioned companies to perform the required services. Then we initiated a pilot study to utilize Three Dimensional Laser scanning for Tunnel Inspection for approximately 183 meter (600 feet) of Tunnel Liner with a local Consulting Engineering Company by name Greenman Pedersen Inc.

2.2 *Application of 3D laser scanning*

Maryland Transit Administration/Consultant utilized a Leica Geosystems Three dimensional Scanner for

Map 1. Baltimore Metro System.

the study. Adequate three dimensional images of the tunnel liner were collected to perform the visual inspection entirely in the office. It was evident as seen in Figure 1, that significant detail is visible.

The image shows the artificial-color image that the scanner creates as a result of the various intensity of the reflected laser light. The 3D scanner captures up to 1,000,000 3D points in 15 minutes, in a rectangular grid – up to 1000×1000. In addition to an X, Y and Z coordinate; each point is also recorded with the previously mentioned intensity value. The value is based upon a number of surface and distance factors. To record approximately 183 meters (600±feet) of single track tunnel used for this pilot project, nine scan setups were required. Later, in the office, the separate scans are "joined" together and registered to a known coordinate system. The resultant "point-cloud" then becomes a virtual model of the tunnel, from which a variety of information can be obtained.

Figure 1. High resolution scan 1000×1000 Grid.

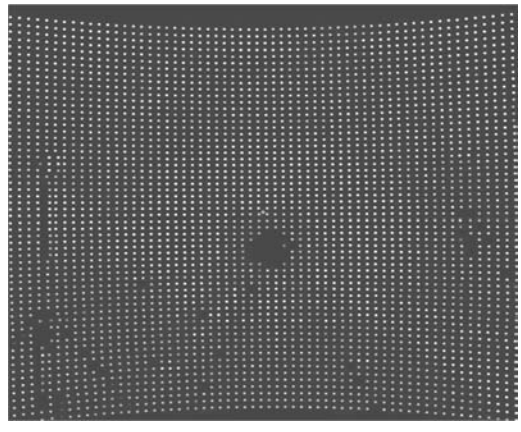


Figure 2. Low resolution scan 60×60 Grid.

2.3 *Data collection method*

To illustrate the orientation and distribution of scanner's grid collection system, an additional scan was collected from the setup. The scan consists of a 60×60 grid matrix. Figure 2 shows the result of the scan. It appears like a flat wall, except for the color of the scan points. Comparing this figure to the previous figure, there are some indications of the scan colors and tunnel liner.

In a scan if fewer points are used, the visibility of the image quickly breaks down. Interestingly, if same scan is viewed without the benefit of perspective (and at a slightly different angle) quite a different picture emerges.

In Figure 3 it is possible to clearly see the tunnel liner shape in the near scan points, but not so easily, as the distance from the scanner increases.

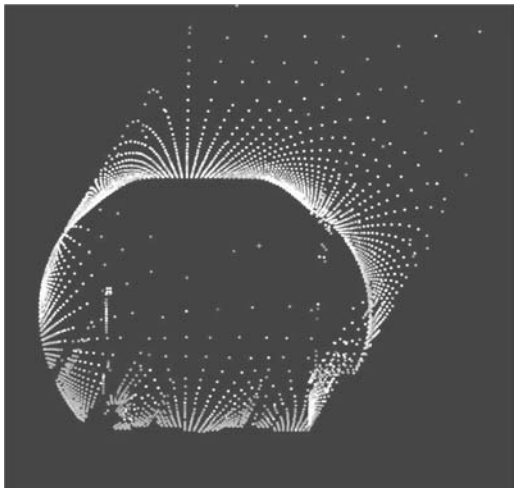

Figure 3. Low resolution scan.

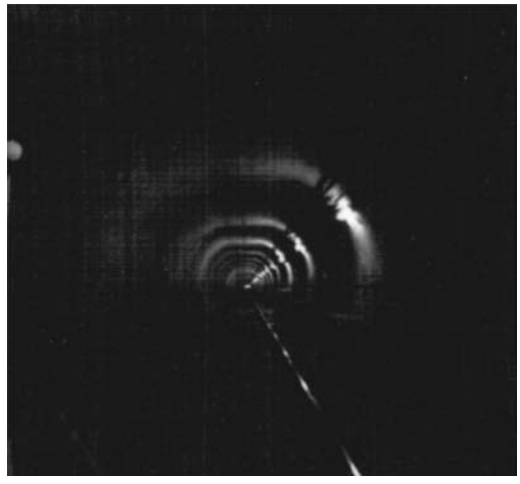

Figure 4. Tunnel image from scanner view finder.

The point dispersal pattern also affects the level of detail that can be seen in dense scans. As the distance from the scanner increases, so does the space between scan points. Due to the geometry of the tunnel, there is no way to avoid this phenomenon.

Additionally, even where there is a dense scan, as one zooms in for a closer look, the spacing between the points becomes visible and the visibility of the image degrades. The effect is similar to what happens to images of aerial or satellite photographs. From a certain distance, the images look highly detailed, but as you zoom in to a certain point, those images also begin to degrade. All of this is not to say that scanning is not a viable tool, but clearly points out that it is important to keep the expectations within the range of capability of not only the scanning technology, but also to the reality of the limitations that the geometry of tunnels will force upon you. Nor does this preclude the possibility of scanning a tunnel at a high level of detail. However, to do so would require far more scans than would be practical or cost effective, for that matter. One very significant benefit of the scanner is that the data that it collects is not affected by available light. Figure 4 shows the image used by the scan operator to align the scanner. As it can be seen the tunnel is extremely dark. Contrast this with the figure 1, the ability of this system has no a trivial benefit. However, this also brings up an other point. The scanner image, with its intensity driven display, while highly visible, may clearly display something, but interpreting what, will require further analysis. The current inspectors can look at the wall in true colors, and tell the type of defect that they are seeing, based in a large part to their past experience. Reading the false-color image from the scanner in a similar manner will take some time to develop. Furthermore, it is as equally possible that defects invisible to the naked eye will be detectable in the scan, and that other areas with markings that look like defects, will actually be simply some discoloration caused by variations in the intensity because of some surface condition that is unrelated to any defect.

2.4 *Extraction of collected data*

Having a fully registered model of the tunnel, in the form of a point-cloud, additional information can be extracted. Few tools come with the scanner where many different tasks can be performed. However, it is not designed for performing drafting.

Recognizing this, additional tools are also available to access the scanned data within the two most popular CAD software used in the transportation industry – Micro Station and AutoCAD. The software's are, CloudWorx, which allows for quick and efficient display and extraction of the scanned data within the CAD platforms. For this project, we primarily used one feature of the tool which allowed the placement of poly-lines and polygons whose vertices are automatically snapped to 3D points within the scan. This made it very easy for the CAD operator to draft outlines of the defects that were true 3D representations of the defect areas. Figure 5 shows a portion of the tunnel after creating these 3D graphics.

It was understood that the actual shape of the tunnel liner, in cross section form, could also be useful for defect analysis to show any deformation. However, with DTM software it is easily understood. Bentley's In Rail software (a rail design package, which also runs with both Micro Station and AutoCAD) has a tool for tunnel surface analysis. The standard DTM was utilized for un-rolling the tunnel data and re-rolling it for display. The way it works is to describe the geometry of the "ideal" or typical tunnel section. Once this

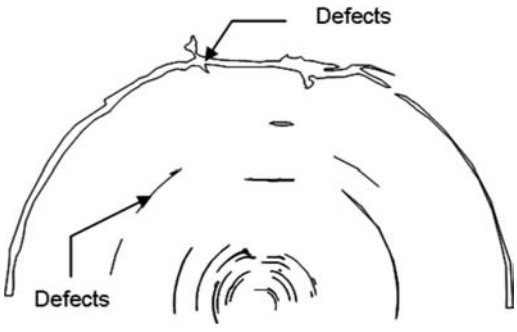

Figure 5. CAD drawing showing defects in view.

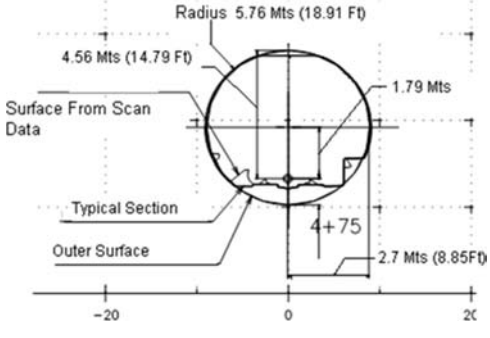

Figure 6. CAD Drawing Tunnel Cross section.

is created, we input the tunnel horizontal and vertical alignments into In Rail along with an ASCII form of the points from the scanned data. Triangulations of surfaces are performed to plot the tunnel cross sections. Figure 6 is an example of one of the cross sections.

In the figure, from the scan, we see indications of the safety walkway, the rails, the third rail with its protective cover, a 3" water line, a triplet run of electrical conduit, and at the center of the ceiling, an antenna wire. The cross sections can be compared in the future for any changes, and can also be compared to the original typical section. Then any deviation can be marked for further investigation back in the field. At this point, we had everything we needed to create drawing that could be used as documents for a repair contract. Utilizing In Rail plan and profile sheets were developed.

2.5 *Interpretation of spatial data*

To create plan sheets, would only require Micro Station and AutoCAD for their drafting capabilities – but to create a profile view would require some additional design software. The initial requirement was to display a left or right side of a tunnel aligned with the plan view of the top of the tunnel, as viewed from below. We also needed to display, in the profile view, the graphics of the defect areas.

- In Rail DTM's have a very powerful feature – and its ability to place points and lines in the DTM that are not used as surface points. Points (also known as random points) which represent discrete locations on the surface of the DTM. At times it is difficult to establish relationships between points.
- Break lines represent lines along changes in the slope of surfaces. Some break lines are very subtle while others are very obvious.

There are other types of data in many DTM's, but are irrelevant to this topic. Both of these sited data types would be used as surface points and would effect how a DTM displays contours and other data. For this task, although the tunnel surface is a DTM to In Rail, it is a special type, and currently only supports points. Since we need to represent linear objects, we used the traditional DTM tools and since some of the sidewall defects violated the 3D rules, if used as part of a surface, we decided to store them in a DTM as "exclude from triangulation" objects. Using In Rail's terminology, every object in a DTM is a feature. Features can be individual points, groups of points, linear elements and groups of linear elements. Every feature must have a unique name. Every feature must have one or more styles. A style is defined in In Rail as display characteristics for CAD elements. You can define a different style for plan, profile and cross section display and there are separate configurations for linear objects, point objects and text objects.

Additionally, it can assign a description to a feature and a "parent" – both of these are the text fields that can be filled with useful text information which can later be used as annotation labels or extracted into a report.

For this project, we created styles for each defect type, and as we stored each element, we gave them a simple generic name – Area 1, Area 2, etc. In the future, it may be possible to use more descriptive names, which will also include the defect type. As used in the profile, we can instruct In Rail to display these "features" on a profile by projecting the points to the profile, and to limit the display to only those features to the right of the centerline or the left of the centerline, as needed. For ease of use, we also wanted to display the scans on the drawings. This proved to be problematic and may eventually be dropped from the process. Since the drawings are not in "true coordinates" and it cannot easily manipulate the location and orientation of the display of the scan points, it was necessary to use images created from plots of the scans. Also, as the density of the scan increases, the software optimizes the display by thinning the number of points it will display (or plot) which limits how much of the scan can be plotted to a single image. Figure 7 displays one of the sheets created in this manner.

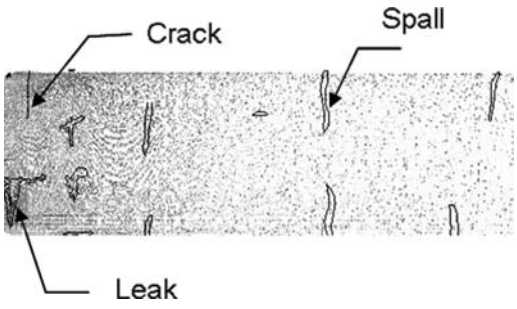

Figure 7. CAD drawing showing tunnel defect.

3 DETAILED REPORTS – SUMMARY

3.1 *Utilization of digital terrain model*

With all of our pilot project defects stored in the DTM, we can now take advantage of the Reporting tools provided with In Rail. In Rail uses an XML (Extensible Markup Language) based system for reporting and translating design data of other software packages. After reviewing the various options for the report tools, we opted to use a clearance report. This allows us to generate a report which relates to the defects, to the alignment, reporting on a relative location to the alignment.

There are two clearance report templates provided with In Rail, a minimum clearance and a general clearance report. The general clearance report creates a table that is grouped by defect feature name includes a listing of every survey point of the feature, including its Northing, Easting Elevation, Station and Horizontal Offset.

Table 2. Defect location report.

Tunnel defect designation	Liner centerline station	O'Clock	Description	Length	Area
Area 01	6+54.43	1.13	Leak	1.38	0.07
Area 02	5+87.51	10.41	Leak	12.29	0.00
Area 03	5+73.39	10.58	Leak	4.3	0.62
Area 04	5+64.39	9.07	Spall	22.82	3.73
Area 05	6+79.08	9.08	Crack	15.41	0.00
Area 06	5+87.85	1.29	Leak	18.94	1.63
Area 07	5+64.33	12.39	Spall	23.13	0.00
Area 08	5+47.36	1.11	Leak	15.94	0.00
Area 09	6+82.72	11.07	Spall	6.59	0.71
Area 10	6+58.50	11.45	Spall	2.64	0.36
Area 11	6+48.68	11.34	Crack	7.71	0.86
Area 12	6+54.14	10.29	Crack	3.23	0.00
Area 13	6+49.13	9.01	Crack	20.44	0.33
Area 14	6+80.97	2.13	Leak	0.78	0.01
Area 15	6+06.32	9.38	Leak	3.17	0.1
Area 16	6+03.82	9.16	Crack	9.08	0.00
Area 17	5+98.15	9.13	Leak	2.46	0.07
Area 18	6+54.43	1.13	Leak	1.38	0.07

The intended use for these reports would be to enable someone to read the data on the report, and from it, to locate a particular defect within the tunnel. The current method of identifying a defect is by the use of a station value and a clock value. The clock value is defined using the standard surveying practice of looking up-station). taken from the hour hand positions on a clock face. Directly overhead would be 12 O' clock at halfway to accomplish this we first had to add a new column to the report. point of the tunnel on the left side would be 9 O' clock and on the right side, 3 O'clock. (Left and right are All In Rail XML reports are created XML file plus an XSL File. After research, we determined that data needed was in column. The modified In Rail report is displayed in Table 1.

Our research into XML and XSL transformations indicated that we would be unable to calculate the clock value with the tools. Additional processing would need to occur to complete the final tables. With In Rail's XML report tools, the report can be saved as an HTML file, which then can be opened in Excel and saved as an Excel File. The final step was to turn pairs of numbers into an angle that could be converted to the clock position. After combining the data from XML report, the finished report is displayed in Table 2.

3.2 *Research and future refinements*

Scanning is one of the powerful tools to perform three dimensional scanning for tunnels where a higher than normal level of details is required and where access

to the area is difficult, restricted or hazardous. With the experience, it is time to further refine the process and utilize the Scanners for the best possible manner. Until enough experience has been developed in use of three dimensional scanners for Tunnel assessment one may anticipate the following research for future refinements:

1. Inspectors to continue perform the initial field identifications of defects and label them in field and record them with digital camera. This approach is similar to one currently employed for identifying wetlands and trees.
2. The scanning team/Inspectors to revisit the tunnel to identify the details of the scan data.
3. Develop features representing each defect, identifying them by their defect type.
4. Compare the Summary reports developed with field data and the scanner data.
5. Repeat the process until one feels comfortable identifying the scanned image to field defects.

4 CONCLUSION

The "Three Dimensional Laser Scanning" can be successfully be used as one of the tool in the system of Tunnel assessment and maintenance. It offers fast, accurate and detailed information. As the advantage of this technology becomes recognized in the market place, this form of comprehensive data collection will become beneficial on the tunnel assessment. It is important that the limitations of technology be understood and the research be developed. Incorporating this new technology requires innovative procedures, methodologies and techniques. If the three dimensional laser scanning can be utilized to its fullest extent in appropriate way, substantial saving may be realized in terms of time and budget. Although the technology has been available for some time, and has been utilized by agencies for performing Tunnel Inspections, but "To date, there is neither a manual nor formal procedure developed for Tunnel Assessment" utilizing the "Three Dimensional Laser Scanning" technology. It shall be imperative for an Institution or an Agency to develop a manual for "Tunnel assessment" utilizing the "Three Dimensional Laser Scanner". Once the manual is developed it shall benefit the Transit Agencies with tunnels around the world.

"Lokve" tunnel rehabilitation – experiences and applied solutions

Z.Tomanović
Faculty of Civil Engineering, Podgorica, Montenegro

ABSTRACT: Building of the tunnel "Lokve", of the length 1117 m, on the trunk road Berane – Rožaje (Montenegro) was finished in 1972. Invert arch, which had been anticipated by the design, was not built. During the first five years of exploitation, abutment approach was 50 cm at several places. At the aim of preventing support dislocation RC struts were placed in the level of foundation of supporting concrete structure for twice, on each 4 m in about 2/3 tunnel length. At this moment support displacements are less, with some raise of road surface and they are located in the section of length approximately 70 m in the middle of the tunnel. In this moment, the basic problem is water inflow in the tunnel through no-fines concrete course, at the length of approximately 400 m with the west tunnel portal. In this paper you can see repair solutions for two particular tunnel sections and work experiences during the rehabilitation.

1 INSTRUCTIONS

Excavation of the tunnel "Lokve" in the period as of 1968 to1971 on the trunk road Berane – Rozaje, was conducted in very hard working conditions. With strong lateral pressures and frequent jets out of the rock in calotte in a form of high wedge shaped "chimneys", water inflow caused great problems during construction works, due to which works were stopped in certain periods. Tunnel lining was made of massive concrete, about 70–150 cm thick. Concrete was made of river unscreened aggregate and insufficient amount of cement compared to the quantities of cement used today. Difficult and complex working environment was the reason why temporary wooden support and plank were not removed from many places between lining and rock mass. Due to a primitive manner of building in concrete, calotte part was not filled in well and therefore now there are caverns between lining and rock. Invert arch, anticipated by the design, was not built. The tunnel was open to traffic in 1971.

During the first five years of exploitation, due to strong rock lateral pressures, abutment approach was 50 cm at several places. For the purpose of preventing horizontal dislocation of support, AB struts were built in twice at the level of foundation of supporting concrete structure (on each 4 m in about 2/3 tunnel length). From 1994 to 1998 (as of the time of beginning of geodetic measurements) support dislocations were reduced and accompanied by lifting of the road surface and were located in the middle part of the tunnel as of $0 + 400$ ch. to $0 + 470$ ch. In this part, struts at the contact point with lining foundation are broken and lifted for about 10 cm. At this section, traffic profile is a bit reduced due to arching ribs which were built at the course of construction because of a strong rock pressures.

Apart from this, water inflow in calotte and spring line represents a significant problem in terms of traffic security and maintenance of electrical installations in the tunnel. Water inflow is particularly expressed at the length of about 400 m along the west tunnel portal, where water sprouts in jets (most frequently sprouting in lining working joints), or appears in a form of leak and dripping from calotte onto the traffic road, or it leaks down spring line, which in winter time causes formation of thick ice layers and icicles.

Works on rehabilitation of the tunnel were conducted in the period 2001–2003.

2 DESCRIPTION OF REHABILITATION MEASURES

Rehabilitation of concrete lining of the tunnel is designed to be conducted with four different types of rehabilitation measures. In the part of lining with relatively good concrete quality, but with water inflow into the tunnel, planned is to set a polyethilene membrane protected with a shotcrete layer $d = 4–6$ cm (TIP-I).

In the part between ch. $0 + 45$ to $0 + 400$ anticipated is a non-construction rehabilitation of lining by putting a 3 cm shotcrete layer (TYPE-II).

For the section from ch. 400–470 m, where abutments are still approaching to a certain extent, planned is to put 20–25 cm of shotcrete, doubly reinforced,

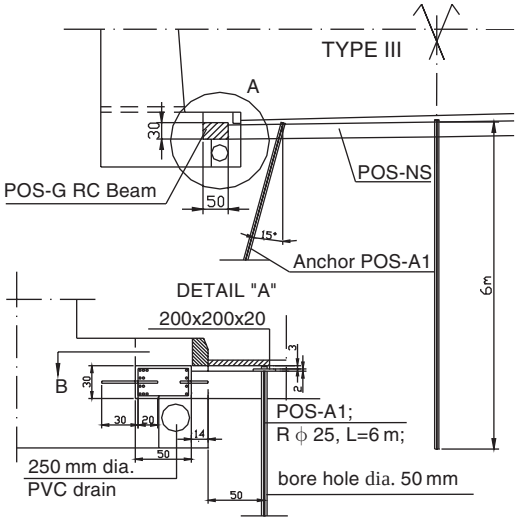

Figure 1. Lining rehabilitation TYPE III, RC struts under pavement.

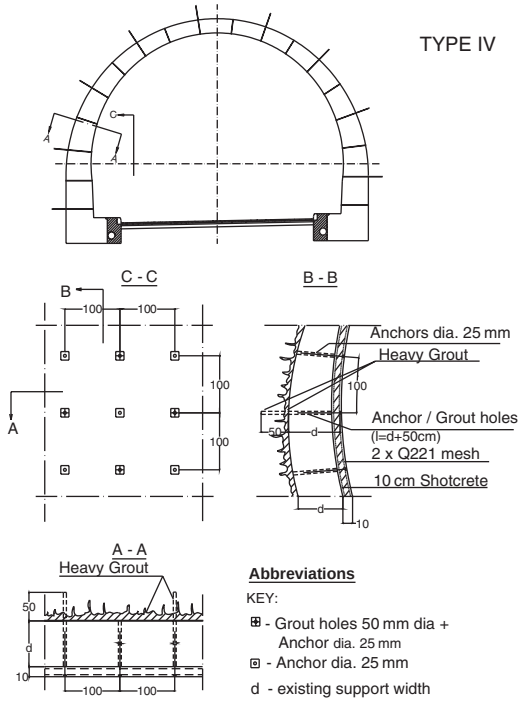

Figure 2. Lining rehabilitation TYPE IV.

between the present arched concrete ribs and anchors 2–3ϕR19/m^2 (60 cm length), as a connector between old and new concrete. Support reinforced in such a way with horizontal struts placed in the same altitude as abutment, makes a closed frame in a shape of timbered horseshoe with a purpose to accept rock mass lateral pressures, which in this zone caused horizontal approach of abutment lining for about 50 cm (TYPE-III, Figure 1).

In the part of the tunnel of ch. 0+750 up to ch. 1+117 (tunnel end) planned is a contact grouting with cement grout and setting of a 10 cm thick shotcrete layer, doubly reinforced and connected with the present lining by anchors: dia 25 mm, one piese/m^2, length 70 cm (TYPE-IV; Figure 2).

Apart from rehabilitation of the tunnel lining, planned is construction of main drainage pipes dia. 250 mm, on both sides of the tunnel, with manholes on each 20 m. Main drainage pipes serve for evacuation of water collected behind the membrane, local drainage systems, horizontal drainage boreholes, and for collection of potential water from the traffic road. Rehabilitation of the traffic road is limited to local repairs of bearing bitumenous layer and to setting of a new wearing course on the total tunnel length.

The design also anticipated total replacement of worn out electrical installations and tunnel illumination, video cameras setting on the tunnel portal zones, SOS stations with fire extinguishing equipment setting (on each 150 m on the left and right sides of the tunnel), automatic fire reporting, visual sign works for cessation of traffic in case of fire, or in the case of concentration of poisonous gasses in the tunnel above the allowed level.

2.1 *Description of the tunnel lining as of ch. 400–470 m (TYPE – III)*

Previously placed AB struts under the traffic road in this part of the tunnel are totally out of function. Namely, AB cleats which conveyed load from abutment to strut were broken (on the place of designed longitudinal beam POS-G). Breakage occurred on inclined planes which indicate that breakage occurred due to shear forces. Planes on which breakage occurred are partly spaced off, even for 10 centimeters.

This rehabilitation anticipates construction of longitudinal beam along with the present lining abutment (POS-G) and replacement of 11 broken AB strut beams. Newly designed struts (POS-NS) are dimensioned in such a way that they can convey twice as much of axial forces compared to the present ones. At the event of shaping of struts cross-section, a small free space between the traffic road and drainage pipes on both sides of the tunnel had a dominant role (see the details – Figure 2). Strut cross section of h/b = 30/70 cm could be placed in that free space. The problem of buckling of a slender present element was

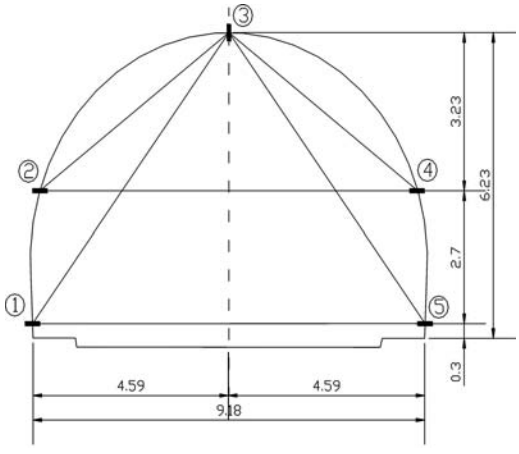

Figure 3. Convergence measurement cross section.

resolved with application of passive rock anchors by which the strut is fixed to a rock. Anchors need to eliminate the problem of vibration of strut arising due to frequent passing of the trucks, which was the cause of breakage of a certain number of struts on other sections of the tunnel.

This part of the tunnel is equipped with five measuring profiles for control of lining convergence during construction works, and for later monitoring in the course of exploitation (Figure 3).

2.2 *Description of rehabilitation of tunnel lining as of ch. 750–1117 m (TYPE – IV)*

Water inflow into the tunnel is mostly present as of ch. 750 m up to ch. 1+117 m and represents a significant problem from the point of view of traffic security. Concrete lining of the tunnel is on the surface greatly degraded, with many places in which ice caved caverns 5–20 cm deep. Concrete quality in regard with solidity is very weak and within the range as of 10–15 MPa on surface zones (thickness of lining in the spring line and abutment in this part of the tunnel is up to 1.5 m). On bad sections concrete can be dug without any special difficulties, with a pick and a jumper. A long-term influence of water and frost made concrete porous (washed cement filling), so that at the times of biggest inflow of underground water, it penetrates into the tunnel as a sprout, leak or dropping on almost complete tunnel lining surface.

Having in mind the fact that at the course of construction many caverns were left behind the lining as well as hardwood timber, which in the meantime putrefied, that water degraded concrete along total volume by constant flow into the tunnel, particularly on the surface (in combination with ice), rehabilitation solution anticipated contact grouting as a protection of the present concrete on the external side and setting of a 10 cm thick shotcrete on the inner side of lining – see Figure 2. The aim was to do conservation of degraded thick concrete layer of the present lining and fill it in, that is, stop further water inflow.

Apart from grouting the contact between lining and rock, purpose of positioning and number of boreholes was to do grouting of concrete lining. At the course of conducting grouting works, this proved to be very efficient. Namely, first grouting cycle (on a significant lining surface) at relatively low grout pressures of 1-2 bars, was actually reduced to grouting of lining itself. Only after the break of several hours and having grout in lining get hard, contact grouting could be initiated.

Attempt to determine rock permeability, that is, quantity of water penetration behind the lining, in order to determine density of grouting mass, at the course of designing, did not give any usable results. Namely, about ten tests of pumping water through borehole made in the lining, deep up to 1.0 m in the rock, gave the results which varied from almost impervious area to the situation where 15 minutes after pumping it was not possible to increase pressure with usage of water of about 100l per minute.

Composition of grout, along with preliminary lab tests, was defined during conducting construction works, depending on the tunnel zone. Water-cement factor ranged from $w/c = 0.7$ to $w/c = 0.5$, with supplement of accelerator of 1–1.5% (applied liquid ingunit – ADING Skoplje). Time of grout setting controlled by standard Vikat's needle, ranged from 45 to 90 min for $w/c \leq 0.55$, and it depended a great deal on small variations of additives quantity.

Interesting is to mention that Contractor tried to conduct grouting by applying packer of external diameter of 32 mm (designed 50 mm), but this was not feasible since it was necessary to decrease water-cement factor under 0.6, with accelerator added in a small percentage. By increasing diameter of packer to 48 mm, this problem was overcome. Best results were obtained by application of grout pumping only through one packer.

Accelerators in grout significantly contribute to plugging of the grouting hose on the branches for packers supply. By dislocating the hose from one packer to the others, the results were much better compared to simultaneous pumping into two or more packers. Grouting on the length of about 300 m of the tunnel length gave very good results; water inflow was reduced to several places only, where water will be accepted on local drainage system and taken to a main drainage pipe. On the remaining 100 m of the tunnel (from ch. 1000 to 1117) results of grouting were a bit worse.

Before putting any layer of shotcrete, lining surface is purified by sand blasting. Attempt to clean lining

by water jet under the pressure of 10 bars did not give desired results, especially in calotte where taken into account should be old and warn out cables under high electrical stress. Mentioned should be that works on rehabilitation were conducted during regular traffic operations, and therefore the existing illumination had to be preserved. Conducting construction works and works on replacement of electrical installations and illumination required a lot of efforts and work to keep minimal illumination of the tunnel on. Conducting works at the course of shuttle traffic caused additional costs of displacement of installations and significant time losses during project realization.

3 MONITORING

At the part of the tunnel where grouting is conducted, and at the part where during the so far exploitation significant abutment dislocation occurred, set was the system of iron pivots-bench marks for measurement of lining dislocation at the course of rehabilitation and at the course of future monitoring. Measurement profiles were set on each 50 m along the tunnel and were equipped with five bench mark out of which two in spring line and one in calotte of the tunnel as shown in Figure 3.

For convergence measuring used is the device with invar band and comparator with preciseness of 0.01 mm. Dislocations registered at the course of 6 months did not exceed 0.1 mm, which equals repetitiousness of results of the device used of 0.05 mm.

Measurement program defines measurement time intervals, directions of measuring, position of instruments at measuring and intervals for gauging of the device, so that all measurements are conducted in the same way. Convergence measurements organized in this way caused interruption of traffic, and therefore during construction works they were conducted once a month, with occasional control measurements of horizontal support dislocation only (direction 1-5, Figure 3).

4 CONCLUSION

Tunnel “Lokve” was built on hydro-geologically unfavourable location. Apart from that, tunnel lining was not made according to project documentation, that is, without invert arch. Major reason for rehabilitation of the tunnel “Lokve”, pointed out several times during 30 years of exploitation, refers actually to these two reasons. Law brand of concrete built in the tunnel lining can satisfy the bearing capacity, but in regard with durability, it represents a significant deficiency in the tunnel, especially for the tunnels placed in the geological area with a lot of water and tunnels on high altitude, especially having in mind icing in winter time.

Grouting with cement grout, applied in the tunnel “Lokve”, with immense water inflow and porous concrete tunnel lining, almost eliminated water inflow into the tunnel on the treated sections. According to the experience referring to grouting in this tunnel, time of grout setting needs to be reduced under 90 min by adding accelerator and adequate water-cement factor. Relatively short setting time needs a very organized work without any interruption in work and preparation of smaller quantities of grout.

Due to the previously mentioned, success of grouting, as a method of rehabilitation, significantly depends on how well organized Contractor is and how experienced are the workers. Also, presence of specialized Surveillance and permanent correction of content of grouting mass, depending on condition of lining, amount of water, caverns between the lining and rock mass have a significant role in achieving good grouting results.

The ring method application to the Prague Metro construction

Petr Vozarik
Metrostav, Prague, The Czech Republic

ABSTRACT: The construction of the first historic line of the Prague Metro started at the end of the 1960s. Czech construction companies lacked experience in projects of similar extent in an urban environment. This was why the experience, mainly for the construction of running tunnels, was sought abroad. The period of searching for suitable techniques and equipment was eventually terminated by a political decision. The basic technology and materials had to be taken over from the construction of the Moscow and Leningrad (today's Petrograd) metro tunnels. Czech technicians, representatives of the designer, employer and constractor, did not acquiesce in the relatively outdone and ineffective excavation technique and outdated design of the tunnels and stations. The ring method using cast-iron and, above all, reinforced concrete segments was improved and a very good technical level and effectiveness of the performance were achieved by the Czech teams during the course of several years. Their endeavour culminated by the development of the Prague-type three-vault station design lined with reinforced concrete segments, running tunnels with reinforced concrete segmental lining, development of new mining equipment, and improvement of the given mining technique. The modified ring method was applied to construction of tens of stations and kilometres of running tunnels.

1 INTRODUCTION

The Prague underground has won the reputation of an indispensable, high-quality and high-capacity means of transport. The underground has provided Prague inhabitants and visitors with a cutting edge public transport system – and a cornerstone of the city public transport. Almost 54 kilometres of lines with 53 stations are in operation today, joining the outskirts of the city through the city centre.

Major part of the 90 km-long single-track driven tunnels built between 1970 and the end of the century have been constructed by the ring method.

It is curious that 1968, the time of political liberalization, brought not only the touches of the freedom of speech and artistic freedom but also the formation of the Prague ring method, which became the major underground tunnel construction technology for the following more than 20 years.

Professor Mencl has defined this method as a tunnel construction technology for such ground types, where the stope stability is sufficient for construction of fixed lining. Its typical features include the use of blasting or machine extraction of the attack path of up to 1–1.5 metres and the installation of ring lining of panels in tunnels of 5.1 metre diameter or more (line tunnels) up to 7.8–7.9 metres (station tunnels). The lining was immediately engaged with the rock through filling grouting. The boring process was performed in short attacks and, typically, as full-face boring in order to enable installation of permanent prefabricated lining in the stope with minimum or no face support measures.

Most tunnels for underground in Prague are excavated in grounds, which provide 1 m attack stope stability of 1 hour through 1 month at maximum. The ground is a Paleozoic Ordovician complex of deposits containing mostly weak clay or silty shale or siltite, sometimes even very strong quartz rock. However, this whole complex is folded and damaged by a system of longitudinal and transversal dislocations.

2 THE RING METHOD USE ON THE FIRST UNDERGROUND LINE "C"

Six months after the government decreed the construction of the underground in 1967, the planning, investment and contracting organizations began to work on new basic technical and technological projects for the new C line. Six months later, the fundamental design solutions and technologies for boring the line tunnels by the ring method were prepared. The contractors' approaches to handling the technology varied. They stemmed from particular geological conditions on their sections of construction and also from their existing experience with tunnelling excavation or mining.

Vodní stavby (later Metrostav), the main contractor, took over the construction of the section involving soft roof, containing chiefly sandy sediments. The 5.1 metre diameter tunnels were excavated with the ring method by means of non-mechanical shields delivered by then Soviet Union. After Russian specialists trained the Czech operators, the technology was mastered to such extent, which permitted monthly advances of about 70–100 m as early as 1971. Another contractor, Vojenské stavby, was working on sections with rigid rocky roof. They used Soviet erectors for ring method boring with the aid of blasting. The monthly advance paths between 33 and 50 meters achieved with Russian-delivered cast iron lining were not impressive. However, with operators' training and collecting experience, this was deemed a fair result.

Yet another contractor, Výstavby kamenouhelných dolů (now the Division 5 of the Metrostav company), having their mining experience, decided to adopt their own technical solution. In the liberal political climate, they aimed to use their experience with construction of underground lines in West European countries. Their technical team has taken up the ring method as the fundamental technique as well. They used reinforced concrete panel lining of 5.2 m diameter by inland manufacturers.

Implementation of the proposed technology involved the most difficult step: developing a usable tunnel boring machine set. While the Soviet-made erectors were moving on skids, the current set, developed by Czech companies, used a different transport mechanism. Its two platforms were moving on track fixed to the tunnel lining at the height of the tunnel axis. The 10.3 metre self-driven two-part machine platform comprised a swivel-based panel segment unloader, extensible and suspended platforms, 2 tonne hoist and shotcreting equipment. Another self-driven 5.3 m-long platform carried 6 and 1.7 tonne hoists for materials handling within the tunnel.

Contrary to the Soviet-made erector, this set had substantial advantages in its motion variability and the free space at the bottom of the face. The latter permitted the use of mechanical equipment: drills and high-capacity transport vehicles, in some cases railless transport.

However, a Salzgiter shoveller with a 400-litre bucket combined with self-dumping railcars were used in the line tunnels of the IC line between the Kačerov and Budějovická and Pankrác – Pražského povstání stations. With this equipment, over 2,400 metres of line tunnels with monthly advances of 70–80 metres have been driven. The promising development of this technology and related equipment was terminated by the political situation of 1970's. Further advancements in the Prague-type ring method were based on Soviet directives and materials.

3 DEVELOPMENT OF THE RING METHOD IN OTHER UNDERGROUND LINES

Full development of technologies, which had been first adopted from the Moscow and Saint Petersburg underground constructions, took place in construction of the basic triangle comprising the A and B lines built between 1972 and 1985.

The expertise of construction and planning engineers was focused on upgrading the technologies and the machine equipment. At the end of the given period, the erectors and non-mechanical shields were fitted with supply equipment by Czech and Western manufacturers. This improved the quality of operation but did not eliminate fundamental drawbacks of obsolete boring machine sets. Heavy stationary equipment of the deposition sections ruled out almost any backward movement away from the face. Combined with the limited bottom space, they were an insurmountable hurdle to modernization of boring and loading and prevented the use of high-capacity loaders. The only substantial upgrade consisted in development of prefabricated lining with flat bottom.

The non-mechanical shields were deployed in A and IIC lines due to construction in greater depths and in more resistant rock. However, an assessment of the practice eventually showed that the technique is beneficial only in those segments where the rocky ground suitable for shield-tunnelling comprises more than 20% of the tunnel length.

The ring method using erectors with reinforced concrete panels for lining became the most widespread and best-proven technique for construction of Prague underground lines. Because of the method's simplicity and safety, the driving teams favoured its universal use in rocky ground containing low or medium strength shale, the stability of which permitted attacks between 1 and 2 metres. However, it disrupted the relationship between the massif and the face conditions. Despite the introduction of the streamline method, the average monthly advance paths did not exceed 70 metres.

Substantial increase in performance of the ring method was only possible through using a non-destructive breaking boring machine set. Throughout the underground construction, these machines were deployed in two instances. First, the Soviet-made TSČB-3 boring machine sets were used on the A line for excavation under Vltava river and the Staré Město quarter. The whole machine set was designed to drill rock of up to 80 MPa strength. Its full-face cutting head of 5.8 m diameter was protected by a hydraulic driven shield. Behind the shield, a device for construction of 60 cm-thick lining of pressed concrete was mounted.

Despite adaptations of the machine set, effective operation with regard to Prague area conditions has not been achieved. Therefore, two machine sets were

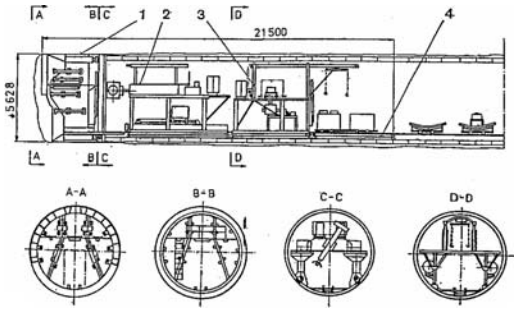

Figure 1. Soviet tunnel machine set KM 34. 1 – non-mechanical shield ŠČN-1; 2 – lining-laying machine; 3 – grouting platform TN 16; 4 – swerving platform.

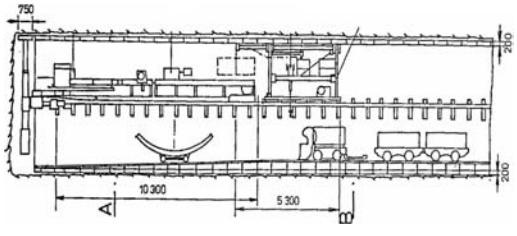

Figure 2. Mechanism of the ring method VKD-RS 218 for line C.

not used further, after drilling a total of 2.2 km length of tunnel.

Another machine set for excavation under geological conditions of Prague was planned and developed at the suggestion of Metrostav, the underground main contractor. This was a shield machine set with a milling tool. The machine set has driven the extension of the B line of 1,530 metres with average monthly advance path of 71 metres.

While we want to make a complex assessment of the ring method, we must not disregard the excavation under the Vltava river. The passage under a river bed has always been a demanding task both for the designer and the contractor. While the first river crossing on the A line was driven with a mechanical shield experiencing numerous difficulties tackled with consolidation grouting, the B and C line crossings were built with the conventional ring method using erectors for fitting the tubbing lining. In all these instances, advance headings have been driven to obtain precise data on geological and hydrogeological conditions. Best results were achieved in the passage of the C line. Its heading was driven with a non-destructive Alpine-50 milling tool and the subsequent ring method boring was troublefree with advance paths exceeding 50 m.

4 CONCLUSION

Upon the construction of the Prague underground, the ring method became the standard technology for excavation of both line tunnels and driven three-bay station tunnels. It turned out that specialist predictions and decisions based on results achieved between 1965 and 1969 were correct and viable. After all, this method has been used for more than 20 years to excavate tens of kilometres of line tunnels and kilometres of station tunnels. Despite the limiting conditions of the imported and obsolete machinery and materials, remarkable results were achieved. Sadly, though, the promising development of domestic equipment used for the first C line could not continue further.

For the last time, the ring method was used to large extent for line and station tunnels of the B-line final sections in 1980's and 1990's. However, the IVB line and last extensions of the C line to Severní město quarter make full use of the state-of-the-art NATM (New Austrian Tunnelling Method) with shotcrete lining and cast-in-place concrete.

Value preservation of underground infrastructure through focused conceptional planning

N. Winkler
Civil Engineer TU (MSc), Amberg Engineering Ltd., Regensdorf, Switzerland

A.W. Ackermann
Civil Engineer FH (BSc), Amberg Engineering Ltd., Regensdorf, Switzerland

ABSTRACT: Tunnels have a high economic value. Owners of tunnel infrastructure all have one goal in common: to maintain operational safety, serviceability and structural safety of their tunnels as economically as possible over the long term. To achieve these goals, a condition assessment is inevitable in order to focus the process of value preservation. The data collection is supported by modern digital technologies such as laser scanning and digital mapping software. Yet, the data are not only to be administered, but must flow into a long-term maintenance and value preservation concept. The core question arises as to how the acquisition and further processing of data should be linked in order to plan future actions and costs required to maintain tunnel safety and availability. This paper points out some key questions concerning value preservation concepts for tunnels and details the challenges for conceptional planning.

1 INTRODUCTION

The basis for the economic operation of transportation infrastructure is the long-term availability of the system. Specifically, negative consequences would result for the operator and the user, as well as for the economy and the environment, if the system or parts of it had to be unexpectedly removed from service due to the loss of safety or serviceability, even for a short period of time.

For road infrastructure, the closure of road sections would lead to delays and detours for the users, and thus to a greater environmental impact. In the case of unexpected closures, the operator will be faced with higher investments in order to refurbish his facilities.

In the case of rail infrastructure, interruptions in service result in high costs due to the irregularities of the schedule and/or the implementation of a shuttle service for passengers. Freight transport will also be affected. Refurbishment costs for railways, as in the case of roads, will increase accordingly.

These two examples involving critical transport infrastructure demonstrate the value of the facilities and the importance of preserving this value over the long term.

Civil structures, and especially underground facilities or tunnels, are key elements of road and railway networks worldwide. But underground structures are also utilized in supply and waste infrastructure, energy production, distribution infrastructure as well as military facilities.

Owners of all these types of infrastructure have one goal in common, namely to preserve the value of their facilities with the lowest possible financial burden over the long term by maintaining operational safety, serviceability and structural safety.

One of the most important boundary conditions of a value preservation concept is the accurate knowledge of the condition of the tunnels.

2 CONDITION ASSESSMENT OF TUNNELS

Only detailed knowledge of a tunnel's condition yields the basis for a focused management process to determine all necessary measures for structural value preservation.

Knowledge about the tunnel state is obtained in two steps. The first step – documenting the condition – consists of the comprehensive collection of technical data that concern the properties, characteristics and condition of the tunnel:

- Construction materials and their properties
- Geometry and profile of the cavity
- Installations for operation and clearance envelope
- Damage and deficiencies

Additional data and indications should be collected concerning the factors that could cause and influence the condition (subsequently called influence factors), such as:

- Construction method and tunnel age
- Geology and geologically induced forces
- Hydrogeology and chemistry of the groundwater
- Climatic conditions
- Rolling stock and operation types

A tunnel specialist can then carry out the evaluation and interpretation of the data in a second step to support assessment of the tunnel condition.

The condition assessment may indicate the necessity of various preservation measures and activities. National standards of different countries utilize highly varying terminology for tasks involving structural preservation and maintenance, whereby all standards basically express the same content: preservation is divided into surveying measures and maintenance measures.

Surveying measures are subdivided into inspections, visual and control measurements, as well as functional and material tests. Maintenance measures are subdivided into preventative maintenance, corrective maintenance and renewal measures.

Surveying measures serve both as the initial documentation of the condition, and as continuous or periodic documentation of the condition development.

Nowadays the tunnel engineer disposes over numerous computer-aided tools for carrying out the survey activities and data analysis.

3 MONITORING AND INSPECTION TECHNOLOGIES

IT developments have given the engineer opportunities to accomplish and evaluate measurements, inspections, tests, etc. faster and more efficiently by means of high-tech equipment and modern software solutions.

The digital tunnel scanner GRP 5000, for instance, which is capable of supplying both continuous profile measurements and a visual gray-scale image of the cavity surface, is the basis for further investigations such as clearance profile analyses and tunnel inspections.

The inspection software TunnelMap is a tool that allows a tunnel inspection to be carried out through digital data collection and analysis. Besides a graphical display (Fig. 1), the software also generates a statistical analysis of construction materials, operational equipment and damage. It exports the data into other software such as CAD for drawings (i.e. tunnel maps) and spreadsheets for the further processing of statistics.

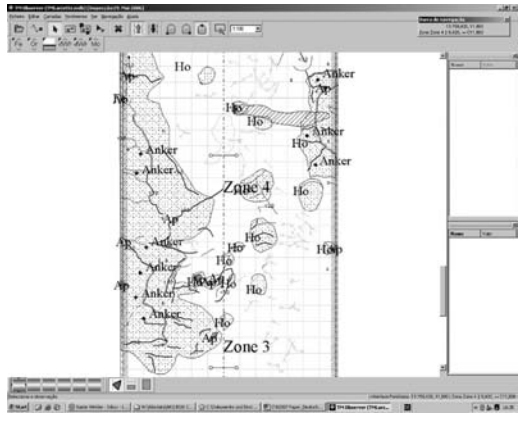

Figure 1. Example of a tunnel map generated with the TunnelMap software.

The link of these two technologies, which were developed within the Amberg Group, is the most efficient overall solution in the field of tunnel surveying:

Importing the gray-scale images recorded by GRP 5000 scanners into TunnelMap software has the decisive advantage of reducing inspection time in the tunnel to a minimum. For safety reasons, the inspections typically have to be carried out when the tunnel is closed to traffic (and with the catenary system turned off in railway tunnels), which often is only possible during night shifts. This process is accordingly time consuming and expensive. Higher efficiency is made possible by carrying out a pre-inspection in the office using the scanned image as background image for TunnelMap. The tunnel model, materials, installations and damage that have been input into the software prior to the field inspection must only be checked, corrected or supplemented during inspection in the tunnel.

Survey data collected and analyzed through these technologies constitute the basis for the condition interpretation and assessment by the tunnel engineer.

It is current practice that an experienced engineer assesses the state of a tunnel and plans the further measures. Naturally, this assessment is subjective, and thus various procedures are possible.

Current research and development projects address the topic of possible further processing of tunnel data. The goal is to help the engineer execute the condition assessment and plan economic value preservation concepts. The influence of subjectivity has to be reduced without relieving the engineer from responsibility.

4 DEVELOPMENT OF A MAINTENANCE MANAGEMENT TOOL

Several past and current research projects worldwide concern the topic of condition assessment and

(structural) maintenance concepts for tunnels. Some of the research projects conducted in Europe include:

- Instructions 779–10, UIC-Codex
- Guide de l'inspection du génie civil des tunnels routiers, CETU, France
- Tunconstruct, EU research project
- Prognosis model, SBB, Switzerland

Various manuals already contain basic concepts and recommendations for inspections and maintenance of tunnels. They represent a comprehensive collection of experience that helps the engineer analyze damage and the causes of damage. Thus, they represent a reference or support for determining the right maintenance measures.

Current research projects have set the goal of developing a comprehensive software solution that utilizes digital condition data and automatically:

- carries out the condition assessment,
- determines the life-cycle costs of a tunnel,
- defines the optimal maintenance intervals and
- recommends the most economic maintenance strategy.

Some projects also consider the question as to which issues have to be dealt with in the design phase of a new tunnel in order to optimize the costs during the operation and maintenance phase. However, this paper only treats the value preservation of existing tunnels.

A management tool shall be made available for the responsible owner of tunnels, which gives a quick and simple overview of the necessary investments to be made. The tool shall also make a statement concerning the optimal time intervals and the priority of the interventions.

In other words: How much money has to be invested in which tunnel and when, in order to obtain a 100% availability of the infrastructure? This core question is the object of a prognosis model that will be integrated into the inspection software TunnelMap.

5 PROGNOSIS MODEL

The prognosis model is the first step when developing a comprehensive software solution to support implementation of a value preservation concept. The objective of the prognosis model is to support the operator in determining the most economic maintenance strategy with regards to maintaining operational safety and serviceability. A maintenance strategy is the combination of various preventative maintenance, corrective maintenance and renewal measures.

After complete data acquisition regarding the damage and deficiencies of all tunnels on a network, the automatic condition assessment has to be calibrated and adjusted based on experience. The assessment is reasonable to define in accordance with the extent of damage in each zone. For the sake of simplicity, the classification can be carried out independently of the geometric position of the damage.

The result is the classification of each tunnel zone (typical zone length 10 m) into a condition class (mark). A possible definition of condition classes is as follows:

- 1 . . . Good
- 2 . . . Sufficient
- 3 . . . Insufficient
- 4 . . . Severe

Frequently, combinations of several damage types and deficiencies occur in the same zone. This situation is challenging with regards to the calculation of costs due to possible maintenance synergies.

It must be decided whether to apply maintenance measures to the whole zone for the sake of simplicity, or only to consider the effective damage area. This decision can again vary in accordance with the type of damage, and thus economic considerations have to be taken into account.

Furthermore, it has to be defined as to which standard of maintenance measures (preventative or corrective maintenance or renewal) is going to be applied to the different condition classes 2 to 4. In zones with a classification of 4, corrective maintenance or renewal measures must certainly be carried out. In zones with a classification of 2, preventative maintenance measures may be sufficient. This simple consideration leads to the question of how to define the effect of a measure. What shall be achieved with the measure? It is possible to define the maintenance goal as varying periods of operational time without the necessity of interventions, e.g. from 5 to 50 years? If so, this goal already has to be considered in the choice of the measures. In the end, the economic efficiency will be decisive, i.e. the relation between the overall maintenance costs and the period of time without the necessity of investments after the intervention.

Another important component of the prognosis model is the cost caused by the choice of construction measures. The maintenance measures, which correspond with a condition class (marks 2, 3 and 4) and with a damage type, have to be listed in a construction cost matrix. Examples of damage types include deformations, cavities, cracks, water inflow, joints, corrosion, etc.

It is important to consider, whether the costs should always be related to each m^2 of refurbished tunnel surface, even if the damage type is punctual, linear or planar. This question mainly has to be asked when cracks are considered. In order to obtain an order of magnitude for the construction costs, it is helpful to consult already realized refurbishment projects.

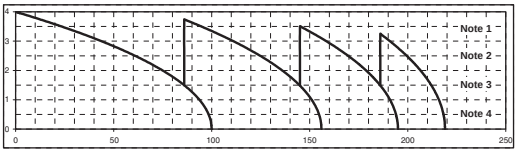

Figure 2. Visualization of an ageing curve by means of root functions.

The definition of the different cost components is also a very important aspect for the model. Do the costs only consider the construction works, or must the design and the construction management also be taken into account in this phase? How can the usually high costs for the site equipment be calculated? How can synergies be achieved that are able to reduce costs? These questions have to be clearly defined during the elaboration of the model concept.

All the above described considerations for the prognosis model are based on the actual state of a tunnel structure. When a necessary measure has to be postponed due to its lower priority, the condition of the tunnel can change because of the ageing of the structure.

Since the ageing curve and the damage development of a tunnel depend on different influence factors such as use, stresses, geology, cross-section, temperature etc., it is difficult to predict the ageing of a structure. For visualization purposes, it can be approximated by a root function (Fig. 2). It is hardly possible to make quantitative statements concerning the remaining service life or the expected costs. The latest possible intervention time is defined by the worst condition class.

Thus, such a prognosis model is conceptualized as an assessment system, which is based on the actual condition of the tunnels and which supports the operator in his choice of the most economic maintenance strategy, i.e. the right combination of maintenance measures. It is related to all the tunnels in a network of an operator and thus, does not make any statement concerning a specific tunnel. It only allows the emphasis of certain actions to be taken within the network. It is the basis upon which the owner can elaborate finance plans and intervention schedules.

Numerous factors and questions that influence the maintenance concept of a specific tunnel are being considered in the prognosis model as simplifying assumptions. These issues have to be further examined in current and future projects.

6 CHALLENGES FOR A MAINTENANCE MANAGEMENT TOOL

The goal of developing a computer aided management tool for a comprehensive value preservation concept makes it necessary to consider as many tangible influence factors as possible.

In order to obtain a detailed finance plan and intervention schedule, it is absolutely necessary to elaborate the maintenance concept for a specific tunnel, because the influence factors vary strongly in different tunnels.

One of the most important topics is the damage evolution and the interdependent ageing properties of a tunnel.

6.1 *Ageing curves of tunnels*

The ageing curves in many projects and publications represent only a qualitative visualization of the value consumption of an infrastructure (Fig. 2). This value consumption is related to the calculated depreciation period, at the lapse of which the construction costs are amortized. For reasons of amortization calculations, even a linear curve is sufficient. But these curves do not tell anything about the influences for instance of the geology, how long it takes that a zone moves from one condition class to a worse, or how long a zone remains in class 1 after refurbishment.

Thus, the numerical modelling of ageing curves certainly should be a subject-matter for further research activities. It should be related to specific tunnels or even – if necessary – to specific tunnel zones, and should also consider the factors listed in chapter 2, which cause and influence the damage. Of course, complete archive documents and existing damage documentation will be useful. For specific phenomena such as the corrosion of steel, the development of damage can be described by chemical-physical models.

By means of specific ageing curves it would be possible to predict – based on the actual condition – to which prolongation of the remaining service life a certain maintenance measure would lead to. Furthermore, the definition of the right intervention time would thus be possible.

But first, some questions arise concerning the factors that cause and influence damage.

6.2 *Influence factors of damage*

Without the evaluation of the precise geometric position of damage, only simplified statements can be made that serve as a means for the specification of priorities (which zones of a tunnel or network have to be maintained first?). For a detailed maintenance concept, this procedure is insufficient.

Different geometric positions of the same damage could lead to different condition assessments and thus to the necessity of different maintenance measures. Considering the geometric position therefore allows a more accurate calculation of maintenance costs. A leaking point in the tunnel crown for instance is more dangerous than in the side wall, a longitudinal crack more dangerous than a radial crack.

Thus, the appearance of several different damage types in one zone will also be taken into account. It is not necessary to treat the whole zone with the measure according to the worst damage, but only the corresponding area. Overlying damages can be dealt with in this way, which can have a different effect on the condition assessment. However, in these cases it is important to consider not only the geometric position of damages, but also their extent. In this context, the damage extent is not only important as a threshold for the classification of the zone, but also for the detailed calculation of the maintenance costs.

Another important influence factor is the construction material of the tunnel lining. A crack is more likely a sign of a weak point when appearing in reinforced shotcrete than when a similar crack appears in brick masonry. It would therefore be advantageous to model the influence of the construction material on the damage development.

The influence factors shown in the non-exhaustive list in chapter 2 are part of a complex interaction system. The combination of different causes can lead to new types of damage, which alone would not occur. For example, the combination of sprayed concrete and water containing sulfates leads to damage of the concrete, whereas the individual factors would not have the same damage potential without the influence of the other. It is therefore sensible to simulate the damage development for typical combinations of damage causes.

Planning maintenance measures for tunnel structures, those damages and deficiencies also play an important role, which are not immediately visible and require a special survey. The tunnel profile e.g. can only be monitored by measurement, and the tunnel drainage must be checked by function tests. The condition of the tunnel invert could for example be investigated using georadar measurements. Future research must therefore determine how these types of damage can flow into the automatic assessment and maintenance concept.

Besides the influences that are relevant for damage, there are also a series of topics related to the costs.

6.3 *Cost-relevant factors*

Like construction costs, maintenance costs of infrastructure consist of several components, whereby the most important are the following:

- Engineering fees for design, supervision etc.
- Construction works
- Site equipment and cleanup
- In-house services of the operator/owner
- Sales losses of the operator

Hence, it can only serve as decision aid for the choice of the best strategy if only the construction costs are considered. The detailed finance plan for maintenance is not possible without taking the other partial costs into account. The following considerations are decisive for the maintenance concept:

1. How can synergies be used when maintaining different zones/tunnels? Is it possible to install equipment in just one area for maintenance works in two tunnels? Is it reasonable to shift maintenance of a zone/tunnel temporally, in order to work more efficiently simultaneously to other nearby zones/tunnels?
2. Combination of structural and operational maintenance: Is it possible to execute structural maintenance during the same operational closures, in which maintenance for lighting, ventilation, tracks, catenary etc. is carried out?
3. Logistics: Can the construction yard be reached from the road network? How long does transport between the construction yard and the jobsite take? Must the transport be road or rail bound?
4. Working shifts: Can works be conducted during day shifts or only during night shifts? How long are operational closures? How long is the effective shift, how long are preparation and cleaning works before daily reopening?
5. How rising construction prices should be considered when planning maintenance measures long in advance?
6. Combination of economic and technical requirements: Is the construction of a new tunnel tube and the subsequent refurbishment of the old tunnel reasonable with regards to new safety requirements?

The evaluation of such very specific questions as well as the assessment of influence factors such as those mentioned in this chapter represent a challenge for any maintenance management tool, and is a possible subject for future research project.

7 CONCLUSION

In this paper, the topic of value preservation of tunnel infrastructure though focused maintenance planning is addressed. Modern digital technologies help the tunnel engineer incorporate and evaluate all relevant facts and data, such as:

- Condition and ageing of tunnel structure
- Influence factors of damage and deficiencies
- Measures and cost-relevant factors

On this basis, the condition assessment can be carried through.

By means of a prognosis model, a maintenance strategy for tunnel networks can be elaborated. The prognosis model serves as decision aid for the evaluation of necessary action and yields rough estimates of construction costs and time requirements.

The maintenance planning of specific tunnels requires detailed studies based on the prognosis model, which point out particular measures and detailed costs.

Comprehensive software solutions that shall support the engineer in this task are being developed worldwide. This paper discusses concrete questions and challenges for the development of a maintenance management tool from the standpoint of a tunnel engineer.

However, the engineer's experience and responsibility must remain in the foreground in order to verify the plausibility of the software results.

Diagnosis and repair of a subway tunnel 75 years old

T. Yamamoto & S. Matsukawa
Tokyo Metro Co., Ltd, Tokyo, Japan

ABSTRACT: More than 75 years have passed since the Suehirocho Station to Asakusa Station section of the Ginza Subway Line began service as the first subway in Japan. This section of the line has a box-section tunnel with a steel-framed reinforced concrete structure. Daily inspections and necessary repairs have been made. We recently conducted a detailed inspection, made predictions of the progress of deterioration, and performed structural analysis to ensure prolonged, safe use of the tunnel. This paper reports on the specific management and maintenance methods used in these activities.

1 INTRODUCTION

The Ginza Subway Line, specifically the section from Ueno Station to Asakusa Station, was opened for service in 1927 as the first subway in Japan. Since then, daily inspections and necessary repairs have been made for maintenance.

We have conducted detailed inspections, made predictions of the progress of deterioration, and conducted structural analysis, evaluation, and reviews of countermeasure methods according to JSCE Standard Specifications for Concrete Structures – 2001 "Maintenance." Our objectives were to evaluate overall present and future soundness in order to establish a maintenance policy for the future and to ensure prolonged safe use of the tunnel.

2 OVERVIEW OF THE TUNNEL

2.1 *Tunnel structure*

The Suehirocho Station to Asakusa Station section (3.3 km) of the Ginza Line covered by this inspection is a box-section tunnel of steel-framed reinforced concrete constructed while referring to the subway construction technologies in Berlin and New York in those days. (Photograph 1, Figure 1).

The overburden depth of this tunnel section ranges from 2 to 5 m.

2.2 *Tunnel design*

Reference documents from the time of tunnel design describe the allowable stress design method that was employed. The allowable compressive stress due to bending of concrete was specified at 3.5 N/mm^2, which suggests that the concrete used was expected to offer strength about one half that expected today. On the other hand, the allowable stress of steel was 120 N/mm^2, which is roughly equivalent to the present standard.

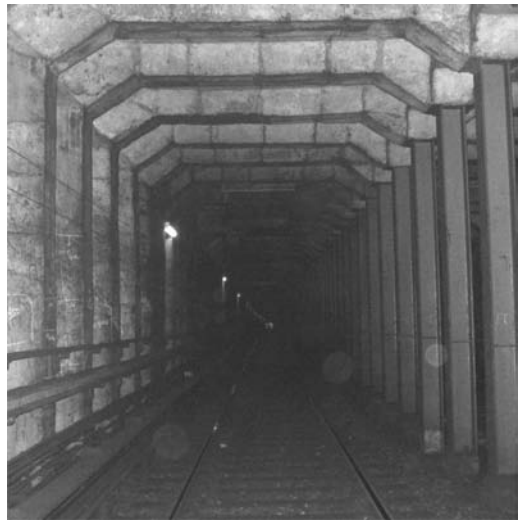

Photo 1. Current interior state of the tunnel.

We also found that the design road traffic load was substantially smaller than the current standard value.

2.3 *Materials used*

The cement used was Portland cement, with a mixing ratio of 1:2:4 (the volume ratio of cement: sand: aggregate).

For reinforcement, 13 mm and 16 mm plain round steel bars were used. The bar spacing and the concrete

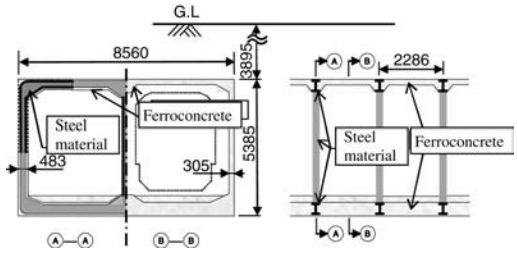

Figure 1. Tunnel structure.

Table 1. Inspection items and No. of inspection points.

Inspection items	No. of inspection points
Visual and hammering checks	12 points
Compressive strength test of concrete	105 pieces
Tensile strength test of reinforcement	9 pieces
Measurement of carbonated thickness of concrete	261 points
Measurement of concrete cover on embedded bars	261 points
Inspection of corrosion of reinforcement	17 points
Inspection of corrosion of steel frame	5 points
Measurement of water content of concrete	24 points
Estimate of concrete mix proportion	5 pieces at 5 points
Inspection for water leakage	Whole section
Component analysis of leaking water	3 points
Humidity and temperature measurement in tunnel	20 points
Vibration measurement of tunnel ceiling	1 point

cover were 100 to 150 mm and 50 to 75 mm, respectively, which were nearly equivalent to present design levels.

2.4 *Construction*

The tunnel in this section was constructed by the cut-and-cover method with concurrent road decking. Namely, steel frames were lined first at a given interval, followed by placement of reinforced concrete slabs between them.

As the tunnel was built below the groundwater level, an asphalt waterproofing layer was provided over the periphery of the tunnel structure.

3 INSPECTIONS

3.1 *Inspection items*

Table 1 shows the principal inspection items and the number of inspection points.

3.2 *Result of visual and hammering checks*

Deformation observed in the section included cracks, looseness, honeycomb, water leakage. There was no rust fluid indicating corrosion of reinforcement. The crack widths were about 0.1 to 0.3 mm

None of these deformation elements differed significantly from those cited in inspection results 15 years ago.

3.3 *Strength tests*

Concrete compressive strength was measured by a core-sampling test. In spite of a downward trend in strength in parts of the section, the average strength was 21.2 N/mm^2, and the measured values exceeded the estimated design standard strength of 10 N/mm^2 in all locations. No strength deterioration was observed from the inspection results 15 years ago.

The tensile strength of steel frames and reinforcement was also found to be sufficient.

3.4 *Measurement of carbonated thickness and concrete cover on embedded bars*

The carbonated thickness was measured by the drilling method while the concrete cover on embedded bars was determined by the electromagnetic induction method. The averaged carbonated thickness was 18 mm, and the averaged concrete cover was 43 mm.

Carbonated thickness data is distributed within an approximate range of 2 mm to 40 mm, with certain data exceeding 100 mm in a part of section. The concrete cover data is distributed within an approximate range of 20 mm to 70 mm.

3.5 *Inspection for corrosion of reinforcement*

We inspected for corrosion of reinforcement according to the self-potential method and by directly viewing the covering concrete that was partially chipped. The results showed that, in spite of the more than 75 years that had elapsed since construction, there was almost no corrosion proceeding in most locations. The condition was actually, “no corrosion” to “slight rust spots.” However, in certain locations there were signs of water leakage inside the tunnel, and some thin loose rust was detected in a few spots. (Photo 2).

Generally, it is said that corrosion of reinforcement proceeds when the carbonated thickness exceeds the depth of reinforcement. However, in the section inspected, there were many location points where corrosion was limited in spite of propagation of carbonation.

3.6 *Measurement of water content of concrete*

In this context, concrete water content, which influences reinforcement corrosion speed, was measured

Sound portion (no corrosion)

Leakage points (minor defect)

Photo 2. Corrosion state of reinforcing bar.

by using an electric resistance moisture meter. The results indicated that the concrete was considerably dry with both the surface and internal water content being extremely low; about 1–2% and about 0–1% respectively.

In other words, the tunnel was almost free of corrosion because of limited water supply in spite of propagation of carbonation beyond the reinforcement position.

The concrete had remained in a dry condition because there was naturally no rainfall inside the tunnel and because of the firm waterproofing layer provided at the time of construction.

However, around the points showing leaking of water, the internal water content was high at 5% or more at the source of the leak, and at the wet surface area below the source. It could be confirmed that corrosion of reinforcement there had proceeded because of the water supply.

3.7 *Vibration measurement of tunnel ceiling and verification of fatigue*

This tunnel has a small overburden depth and carries a load on the road surface that is larger than that at a time of design. The vibration of the tunnel ceiling was measured with a laser Doppler vibrometer (Fig. 2) to check for possible adverse affects from the repeated road traffic load on the tunnel.

The result shows that the maximum value of displacement (half amplitude) was extremely low at 0.075 mm.

Fatigue verification conducted to confirm this proved that the fatigue was not at a level that would cause fatigue failure within the service period.

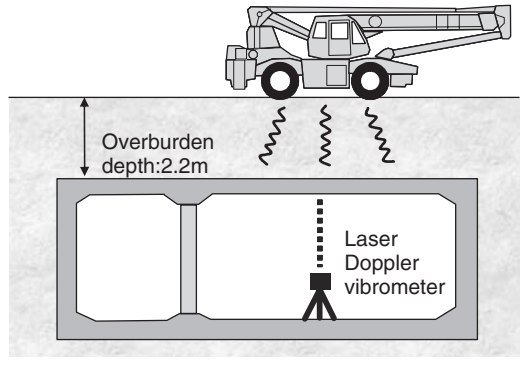

Figure 2. Conceptual view of vibration measurement of the tunnel upper portion using a laser Doppler vibrometer.

4 STRUCTURAL ANALYSIS

4.1 *Purpose of analysis*

A considerable number of years have passed since this tunnel was constructed, and environmental conditions have changed. In addition, the original design calculation sheets have been lost. Therefore, structural analysis was implemented using current load conditions and material physical values to assess the existing proof stress.

4.2 *Analytical model*

A two-dimensional frame linear analysis with a good track record was adopted as the analytical model. For analysis and verification we used a three-dimensional solid model that is an assembly of hexahedron solid

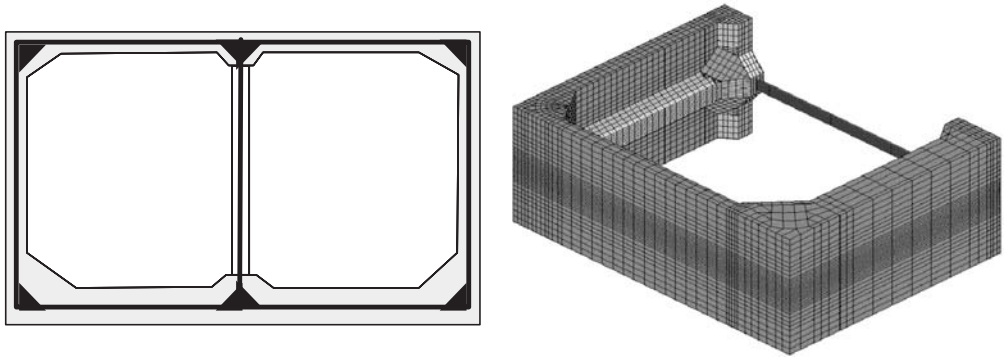

Figure 3. Analytical model.

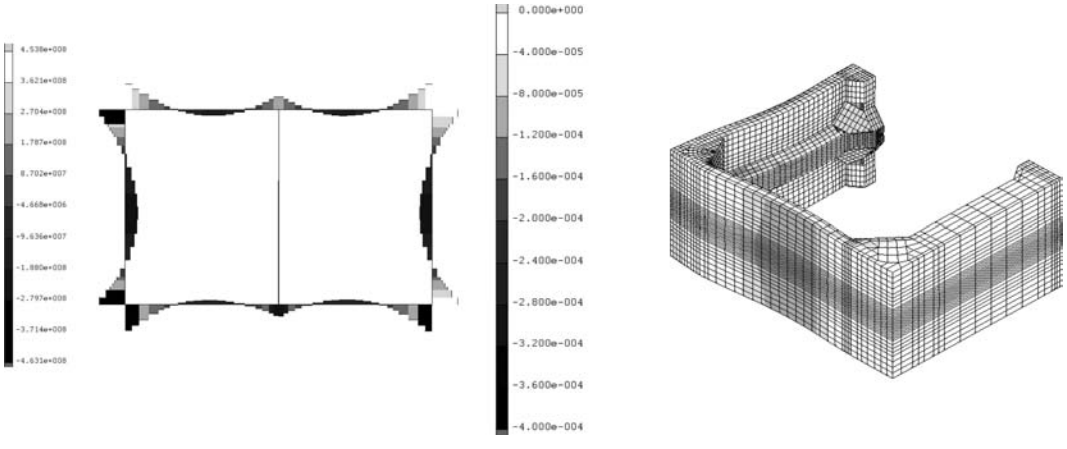

Figure 4. Typical analytical output results.

elements, to faithfully reproduce the complicated structure of steel-framed reinforced concrete.

Examples of the analytical model and output results are shown in Figs. 3 and 4, respectively.

In the actual field, partial loss or honeycomb were also observed in the covering concrete, which meant that the three-dimensional-model analysis involved an assumed case of loss or rigidity deterioration in a part of these concrete elements.

The results of the test implemented this time were used for property values, such as the material strength, etc. in analysis and verification.

4.3 *Results of analysis and verification*

In the two- and three-dimensional analyses, the response values I_{R_d} for flexural strength, axial strength, and shear strength were below the design strength I_{L_d}. The verification result from a three-dimensional model analysis was approximately $I_{R_d}/I_{L_d} = 0.3$ to 0.6, which proves sufficient allowance in strength.

The strength allowance could also be confirmed for cases in which the concrete element was partially lost.

5 PREDICTION OF THE PROGRESS OF DETERIORATION

5.1 *Purpose of prediction*

Judging from the in-situ inspection and test results, the principal deterioration mechanism of this tunnel was presumed to be carbonation. Therefore, we first predicted progress of carbonation. In this section where the concrete moisture content is low, however, it was presumed that the corrosion speed of reinforcement would be extremely low if there was no water leakage even when carbonation had progressed. Therefore, using the water content determined from the in-situ inspection, the time period from onset of carbonation at the reinforcement position up to occurrence of cracking caused by reinforcement corrosion was predicted.

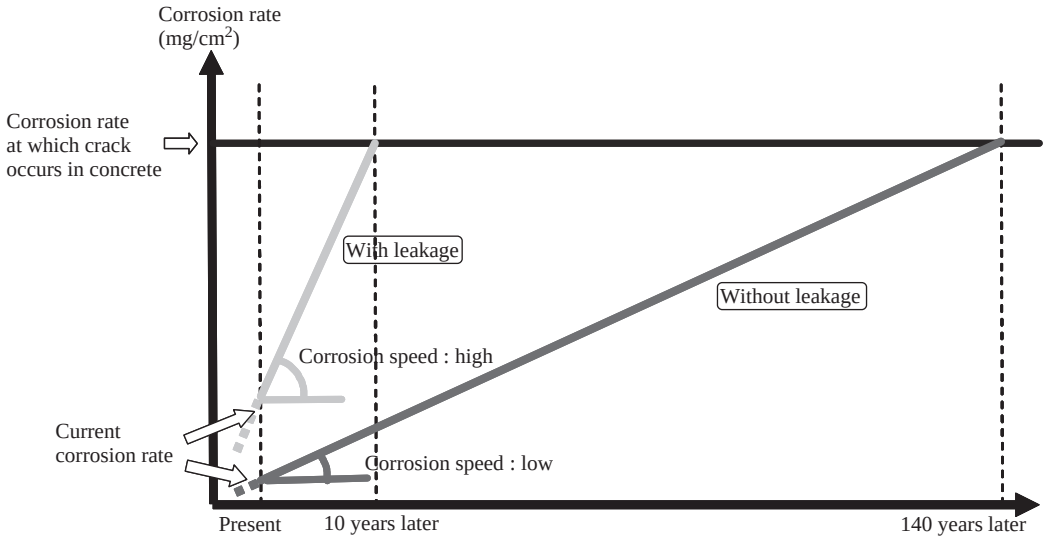

Figure 5. Conceptual view of predicting the timing of crack occurrence due to corrosion of reinforcement bar.

5.2 *Prediction of the progress of carbonation*

The progress of deterioration was predicted by using the following equation:

$Y = b\sqrt{t}$

Y: Carbonated thickness (mm)
t: Carbonation period (years)
b: Carbonation speed factor (mm/$\sqrt{t}$ year)

The carbonation speed factor "b" was determined by the actual measurement of carbonated thickness by drilling. The average carbonation speed factor "b" of all samples was 2.1; as compared with the average of 2.3 on the tunnel side. The average at the ceiling was as low as 1.5.

When viewed as the average between stations, deterioration progress could be predicted not to reach the reinforcement position in the five decades to come, that is, even 130 years after construction. Note, however, that in some locations where carbonation had progressed considerably, it was predicted that carbonation had already reached the reinforcement position or would reach it in the near future.

5.3 *Prediction of time of crack occurrence due to reinforcement corrosion*

Judging from the prediction average, carbonation may not reach the reinforcement position for a long period in the future. However, individual measurements indicate variances, and speed of reinforcement corrosion may vary greatly depending on the concrete moisture content.

Though there only a few research examples are now available, we did refer to cases that exist in order to predict the crack occurrence timing due to reinforcement corrosion by carbonation. This was done to obtain one set of judgment data to determine whether or not countermeasures would be necessary at present.

Prediction involved calculation of the corrosion speed from the concrete moisture content and calculation of the period up to occurrence of cracks by setting the corrosion amount at which cracks appear and the current corrosion amount.

The prediction results were as follows: the period up to occurrence of cracks is 140 to 200 years, provided there is no water leakage. It was predicted that, if water leakage occurs, cracks could be expected in about ten years. (Fig. 5)

6 EVALUATION

Firstly, in regard to load bearing capacity, visual inspection, structural analysis, and vibration measurement yielded sufficiently satisfactory results because there were no adverse effects from external forces such as overload or fatigue.

Fine cracks observed during inspection were judged to be predominantly due to drying shrinkage rather than insufficient bearing capacity or time-course deterioration.

As regards durability, various inspection results indicated that deterioration was mainly due to carbonation, not the effects of salt damage, alkali-aggregate reaction, or chemical corrosion.

In almost all locations, the existing deterioration progress due to carbonation had not yet reached the stage of starting reinforcement corrosion. In addition, as the deterioration progress prediction indicates, it could be confirmed that, in locations without water leakage, the possibility of reinforcement corrosion and thus crack occurrence would be small even 140 years from now.

7 COUNTERMEASURES

It was determined from the above results that the tunnel in its present state does not require any reinforcement to recover or enhance load-bearing capacity or rigidity. Countermeasures against deterioration for the entire tunnel were also judged to be unnecessary. Since cracks or loose portions were observed near localized water leakage, however, maintenance and repair work, including leak repair and recovery of those sections will be implemented without fail.

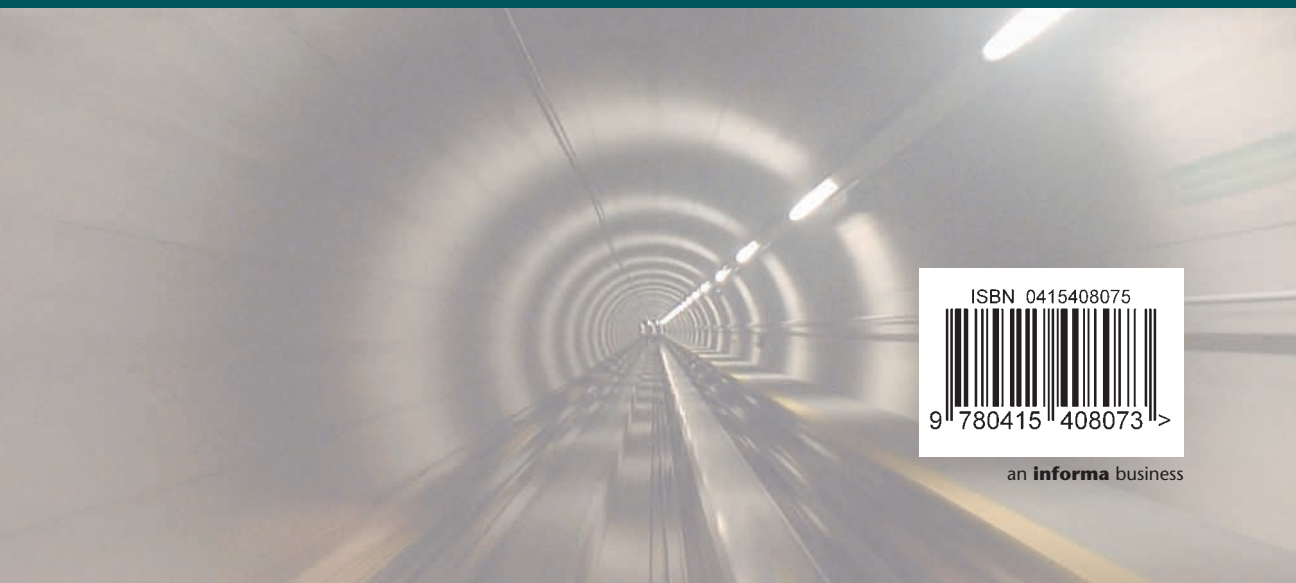
Research is still in progress in the fields in which analysis and inspection were conducted. For this reason and because each category of data contained unconfirmed elements, we decided to continue regular monitoring to follow the diagnostic results over a long period of time.

8 CONCLUSION

This inspection and diagnosis has proved that the tunnel, which was built over 75 years ago, can remain in service in sound condition if adequate maintenance is performed.

This fact is due to the implementation of the best design, construction, and maintenance work possible under past conditions by our forerunner railway civil engineers.

In a position to maintain an important property serving as social infrastructure, we will continue to perform the tasks required to ensure effective maintenance.



ACKNOWLEDGEMENTS

We would like to express our deepest gratitude for the kind guidance and cooperation extended by Professor Uomoto and Professor Kato of Tokyo University, Professor Futaba of Tokyo University of Technology, Professor Okui of Saitama University, Professor Koyama of the Regional Geo-Environment Institute, the staff of the Railway Technical Research Institute, the staff of Uomoto Laboratory, and all others who contributed to the inspection and diagnosis.

The so-called fourth dimension of a metropolis is the underground space beneath a city which typically includes structures such as tunnels, which facilitate transport, as well as providing gas, water and other supplies. Underground space may also be utilised for living, working and recreational facilities and provide storage for industrial materials.

Underground Space – the 4th Dimension of Metropolises focusses on underground city design and planning of subterranean constructions; geotechnical survey and improvement of ground mass; research, development and design of underground constructions in built-up areas; urban tunnelling, both conventional and mechanized, and its monitoring; underground constructions executed from the surface in built-up areas; concrete in underground construction; distribution and management of risks and accidents during tunnelling; tunnel equipment; fire and operational safety; and historical underground constructions.

Underground Space – the 4th Dimension of Metropolises reviews the state-of-the-art in tunnelling, discusses current tunnelling research and presents expectations for future development. This collection of papers will be invaluable to researchers, scientists, engineers and professionals working in tunnelling.
